The ideal IOA would have the following advantages: It would protect the FOB from damage caused by the patient's teeth or jaws, shield the FOB from the tongue and soft tissues, have an ideal length to form a path leading to the glottis, allow passage of an adequate-sized ETT, permit maneuverability of the ETT and FOB within it, possess a breakaway quality for easy removal after intubation, and have the ability to assist with mask

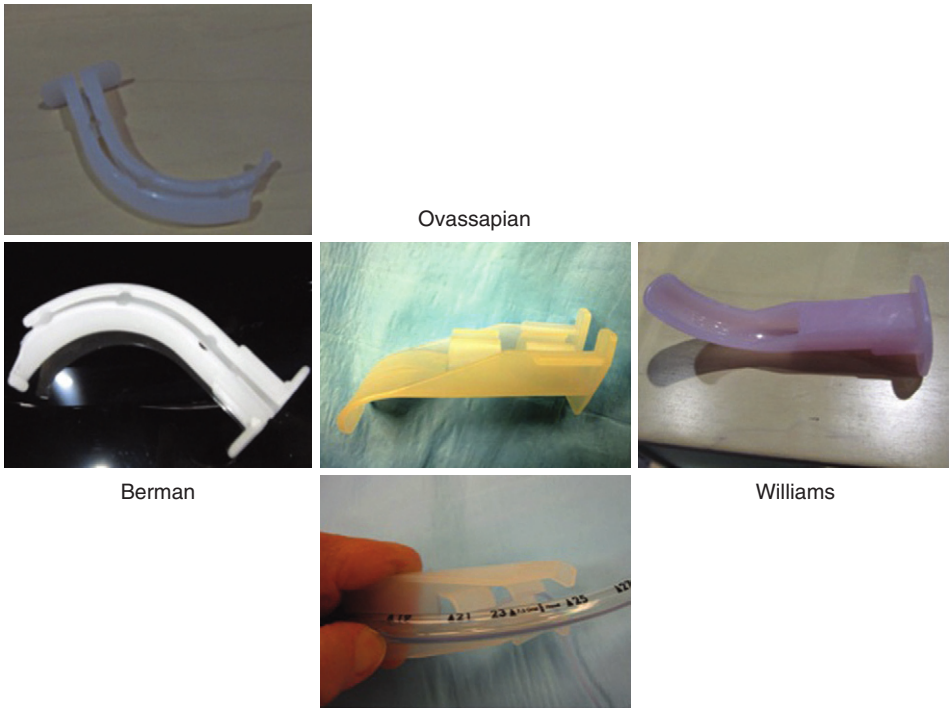

Figure 19-10 From left to right, Berman, Ovassapian, and Williams intubating oral airways.

ventilation as needed. In a truly ideal world, this ideal IOA would provoke no gag reflex, even without local anesthesia (LA).

Most studies comparing characteristics of different IOA involve non-DA.[64] No IOA is ideal, and some have disadvantages: Sizes may be too great for patients with small mouth openings; their construction may cause palate or other tissue discomfort or trauma during placement; they may lead the FOB astray (off midline); ETT cuffs may catch and tear on them; and their removal may be slightly intricate. All IOAs are disposable except for the aluminum-made Patil-Syracuse (Anesthesia Associates, Inc. (AincA), San Marcos, CA) oral airway.

The Berman intubating pharyngeal airway (Teleflex Medical Research, Triangle Park, NC) admits ETTs of 8.5 mm or smaller diameter and comes in various adult, child, and neonatal sizes. Its full-length tubular shape does not permit FOB maneuvering, but it has a wide slit the length of its side for breaking away from the ETT after intubation. If kept midline, it provides a better lead to the glottis, assuming its length is appropriate.[65] If the length is too long, its distal end is usually found in the vallecula; pulling it out 1 to 2 cm may rectify that situation. Lateral breaking away of this airway from the ETT can be difficult, particularly if periglottic ETT impingement has occurred.

The proximal half of the Ovassapian fiberoptic intubating airway (Teleflex Medical Research Triangle Park, NC) has a channel that permits passage of an ETT with a diameter of 9 mm or less. This channel has flexible lateral walls and an opening posteriorly for easy ETT removal. The distal half of the airway has a wide, flat, curved area designed to keep the tongue and soft tissues away from the FOB. Its flatness makes it easier to keep it in the midline, and its openness permits free FOB movement throughout its length. Once the FOB is near the carina and the ETT enters between the teeth, this IOA can be partially broken away to avoid tearing the ETT cuff on its corners. FOB orientation during passage through the device can be assisted by drawing a line with a marker lengthwise down the middle of the concave surface of the IOA.[66]

The Williams airway intubator (Williams Airway Intubator LTD, Calgary, Canada) has two adult sizes that allow passage of an ETT of 8.5 mm diameter or smaller. Proximally, it has a circumferentially closed channel and a distally curved section with a scalloped opening on the lingual surface. The distal area permits free FOB movement. As long as this airway is kept midline and its length is appropriate, it may be the best guide to the larynx.[67] If it is too long, visualization can be problematic. There may be a concern for more frequent cuff damage with ETT sizes larger than 7.0 mm when using the smaller size of this IOA. For removal, the ETT has to be disengaged from the 15-mm ETT connector. The enclosed channel part should have been liberally prelubricated to accomplish easier ETT release. Sometimes removal can be difficult.[68]

3. Short, Soft Nasopharyngeal Airways

Two techniques have described use of nasopharyngeal airways (NPAs) during FOB intubation. A method to simplify nasal FOB intubation by using a lengthwise, laterally cut NPA for breakaway capability was reported by Lu and colleagues (Fig. 19-11).[69] The lubricated, modified NPA is gently inserted into one nostril. Afterward, the lubricated FOB is guided through this NPA with the idea that the FOB tip will lead directly toward the glottis. After the FOB has entered just above the carina, the NPA is stripped away, and the ETT is railroaded over the FOB into the trachea.

A second advantage of NPA use is its role during FOB intubation in oxygen administration and as a conduit for inhalation anesthesia administration (most commonly in pediatric patients).[70,71] This is particularly advantageous when FOB intubation is preferred to be undertaken unhurriedly in spontaneously breathing patients who need extra anesthesia. An NPA (often with a Murphy eye–type hole cut distally) is placed in one nostril and attached to a breathing circuit by a 15-mm ETT adapter while the FOB intubation procedure is completed orally or nasally through the opposite nostril.[72]

4. Endotracheal Tubes

Regular polyvinylchloride (PVC) ETTs are used for most FOB intubations. However, the most distal ETT tip area can get caught on the arytenoids, especially the right, causing difficulty for passage into the trachea. Other

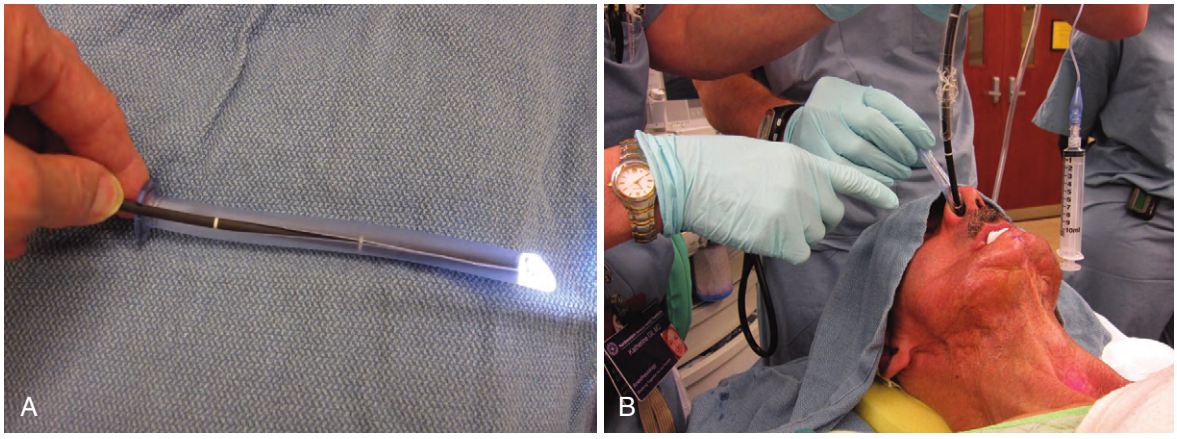

Figure 19-11 **A,** A cut breakaway nasopharyngeal airway (NPA). **B,** Once the carina is visualized, the breakaway NPA is removed from the fiberoptic bronchoscope to allow passage of an endotracheal tube.

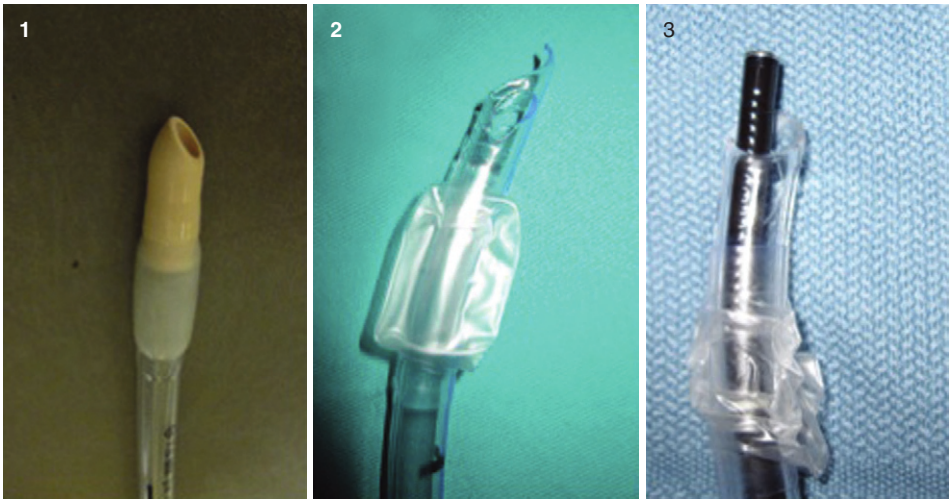

Figure 19-12 Comparison of curved-tipped versus straight-tipped endotracheal tubes: *1,* Fastrach (LMA North America, San Diego, CA); *2,* Parker (Parker Medical, Englewood, CO); *3,* polyvinylchloride (PVC) type.

centrally-curved, soft-tip ETTs have been reported to have greater success rates of passage.[73-75] However, Joo and coworkers demonstrated no difference in insertion success rate or number of manipulations required during awake FOB intubation when these two types of ETTs were compared, so long as the correct orientation of the common PVC ETT tip was made. The orientation required during insertion is that in which the Murphy eye of the ETT faces anteriorly with respect to the patient's body, to avoid arytenoid contact. This represents a 90-degree counterclockwise rotation of the ETT from the normal ETT direction used during rigid laryngoscopy (Fig. 19-12).[76]

V. CLINICAL TECHNIQUES OF FIBEROPTIC INTUBATION

A. Oral Fiberoptic Intubation of the Conscious Patient

FOB intubation techniques tend to be more successful in "awake" circumstances for a number of reasons, even though the airways can be very challenging. In the conscious patient, several factors contribute to this success: The preservation of muscular tone avoids obstructive soft tissue collapse; spontaneous ventilation is more likely to dilate airway structures; and the ability to deep breathe on command can sometimes reveal obscured airway passages.

During awake FOB intubation, the patient's state of consciousness may vary from completely awake to arousable with moderate stimulation (level 3 or 4 on the Ramsay scale) (Box 19-4).

Patients should have an awake FOB intubation under any of the following circumstances: anticipated very difficult intubation, a high likelihood of difficult mask ventilation and intubation, a DA with comorbidities likely to result in adverse effects if intubation is not easily accomplished, and after a failed asleep intubation (using any device). Application of excellent local airway anesthesia before endoscopy significantly decreases the odds of hemodynamic changes, severe coughing, laryngospasm, and failure.

1. Equipment, Monitoring, and Drug Availability

A preexisting intravenous route for drug administration is preferable, although intramuscular medication may be necessary for uncooperative patients until an intravenous line is established.

Unless emergency circumstances dictate otherwise, very strongly recommended standard equipment should include a full FOB cart, an ordinary airway cart, a checked oxygen delivery system, two available suctions (one for the FOB, the other for airway suctioning), monitors (blood pressure, electrocardiography, pulse oximetry, and capnography), drugs (local anesthetics, vasoconstrictors, sedatives, narcotics, reversal agents for these drugs, and possibly inhalation agents), and perhaps target-controlled infusion devices. If the patient's airway is anticipated to be very risky for ordinary awake FOB intubation, the DA cart should be present as well, for safety backup. Under any circumstances, if an FOB intubation is perceived as not going smoothly, the DA cart should be summoned to the site. This is particularly true if the patient has any difficulty breathing.

2. Psychological Preparation of the Patient

Psychological preparation of a patient is a basic step that is easily achieved with an explanatory, reassuring, and professional discussion. The following subjects can be emphasized: benefits of using the FOB method in relation

Box 19-4 Ramsay Sedation Scale

1. Patient is anxious and agitated, restless, or both.
2. Patient is cooperative, oriented, and tranquil.
3. Patient responds to commands only.
4. Patient exhibits brisk response to light glabellar tap or loud auditory stimulus.
5. Patient exhibits a sluggish response to light glabellar tap or loud auditory stimulus.
6. Patient exhibits no response.

to the patient's indications for the technique, probable amnesia for the procedure, effects of sedation versus respiratory depression, and the experience of the endoscopist. LA can be described as sprays, as injections with very tiny needles, and so on. The patient should be informed about any unpleasant taste, and a comparison with tonic water may be helpful. Advanced notice of enlisting patient aid during the process should be mentioned, such as gargling, swallowing, taking deep breaths, or exhaling completely, if needed. Oral intubating airways do not need to be mentioned, but their presence can be depicted as sensing a piece of plastic like a whistle in the mouth. Detailing similarities to other, more pleasant LA procedures; mentioning that a professional familiar with LA is involved; and alluding to actual FOB and ETT passage as being painless under LA (even with no sedation), can give a good frame of reference. Describing the expectation that patients will not notice much difference between sedation and general anesthesia (GA) can alleviate patient fears if sedation is not a concern and GA is planned after intubation.

Only oxygen is given if airway endangerment is a concern (i.e., no sedative or narcotic). Certainly, those patients for whom no sedation or extremely little sedation is advisable must be prepared to understand why. Explaining safety and how cooperation makes the process easier, faster, and less worrisome is beneficial.[77] Hypnosis has been used for FOB use, but special training is required.

3. Rationale for Pharmacologic Therapy

Supplemental oxygen is highly recommended but is not mandatory except in cases of a compromised airway.

If any topical intraoral anesthetic is planned, an antisialogogue is given 15 to 20 minutes beforehand to allow sufficient onset time, unless contraindicated. These agents minimize dilution of LAs, formation of a secretion barrier between LAs and the mucosa, and washing away of topical agents down the esophagus. In addition, they reduce the volume of secretions or blood that might obscure the optics of the FOB. Because of lesser degrees of tachycardia and side effects, glycopyrrolate (3 μg/kg) may be preferable to atropine (6 μg/kg) except in children.

Use of sedatives, narcotics, and LA agents depends on the urgency and respiratory status of the patient's situation. Sedatives may be titrated before the procedure for noncompromised patients. The most popular short-acting, amnestic anxiolytic is midazolam (15 to 30 μg/kg). Diazepam (35 to 70 μg/kg) and lorazepam (30 μg/kg) are alternatives that have much longer durations of action. Narcotics are only administered sparingly if the patient is in pain or if a painful or uncomfortable maneuver is anticipated (e.g., an injection).

B. Respiratory Monitoring Methods

The concern for respiratory events, especially after sedative and narcotic administration, has made continuous pulse oximetry a mandatory constant in addition to various monitoring schemes.

One solution involves surveillance by nasal cannula, using a side port for detection of end-tidal carbon dioxide pressure (P_{ETCO_2}) detection and setting alarm parameters for P_{ETCO_2} and respiratory rate. There are several drawbacks. First, many FOB operators frown upon this method. Their concern is particularly valid when ETT passage is difficult. They do not want to get into a frantic disconnection of the P_{ETCO_2} sampling tubing from the nasal cannula and then go through a subsequent reconnection to the ventilatory system to verify correct ETT placement, through the presence of P_{ETCO_2}. Second, endoscopists complain that this monitoring draws away their attention if they are constantly having to look at the respiratory screen while performing airway maneuvers. Third, alarms may be erroneous when patients breathe through the mouth and not the nose.

Respiratory rate monitoring is also possible on electrocardiographic equipment that measures impedance during thoracic excursion. The drawback to this method is that waveforms are not always reliable, particularly with large body habitus, lack of thoracic impedance, and placement of electrocardiographic leads away from the chest.

C. Sedation and Analgesia

As vital as the pharmacologic approach is, a quiet, peaceful, and stress-free atmosphere is of paramount importance when performing an awake FOB intubation. Any external pressure from non-airway experts must be gently but firmly excluded. Other personnel should be advised of the reasoning for the procedure and a realistic waiting time until completion of airway management.

As the FOB process is about to begin, sedation may continue to be titrated with caution. Sedatives tend to be more associated with dysphoria and patient combativeness than narcotics, which can be used to offset discomfort and airway reflexes. In addition to respiratory depression, sedatives and narcotics are associated with increased collapse of airway soft tissues, aspiration, and laryngospasm. One must be on guard for obstruction during sedation, even at low dosages.

Many combinations have been used with expert care, including midazolam (1 to 2 mg) for amnesia and sedation and fentanyl (0.7 to 1.5 μg/kg) for analgesia and antitussive effects. Other agents commonly used include ketamine (0.025 to 0.15 mg/kg) for sedation and analgesia, a combination of ketamine and propofol, propofol (25 to 75 μg/kg/min) for sedation, and remifentanil (0.05 to 0.01 μg/kg bolus followed by 0.03 to 0.05 μg/kg/min infusion) for analgesia.

Ketamine produces less respiratory depression but is longer acting and has no known reversal therapy in humans. One study on ketamine/xylazine use in primates showed reversal with atipamezole (Antisedan), an α-adrenergic antagonist, but because xylazine is a clonidine analogue, it is difficult to say whether the ketamine alone would be reversed to the same extent.[78]

Dexmedetomidine (0.7 to 1.0 μg/kg bolus over 10 minutes followed by 0.5 to 1.0 μg/kg/hr infusion) is associated with hypnosis, amnesia, analgesia, and less respiratory depression. It has been used and titrated so that the patient remains responsive to verbal command. In animal studies, dexmedetomidine has been shown to

be reversible by atipamezole, but no human studies are available.[79]

The most appropriate way to administer precisely titrated sedation seems to be with target-controlled infusion. The technique described for nasal FOB intubation has valid principles for oral approaches. Propofol and remifentanil have been studied most extensively.[80] Mean target plasma concentrations for propofol and remifentanil were 1.3 $\mu g \bullet mL^{-1}$ (standard deviation [SD], 0.2 $\mu g \bullet mL^{-1}$) and 3.2 $ng \bullet mL^{-1}$ (SD, 0.2 $ng \bullet mL^{-1}$), respectively. Rai and colleagues found no difference in patient satisfaction between the two but reported better FOB intubation conditions and a higher incidence of recall with remifentanil than with propofol.[81] Similar results were found by Cafiero and coworkers.[82] In patients with cervical trauma, a remifentanil effect site concentration as low as 0.8 $ng \bullet mL^{-1}$ proved to be effective for awake FOB intubation.[83] The very short induction and recovery times with remifentanil may represent a major advantage. Nevertheless, the possibility of increased thoracic wall rigidity and laryngospasm should be kept in mind.[84]

D. Local Anesthesia Purposes and Preparedness

Ideally, LA application is performed to achieve an excellent state of airway anesthesia to prevent discomfort, psychological distress, hemodynamic changes, and lack of cooperation. When it is appropriately executed, FOB intubation is made markedly easier and more successful. If the patient still has secretions in spite of antisialogogue action, wiping the tongue or directing the patient to suck on gauze can be helpful to soak up excess saliva. Before administration of LA, the relevant anatomy, drug concentrations, appropriate and maximum dosages, time of onset, toxicity, and alternative techniques must be known. Drugs and full resuscitation equipment must be readily available for treatment of toxic reactions. The systemic effects of two or more local anesthetics are additive, and consideration has to be given to the age and size of the patient, the site of application, and combinations of local anesthetics planned. In particular, the tracheobronchial tree is known to have very rapid systemic absorption of these agents. Vasoconstrictors have little effect on duration of action or prevention of toxicity from topical oropharyngeal anesthetics.

1. Innervation of Orotracheal Airway Structures

Cranial nerve IX, the glossopharyngeal nerve (GPN), supplies sensory innervation to the soft palate, the posterior third of the tongue, the tonsils, and most of the pharyngeal mucosa.[85,86] Some fibers also supply the lingual surface of the epiglottis.[87] This nerve controls the afferent component of the gag reflex. Cranial nerve V, the trigeminal, gives sensory supply to the anterior two thirds of the tongue but this area rarely needs anesthesia.

Cranial nerve X, the vagus, also forms part of the pharyngeal plexus, giving motor function to the soft palate and pharyngeal muscles. The superior and inferior laryngeal branches of the vagus carry out sensory supply to the laryngopharynx. The superior laryngeal nerve has an internal division that supplies sensory innervation to the base of the tongue, vallecula, epiglottis, piriform recesses, supraglottic mucosa, and the laryngeal vestibule above the vocal cords. Its external division provides motor control to the adductors/tensors, the cricothyroid muscle, and the cricopharyngeal part of the inferior constrictor of the pharynx. The inferior branch of the vagus, the recurrent laryngeal nerve, receives sensory input below the vocal cords, including the subglottic mucosa.

2. Topical Orotracheal Anesthesia Techniques

Determination of what technique is needed for local airway anesthesia depends on the intended approach for FOB intubation. Relative and perhaps absolute contraindications to these techniques include infection in the area, inability to determine anatomy, lack of patient cooperation, and any comorbidity such as coagulopathy or documented allergy that would pose an unwarranted risk. For a completely insensate oral approach, anesthesia must be provided to some of the soft palate, posterior tongue, posterior wall of the pharynx, vallecula, periglottic area, larynx, and trachea.

LA of the airway can be performed without sedation and should be the method of choice if patients have significant airway compromise. If possible, however, it is more desirable to give sedation before any deep pharyngeal/laryngeal anesthesia, to mask the choking feeling that many patients may experience and avoid this potentially distressing sensation. The bitter taste of the LAs can be somewhat masked by the use of mint strips.

a. GLOSSOPHARYNGEAL ANESTHESIA

In advance of performing a GPN nerve block, give instructions to the patient that he or she may be requested to take deep breaths, gargle, or swallow. It is helpful to vocally mimic gargling so that the patient understands this directive. While pressure is applied on the lateral tongue surface with a tongue depressor, the operator shifts the tongue medially and sprays the LA during inspiration at the anterior tonsillar pillar (Fig. 19-13). After waiting a number of seconds for patient recovery, the process is repeated on the opposite side, then once more on both sides.

Advantages include a lower likelihood of provoking gagging and greater cooperation when the tongue pressure is initiated laterally, compared with a midline approach. Also, inhaling and gargling are more likely to maximize anesthetic spread, as opposed to coughing the aerosol at the endoscopist. Optional methods include using a 3-mL syringe of 3% lidocaine on a MADgic atomizer (LMA North America, San Diego, CA) or Exactacain spray (benzocaine 14%, butamben 2%, tetracaine hydrochloride 2%), or alternatively, by touching the pillars for 5 seconds with a swab or pledget soaked in LA. An uncommon and not recommended technique is to actually inject the area with the LA. This last method is fraught with danger to the endoscopist (from biting) and to the patient due to the chance of hematoma formation or toxicity secondary to injection into a very vascular area.

b. ALTERNATIVE METHODS OF INTRAORAL ANESTHESIA

Alternative methods of intraoral anesthesia may anesthetize not only the GPN distribution but also the laryngeal

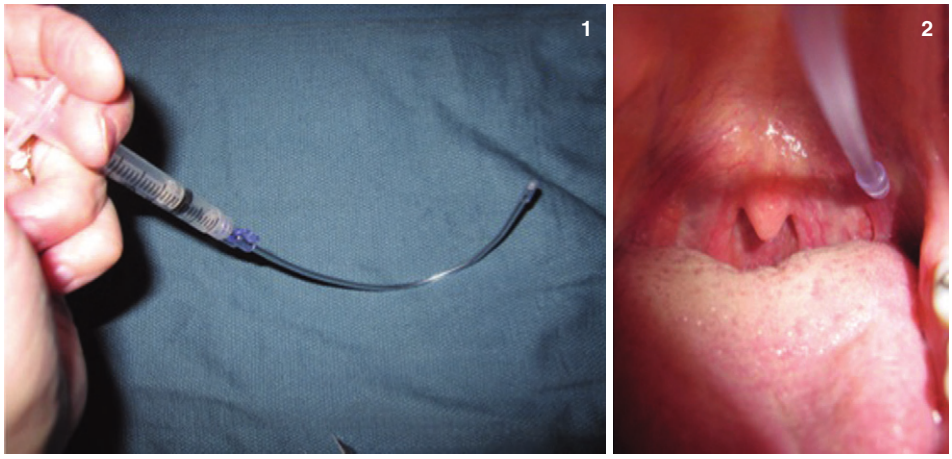

Figure 19-13 *1,* Flexible memory of MADgic atomizer. *2,* Glossopharyngeal nerve block in tonsillar fossa.

area or even the trachea as drugs are either inhaled or aspirated. With the atomized technique, lidocaine solution is applied via the MADgic to the palate, tonsillar pillars, vallecula, epiglottis, and larynx during deep inspiration by bending the stylet-like applicator in whatever curve is needed.

In the "lollipop" method of LA, 3 cm of lidocaine paste is placed on both sides of one end of a tongue depressor. The operator puts this end on the middle of the patient's tongue and advises the patient to keep the depressor held in place between the teeth. For the "toothpaste" method, the gel is placed directly down the middle of the tongue, while the tongue tip is held with gauze (Fig. 19-14). In these latter two instances, the lidocaine is left to dissolve over 5 to 10 minutes.

With the gargle method, a "slurry" or 4 mL viscous lidocaine is gargled continuously for 5 minutes. Finally, the Tessalon Perle (benzonatate) method involves keeping the Perle in the middle of the tongue so that it dissolves. If the Perle does not start to dissolve within a few minutes, it can be bitten slightly to permit leakage of the drug.

c. SUPERIOR LARYNGEAL NERVE BLOCK

The superior laryngeal nerve (SLN) block is advantageous for patients who have limited intraoral cooperation (e.g., perhaps only allowing a quick peritonsillar spray), for those who have no possible oral cavity entry (i.e., requiring nasopharyngeal FOB intubation), or as a rescue method after a failed internal SLN attempt when coughing or hemodynamic changes from sprays are undesirable.

Two techniques are available for the external neck approach to bilateral SLN block. In the simpler technique, attach a 10-mL syringe with 6 mL of 1% lidocaine to a 21- or 22-G needle as an injection system (Video 19-1). Clean the neck area with antiseptic solution and locate both hyoid cornua (Fig. 19-15). Keep the forefinger of the nondominant hand by one cornu for visual reference, and hold the syringe dart-like near the needle hub while advancing the needle perpendicularly toward that cornu. Once bone is felt, shift the nondominant hand to brace against the neck and hold the system near the hub. Aspirate the syringe gently; if no blood returns, inject 3 mL slowly. Repeat the process on the other side.

The second external approach to SLN block is more complex and takes longer to perform. The same system is used to hit the cornu. Then the operator walks off anteromedially and caudally 0.1 to 0.4 cm and feels the click of going through the thyrohyoid membrane at a depth of 1 to 2 cm.[88] The needle is then braced, and the remainder of the technique is identical. The block has to be repeated on the other side.

Internal anesthetization of the SLN can be accomplished by previously mentioned intraoral techniques including spraying toward the "imagined larynx." An uncommon method involves putting pressure in the piriform fossa with a gauze soaked in local anesthetic; the gauze is held in place by a curved clamp for 10 minutes.

Figure 19-14 Glossopharyngeal nerve block and internal superior laryngeal nerve block. Five percent lidocaine is used for the toothpaste technique of intraoral anesthesia.

Figure 19-15 Superior laryngeal nerve block. The assistant holds pressure on the right hyoid cornu while the operator directs the local anesthetic 22-G needle at the left hyoid cornu.

Trouble-Shooting

1. The cervical collar is in the way: Open the collar on one side of the neck and flip its anterior portion over to the other side. Perform both blocks and close the collar when finished.
2. The hyoid is hard to feel with only one hand: It will be more prominent if an assistant presses gently against the opposite hyoid cornu toward the operator's finger on the side being blocked.
3. Blood is aspirated: The system has to be withdrawn slightly, redirected, and braced until aspiration is negative. (This is particularly important to prevent intracarotid arterial injection and seizures.)
4. Bone is felt but injection is not possible: The needle tip is probably in the periosteum. Using two hands, brace the system constantly, and imperceptibly withdraw 1 mm at a time until negative aspirations are followed by the ability to inject. Excessive distance during withdrawal can cause failure.

d. TRANSTRACHEAL BLOCK

If a collar is in place, locate the cricothyroid area through the anterior collar opening or by flipping the anterior part laterally, as described previously (Video 19-2). Apply antiseptic, and mark the area before refastening the collar. Straddle the trachea with two digits of the nondominant hand. With the dominant hand, direct a 10-mL syringe containing 4 mL of 4% lidocaine attached to a 21- or 22-G needle as a system, aiming posteriorly in the cricothyroid space while aspirating gently (Fig. 19-16). Shift the other hand to keep the system braced on the neck, if possible, and help guide it until many air bubbles are freely obtained. At this point, brace or encircle the system firmly while the dominant thumb is poised to inject. Instruct the patient to breathe in gently and exhale gently but maximally. When exhalation is at completion, rapidly inject the anesthetic. As the LA enters the trachea, the patient may cough, but because exhalation has taken place, a quick breath must be taken to initiate any more cough, and this will help spread the anesthetic. Usually more coughing ensues. By bracing against the neck (or collar) and encircling the system, one need not worry about excessive needle penetration, removal, or breakage even if the patient's neck moves quite a bit. The system can be removed when finished.

According to Todd, concern about coughing in patients with cervical spine risk is unfounded, because patients cough periodically and those coughing during transtracheal blockade have never been shown to develop secondary neurologic damage.[89] Some clinicians prefer using a 20-G angiocatheter in lieu of the needle. They perform the technique in a similar fashion, but after air is aspirated they advance the catheter 0.5 to 1 cm, brace the catheter, remove the needle and syringe, disconnect the syringe, connect the syringe to the catheter, aspirate the catheter for air, and proceed in as previously described. The benefit of the needle technique is that it is faster, it is less likely to provoke more coughing caused by hitting the posterior tracheal wall (particularly when the catheter is threaded in too far), and it is more successful (because the needles are shorter, less flexible, and, even if pulled out of the trachea, can be advanced easily). In contrast, with a catheter coming out of the trachea, the needle would have to be reinserted with it, or the angiocatheter would have to be entirely replaced if the plastic is damaged.

Trouble-Shooting

1. The cricothyroid space is impossible to feel: A cricotracheal injection is acceptable.
2. More than a tiny wisp of blood is aspirated: Remove the system and refill the syringe with fresh local anesthetic to avoid injecting blood into the respiratory system.
3. The hyoid bone seems very close to the cricothyroid space: Reassess anatomy or abandon the technique to prevent vocal cord damage.

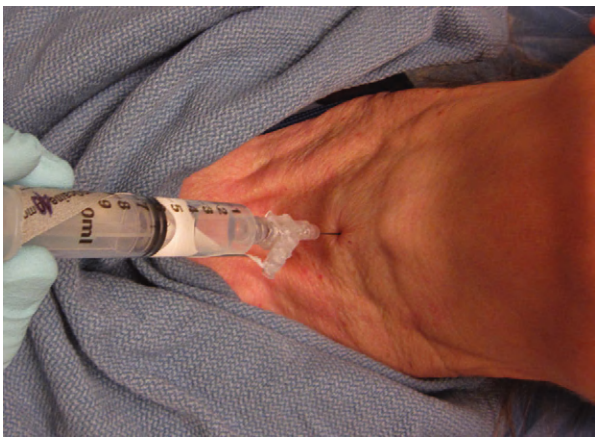

Figure 19-16 Transtracheal block. The operator braces his or her hand on the patient's chest while aspirating for air through the cricothyroid membrane.

4. The patient is at very high risk for aspiration: To maintain the patient's protective reflexes, avoid transtracheal anesthesia. Instead, use the "spray as you go" technique (discussed later) on the visualized vocal cords. Rapidly insert the FOB, and follow immediately with ETT passage and cuff inflation.

The combination of the three blocks described (GPN, SLN, and transtracheal) provides the quietest airway. Any order can be chosen, but usually the oropharynx is anesthetized first because it requires more cooperation on the part of the patient. The external neck approach to the SLN would be next if needed, followed by the transtracheal block, in order to have the procedure that elicits the most patient reaction (i.e., coughing) come last.

e. AEROSOL METHOD

The advantage of the aerosol method is that nebulized local anesthetic can be administered without needling and without much cooperation if given by mask. If it works, it is the best method to avoid coughing. This may take up to 15 minutes with some aerosols but can be faster with others such as the Aeroneb Go nebulizer (Dangan, Galway, Ireland). Nebulized lidocaine (5 mL, 4%) can be given via a mouthpiece for oral approaches. Instruct the patient to inhale only through the mouth until nebulization is complete (i.e., to prevent dilution of inhaled anesthetic from breathing through the nose). More cooperation is necessary for success, and the patient needs constant observation to ensure that instructions are actually being followed.

f. "SPRAY AS YOU GO" TECHNIQUE

The "spray as you go" method is used for patients who have partial or no pharyngeal, superior laryngeal, or transtracheal anesthesia. The operator uses an adult FOB with working channels of 2 to 2.5 mm and directs an assistant to give a quick pulse of 1 mL of 2% to 4% lidocaine (4 mL total), when areas with insufficient anesthesia are approached. If the working channel diameter is small (≤1 mm), this permits smaller incremental doses of LA administration (0.2 mL) to jet out as a spray. Do not employ simultaneous suction, because anesthetic will be lost in the suction.

Patients are more likely to react and cough after these pulses, and the FOB view may be obscured for some seconds, after which the FOB can be advanced until another unanesthetized area is reached.[90] An interesting method to avoid the obscured view is to attach a syringe containing local anesthetic to an epidural catheter (0.5 to 1 mm ID, single distal hole) and pass it through a three-way stopcock attached at the FOB injection port through the working channel. On the second stopcock port, attach the suction tubing for easy use by a simple turn. Extend the catheter tip 1 cm beyond the FOB tip so that as LA is injected, the spray goes a farther distance away, causing less visual disturbance to the FOB. Taping the proximal epidural at the working channel port area keeps its tip a fixed distance.

3. Local Anesthetic Drug Choices

LA dosing for various airway blocks is listed in Table 19-2. Toxicities of these injectable drugs have been described elsewhere, but with regard to the airway, some considerations need clarification.

Nydahl and colleagues demonstrated that 20 mL of 2% lidocaine gel in the nasopharynx was mostly swallowed in the stomach. Only one eighth of the described toxic blood level of an equal amount of injected drug resulted. Doubling the volume to 40 mL was equivalent to producing less than one third of the toxic level.[91]

Higher dosing and routes are most significant and should depend on a patient's height and size. Woodall and associates reported symptoms attributable to local anesthetic in 36% of 200 healthy subjects (anesthesiologists attending an FOB course).[92] Local anesthetics used

TABLE 19-2
Oropharyngeal Local Anesthesia

Drug	Form	Appropriate Blocks
Lidocaine	Pacey's paste (slurry): 7 mL 2% solution + 7 mL 2% viscous in two syringes with 3 mL air each + sweetener (mix back and forth via three-way stopcock); should be swished intraorally in 2 aliquots	
	2-4% solution	All blocks except as listed below
	1% solution	Preferred for SLN neck blocks
	4% solution	Preferred for transtracheal blocks
	2% viscous lidocaine	Intraoral or nasopharyngeal
	2-5% gel/ointment/paste	Intraoral
Exactacain (benzocaine, butamben, tetracaine HCl)	Metered spray	Intraoral
Cetacaine (benzocaine, tetracaine HCl, butamben, benzalkonium chloride)	Spray	Intraoral
Hurricaine (benzocaine)	Spray	Intraoral
Tessalon Perle (benzonatate)	200-mg capsule	Intraoral

SLN, Supralaryngeal nerve.

included nebulized lidocaine (200 mg or 5 mL 4%), nasopharyngeal lidocaine (100 mg or 2 mL 5%), and "spray as you go" lidocaine (600 mg or the equivalent of 15 mL 4%). The maximum dose in their study, 9 mg/kg lidocaine, was somewhat higher than the average dose of 5 mg/kg cited for performance of the described blocks in this chapter whose total dosage is 370 mg (i.e., GPN, 150 mg; SLN, 60 mg; and transtracheal, 160 mg).

Exactacain spray is a metered anesthetic with a six-spray maximum limit in adults to reduce the risk of toxicity. Each spray delivers 9.3 mg of benzocaine. Onset is within 30 seconds, and the duration is 30 to 60 minutes. Care must be taken to avoid use in patients with ester allergies or if the possibility of methemoglobinemia is likely due to patient comorbidities or concomitant drug therapy. Methemoglobinemia is more often associated with unlimited, continuous spraying of the Cetacaine spray (benzocaine 14.0%, butyl aminobenzoate 2.0%, tetracaine hydrochloride 2.0%) or Hurricaine spray (benzocaine 20%), which deliver 28 mg of benzocaine in a 0.5-second spray.[93-95] According to Khorasani and colleagues, dosing can be variable with these agents due to the orientation of the container to the patient during spraying or fluctuations in LA canister volume.[94] Between 1950 and 2005, only 26 of 126 total reported methemoglobinemia cases were related to endotracheal intubation. Transesophageal echocardiography was the procedure with the most frequent association, with a documented incidence of 0.115%.[95] Some sources consider this to be an underestimation. Because of recent Exactacain straw applicator connection manufacturing changes, care must be taken to use the same straws that come with the local anesthetic canister or to hold them securely while spraying, to prevent "popping off" of straws into a patient.[96]

A general plan of patient preparation is itemized in Box 19-5. Steps that are inappropriate for any specific patient should be eliminated or changed.

Box 19-5 General Plan of Patient Preparation for Awake FOB Intubation

1. Check FOB equipment.
   - Choose FOB diameter closest in size to ETT diameter (have lubricant available if very close).
   - Plug in electrical outlet, turn on light source, and adjust according to FOB instructions.
   - Test lever and FOB tip motion, clarity, and focus by looking at printing on a nearby object.
   - Use defogger or insert FOB into warm irrigation bottle.
   - Place tested ETT in warm irrigation bottle, choosing at least one-half size smaller if a difficult airway is present.
2. Obtain history and physical examination and discuss the plan with the patient (psychological preparation).
3. Administer antisialogogue.
4. Administer sedative and insert an intravenous line if none is present.
5. Administer sodium citrate if aspiration risk is present.
6. Monitor the patient.
7. Lower the bed maximally.
8. Administer oxygen by cannula.
9. Position patient supine (ideally), or sitting for patients who are unable to lie flat, with the intention of facing the patient during endoscopy (note that anatomy will be inverted in the latter case). See obesity concerns discussed in the text.
10. Titrate sedative/narcotic while local airway anesthesia is applied.

ETT, Endotracheal tube; *FOB,* fiberoptic bronchoscope.

E. Fiberoptic Orotracheal Technique

1. Three Successive Directions for Fiberoptic Guidance

Airway specialists are remarkably familiar with the upper airway configuration as routinely observed during direct laryngoscopy. On the other hand, the different axes successively followed by the structures involved during FOB intubation, and their reciprocal spatial organization, are less a matter of emphasis in the classic teaching programs. Moreover, many sketches or drawings in medical textbooks are inaccurate, showing the upper airways as a regularly curved line joining the oropharynx or nasopharynx to the carina. This is obviously misleading, because three successive directions must be followed in the supine patient in order to reach the trachea through the nasal or the oral route.[97] These successive directions are (1) downward to the posterior wall of the oropharynx or nasopharynx, (2) upward to the anterior commissure of the vocal cords, and (3) downward again into the laryngeal and tracheal lumen to the carina.

Oral FOB entry is usually midline but a retro-molar entry is possible in some patients with limited openings. When one is performing an FOB intubation via the oral route, it can be difficult to stay in the median sagittal plane, and this problem gets worse when obstructive flaccidity of the pharynx is present. The difficulty can be overcome with the use of a special airway (e.g., the Ovassapian device), help from an assistant, or FOB intubation through a supraglottic airway such as a laryngeal mask airway (LMA; LMA North America, San Diego, CA).

During the second phase of the fiberscope progression, in the upward direction to the anterior commissure of the vocal cords, the posterior part of the glottic aperture comes into view. In the absence of anatomic distortions, the temptation to push the fiberscope unswervingly in this direction should be resisted. It may be better to continue toward the anterior commissure of the cords, keeping the tip of the device in a sharp anterior path (by pushing down with the thumb on the button of the handle). Only when the anterior commissure is approached should the tip be angled correctly downward, toward the middle of the lumen of the larynx. This maneuver aligns the fiberscope with the anatomic axis of the larynx successively in its supraglottic and infraglottic segments, avoiding contact damage to the mucosa and arytenoid cartilages (Fig. 19-17).

2. Practical Application

Preparation before the FOB procedure should follow in sequence while adjustments are made depending on

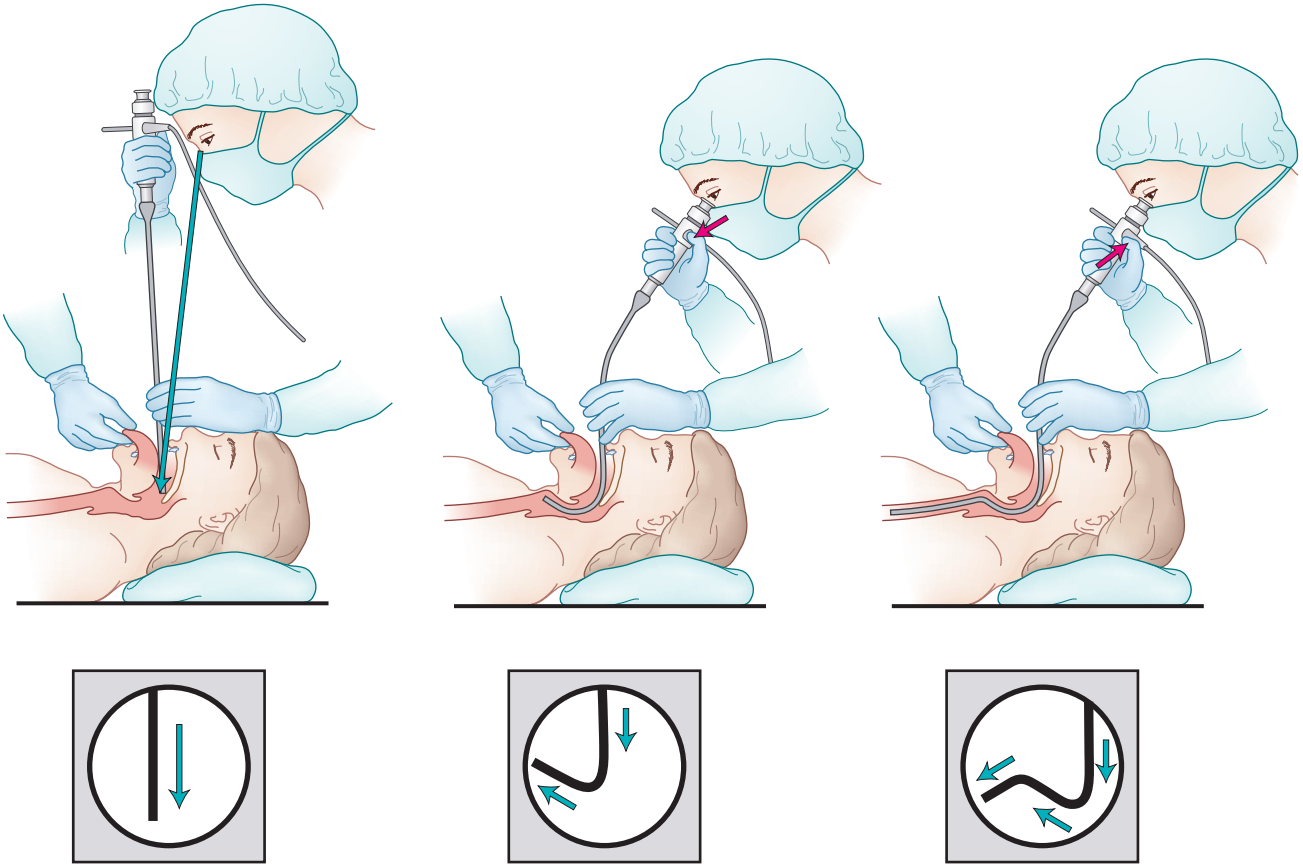

Figure 19-17 Three directions in the anatomic approach to fiberoptic intubation *(left to right)*: downward into the pharynx, upward through the vocal cords, and downward into the trachea.

individual patient concerns: equipment preparation, patient preparation, antisialogogues, sedatives, narcotics, local anesthetics, monitoring, and nasal cannula oxygen (if permitted; see Box 19-5). If there are not enough people available for assistance, the thumb-control port of the suction may be sealed ahead of time with tape, to make it a one-handed tool, which may help in the midst of a busy FOB procedure. The bed or table is moved to its lowest setting while keeping the patient supine. Use a stepstool to keep the FOB straight, if needed; in the case of a sitting, dyspneic patient approach the FOB procedure by facing the patient.

Employ the back-up bed position at whatever height makes the patient's comfort of breathing better. Traditionally, endoscopists like to "ramp" overweight patients up with many blankets under the upper thorax, neck, and head regions to align the airway when using RL, to decrease soft tissue encroachment on the airway. Rao and colleagues compared ramping with elevating the back of the bed until the patient's external auditory meatus is at the level of the sternal notch (Fig. 19-18).[98] There was no difference between the two methods in demographics, time to intubation, grade of glottic view, or number of RL attempts until intubation was successful. There was a significant difference in the added time and effort needed to position patients with blankets and then to remove blankets (and most likely in laundering cost, at 75¢ per blanket, although this was not mentioned in the study). By extrapolation, elevating the back of the bed or using a reverse Trendelenburg position to align the external auditory meatus with the sternal notch may facilitate FOB intubation in obese patients with less wasted resources.

Once oropharyngeal LA is accomplished, many FOB operators direct patients to close their eyes, placing a surgical towel loosely on the upper face as a barrier to avoid injury to the eyes (e.g., from stray liquid agents). The towel can also serve to promote sedation by preventing patient observation of needles and instruments. After the remainder of the airway anesthesia has been completed, gently suction the oropharynx, curving anteriorly and caudally toward the larynx in the midline with a soft suction catheter if the mouth opening is limited, or with a Yankauer suction catheter. If the patient gags, GPN anesthesia is lacking, whereas if coughing occurs, SLN anesthesia is inadequate. This can be rescued by administering the appropriate block, or by using the "spray as you go" technique. Another benefit of suctioning is to remove secretions or blood out of the viewing path of the FOB.

Have an assistant hold the tip of the patient's tongue with gauze by grasping its anterior and posterior surfaces and extending it carefully so as not to cause tearing of the frenulum linguae. This lifts the tongue off the palate and elevates the epiglottis (Fig. 19-19). Apply 2 cm of 5% lidocaine paste to the distal lingual side of the IOA

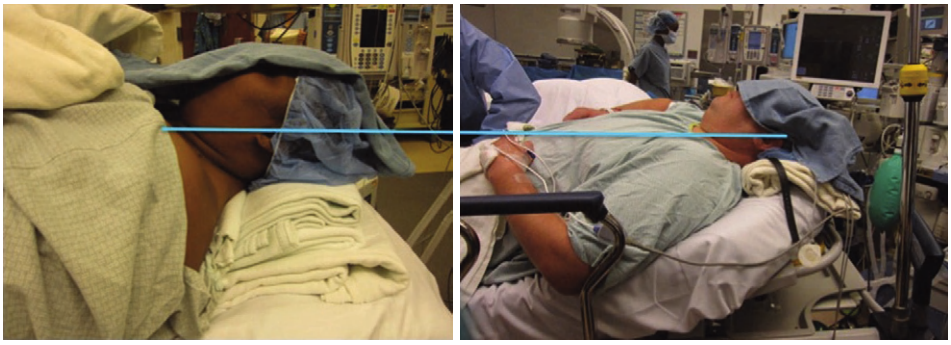

Figure 19-18 Comparison of positions for intubation in patients with increased body mass index. *Left,* Ramping with multiple blankets, which need to be situated and then removed after intubation. *Right,* More simplistic back-up bed position. Reverse Trendelenberg or back-up positions are used to align the external auditory meatus with the sternal notch *(blue line)*. Following intubation, the bed is easily returned to normal.

before gently positioning it, but only if using an Ovassapian or Berman type of airway. The assistant should hold the IOA midline during endoscopy to prevent deviation from the path to the larynx.[99] Alternatively, use a bite block (e.g., BiteGard [Gensia Automedics, San Diego, CA]) placed between the premolars to protect the FOB from dental trauma (Fig. 19-20).

Slide the lubricated ETT completely up the FOB, and either tape the connecter there or hold the ETT syringe with a little finger. Many FOB operators recommend holding the FOB handle in the nondominant hand, because thumb movement of the lever or forefinger depression of the suction valve are not as intricate movements as directing the FOB tip with the dominant hand. Control FOB progress into the mouth and keep it midline by using the dominant hand's thumb and first two fingers, similar to holding a pen. The fourth and fifth fingers are placed on the patient's upper lip or cheek. This precise anchorage allows for firm stabilization of the FOB to prevent tremulous movement of the view and also prevents eye injuries caused by a stray little finger while the endoscopist's visual concentration is fixed on the screen or through the eyepiece during advancement. Old-school teaching used the hands in reversed roles, and many still prefer this idea.

To keep the FOB straight and prevent bending damage, rest the hand holding the FOB handle high on that extremity's ipsilateral shoulder to lessen fatigue.

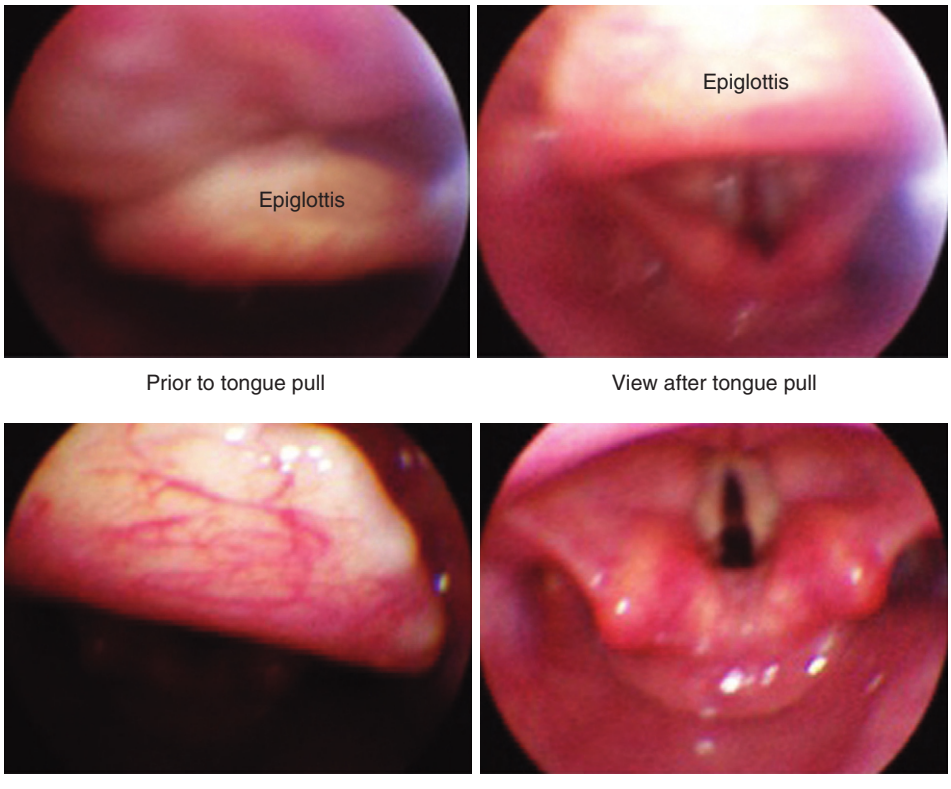

Figure 19-19 Effects of tongue pull and jaw thrust on epiglottic and glottic views.

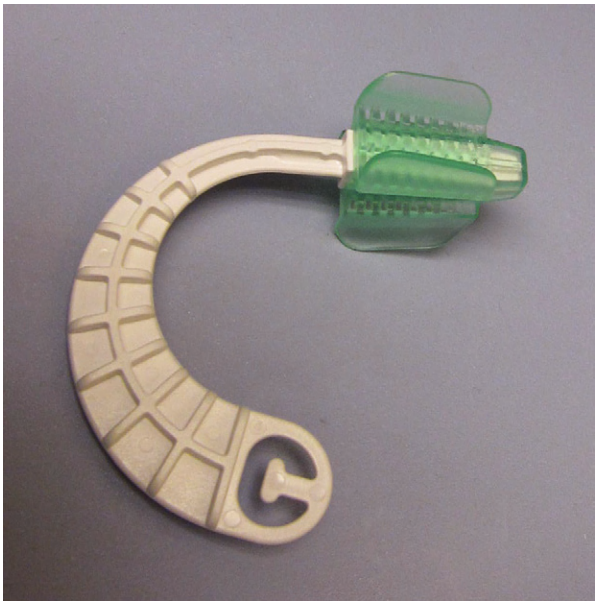

Figure 19-20 BiteGard for dental and fiberoptic bronchoscope protection is inserted between the premolars.

Alternatively, hold the instrument vertically straight adjacent to the patient. The patient's head and neck normally stay in a neutral position.

Insert the FOB into the patient's mouth, following the IOA while keeping the demarcation between the color of the IOA and the color of the mucosa in the center of view. Use the lever to look up or down and turn the FOB as a unit to look left or right, always keeping recognizable structures along the desired path in the center of view. Go around unwanted obstacles, such as secretions. If urgency is not a factor, slowly feed the FOB 6 to 8 cm, past the palate and past the uvula, and use the lever to look for the epiglottis, glottis, and tracheal rings. Stop two to three rings above the carina. If nothing is recognizable along the way, back up and look around with slow lever motion until structures are familiar, then proceed again. Do not provoke coughing by getting too close to the carina, which is unlikely to be anesthetized.

Hold the scope immobile and slide the ETT forward with the Murphy eye oriented anteriorly if using a PVC ETT, to prevent it from getting hung up on the arytenoid. Statistically, it gets caught on the right side most often.[100] Do not let the FOB go forward as the ETT advances toward the back of the oropharynx. At this point, look at the patient to judge when the ETT may be near the larynx. Ask the patient to take some deep breaths so that the vocal cords open more widely to admit the ETT. Time the breathing, and when ready, quickly push the ETT forward. After judging that it has gone beyond the vocal cords, look at the FOB tracheal view again, and slide the ETT until it ends up two to three rings above the carina and has just passed the FOB tip. Inflate the ETT, stabilize it, and remove the FOB. Put the FOB in the used vertical holder, or hand it in a straight fashion to an assistant. Attach the ventilating system while checking for P_{ETCO_2}, tape the ETT, and continue whatever patient care is anticipated next.

For very difficult airway and ETT insertions, it is worthwhile to check placement with the FOB after taping and patient positioning, which may be a source of ETT dislodgement.

Trouble-Shooting

1. The tongue extended preoperatively, but now, just before FOB insertion, it cannot be fished out for a tongue pull: Have the assistant firmly apply a large suction tubing to the tongue and slowly draw it out enough so that it can be grasped with the gauze. An alternative, especially for larger tongues, is to snag it with a clamp (e.g., ring forceps) or, rarely, with a large-diameter suture.
2. The patient has excessive oropharyngeal secretions or blood, and visualization with the FOB is almost impossible:
   - Have an assistant suction the oropharynx, even continuously if necessary. If possible, use an IOA. If not, insert the FOB midline between the fingers of an assistant at the entry point into the mouth. Keep the tip straight while it goes into the mouth a distance equal to two thirds of the distance from the mouth to the ear. Have someone turn off the room lights, and use the FOB similar to a lightwand. With lever manipulation, angle the tip forward and use transillumination to advance the FOB until an extremely bright pretracheal glow is seen. If the light appears off to one side of the neck, retract the FOB slightly and move it away from that side. If the light glow is anterior but less strong and resistance is felt, the tip may be in the submental area. Retract it slightly and redirect it posteriorly. If the glow is very dim, entry into the esophagus is most likely. Again, retract and angle anteriorly until the pretracheal glow brightens. At the glottis, the FOB entry into the trachea is exceedingly bright and visual optics may return. If not, suction via the FOB and continue forward until trachea or carina reaction is observed or those structures are visualized. An epidural catheter could be inserted for confirmatory P_{ETCO_2} monitoring.
   - An alternative approach is to insert an IOA or any SGA to seal the periglottic area. One with a gastric access tube may be the best choice. Then the ventilating lumen should be suctioned clear of secretions or blood and tested for P_{ETCO_2}. The FOB can be passed through it for intubation, knowing that there is less chance of continued soiling of the FOB or the airway.
   - Another alternative is to have a long (≥80 cm) guidewire with a few centimeters extending from the FOB tip that is nestled within an ETT just short of the ETT's distal end. Secure the wire proximally. With ongoing oropharyngeal suctioning, the FOB may stay clear of the soiling fluids, and the wire may be directed into the trachea. Once the wire is at least 8 cm into the trachea, the FOB and then the ETT can quickly be advanced, with rapid cuff inflation to prevent aspiration.
   - Lastly, a retrograde-FOB assisted intubation may be successful (see "Retrograde Incubation").
   - At some point, consider a surgical airway.

3. The optics are not clear; maybe the FOB is fogged: For an unclear view, try turning the focus dial. For fogging, touch the FOB tip on mucosa to clear it (Video 19-3). For secretions, suction with the FOB or use a suction catheter in the oropharynx, or both. Otherwise, FOB removal and cleaning of the tip may be the last choice. To clean, do not jab the FOB tip into anything, because delicate fibers can be broken. Hold the tip still but quite tightly near the very end, and gently wipe with alcohol.
4. It is impossible to look to the left or right because the lever only moves the FOB tip up and down: To look left, loosen the grip on the distal FOB insertion section between the thumb and two fingers while simultaneously rotating the handle section counter-clockwise, to avoid torque. To look right, turn the handle section clockwise in a similar fashion. Alternatively, rotate both hands equally in the same direction.
5. The FOB cannot get under the epiglottis because it is stuck on the posterior pharynx: Ask the assistant to pull the tongue out farther and perform a jaw thrust maneuver to lift the epiglottis (see Fig. 19-19).[101] Try moving the FOB more caudally or laterally, to get under the epiglottis.
6. The patient keeps gagging or coughing as the FOB advances: Consider repeating the LA blocks or use the "spray as you go" method.
7. After the FOB enters the trachea, the patient gets agitated and desaturates: In a compromised patient with tracheal stenosis or obstructive pathology, this may be the result of inadequate room around the FOB for the patient to breathe. The intubation process should be sped up, and the FOB should be removed as soon as possible. Be especially wary of starting oxygen insufflation through the working channel in this situation, in case not enough tidal volume can be expelled around the FOB. This sequence of events could precipitate the development of a pneumothorax.
8. The FOB is above the carina, but the ETT will not enter the trachea: Try not to jam the ETT, because it is advancing blindly and could damage perilaryngeal structures. Withdraw the ETT 1 to 2 cm, turn it 180 degrees counter-clockwise, and advance it rapidly after asking for a deep breath. If this is unsuccessful, rotate the ETT 180 degrees clockwise and repeat. If it is still not passing, repeat the other way. Try giving jaw thrust or even releasing jaw thrust. Use cricoid pressure, or neck flexion.[85] Finally, a rescue may be effected by removing the FOB and trying a smaller ETT; using a centrally curved, soft-tip ETT; inserting an Aintree Intubation Catheter (Cook Medical Inc., Bloomington, IN) on a pediatric FOB; or using a nasopharyngeal approach.
9. While using a pediatric FOB in an adult patient, tracheal rings were seen; the ETT went in, the FOB was removed, and the ETT was attached to the ventilator, but there was no P_{ETCO_2}, breath sounds, or chest movement: The tip of the FOB must end up within 2 to 3 cm of the carina in an adult, particularly if a pediatric FOB is being used. If it is only partially down the trachea, pressure against the ETT as it pushes forward in the periglottic area against tissue (e.g., arytenoid) may divert it into the esophagus or bend it back into the oropharynx and cause "flippage." Flippage may occur when a stiff ETT tip indents into the somewhat flexible insertion section of the FOB as the ETT is diverted into the esophagus or pharynx, causing the short entry of the FOB to flip out of the trachea.
10. A centrally curved, soft-tip ETT was partially inserted into the oropharynx of an adult patient; next, the FOB was inserted through the ETT, and the tip of the adult FOB was positioned 2 to 3 cm above the carina; the ETT was then railroaded over the FOB, but in spite of all maneuvers, it will not pass through the glottis: If time and resources are available, look in the oropharynx with another FOB to diagnose the problem. If the FOB crossed through the Murphy eye, the ETT will never advance into the trachea. Trying to force the ETT forward may cause serious FOB damage and injure the patient. Occasionally, when this happens, the FOB might not even be able to be withdrawn easily, particularly if forceful moves were already made. Strong attempts at removing an FOB stuck in the ETT may result in severe damage due to "sharper" Murphy eye edges digging into the outer plastic wrap of the FOB. If any significant resistance occurs in this "ETT insertion first" type of scenario, remove both devices simultaneously.
11. More than just a few drops of blood are in the trachea after a transtracheal injection: Do not give positive-pressure ventilation (PPV). Attach the oxygen system, and suction the ETT. To avoid coughing, give sedative agents and, if desired, muscle relaxants before suctioning.

F. Nasal Fiberoptic Intubation of the Conscious Patient

The patient must be questioned regarding prior coagulation status or anticoagulant therapy, nasal abnormalities, trouble breathing through either side of the nose, and any previous surgery in the area (e.g., recent transsphenoidal surgery). Psychological preparation, monitoring, and pharmacologic therapy concerns are similar to those for oral FOB intubation. Any one-sided nasal pathology should be avoided. If there is a deviated septum, the larger nasal passage should be selected, to steer clear of situations in which the FOB can easily enter the trachea, but the ETT cannot traverse the nasopharyngeal passage.

1. Innervation of Nasopharyngeal Airway Structures

Cranial nerve V, the trigeminal, supplies sensation to the anterior half of the nasopharynx by its first branch. The second branch of the trigeminal nerve forms part of the sphenopalatine ganglion, innervating some of the anterior, superior, and central regions.[85,86] Cranial nerve IX, the GPN, supplies parasympathetic innervation, while the carotid plexus supplies sympathetics.[102] Cranial nerve VIII, the facial nerve, has parasympathetic function and forms part of the sphenopalatine ganglion to assist in control of nasopharyngeal reflexes.

2. Topical Nasopharyngeal Local Anesthetic Techniques

A completely insensate nasotracheal FOB intubation approach would involve anesthetization of the nasopharynx, posterior wall of the pharynx, periglottic area, larynx, and trachea. Techniques that work well include a triple combination of nasal, SLN, and transtracheal LA; use of a face mask nebulizer, and the "spray as you go" technique. When administering nonaerosolized agents, apply them to both nasal passages whenever possible in order to find the largest pathway. Another benefit to anesthetizing both passages may result in cases in which it is impossible to complete FOB or ETT entry on one side: there will be no delay due to suddenly having to anesthetize the other route.

Besides anesthetization, the nose requires the addition of a vasoconstrictor to decrease the likelihood of epistaxis (see Table 19-2). Dip four Q-tip swabs into solutions of cocaine or a vasoconstrictor mixed with local anesthetic. Swab insertion gives the FOB operator an idea of the caliber of each nasal passage. Apply a single swab to the outermost part within the nostril. Push it inward with a forefinger, perpendicularly to the plane of the face, until slight resistance is met (Video 19-4). Put the next swab in the opposite nostril, and continue alternating insertion of swabs parallel to previous ones. By the time the last swab is placed, the initial insertions will have caused some vasoconstriction, and slight swab pressure will push each one in further. If desired, midway through the process, spray 0.2 mL of solution with a 20-G angiocatheter (needle removed) in three different directions within each nostril. Continue this process until all swabs are at the back of the nasopharynx. This method uses a total of 2 mL (80 mg) of cocaine. If the possibility of tachycardia is a concern, apply a mixture of lidocaine and a vasoconstrictor instead of cocaine, with swabs positioned as described. Some FOB operators recommend another technique, using lidocaine gel and phenylephrine as a coating on short nasal airways to gauge nasal passage size. Any excess drug that is not absorbed usually drips back to anesthetize the posterior pharyngeal wall.

As an alternative, spray the mixture twice in each nostril, but only in an upright patient. Spraying in supine patients can result in overdoses if the spray becomes a stream. Several case reports have been published in which application of topical phenylephrine or a potent vasoconstrictor resulted in dangerous hypertension. Beta-blocking agents administered in this circumstance may promote the occurrence of pulmonary edema and should be avoided, according to the New York State guidelines on the topical use of phenylephrine in the operating room.[103]

For nasotracheal intubation under GA, vasoconstrictors are very useful to prevent epistaxis.

3. Vasoconstrictors and Local Anesthetic Drug Choices

Drugs are listed in Box 19-6.

Box 19-6 Nasopharyngeal Drug Therapy Before Intubation Using a Fiberoptic Bronchoscope

Vasoconstriction

Phenylephrine 0.5% spray
Oxymetazoline 0.05% spray

Local anesthesia

Lidocaine 2-4% spray, gel, viscous, paste

Both Vasoconstriction and Local Anesthesia

Cocaine 4% with a maximum dose of 1.5 mg/kg[104]
Mixture of 2-4% lidocaine (3 mL) + 0.5% phenylephrine (1 mL) or 0.05% oxymetazoline (1 mL)

G. Fiberoptic Nasotracheal Technique

Because of the relative narrowness of the nasal passage, an ETT at least one-half size smaller than would be chosen for the oral route should be selected, depending on the patient's history or size. Some endoscopists erroneously think that inserting progressively larger nasal airways or "trumpets" can mechanically "dilate the passage." However, Adamson and coworkers reported that use of this method caused increased trauma, hemorrhage, and delay of intubation.[104]

Pre-block preparation is similar to that for the oral approach, although antisialogogues are not quite as important if intraoral LA is not planned. The well-lubricated FOB can initially be introduced in one of three ways: (1) by itself for a distance of 12 to 15 cm, (2) within a lubricated short nasal airway that is designed to break away, or (3) after a well-lubricated ETT is first partially inserted into the posterior nasopharynx. After inserting the FOB, steer it to follow the dark conduits or openings of the nasal passage until the epiglottis is seen. As a substitute technique, insert the breakaway nasal airway or partially insert the ETT before FOB entry. This will virtually lead the FOB tip directly toward the larynx. Avoid the "ETT before the FOB" technique in coagulopathic patients and in situations in which bleeding is more likely to occur.

After locating the larynx and entering through the glottis, the remainder of the procedure, including depth of FOB passage, orientation of the Murphy eye, and ETT railroading to the correct depth, is similar to that for oral FOB intubation.

Whether the ETT is inserted before the FOB or after it, direct its leading edge along the septum. Through the left nostril, one may insert the ETT in the usual fashion until the back of the nasopharynx is reached. Through the right side, however, the concave surface of the ETT should face cephalad until the ETT tip reaches the back of the nasopharynx. At this point, the ETT is rotated 180 degrees to align the concavity anteriorly. This may help to prevent evisceration of the turbinates.

A proactive method to avoid trauma is to insert, as a unit, a lubricated and slightly protruding nasogastric or suction tube that almost fills up the lumen of the ETT. This prevents scooping or cutting into tissues by the firm,

leading ETT edge. Another option is to use a centrally curved, soft-tip ETT.

Trouble-Shooting

1. The plan was to partially insert the ETT first, but it does not want to pass: Be gentle and do not exert force. Try the other side. If that does not work, try alternative methods listed previously.
2. Partially inserting the ETT caused epistaxis (no FOB yet): Inflate the ETT cuff to tamponade the area, or externally pinch the nose for 5 to 10 minutes. If blood is welling out of the nostril but no blood trickles into the back of the pharynx (i.e., there is no choking, swallowing, or continual need for suctioning), try pulling the deflated ETT a little and reinflating the balloon at what may be the site of injury. To prevent additional trauma, try not to remove the ETT unless blood keeps entering into the back of the pharynx regardless of the number of times these maneuvers were engaged.

H. Oral or Nasal Fiberoptic Intubation of the Unconscious Patient

1. Under Routine General Anesthesia

Eyes should always be protected in unconscious patients before any airway manipulation. If mask ventilation is expected to be easy under GA before surgery, a purely elective FOB procedure can always be used to intubate patients if consciousness is not required. This form of achieving intubation is very acceptable. It is considered ethical not to inform the patient of this plan because it is one normally used by many patient caregivers.[105] In some circumstances, "asleep" FOB intubation may have specific indications (e.g., a patient with extensive anterior dental work).

Preparation should include administration of an antisialogogue, complete FOB equipment readiness, premedication, monitoring, and positioning. If the surgery dictates a preference for nasotracheal intubation, nasal vasoconstrictor sprays should be applied while the patient is awake and in the sitting position. Because tissue laxity can obscure the airway in comparison to awake states, a smaller-sized ETT should be used. Positive-pressure face mask oxygenation is standard after induction and muscle relaxant delivery until the drugs have taken effect. At that point, lift the mask off the patient's face while the assistant performs a tongue pull, places the IOA, or gives a jaw thrust as needed. Insert the FOB and intubate as described previously. If desired, direct someone to keep track of passing time (Video 19-5; see also Video 19-3).

Trouble-Shooting

1. The technique is not succeeding: Careful monitoring and awareness of 2 to 3 minutes' passage of time, even in the case of technical difficulty, should keep the situation under control. If unsuccessful, always reinstitute face mask ventilation and decide whether the problem is caused by anatomic difficulty, being off-midline, insufficient assistance, or a lack of equipment. Think about giving more anesthetic before another attempt, or use an alternative intubation plan (e.g., intubation with another device). Frequently, combination FOB techniques should be considered (see "Combination Techniques").

2. After Rapid-Sequence Induction

Although they are not common, scenarios may arise in which patients with high aspiration risk have a DA but are not candidates for the awake intubation technique. An FOB can also be used electively after induction of GA in patients who are too young to understand or in uncooperative patients. In the former situation, the steps involved in an awake FOB intubation might cause an unwanted degree of psychic trauma, whereas in the latter case, the primary concern is risk to the patient or even to the FOB due to fighting or biting. Because of the risk of aspiration or airway loss, only a very experienced endoscopist, who expects a very high chance of success, should embark upon this procedure from the start under GA. Otherwise, initiation of this method during GA is inappropriate, and it is an especially poor choice for patients with very difficult airways.

If the decision is made to proceed, have two operable suctions attached, one on the FOB and the other on a Yankauer or soft suction tubing in case of regurgitation. Choose a smaller-sized ETT. If not contraindicated, preoperative preparation is identical to that used for rapid-sequence GA, with inclusion of an antisialogogue, clear oral antacid, histamine H_2-blocker, and/or gastric motility–inducing agent. After induction and cricoid pressure applied as originally explained by Sellick,[106] use the FOB intubation technique with good assistance. Once the FOB nears the carina, the ETT should be inserted quickly and the cuff inflated immediately.

Sometimes, asleep FOB intubation may be selected as a rescue tactic for patients who have incurred failed intubation with another device. Early use of an FOB for intubations that have gone awry is much less likely to cause the devastation that can result from repeated failed RL attempts.

Trouble-Shooting

1. The epiglottis and periglottic areas are easily seen, but the glottis is very small with closed vocal cords, and the FOB cannot enter: Check the nerve stimulator for degree of muscle relaxation. If this is insufficient and laryngospasm is suspected, spray down the FOB with 4% lidocaine. If the patient is relaxed, ask the assistant to slowly decrease the cricoid pressure to see if things improve, because this pressure can be associated with impaired glottic visualization. If regurgitation occurs, another assistant should suction the oropharynx, and pressure may need to be reinstituted, with a tentative release tried later.

I. Fiberoptic Intubation in Unconscious, Unanesthetized Patients

For emergency FOB intubation in unconscious, unanesthetized patients, ideally all equipment is available. The approach must be speeded up, however. Three important caveats must be considered before FOB technique in this situation: a full stomach must be assumed, cricoid pressure must be employed, and the most experienced FOB

endoscopist should perform the procedure. More descriptive directions may be required for assistants, who are likely to be less experienced in these urgent cases.

VI. COMBINATION TECHNIQUES

Whether the patient is awake or under GA, an FOB can be combined with ancillary devices and laryngoscopy instruments to accomplish intubation. FOB combinations have practical utility in realizing improved airway control, assisting in diagnostic and therapeutic efforts, and rescuing failed intubations. In many combination techniques, physical maneuvers (tongue pull and jaw thrust) are very advantageous.

Elective use of an FOB combination with other airway management equipment has a very high rate of success with the added luxury of planning. This may be extraordinarily beneficial in the most difficult airway predicaments. As an illustration, a Fastrach intubating laryngeal mask airway (LMA North America) may be desirable to seal off the laryngeal area from blood and accomplish ventilation in a patient who is difficult to mask ventilate, difficult to intubate, and has significant intraoral bleeding. This intubating airway has a moderately high success rate for blind insertion of its ETT (90% to 96.2% with ≤3 attempts or adjusting maneuvers).[107-109] Its use in combination with an FOB, however, can change a blind technique to a more controlled visual one, with a greater chance of success.[110]

Examples of diagnostic abilities of an FOB often become evident in patients who have undergone prolonged spinal surgery in the prone position. If such a patient's airway pressure rises intraoperatively, FOB examination through a bronchoscopy swivel adapter can be used to determine the cause (e.g., secretions, endobronchial intubation, a kinked ETT). A therapeutic role periodically occurs at the end of this type of surgery. A degree of indecision as to how well the patient might fare after extubation (due to length of surgery and airway edema) can be remedied by the therapeutic capability of combination use of an FOB with an Aintree catheter through the existing ETT. The Aintree is left as an "airway stent" and then secured in place after the ETT and FOB have been removed. Should the patient appear to be failing the extubation trial, an ETT-fitted FOB is reinserted down the Aintree for reintubation.

A common failed intubation scenario occurs in a morbidly obese patient with redundant intraoral tissues who is undergoing GA and laryngoscopy with an RL that reveals a Cormack-Lehane grade 3 view. Intubation failure despite the use of an intubation guide catheter can result in a deteriorating situation after multiple attempts due to tissue trauma, and it is made notably worse if mask ventilation becomes problematic. Attempts at FOB rescue by itself might be difficult. In combination, however, the RL can be used to elevate tissues out of the way of the FOB in order to obtain the best laryngoscopic view by RL, even if it only reveals the epiglottis. This can offer a much easier route for the FOB to follow to achieve the goal of intubation.

Finally, combining multiple approaches to manage the DA is just another illustration of the general concept of multimodal therapy, in contrast to monotherapy. Multimodal therapy is used in the everyday practice of health caregivers, such as when different classes of drugs are used to provide an overall "tailored" anesthetic, or when combinations of various analgesics are used for chronic pain control. The multimodal approach to the airway, unduly disregarded for a long time, seems to be increasingly accepted as the drawbacks of individual airway devices or techniques become more obvious and the failures of each, when used alone, are more frequently reported.[111]

A. Superficial Airway Devices and Flexible Fiberoptic Bronchoscopes

1. Combination with Endoscopy Masks

Very often the FOB-endoscopy mask combination can help to obtain either the objective of anatomic airway examination or actual airway control. These masks may have one or more openings for simultaneous FOB and ETT passage. A model that seals around both is ideal. Be cautious of models having a port that seals only around an FOB, because ETT insertion can result in a leak to the atmosphere with inability to ventilate the patient.

Preparation for use of the FOB-endoscopy mask combination during GA is the same as detailed earlier. The ETT, with its 15-mm connector removed, is placed over the FOB. Keep the connector in a secure spot. After induction, insert an IOA and strap the mask in place with 100% oxygen while an assistant holds the mandible to prevent obstruction. If no muscle relaxant is used, the patient should be relatively deeply asleep to prevent laryngospasm when the larynx is touched. This can be treated by instilling LA in a "spray as you go" technique. With muscle relaxation, the patient does not have to be as deeply anesthetized, but the assistant must be competent enough to maintain positive-pressure mask ventilation.

Insert the ETT-loaded FOB sequentially through the port, IOA, and trachea for subsequent intubation (Fig. 19-21). After ETT intubation, remove the FOB and mask and join the ETT to the ventilation system. If patient

Figure 19-21 Combination of a fiberoptic bronchoscope with an endotracheal tube through an endoscopy mask.

conditions warrant urgent ventilation, institute it through the ETT after removal of the FOB. Retire the mask at any time thereafter. One advantage of using this technique for an elective case is that it affords more time for endoscopy, particularly if surgery will not be delayed because the incision site is at the other end of the body.

These masks can also provide a supplementary method for administering oxygen during awake FOB intubation in a patient who is so respiratory-compromised that a nasal cannula might be insufficient. Administer nasal cannula oxygen during mask-lifting periods while LA is being given. After LA administration and airway suctioning, follow the same FOB-endoscopic mask steps detailed earlier.

If an FOB and an ETT are inserted simultaneously into the endoscopy mask port at the beginning of the procedure, FOB manipulation is not a significant problem in the straight forward-aiming oral route to the larynx. For nasotracheal intubation, it is better not to insert both initially, because the ETT might limit FOB maneuverability in entering the nasopharynx. During simultaneous insertion, this transpires when the exiting direction the FOB takes from the ETT is at odds with the entry into the nasal passage. In this case, insert the FOB well ahead of the ETT until the carina is located, and then advance the tube.

2. Combination with Swivel Adapters

A bronchoscopy swivel adapter for FOB examination or intubation can be placed between the ventilation circuit and an ordinary face mask, an SGA, or an ETT.

For intubation purposes, the combined use of an FOB and a swivel adapter can be undertaken under GA or oxygen-enrichment conditions similar to those for FOB-endoscopy mask use. With the patient under GA, insert a pediatric FOB within an Aintree intubation catheter (ID 4.7 mm, OD 6.3 mm) through the swivel adapter port while the patient is breathing spontaneously or being mask ventilated (Fig. 19-22). Once the FOB enters the trachea and nears the carina, slide the Aintree over it until it is two to three rings above the bifurcation. Hold the Aintree securely while noting the depth of insertion, and take out the FOB. Remove the Aintree connector to extract the mask, SGA, or old ETT. Then, slide a lubricated ETT-loaded FOB through the Aintree and down the trachea, stopping again near the carina. Pass the ETT farther down over the Aintree until the ETT tip lies 2 to 3 cm above the bifurcation. While firmly holding the ETT, remove the FOB and the Aintree. Reconnect the ETT to the ventilation circuit.

Optionally, apply ventilation via the Aintree 15-mm connector when the device is first placed if urgent respiratory assistance is needed or to confirm P_{ETCO_2} return before attempted ETT passage. This is also an alternative method to ventilate patients in cases where the ETT fails to enter the trachea.

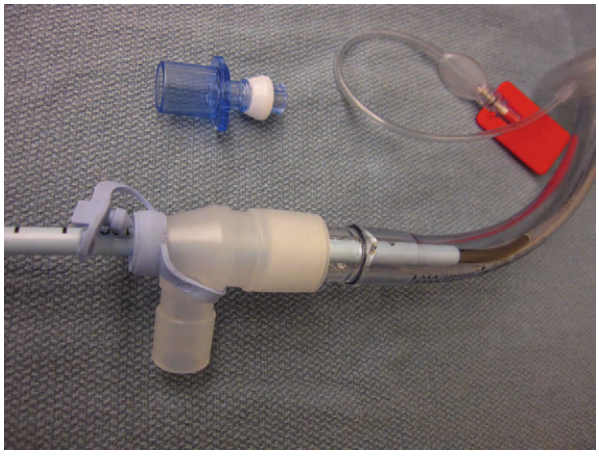

Figure 19-22 Combination of a fiberoptic bronchoscope with an Aintree catheter through a swivel adapter.

3. Combination Using Short, Soft Nasal Airways

The role of the breakaway soft nasal airway in facilitation of awake FOB intubation was detailed earlier (see "Fiberoptic Nasotracheal Technique"), and the principle can be transferred to generate similar results in patients under GA.

In addition, soft nasal airways may serve a very different function, as a conduit for GA gases while FOB intubation is pursued. In this technique, attach the anesthesia machine to a 15-mm ETT connector inserted into an intact nasal airway in a spontaneously breathing, very deeply anesthetized patient for the FOB manipulation. When the NPA method is used, considerable amounts of anesthetic gases are lost to the atmosphere, which is less than ideal. Nevertheless, it is the best choice in many cases. For example, an NPA is more commonly chosen for pediatric patients, who are prone to desaturate rapidly when intubation attempts are made during stoppages in mask ventilation. For nasotracheal intubation, it is not unusual to see this technique used on one nostril, with a breakaway NPA for intubation on the opposite side. During total intravenous anesthesia, the NPA only supplies oxygen.

B. Supraglottic Airways and Flexible Fiberoptic Bronchoscopes

The original LMA for ventilation had obvious airway management benefits from its inception, particularly for difficult mask ventilation and for DI. This device has saved countless lives and is rightfully prominently embedded in the ASA DA algorithm. It can be used in patients who are unconscious, awake with local airway anesthesia, or under GA. Since its development, dozens of SGA and intubating SGA devices have been invented. The idea of performing FOB intubation through the LMA was spawned by the knowledge that, when seated properly, this SGA had to be situated around the glottis and could provide a pathway for an ETT. The combination of FOB-SGA for ETT intubation has been successfully tried with numerous SGA brands (Fig. 19-23).

The FOB has also been combined with this sort of airway for trouble-shooting SGA insertion problems (e.g., high airway pressures, leak), as described earlier. The combination can also be used for assistance in accomplishing placement of the SGA itself, by having the FOB just recessed within the airway's "bowl" as the SGA is advanced into the oropharynx.

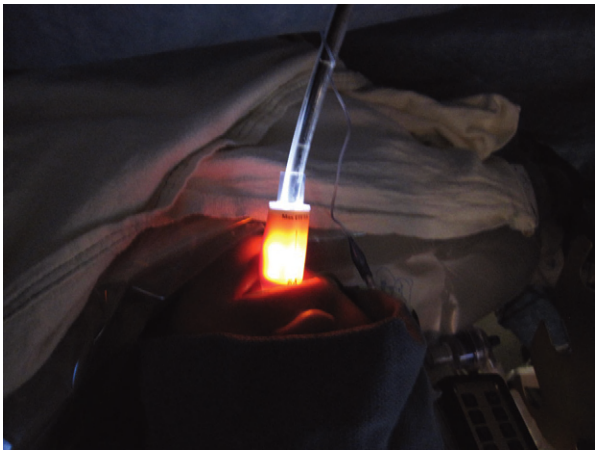

Figure 19-23 Intubating with the combination of a fiberoptic bronchoscope within an Ambu Aura-i intraoperatively.

1. Combination with SGA and Multiple Endotracheal Tube Techniques

If an FOB-SGA combination technique is being used for intubation, ascertain first that the desired lubricated ETT size is able to traverse through the SGA. Of course, the ETT must also be appropriate in size for the FOB. Many SGA have indicators for the maximum tolerated ETT size, and the larger ones permit entry of an adult-sized FOB. For smaller SGAs, a pediatric FOB and a smaller ETT are better choices. With the LMA brand, alignment of the bevel of the ETT in a transverse plane or preemptive cutting of the epiglottic deflectors will avoid situations in which the FOB tip and the ETT tip straddle an aperture bar. ETT sizes usually must be smaller.

Induce GA and position the SGA. While administering 100% oxygen, in a spontaneously breathing, deeply anesthetized patient or a ventilated, muscle-relaxed patient, try to obtain an optimal P_{ETCO_2} waveform with good chest excursions. Disconnect the SGA from the circuit, and slide the ETT-loaded FOB down the SGA until the glottis is visualized. Place the FOB tip near the carina and advance the ETT. Remove the FOB and confirm ETT placement with P_{ETCO_2}. Remove the 15-mm ETT connector, and use a smaller ETT as a push rod (similar to the Fastrach pusher rod). With the pusher, keep the first ETT steady, and slide the SGA out until the first ETT can be grasped in the oropharynx. Then remove the second ETT and SGA and connect the first ETT to ventilate the patient.

Trouble-Shooting

1. The only ETT that could pass is small and too short, prompting concern that its cuff will lodge between the vocal cords:
   - An option is to cut and discard a 4-cm section of the tubular end of the SGA, allowing for deeper ETT insertion. Push the ETT deeper, using a one-size-smaller ETT, impinging it in the first one's proximal end like a pusher rod. After pushing in 4 to 5 cm, hold the ETT system steady and withdraw the SGA. After seeing the first ETT in the oropharynx, continue with the same technique described earlier.
   - Alternatively, consider wedging a larger ETT circumferentially around the first ETT's proximal end. Then employ the same technique.
   - A very much longer Micro Laryngeal Tube (Rüsch Incorporated, Duluth, GA) (26 to 33 cm long, cuff sizes equivalent to an 8-mm ETT) is a better option. The SGA can be extracted over the Micro Laryngeal Tube with no need for a second ETT. Also, remember that SGA removal is not mandatory; simply leave it in place and deflate its cuff.

2. Combination with SGA and Aintree Catheters

As detailed earlier, intubate with an Aintree-loaded FOB via an SGA. Fix the Aintree, and remove the FOB and SGA. Complete the intubation with the ETT-loaded FOB via the Aintree (Fig. 19-24A).

3. Combination with SGA and Guidewires

Similarly, thread a long guidewire (110 to 145 cm long, 0.38 to 0.97 mm diameter) through the working channel of the FOB far into the trachea by way of the SGA (see Fig. 19-24B). While holding the wire in place, extract both FOB and SGA. Subsequently, thread the near end of the wire through the FOB tip, up the working channel of an ETT-loaded FOB. Use the FOB to visually follow the wire into the trachea for completion of ETT intubation.

4. Concerns

There are some limitations to FOB and SGA combinations:

- Correct SGA placement is not successful in 100% of cases.
- The ETT may not fit or pass through the SGA, so the combination must be prechecked.
- Not all lubricants are equally adept at lubricating the ETT. Viscous lidocaine, Exactacain, and Neosporin (polymyxin B sulfate, neomycin sulfate, bacitracin zinc) ointment achieve a far greater degree of "slickness" than common surgical lubricants.
- Compare the length of the ETT with the length of the SGA, because the distance from the periglottic opening of the SGA to the vocal cords may be 3.5 cm or more. Inattention to lengths may produce a "too short" ETT picture. Trying to cut a 4-cm section of a SGA tube to avert this problem (as mentioned earlier) may lead to problems: the SGA connector may not separate easily from its original seat within the SGA tube, or it may have a poor fit when plugged into the cut-off SGA section.

C. Intubating Supraglottic Airways and Flexible Fiberoptic Bronchoscopes

Reports of FOB intubation through the LMA prompted the development of the Fastrach. This silicon-covered, steel-body, intubating SGA comes in three sizes for patients weighing more than 30 pounds and has a moveable epiglottis deflector bar. Its dedicated centrally curved, soft-tip ETT more readily traverses the glottic aperture in comparison to PVC ETTs.

A number of intubating SGA models have now been manufactured. The Ambu Aura-i (Ambu, Glen Burnie,

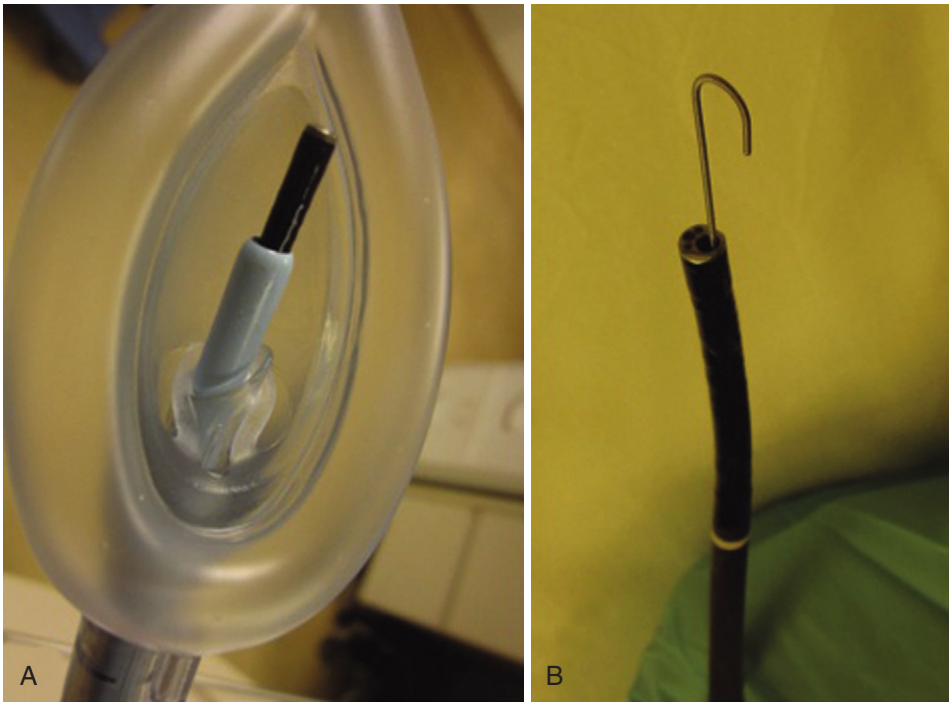

Figure 19-24 *A,* Combination of a fiberoptic bronchoscope (FOB), Aintree catheter, and ETT in a laryngeal mask airway. *B,* The guidewire is shown within the working channel of the FOB.

MD) is a soft, rounded PVC SGA available in infant to large adult sizes. It was designed with less of a J-curve, and on its bite block area the maximum ETT size able to pass through it is clearly labeled.

Intubating SGAs were originally designed to act as conduits with high success rates for blind passage of an ETT into the trachea. They are more aptly designed for this purpose than most SGA devices, because larger ETTs can be deployed. When used with an FOB in a similar fashion to FOB-SGA combinations, their intubation success rate soars (Fig. 19-25). In a study by Erlacher and associates, 180 patients were intubated blindly through CobraPLUS (Pulmodyne, Indianapolis, IN), air-Q (Trudell Medical Marketing Limited, London, Ontario, Canada), and Fastrach devices with success rates of 47%, 57%, and 95%, respectively.[112] Of the approximately 60 patients for whom blind intubation failed when these intubating SGAs were used alone, FOB insertion for intubation was attempted; the overall success rate for the FOB-intubating SGA combination was greater than 98%.

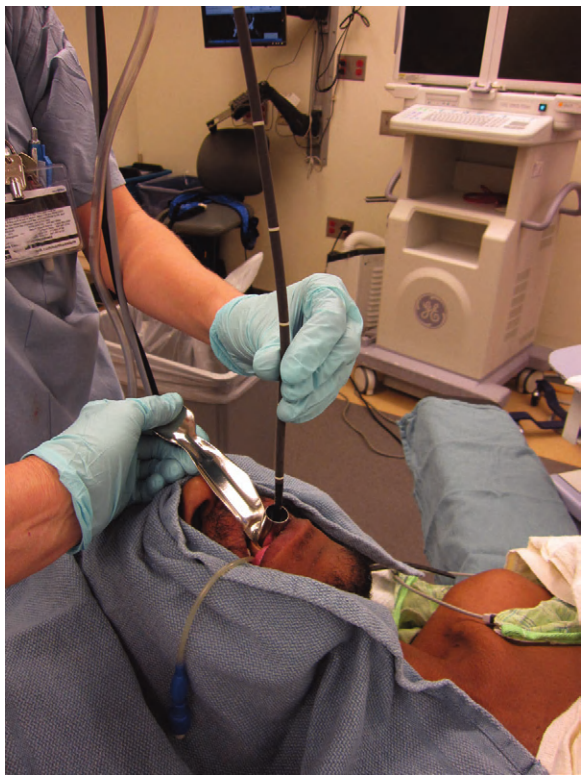

Figure 19-25 Intubating with a combination of a fiberoptic bronchoscope through a Fastrach.

D. Combination with Rigid Laryngoscopes

Occasionally, when an FOB is used as the sole airway device, impediments may prevent entry into the glottis; examples include a nonmobile or floppy, posteriorly directed epiglottis and upper airway edema. An RL can assist in lifting the mandible and moving obstructing tissues out of the way to improve the route for the FOB (Fig. 19-26). The FOB-RL technique requires at least two people: two endoscopists, or one endoscopist and a very knowledgeable assistant. The assistant must be able to hold the RL immobile after it has been placed optimally or to manage the FOB controls.[110,113] The clinical

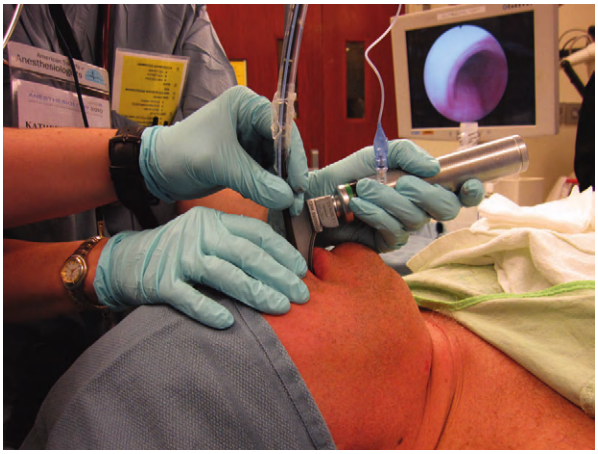

Figure 19-26 Fiberoptic intubation assisted by a rigid laryngoscope with video view of the trachea.

situation, together with the knowledge and technical abilities of the personnel involved, dictate who handles the RL and who directs the FOB tip or completes glottic insertion of the FOB or both. Successful FOB-aided controlled tracheal extubation and reintubation using the RL-FOB combination has been reported in intensive care unit patients.[114]

A possible, but not proven, advantage may be reduced nociceptive stress of intubation in response to lower RL blade pressure at the base of the tongue during use of FOB-RL combinations.

1. Nonsoiled Airway Situation

Use the RL to visualize the airway toward the glottis as much as possible, while moving blocking structures out of the way. Ensure that the RL is fixed in place. Before FOB insertion, suction the airway as needed. Endeavor to use the visual features of the ETT-loaded FOB to advance its tip by hand under the epiglottis, toward the larynx, for entry into the trachea and intubation. During maneuvers, direct the assistant to hold the RL steady or to manage the FOB controls.

2. Soiled Airway Situation

If it is impossible to use the visual features of the FOB due to soiling, obtain the best overall view with the RL. Direct an assistant to manage the controls. While holding the RL steady, advance the FOB tip under the epiglottis by looking directly in the mouth, similar to inserting an ETT. Do so by using the light from the RL, not the optical system of the FOB. Once the FOB tip is beyond the epiglottis, monitor its progress by using the FOB visual capability, and advance the insertion section while instructing the assistant to move the tip up or down. Continue until the glottic aperture is reached, while holding the RL firmly in place. When necessary, clear the FOB tip by touching it on mucosa or requesting the assistant to suction the patient, or both. After the trachea has been entered, insert the FOB tip near the carina and ask the assistant to railroad the ETT. Considerable cooperation is important.

Alternatively, after the best view is obtained with the RL, direct the assistant to hold the RL fixed. Introduce the FOB as far as possible under direct vision next to the RL (again, similar to inserting an ETT). Once further insertion under direct vision is impossible, monitor via the FOB and handle the controls until trachea and carina are secured. Then railroad the ETT.

E. Combination with Video Laryngoscopes or Optical Laryngoscopes

VLs and OLs are amazing devices that have a firmly rooted place in airway management and definitely should be part of the DA algorithm. Many can give stunning images due to options such as wide-angle camera capability, exceptionally clear optics, and video monitoring. Their learning curves are very fast. In most patients, the 60-degree angulation design with video or optical mirror capability improves Cormack-Lehane views of the larynx by one to two grades over those seen with the RL.[115-117] VL devices will most heavily impact what is now obviously an inferior device for airway management—the RL—and will result in continual declining use of that instrument.[118]

Despite superior visual capabilities, these devices can have failures in diverse airway cases.[117-119] It is unlikely that VL will replace FOB use because of the very nature of FOB—the flexibility to conform to intricate airway pathology. The VL can optimize laryngoscopy but does not share the FOB's second most desirable property, the ability to mechanically guide the direction of an ETT into the trachea to a specific end point. Clinicians may be delighted by the improved images from the VL, but they also are disappointed periodically when it remains impossible to intubate a patient despite "a perfect laryngeal view." Many such failures have been reported with all types of VLs and OLs.[59,119] In addition, pharyngeal perforation (palate or tonsillar pillars) may rarely result from the ETT tip during VL use. The cause is simple to understand. Whereas the ETT is initially advanced under direct vision, at some point it is pushed ahead blindly until it is finally seen again on the video screen.[120-122] Care taken to directly observe the ETT hugging the tongue and curving it centrally and caudally within the airway greatly lessens this possibility. This type of trauma is unlikely with an FOB system in which the ETT slides over its insertion section.

Even the FOB has limitations compared to VL devices. FOBs have a more narrow-angled field of view, a shorter focal distance, a greater possibility of obscured optics if the airway is soiled, an inability to open the airway, and a degree of inability to maintain a midline position in the pharynx while advancing toward the glottis.[123]

Ideal circumstances combine an FOB with a VL to employ the strengths of both techniques. Having both FOB and VL screens available would be a situation of truly superior airway management. With this combination, the VL is used to keep the oropharynx open and lift tissues away from the glottis and epiglottis during oropharyngeal or nasopharyngeal FOB intubation. The VL view of the FOB position and the simultaneous FOB view of pharyngeal and later laryngeal anatomy permits better FOB control and a greater range of vision. This combination of an FOB with a VL assists in reaching and entering

the larynx by reducing unwanted FOB movements in lateral directions.

VLs can also help diagnose FOB problems. In many cases, the FOB-VL technique provides visualization of the passage of the ETT over the fiberscope into the glottic area, aiding in the resolution of ETT "hang ups" at the arytenoid and other passage difficulties. The combined technique does have a drawback in that it requires both an endoscopist and a very knowledgeable assistant, but management of DI may necessitate two operators in any event. Indeed, use of the combination of FOB and VL has been shown to be advantageous and has been reported in DA patients.[124]

Another virtue of the FOB-VL combination is that it permits the use of a VL to fully observe FOB manipulation by trainees. This can enhance instruction and maximize learning experiences.[125]

1. Non–Channel-Loading Devices and Fiberoptic Bronchoscopes

The type and number of personnel and the technique involved with combination of an FOB and a non–channel-loading device are similar to those of the combined FOB-RL method. Situate FOB and VL video screens, if available, near one another. After GA induction, attempt laryngoscopy with the VL until the best view is achieved. While holding the VL in place, direct the tip of the FOB under the epiglottis and toward the glottis (Fig. 19-27). Instruct the assistant to control the FOB tip. When the tip is beyond the view of the VL, use the FOB view. Continue to advance the insertion section, and after locating the tip near the carina, ask the assistant to railroad the ETT as described previously. Alternatively, after the VL attempt, have the assistant fix the VL in place. Take over total control of the FOB to locate the glottis, trachea, and carina and complete ETT passage.

In the event of a soiled airway, the FOB-VL combination can be used in a fashion somewhat similar to the FOB-RL methods under soiled conditions.

Trouble-Shooting

1. The brightness of the VL is making the FOB view excessively "whited out": Dim the brightness of the VL model, if it possesses this feature, to prevent excessive glare when viewing through the FOB (Fig. 19-28). If the VL model does not have this capability, power it off after the FOB insertion if this problem arises. Power it back on intermittently to monitor FOB and ETT progress.
2. It is impossible to get the FOB tip under the epiglottis, even when directly looking into the mouth to position it: The FOB tip may be too flimsy to execute this maneuver. Observe the VL view of the FOB, gently advance the ETT just past the FOB tip, and snake the ETT under the epiglottis. Request a tongue pull or jaw thrust, or both. If successful, advance the FOB and complete the intubation.

Figure 19-27 Intubating with a combination of a fiberoptic bronchoscope and a GlideScope video laryngoscope.

2. Channel-Loading Devices and Fiberoptic Bronchoscopes

Visualization of the larynx may be perfect with the channel-loading type of VL or OL and yet result in failure of ETT intubation. In this scenario or even if insufficient visualization occurs, the VL may be used to open an airway path. Insert the FOB within an ETT either in the channel or next to the device. Direct it toward the glottis if it seems easy to do so, or use the FOB-VL techniques detailed earlier (Fig. 19-29).

Controlled VL brightness permits good FOB viewing

Excessive VL brightness may impair FOB viewing

Figure 19-28 Controlled brightness with the GlideScope video laryngoscope *(VL)* prevents glare during combined fiberoptic bronchoscopic *(FOB)* viewing.

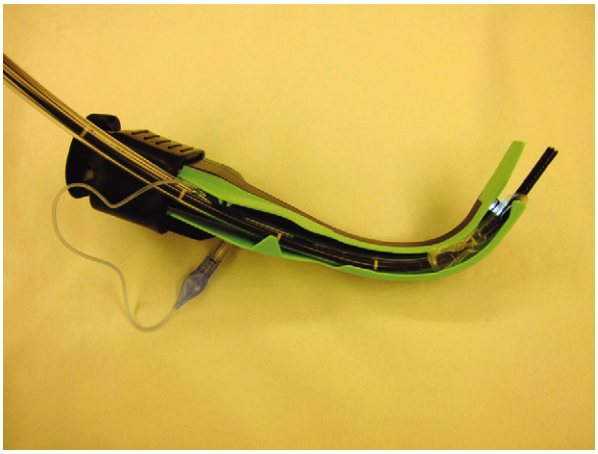

Figure 19-29 Combination of a fiberoptic bronchoscope with an endotracheal tube within an Airtraq optical laryngoscope.

VII. SPECIAL FLEXIBLE FIBEROPTIC BRONCHOSCOPE USES

Attempts at airway control may be undertaken by using equipment in a suboptimal manner, with little assurance of having good outcomes. Here, FOB assistance can increase the rate of success. In these instances, the FOB is most likely to avoid esophageal instrumentation, which is especially ideal if this structure is at a greater risk than usual. Also, it is often a preferred technique in patients with cervical spine risk.

Before embarking on these procedures, make sure that a sufficient number of aware personnel, monitoring equipment, and emergency airway equipment are readily available in the vicinity. This is particularly important in DA patients and in those who are unable to tolerate short periods of apnea. Have alternative management plans in mind, and consider marking off the area of the cricothyroid membrane, applying antiseptic solution, and draping a sterile towel on the neck, in readiness for surgical access.

A. Endotracheal Tube Exchange

Patients may require exchange of an existing ETT for a number of reasons: (1) incorrect ETT size, (2) ETT obstruction, (3) cuff leakage, (4) requirements for a specialty type of tube (e.g., preformed ETT), (5) preference for a regular ETT in place of a preexisting specialty tube, or (6) the need for an alternative route for ETT intubation (e.g., a nasal ETT in place of an oral one).

Commonly, an RL has been used to observe the old ETT within the glottis, placement of a new ETT nearby, and the exchange itself, as an assistant simultaneously withdraws the old ETT and a new one is inserted in its place. On the other hand, a Cook Airway Exchange Catheter (Cook Medical) has been used to blindly carry out this process. However, these two methods are not always successful in DA situations, which become fraught with airway losses, morbidity, and mortality. Use of an FOB to facilitate this exchange can provide a more controlled, successful completion of the goal.

In addition to the following, multiple combination techniques and the usual intubation maneuvers (e.g., jaw thrust) may be beneficial. Also, spraying local anesthetic in the periglottic/glottic area minimizes reactivity and hemodynamic changes. Preoxygenation and use of positive end-expiratory pressure, as indicated, are required for at least 10 minutes unless the situation is urgent.

1. FOB-Aintree method: Pass an FOB within an Aintree catheter into the old ETT to carry out the exchange. When just above the carina, remove the FOB while bracing the Aintree. Remove the old ETT from around the secured Aintree. Insert a new ETT-loaded FOB down the Aintree until just above the carina. Situate the new ETT, and extract the FOB and Aintree from the patient.
2. FOB-wire method: Thread a wire into the working channel of the FOB until it projects 2 to 3 cm beyond the tip. Slide both into the old ETT, and remove everything except for the wire. Pass an ETT-loaded FOB along the wire by inserting the end projecting out of the oropharynx into the working channel at the FOB tip. Advance the FOB to the precarina area, and railroad the ETT into the patient.
3. FOB-ETT or FOB-wire side-by-side method (especially if a different route of ETT intubation is needed): Insert an ETT-loaded FOB under visual control into the trachea along the anterior commissure next to the preexisting ETT. When the FOB tip reaches the old cuff, deflate it to ease FOB passage until it rests two to three rings above the carina. Constantly observing the carina through the FOB, withdraw the old ETT and advance the new one.[126] Alternatively, insert a wire projecting from the loaded FOB, 8 to 10 cm into the trachea (deflate cuff for passage, if needed). Remove the old ETT, follow the wire toward the carina, and proceed with intubation.

Trouble-Shooting

1. The FOB cannot enter the trachea beside the old ETT: Keep the FOB tip next to the glottic opening so that as the old ETT is slowly withdrawn, the tip can quickly be tucked into the glottis. Note that a combination with a RL may assist in this procedure by opening the pathway.
2. Too many tracheal secretions by the old ETT are preventing FOB visualization: Deflate the old ETT and give two PPV breaths to blow secretions out of the peri-ETT region above its cuff. Reinflate the cuff, suction the secretions, and reattempt the exchange procedure.

B. Preexisting Combitube or Rüsch EasyTube and Intubation

There are a number of reasons for removal of a Combitube (Tyco Healthcare, Mansfield, MA) or a Rüsch EasyTube (Teleflex Medical, Research Triangle Park, NC) in exchange for an ETT. First, these devices are available only in very large sizes, which have a limited timeline for remaining in a patient because of concerns regarding direct pressure effects on esophageal or airway structures. Second, suctioning of the trachea for pulmonary toilet can be difficult because of the intra-oropharyngeal

obstruction that is normally inherent with the presence of these devices. Moreover, studies have shown that a Combitube has a 5% chance of being placed in the trachea during blind insertion.

FOB assistance in performing endotracheal intubation should be undertaken before the Combitube is removed, to prevent regurgitation and aspiration. Ovassapian and colleagues found that the bulkiness of these types of tubes often created obstacles to manipulation of the FOB. Nevertheless, the exchange success rate was relatively high because the Combitube often caused a lifting up of the epiglottis, making FOB targeting easier.[127]

When an ETT is needed, prepare to exchange these in-dwelling tubes by loading an FOB according to desired ETT, Aintree, or wire combination technique. After maximal oxygenation, partially deflate the oropharyngeal Combitube or EasyTube cuff to allow passage of the loaded FOB into the oropharynx for subsequent exchange. Proceed with FOB placement by using the methods previously described for ETT exchange (see "Endotracheal Tube Exchange").

C. Trouble-Shooting Blind Nasotracheal Intubation

In the case of a spontaneously breathing patient with abnormal obstructive nasopharyngeal or oral pathology, traversing next to nasal abnormalities may cause visual confusion during FOB use. If the patient is able to breathe well through one passage, it is possible to succeed by slow, gentle insertion of a nasal ETT in a mode similar to that used for blind nasal intubation (i.e., feeding it forward while listening to breath sounds). As the sounds increase greatly in volume, insert the FOB through the ETT to enable visual localization of the entrance into the trachea, and continue with the intubation process.

If the nasopharyngeal opening is too small for FOB and ETT admission together, put the FOB in the opposite nasal passage. From this vantage point, insert the ETT into the other nostril. Observe its course as an assistant pushes it forward, and help the assistant to steer it by giving advice about turning the ETT or moving the patient's head and neck.

D. Use of the Fiberoptic Bronchoscope as a Lightwand

A lightwand is a malleable, lighted, stylet-like device that is inserted into a lubricated ETT for blind intubation. An example is the Bovie Aaron Surch-Lite (Bovie Medical Corporation, Clearwater, FL). It is bent at a 45- to 90-degree angle within the ETT while its tip is kept just within but near the ETT tip. Both are placed centrally as a unit into the oropharynx while the patient's mandible is lifted. The room lights are turned off, and the unit is directed toward the glottis. A very bright pretracheal transillumination is sought in the neck, indicating imminent entry into the glottis. Successful intubation rates approach 90%.

When used identically in a darkened room, an FOB may improve the success rate of intubation, but its tip does not need to lie within the ETT, because this is a visually controlled technique.[128] In comparison to the lightwand, with which extension beyond the ETT is not advised, the flexibility of the FOB is unlikely to cause trauma, and there is no worry about thermal injury (which, in reality, is also unlikely with the lightwand). This technique can be advantageous in two ways. First, when one is assisting someone in directing an FOB with no video monitor available, rather than constantly interrupting the operator's view to personally look down the eyepiece to survey nearby anatomy, one should look for FOB transillumination in the neck to prompt advice as to the direction in which the operator should lead the FOB. Second, FOB transillumination may be very useful in patients with soiled airways that interfere with FOB visual reconnaissance. In such cases, transillumination can be used through the soiled surroundings, with the hope that at some point the view will clear to confirm anatomic structures.

E. Double-Lumen Tube or Bronchial Blocker Assistance

Very frequently, lung isolation is accomplished with a DLT by auscultation of the ipsilateral side of the chest during one-lung ventilation and repeated auscultation during ventilation of the opposite side.[129] Periodically, there may be a desire to ensure the correct location of the DLT initially during insertion, or a doubt may arise about its correct placement. The FOB is uniquely suited to aid in the initial alignment or to diagnose proper positioning of the DLT. In addition, the FOB is particularly appropriate to direct the placement of bronchial blockers.

1. Double-Lumen Tube

For a left-sided DLT placement, load a lubricated pediatric FOB down the bronchial lumen of a tested, lubricated DLT. After induction of GA and positive-pressure mask ventilation with 100% oxygen, insert an IOA with careful monitoring to keep the patient appropriately anesthetized during manipulations. Pass the FOB into the trachea until it is above the carina, remove the airway, and slide in the DLT. After seeing the DLT within the trachea, feed the FOB tip into the left bronchus. Continue sliding the DLT until it also ends up within the left bronchus (resistance is felt). Inflate the tracheal cuff, remove the FOB, and ventilate the patient. Attach a swivel adapter to permit continuous respiration. Check left bronchial positioning by inserting the FOB via the adapter down the tracheal lumen. Position the FOB tip to observe the carina and left bronchial area. Inflate the left bronchial cuff. If the inflated cuff is barely bulging out of the left bronchus, the DLT should be secured at this depth. Otherwise, move the DLT in or out until this end point is reached. Use an identical technique (but on the opposite side) to place a right-sided DLT. Note that for a smaller DLT, a pediatric-sized FOB may prevent excessive airway pressures from the FOB's obstructing bulk within the lumen during observation.

Trouble-Shooting

1. During surgery, it is apparent that the bronchial position is incorrect: Observe down the tracheal lumen. Deflate both cuffs, and withdraw the DLT over the

FOB until the carina is identified. Reinsert the DLT into the bronchus. Again, check its position by using the FOB in the tracheal lumen.

2. Bronchial Blocker

Induce GA and intubate the patient's trachea. Pass a preshaped bronchial blocker, with the FOB following alongside it for direction, through the port of a swivel adapter during continuous ventilation. An alternative technique, especially for right-sided blockade due to the high takeoff of the first bronchial branch, is to use a 6- or 8-F, styleted Fogarty venous embolectomy catheter with a 10-mL inflatable balloon. Using a prebent shape, this can be inserted through the ETT next to the FOB and directed into the bronchus.

The Arndt blocker (Cook Medical) (9 F, 75 cm long) comes with a three-port adapter for the ventilatory system, FOB, and bronchial blocker. Insert the FOB down the middle of this adapter to catch the blocker loop on its tip. Insert both, and after entering into the targeted bronchus, disengage the loop to leave the blocker and slowly withdraw the FOB until blocker inflation within the bronchus is in the optimal position.

F. Retrograde Intubation

In some cases, the FOB or other devices for intubation may fail due to abnormal anatomy or airway soiling. Retrograde intubation can be a rescue in these circumstances. This technique utilizes passage of a guidewire through a cricothyroid/thyrotracheal needle or angiocatheter that is directed cephalad. The wire exits the mouth or nose or is fished out with a clamp. The object of this technique is to slide a Teflon guide catheter down the wire to lead an ETT around it into the trachea while the wire is under tension at the neck insertion site and the end is projecting from the 15-mm ETT connector. It is not always successful because of the wire's acute angle and hang-ups at the glottis.

An FOB can be used for rescuing the retrograde technique if placement of the wire is successful but the ETT will not enter the trachea as a result of discordant diameter sizes of the ETT and the wire. The diameter of the FOB can act like a bridge between the ETT and the wire. After passing and securing the wire by the retrograde method, thread the cephalad end of the wire into the working channel at the FOB tip until it exits near the handle. Slide the FOB along the tensed wire into the periglottic area under visual control toward the wire's tracheal entry. Ask for a release of wire tension at the neck and continue the FOB journey toward the carina. At that point, remove the wire and railroad the ETT. An FOB-retrograde combination may be the easiest and most successful technique to pursue any time a retrograde intubation technique is considered.

VIII. RARELY RECOMMENDED: OXYGEN INSUFFLATION VIA BRONCHOSCOPE

Previously, oxygen insufflation at 3 to 5 L/min via the FOB working channel in adults during intubation was proposed to supply supplementary oxygen, clear secretions, and prevent fogging.[52,130,131] Benumof described this technique but recommended that it had to be used very cautiously.[52] If flow of oxygen into the patient exceeds gaseous escape into the atmosphere, serious barotrauma may occur. An FOB squeezing by a significant airway obstruction during endoscopy can limit the egress of gases and result in a pneumothorax. Pneumothorax has also been reported in children and in an infant when flows of 3 to 5 L/min were used.[132,133] Adult flow rates are excessive for tiny pediatric airways. Acute cervical, facial, and thoracic emphysema were reported in one patient.[134] Gastric rupture with subsequent mortality has been documented. It is most likely to occur when oxygen flow is directed into the esophagus or into an area that is unrecognizable (which could be the esophagus).[135-137] Ovassapian and Mesnick declared this to be a technique that should not be recommended.[138] More acceptable during FOB use is the supply of oxygen via nasal cannula, mask, or a catheter in the mouth. FOB oxygen insufflation definitely should not be employed if the flows are too high for the patient's airway diameter, the FOB tip is down the esophagus, or the tip is in an unidentified area.

In spite of these cautions, oxygen insufflation through the FOB may be of value in certain select cases.[139] There are some reports in which its use may have been very beneficial. Hung and colleagues[140] reported a case of a patient undergoing craniotomy in the prone position who had a pin system holding the neck flexed. Intraoperatively, the ETT was totally dislodged. Because of a very enlarged tongue and neck flexion, FOB nasotracheal reintubation was chosen. The patient was placed in reverse Trendelenburg position with a left-sided tilt, and the endoscopist, while sitting on the floor, used intermittent FOB oxygen insufflation throughout the intubation period. The patient was given passive high-flow oxygen by mask. The oxygen saturation remained greater than 90% during the ordeal, which required less than 6 minutes. Would any FOB endoscopist not have used oxygen insufflation in similar circumstances?

IX. FIBEROPTIC INTUBATION IN INFANTS AND CHILDREN

One could say that the indications and entire production of FOB endoscopy in infants and children is the same as for adults except smaller—but that would ignore the major difference in these two patient groups and would be far too simplistic. Flexible fiberoptic intubation of infants and children is a necessary option that must be readily available, particularly for patients in whom this type of airway management is vital. As with adult patients, confidence and competence are easily attainable through clinical practice and knowledge of pediatric concerns. Otherwise, uncertainty and fear may prevail and make the challenge of airway management cases a dreaded disaster. FOB sizes exist in a broad range to service patients as small as premature infants. These FOB models can assist with intubation using ETTs as small as 2.5 mm ID (see Table 19-1). Be aware that the smallest FOB may lack working channels, if the OD is less than 3.1 mm.

Box 19-7 Summary of Abnormal Anatomic Conditions Affecting the Pediatric Airway

Nasopharyngeal abnormalities: choanal atresia, nasopharyngeal masses, deviated septum
Abnormalities with resultant smaller oropharyngeal access: underdevelopment of the mandible; limitation of mouth opening or temporomandibular joint impairment; macroglossia, glossoptosis, tonsillar enlargement, intraoral masses, cleft abnormalities
Prominent or abnormal mandible or midface hypoplasia
Enlarged mandible or facial feature distortion
Epiglottic abnormalities: epiglottitis, bifid epiglottis, anomalous epiglottis
Glottis abnormalities: laryngomalacia, cysts, arthrogryposis multiplex congenital, interarytenoid web, cri du chat, anterior laryngeal masses, Plott's syndrome
Tracheal abnormalities: subglottic stenosis, webs, atresia, cysts, hemangiomas, tracheo-esophageal fistulas, vascular rings, external compression
Bronchopulmonary abnormalities: asthma, bronchiolitis, cysts, infection
Cervical spine impairment: spine inflexibility or laxity, encephalocele, neck or posterior cerebral masses

Indications for FOB use in infants and children are almost identical to those for adults but are expanded to embrace numerous congenital syndromes and hereditary diseases (Box 19-7). For these special pediatric conditions, many undertakings of FOB endoscopy have been addressed in the literature. Scores of anomalies may have wide-ranging anatomic or systemic effects in this patient population.[141-143] Some have greater effects on localized regions of the airway system and symptomatology. These and acquired pathologic states or trauma can result in DA, aspiration, reactive airways, cough, bronchospasm, and declining respiratory function.

Sleep apnea and increased secretions often figure prominently, and these patients may be more sensitive to drugs and more likely to develop post-extubation failure. Some abnormalities occur more frequently within certain subsets. Altman and colleagues found that 37% of patients with congenital syndromes also had multiple airway abnormalities.[142] Laryngeal abnormalities were three times more common than tracheal ones. Twenty-eight percent of these patients had gastroesophageal reflux. The most common symptom was stridor, in 74%, followed by significant episodes of cyanosis, apnea, and failure to thrive. Nineteen percent of the patients required a tracheostomy for airway management.

Regarding airway control in patients with these problems, mask ventilation may be difficult, and insertion of oral airways may worsen the situation if there is buckling of the tongue posteriorly or if a long epiglottis is folded downward.[143] Patients with noncompressible or nondisplaceable tongues due to lingual enlargement, smaller oropharyngeal access, small mandibles, or cervical spine limitations can be extremely poorly suited to rigid laryngoscopy and, to a lesser extent, video laryngoscopy. Considering the low profile, flexibility, and conformity of FOBs to unpredictable airways, it is often justifiable to consider that an FOB may be the best choice for problematic pediatric cases.

A. Oral Fiberoptic Intubation of the Conscious Pediatric Patient

The approach to oral FOB intubation of more mature or older conscious pediatric patients is very similar to that for adults. With less mature patients, and particularly with younger ones, the differences in monitoring, drugs, psychological preparation, equipment, and technique are striking.

1. Equipment, Monitoring, and Drug Availability

Standard monitoring, capnography, an FOB cart, full airway equipment, oxygen, suctioning equipment, sedatives, opiates, local anesthetics, and vasoconstrictors must be present unless circumstances dictate otherwise. Reversal agents for sedatives or narcotics should be immediately on hand. In the pediatric patient, drugs can be given intravenously, intramuscularly, intranasally, orally, or rectally. Uncommonly, some patients may need inhalation agents until the intravenous line is established. In some cases, a DA cart may be necessary.

2. Psychological Preparation of the Patient

For older children, psychological preparation is useful, and the presence of guardians may contribute to patient cooperation and understanding. For younger ones, preparation may be impossible.

3. Rationale for Pharmacologic Therapy

Antisialogogues, sedatives, and narcotics may be administered after dosing considerations in addition to observation of clinical effects. Before FOB instrumentation, antisialogogues should be given either intravenously, as soon as that route is established, or intramuscularly. Short-acting sedatives or narcotics are preferred because of the propensity for younger pediatric patients to desaturate when obstruction or respiratory depression occurs. Patient fears due to immaturity or lack of intellectual understanding often increase drug resistance until significant respiratory deterioration transpires.

Ketamine is especially suited for infants, small children, and mentally handicapped patients, but transient apnea of less than 60 seconds duration has been reported.[145] In the patient with DA or respiratory compromise, however, ketamine may be advantageous because respiratory function tends to be adequate with fewer adverse breathing difficulties, as demonstrated by Hostetler and colleagues.[144] Prior administration of antisialogogues will offset ketamine's effect in increasing upper airway secretions, occasionally to the point of inciting laryngospasm or causing interference with FOB endoscopy. As a reminder, the airway should be suctioned before FOB instrumentation. During FOB endoscopy, no difficulties due to increased airway reactivity have been documented with this drug.[145]

Drug dosages used for pediatric patients are listed (Table 19-3). Maintenance of spontaneous ventilation together with a degree of sedation or analgesia (or both) is the objective, unless contraindicated.

TABLE 19-3
Pediatric Drug Dosages Assisting Fiberoptic Intubation

Drug	Dosage
Atropine	0.02 mg/kg IV or IM
Glycopyrrolate	0.004 mg/kg IV or IM
Fentanyl	0.5 µg/kg IV increments
Ketamine	0.5 mg/kg IV increments (4-5 mg/kg IM if lesser airway difficulty)
Ketamine	2 mg for each 1 mL propofol infused as a propofol drip at 50-200 µg/kg/min
Midazolam	10-20 µg/kg IV increments
Propofol	0.5-2.0 mg/kg IV bolus; infused as a drip at 50-200 µg/kg/min
Remifentanil	infused as an IV drip at 0.05-0.1 µg/kg/min

Dexmedetomidine and propofol are titratable sedatives that are advantageous for quick onset and rapid awakening. Less respiratory depression and more analgesia make dexmedetomidine the more attractive of the two, although it would be an off-label.

4. Anatomic Specifics of Pediatric Airway Structures

Anatomic differences between the airways of the adult, child, and infant are described in Chapter 36. In pediatric patients, the tongue is relatively larger, the larynx is more rostral, and the vocal cords are more inclined.[146] In contrast to adults, the larynx in newborns is not only relatively smaller in comparison to their bodies but softer and more sensitive. The shape is funnel-like, and as a result the cricoid cartilage is at the narrowest point. As the infant ages, the larynx descends in a caudad direction toward the final adult location (Table 19-4).[143]

The infantile omega-shaped epiglottis is floppier, longer, and tubular in comparison to that of adults. It is often directed posteriorly, although variations can occur. Innervation of the airway is similar to that in adults, except that the left recurrent laryngeal nerve takes a relatively longer course around the aortic arch and, therefore, may be more prone to pathology.

5. Topical Orotracheal Anesthesia Techniques

LA techniques can make FOB use a very quiet, efficient procedure for awake intubation. Even under GA, this technique is useful as a method for reducing hemodynamic responses and reflexes that are particularly prone to occur in pediatric patients. Techniques for local airway anesthesia are very similar in the pediatric population and in adults with some exceptions, mostly involving younger patients.

TABLE 19-4
Changing Levels of the Larynx from Fetus to Puberty

Age	Spinal Level (Cervical Vertebrae)
Fetus	C2 and C3
Newborn	C4
Age 6 years	C5
Puberty	C6-C7

For transtracheal anesthesia, the cricothyroid area is much smaller and harder to palpate in infants younger than 6 months of age. In addition, needling of very small tracheas should be avoided, because any drops of blood within the trachea would compromise the airway to a much greater extent than in larger patients. One should also be wary of any needling in the neck for the external approach to the SLN. In the smallest patients and those with the most difficult airways, intra-arterial injection is more likely because of the closer proximity of relatively miniature structures, even if tiny needles are used. Intraoral techniques may work well for patients who are able to cooperate. Aerosolized techniques tend to be most effective when patients have a history of using inhalers and can relate to the idea of breathing in medicines.

6. Local Anesthetic Drug Choices

These patients are smaller, and dosages must be tapered down accordingly. Drugs containing benzocaine must not be administered to infants because of concerns for methemoglobinemia. They should probably be avoided also in small children weighing less than 40 kg, because the spray method of delivery increases the complexity of gauging drug dosages accurately.

Suggested dosages for aerosolized lidocaine should be reviewed before administration (Table 19-5).

7. Positioning of Infants and Small Children

Usually, the head and neck can remain in neutral position. In some cases, a slight extension of the neck with a towel under the upper thorax may be useful if the head is large and tends to produce neck flexion in the supine position.

The table or bed height should be adjusted to a low but appropriate level to keep the FOB relatively straight. In some cases, a stepstool may be of value. Infants can be swathed in a towel or sheet with sufficient length for one end and then the other to be wrapped over the baby's arm and stuffed under the body. No restriction of ventilation results from this restraining method, in contrast to an entire body wraparound.

8. Endotracheal Tubes: Uncuffed Versus Cuffed

The choice of an uncuffed ETT for patients younger than 8 years of age has been a tradition for decades owing to various apprehensions. One concern was that a smaller-ID, high-volume, low-pressure, cuffed ETT would have to be

TABLE 19-5
Aerosolized Lidocaine: Suggested Dosing According to Weight

Weight (kg)	Volume of 4% Lidocaine (mL)	Volume of Saline (mL)
10-14	0.5	2
15-19	1.0	2
20-24	1.5	3
25-29	2.0	4
30-34	2.5	0
35-39	3.0	0
40-44	3.5	0
≥45	4.0	0

selected, rather than an uncuffed ETT, because of the added width of the deflated cuff within the trachea. Downsizing the ETT prompted a worry that there might be increased resistance to ventilation. However, because the trachea is relatively large for the pediatric body habitus, this should not be a factor as long as an ETT size is chosen appropriately for the patient's age and dimensions.[147] Another worry was that cuff pressure might result in a higher incidence of subglottic ischemia and stenosis.[148,149] Particularly in tiny patients, there was a concern that although the tip of the ETT was within their tracheas, the cuff might remain between the vocal cords.

More recent literature, which includes extensive comparisons of morbidities and outcomes in surgical and intensive care unit patients, may be starting to refute some of these ideas.[150-153] Weiss and associates studied two groups of patients undergoing surgery with a cuffed ETT (Microcuff PET with distance markings [Microcuff GmbH, Weinheim, Germany]) versus an uncuffed ETT (multiple brands). Among the 2246 children with ASA class I or II physical status (mean age <2 years), there was a 15 times lower incidence of repeat laryngoscopy in the cuffed ETT group and, of course, less trauma.[151] The most common cause for repeat laryngoscopy was an initial ETT that was too large or too small. The incidence of stridor between the two groups was almost identical (4.4% and 4.7%, respectively).

An added advantage of cuffed ETT use is better aspiration protection, better seal pressure for ventilation, and less atmospheric contamination during GA. There are still a number of factors that are of concern, however. Longer outcome models are needed with improved pediatric ETT design to eliminate the intraglottic inflated cuff worry and higher ETT costs. If cuffed ETTs are used, intra-cuff pressures should be monitored to a limit of 20 to 25 cm H_2O.[154]

B. Fiberoptic Orotracheal Technique

FOB intubation of infants and children uses similar procedures, techniques, and aiding maneuvers (e.g., tongue pull) as in adults. It requires an assistant and equipment appropriate to body habitus. The patient should receive an antisialogogue before any instrumentation. An IOA such as the VBM Bronchoscope Airway (VBM Medical, Noblesville, IN) can be used. It is produced in newborn and child sizes. This airway initially is three-quarters enclosed with an open side. In its distal half, it gives way to a completely curved and open, spatula-like area, somewhat similar to the Ovassapian fiberoptic intubating airway. A bite block is another choice, with the endoscopist's inserting hand gently resting on the patient's face to keep the FOB midline.

If necessary for oxygen administration, endoscopy masks (e.g., VBM) are available in infant and child sizes (see Fig. 19-21). The advantage of the central endoscopy port of a mask is accessibility in children to both oral and nasal FOB approaches. A regular mask with a bronchoscopic swivel adapter can also be employed. Supplementary oxygen "blow-by" or a nasal cannula is another option.

Place an IOA or brace the hand to facilitate keeping the FOB midline, which is a critical step in dealing with the differences associated with smaller structures in pediatric patients. Hold the FOB and insert it as described previously for adults. For either oral or nasal intubation in younger patients, it is almost always advised to introduce the FOB before the ETT, because if part of the smaller ETT precedes FOB entry into the oropharynx, its size may limit full FOB maneuverability. As always, one should strive to keep recognizable structures in the middle of the view during insertion.

C. Two-Stage Fiberoptic Intubation

Some patients have airways that are too small to admit an FOB. In these cases, intubation can be carried out in two stages. First, thread a guidewire from an airway exchange catheter set (e.g., Cook Pediatric Airway Exchange Catheter [PAEC]) through the working channel of the FOB. The PAEC is available in sizes as small as 8 F (2.7 mm) with a length of 83 cm. Allow only up to 1.0 cm of the wire to exit beyond the FOB tip as the scope is introduced into the oropharynx. When the glottis is visualized, advance the wire into the trachea for a distance approximating the length to the carina. Remove the FOB. For the second stage, use the Cook catheter setup to pass an appropriately sized ETT over the wire, in a manner similar to the ETT exchange technique previously described.

D. Nasal Fiberoptic Intubation of the Conscious Pediatric Patient

Attention should be paid to history and to examination for any nasal anomalies.

Warming the ETT to soften it and pretreatment with phenylephrine or oxymetazoline may help stave off nosebleeds. Antisialogogue, sedative or narcotic, and LA dosages need to be appropriate for the patient's size. A breakaway NPA may be used in older patients.

In the nasopharynx, introduction of the ETT before the FOB heightens anxiety about provoking epistaxis. Hypertrophied adenoids are common between the ages of 2 and 6 years, and they are more susceptible to the trauma of a blind ETT entry. Epistaxis must be seriously avoided, because of the greater degree of difficulty presented by any blood in the small airways of these very small patients.

This technique is similar to that for adults in regard to preparation, except that administration of the anticholinergic (antisialogogue) should absolutely be carried out as a preventative against bradycardia before instrumentation in younger patients. Endoscopy masks and swivel adapters are much more amenable to nasal entry of the FOB in pediatric patients compared with adults, because their noses are closer to their mouths.

Trouble-Shooting

1. The FOB cannot pass through the intended ETT: A technique similar to that described for trouble-shooting blind nasotracheal intubation may be used. Insert the FOB through one nostril and the ETT through the other.[155] While observing the ETT and airway through the FOB, advise the assistant how to move the ETT,

head, and neck to achieve endotracheal intubation. This technique may require one FOB operator and one or more experienced assistants to perform all the maneuvers.

E. Oral or Nasal Fiberoptic Intubation of the Unconscious Pediatric Patient

1. Patient Under Routine General Anesthesia

Again, the patient's eyes should always be protected and an anticholinergic agent given. LA of the airway to limit the reflexes should be considered if the patient is cooperative enough. Full equipment preparation, as described previously, is imperative. This should include two suctions if there is any threat of regurgitation. Older patients may be approached with the same techniques used in adults.

If difficult mask or laryngeal airway management is not anticipated, induce GA and perform mask ventilation with 100% oxygen. Among volatile anesthetics, sevoflurane is popular for its less irritating qualities. With the patient under deep anesthesia with spontaneous respiration or lighter GA with muscle relaxant, remove the mask and execute the FOB intubation as previously described. To ward off laryngospasm, muscle relaxants are advantageous if the patient is too uncooperative to attempt local airway anesthesia preoperatively. However, if spontaneous ventilation is more desirable, 2% to 4% lidocaine may be used on the vocal cords in a "spray as you go" technique. Even if a patient has not reacted to more superficial instrumentation, this may prevent glottic closure as a result of FOB touching of the vocal cords. If intubation is not quickly performed, it is important to remember that this technique of lifting the mask can lead to rapid desaturation in some patients, particularly smaller ones and those at higher risk. For this reason, promptly return to mask ventilation between brief periods of instrumentation.

An alternative is to perform simultaneous mask ventilation and intubation using an endoscopy mask or bronchoscopic swivel adapter. Very good assistance with patient ventilation is needed to ensure safety with this method.

Another possibility is to use an SGA or an intubating SGA. In some cases, pressure from the SGA may direct an epiglottis posteriorly to obscure the laryngeal opening. This can impair correct seating of these perilaryngeal airways or inhibit blind attempts at ETT passage. An FOB can assist with SGA placement, and the FOB-SGA combination for intubation is more likely to result in successful insertion of the ETT. The combination also is more likely to avert trauma from blind attempts near delicate airway structures in very young patients. The pediatric setting is another example of the usefulness of the multimodal approach to the DA.

2. General Anesthesia Using Short, Soft Nasopharyngeal Airways

A breakaway NPA may be used in older children to assist FOB passage, as detailed earlier.

The method of administering anesthesia with an NPA during FOB intubation has also been described previously. This is a more common technique for younger pediatric patients.[156-158] For this technique, adapt an NPA by cutting a Murphy eye–type hole near the distal end and insert the NPA into one nostril.[159] Connect the anesthetic circuit to a 15-mm adapter within the NPA to supply inhalation anesthesia to the spontaneously breathing patient. Meanwhile, proceed with FOB intubation orally or nasally. Alternatively, insert an ETT into one nasal passage and use that for continued anesthetization while executing either oral or nasal intubation through the opposite nostril.

X. ADVANTAGES OF FLEXIBLE FIBEROPTIC BRONCHOSCOPES

It is a universally documented fact that the FOB can be used to perform all aspects of patient intubation for routine airway control before any surgery. The FOB has a long history of having the greatest success of any nonsurgical technique for DA management, and for rescue of failed airway management by other devices, because of its innate ability to enter through very limited oral or nasal openings, glide along aberrant structures, and follow the contour of the airway in patients with any body position, body habitus, or age. Its multimodal ability to be combined with many other airway devices, including surgical ones, is incomparable. These three unique characteristics prove that the FOB is the most superior of all nonsurgical methods for airway control. It is not surprising then, that the FOB can be life-saving and life-altering as a result of its rescue capabilities and capacity to ward off surgical airway takeovers. In extreme situations, its use can accomplish safe intubation and allow GA for operations on patients for whom airway control would otherwise be impossible, even surgically, such as those with severe ankylosing spondylitis (Fig. 19-30).

Figure 19-30 Nasal application of local anesthetic in anticipation of awake fiberoptic intubation in a patient with severe "chin on chest" ankylosing spondylitis, ideally managed with the use of a fiberoptic bronchoscope. (Used with permission.)

Figure 19-31 Fiberoptic nasotracheal intubation is planned for a patient with multiple loose and displaced teeth secondary to an automobile injury.

A. Most Accurate Confirmation of Respiratory Tract Endotracheal Intubation

No other airway management device provides the same degree of certainty of respiratory tract intubation as the FOB, because it is the only instrument that yields detailed visualization of respiratory tract anatomy. Also, FOB use assists and confirms DLT and bronchial blocker placement.

B. Less Patient Trauma or Side Effects

In combination with excellent LA, patients can be intubated with almost no cardiovascular stimulation. Whether the FOB is used to intubate the trachea under LA or under GA, it is the most likely airway instrument to prevent damage to airway structures, especially those most at risk (Fig. 19-31).

C. Minimal Cervical Spine Motion

It has been well documented (Box 19-8) that FOB intubation and blind nasal intubation are associated with the least amount of cervical spine motion during cineradiography, compared with other intubation techniques. Of course, the former is more advantageous, because FOB intubation is a visual technique with a higher success rate and lower propensity for trauma. It is extremely popular in the cervical spine risk setting compared with other carefully performed intubation methods involving a minimum of cervical motion; however, neither of these two techniques has been shown to be safer or more likely to prevent secondary neurologic deficits (Fig. 19-32).

D. Diagnostic Capabilities

The FOB is a multifunctional device with excellent diagnostic capabilities. It is used to investigate vocal cord motion (e.g., detecting recurrent laryngeal nerve injury), tracheal motion (e.g., detecting tracheomalacia after thyroidectomy), high airway pressures, presence of secretions, infection sites, endobronchial intubation, problems with single-lung ventilation (e.g., high takeoff of right upper lobe), foreign bodies, site entry during tracheostomies, malpositioned SGA, folded-over epiglottis, intratracheal or pharyngeal pathology, and other scenarios. It is also useful to assess the quality of a bronchial or tracheal suture and to permit evaluation of the airway status in burned patients.

E. Therapeutic Capabilities

Aside from the capability to assist in successful placement or adjustment of numerous pieces of airway equipment, the FOB can be therapeutic in other ways. It is used for exact positioning of an ETT to bypass obstructive pathology. Changes in oxygenation can be investigated to determine whether endobronchial intubation is a factor, and the FOB can assist with ETT repositioning. The FOB is therapeutic for removal of blood, secretions, or foreign bodies and for exchanging endotracheal or tracheostomy tubes.

XI. DISADVANTAGES AND COMPLICATIONS OF FLEXIBLE FIBEROPTIC BRONCHOSCOPES

This section details only problems related to FOB technique, not those common to all airway control methods (e.g., endobronchial intubation) or LA, which are discussed elsewhere.

A. Unsuccessful Intubation

Although success rates of intubation with FOB intervention are high, failures do occur from a variety of causes. During intubation, the FOB enters into the trachea and the ETT is railroaded over it in a blind fashion. At times, the ETT can get hung up, usually on the right arytenoid, and not pass. If the Murphy eye faces anteriorly, there is a much greater chance of successful intubation. However, failure can transpire occasionally even if the Murphy eye is directed correctly. For additional success, a centrally curved, soft-tip ETT may be the answer.[160] Another solution to this situation is simultaneous use of video laryngoscopy, which allows observation of the passage of the ETT over the FOB near the laryngeal structures to resolve potential conflicts between the ETT bevel and airway structures.

Disparate diameters between the FOB and the ETT is another source for impeding ETT passage. Choosing an FOB diameter closer to that of the ETT or using an Aintree bridge lessens this possibility.

With greater degrees of diameter disparity, flippage is more likely to occur as a cause of failed FOB intubation. When the FOB is advanced into the trachea only a short distance and forceful pressure is exerted on the ETT caught in the periglottic area, the ETT can get even more stuck. The pressure may finally be released through a wayward movement of the ETT into the esophagus. The transmitted pressure of the ETT in the interim may cause pressure on the very flexible FOB, resulting in the insertion section's being flipped out of the trachea. Keeping a long length of the insertion section within the trachea by ensuring that the FOB tip is just above the carina decreases the likelihood of this problem, as does diminishing the disparity between the FOB and ETT diameter.

Another cause for difficulty may result if the ETT is advanced first, part way into the pharynx, and the FOB is passed into the ETT. The FOB may exit out the Murphy eye and prevent successful ETT intubation even though a great view of the carina is evident (Fig. 19-33). Passage of the FOB first obviates this complication, but if passing the ETT first is desired, careful observation and slow FOB passage down the ETT, while being on guard to this possibility, will preclude an adverse result.

Rarely, the FOB enters a wide-open esophagus that is mistaken for the trachea. Identifying what seem to be tracheal rings is not enough to prevent this error. The esophagus may seem to have indentation-like rings, particularly in pediatric patients, in whom structures are in closer proximity. This is also more likely to occur when thick secretions or fogging is present. Identifying the carina provides more definitive proof that the FOB is in the correct system.

The FOB tends to be at a disadvantage in any soiled airway because of the small diameter of the viewing tip, which is more easily obscured as it makes its journey forward through confounding elements. Use of an FOB in these conditions is not completely contraindicated, but success is less likely. Combinations with other devices (e.g., an SGA) may overcome these difficulties.

B. Worsening Respiratory Tract Obstruction

Patients who have preexisting narrowing or obstructive pathology in their upper airways may have difficulty when any non-hollow object is placed in the area. To ward off effects of near or total obstruction once the FOB enters the respiratory tract, FOB manipulation must be speedy and careful.

Figure 19-33 Flexible fiberoptic bronchoscope tip exiting from the Murphy eye on an endotracheal tube; this scenario will prevent intubation.

C. Fragility and Expense

FOB instruments are very delicate and frequently very expensive. Repairs for major teaching centers equipped with full systems, an FOB video screen, and other features can run into thousands of dollars per month. Tapping the FOB tip on cleansing pads, bending the shaft, using the angulation lever to move the tip within an ETT, compressive damage from being bitten or being pinched by a slammed drawer, and dropping the instrument must be avoided. Forcing an FOB through an ETT can shear off outer fabrics or cause kinking. If this damage is very extreme, it could cause ETT obstruction, and the FOB may be permanently stuck within it.

An added expense is cleaning the devices and paying for assistants to clean them. The question of which type of system, disposable or nondisposable, would be cheaper depends on how many usages are involved. Obviously, if very few FOB actions are being undertaken, disposables would be cheaper, but another factor to consider is that success rates are more likely to drop the fewer times FOB technique is used on patients. These concerns affect the choice between a classic FOB and a disposable "chip on the tip" endoscope.

To keep costs to a minimum, an FOB does not need to be stroked or talked to, but it does need to be babied. Constant education and conscientious use are the main requisites that can keep repair costs down—in the range of only a few hundred dollars per scope per year!

D. System Bulk and Storage Space Requirements

The FOBs are lengthy, with long handle parts in addition to insertion sections of approximately 60 cm. For anything beyond an Olympus MAF Airway Mobilescope (Olympus America, Center Valley, PA), an Ambu aScope, or a fiberscope with eyepiece only, an entire system is quite bulky. It may involve a video monitoring tower, light source setup, and areas to hang clean and used instruments (see Fig. 19-7). Adequate storage space often requires logistic help in situating the FOB systems among patients, personnel, and other equipment needed for patient care.

E. Complications

Many expert endoscopists can perform FOB intubation in less than 30 seconds. In comparison to other techniques, however, FOB intubation usually requires slightly more time in routine airway cases. As the period of apnea lengthens, oxygen desaturation is more likely to occur. Close monitoring and rapid correction should stave off any untoward events.

FOB intubation performed under GA only can precipitate hemodynamic changes similar to those observed with rigid laryngoscopy or video laryngoscopy.[161] This may be secondary to the FOB endoscopist's manipulation of the ETT in response to tube impingement during passage or to pain caused by tongue pull or jaw thrust. Preemptive therapy is useful. Vigilance and prompt responsive therapy should avoid complications.

Postoperative sore throat, dysphonia, and dysphagia after FOB intubation in non-DA patients have an identical incidence to that after rigid laryngoscopy. This might be related to the manipulation and to ETT impingement on perilaryngeal structures, particularly if the ETT is vigorously pushed. Gentle technique, optimal ETT usage, and avoidance of forceful actions minimize these effects.

XII. OTHER CAUSES OF FAILURE WITH FIBEROPTIC BRONCHOSCOPES

A. Inexperience

The number one cause of FOB intubation failure is inexperience due to insufficient training and practice with lack of attention to detail in performing the correct steps to execute flawless FOB procedures. To achieve the greatest degree of success, indications and contraindications must be followed. A proactive low threshold for FOB use is important when considering either a DA associated with comorbidities, which could be adversely affected by airway management problems, or just an exceedingly difficult airway. Indiscriminate use of an RL in these circumstances could worsen an already bleak picture, and if FOB attempts are to follow, hopes of success may soon spiral downward.

B. Lack of Assistance

An inadequate number of personnel and poor understanding of what they will be required to perform prevents everyone from functioning as a cohesive unit. Competent assistance with clear direction can turn FOB management into a simple, triumphant procedure.

C. Lack of Preparation

Inferior preparation of patients, equipment, and personnel doom FOB use to difficulty, if not failure. Psychological preparation, equipment, antisialogogues, sedatives, narcotics, and local anesthetics must be optimized and individualized for each patient. Untrained personnel must understand the techniques of tongue pull, jaw thrust, keeping the airway in the midline, and injecting LA through the FOB.

D. Insufficient Trouble-Shooting and Adaptability

An Indian proverb states, "If you live in the river you should make friends with the crocodile." In other words, a frame of mind to adapt to changing conditions and attempt trouble-shooting will eliminate problems as they arise. Have a number of plans available for any possibility. For example, defoggers can be useful on a distal FOB tip, but it might be the eyepiece lens that needs treatment if fogging is occurring proximally due to warm exhaled breath around the FOB operator's mask.[162] One should especially consider multimodal approaches and enlist more than one assisting action to help with techniques.

E. Inadequacy of Local Anesthesia

Obviously, insufficient LA is a hindrance. To avert difficulty, LA levels should be tested; for example, suctioning the oropharynx toward the larynx tests both GPN (gagging) and SLN (coughing) blocks. If one of these is inadequate, the block can be repeated or the "spray as you go" technique can be used. A tongue depressor can be used for testing the GPN, but this lacks the advantage of clearing secretions or blood. Absence of cough during a transtracheal injection should make the adequacy of the technique suspect. A repeat injection of only 1 mL of the LA can be used to test for cough. If the patient coughs, it is likely that the drug was not injected in the correct area the first time, and the remainder of the dose should be given. If no cough occurs, it is probably unnecessary and perhaps dangerous to give the rest. Good LA prevents gagging, vomiting, coughing, and laryngospasm, which can impede laryngeal visualization and intubation. It also prevents hemodynamic responses to the FOB.

F. Failure to Remember Airway Device Combinations

The combination option should be high on the priority list for rescue of difficult FOB intubation or other airway device techniques. The multimodal approach is most likely to impact airway control in patients with upper airway bleeding, secretions, or edema and those with periglottic or periepiglottic pathology.

G. Discordance in Fiberoptic Bronchoscope and Endotracheal Tube Diameter

Impingement problems with discordance between the FOB and ETT diameter size have been described and can be avoided with better selection of the FOB or ETT and use of an Aintree catheter (Fig. 19-34). Make sure that the lubricated FOB easily traverses the ETT to prevent intussusception of its outer cover. Initial insertion with the FOB rather than the ETT usually improves its maneuverability.

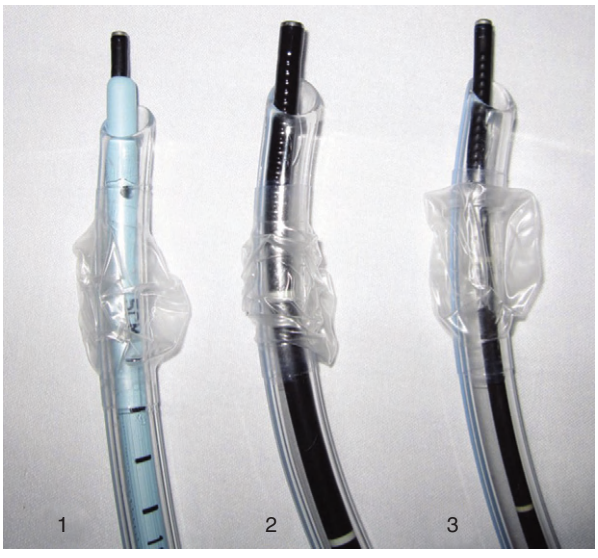

Figure 19-34 Diameter differences should be minimized: *1,* pediatric fiberoptic bronchoscope (FOB) within Aintree within endotracheal tube (ETT); *2,* adult FOB within ETT; *3,* pediatric FOB within ETT.

XIII. LEARNING FIBEROPTIC INTUBATION

It has been more than 50 years since Shigeto Ikeda catapulted airway control, from use of a steel, 1940s-style RL to use of a sleek video-emitting FOB. FOBs have consistently been used to rescue patients from failures of that 1940s device, but the opposite is rarely true in competent hands. A wealth of studies and case reports in the most difficult of situations have described superiority of the FOB. Thanks to this instrument, surgeries have not been cancelled, teeth have not been knocked out, slashing of necks with subsequent scarring has been avoided, complications have not come to pass, and lives have been saved.

How is it, then, that patient caregivers in airway management, whether in the fields of anesthesiology, emergency medicine, or critical care medicine, are still reluctant and insufficiently resolved to master this technique? A technique with which a novice can be successful 95% of the time on the first attempt at FOB intubation after 10 cases, while averaging 91 seconds to completion?[163] A technique that 94% of respondents in 2007, from 23 medical schools, characterized as a basic residency skill?[107] Fortunately, as medical care advances, more professionals have realized the value of the unique, multifaceted qualities of the FOB.

Learning FOB intubation should not be just a technical skills endeavor. It should be integrated into a broader frame of airway management that emphasizes technical skills as well as decision-making strategy. Strategy acquisition will lead to appropriate decisions in stressful situations and the ability to act as a team leader in emergency and nonemergency settings.

A. Understanding the Fiberoptic Bronchoscope: Resources

Priorities in becoming a totally competent airway management specialist must be set. Although the FOB may seem formidable, it is not. Familiarity with its delicate construction and function will breed enlightenment. Like video games or golf, FOB use requires practice.

Box 19-9 presents a personal quotation that was authored by Dr. Ovassapian for use at the Annual Meeting of the ASA Basic Adult Fiberoptic Laryngoscopy Workshop and has been cited at every ASA Basic Adult Flexible Fiberoptic Intubation Workshop since 2007.

Getting to know and become friends with the FOB offsets any reluctance toward it. This can be achieved through in-service training (equipment representatives are excellent resources to assist clinicians), digital video discs, videos, on-line sources such as YouTube.com, textbooks, journal articles, and FOB workshops. Internet resource sites are listed in Silos and Bolliger's article on educational resources for bronchoscopy with small summaries concerning their content and even a star rating

Box 19-9 A Quotation Reapeated Yearly since 2007 During Presentations to the Annual Meeting of the American Society of Anesthesiologists' Basic Adult Fiberoptic Laryngoscopy Workshop

"In my personal experience by observing residents, following their advancement, etc., it seems that 50 uses of the Fiberscope (FOB) of any kind give residents enough confidence in use of it, and they use the FOB when they leave the program and start a new job in a new environment. The number 50 comes from some gastrointestinal literature and surgical literature that indicated after 50 colonoscopy or other procedures residents did well on independent use of colonoscopy.

After this experience, if the FOB is used 50 times for awake or asleep intubation, for airway evaluation, Double Lumen Tube placement, etc., this will give them enough experience for independent use of the FOB with an acceptable success rate."

—Andranik Ovassapian, MD

system for the value of each Web site.[164] These resource sites include the following (all accessed May 2012):

http://www.bronchoscopy.org/education/BiEducEB_.asp
http://www.bronchoscopy.org/education/BiEducArt_vw_.asp
http://www.bronchoscopy.org/education/BiEducStep_.asp
http://www.thoracic-anesthesia.com/?page_id=2
http://www.lumen.luc.edu/lumen/MedEd/medicine/pulmonar/procedur/bronchd.htm

Many of these resources are instructional and have free downloads, and some are even fun to watch.

B. Handling the Fiberoptic Bronchoscope

Practicing on an intubation mannequin is a fairly interesting experience, and attending a fiberoptic workshop is always worthwhile. Practice in these arenas will overcome the suspicion that lack of manual dexterity and insufficient competence in this technique can rule the professional lives of airway specialists, whether in the intensive care unit, emergency room, or operating room.

1. Practice with Dexterity Models and Simulators

Many dexterity models are available commercially to exercise hand-eye coordination and optical recognition. There is research evidence that higher benefits are derived from practice with these models than from didactic lectures. Some are free, whereas others cost thousands of dollars (Video 19-6).

This type of learning is based on the concept of "part or partial task training," which involves the deconstruction of a complex psychomotor task —FOB intubation— into several elementary tasks. An example of one part learned through simulation would be to follow precisely the three directions of entering the oropharynx, traversing the larynx, and advancing into the trachea (i.e., downward, upward, and downward again). Subsequently, the acquisition of multiple partial tasks results in integration of all the different acquired steps.[165]

How much practice is needed? Participants usually find that intubating head models are very straightforward, very easy, and hardly challenging. Whatever dexterity model is chosen, the end point for practice is when FOB maneuvers are carried out as intended, without excessive back-pedaling or repeats. Then it is time to move on to live subjects.

a. HIGH-FIDELITY INANIMATE AIRWAY MODELS

Expensive, human-looking models are available that mimic the airway down to the level of the first bronchi to aid in FOB training. The CLA Broncho Boy series (CLA, Coburg, Germany) has models that simulate pathology. One model even has a fluorescing bronchial tree. The Laerdal Airway Management Trainer (Laerdal Medical, Wappingers Falls, NY) is similarly designed but can simulate multiple DAs (e.g., tongue obstruction, laryngospasm) through its accompanying computer and computer program.

b. PAPIER MACHÉ RESPIRATORY TRACT MODEL

On the cheaper side, Di Domenico and coworkers made a wire and papier maché model of the respiratory tract for FOB practice that was used successfully by participants to gain fiberoptic dexterity.[166]

c. PURELY COMPUTER-BASED BRONCHOSCOPY SIMULATORS

A computer-generated model was developed to improve understanding of the most distant airway anatomy, FOB technique, and dexterity. Diemunsch developed the Virtual Fiberoptic Intubation (VFI) program (Fig. 19-35).[167] This system anatomically presents clinical scenarios, with and without multiple types of airway pathology, for which FOB use can be practiced easily on a personal computer. To give a better understanding of overall anatomic structures, three separate images are available for simultaneous review: a transparent reconstructed image derived by virtue of computed tomography or magnetic resonance imaging scans, the scans themselves, and simulated airway anatomy imagery through which an FOB is directed. Insertion of the FOB can be chosen through oropharyngeal or nasopharyngeal routes. As the participant chooses a scenario and follows predesigned motions to advance the fiberscope within a patient, the computer-generated picture of anatomy seen by the fiberscope can simultaneously be compared with the other images to give an understanding of spatial relationships. The VFI program eliminates the need for expensive and elaborate simulation setups, takes up no space, and is available in compact disc form at no cost from Karl Storz GmbH, Tuttlingen, Germany.

Alternatively, computer-based integrated endoscopic manipulation simulators are somewhat expensive systems that use simple, face-like models for FOB entry and practice with bronchoscopes. A computer-based interface aids in training, and the system can act as a testing site for competency; examples include the National Taiwan University Endoscopic Simulation Study Group (NTUSEC) computer-based bronchoscopy simulator and the AccuTouch bronchoscope simulation system (Immersion

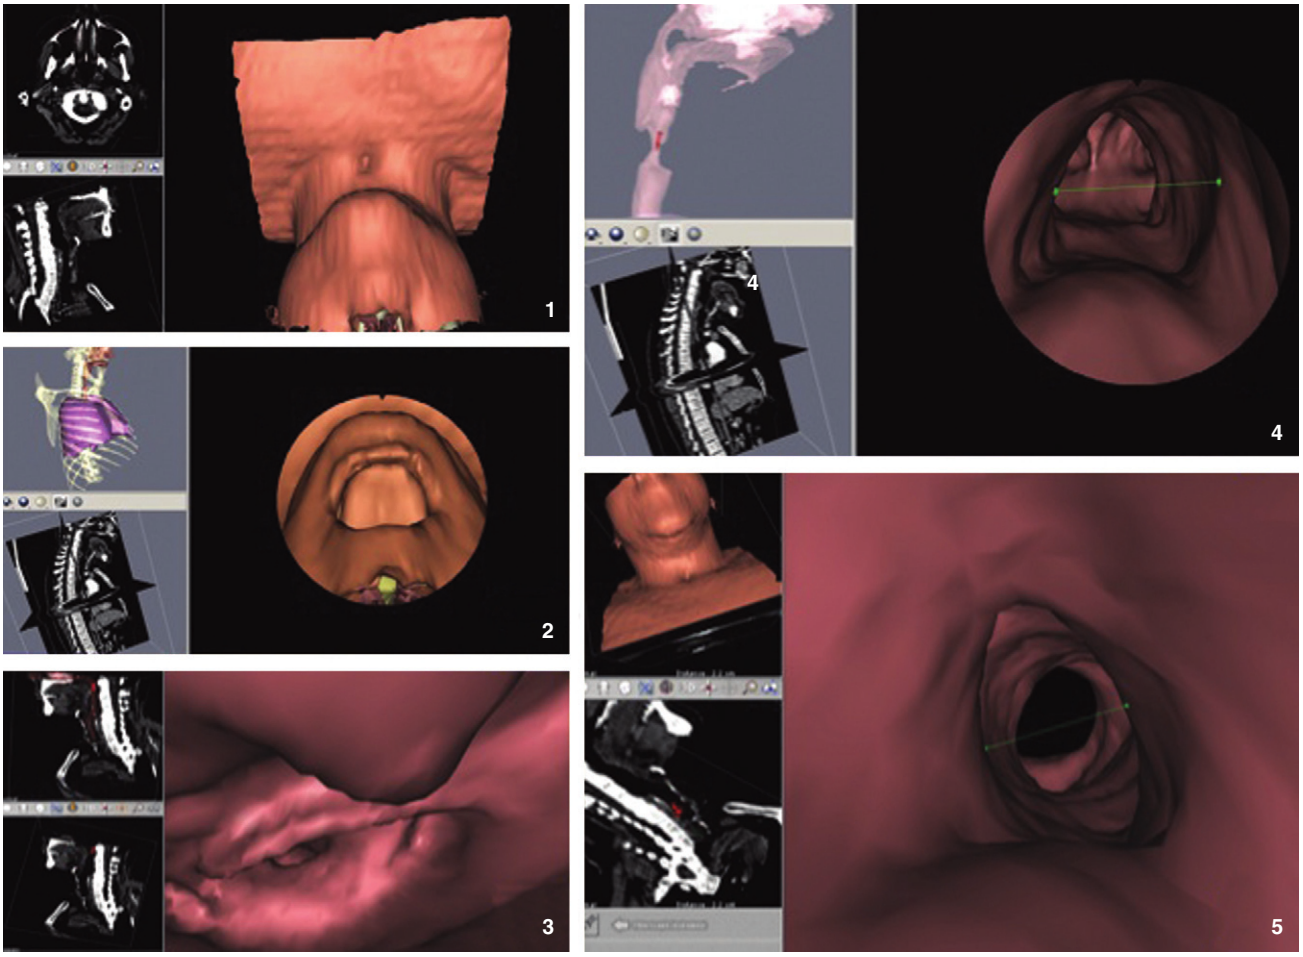

Figure 19-35 Virtual Fiberoptic Intubation (VFI) images: *1,* comparison with radiologic scans; *2,* transparent anatomic and radiologic comparison with pharyngeal entry; *3,* posterior nasopharyngeal view of uvula above and posterior larynx below; *4,* carina comparison with imaging planes; *5,* intratracheal view.

Medical, Gaithersburg, MD).[168-170] Surprisingly, Chandra and coworkers demonstrated that training on the costly AccuTouch simulator did not bring additional benefits compared with training on a low-cost, low-fidelity model consisting of three wooden panels with holes ("Choose The Hole") into which the trainee is asked to insert the FOB in different directional combinations.[171]

d. COMMERCIAL DEXTERITY MODEL

Dexter (Dexter Endoscopy, Wellington, New Zealand) is an expensive semi- or non-anatomic, modular training system featuring multiple paths, bifurcations, conduits, and maps by which an FOB can be directed to improve dexterity.

e. GIL 5-MINUTE FIBEROPTIC DEXTERITY MODEL

The Gil dexterity model has no computer, costs little, and requires only 5 minutes for anyone to make (Fig. 19-36). If rusty FOB dexterity skills need refurbishing, this cheap dexterity model can be constructed quickly from pieces of readily available materials (i.e., tape, pieces of ventilation hose, ETTs, and suction tubing).[172] Tape the elements down in a "dexterity course layout," and cover the layout with a towel. Practice for 10 minutes before the patient arrives in the care area. Remember that on the model, insertion of the FOB between the simulated vocal cords under the towel is no challenge; the dexterity challenge comes in choosing a bronchus for the FOB and aiming for one of multiple tubing targets. Difficulty can be added by moving the simulated bronchi sideways or placing something under them to produce a slight misalignment with the simulated trachea or the targets. The indicated steps for model construction are presented in Video 19-7.

2. Practice with Intubation Mannequins

Very expensive intubation mannequins such as SimMan (Laerdal Medical) afford much more realistic anatomic structures to search through and to search for, compared with intubating heads. Many pathologic states are programmable for added challenge and dexterity practice. They can be used for a variety of airway techniques such as FOB combination methods and insertion of bronchial blockers.

3. Practice with Patients

Whereas practice on mannequins is interesting, there is nothing like the astonishing reality of using an FOB to see vibrant, living, anatomically amazing tissues in a living patient. The easiest approach is to examine the airway of

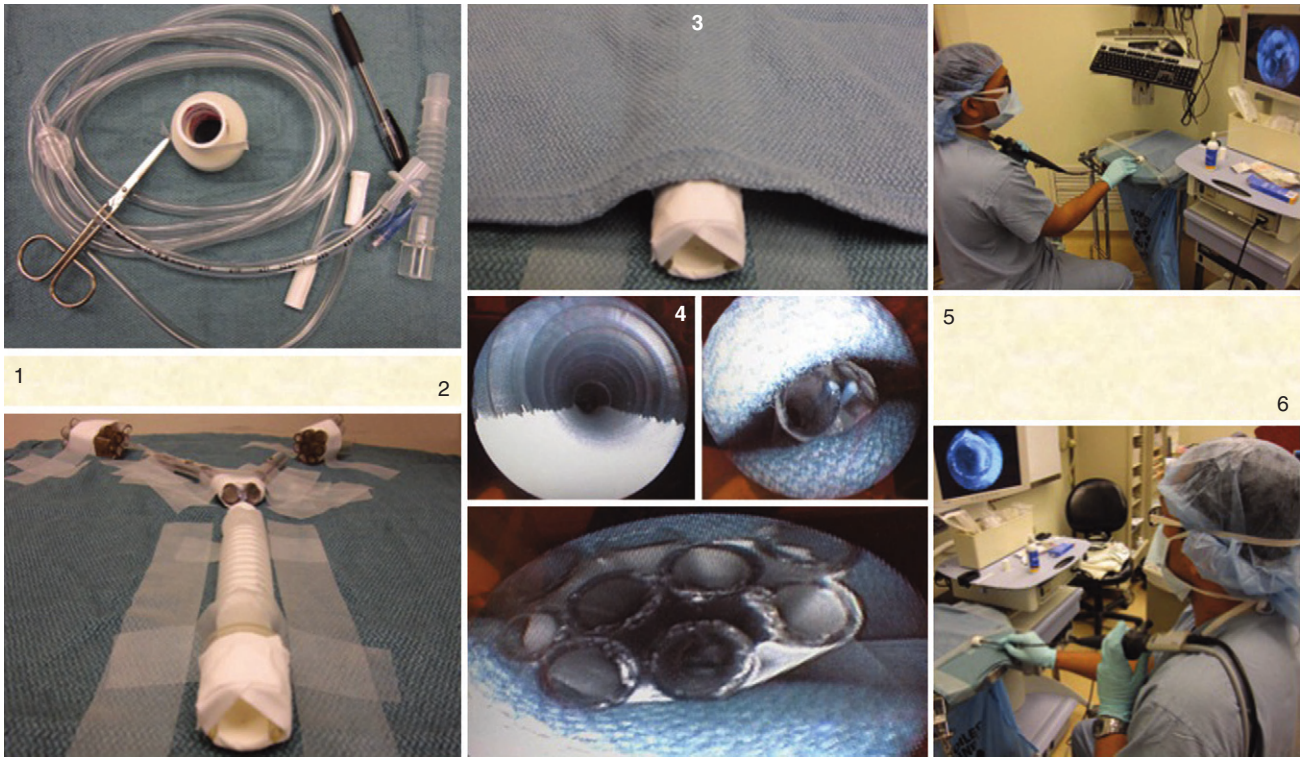

Figure 19-36 Gil 5-Minute Dexterity Model: *1,* simple discarded or inexpensive materials for model construction; *2,* model shown to trainee with "trachea" leading to "carina" leading to two sets of targets; *3,* covered model; *4,* fiberoptic views seen—flexible corrugated tubing "trachea" with "membranous" posterior tape, "carina," and one set of suction tubing "targets"; *5,* trainee visualizing one set of targets, with correct hand position and care of the fiberoptic bronchoscope evident; *6,* trainee successfully entering chosen target.

a patient under GA. The survey of trainees by McNarry and colleagues revealed that 82.7% found no ethical concern in performing FOB intubation in patients under GA without the patient's prior knowledge or consent to performing this task.[105] This attitude is most likely related to the influence of many anesthesiologists who use FOB for most patients who require intubation in the operating room as a standard of practice, secondary to its high rate of success and minimal trauma.

Simple initial goals during FOB use in patients with a "normal" airway under GA provide the visual reality and dexterity practice that will one day be required in more difficult situations. It is important to select younger, healthier patients with surgical sites distant from the airway and to have no one pressing for a hurried approach to intubation. Discussing a plan for expanding FOB experience alleviates the concerns of nearby colleagues and personnel and enlists their concurrence in a quest to become proficient. One or more FOB techniques could be tried in the following scenarios.

a. AN ALREADY INTUBATED PATIENT

Use the FOB to examine airway anatomy in a sufficiently anesthetized or paralyzed patient. Examine all structures within the oropharynx, including the glottis. With extreme gentleness, while using the smallest lubricated FOB available, inspect the nasopharynx down to the larynx if possible. Do not use vasoconstrictors, because this exposes a patient to a drug that is unwarranted for a pure examination technique. Definitely do not pass the FOB down the nasal passage if even the slightest resistance occurs.

b. AN ANESTHETIZED PATIENT WITH AN ENDOSCOPY MASK OR SWIVEL ADAPTER

Use an FOB to examine and perhaps even intubate patients, but make sure they are deeply anesthetized or that someone is assisting them if muscle relaxant is being used. Some pressure-assist ventilators can carry out this function. Make sure that ventilation and vital signs are observed.

c. A PATIENT UNDER GENERAL ANESTHESIA WHO HAS HIGH AIRWAY PRESSURE, LOW SATURATION, OR A NEED TO CHECK FOR CORRECT SUPRAGLOTTIC AIRWAY POSITION, ENDOBRONCHIAL INTUBATION, OR ONE-LUNG ISOLATION

An FOB can be used for examination down the ETT to check for obstruction, secretions, and endobronchial intubation, as well as SGA and DLT positioning, as described previously. The use of an FOB in these cases adds to experience that can be translated to eventual successful FOB intubation and use.

d. A PATIENT WHO NEEDS A GENERAL ANESTHESIA AND INTUBATION

Inform the staff that, to provide experience, the patient will be anesthetized and mask-ventilated with 100% oxygen, and 2 minutes will be taken to perform FOB laryngoscopy while an assistant helps with maneuvers and watches ventilation and vital signs and someone is looking at the clock. A video screen helps gain the

cooperation of others, because direct observation improves their understanding. After 2 minutes, if the trachea is entered, railroad the ETT. If the trachea is not entered, use the usual fall-back intubation technique (e.g., RL). Make sure to decide whether more anesthetic agent or mask ventilation (or both) is necessary for this attempt.

e. A PATIENT WHO NEEDS AWAKE FOB INTUBATION

Perform all facets of this technique as detailed earlier. The technique of awake FOB intubation definitely requires patient consent and is not one recommended for developing experience or dexterity. However, after one has performed at least 20 FOB intubations on patients under GA, the awake approach can be taken with a good degree of confidence in patients with relatively normal airway anatomy. If an operator with a greater degree of FOB expertise is available, that person's assistance would be beneficial to heighten the learning experience in these circumstances and ensure a high likelihood of success.

XIV. ASSESSING PROFICIENCY

A. Instruction

Trainee proficiency cannot be expected to take place unless participants have experienced very adequate and thorough teaching. Instruction in FOB use must include imparting knowledge of FOB mechanics, patient preparation, and FOB technique. Model and dexterity practice must be encouraged.

Instructors in clinical areas need to choose less problematic patients for novice trainees and should emphasize the delicacy of the equipment and correct procedures. The situation in all cases can be optimized, but this is especially so in the case of novices or trainees with DA patients. It is helpful to plan on carrying out adjunct maneuvers, such as tongue pull and jaw thrust, and on keeping the FOB or IOA in the midline.

The use of a video monitor, visible to all personnel, is extremely advantageous to facilitate instruction. If only an eyepiece is available, consideration should be given to turning the lights off after FOB insertion and observing trainee movements of the FOB via transillumination in the neck, similar to a lightwand. Otherwise, if the trainee is uncertain of the anatomy being observed, the instructor might have to periodically look through the eyepiece, while the trainee braces the FOB, to supply instruction.

If video monitoring is not available, many endoscopists choose the nasotracheal route as a good method for an initial attempt, because it tends to lead the trainee most easily to the epiglottis and larynx. Vasoconstriction is mandatory. Passage through a lubricated, breakaway NPA or a partially inserted, lubricated ETT will virtually direct the FOB tip toward the glottis within seconds.

As mentioned earlier, Johnson and Robert's studies in first-year residents who were novices to FOB use showed that they were successful in 50% of their first 5 cases, in 90% of their next 5 cases, and in 100% of their final 5 cases.[163] After 10 cases, the average time to successful FOB intubation was 90 seconds or less. This fast learning curve correlated with the marked improvement exhibited after 10 nasotracheal intubation cases by emergency room trainees, as reported by Delaney and Hessler.[173]

B. Assessing Planning and Technique

Proficiency evaluation for trainees must include appropriate appreciation of a number of factors: the indications for and contraindications to FOB use, the ability to inform patients properly, complete equipment preparation, monitoring, positioning, use of assistants, and administration of drugs such as antisialogogues, sedatives, narcotics, and local anesthetics. Some of this knowledge can be gauged through written testing or clinical observation.

The method usually described to assess residency proficiency in actual FOB use is simplistic recording of the total number of FOB experiences. Nevertheless, as described in Dr. Ovassapian's quotation (see Box 19-9), the performance of 50 FOB experiences is estimated to provide competence with the technique and the ability to perform FOB intubation independently. His opinion was that 15 to 20 of these practice experiences should be asleep FOB intubations, and 15 to 20 should be awake FOB intubations. Competency of FOB use in DA cases is more difficult to determine, but Dr. Ovassapian also documented that use of the FOB for the myriad of purposes and techniques described in this chapter could lead one to the expert level of 100 or more FOB cases by the end of residency.[162]

Besides determining proficiency by pure numbers, the quality of the FOB intubations has been evaluated in several studies. Proposed items to be recorded for this determination include success or failure, time needed to achieve the FOB intubation, a validated global rating scale, and a performance checklist, as described by Chandra and associates.[171]

XV. INTRODUCING FIBEROPTIC INTUBATION INTO ONE'S OWN PRACTICE

Lack of FOB training or rusty skills in this technique are obstacles that can easily be eliminated whether one works in a teaching hospital or in private practice. Considering role reversal: Would any airway management professional in the fields of emergency medicine, anesthesiology, or critical care medicine prefer to be a patient in the hands of someone lacking FOB intubation skills? In spite of knowing that all airway specialists regard their patients as having the highest priority, there are still factors that prompt some hesitancy in the use of FOB techniques.

One factor is time. There is a concern (particularly in private practice) that too much time will be needed to perform an FOB technique. Perhaps the realization that far more time may be spent on unsuccessful airway management using non-FOB methods would change negative thinking toward FOB use—to say nothing of the vast difference that might develop in costs resulting from subsequent patient complications.

Of significant concern here is the idea that other health personnel might harass anyone trying to become more experienced. Gaining FOB experience is not really

Box 19-10 Steps to Introduce Fiberoptic Intubation Techniques into a Practice

Step 1: Go to the Web sites, and read the literature; DVDs and videos are also available.
Step 2: Attend workshops on use of fiberoptic bronchoscopes (FOBs) or use the FOB representatives to provide in-service training, or both.
Step 3: Practice on mannequins and dexterity models.
Step 4: Have all equipment prepared ahead of time.
Step 5: Look for proper prospects—healthy, young patients undergoing general anesthesia whose surgical sites are far removed from the airway.
Step 6: Use the FOB to examine and to observe normal anatomy in anesthetized patients, not plastic models.
Step 7: Emphasize the fact that experience equals safety by enlisting surgery, nursing, and technical colleagues.

a long trek. For most airway management professionals, it can be one of their best journeys, and the success obtained in a particularly vital patient rescue while averting disaster will make an endoscopist soar to the highest peaks. To begin the journey, however, steps must be taken (Box 19-10).

Emphasize to all colleagues and ancillary personnel the desire to gain experience and become an expert to avoid trauma, cost, and anxiety in difficult, uncontrolled cases. Maintain a self-imposed time limit of 2 to 3 minutes for FOB intubation, to be followed by routine alternatives if unsuccessful. Success usually follows within a short time span! Communication, preparation, and time limits for reverting to an alternative plan will ensure that impressions of the FOB approach are positive and professional, no matter the outcome. Lack of any of these points raises concern and may present a bad impression. Avoid this by all means.

XVI. SKILL RETENTION

Psychomotor skills can deteriorate with infrequent FOB use. Dexterity models, mannequins, and FOB workshops should be utilized frequently if patient practice is not possible. Voluntary enrollment in a systematic program, such as the one developed by Dr. K. Gil in the framework of the ASA Annual Meeting's Basic Fiberoptic Workshop, is a structured way to ensure success. Fundamentally, however, real patient practice is crucial to maintaining skills. A good method is to designate a certain day of the week or twice a month as "Fiberoptic Day." Planning a set pattern in which FOB use must take place on a particular day will become a routine, and expectations to gain experience will not surprise colleagues or assistants.

XVII. CONCLUSIONS

Airway loss is a two-word phrase that chills the hearts of all health-related professionals. Closed claims analysis and numerous reviews reveal the importance of the capability to perform all techniques of airway management.[174,175] The superiority of FOB use for patient safety cannot be denied. Nor can the training needed to develop expertise and the cost, maintenance, and space requirements be ignored. With developments in microchip camera technology and video transmission, both costs and equipment bulk are beginning to decrease.

The costs of FOB purchase and maintenance should be balanced in relation to the cost of a failed intubation or lost airway and subsequent injury to cardiac, neurologic, or other systems. The expense of airway management failure and resulting complications may vastly exceed the cost of one FOB system. There is no question that the role and value of FOB techniques are secured. As proof of its importance, every single printed airway management text in anesthesiology, critical care, or emergency medicine places an extremely high value on this technique, making it a required skill with a place in the armamentarium of every professional airway management caregiver in each of these fields.

XVIII. CLINICAL PEARLS

- A proactive low threshold for use of the fiberoptic bronchoscope (FOB) is important when considering a difficult airway. Indiscriminate use of a rigid laryngoscope (RL) in these circumstances could worsen an already bleak picture, and if FOB attempts are to follow, hopes of success may soon spiral downward.
- FOB instruments are very delicate and frequently very expensive. Yet it is important to consider the balance of FOB purchase and maintenance costs in relation to the expense of a failed intubation or lost airway with subsequent injury to cardiac, neurologic, or other systems.
- When any topical intraoral anesthetic is planned, an antisialogogue (glycopyrrolate) should be administered 15 to 20 minutes beforehand. Supplemental oxygen is highly recommended. Use of sedatives, narcotics, or local anesthetics is dependent on the urgency of the patient's situation and respiratory status. Proper topicalization should prevent discomfort, psychological distress, hemodynamic changes, and lack of cooperation.
- After laryngeal entry, three directions must be followed successively in the supine patient to reach the trachea through the nasal or the oral route: downward to the posterior wall of the oropharynx or nasopharynx, upward to the anterior commissure of the vocal cords, and downward again into the laryngeal and tracheal lumen to the carina.
- The number one cause of FOB intubation failure is inexperience due to insufficient training and practice. Getting to know the FOB will offset any reluctance toward it. This can be achieved with understanding and practice involving indications, contraindications, and handling of the FOB.
- Inferior preparation of patients, equipment, and personnel doom FOB use to difficulty, if not failure. Psychological preparation, equipment, antisialogogues, sedatives, narcotics, and local anesthetics must be optimized and individualized for each patient. Untrained

personnel must understand the techniques of tongue pull, jaw thrust, keeping the intubating oral airway in the midline, and injecting local anesthetic through the FOB.

- Rarely, the FOB enters a wide-open esophagus that is mistaken for the trachea. Identifying what seem to be tracheal rings is not enough to prevent this error. Identifying the carina provides more definitive proof of the location of the FOB.
- The option of combined use of an FOB with other airway devices should be high on the priority list for rescue of difficult FOB intubation or other types of difficult intubations. The multimodal approach is most likely to impact airway control in patients with upper airway bleeding, secretions, or edema and those with periglottic or periepiglottic pathology.
- One situation in which the FOB tends to be at a disadvantage is in any soiled airway, because of the small diameter of the viewing tip. Combinations with other devices such as a supraglottic airway (SGA) may overcome these difficulties.
- Patients who have preexisting narrowing or obstructive pathology in their upper airways may have difficulty when any non-hollow object is placed in the area. To ward off effects of near or total obstruction once the FOB enters the respiratory tract, FOB manipulation must be speedy and careful.

Acknowledgment

This chapter was undertaken with the specific intention of expanding on the vision that many others have had while contributing to education in the service of patient care. Although the entire substance of the material in this chapter has been researched thoroughly and is unique, we are pleased to retain a number of the topics in fond remembrance of Dr. Andranik Ovassapian, as can be noted in the chapter he co-authored with Dr. Mellissa Wheeler in the first and second edition of this textbook. We are particularly appreciative of the magnitude of Dr. Ovassapian's experience and instruction of countless airway management specialists throughout his career.

I. HISTORY

The first reported case of retrograde intubation (RI) was by Butler and Cirillo in 1960.[1] The technique involved passing a red rubber catheter cephalad through the patient's previously existing tracheostomy. When the catheter exited the oral cavity, it was tied to the endotracheal tube (ETT), allowing it to be pulled into the trachea.

The first person to perform RI as presently practiced was Waters, a British anesthesiologist in Nigeria.[2] In 1963, he reported treating patients who had cancrum oris, an invasive gangrene that deforms the oral cavity, severely limiting mouth opening. His technique involved passing a standard Tuohy needle through the cricothyroid membrane (CTM) and feeding an epidural catheter cephalad into the nasopharynx. He "fished" the catheter out of the nasopharynx through the nares, using a hook he devised. The epidural catheter was then used as a stylet to guide the ETT through the nares and into the trachea.

Over the ensuing years, RI did not gain clinical acceptance because of its invasiveness and the potential for complications from the CTM puncture. After 1964, when fiberoptic technology became available, RI was irregularly but occasionally discussed in the literature.[1-165] In 1993, RI was designated as part of the anesthesiologist's armamentarium by the American Society of Anesthesiologists (ASA) Difficult Airway (DA) Task Force.[3]

The term *retrograde intubation*, used by Butler and Cirillo, is a misnomer.[4] The technique is actually a translaryngeal guided intubation, but for historical reasons we continue using the name retrograde intubation.

II. INDICATIONS

The RI technique has been used both in the hospital setting and in prehospital mobile units (in the field).[5,6] It has been employed with both anticipated and unanticipated DAs[2,5-20]; after failure to intubate by conventional means (direct laryngoscopy,[6,9,11] blind nasal intubation,[10,11] bougie,[13,21] laryngeal mask airway [LMA], and fiberoptic laryngoscopy[18,22-24]); and in both humans and animals.[25,26] In the literature, including my own experience (31 patients), there have been approximately 807 cases (670 patients and 137 cadavers) in which RI was used as a means of securing the airway. Although in most cases RI has been used to place a single-lumen ETT, one case report described placement of a double-lumen ETT through RI.[7]

A wide variety of airway diseases have necessitated RI (Box 20-1). RI has been most frequently associated with limited range of motion of the neck (153 trauma victims with potential cervical spine injury), and its use has been reported in facial trauma. It has been employed in both adults and pediatric patients with success (Box 20-2).

BOX 20-1 Number of Retrograde Intubations in the Literature (539 Patients and 137 Cadavers)

Oral Cavity
Cancrum oris, 27
Mandibular or maxillary fracture, 31
Mandibular prognathia, 1
Perimandibular abscess, 1
Ankylosis of temporomandibular joint, 8
Microstomia, 1
Macroglossia, 1
Cancer of tongue, 8
Oral myxoma, 1
Lingual tonsil, 1
Hypopharyngeal tumors, 2

Cervical
Spinal cord injury, 98
Ankylosing spondylitis, 19
Rheumatoid arthritis, 32

Pharynx and Larynx
Laryngeal cancer, 163
Pharyngeal abscess, 1
Epiglottitis, 1
Pharyngeal edema, 1
Laryngeal edema after burn, 3

Others
Pediatric anomalies, 27
Obesity, 13
Coronary artery bypass grafting (failure to intubate), 28
Tracheostomy stoma, 16
Trauma (failure to intubate), 34
Disease not specified (failure to intubate), 21
Cadaver studies, 137

From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.

Not all reports have described the amount of time required to perform the technique, but in one study involving emergency medical service personnel (paramedics and registered nurses) using training mannequins, the average time was 71 seconds (range, 42 to 129 seconds).[27] Barriot and Riou described 13 patients with maxillofacial trauma who could not be intubated in the field using direct laryngoscopy (six attempts; average time, 18 minutes).[5] Intubation was subsequently performed in these patients on the first RI attempt, with an average time of less than 5 minutes. An additional 6 patients were intubated in less than 5 minutes when RI was used as the initial method of choice. Slots and colleagues reported a modified technique using a Mini-Trach II set on 20 cadavers with an average time for intubation of 6.7 seconds (range, 3 to 10 seconds); it was subsequently used on an emergency basis on 3 patients with an average time of 10 seconds. The investigators concluded that the RI technique was a rapid, efficacious method for intratracheal intubation of trauma patients, especially patients with maxillofacial trauma.[28]

Historical indications for RI are the following:

1. Failed attempts at laryngoscopy, LMA, or fiberoptic intubation (FOI)
2. Urgent establishment of an airway where visualization of the vocal cords is prevented by blood, secretions, or anatomic derangement in scenarios in which ventilation is still possible
3. Elective use when deemed necessary in clinical situations such as unstable cervical spine, maxillofacial trauma, or anatomic anomaly

BOX 20-2 Characteristics of Retrograde Intubations (RIs) in the Literature

Number of adult patients (RI): 509
Number of pediatric patients (RI): 30
Age range: 1 day (weight, 2.9 kg) to 84 yr
Average time for technique: 0.2 min (range, 0.5–15 min)
Elective cases: 249 patients
Failed attempts using RI: 12 patients

From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.

III. CONTRAINDICATIONS

Contraindications to RI have been cited, often anecdotally (Box 20-3). Most are relative contraindications and can be divided into four categories: unfavorable anatomy, laryngotracheal disease, coagulopathy, and infection.

A. Unfavorable Anatomy

Because in most cases RI is performed above or below the cricoid cartilage, absolute lack of access to this region, as in patients with severe flexion deformity of the neck, poses a contraindication if not an impossibility.[29,30] For the same reason, the patient with nonpalpable landmarks,[31-33] obesity,[34] overlying malignancy,[32] or large thyroid goiter should be approached cautiously.[32] Shantha reported a case of RI in a patient with a large thyroid goiter.[35] After failure of conventional intubating methods (including FOI), the surgeons dissected down to the CTM and subsequently passed the catheter cephalad. Thirteen cases of RI have been reported in obese patients without major complications.[12,18,34,36]

BOX 20-3 Contraindications to Retrograde Intubation and Examples

Unfavorable Anatomy
Lack of access to cricothyroid muscle (severe flexion deformity of the neck)
Poor anatomic landmarks (obesity)
Pretracheal mass (thyroid goiter)

Laryngotracheal Disease
Malignancy
Stenosis

Coagulopathy

Infection (Pretracheal Abscess)

From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.

B. Laryngotracheal Disease

Theoretically, laryngotracheal stenosis may contraindicate RI because narrowing of the trachea or larynx could be made worse by either the needle puncture or the catheter.[2,31] However, RI has been used in patients with laryngeal cancer,[37] epiglottitis,[38] and laryngeal edema resulting from burn injuries.[16,24] It should not be used if laryngeal tracheal stenosis is present directly under the intended puncture site.

C. Coagulopathy

Preexisting bleeding diathesis should be considered a relative contraindication.[31,32,39-44] Although there is a potential for bleeding, the CTM is considered to be a relatively avascular plane (see later discussion). A small, self-limited hematoma was reported in a patient who underwent a coronary artery bypass grafting with intraoperative heparin and postoperative disseminated intravascular coagulation.[9]

D. Infection

RI in the presence of preexisting infection over the puncture site or in the path of the puncture, as in pretracheal abscess or Ludwig's angina, could result in transmittal of bacterial flora into the trachea and should be avoided. This, again, should be considered a relative contraindication, because transtracheal aspiration is performed to obtain a sputum sample in patients with pneumonia despite the possibility of pretracheal abscess (see "Complications").[31,32,43,45-47]

IV. ANATOMY

The performance of RI requires basic anatomic knowledge of the cricoid cartilage (Fig. 20-1) and the structures above and below it to minimize complications and failure. Indeed, regardless of the intubation technique planned, the cricoid cartilage and CTM should be identified preoperatively in every patient.[48] Cartilage and membrane, vascular structures, and the thyroid gland are relevant anatomic structures.

A. Cartilage and Membrane

The cricoid cartilage has the shape of signet ring (see Fig. 20-1). It consists of a broad, flat, posterior plate called the *lamina* and a narrow, convex, anterior structure called the *arch*.[49,50] In most cases the cartilage can be easily palpated by identifying the thyroid notch and running a finger down the midline in a caudad direction until a rigid, rounded structure is encountered. The vertical height of the arch is 0.5 to 0.7 cm (Fig. 20-2).[50] The CTM connects the superior border of the arch to the inferior border of the thyroid cartilage and measures approximately 1 cm in height and 2 cm in width.[49,51] The lateral borders are the paired cricothyroid muscles.[45] The cricotracheal ligament connects the inferior border of the arch to the upper border of the first tracheal ring and measures 0.3 to 0.6 cm in height.[52] The distance between the inferior border of the thyroid cartilage and the vocal cords varies with gender but is approximately 0.9 cm.[53]

B. Vascular Structures

There are paired major blood vessels above and below the cricoid cartilage: the cricothyroid artery and the superior thyroid artery (Fig. 20-3).

The cricothyroid artery,[50,51,53-55] a branch of the superior thyroid artery, runs along the anterior surface of the CTM, usually close to the inferior border of the thyroid cartilage. In some cases, the cricothyroid arteries anastomose in the midline and give rise to a descending branch

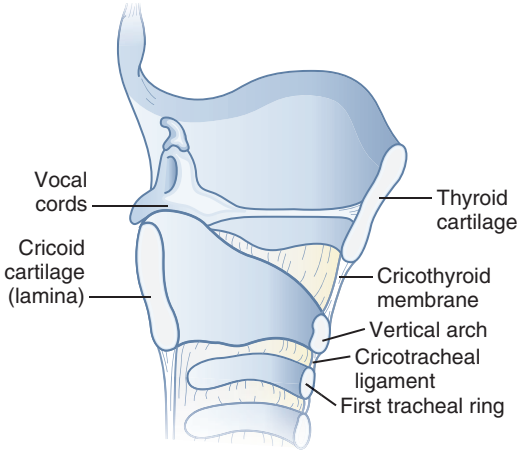

Figure 20-1 Anatomy of the cricoid cartilage. Midsagittal view of the larynx and trachea. (From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.)

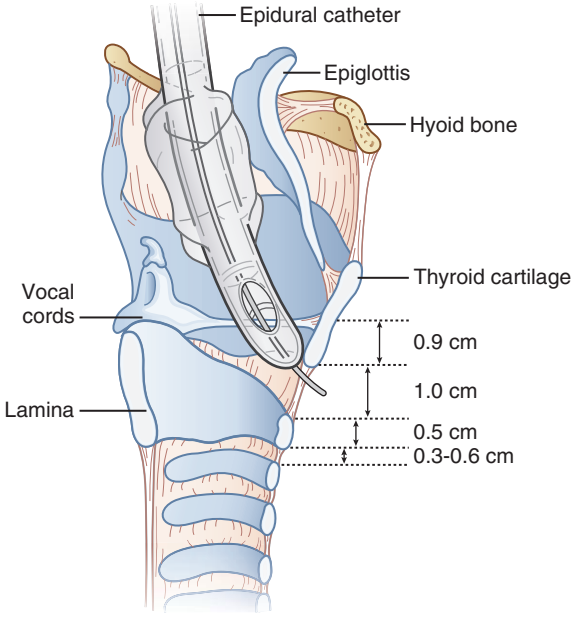

Figure 20-2 Midsagittal view of the larynx and trachea showing the distance between the vocal cords and the upper border of the first tracheal ring. Only a small portion of the Murphy eye of the endotracheal tube is below the vocal cords. (From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.)

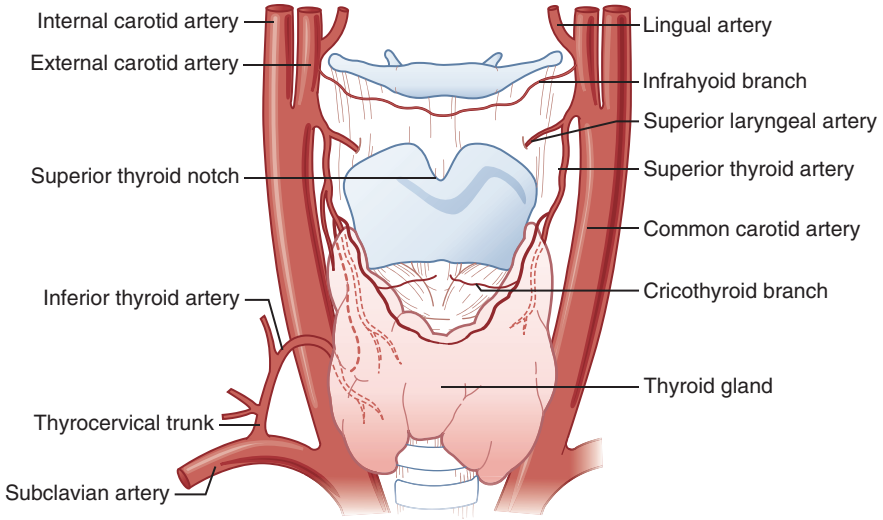

Figure 20-3 Vascular anatomy above and below the cricoid cartilage. (Modified from Naumann H, editor: *Head and neck surgery,* Philadelphia, 1984, WB Saunders.)

that feeds the middle lobe of the thyroid gland when present. On the basis of dissections that I have performed on cadavers, the cricothyroid artery becomes insignificant in size as it approaches the midline. No major venous plexus could be found mentioned in the literature, and none was found in my own dissections.

The anterior branch of the superior thyroid artery runs along the upper border of the thyroid isthmus to anastomose with its counterpart from the opposite side.[50,53-55] The inferior thyroid artery also anastomoses with the superior thyroid artery at the level of the isthmus. The arteries are remarkable for their large size and frequent anastomoses. In fewer than 10% of the population, an unpaired thyroid artery ascends ventral to the trachea (from either the aortic arch or the brachiocephalic artery) to anastomose at the level of the isthmus. It is usually small but may be very large. A rich venous plexus is formed in and around the isthmus.

C. Thyroid Gland (Isthmus, Pyramidal Lobe)

The isthmus of the thyroid gland (see Fig. 20-3) is rarely absent and generally lies anterior to the trachea between the first and fourth tracheal rings (usually between the second and third), although there are many variations. Its size and vertical height vary; the average vertical height and depth are 1.25 cm. Extending from the isthmus, the highly vascular pyramidal lobe (Fig. 20-4) is well developed in one third of the population. It is found more frequently on the left of the midline and may extend up to the hyoid bone (the upper continuation is usually thyromuscular).[25,49,50,54,55]

V. PHYSIOLOGY

Sympathetic stress responses—increased heart rate, blood pressure, intraocular pressure, and intracranial pressure and elevated catecholamine levels—have been reported with laryngoscopy, endotracheal intubation, coughing, translaryngeal local anesthesia, laryngotracheal anesthesia, and FOI. Therefore, concern is appropriate when performing RI in patients with coronary artery disease, elevated intraocular pressure, or elevated intracranial pressure.[29,30,56-62] It is reasonable to argue, however, that RI, performed skillfully, is not more stimulating than any other technique for managing the airway.

No apparent significant changes in hemodynamics were reported in multiple case reports of patients with cardiac disease (congenital anomalies, ischemic coronary artery disease, valvular disease, pericarditis, and congestive heart failure) who underwent RI, both awake with topical anesthesia and under general anesthesia.[9,11,15,17,38,63-68] Casthely and colleagues reported on 25 patients with DA due to rheumatoid arthritis who underwent open heart surgery (coronary artery bypass graft and valve replacement).[9] The patients had invasive monitors (Swan-Ganz catheters and peripheral arterial lines) placed preoperatively. The initial 24 patients underwent a cardiac induction of anesthesia (diazepam 10 mg, fentanyl 25 to 30 µg/kg, and pancuronium 0.1 mg/kg) before rigid laryngoscopy followed by RI. Comparison of hemodynamic responses to rigid laryngoscopy (Macintosh and Miller blades) versus RI demonstrated that the former approach was more stressful (Table 20-1). Patient 25

TABLE 20-1
Hemodynamic Effects of Retrograde Intubation

	Laryngoscopy	Retrograde Intubation
HR	Increase	No change from baseline
MAP	Increase	No change from baseline
CI	Decrease	No change from baseline
PCWP	Increase	No change from baseline
ECG	3-mm ST depression	No change from baseline

CI, Cardiac index; *ECG,* electrocardiogram (ST segment changes in lead V5); *HR,* heart rate; *MAP,* mean arterial pressure; *PCWP,* pulmonary capillary wedge pressure.
Modified from Casthely PA, Landesman S, Fynaman PN: Retrograde intubation in patients undergoing open heart surgery. *Can Anaesth Soc J* 32:661, 1985.

underwent RI before induction of anesthesia after application of topical anesthesia with no significant hemodynamic response.

Two case reports documented patients with a previous history of DA and intracranial pathology (pseudotumor cerebri and intracranial tumor with elevated intracranial pressure) who underwent elective, awake RI after topical anesthesia with no evidence of further increase in intracranial pressure.[8,14] I myself, unmedicated except for topical lidocaine, underwent awake RI with no significant hemodynamic changes.[48]

VI. TECHNIQUES

A. Preparation

1. Positioning

The ideal position for RI is the supine sniffing position with the neck hyperextended.[69,70] In this position, the cervical vertebrae push the trachea and cricoid cartilage anteriorly and displace the strap muscles of the neck laterally. As a result, the cricoid cartilage and the structures above and below it are easier to palpate. RI can also be performed with the patient in a sitting position,[48] which may be the only position in which some patients can breathe comfortably. Potential cervical spine injury or limited range of motion of the cervical spine may necessitate RI with the neck in a neutral position, which is a well-documented practice (see Box 20-1).

2. Skin Preparation

Although most documented RIs have not been elective, every effort should be made to perform RI using aseptic technique. Recommendations have been made for prophylactic antibiotics in diabetic or immunocompromised patients, who may be more susceptible than others to infection.[71]

3. Anesthesia

If time permits, the airway should be anesthetized to prevent sympathetic stimulation, laryngospasm, and discomfort. In the literature, many different combinations of techniques have been described:

1. Translaryngeal anesthesia during intravenous sedation or general anesthesia[2,8-10,16,18,72]
2. Translaryngeal anesthesia with superior laryngeal nerve block[5,6,73]
3. Translaryngeal anesthesia with topicalization of the pharynx (aerosolized or sprayed)[7,14,74,75]
4. Glossopharyngeal nerve block and superior laryngeal nerve block with nebulized local anesthetic[17]

(Refer to Chapter 11 for a detailed description of neural blockade of the airway.)

In my own experience,[48] an awake RI can be performed using translaryngeal anesthesia (4 mL 2% lidocaine) supplemented with topicalization (nebulized or sprayed local anesthetics) of the pharynx and hypopharynx. Special caution should be exercised when performing the translaryngeal anesthesia, because coughing, grunting, sneezing, or swallowing causes the cricoid cartilage to travel cephalad, with the potential for breaking the needle in the trachea.[76,77] To avoid this, one can insert a 20-G angiocatheter and remove the needle before injecting the local anesthetic.

4. Entry Site

The transtracheal puncture for RI can be made either above or below the cricoid cartilage. The CTM is relatively avascular and has less potential for bleeding (see "Anatomy"). The disadvantages of the CTM are that initially only 1 cm of ETT is actually placed below the vocal cords, and the angle of entry of the ETT into the trachea is more acute. An initial puncture performed at the cricotracheal ligament or lower affords the added advantage of allowing the ETT to travel in a straighter path as well as allowing a longer initial length of ETT below the vocal cords. The disadvantage is that this site (below the cricoid cartilage) has more potential for bleeding (although none has been reported). Both entry sites have been used successfully. In cadaver studies, the success rate for RI was higher with less vocal cord trauma when the cricotracheal ligament rather than the CTM was used. Vocal cord trauma has not been reported in living patients.[78,79]

B. Classic Technique

The classic technique of RI is performed percutaneously using a standard 17-G Tuohy needle and epidural catheter.

After positioning (Fig. 20-5), skin preparation, and anesthesia, a right hand–dominant person should stand on the right side of the supine patient. The left hand is used to stabilize the trachea by placing the thumb and third digit on either side of the thyroid cartilage. The index finger of the left hand is used to identify the midline of the CTM and the upper border of the cricoid cartilage.

Because the Tuohy needle is blunt, a small incision through the skin and subcutaneous tissue with a no. 11 scalpel blade is recommended. Because of the significant force required to perforate the skin and the CTM, there is a risk of perforating the posterior tracheal wall as well. This has been verified in cadaver studies with the use of a fiberoptic bronchoscope (FOB).[34]

The right hand then grasps the Tuohy needle and saline syringe like a pencil (using the fifth digit to brace

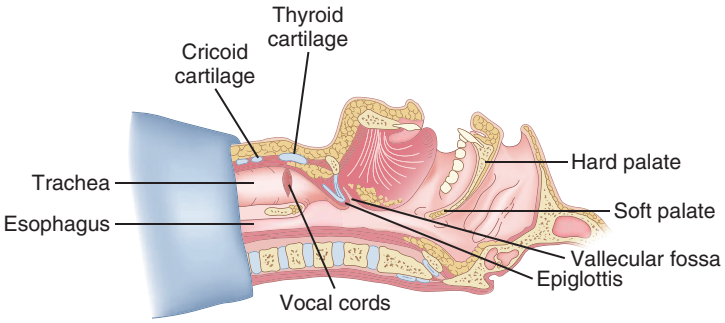

Figure 20-5 Classic technique. Midsagittal view of the head and neck. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

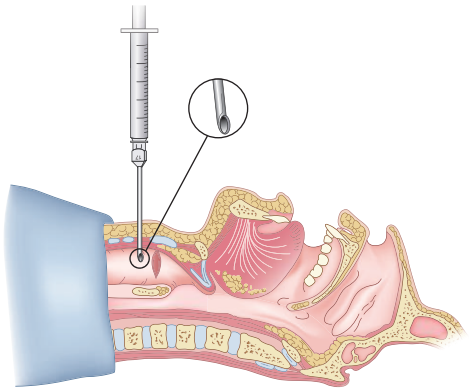

Figure 20-6 Classic technique. Standard no. 17 Tuohy needle (with saline-filled syringe) is advanced (with bevel pointing cephalad) through the cricothyroid membrane at a 90-degree angle, trying to stay as close as possible to the upper border of the cricoid cartilage. Entrance into the trachea is verified by aspiration of air. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

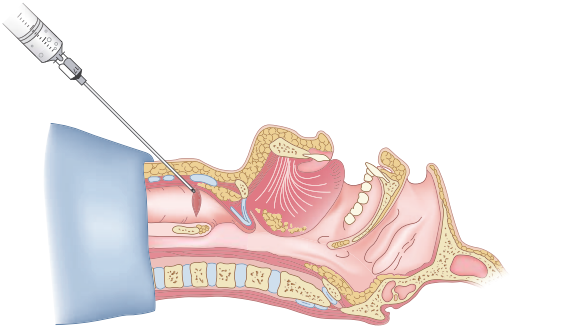

Figure 20-7 Classic technique. The angle of the Tuohy needle is changed to 45 degrees with the bevel pointing cephalad, again verifying position by aspirating air. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

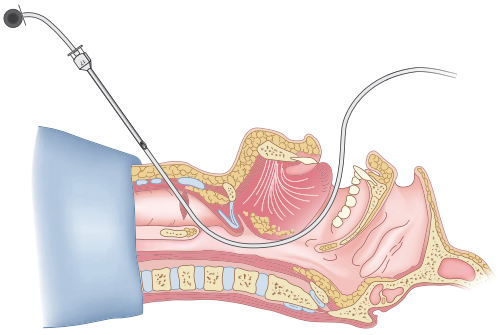

Figure 20-8 Classic technique. An epidural catheter is advanced through the vocal cords and into the pharynx. During this time, the patient is asked to stick the tongue out or tongue can be pulled out manually. Most of the time, the epidural catheter comes out of the mouth on its own. The Tuohy needle is then withdrawn to the caudal end of epidural catheter. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

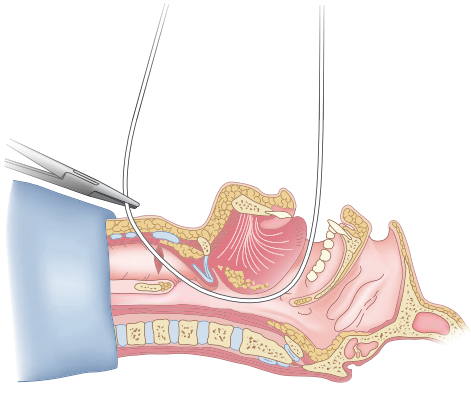

Figure 20-9 Classic technique. Pull the epidural catheter out of the mouth to an appropriate length; then clamp a hemostat flush with the skin. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

the right hand on the patient's lower neck) and performs the puncture, aspirating to confirm placement in the lumen of the airway (Figs. 20-6 and 20-7).

Once the Tuohy needle is in place, the epidural catheter is advanced into the trachea (Fig. 20-8). When advancing the epidural catheter, it is important to have the tongue pulled anteriorly to prevent the catheter from coiling up in the oropharynx. The catheter usually exits on its own from either the oral (Fig. 20-9) or the nasal cavity. A hemostat should then be clamped to the catheter at the neck skin line to prevent further movement of the epidural catheter. If the catheter has to be retrieved from the oropharynx, my preferred instrument is a nerve hook (V. Mueller NL2490, Baxter, Deerfield, IL). Magill forceps have been used, but these were designed to grasp large structures such as an ETT and may not grip the relatively small catheter (the distal tips of the forceps do not completely occlude); in addition, they may traumatize the pharynx. Arya and associates described an innovative atraumatic method of retrieving catheters from the oral pharynx in patients with limited mouth opening. They used a "pharyngeal loop" that they devised from a ureteral guidewire that was threaded through a 3-mm uncuffed polyvinyl chloride ETT and doubled up to form a loop.[80]

Originally, the catheter was threaded through the main distal lumen (beveled portion) of the ETT. Bourke and Levesque modified the technique by threading the

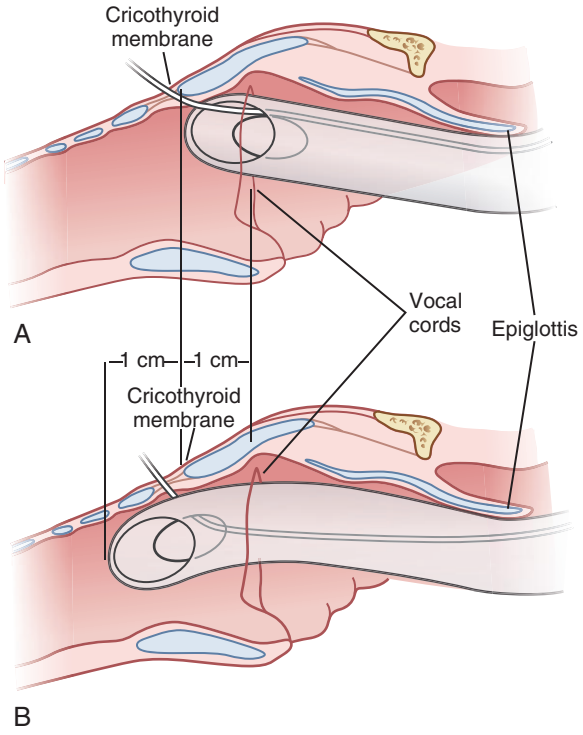

Figure 20-10 Classic technique. Cross section of larynx and trachea with endotracheal tube (ETT) and catheter guide passing through the cricothyroid membrane. **A,** Catheter passes through end of ETT, and 1 cm of ETT passes the cords. **B,** The catheter exits the side hole, allowing 2 cm of ETT to pass beyond the vocal cords. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

catheter through the Murphy eye (Fig. 20-10), reasoning that this would allow an additional 1 cm of ETT to pass through the cords.[81] Lleu and coworkers,[78,79] in cadaver studies, showed that using the cricotracheal ligament as the puncture site in combination with threading the epidural catheter through the Murphy eye enhanced success compared with the original technique.

When the ETT is being advanced over the epidural catheter (Figs. 20-11 through 20-13), a moderate amount

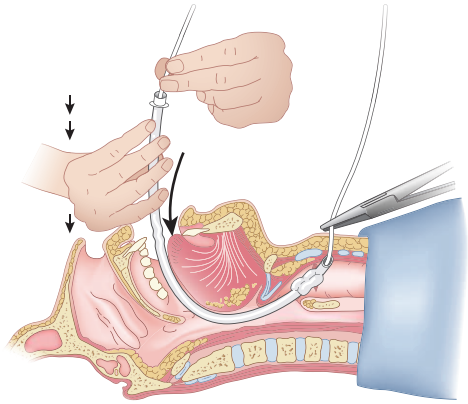

Figure 20-12 Classic technique. When the endotracheal tube (ETT) reaches the cricothyroid membrane (CTM), it is important to maintain pressure *(small arrows),* forcing the ETT into the oropharynx *(large arrow)* to cause continuing pressure against the CTM with the tip of the ETT. Moderate tension is still maintained on the epidural catheter. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

of tension should be employed.[13,40] Excessive tension pulls the ETT anteriorly, making it more likely to be caught up against the epiglottis, vallecula, or anterior commissure of the vocal cords. If there is difficulty in passing the opening of the glottis, the ETT can be rotated 90 degrees counterclockwise or exchanged for a smaller tube.[13,23,34]

Ideally, one would like to verify that the ETT is below the vocal cords before removing the epidural catheter (Fig. 20-14; see Fig. 20-13). The methods of verification are the following:

1. By direct vision, using the FOB (see "Fiberoptic Technique")
2. If the patient is breathing spontaneously, by listening to breath sounds through the ETT
3. By capnography, using a fiberoptic elbow adapter connected to a capnograph[82]
4. By luminescent techniques using a light wand[83]

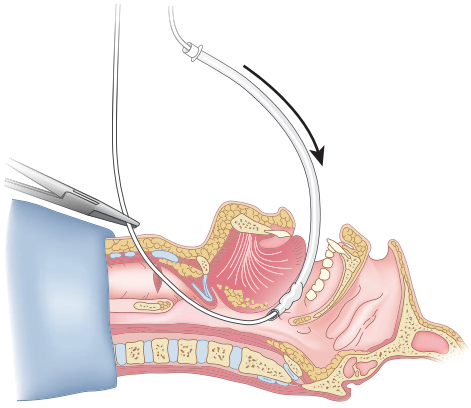

Figure 20-11 Classic technique. Thread a well-lubricated endotracheal tube (ETT) over the epidural catheter. Maintain a moderate amount of tension on the epidural catheter *(arrow)* as you advance the ETT forward; you will feel a small click as the ETT travels through the vocal cords. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

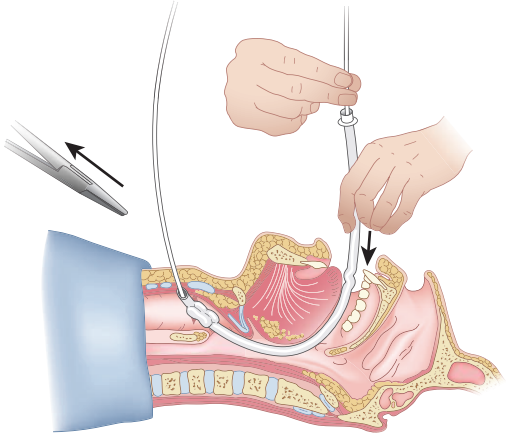

Figure 20-13 Classic technique. Have an assistant remove the hemostat *(large arrow)* while pressure is maintained *(small arrow)* to push the endotracheal tube up against the cricothyroid membrane. (The epidural catheter may be cut flush with the hemostat before hemostat is removed.) (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

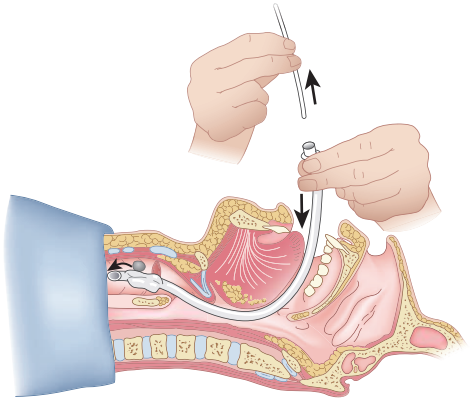

Figure 20-14 Classic technique. Simultaneously remove epidural catheter as you advance the endotracheal tube (ETT) *(straight arrows)*. The tip of the ETT will drop from its position up against the cricothyroid membrane to the midtrachea *(curved arrow)*. Advance the ETT to the desired depth. (From Sanchez AF: *The retrograde cookbook*, Irvine, 1993, University of California, Department of Anesthesia.)

C. Guidewire Technique

The modified technique using a guidewire was developed because the flexible epidural catheter is prone to kinking.[4,7,13-15,19,23-25,31-33,38,39,59-63,72-74,84-91] Equipment consists of an 18-G angiocatheter, a J-tip guidewire with 0.038 inch outer diameter (OD) and 110 to 120 cm in length, and a guide catheter (Fig. 20-15).

Use of a guidewire offers the following advantages:

1. The J tip tends to be less traumatic to the airway.[24,39,74,87]
2. Retrieval of the guidewire from the oral or nasal cavity is easier.[33,74,87]
3. The guidewire is less prone to kinking.[92]
4. The guidewire can be used with the FOB (see "Fiberoptic Technique").
5. The guidewire is easy to handle.[32,73,87]
6. The technique takes less time to perform than the classic technique.[27,33]

Discrepancy between the external diameter of the guidewire and the internal diameter (ID) of the ETT allows a "railroading" effect to occur, with the tip of the ETT catching peripherally on the arytenoids or vocal cords instead of going straight through the cords. Sliding the guide catheter over the guidewire from above (antegrade) when it has exited the mouth or nose increases the external diameter of the guidewire,[82] and use of the guide catheter in combination with a smaller-diameter ETT allows the ETT to enter the glottis in a more centralized position with respect to the glottic opening.

Various types of antegrade guide catheters have been used: FOBs (described in the next section), nasogastric tubes,[34,93] suction catheters,[34,94] plastic sheaths from Swan-Ganz catheters,[88] Eschmann stylets,[13] and tube changers.[24,89] The Cook Critical Care retrograde guidewire kit (Cook Incorporated, Bloomington, IN) contains a tapered antegrade guide catheter, which is my choice of antegrade guide catheter (see Fig. 20-15) and is used here to describe the basic guidewire and antegrade guide catheter technique.

The guidewire and antegrade guide catheter technique is as follows. The trachea is identified (Figs. 20-16 to 20-18) with the syringe and 18-G angiocatheter. The J wire is then fed through the intratracheal catheter (Fig. 20-19) until it passes out the mouth (Fig. 20-20). The guidewire is clamped at the neck skin line, and the tapered antegrade guide catheter is fed over the guidewire (Fig. 20-21) until the antegrade guide catheter reaches the CTM (Fig. 20-22). The ETT is then fed over the antegrade guide catheter (Figs. 20-23 and 20-24) and the antegrade guide catheter is removed (Fig. 20-25). The standard Cook RI set has been modified to include a tapered antegrade guide catheter with distal sideports and Rapi-Fit adapters (Arndt Airway Exchange Catheter) to allow oxygenation and ventilation of the patient and to facilitate placement of an ETT.

Three other modifications have been reported using guide catheters. First, the guidewire is removed when the guide catheter abuts against the CTM (see Fig. 20-21). The guide catheter alone is then advanced farther into the trachea and used as a stylet for the ETT.[88,72,89] Second,

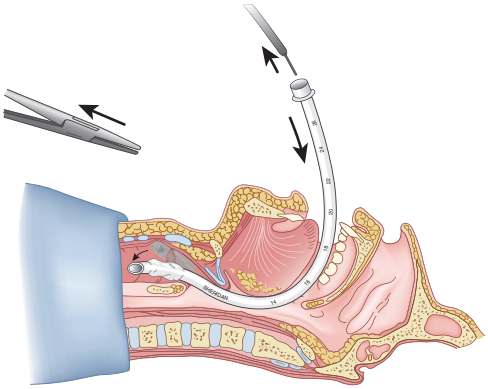

Figure 20-25 Guidewire technique. Remove the wire and catheter as in classic technique, except that the guidewire and guide catheter are removed simultaneously. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

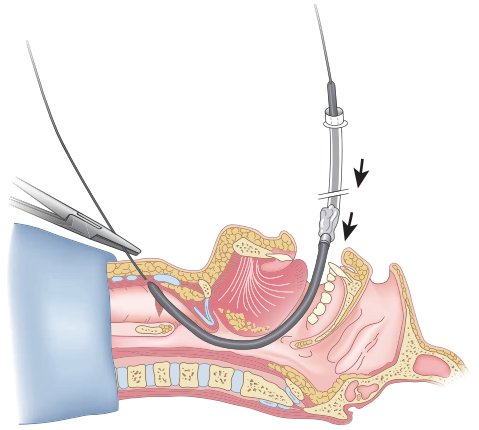

Figure 20-23 Guidewire technique. Advance the endotracheal tube (ETT) over the entire structure *(arrows)*. Use an ETT that has an inner diameter of 6.0 to 7.0 mm. The size of the ETT is dictated by the external diameter of the guide catheter. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

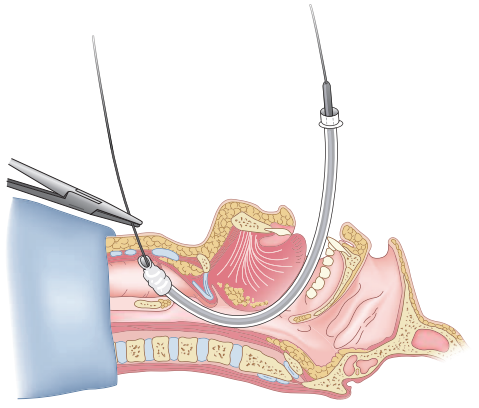

Figure 20-24 Guidewire technique. Advance the endotracheal tube through the vocal cords and up against the cricothyroid membrane. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

an RI is performed with the bare guidewire (or epidural catheter) alone. When the ETT abuts the CTM, the guide catheter is advanced through the ETT from above (antegrade), passing distally to the carina.[11] The guidewire is then removed, and the guide catheter is again used as a stylet for the ETT. In my opinion, the best results from a blind RI are obtained by using the cricotracheal ligament as a puncture site and the technique in which the guide catheter is passed over the guidewire. Third, an LMA has been used as conduit for the exit of the guidewire; a jet stylet is then placed over the guidewire, and both LMA and guidewire are removed, leaving the jet stylet as a guide catheter for the ETT. The benefits of this technique include a longer time for ventilation and the ability to place a larger ETT than the LMA would have accommodated.[95]

D. Fiberoptic Technique

The FOB is a versatile tool for the anesthesiologist,[54] but like RI, has its limitations. In some cases, the combination of two techniques, when previously either technique alone has failed, allows achievement of tracheal intubation.[14,15,19,34,38,63,73,82] The combination of RI with direct laryngoscopy or RI using FOB can improve the chance of successful intubation.[14,15,19,38,63,73] The advantages of passing an FOB antegrade over a guidewire placed by RI are as follows:

1. The OD of the guidewire and the ID of the suction port of the FOB form a tight fit that prevents railroading between the two cylinders, allowing the FOB to follow a straight path through the vocal cords without being caught on anatomic structures.
2. The FOB acts as a large antegrade guide catheter (see "Guidewire Technique") and prevents railroading of the ETT.
3. When the FOB has passed over the wire through the vocal cords, it can be advanced freely beyond the puncture site to the carina, which eliminates

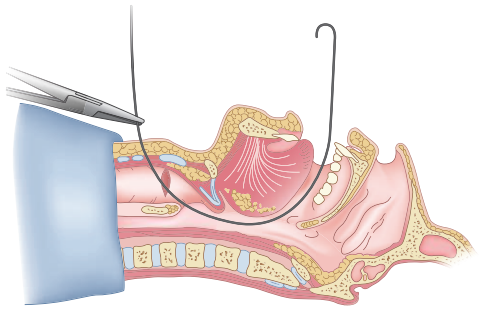

Figure 20-26 Fiberoptic technique. The guidewire is placed as in the guidewire technique and pulled out to appropriate length to accommodate the fiberoptic bronchoscope (hemostat in place). (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

the problem of distance between vocal cords and puncture site.

4. Use of the FOB allows placement of the ETT under direct vision.
5. The FOB can be used by less experienced operators.
6. Oxygen can be delivered continuously through the FOB with the guidewire still in place (see "Pediatrics").

Preparation of the FOB should be completed before RI is initiated. The rubber casing from the proximal portion of the suction port must be removed (to allow the guidewire to exit from the FOB handle), and the FOB should be armed with the appropriate-sized ETT (6.5 to 7.0 mm ID). The RI is performed using the guidewire technique (Fig. 20-26), and the FOB is then passed antegrade over the guidewire like a guide catheter (Figs. 20-27 through 20-30). Once the tip of the FOB abuts the CTM (Fig. 20-31), there are the following options:

1. *Option 1:* Remove the guidewire distally (Fig. 20-32) or proximally (through the fiberoptic handle) and, after advancing under direct vision to

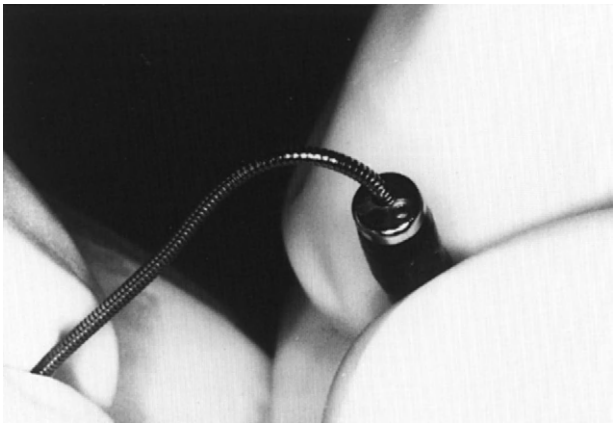

Figure 20-28 Fiberoptic technique. Close-up view of J tip being fed into suction port of fiberoptic bronchoscope. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

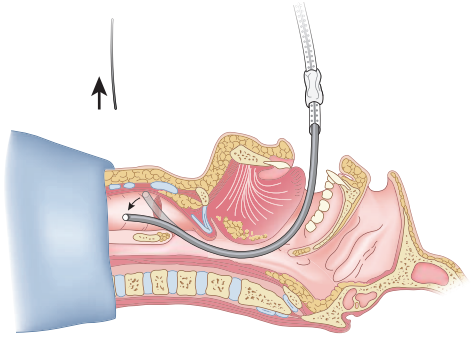

Figure 20-33 Fiberoptic technique. Remove the guidewire from the cricothyroid membrane *(straight arrow).* The tip of the fiberoptic bronchoscope then drops into midtracheal position *(curved arrow).* (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

the carina, intubate (Figs. 20-33 and 20-34). Removal of the guidewire distally is less likely to dislodge the FOB from the trachea, but anecdotal reports suggest that removal proximally should decrease the incidence of infection resulting from oral contaminants.[71,96]

2. *Option 2:* Instead of removing the guidewire, allow it to relax caudad into the trachea, advance the FOB below the cricoid cartilage, and then remove the guidewire. This allows a greater length of the FOB in the trachea before the guidewire is removed.
3. *Option 3:* Remove the guidewire proximally only until it is seen through the FOB to have popped out of the CTM and into the trachea; then advance the guidewire through the FOB to the carina. The FOB can then be advanced antegrade over the guidewire to the carina. (Caution: Be sure both ends of the guidewire are floppy.)
4. *Option 4:* Tobias used a fiberoptic technique that did not make use of the suction port of the FOB.[19] A standard RI was performed, feeding the guidewire or epidural catheter first through the main lumen (bevel) of the ETT and immediately exiting out of the Murphy eye. The ETT was then advanced to the level of the CTM (Fig. 20-35). At this time, the FOB was advanced proximally through the ETT to the level of the carina. The retrograde guidewire was then removed, and a standard FOI was performed.

(My own preference is for option 3.)

The combination of FOB and RI is the easiest to perform of all the RI techniques. The disadvantages are that it requires more equipment (not readily available in cases of emergency) and more preparation time and may not be suitable in certain conditions (e.g., an airway with large amounts of blood or secretions).

E. Silk Pull-Through Technique

Various pull-through techniques have been described using epidural catheters,[39,97] central venous pressure catheters,[67] monofilament sutures,[75] and Fogarty catheters[98]; the silk technique is also a pull-through technique.[34,36,48] The basic principle involves advancing the epidural catheter retrograde as in the classic technique, attaching it to a length of silk, attaching the length of silk to the tip of the ETT, and then using the catheter-silk combination to pull the ETT into the trachea. The silk technique offers the following advantages:

1. The necessary equipment is readily available in the operating room.
2. The silk is intimately attached to the ETT, eliminating railroading.
3. Multiple attempts at intubation are allowed without having to repeat the procedure (CTM puncture) if it fails initially.

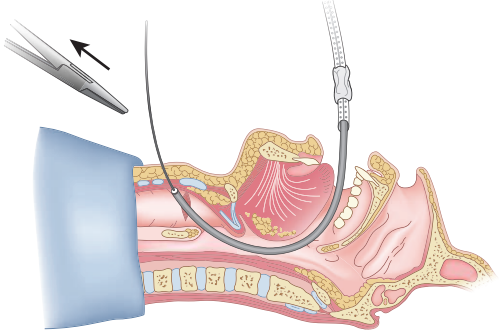

Figure 20-32 Fiberoptic technique. Have an assistant remove the hemostat *(arrow).* (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

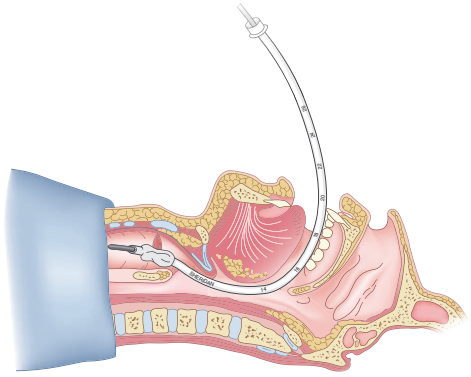

Figure 20-34 Fiberoptic technique. Continue as for a standard fiberoptic intubation. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

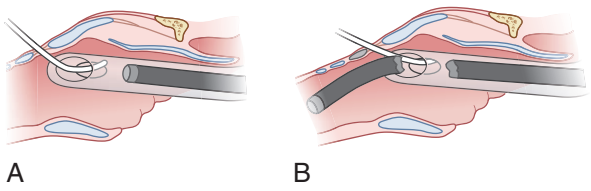

Figure 20-35 Fiberoptic technique. **A,** Midsagittal view of the larynx with the tip of the endotracheal tube (ETT) at the level of the cricothyroid membrane. The fiberoptic bronchoscope (FOB) is advanced through the main lumen of the ETT. **B,** The FOB is advanced to the level of the carina before the guidewire is removed. (Modified from Tobias R: Increased success with retrograde guide for endotracheal intubation (letter). *Anesth Analg* 62:366, 1983.)

4. Oxygen can be delivered through the ETT using a standard anesthesia circle system, and in-line capnography can be used to verify placement of the ETT.
5. If necessary, postoperative reintubation can be accomplished using the silk, which is left in place until the time of discharge from the recovery room.

The silk technique employs the principles and equipment of the classic technique, with the addition of a length of silk suture (3-0 nylon monofilament may also be used). Once the epidural catheter (which is used only to place the silk) is out of the oral or nasal cavity, the silk suture is tied to the cephalad end of the catheter (Fig. 20-36), and the silk is pulled antegrade through the CTM (Fig. 20-37). The epidural catheter is cut off and discarded (see Fig. 20-37), and the cephalad end of the silk is tied to the Murphy eye (Fig. 20-38). The silk suture is then used to pull the ETT gently into the trachea (Fig. 20-39). If a floppy epiglottis causes obstruction, one can deliberately intubate the esophagus; as the ETT is being gently withdrawn from the esophagus, tension applied simultaneously to the distal end of the silk pops the tip of the ETT anteriorly, lifts up the epiglottis, and allows the ETT to enter the larynx. When the ETT abuts against the CTM, the tension on the silk suture is released and the ETT is passed further to enter the trachea (Fig. 20-40). If a nasal intubation is required, a urologic

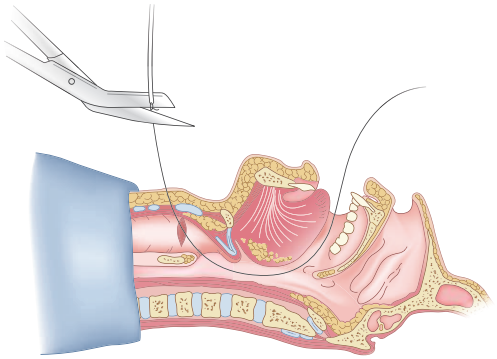

Figure 20-37 Silk pull-through technique. Pull the epidural catheter caudad until the silk suture exits the skin above the cricothyroid membrane; then cut off the epidural catheter. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

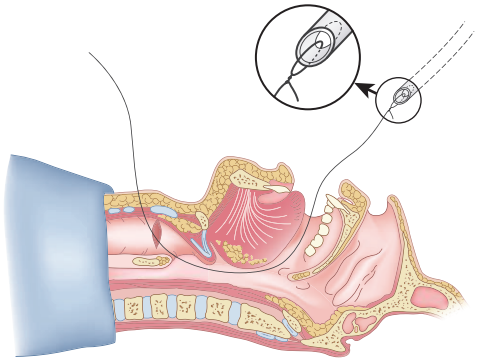

Figure 20-38 Silk pull-through technique. Tie the suture to the Murphy eye as shown *(inset).* Have an assistant pull the patient's tongue forward. Begin pulling the suture with one hand while the opposite hand holds the endotracheal tube (ETT) steady and in midline. At all times maintain tension on the suture while advancing the ETT. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

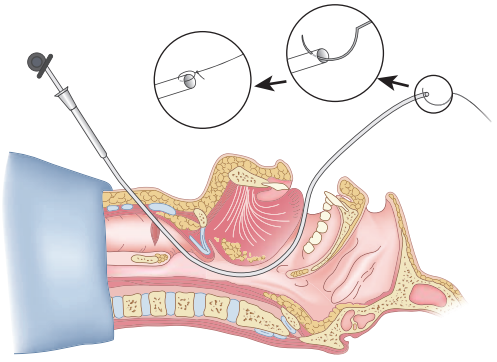

Figure 20-36 Silk pull-through technique. Proceed as in the classic technique. After the epidural catheter has exited the oral cavity, tie it to a 3-0 noncutting silk suture (30-inch length), as shown in the insets. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

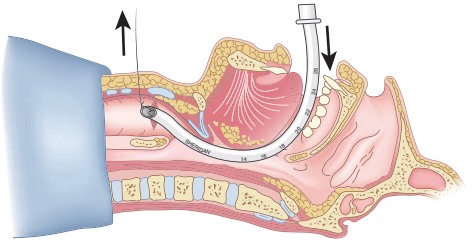

Figure 20-39 Silk pull-through technique. Simultaneously pull the silk caudad *(arrow at throat)* as you advance the endotracheal tube *(arrow at oral cavity)* with the opposite hand. Advance the endotracheal tube to the cricothyroid membrane. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

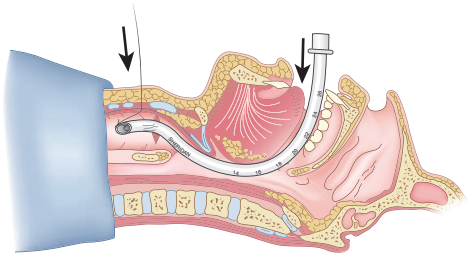

Figure 20-40 Silk pull-through technique. Release the suture, and with the opposite hand advance the endotracheal tube (ETT) to the desired depth. The suture partially retracts *(arrow at throat)* into the trachea as the ETT is advanced *(arrow at oral cavity)* past the cricothyroid membrane. The remaining suture is secured to the neck with transparent dressing. On extubation, the silk is left in place as a precaution, should reintubation be required. The suture is removed in the recovery room on the patient's discharge by cutting it flush with the skin and pulling it out of the oral cavity. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

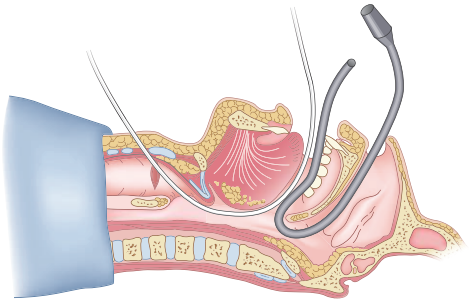

Figure 20-42 Silk pull-through technique. The tip of the urologic catheter is retrieved from the oral cavity. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

catheter can be used to cause the epidural catheter to exit the nasal rather than the oral cavity (Figs. 20-41 through 20-44).

In practice, it may be difficult to suture the silk onto the epidural catheter. A small learning curve is required not to allow any slack on the silk until the CTM is reached and to gauge properly the fine balance between pulling on the silk and simultaneously advancing the ETT. The technique is easy, and because the silk can be left in place with no discomfort for the duration of the anesthesia and after extubation, emergent reintubation can be accomplished. I have had two occasions to reintubate in the recovery room using this technique; both patients had suffered maxillofacial trauma, had initially been intubated awake using the retrograde silk technique, and had arch bars placed in the operating room.

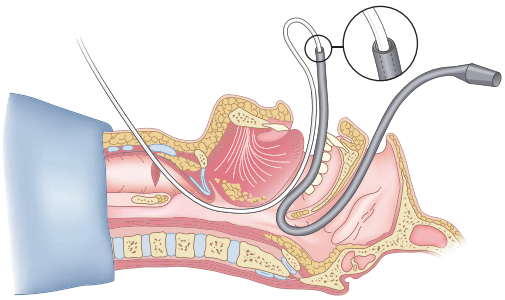

Figure 20-43 Silk pull-through technique. The epidural catheter is fed into the urologic catheter *(inset)* and may be tied together. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

VII. PEDIATRICS

In pediatric patients, the physician is faced with the formidable problems of small anatomic structures that are difficult to palpate, immature anatomic structures such as anterior larynx and narrow cricoid cartilage, congenital anomalies, and pathologic disorders that intimately affect

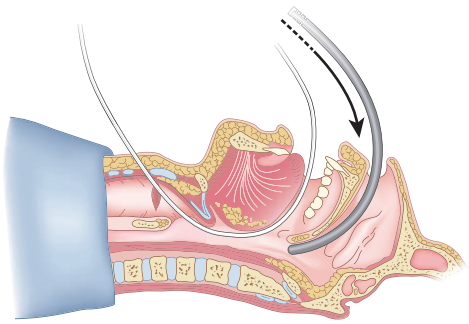

Figure 20-41 Silk pull-through technique. With the epidural catheter already in place, a 16-F red rubber urologic catheter is advanced through the nose *(arrow).* (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

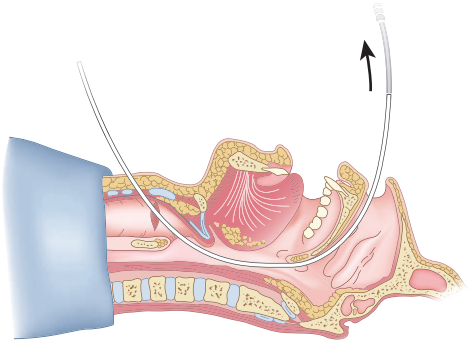

Figure 20-44 Silk pull-through technique. The urologic catheter is removed *(arrow)* so that the epidural catheter exits the nose. The epidural catheter can now be used as a nasotracheal guide. (From Sanchez AF: *The retrograde cookbook,* Irvine, 1993, University of California, Department of Anesthesia.)

the airway (e.g., acute epiglottitis). Because the pediatric airway is different, concerns have been raised about whether RI is indicated or contraindicated in infants.[69,70,74,99] Some have claimed that RI is dangerous but without citing any clinical supportive evidence.[99] The number of articles and case reports in the medical literature on the subject of RI in the pediatric population is limited.[2,10,11,16,20,34,38,40,69,70,73,74,81,99]

RI has been used with both anticipated and unanticipated pediatric DA, primarily after failure of conventional intubating techniques (blind nasal intubation, direct laryngoscopy, or FOI). The technique used is the same as in the adult, but a higher incidence of difficulties has been reported, including problems in cannulating the ETT and inability to pass the ETT through the glottic opening.[11,73,100]

In some cases, combined techniques have offered more success than blind RI. In one case report of a 16-year-old patient with acute epiglottitis, intubation was accomplished only by RI combined with rigid laryngoscopy; the retrograde catheter marked a path through an otherwise completely distorted anatomy.[38] The largest pediatric series with the highest success rate was reported by Audenaert and colleagues[73]; in that series, RI was performed for 20 pediatric patients, aged 1 day to 17 years, with DAs primarily resulting from congenital anomalies (Table 20-2). The authors' preferred approach, a combination of FOI with retrograde guidewire, offers the following advantages:

1. Higher success rate
2. Faster intubation
3. Ability to insufflate oxygen through the suction port of the FOB with the guidewire in place (Table 20-3)
4. No hanging up of the ETT in the glottis
5. No need to rely on anatomic landmarks to guide the FOB into the trachea
6. Less requirement for experience to manage the FOB

No major complications were reported, and the technique was considered a valuable addition to pediatric airway management.[73]

Przybylo and Stevenson described a unique method of managing the airway in a pediatric patient for closure of a tracheocutaneous fistula. The patient was a 4-year-old girl with severe micrognathia and limited temporomandibular joint motion and mouth opening who required a tracheostomy in the neonatal period for upper airway obstruction. Attempts at oral-nasal FOI were unsuccessful; the FOB was passed through the existing tracheocutaneous fistula in a cephalad direction, into the nasal cavity, and the FOB was then used as a stylet for nasal intubation.[101]

VIII. COMPLICATIONS AND CAUTIONS

Although it has been demonstrated that transtracheal needle puncture is safe and associated with only minor complications (Box 20-4), numerous potential complications of RI have been cited in the literature (Box 20-5). Documented complications of RI are relatively few, and most were self-limited (Box 20-6). The most common

AUR-8 urethroscope (Circon ACMI, Stamford, CN); *ID,* inner diameter of endotracheal tube; *LF-1* tracheal intubation fiberscope (Olympus, Center Valley, PA).

*Case numbers have been assigned for reference and convenience only. The tracheas of patients 11 and 14 were each intubated twice with retrograde-assisted fiberoptic technique.

†*Nonvisualization* refers to failure to expose the cords or arytenoid cartilages with direct laryngoscopy. On all occasions on which the AUR-8 scope was used, the 22-G catheter and 0.018-inch wire were also used. Likewise, when the LF-1 scope was used, the 20-G catheter and 0.025-inch wire were used.

‡This column reveals a few patients in whom this technique was used primarily, usually for cervical spine consideration *(C)* or when the airway was known to be extremely difficult by history or previous experience *(H)* or by preoperative assessment *(A)*. Direct laryngoscopy *(D),* fiberoptic laryngoscopy *(F),* light wand *(L),* and retrograde alone *(R)* techniques were attempted unsuccessfully where so noted.

§Use of a Bullard rigid fiberoptic laryngoscope afforded an excellent view of the vocal cords, but owing to limited mouth opening the endotracheal tube could not be properly positioned.

Modified from Audenaert SM, Montgomery CL, Stone B: Retrograde-assisted fiberoptic tracheal intubation in children with difficult airways. *Anesth Analg* 73:660, 1991.

TABLE 20-3
Flow Measurement of Various Fiberscopes*

Scope (Mfgr.)	Outer Scope Diam. (mm)	Inner Lumen Diam. (mm)	Working Length (cm)	Maximum Tip Flexion (degrees)	Scope Configuration	Max. O_2 Flow (L/min)
AUR-8 (Circon ACMI, Stamford, CN)	2.7	0.8	37	140	Straight	9.4 ± 0.1
					90-degree curve and 90-degree tip flexion	9.4 ± 0.0
					90-degree curve with 0.018-inch wire in place	4.37 ± 0.01
LF-1 (Olympus, Center Valley, PA)	3.8	1.2	60	120	Straight	18.1 ± 0.2
					90-degree curve and 90-degree tip flexion	17.9 ± 0.1
					90-degree curve with 0.025-inch wire in place	12.4 ± 0.1
BF-1 (Olympus, Center Valley, PA)	5.9	2.8	55	100	Straight	159 ± 5
					90-degree curve and 90-degree tip flexion	152 ± 1
					90-degree curve with 0.035-inch wire in place	145 ± 1

complications were bleeding and subcutaneous emphysema.[5,6,9,20,31,37,39,40,92]

A. Bleeding

Insignificant bleeding (4 to 5 drops of blood) has been observed with CTM puncture during RI.[40,92] Even a patient who had received heparin intraoperatively and had postoperative disseminated intravascular coagulation experienced only a small, self-limited hematoma after the procedure.[9] Controversy exists with respect to making the puncture below the cricoid cartilage because of a greater potential for bleeding.[2,39,79] Three studies involving 57 patients who underwent RI with punctures at the cricotracheal ligament or between the second and third tracheal rings showed no evidence of major bleeding.[6,20,39] There are, however, scattered reports of severe hemoptysis after transtracheal needle puncture with resultant hypoxia, cardiorespiratory arrest, dysrhythmias, and death.[41,44,102-104] Two patients had epistaxis after nasal intubation (no vasoconstricting agent was used).[25,40] The following measures have been suggested to decrease the potential for bleeding:

1. Avoid RI in patients with bleeding diathesis.
2. Apply pressure to the puncture site for 5 minutes.
3. Apply pressure dressing to the puncture site for 24 hours.
4. Maintain patient in the supine position for 3 to 4 hours after puncture.

B. Subcutaneous Emphysema

Subcutaneous emphysema localized to the area of a transtracheal needle puncture site is common but self-limited.[6,20,30,42,76,82,102-108] In severe cases, air may track through the fascial planes of the neck, leading to tracheal compression with airway compromise, pneumomediastinum, and pneumothorax.[29,30,29,30,42,44,77,106,108,109] Accumulation of air occurs gradually (1 to 6 hours) after a transtracheal puncture.[42,106] Severe subcutaneous emphysema has been attributed to use of a large-bore needle, multiple CTM punctures, and exposure of the puncture site to persistent elevated intratracheal pressure (coughing, grunting, or sneezing). In addition, pneumomediastinum has been reported in patients who underwent transtracheal puncture with a needle and was attributed to elevated endotracheal pressure (paroxysmal coughing and sneezing).[41-43] When the patient has been intubated by the retrograde technique, elevated peak inspiratory pressure (PIP) and elevated end-expiratory pressure (PEEP) should not increase the likelihood of these complications intraoperatively, because the puncture site is located above the ETT cuff, so that the area of the initial puncture site is not exposed to high pressure. Lee and coauthors reported on a patient with a history of noncardiogenic pulmonary edema and atelectasis who, after RI, received 7.5 cm H_2O with PEEP with no complications (PIP values were not reported).[65]

C. Other Complications

Other reported self-limited complications were breath holding and travel of the catheter (a straight, flexible guidewire) caudally.[20,40,84]

Complications that were not self-limited were as follows:

1. Trigeminal nerve trauma,[12] which the author suspected was due to multiple laryngoscopies
2. Guidewire fracture, in which wire had to be surgically removed[64]
3. Loss of hook (the type that was originally used by Waters and is no longer used)[2,40,100]

4. Pneumothorax, which necessitated use of a chest tube[42]
5. Pretracheal abscess in diabetic patients after multiple punctures at the CTM requiring incision and drainage[71]

IX. CONCLUSIONS

The anesthesia care provider is charged with the responsibility for securing the airway. In most cases, this can be accomplished with the use of conventional techniques, but in a small number of cases these techniques cannot be successfully applied to the clinical problem at hand. No method, including RI, offers 100% success; therefore, it is wise to have multiple available options and to be facile with alternative techniques for intubation.

RI has been a particularly useful alternative in difficult intubations after multiple manipulations that have caused bleeding, in facial injuries in which bleeding is already present, and in patients with limited neck movement and mouth opening. The technique is easy to learn, requires little equipment, and in practiced hands is a rapid, safe, and effective method for intubating the trachea.

International awareness (in multiple specialties) of the value of RI in selected clinical settings has increased.[110,111] In my opinion, RI is a valuable additional airway management technique and should be included as part of the armamentarium of health care providers involved in the care of seriously injured or ill patients.

X. CLINICAL PEARLS

- Have the equipment readily available!
- Know your anatomy and practice daily: During your daily patient airway evaluation, make sure to palpate and note the location of the arch of the cricoid cartilage on every patient (important for RI and for emergency cricothyrotomy).
- Positioning of the patient and, more importantly, positioning of the anesthesiologist should be practiced on the mannequin until it becomes second nature.
- The initial puncture site through the cricothyroid membrane (CTM) should be as close to the upper border of the arch of the cricoid cartilage as possible. This allows for a longer length of the ETT to be below the vocal cords before removal of the guidewire (preventing the ETT from buckling backward into the esophagus).
- Use an ETT with smaller inner diameter (6.5 to 7.0 mm ID) to prevent "railroading." I believe many of the failures are caused by the use of a large ETT that gets caught on the arytenoids (similar to the problem found during FOIs).
- Although it is more time consuming and more cumbersome to perform, the silk pull-through technique is my method of choice because it addresses most of the challenges encountered (railroading , potential need to perform multiple attempts, and ability to reintubate the patient postoperatively).

Acknowledgments

This writing is dedicated to my daughter, Danielle. Special thanks to Mrs. Debi Quilty, Mrs. Norma Claudio, and Elsie Vindiola for their research assistance and to Tay McClellan for her outstanding medical illustrations.

I. INTRODUCTION

The procedure of placing an endotracheal tube (ETT) in the trachea for ventilation and oxygenation is more than a thousand years old. It was first performed on pigs by the Persian physician, Avicenna, between 980 and 1037 AD.[1,2] Blind digital intubation in humans was first described in 1796 by Herholdt and Rafn in a resuscitation protocol for drowning victims.[3] In 1880, Macewen described blind digital intubation in awake patients using a curved metal tube.[4] However, modern methods of laryngoscopic endotracheal intubation did not emerge until early in the 20th century, after the introduction of a flexible metal tube by Kuhn[5] and of the laryngoscope by Jackson.[6]

Over the years, direct laryngoscopic intubation has been shown to be an effective, safe, and relatively easy technique. In fact, using a laryngoscope to obtain line of sight to the laryngeal inlet has become the standard method of endotracheal intubation in the operating room, the intensive care unit, and the emergency department. However, even in the hands of experienced laryngoscopists, accurate and prompt placement of the ETT remains a significant challenge in some patients. This is particularly true in "unprepared" patients and in patients requiring emergency intubation. With any standard laryngoscope, obtaining line of sight to the patient's larynx can prove difficult in the presence of specific anatomic variations such as a receding mandible, prominent upper incisors, a restricted mouth opening, or limited movement of the cervical spine. It has been estimated that 1% to 3% of surgical patients have a so-called difficult airway (DA), making laryngoscopic intubation problematic and sometimes impossible.[7] In the obstetric population, the incidence of failed laryngoscopic intubation has been reported to be 0.05% to 0.35%.[8] Many predictors of difficult laryngoscopy (DL) have been suggested in the literature,[9,10] but the sensitivity and specificity of these tests remain relatively low.[11-13] Therefore, all clinicians must be prepared to deal with the prospect of both anticipated and unanticipated DLs.

Given that direct laryngoscopic visualization of the glottis may not be possible, especially in a timely manner during emergency situations, a number of devices have been developed to enable the clinician to pass the ETT "blindly" into the trachea. During the last few decades, the use of intubating guides such as stylets and introducers and light-guided intubation based on the principle of transillumination have proved to be effective, safe, and

simple approaches. This chapter briefly reviews the principles and techniques of these alternative intubation procedures.

Many types of intubating guides and lighted stylets have been commercially available for many years. Where possible, this chapter focuses on devices that have been proven to be effective and safe in the medical literature. However, the concepts and techniques discussed here may be applicable to other similar devices.

II. INTUBATING INTRODUCERS AND STYLETS

A. History

Intubating guides or introducers were first reported in the late 1940s. In 1949, Macintosh described "the use of a gum elastic introducer as an aid to passing endotracheal tubes" (Fig. 21-1) as follows[14]:

> *This projects some 2-3 inches beyond the distal end of the tube, and since it is malleable the curve can be shaped to facilitate its introduction through the cords. Once the tip of the introducer lies within the trachea, the ETT slides over it, easily, into position. This device has proved of real worth on rare occasions, when, for one reason or another, it has not been possible to obtain a view of the vocal cords. Provided the epiglottis can be seen, it has been possible to direct the curved introducer posterior to it, and then through the underlying glottis. The ETT now follows into position.*

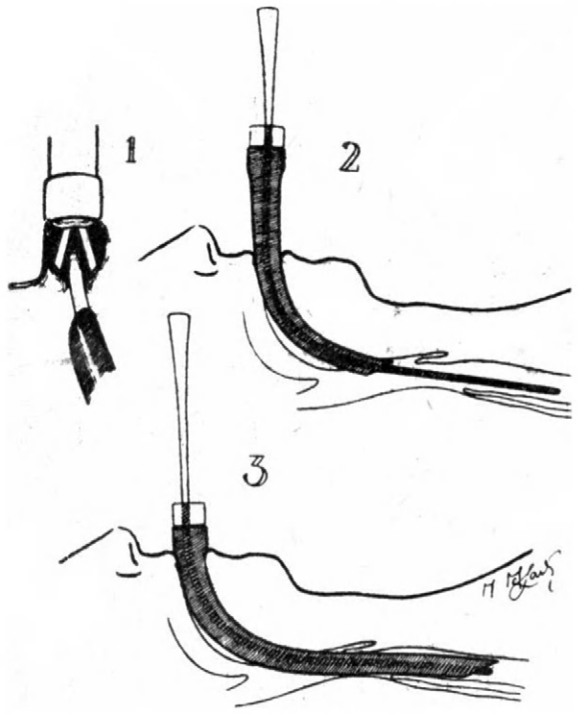

Figure 21-1 Images from Macintosh's 1949 paper demonstrating use of a "long gum-elastic catheter" as "a guide to aid intubation." (From Macintosh RR: An aid to oral intubation. *Br Med J* 1:28, 1949.)

B. The Eschmann Introducer

Use of an introducer in this fashion did not become widespread until the development of the Eschmann Introducer (EI) by Venn in 1973. Venn's design has several key features. First, it is relatively long at 60 cm (Fig. 21-2), allowing one to place the introducer between the cords before "railroading" the ETT over its distal end. It has been suggested that a naked introducer affords better dexterity and tactile sensation to the user compared with an introducer on which an ETT has been preloaded.[15] Second, the EI has a coudé tip (a 40-degree bend) for "hooking" under the epiglottis. The material from which the EI is made—a combination of a polyester core and resin covering—no doubt has contributed to its success.[15] The EI is malleable, firm enough to direct, yet flexible enough to yield on contact. Furthermore, it is a multiuse device that can be sterilized between uses. The EI is commonly referred to as a "gum elastic bougie" despite not being made of gum, having no elastic properties, and not being a "bougie" at all (a bougie being a dilating device).[16,17] The EI is currently sold under the name "Portex Venn Introducer" (Smiths Medical, UK.)

Although an EI can be used to direct the ETT toward an "anterior" or narrow larynx, its real strength lies as a tool to facilitate intubation when the laryngeal aperture cannot be seen during laryngoscopy (e.g., Cormack-Lehane grade 3 view).[18] If the epiglottis cannot be visualized at all (i.e., Cormack-Lehane grade 4 view), we do not recommend use of the EI, because the likelihood of successful intubation with the EI is unacceptably low. In cases in which the epiglottis can be seen, the coudé tip can be hooked under the epiglottis and the EI advanced blindly through the glottis. The success of this maneuver is improved if the EI has been preshaped into a curve.[19] As the introducer is advanced further, the tracheal "clicks" are felt approximately 90% of the time if the EI is correctly placed,[20] whereas no "clicks" will be observed if the EI has been advanced into the esophagus. We

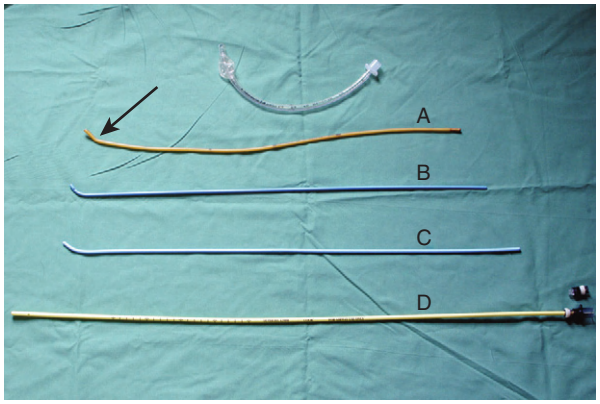

Figure 21-2 Tracheal introducers. *A,* The Eschmann Introducer, or EI, commonly known as the "gum elastic bougie," with a J (coudé) tip (*arrow*), (currently sold as "Portex Venn Introducer," Smiths Medical, UK). *B,* The hollow Frova Intubation Introducer. The optional rigid internal cannula has been removed, and one of the two ventilation ports can be seen near its tip (Cook Inc., Bloomington, IN). *C,* The single-use Endotracheal Tube Introducer (Sun Med, Largo, FL). *D,* The Cook Airway Exchange Catheter (Cook Inc., Bloomington, IN).

believe that "clicks" are more likely to be perceived if, once the tip of the EI is through the cords, the introducer is advanced at a shallow angle relative to the patient. This maneuver is intended to ensure that the tip of the introducer will contact the cartilaginous rings on the anterior tracheal wall as it advances, producing the "clicking" sensation. One can imagine that "clicks" are less likely to be felt if the only contact between the trachea and the EI is the coudé bend in the introducer that is sliding along the posterior tracheal wall, or even along the trachealis muscle.

Additional clues to confirm correct tracheal placement include the perception that the EI slightly deviates to the right as it advances into the right main bronchus and a "hold up" felt at the 30- to 35-cm mark as the EI becomes lodged in a distal airway (reportedly a 100% reliable sign).[20] In contrast, if the EI is placed in the esophagus, the entire EI could be advanced without encountering any resistance, although theoretically it would be possible for a pharyngeal pouch to hold up the introducer if one were present.[21] Some authors have cautioned against the use of the hold-up sign, believing that it increases the risk of airway trauma. If clicks are felt, then the hold-up test is not required.[20]

After tracheal placement, the ETT is advanced distally over the EI into the trachea. A jaw lift-jaw thrust by the nondominant hand of the clinician or by a laryngoscope will facilitate the advancement of the ETT over the EI by elevating the tongue and epiglottis. If difficulty persists while the ETT is being advanced, rotating the ETT 90 degrees counterclockwise will turn its bevel posteriorly and minimize the risk of catching on the structures of the glottic opening.[22] After intubation, the position of the ETT is confirmed by conventional methods such as measurement of the end-tidal carbon dioxide concentration (Et_{CO_2}) and auscultation.

The EI is long enough to be useful for nasal intubations and can also be used to place supralaryngeal airways (SLAs) or double-lumen tubes.[23] The long length of the EI enables it to be used as an airway exchange device; it can be placed down the lumen of a correctly placed ETT or SLA, which can then be removed over the introducer and discarded before a new airway is "railroaded" in its place. During the whole maneuver, the EI remains within the trachea, thereby guiding correct placement of the new airway. After the EI is removed, as always, the position of the new airway should be confirmed with the use of standard methods.

C. Other Types of Intubating Guides

Many intubating guides of different sizes, shapes, lengths, and materials have been developed. All of the designs serve a function similar to that of the EI, but many have some additional features. Some are single-use devices that were designed after concern was raised regarding the possibility of prion transfer between patients with multiuse airway equipment. However, there is growing skepticism about whether disease transfer from reused but sterilized medical instruments poses any tangible risk to patients, whereas the risk to patients from the use of suboptimal airway equipment with limited clinical evaluation is very real. Clinicians should be wary of new equipment and always insist on using only instruments that have proved to be effective and safe.[24]

1. Frova Intubation Introducer

The Frova Intubation Introducer (Cook Inc., Bloomington, IN) is a single-use introducer, firmer than the EI, that has a 35-degree coudé tip, two side ports, and a hollow lumen (see Fig. 21-2). It comes with a Rapi-Fit connector that connects directly to standard ventilatory equipment, such as the bag of an air-mask-bag unit (AMBU) or an anesthetic circuit, enabling the Frova to also serve as a conduit for O_2 delivery or ventilation. This requires extreme caution however, because high-pressure source ventilation via the narrow lumen may result in severe barotrauma. The Frova may be connected to an esophageal detection device so that one can confirm correct placement before "railroading" the ETT.[25] The rigid, removable internal cannula is designed to increase the stiffness of the Frova; it has limited clinical indication and may increase the risk of trauma. The Frova introducer has two sizes: a 65-cm-long blue adult version for ETTs with greater than 5.5 mm inner diameter (ID) and a 33-cm-long yellow pediatric version for ETTs with 3.0 to 5.0 mm ID. First-pass success rates with the Frova introducer are similar to those with the EI and are substantially better than those of the similarly shaped Portex introducer.[26] It is presumed that this success is due to the increased malleability of the EI and the Frova, which enables preshaping of the device, compared with the Portex introducer.[26]

2. Endotracheal Tube Introducer

The Endotracheal Tube Introducer (Sun Med, Largo, FL) is an example of a single-use version of the EI (see Fig. 21-2). It is similar to the EI in size and shape but 10 cm longer (i.e., 70 cm long). Like the Frova, it is stiffer than the EI. There are 10-cm markings on the top of the Sun Med introducer to indicate the depth of insertion. Although it is marketed as a single-use, disposable device, resterilization is possible.

3. Parker Flex-It Directional Stylet

The Schroeder Oral/Nasal Directional Stylet, also known as the Parker Flex-It Directional Stylet (Parker Medical, Englewood, CO), is a disposable articulating stylet that requires no bending before intubation. Inserting the stylet into an ETT allows the clinician to elevate the tip of the ETT by wrapping all four fingers around the proximal ETT and using the base of thumb to depress the proximal end of the stylet (Fig. 21-3). Although the stylet is suitable for both oral and nasal intubation, it has been reported to be somewhat awkward to use, and the curvature created is not at the tip but rather over the distal half of the tube.[27] However, it has been reported to be effective for difficult intubations (DIs) as well as for blind intubations.[28]

The effectiveness of intubating guides in patients with a DA has been well established.[29-31] Most of these studies used the EI. With only a few exceptions, there are currently few data to support the use of the newer introducers for endotracheal intubation, particularly in patients with a history of DA. It should be emphasized that most of these new intubating guides and stylets are disposable

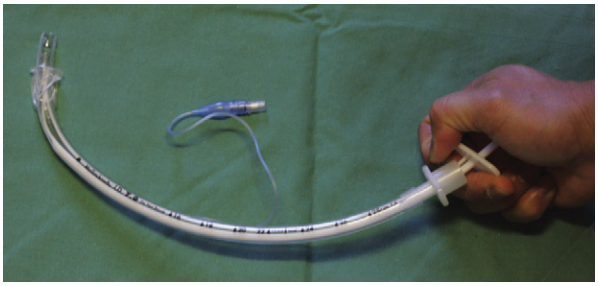

Figure 21-3 The Schroeder Directional Stylet can be used to elevate the tip of the endotracheal tube (ETT) by wrapping all four fingers around the proximal ETT and using the base of thumb to depress the proximal end of the stylet.

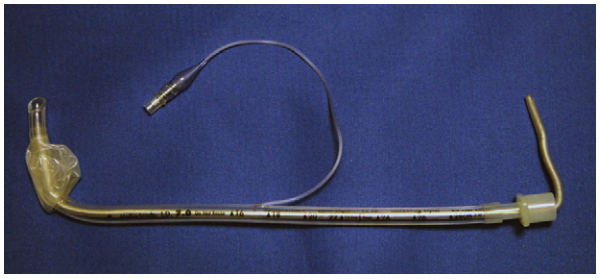

Figure 21-4 An endotracheal tube (ETT). The stylet remains "straight to cuff," at which point the ETT can be bent to the desired angle, resembling a hockey stick.

and designed for single-use. In contrast, the EI is more cost-effective because it is reusable.

D. Tube Exchangers

Although the EI can be used as a tube exchanger, several devices have been created especially for this purpose.

1. Cook Airway Exchange Catheter

The Cook Airway Exchange Catheter (CAEC; Cook Critical Care, division of Cook Inc.) is a hollow, flexible, straight tube that is designed as a tube exchanger for patients with a DA. The CAEC can be used to ventilate patients under difficult circumstances through the inner lumen and the distal ports after fitting the provided adaptor at the proximal end (see Fig. 21-2).

2. Sheriden Tube Exchanger

The Sheriden Tube Exchanger (Sheriden Catheter Corp., Oregon, NY) serves a similar function as the CAEC.

E. Stylets

A stylet is a plastic-coated metal rod that can be placed inside the lumen of an ETT before intubation to stiffen or preshape the ETT. Unlike the EI and other introducers, the stylet should not protrude past the tip of the ETT, so as to avoid unnecessary trauma. Water-based lubricant should be used, and easy passage of the stylet in and out of the ETT should be demonstrated before use. The "best" shape for a stylet-shaped ETT depends on the clinician's preference and the patient's position and anatomy. However, Levitan and colleagues showed that the line of sight to the larynx can be improved if the stylet remains "straight to cuff,"[32] at which point the ETT can then be bent to the desired angle (i.e., shaped like a hockey stick) (Fig. 21-4). An angle of 35 degrees or less reduces the risk of traumatic injury.[32] Once the ETT has passed through the vocal cords, the stylet should be withdrawn as the ETT is advanced into the trachea.

In a randomized trial, Gataure and associates compared the efficacy of the EI with that of the malleable stylet in 100 patients with simulated DL (Cormack-Lehane grade 3 view) under general anesthesia. The EI group had a success rate of 96% after two attempts, compared with 66% in the stylet group.[33]

F. Complications

Despite long-standing and widespread use, complications caused by ETT introducers, tube exchangers, and stylets are rare. To date, there have been only half a dozen case reports of pharyngeal, laryngeal, or tracheal perforation during airway manipulation that may have been caused by introducers or stylets.[34,35] Reports of trauma during airway management frequently come from cases in which multiple attempts at securing the airway occurred and multiple devices were used, making it difficult to attribute damage to a single device. Because of their firmer material, single-use ETT introducers exert more pressure at the tip compared with the multiuse EI.[26] Whether this corresponds to greater risk of airway trauma remains unknown.[25] However, as with all airway devices, undue force should always be avoided. Holding an ETT introducer close to the coudé tip (i.e., with Magill's forceps) increases the pressure exerted at the tip and therefore is not recommended.

After endotracheal intubation, all introducers and stylets should be inspected to ensure that no part of the device has been left behind. One report described a case in which the tip of an EI became detached and lodged in a patient's airway,[36] and in a similar case, plastic coating peeled off a stylet, blocking the ETT.[37] An unusual case report described the involution of an ETT at its tip while the EI was being withdrawn, which caused the EI to lodge firmly within the ETT and necessitated removal of both instruments.[38] Routine generous lubrication of intubating guides should reduce the likelihood of such events.

G. Clinical Utility

Intubating introducers, stylets, and tube exchangers have been used successfully to facilitate endotracheal intubation for many decades. In particular, the EI is a cheap, reliable, and familiar tool in the hands of anesthesia practitioners and, more recently, those of emergency physicians and in the prehospital setting.[39-42] Although the popularity of these nonvisual intubating techniques may decrease because of the improved glottic view afforded by the new video laryngoscopes, studies report the efficacy and usefulness of stylets and introducers to assist videoscopic intubation,[43-48] suggesting that these instruments will remain a mainstay of intubating adjuncts.

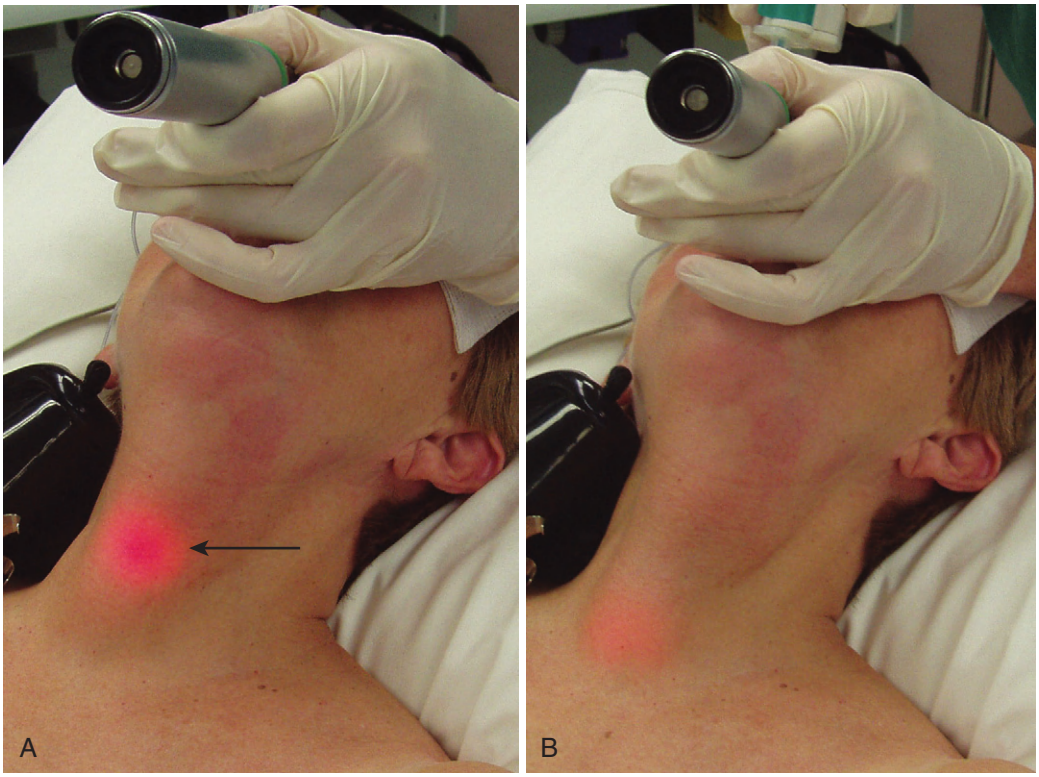

Figure 21-5 **A,** When the tip of the endotracheal tube (ETT) with the lighted stylet is placed at the glottic opening under direct laryngoscopy, a well-defined, circumscribed glow (*arrow*) in the anterior neck just below the thyroid prominence can be readily seen. **B,** If the tip of the ETT is in the esophagus, the transmitted glow is diffuse and cannot be readily detected under ambient lighting conditions.

III. LIGHTED STYLETS

A. History

Macintosh and Richards are frequently credited with being the first to use a lighted stylet for orotracheal intubation. In 1957, they reported the use of a lighted introducer to assist the placement of an ETT in the trachea under direct vision using a laryngoscope.[49] However, they did not describe the technique whereby transillumination of the soft tissues of the neck is used to guide the placement of the ETT. This transillumination technique was likely first described by Yamamura and colleagues, who reported the use of a lighted stylet for nasotracheal intubation in 1959.[50]

Modern lighted stylets use the principle of transillumination of the soft tissues of the anterior neck to guide the tip of the ETT into the trachea. This method takes advantage of the anterior (superficial) location of the trachea relative to the esophagus. When the tip of the ETT with the lighted stylet enters the glottic opening, a well-defined, circumscribed glow can be readily seen slightly below the thyroid prominence (Fig. 21-5A). However, if the tip of the ETT is in the esophagus, the transmitted glow is diffuse and cannot be readily detected under ambient lighting conditions (see Fig. 21-5B). If the tip of the ETT is placed in the vallecula, the light glow is diffuse and appears slightly above the thyroid prominence. Using these landmarks and principles, the clinician can guide the tip of the ETT easily and safely into the trachea without the use of a laryngoscope.

Despite its potential clinical advantages, intubation using a lighted stylet (lightwand) did not receive widespread popularity until a commercial intubating device became available. During the past 30 years, several versions of a lighted stylet have been introduced, including the Fiberoptic Lighted-Intubation Stilette (Benson Medical Industries Inc., Markham, Ont., Canada), the Flexilum (Concept Corporation, Clearwater, FL), the Tubestat (Concept Corporation), and the Fiberoptic Lighted Stylet (Fiberoptic Medical Products, Inc., Allentown, PA) (Fig. 21-6). Over the years, these devices have proved to be effective and safe in placing the ETT both orally and nasally.[51-53] Despite favorable results and growing experience with the technique of light-guided intubation,[51-54] early commercial lighted stylets had some limitations. These included: (1) poor light intensity; (2)

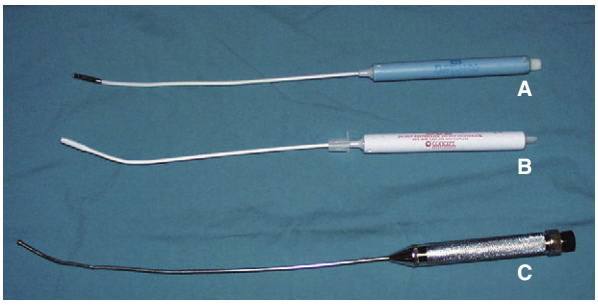

Figure 21-6 Some commercially available lighted stylets. *A,* Flexilum. *B,* Tubestat. *C,* Fiberoptic Lighted-Intubation Stillete.

short length, which limited the use of the lighted stylet device to short or cut ETTs; (3) absence of a connector to secure the ETT to the lighted-stylet device; (4) rigidity of the lighted stylet, which hampered use of the devices for other intubating techniques, including light-guided nasal intubation; and (5) single-use design in most lighted stylets, which increased the cost of intubation.

To address the shortcomings of these existing devices, the Trachlight (Laerdal Medical Corp., Wappingers Falls, NY) was introduced in 1995. The Trachlight was longer than its predecessors and incorporated an improved light source and a more flexible wand portion of the device. These features added flexibility, broadened the utility of the device for both oral and nasal intubation, made intubation easier, and permitted evaluation of the position of the tip of the ETT after intubation. To date, the Trachlight has been the most popular and best studied of the lighted stylets. Although the Trachlight is no longer manufactured, a new, similar version of this lighted stylet is being developed. We have had considerable experience with the Trachlight, and one of us (OH) was a key player in its design and development. Much of what follows reflects this experience and partiality toward the Trachlight. Nevertheless, the concept and principles of intubation using transillumination are applicable to all other lighted stylets.

B. Trachlight

The Trachlight consists of three parts: a reusable handle, a flexible wand, and a retractable metal wire stylet (Fig. 21-7). The power control circuitry and 3 AAA batteries are encased within the handle. The stylet or "wand" consists of a durable, flexible plastic shaft with a bright light bulb affixed at the distal end. Enclosed within the wand is a stiff but malleable, retractable wire stylet. This stylet may well be the most important feature of this device, because it significantly improves its ease of use.

A major feature of the Trachlight is its improved light source, which in most cases permits intubation under ambient lighting conditions. After 30 seconds of illumination, the light bulb blinks to minimize heat production and provide a convenient reminder of elapsed time. Because the tip of the stylet is encased within the ETT, and because of the efficient heat-exchange capacity of the upper airway mucosa, it is extremely unlikely that heat from the bulb would cause any thermal injury during intubation. An animal study confirmed that there were no histopathologic changes after use of the Trachlight.[55]

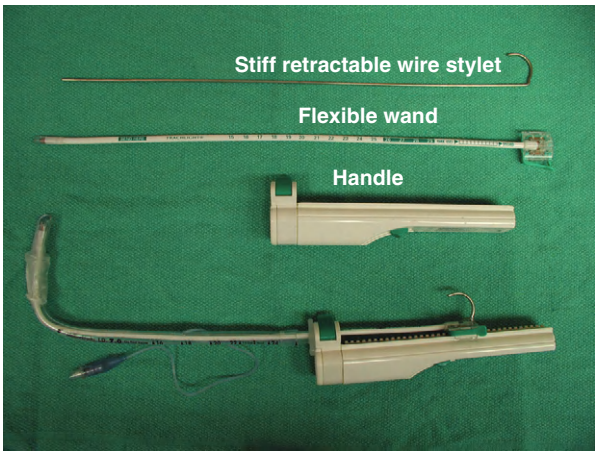

Figure 21-7 The Trachlight consists of three parts: a handle, a flexible wand, and a stiff retractable wire stylet. With the Trachlight placed inside the endotracheal tube (ETT), the ETT-TL unit is bent at a 90-degree angle just proximal to the cuff of the tube in the shape of a field-hockey stick.

The flexible wand can be adjusted to any length deemed clinically appropriate by means of a plastic connector that slides along the Trachlight handle. The same connector is used to attach or completely detach the wand from the handle. An optional retractable wire stylet within the wand adds stiffness and malleability. Once the handle, wand, and wire stylet are connected as a unit, the lubricated wand is placed inside an ETT, and the ETT is firmly secured to the Trachlight by means of a clamp on the Trachlight handle. To avoid unnecessary trauma, the wand should not protrude beyond the tip of the ETT. Final adjustments to wand length can be made by using the handle's sliding plastic connector.

For standard orotracheal intubation, the retractable wire stylet is best used to shape the ETT into the form of a field-hockey stick (see Fig. 21-7). This configuration directs the bright light of the bulb against the anterior wall of the larynx and trachea. In addition, the hockey-stick configuration enhances maneuverability during intubation and facilitates placement of the ETT through the glottic opening. However, this is an awkwardly shaped object to advance into the trachea. Therefore, once the tip of the ETT-Trachlight (ETT-TL) unit has passed through the glottic opening, the wire stylet should be retracted by approximately 10 cm. This makes the distal end of the ETT-TL unit pliable and enables advancement into the trachea safely and without difficulty.

The glow emitted from the Trachlight can be seen to migrate down the patient's neck and may be used to confirm correct placement of the ETT. When the glow reaches the sternal notch, the tip of the ETT is located about halfway between the vocal cords and the carina.[56] The clamp securing the ETT to the Trachlight is released, and the Trachlight is removed, leaving the ETT in place.

C. Lighted-Stylet Intubation: Detailed Technique

1. Preparation

The importance of preparation, a frequently overlooked or rushed step, cannot be overstated. Proper preparation will make the use of lighted stylets much easier and increase the likelihood of successful intubation.

The Trachlight wand has an internal wire stylet that is best lubricated using silicone fluid (Endoscopic Instrument Lubricant AE-1, ACMI, Southborough, MA). This ensures its easy retraction during intubation. With the internal wire stylet in place, the clinician attaches the wand to the handle. As with any standard stylet, the outside of the flexible wand should be well lubricated

with a water-soluble lubricant to facilitate ready removal after tracheal placement of the ETT. Once the wand is inserted into the ETT, a clamp firmly attaches the ETT to the Trachlight handle. The length of the wand can be easily adjusted by sliding the wand along the handle, and the light bulb is placed close to, but not protruding beyond, the tip of the ETT.

With the Trachlight in place, the ETT-Trachlight (ETT-TL) unit is bent at a 90-degree angle just proximal to the cuff of the tube, similar to a field-hockey stick. The degree of bend should be individualized to the patient, but the 90-degree bend usually makes the intubation considerably easier and is our preference for most orotracheal intubations. When the tip of the ETT is in the glottic opening, the 90-degree bend projects the maximum light intensity toward the surface of the skin, producing a well-defined, circumscribed exterior glow through the soft tissues of the neck. In contrast, if the Trachlight is bent to 45 degrees, the maximum light intensity will be directed down the trachea, and the glow will not be so readily seen. For obese patients and patients with short necks, a more acute bend (>90 degrees) provides better transillumination. The exact point at which to make the bend in the Trachlight has been debated, although it is our experience that 6.5 to 8.5 cm is suitable for most patients. A study by Chen and colleagues suggested that the bent length of the Trachlight should be adjusted according to the patient's thyroid prominence-to-mandibular angle distance (TMD) after demonstrating that a shorter bent length (6.5 cm) was more suitable for patients with a shorter TMD (<5.5 cm).[57] It stands to reason that the shape of the Trachlight should be individualized to the patient's anatomy.

Finally, the tip of the ETT should be coated with a water-soluble lubricant to facilitate its passage into the trachea.

2. Positioning

In the hospital setting, the clinician usually stands at the head of the table or bed. It is also possible to use the Trachlight from the front or side of the patient, making it a useful tool in the prehospital environment. Depending on the clinician's height, it may be advisable to lower the table or to use a footstool to allow maximal visualization of the anterior neck of the patient during intubation. In contrast to the technique for laryngoscopic intubation, the patient's head and neck should be in a neutral or relatively extended position, not in the "sniffing" position. The epiglottis is in close contact with the posterior pharyngeal wall when the head is in the sniffing position, making it more difficult for the Trachlight to pass posterior to the epiglottis. In contrast, the epiglottis is lifted off the posterior pharyngeal wall when the head is extended, facilitating entrance of the ETT into the glottic opening.

3. Control of Ambient Light

Compared with its predecessors, the light emitted by the Trachlight is extremely bright, with a directed beam that enhances soft tissue transillumination of the neck. In most cases, endotracheal intubation can be performed easily under ambient lighting conditions. In a large clinical study, endotracheal intubation using the Trachlight was successfully performed under ambient light in 85% of the cases.[58] In very thin patients and in children, it is possible to mistakenly interpret an esophageal intubation as an intratracheal placement, although the glow generated from inside the esophagus is more diffuse in character. Dimming of the room lights should be done only when absolutely necessary, such as in the case of an obese patient or a patient with a thick neck. In the emergency department or prehospital setting where control of the ambient lighting is not possible, it may be helpful to shade the neck with a towel or hand.

4. Technique of Intubation

a. OROTRACHEAL INTUBATION

As with other intubation techniques, proper denitrogenation should precede airway manipulation. Full muscle relaxation is recommended, if clinically appropriate. In a study of 176 patients, Masso and colleagues showed that muscle relaxation is associated with a lower failure rate, decreased intubation time, and fewer attempts when performing lighted-stylet orotracheal intubation.[59] When the patient is under anesthesia and lying supine, the tongue falls posteriorly, pushing the epiglottis against the posterior pharyngeal wall (Fig. 21-8). In order to have a clear passage to the glottic opening during intubation, it is necessary for the clinician to grasp the jaw or mandible and lift it upward using the thumb and index finger of the nondominant hand (Fig. 21-9). This lifts the tongue and epiglottis away from the posterior pharyngeal wall to facilitate placement of the tip of the ETT posterior to the epiglottis and into the glottic opening. The nondominant hand must be kept close to the corner of the mouth to ensure an unobstructed path in the midline for the lighted stylet.

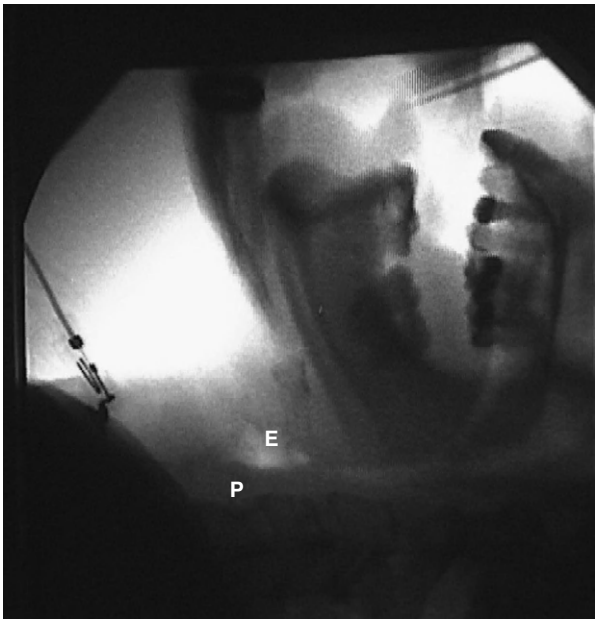

Figure 21-8 Lateral radiographic view of the upper airway of an anesthetized patient shows that the tongue falls posteriorly, pushing the epiglottis *(E)* against the posterior pharyngeal wall *(P)*.

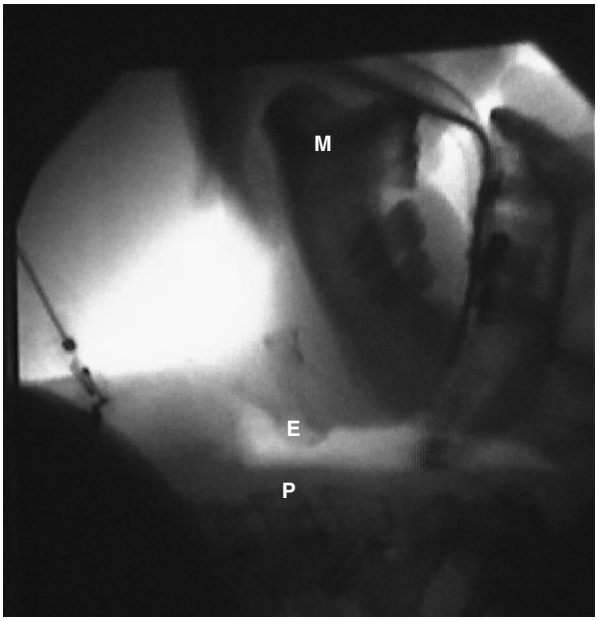

Figure 21-9 Lateral radiographic view of the upper airway of an anesthetized patient shows that a jaw lift, or mandible *(M)* lift, can elevate the tongue and the epiglottis *(E)* off the posterior pharyngeal wall *(P)*, providing an open passage for the endotracheal tube-Trachlight (ETT-TL) unit to enter the glottic opening.

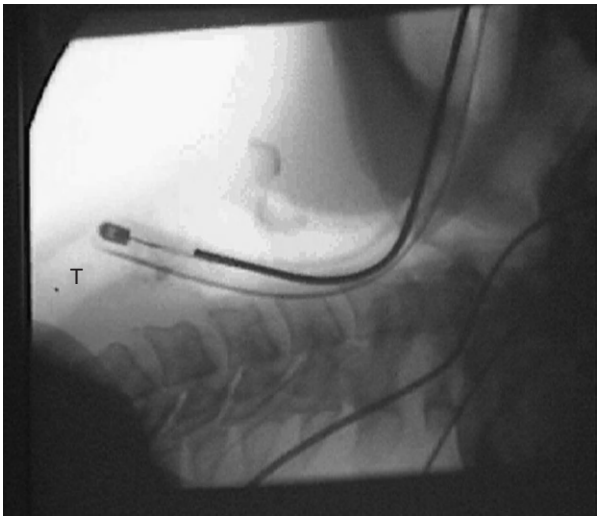

Figure 21-10 Lateral radiographic view of the upper airway of an anesthetized patient shows that when the tip of the endotracheal tube-Trachlight (ETT-TL) unit is placed at the glottic opening, the ETT cannot be advanced readily into the trachea *(T)* because of the preshaped hockey-stick configuration of the Trachlight.

With the Trachlight switched on, the ETT-TL unit is grasped by the dominant hand and inserted into the midline of the oropharynx. The midline position of the ETT-TL is maintained while the device is advanced gently along an imaginary arc in the sagittal plane, thereby moving the light source closer to the larynx. Commonly seen, but ill-advised, is the practice of enthusiastically placing the ETT-TL within the oropharynx while looking for a glow in the anterior neck. Such gross unsupervised movement of the ETT-TL increases the risk of pharyngeal trauma. Instead, under visual guidance, the ETT-TL should be able to be placed and angled so that the tip is very close to the larynx before transillumination of the neck tissues is sought. The ETT-TL should always be manipulated gently.

Once satisfied that the tip of the ETT-TL is close to the larynx, the clinician looks to see a glow in the anterior neck. The dominant hand can then be used to slowly rotate the Trachlight slightly to the right or left. These movements are exaggerated at the tip of the ETT-TL. By watching the transillumination in the patient's neck moving from side to side, the degree of rotation required to ensure that the tip of the Trachlight is exactly midline can be established. Once it is in the midline, a faint glow seen above the laryngeal prominence indicates that the tip of the ETT-TL is located in the vallecula. A jaw lift or a retraction of the tongue[60] helps to elevate the epiglottis and enhance passage of the ETT-TL under the epiglottis, and "rocking" the handle backward advances the tip of the lighted stylet toward the vocal cords. When the tip of the ETT-TL enters the glottic opening, a well-defined, circumscribed glow can be seen in the anterior neck slightly below the laryngeal prominence (see Fig. 21-5A). However, the ETT-TL cannot be readily advanced into the trachea because of the preshaped hockey stick configuration of the Trachlight (Fig. 21-10).

Retraction of the stiff internal wire stylet approximately 10 cm makes the distal portion of the ETT-TL unit more pliable, allowing advancement into the trachea with reduced risk of trauma (Fig. 21-11). Advancement of the pliable ETT-TL unit into the trachea before removal of the Trachlight improves the success rate of intubation. This is analogous to the successful placement of an intravenous cannula by advancing the angiocath together with the needle a few millimeters into the vein after the needle tip has entered the vein. This ensures that the catheter is inside the vein before the needle is removed from the angiocath. The glow from the ETT-TL can be seen migrating down the neck. When the glow

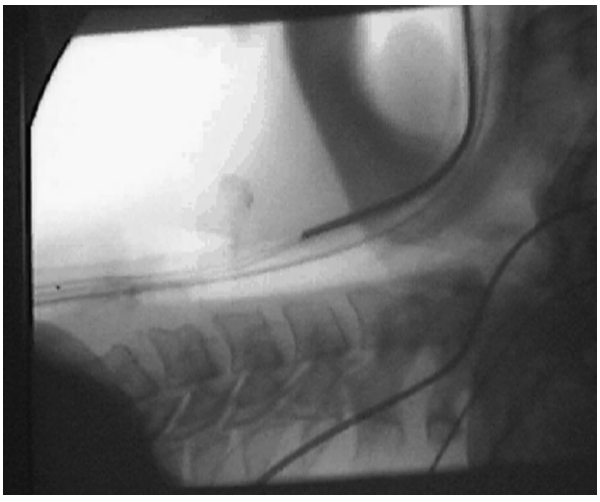

Figure 21-11 Lateral radiographic view of the upper airway of an anesthetized patient shows that with the stiff internal wire stylet *(S)* retracted approximately 10 cm, the distal endotracheal tube-Trachlight (ETT-TL) unit becomes more pliable, allowing easy advancement of the ETT into the trachea.

Figure 21-12 After retraction of the stiff internal wire stylet, the endotracheal tube-Trachlight (ETT-TL) unit becomes pliable, permitting the ETT to be advanced further into the trachea. The ETT is advanced until the glow is at the sternal notch.

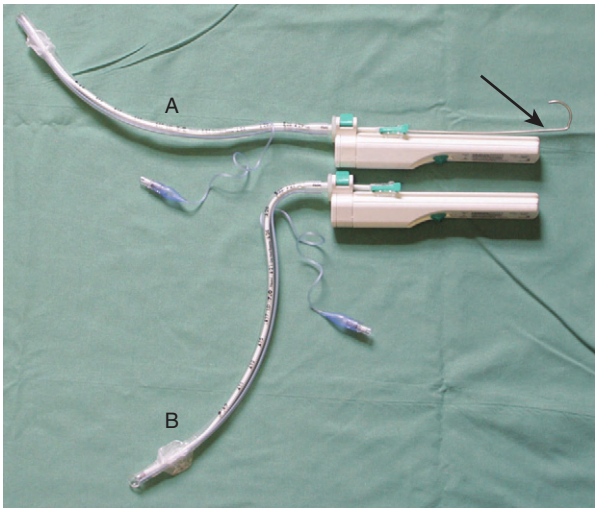

Figure 21-13 If a nasal RAE endotracheal tube (ETT) is used, the stiff internal wire stylet *(arrow)* of the Trachlight can be retracted halfway (approximately 15 cm) to allow unbending of the proximal curvature of the nasal RAE ETT *(A)* or its complete removal *(B)*.

begins to disappear at the sternal notch (Fig. 21-12), the tip of the ETT is approximately 5 cm above the carina in the average adult.[61]

After release of the locking clamp, the Trachlight can be removed from the ETT. The ETT cuff is inflated, and correct ETT placement is confirmed by standard means, such as chest auscultation and capnography. Although structural damage to the Trachlight during intubation would be an unlikely event, it is good practice to examine the Trachlight for structural integrity after intubation lest a foreign body be inadvertently left in the airway.

Occasionally, the circumscribed glow cannot be readily seen in the anterior neck due to anatomic features such as morbid obesity or a short neck. Neck extension, as described earlier, may be helpful. Placement of a support under the shoulders may further assist neck extension.[62] Retraction of the breast or chest wall tissues caudally together with indentation of the tissues around the trachea by an assistant enhances transillumination of the soft tissues in the anterior neck. Dimming of the ambient light is required only in some occasions.

After retraction of the internal wire stylet, the tip of the tube and lighted stylet can sometimes be difficult to advance. This may occur because the tip of the ETT-TL is caught at the vestibular folds of the cords, or the tip may abut the anterior wall of the larynx or trachea. Such a hold-up can usually be overcome by rotating the ETT-TL sideways 90 degrees or more to the right or left side of the head. The tip of the ETT will then be pointing to the side or downward, disengaging the hold-up and allowing ready entrance of the ETT into the trachea. Alternatively, the clinician may grasp the anterior larynx with the nondominant hand with an upward lift to help the tip of the ETT come off the vestibular folds or tracheal ring.

b. NASOTRACHEAL INTUBATION

Light-guided nasotracheal intubation using the Trachlight is particularly useful when guided or "blind" nasal intubation is indicated, such as in emergency situations in patients with a limited mouth opening and cervical spine instability. Although similar to Trachlight oral intubation, Trachlight nasal intubation differs in a few important ways.

Complete removal of the internal stiff wire stylet from Trachlight makes the ETT-TL unit pliable enough for atraumatic nasotracheal intubation. If a nasal Ring-Adair-Elwyn (RAE) ETT is used, the internal stiff wire stylet of the Trachlight can be retracted halfway (about 15 cm). This "unbends" the proximal curvature of the nasal RAE ETT (Fig. 21-13), making lighted-stylet nasal intubation with a RAE ETT easier.

Application of a vasoconstrictor nasal spray to the nasal mucosa before intubation may minimize bleeding. If time permits, the ETT-TL should be immersed in warm sterile water or saline to soften the ETT and further reduce the risk of mucosal damage during nasal intubation. Water-soluble lubricant is applied to the nostril to facilitate entry of the ETT-TL through the nose.

As with oral Trachlight intubation, the head is placed in a neutral or extended position, not the sniffing position. The Trachlight is switched on once the tip of the ETT-TL has been advanced into the oropharynx, positioned in the midline, and advanced gently using the light glow as a guide. A jaw-lift maneuver is necessary to lift the epiglottis from the posterior pharyngeal wall (Fig. 21-14). However, without the stiff internal wire stylet in situ, difficulty may be encountered controlling the tip of the ETT during blind nasal intubation. In particular, because of the natural curvature of the ETT, the tip commonly goes posteriorly into the esophagus. Various maneuvers may help. To bring the tip of the ETT anteriorly during intubation, it is sometimes necessary to flex the neck of the patient while advancing the ETT-TL slowly. If flexing of the neck is contraindicated, inflating the ETT cuff completely with 20 cc of air will help to elevate the ETT tip and align it with the glottis during intubation.[63] Alternatively, an ETT with a controllable tip (the Endotrol tube by Mallinckrodt Critical Care, Inc., St. Louis) can be used for nasotracheal intubations and

Figure 21-14 During nasotracheal intubation using the Trachlight, the jaw is grasped and lifted upward by the nondominant hand. This elevates the tongue and epiglottis away from the posterior wall of the pharynx to facilitate placement of the tip of the endotracheal tube (ETT) into the glottic opening. When the ETT-Trachlight (ETT-TL) unit enters the glottic opening, a well-defined, circumscribed glow will be seen in the anterior neck just below the thyroid prominence *(arrow)*.

directed toward the glottis.[64] In some difficult circumstances, nasotracheal intubation can be performed effectively and safely with the internal stiff wire stylet in place.[65,66] Although there can be an increased risk of nasal trauma with the wire stylet in place, this technique may be associated with fewer head-neck manipulations and perhaps better control of the tip of the ETT.

D. Clinical Utility of Lighted Stylets

1. Routine Use

Endotracheal intubation using a lighted stylet is easy to learn. The Trachlight has a learning curve of 10 to 30 intubations.[67,68] Once mastered, the Trachlight is quick to use. A large study involving 950 elective surgical patients demonstrated Trachlight intubation to be statistically significantly faster than direct laryngoscopic intubation (15.7 ± 10.8 versus 19.6 ± 23.7 seconds, respectively),[58] although such a small time difference is unlikely to be clinically significant. In the same study, the Trachlight appeared to compare favorably with the conventional laryngoscopic technique with regard to effectiveness and failure rate. There was a 1% failure rate with the Trachlight, and 92% of intubations were successful on the first attempt, compared with a 3% failure rate and an 89% success rate on first attempt using a standard laryngoscope. There were significantly fewer traumatic events and sore throats in the Trachlight group compared with laryngoscopy patients. Tsutsui and Setoyama reported similar findings in a study with 511 patients.[69] Trachlight intubation appeared to be highly effective (99%), with successful intubation after one attempt in most cases (93%). Unsuccessful intubation, even after three attempts, occurred in 3 patients (1%).

Other lighted stylets have been less well studied. However, in 1991, a letter to the editor reported on 1200 TubeStat intubations in one institution over a 2-year period. In that series, the TubeStat was used without laryngoscopic assistance. Although most intubations were undertaken with the patient under general anesthesia, some were performed with topical anesthesia in anticipation of a probable DA. The authors reported that the TubeStat had a high success rate after failed laryngoscopic intubation and a low failure rate when used as a first-choice device. They concluded that "in the majority of elective cases, TubeStat intubation is our method of choice."[70]

2. Difficult Airway

The Trachlight has also proved to be useful for nasal or oral intubation in patients with anticipated or unanticipated DAs.[71] During the development of the Trachlight, a study reported on its clinical utility in 265 patients with DAs. Group 1 (n = 206) had a documented history of DA or anticipated DA, whereas group 2 (n = 59) were anesthetized patients with an unanticipated failed laryngoscopic intubation. In group 1, intubation was successful in all but 2 of the patients, with a mean (±SD) time to intubation of 25.7 ± 20.1 seconds. The tracheas of these 2 patients (1 morbidly obese patient weighing 220 kg and 1 patient with severe flexion deformity of the cervical spine) were intubated successfully using a flexible fiberoptic bronchoscope (FFB). Orotracheal intubation with the Trachlight was successful in all patients in group 2, with a mean time to intubation of 19.7 ± 13.5 seconds. Apart from minor mucosal bleeding (mostly from nasal intubation), no serious complications were observed in any of the study patients.

Other investigators have also reported successful use of the Trachlight for tracheal placement in patients with a DA. These reports have included patients with a history of limited mouth opening,[72] severe burn contractures,[73] pediatric tongue-flap surgery,[74] Pierre-Robin syndrome,[75] other pediatric craniofacial abnormalities,[76] and patients with DA and cardiac conditions.[77]

The Trachlight can also be used for patients with cervical spine abnormalities. In a randomized crossover trial of 36 healthy patients, Turkstra and associates compared cervical spine motion produced by Macintosh laryngoscopy, the Glidescope video laryngoscope, and the Trachlight when manual in-line stabilization was applied.[78] Using fluoroscopic video, these investigators showed that the Glidescope and Trachlight methods of intubation produced roughly half as much cervical spine motion as Macintosh laryngoscopy. This study, and another by Huang,[79] found Trachlight intubation to be considerably faster than Glidescope intubation in healthy anesthetized patients with simulated in-line cervical spine stabilization. In Huang's randomized study of 60 patients, time to intubate was 15 ± 5 seconds in the Trachlight group and 33 ± 9 seconds in the Glidescope group ($P < 0.05$).[79] In a more recent prospective, randomized crossover trial of 20 patients, the Trachlight produced as little cervical spine motion as intubation using an FFB in anesthetized, paralyzed adults with a normal cervical spine.[80] A prospective, randomized trial of 148 patients with cervical spine abnormalities compared airway management with the Trachlight versus the Fastrach laryngeal mask airway (LMA), an intubating LMA (iLMA). The Trachlight was found to be considerably quicker (23 ± 9 versus 71 ± 24 seconds) and more reliable (97.3% versus 73.0%

successful intubations after a maximum of two attempts) than the iLMA in this patient population.[81]

The utility of lighted stylets for the management of predicted DA is not limited to the Trachlight. In 2009, Rhee and coworkers randomly assigned 60 patients with high Mallampati scores (class III or IV) to receive endotracheal intubation using either the standard laryngoscope or the Surch-Lite lighted stylet (Aaron Medical Industries, St. Petersburg, FL). The rate of successful endotracheal intubation was significantly higher in the Surch-Lite group after one attempt (97%, versus 80% in the direct laryngoscopy group), and Surch-Lite intubation was also significantly quicker (12 ± 6 versus 17 ± 12 seconds, respectively).[82]

3. Hemodynamic Effects

Although many studies have reported on the comparative hemodynamic changes associated with Trachlight intubation and laryngoscopic intubation, the results have been inconsistent. Several studies involving only a small number of patients (26 to 60) showed that there were no statistical differences in the hemodynamic changes occurring after endotracheal intubation using either the lighted stylet or the laryngoscope.[83-87] However, most of these studies did not perform a power analysis to determine the appropriate sample size for the study, thereby running the risk of having a type II error. Although the study by Siddiqui and colleagues comparing conventional laryngoscopy to the Trachlight and the Glidescope was properly powered to detect changes in blood pressure and heart rate, there was no significant difference in these parameters between the groups.[86] One study did not include a standardized general anesthetic technique.[83]

These findings were not consistent with the results of other studies that showed lower hemodynamic responses after endotracheal intubation using a lighted stylet compared to a laryngoscope.[69,88-90] In one large study (n = 511), Tsutsui and Setoyama reported that Trachlight intubation was associated with less elevation of the blood pressure during intubation, compared with laryngoscopic intubation.[69] During the development of the Trachlight, a study involving 450 elective surgical patients showed that the increases in mean arterial pressure (MAP) and heart rate occurring after intubation were significantly less with the Trachlight than with laryngoscopy.[88] However, the anesthetic technique used in this study was not standardized. In a study by Rhee and associates of 60 patients with high Mallampati scores (class III and IV), those patients who received direct laryngoscopy had significantly higher increases in MAP and heart rate after intubation than did those in the Surch-Lite lighted-stylet group.[82]

In a small study (n = 40), Nishikawa and coworkers showed that the lighted-stylet technique significantly attenuated hemodynamic changes after intubation in normotensive patients, compared with the laryngoscopic technique.[89] However, they did not find any significant difference in hemodynamic changes between the two techniques in patients with hypertension. These results were in direct contrast to the findings of another comparative study of the hemodynamic changes using three intubating techniques: a Macintosh laryngoscope, a Trachlight, and an iLMA in 75 patients.[90] The investigators in that study reported that both the iLMA and the Trachlight attenuated the hemodynamic stress response to endotracheal intubation, compared with the Macintosh laryngoscope, in hypertensive but not in normotensive patients.

In a randomized, controlled trial of 80 patients with coronary artery disease, Montes and colleagues compared hemodynamic responses to intubation with the Trachlight versus direct-vision laryngoscopy.[91] Although the results were not significantly different, the Trachlight group tended to have lower blood pressure and heart rate during the intubation period.[91] Clearly, future studies involving large numbers of patients are necessary to clarify these conflicting data regarding the hemodynamic stimulation associated with endotracheal intubation using a lighted stylet.

4. Pediatric Use

The pediatric Trachlight has been used both orally and nasally,[92] including in patients with a DA.[74,93] In 2008, Xue and coworkers published a case series of four children with craniofacial abnormalities who were unable to be intubated via direct laryngoscopy (all children had Cormack-Lehane grade 4 views) or with a FFB.[76] The tracheas of these four children were intubated successfully within 30 seconds using the Trachlight. The small body of published pediatric Trachlight experience suggests that some adjustments to technique may be necessary. Suggestions include the following[76]:

1. The Trachlight should be bent to 60 to 80 degrees instead of the usual 90 degrees to better suit pediatric anatomy.
2. The distance before the bend in the Trachlight should reflect the short length of the pediatric airway.
3. Because of the small distances involved, transillumination must be expected soon after insertion of the Trachlight.
4. The Trachlight glow is so readily seen through the relatively small amount of tissue in a child that transilllumination from the esophagus can more easily be mistaken for that from the trachea, although experience will enable the clinician to tell the difference.

5. Synergy with Direct Laryngoscopy

Endotracheal intubation can fail with the Trachlight as well as with the laryngoscope. However, in an early study of 950 patients, all Trachlight failures were resolved with direct laryngoscopy.[58] Similarly, all failures of direct laryngoscopy were resolved with Trachlight. These results suggest that a success rate approaching 100% can be achieved in endotracheal intubation by combining the two methods.

The techniques can even be used simultaneously, which may be particularly useful for unanticipated DL (e.g., patients with a Cormack-Lehane grade 3 laryngoscopic view).[18] While maintaining the grade 3 view with a standard laryngoscope in situ, the clinician can use an ETT-TL with a 90-degree bend. Under direct laryngoscopy, the tip of the ETT-TL can be "hooked" under the epiglottis. If the tip of the ETT is placed at the glottic opening, a well-defined, circumscribed glow can be seen in the anterior neck slightly below the laryngeal

prominence. If a glow is not seen, the ETT-TL should be repositioned until a glow can be seen in the anterior neck. Since the development of the Trachlight, we have recorded more than a dozen failed intubations using either the Trachlight or a laryngoscope, but in each of these failures, endotracheal intubation was successful using the laryngoscope together with the Trachlight. Others have also reported the successful use of this combined technique. In one study, the investigators successfully performed endotracheal intubation in all 350 study surgical patients with a simulated DA using the laryngoscope together with the Trachlight.[94]

6. Use with Other Airway Devices

In addition to its use with the laryngoscope, the Trachlight has been combined successfully with other intubating techniques. These include intubation through the LMA-Classic,[95,96] through the iLMA,[97] with the Bullard laryngoscope,[98,99] and with a retrograde intubating technique.[100]

7. Percutaneous Tracheotomy

The Trachlight can be used to identify the intratracheal position of the tip of the ETT during percutaneous tracheostomy.[101] This simple technique can help to avoid puncturing the ETT or the cuff, thus ensuring adequate ventilation and oxygenation during the percutaneous tracheotomy. This technique is also inexpensive and minimizes the risk of damaging equipment such as the FFB. If it is used properly, it is possible that this simple, light-guided technique can also be used to accurately determine when the tip of the ETT is above the surgical tracheotomy site as the tube is pulled back during surgical tracheotomy.

E. Limitations

Although the Trachlight and other lighted stylets have been demonstrated to be effective and safe for oral and nasal intubation, the technique requires transillumination of the soft tissues of the anterior neck without visualization of the laryngeal structure. Therefore, it should not be used in patients with known abnormalities of the upper airway, such as tumors, polyps, infection (e.g., epiglottitis, retropharyngeal abscess), or trauma of the upper airway, or if there is a foreign body in the upper airway. In these cases, other alternatives using direct laryngoscopy or fiberoptic intubation (FOI) should be considered. The lighted stylets should also be used with caution in patients in whom transillumination of the anterior neck may not be adequate, such as patients who are grossly obese or who have limited neck extension. Intuitively, this light-guided technique should not be attempted with an awake, but potentially uncooperative patient unless a bite block is used to prevent damage to the device or injury to the clinician.

F. Complications

Since its introduction in 1995, the Trachlight has been used extensively in many countries. Although there is a potential risk of damage to the glottic opening during endotracheal intubation using a "nonvisualizing" intubating technique, there have been very few case reports of complications.

In 2001, Aoyama and colleagues reported that the epiglottis of a patient was partially pushed into the laryngeal inlet, along with the ETT, after Trachlight intubation.[102] To investigate the potential risk of laryngeal damage during Trachlight intubation. Hung and colleagues placed an FFB in the nasopharynx. They reported that during orotracheal placement of the ETT using the Trachlight, structures around the glottic opening, including the epiglottis and the arytenoids, could be transiently displaced. In some instances, the epiglottis was pushed into the glottic opening. Usually, the epiglottis spontaneously returned to the correct position. The authors suggested that there are potential risks of laryngeal damage in addition to downfolding of the epiglottis during ETT placement using the Trachlight, but such occurrences have not been observed to cause permanent damage, and the reduction in the incidence of sore throat in patients undergoing Trachlight intubation compared to laryngoscopic intubation suggests that such occurrences are of little clinical significance.[58]

Subluxation of the cricoarytenoid cartilage occurs rarely but was reported in a study using an older version of a lighted stylet (Tubestat).[103] However, with correct use of the retractable wire stylet, the risk of damaging the arytenoid cartilage during Trachlight intubation is low.

In 2008, Zhang and associates reported a case in which the part of the silicon sheath that protects the Trachlight wand and bulb broke from the Trachlight unit during intubation and was left behind within the lumen of the ETT.[104] This is the only such published case involving the Trachlight, although there have been four similar case reports of instrument disarticulation with other lightwand devices.[105-107] In Zhang's case, "the wand was withdrawn from the ETT with some difficulty."[104] Softening the ETT before intubation by placing it in warm saline makes it more malleable, and lubricating the wand with a water-based lubricant makes disengaging the Trachlight from the ETT unit much easier. These steps, together with the mindset that undue force should always be avoided, will likely reduce any structural damage to the Trachlight. Nevertheless, it is good practice to always examine the Trachlight after intubation for structural integrity.

Noguchi and colleagues reported that application of 8% xylocaine in a pump spray as a lubricant for the Trachlight resulted in disappearance of the print markings of the wand.[108] However, lidocaine jelly and glycerin showed no effect on the print marks. The investigators suggested that lidocaine pump spray should not be used as a lubricant on the Trachlight wand.

Although the lighted stylet has been shown to be an effective and safe intubating device, its potential risks and complications, as well as its indications, must be kept in mind.

IV. CONCLUSIONS

Occasional DL has led to the development of many alternative techniques for placing an ETT. Use of an intubating guide such as the reusable and malleable EI or "gum elastic bougie" has been shown to be a safe, effective, and

quick method of guiding the ETT into the trachea when the laryngeal aperture cannot be well seen under direct vision using a laryngoscope. Use of the EI is well supported by many reports and 40 years of clinical use. Some newer, single-use ETT introducers, such as the Frova, have also performed well in studies, although they tend to be stiffer and less malleable than the EI. The longer and larger-diameter ETT exchangers are introducers specifically designed to be securely placed in the trachea so that ETTs can be "railroaded" over the top of the exchanger. Because they are hollow, they can also be used as temporary conduits for oxygen delivery and ventilation. ETT exchangers are useful when a secure airway should be changed or temporarily removed but direct-vision laryngoscopy is likely to be difficult. Stylets, the plastic-coated metal rods that enable stiffening and reshaping of an ETT before intubation, have been used for many years but are not well studied. Limited evidence suggests that these stylets are not as effective as introducers when used for the management of DAs.

Transillumination of the soft tissues of the neck using a lighted stylet has been shown to be an effective intubation technique for decades. Although there are many versions of lighted stylets, the Trachlight is the best studied and has incorporated many design modifications to facilitate both oral and nasal intubation in awake and anesthetized patients. It has been demonstrated to be an effective and safe intubating device in a large variety of surgical patients, including those with documented DAs. However, lighted stylets should not be used in patients with anatomic abnormalities or distortions of the upper airway. As with any intubation technique, regular use and practice with these intubating devices will improve performance and may also reduce the likelihood of complications.

V. CLINICAL PEARLS

- The Eschmann Introducer (EI) is best used when the epiglottis can be seen under direct laryngoscopy (Cormack-Lehane grade 3 view); the coudé tip can be hooked under the epiglottis and the EI advanced blindly through the glottis. The success of this maneuver is improved if the EI has been preshaped into a curve.
- If "clicks" are felt on blind advancement of the EI into the trachea, the potentially more traumatic "hold-up sign," though reliable, need not be sought.
- To facilitate the advancement of the ETT over the EI after tracheal placement, the tongue and epiglottis should be elevated by a jaw lift, or preferably by a laryngoscope.
- During blind nasotracheal intubation, inflating the ETT cuff completely with 20 cc of air can help to elevate the ETT tip and align it with the glottic opening, facilitating tracheal placement.
- In order to have a clear passage to the glottic opening during lightwand intubation, it is necessary for the clinician to perform a jaw lift, which will elevate the tongue and epiglottis away from the posterior pharyngeal wall to facilitate placement of the tip of the ETT posterior to the epiglottis and into the glottic opening.
- Although the lightwand has been demonstrated to be effective and safe for endotracheal intubation, the technique requires transillumination of the soft tissues of the anterior neck without visualization of the laryngeal structure. Therefore, a lightwand should not be used in patients with known abnormalities of the upper airway, such as tumors, polyps, infection, or trauma of the upper airway.

XIII. Clinical Pearls

I. INTRODUCTION

The laryngeal mask airway (LMA, LMA Company, Henley, England) is a supraglottic airway device developed by Archie Brain, a physician and honorary consultant anesthetist of the Royal Berkshire Hospital, Reading, England. It was introduced into clinical practice in 1988. In the first paper on the LMA,[1] Brain described the device as "an alternative to either the endotracheal tube (ETT) or the face-mask with either spontaneous or positive-pressure ventilation (PPV)." Twenty years and more than 200 million safe uses later, the LMA has significantly improved the comfort and safety of airway management worldwide. Many authorities in anesthesia consider the LMA to be the most important development in airway management in the past 50 years.

While experimenting with different shapes and materials for the LMA, Brain recognized the importance of studying, understanding, and incorporating into its design the anatomic and physiologic principles that govern the oropharyngolaryngeal complex. This effort resulted in an effective airway device that is minimally intrusive. Realizing that one LMA model could not fulfill all clinical needs, Brain introduced three additional models of the LMA from 1993 to 2003: the flexible LMA (FLMA), the Fastrach intubating laryngeal mask airway (ILMA), and the ProSeal LMA (PLMA). These models represent only a fraction of the potentially useful clinical designs that have originated from Brain's research.

The LMA is a minimally invasive device designed for airway management in the unconscious patient. An inflatable mask is fitted with a tube that exits the mouth to

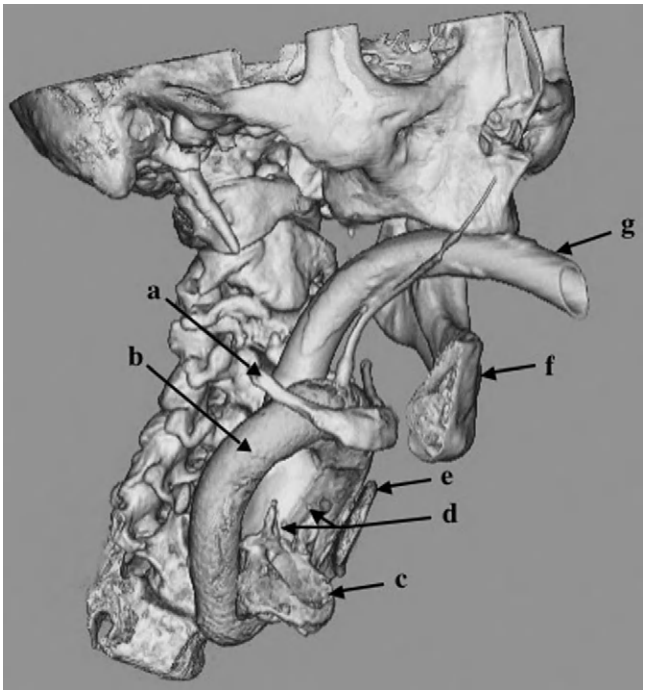

Figure 22-1 Three-dimensional radiologic reconstruction of the human airway with the laryngeal mask airway (LMA) in situ: hyoid bone *(a)*; LMA's cuff *(b)*; cricoid ring *(c)*; arytenoid cartilages *(d)*; thyroid cartilage *(e)*, which is digitally partially removed to demonstrate the position of the LMA; mandible *(f)*, which is digitally partially removed to demonstrate the position of the LMA; and the LMA's shaft *(g)*. The LMA's cuff forms a seal with the periglottic tissues and provides a continuous connection between the natural airway and the device.

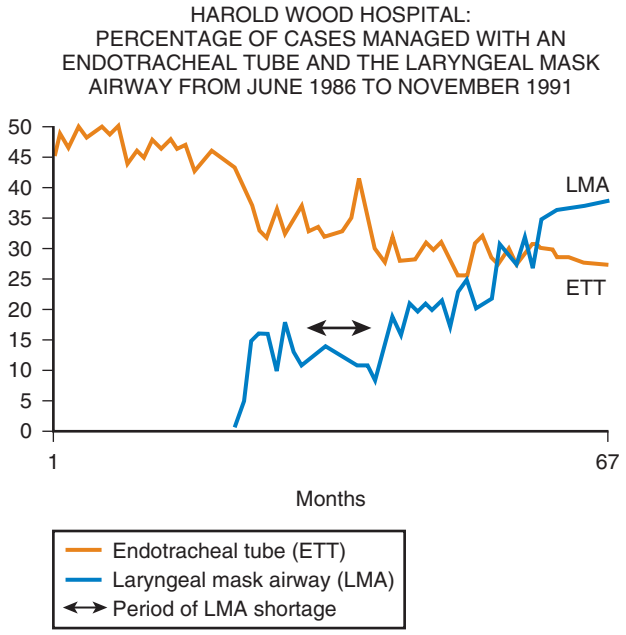

Figure 22-2 Harold Wood Hospital (England) data show the percentage of cases managed with an endotracheal tube *(ETT)* or laryngeal mask airway *(LMA)* from June 1986 through November 1991. Use of the ETT has significantly declined in favor of the LMA in the United Kingdom.

permit ventilation of the lungs. The mask fits against the periglottic tissues, occupying the hypopharyngeal space and forming a seal above the glottis instead of within the trachea (Fig. 22-1). Originally produced as a single, general-purpose design in a range of sizes, it is currently made in various forms to satisfy different requirements.

The LMA is a supraglottic airway management device. A substantial body of literature, while supporting the wisdom of exercising caution when learning to use the supraglottic approach, provides ample evidence of a wide range of uses that go beyond those originally postulated.[2] For example, the LMA is becoming increasingly popular outside the operating room, as evidenced by its endorsement by the European Resuscitation Council and the American Heart Association.[3] Its more exotic uses include the adoption of the Fastrach ILMA, which is the intubating form of the LMA, by the National Aeronautics and Space Administration (NASA) as part of its emergency medical kit for space travel. A literature search indicates that the later varieties of the LMA, including the FLMA, ILMA,[4] and PLMA,[5] may be more appropriate tools for specific uses than the original LMA.

More than 2000 scientific articles have described the impact of the LMA on modern anesthesia, and a full review is beyond the scope of a single chapter. Our aim instead is to provide an overview of the LMA's uses worldwide. After a historical review and comments regarding the correct LMA insertion technique, we explore the principal uses of each LMA model, discuss possible problems, and offer suggestions for getting the best results from each device. We describe the evolution of the LMA's use in patients with difficult-to-manage airways and provide the current recommendations for LMA use from the American Society of Anesthesiologists (ASA) difficult airway algorithm.[6]

II. HISTORY AND DEVELOPMENT

In 1988, the definitive device, now referred to as the LMA Classic, was released commercially in the United Kingdom. Although the LMA was rapidly adopted there, it was not until 1991 that the U.S. Food and Drug Administration permitted release of the device in the United States and then only with the stricture that "the LMA is not a replacement for the endotracheal tube." Because the LMA was at that time a very unconventional way of managing the airway, this caution was understandable. Nevertheless, it resulted in a somewhat slower acceptance of the concept of "masking the larynx" in the United States than in the United Kingdom, where the LMA was purchased by every health authority within 2 years of its launch, resulting almost immediately in a reduction in ETT use (Fig. 22-2).

A. From Idea to First Prototype

Brain is often asked how the idea of the LMA first arose. Like many before him, he thought that a supraglottic approach would be less traumatic than intubation and therefore more desirable, provided the method could be easier to control and more reliable than the face mask. Other inventors had mainly explored the oral and pharyngeal spaces above the larynx,[7-12] but the LMA was the

Figure 22-3 The Goldman dental nose piece was used to develop the early cuffs for the laryngeal mask airway prototypes. The central portion of the mask was cut out to allow attachment of the tube.

first device to encircle the periglottic tissues in the hypopharynx with a mask. The idea was conceived in early 1981, and later that year, Brain began providing dental anesthesia at the outpatient clinic of the Royal London Hospital. At that time, a device known as the Goldman dental nose piece was being used for airway maintenance during dental extractions in anesthetized patients. It was a reusable, vulcanized rubber mask that could be detached from its rigid base for cleaning (Fig. 22-3). The mask was designed to fit over the nose, leaving the mouth free for surgical access. Noticing a certain similarity between the contours around the nose and those around the glottis, Brain wondered if the Goldman mask could be modified to fit over the larynx. Placing a device over the larynx would short-circuit the upper airway passages, perhaps eliminating some of the problems associated with maintaining their patency under anesthesia.

Because the Goldman mask was scheduled to be discontinued in favor of a disposable version, Brain was able to obtain samples for experimentation. Using an acrylic adhesive, he glued a diagonally cut, 10-mm Portex ETT to the rubber mask's attachment flange, which he had to draw across the mask aperture into the midline to form a base (Fig. 22-4). Figure 22-5 is a 1981 photograph of the inventor as he is about to insert one of the resulting prototypes into his anesthetized pharynx to test the validity of his hypothesis. In his diary, he recorded an absence of any complications, despite having repeated the experiment four times. This observation, combined with a broadly worded institutional review board approval, provided the justification for subsequent extensive clinical investigations, which occupied him for the next 7 years. During this time, he built many prototypes, which he used in approximately 7000 patients.[13] He also kept extensive notes in private diaries to record his

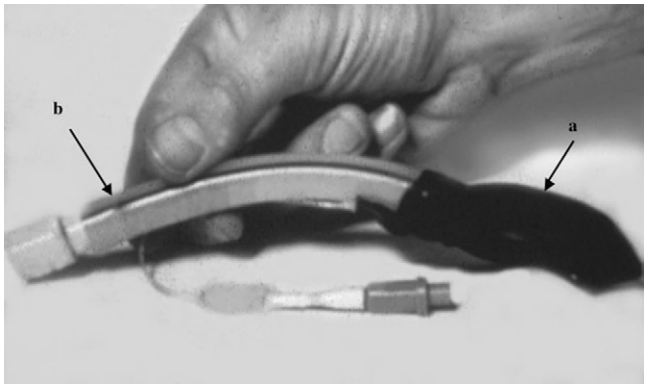

Figure 22-4 The early laryngeal mask airway (LMA) prototype was made of a Goldman dental nose piece modified to form a cuff (a) and a diagonally cut endotracheal tube (b). The two pieces were glued together to form the first LMA to be tested clinically.

progress but published only a small number of cases, because he believed there was little point in presenting data concerning an invention that was not ready for production.

B. Early Publications

The first article about the LMA, published in the *British Journal of Anaesthesia* in 1983, presented data from only 23 patients and received little attention.[1] A second description 2 years later in *Anaesthesia* was subtitled "Development and Trials of a New Type of Airway" and detailed the LMA's use in 118 patients, although it also reported that Brain and colleagues had gained experience

Figure 22-5 Archie Brain, MD (1981), was the inventor of the laryngeal mask airway (LMA). He is shown about to insert one of the LMA prototypes into his anesthetized pharynx to test his hypothesis that a supraglottic device was effective, safe, and much less invasive than the endotracheal tube.

in more than 500 cases.[14] On the basis of this experience and a case report published the previous year in *Archives of Emergency Medicine,*[15] Brain and colleagues felt justified in concluding that "the laryngeal mask may have a valuable role to play in all types of inhalational anesthesia, while its proven value in some cases of difficult intubation indicates that it may contribute to the safety of general anesthesia."[14]

In the same issue of *Anaesthesia*, Brain presented further evidence of the potential usefulness of the device in cases of difficult intubation, but there was still no response to these claims from the profession, perhaps because no product was available for independent assessment.[16] However, he had given one of his prototypes to a visiting American anesthesiologist, Ronald Katz, a physician and chairman of the anesthesiology department at the University of California–Los Angeles. Katz provided the first independent description of the LMA based on his experience with this prototype, writing in *Wellcome Trends in Anesthesiology* in October 1985 and again in February 1986.[17,18] The second article provided the first published image—reproduced from one of the inventor's transparencies—of the glottis seen fiberoptically through the LMA prototype and mentioned the potential of the device to overcome intubation problems. American awareness of the LMA preceded its availability in the United States by 6 years.

C. From Handmade Models to Clinical Use

There were three reasons why the LMA took so long to become clinically available: the initial lack of commercial interest, which meant there were no models available for others to use; the solitary nature of the LMA's development, which was carried out virtually singlehandedly by a clinician who continued to work with largely homemade equipment until the first commercial prototypes were made in early 1988; and the complexity of the airway anatomy, which made it hard to design a device that was safe and effective. One advantage of the long development process was that the considerable clinical history that the inventor accumulated between 1981 and 1988 guided the development of the LMA, and the first factory-made models required little modification. They were produced in Gary, Indiana; tested by Brain; and then demonstrated to colleagues at the Royal East Sussex Hospital, Hastings, United Kingdom, in April 1988. Colin Alexander, the chairman of the anesthesiology department at the Royal East Sussex Hospital, immediately authorized the LMA's use in his department and published his experience in a letter ("Use your Brain") in *Anaesthesia* that year.[19] He concluded that the device "should be considered whenever the indication for tracheal intubation does not include protection of the airway from gastric contents." Meanwhile, a few colleagues who had been given prototypes by Brain (one person built his own) continued to explore the LMA's use in known cases of difficult intubation, with encouraging results.[13]

Arguably, the most influential clinical study using Brain's hand-built prototypes was not published until 1989, after the commercial form of the device had become available. Brodrick and colleagues studied 100 cases in which the patients breathed spontaneously.[20] Eighteen anesthesiologists took part in the study and recorded a "clear and unobstructed airway in 98% of cases," but obstruction on initial placement of the LMA occurred in 10 cases and "appeared to be as a result of downfolding of the epiglottis." A stainless steel introducer tool with a handle similar to that of the Fastrach ILMA and a blade fitting into a slot in the distal anterior end of the LMA's mask had been designed to overcome this problem. An aperture in the blade into which the epiglottis fit caused the epiglottis to be drawn upward as the tool was removed from the patient's pharynx. This insertion tool was used successfully in these cases, but fears that it could cause trauma led to it being abandoned in the commercial form of the LMA. Brodrick is often quoted in support of limiting the use of the LMA to spontaneously breathing patients. However, because the LMAs used by Nunn's group were prototypes, only a size 3 device was available for use in 72 men and 28 women (weight not recorded). Given the possibility that the LMA's size was less than optimal, it is not surprising that eight patients could not be ventilated using positive pressure without unacceptable leaks and that the mean leak pressure was 17 cm H_2O, similar to that recorded by Brain 6 years earlier.[13]

In addition to the information accumulated in his clinical work, study of the anatomy and physiology of the larynx and pharynx guided Brain throughout development of the LMA. As the work progressed, he struggled to achieve a balance in simplicity, efficacy, and safety. In designing a device that fit into the lower pharynx, measures favoring efficacy tended to counteract those favoring simplicity. Improving the seal, for example, required more complex construction to avoid potential trauma related to high mucosal pressures. Likewise, an effort to make the device easier to insert led to the development of an insertion tool, which was determined by Brain to be potentially unsafe and therefore abandoned, despite the efficacy it demonstrated.[13] Ultimately, the solutions chosen were compromises. For example, Brain realized that seals with a leak pressure much higher than 20 cm H_2O were rarely necessary in practice and that an inadequate seal often could be overcome by using a more appropriately sized device, using a better fixation technique, or giving a more appropriate anesthetic. To make insertion of the LMA maximally reliable and minimally traumatic, a technique gradually evolved that was based on the swallowing mechanism. Unfortunately, he underestimated the difficulty of teaching others to master such a subtle technique, which is virtually impossible to learn without direct, hands-on demonstration and guidance.[21] As a result, many articles in the LMA literature suggest variant insertion methods, most of which had already been tried and rejected by Brain for being unreliable or traumatic.

Despite these difficulties, the history of the LMA since its first commercial launch is essentially a story of steady expansion in use around the world. Availability, cost, and user education have governed the speed at which the various forms of the LMA have been accepted. Figure 22-2 demonstrates data collected by the anesthesiology

department of Harold Wood Hospital, a typical general hospital near London, on the influence of the LMA Classic in the first 3 years of its availability and on the use of the ETT and the face mask. The dip in the curve representing LMA use indicates a period when it was commercially unavailable. These data show that use of the ETT almost immediately declined in favor of the new method of airway management, and they illustrate the rapid growth of LMA use in the United Kingdom. They also cast some doubt on the widely held view that the popularity of the LMA in the United Kingdom has been due to the more frequent use of the face mask there than in the United States.

As new models of the LMA have become available, countries with different anesthesia traditions have responded to them with various degrees of enthusiasm. In all cases, however, use of the LMA has steadily increased (personal communication, LMA International SA, March 2004).

III. LARYNGEAL MASK AIRWAY INSERTION TECHNIQUE

The LMA occupies a potential space that is shared by the respiratory and alimentary tracts, which are subject to the control and coordination of several complex reflexes. Although anesthesiologists do not need a detailed knowledge of the specific reflexes to use the LMA, they do need to understand the basic concept behind the recommended insertion technique, which ensures the greatest success and results in the fewest complications. Physiologically, the alimentary tract is capable of accepting (i.e., swallowing) or rejecting (i.e., vomiting) liquids or solids in the form of food. In contrast, the respiratory tract mobilizes defensive responses (e.g., coughing, laryngospasm, bronchospasm) only when invaded by liquids or solids (e.g., an ETT). When inserted correctly, the LMA does not stimulate the respiratory tract defenses because the device forms an end-to-end seal against the periglottic tissues.

Investigations using magnetic resonance imaging (MRI) to assess the effect of the LMA on the anatomy of the airway may help to explain the reliability of the device. A study by Shorten and coworkers of 46 adults requiring sagittal MRI views of the head and neck compared the anatomic differences in awake, sedated, and anesthetized patients.[22] With an LMA in place, the epiglottic angle was more than twice as great with respect to the posterior pharyngeal wall in the anesthetized group as it was in the sedated or awake group. This had no apparent effect on ventilatory function in most patients, probably due to the depth of the LMA bowl, which the inventor found to be a critical dimension when experimenting with different design ideas during the 1980s. The recommended standard insertion technique evolved slowly as Brain gained experience, and it was not until he had been inserting LMAs for almost 10 years that he realized that his technique was becoming more and more similar to the physiologic act of swallowing food. When he realized this, it was a simple matter to study this mechanism more closely and make allowances for the fact that in the anesthetized patient, this reflex is partially or completely abolished. The following key points emerged:

1. *Correct mask deflation is important*. The purpose of chewing food is to form a soft, atraumatic paste that can easily be passed through the pharynx and esophagus. At the onset of swallowing, this paste (i.e., food bolus) is pressed by the tongue into the hard palate. The pressure generated is distributed widely over the palatal surface, so there is no localized high-pressure point, which would give the sensation of a sharp object and lead to rejection instead of swallowing. Brain realized that to imitate the sensation of a soft food bolus, he needed to deflate the mask so that it presented an elastic, hollow shape. When this shape was pressed into the dome of the palate, the hollow form would need to be inverted. The pressure required by inserting the finger to achieve this would cause the outer rim of the mask to act like a gentle spring, producing the desired effect of spreading pressure smoothly over the entire posterior surface of the mask. This spring effect cannot be achieved without deflating the mask to a vacuum pressure of about –40 cm H_2O. Only in this way was it possible to prevent the pointed distal end of the mask bowl from transmitting an irritating localized pressure point as it was pressed into the oropharyngeal curve. Partial mask inflation could not achieve this aim, however, because the soft distal end of the mask rolled backward, allowing the pointed tip of the mask bowl to scratch the palatal surface. Deflating the mask such that it followed the curvature of the palate had the same disadvantage, because it made the pointed end even more prominent. Inserting a fully inflated mask introduced excessive bulk, which created the possibility of tearing the cuff against the teeth and was physiologically equivalent to swallowing too large a bolus of food, which could lead to the rejection reflex.
2. *The deflated mask must be lubricated if the oral cavity is not already wet*. There is a parallel with swallowing because lubrication is a key part of deglutition. Because the mask is slid against the palate, it makes sense to apply a bolus of lubricant to the distal hollowed posterior surface of the mask immediately before insertion. Water-soluble jelly is a good substitute for oral secretions. It is not necessary or desirable to spread the lubricant over the whole surface of the mask before insertion.
3. *Flatten the mask against the hard palate*. Initially during swallowing, the tongue flattens the softened food bolus against the hard palate; during the first step in LMA insertion, the mask, correctly prepared to impart a sensation similar to that of a soft food bolus, is flattened by pressing it against the hard palate. Placing the index finger on the airway tube at its junction with the mask under the deflated proximal rim of the cuff is the best way to impart the necessary force.
4. *Cranioposterior movement of the index finger*. In swallowing, the bolus of food is advanced into the pharynx, esophagus, and stomach through precise coordination of several muscle groups, beginning with the tongue. During LMA insertion, the clinician must use her or

his index finger to advance the mask in the cranioposterior direction, imitating the action of the tongue. This allows a completely deflated tip to slide smoothly along the hard palate, soft palate, and posterior pharyngeal wall while minimizing the contact of the mask with anterior structures such as the base of the tongue, epiglottis, and laryngeal inlet. The finger must continue to push in a cranioposterior direction even though the anatomy forces the mask and the finger to move caudally. The finger must never consciously be directed caudally and should be inserted to its fullest extent until resistance is felt as the mask tip enters the upper esophageal sphincter (UES). It is anatomically impossible to perform this action correctly without extending the proximal metacarpophalangeal joint of the index finger and flexing the wrist.

5. *Widening the oropharyngeal angle is the first role of the nondominant hand*. Cadaveric work demonstrates that if the head of the supine subject is pushed by the supinated hand in a caudal direction, head extension, neck flexion, and mouth opening are simultaneously achieved. This maneuver widens the oropharyngeal angle to greater than 90 degrees in the normal subject and draws the larynx away from the posterior pharyngeal wall. Both effects facilitate LMA insertion. The nondominant hand should therefore maintain firm caudal pressure on the occiput from the start of insertion until the mask has passed behind the tongue.
6. *Removal of the index finger is the second role of the nondominant hand*. To prevent the mask sliding out of position after it is fully inserted, the nondominant hand should move from behind the head to grasp the proximal end of the LMA before the index finger is removed. As the index finger is removed, the mask is held steady, or if it has not been fully inserted, it can be pressed further into position by the nondominant hand.
7. *The mask is inflated*. As the mask is inflated, its increased bulk and the relatively large radius of the airway tube cause it to slide cranially. It can be shown anatomically that this results in loss of contact between the mask tip and the UES. However, the LMA should not be held in place during inflation because this can result in the distal end of the mask stretching the UES. All LMAs should be inflated to a pressure of less than 60 cm H_2O; pressures above this have been found to cause discomfort in awake volunteers.
8. *Device fixation restores stability of the seal against the UES*. The distal end of the tube is again pressed into the curve of the hard palate to reestablish firm contact between the proximal end of the device and the UES. While this pressure is maintained, adhesive tape is applied to the maxilla on one side of the patient's face and passed over and under the tube in a single loop before fixing to the opposite maxilla. This form of fixation ensures stability of the device and is likely to afford maximum protection in the event of unexpected regurgitation, and it reduces the incidence of gastric insufflation during PPV.*

*One study involving 108 patients showed that a malpositioned LMA was 26 times more likely to be associated with gastric insufflation.[171]

The basic insertion technique is identical for all LMA models. Unfortunately, misunderstanding of and a lack of commitment to mastering this technique are widespread, as reflected in the multiplicity of insertion methods advocated in the literature and the common belief that a failure rate of 10% is acceptable. When variant insertion techniques are used, the failure rate is about fivefold higher than it is with the standard insertion technique. The risk of complications, such as laryngeal or pharyngeal trauma and pulmonary aspiration, probably increases even more than the failure rate when the standard insertion technique is not used. The use of variant insertion techniques also may hinder or prevent the user from acquiring the skills necessary for advanced clinical applications of the LMA. As shown in several reports, use of the standard insertion technique results in a reliable airway, a minimal stress response, and an extremely low risk of complications, probably because the LMA's position in relation to the respiratory and alimentary tracts is optimal when the standard insertion technique is used. The manuals for the LMA Classic, the FLMA, the Fastrach ILMA, and the PLMA offer step-by-step instructions on the recommended insertion technique.[23]

IV. CLASSIC LARYNGEAL MASK AIRWAY

A. Basic Uses

1. Indications for Use

Indications for LMA use have evolved since its invention. Although it has long been accepted that success rates for establishing an airway with the LMA tend to be high, even in relatively unskilled hands, it is equally clear that there is more to the art of using the LMA than getting it into place. Indications have steadily expanded as the device's popularity has spread. Just as complications tend to diminish with increasing user experience, so the more confident and more adept user seems to find applications for the LMA that might previously have seemed inappropriate. Using the LMA for airway maintenance during atrial septal defect repair in children, for example, would no doubt strike many American anesthesiologists as highly unconventional, just as it would have alarmed the inventor had it been suggested he try this in 1988.[24]

The problem of defining indications for the LMA is perhaps best resolved by recommending that, as with any skill, it is best to start at a simple level and progress gradually to more complex uses. What are appropriate basic uses for the LMA? Broadly speaking, any nonemergency case requiring general anesthesia in a patient in the supine position who has an ASA classification of I (ASA I) or II and in whom the surgeon is performing a routine, short procedure that does not involve the alimentary or respiratory tract would constitute an appropriate basic use. In practice, such cases are likely to be found in the ambulatory setting and include simple orthopedic, urologic, superficial, or gynecologic procedures. Although it involves external manipulation of the bowel, inguinal canal surgery also falls within this category.

2. Inherent Teaching Difficulties: A Vicious Circle

The learning curve for correct LMA insertion extends beyond the often cited 10 to 15 uses by one or two orders of magnitude.[25] For the anesthesiologist who is just starting to get used to the LMA, an important advantage of confining its use to simple cases is that they represent the greater part of the surgical caseload in many locations, and there are many opportunities for learning and practice. Most anesthesiology residents, however, start out in a teaching hospital, where the caseload tends to be weighted more heavily toward long and complex procedures for which LMA use would be inappropriate in any but the most experienced hands. For this reason, it is common to hear experienced U.K. and U.S. consultant anesthesiologists complain that newly appointed colleagues, who have spent the greater part of their training years in teaching hospitals, appear to have only the most rudimentary concept of LMA use. It is, unfortunately, the same academic colleagues who carry out many of the studies that make up the core of evidence-based knowledge for the LMA. This represents a vicious circle that is not easy to break, particularly at a time when there is increasing pressure on the medical profession to justify all clinical activity by reference to proven techniques. A suggested way out of this impasse is outlined subsequently.

3. Graduating from Simple to Specialized Uses of the Laryngeal Mask Airway

The safety of the patient must be the guiding principle when deciding whether someone is qualified to perform specialized uses of the LMA. A clinician whose first-time insertion success rate is 90% or less should not be considered adequately trained to progress beyond the simplest procedures in ASA I patients. Davies and colleagues reported a success rate of 94% in the first 10 cases in which naval medical trainees used the LMA for the first time in ASA I anesthetized patients.[26] The insertion success rate depends on the types of cases routinely encountered, and the preceding generalization applies to clinicians in an average peripheral hospital that performs a broad range of common procedures.

Those who wish to gain greater expertise in the use of the LMA, but whose practice is based in specialized centers that lack suitable simple cases, can consider the practice of inserting an LMA routinely at the start of a case and then switching to the preferred airway technique before the surgery. Brain found this to be a useful strategy in the teaching hospital environment. Its justification is that the skills acquired could be lifesaving in the event of an airway emergency. If the LMA has been inserted successfully and the patient subsequently proves impossible to intubate, the clinician has an already proven way of at least maintaining oxygenation while other strategies are considered. Alternatively, if the clinician has been unable to use the LMA successfully in a certain patient, time is not wasted in trying to use it after a subsequent failed intubation in this patient.

1. Procedures Outside the Operating Room

a. RADIOLOGY AND MAGNETIC RESONANCE IMAGING

The potential advantages of the LMA in investigative imaging were first described in a letter to *Anaesthesia* from Glasgow, Scotland, in 1990.[27] The investigators pointed out that the LMA permitted hands-free control of the airway in patients who needed to be kept immobile for prolonged periods, a situation often necessitating general anesthesia in restless or young patients. To improve its performance and durability, the LMA's valve later was fitted with a small, stainless steel spring, which unfortunately interfered with MRI of the head and neck. However, LMAs equipped with valves made of nonferrous material were subsequently made available for use in this situation. Stevens and Burden, in a letter to *Anaesthesia* in 1994, commented that they had used the LMA Classic with the modified, nonmetallic valve in more than 500 small children undergoing MRI and that it had proved safe and reliable.[28] They also presented an MRI image demonstrating that the FLMA could not be used for investigations involving the head and neck because the tube contained a wire, which obliterated the image of the surrounding area.

Goudsouzian and associates were the first Americans to report the efficacy of the LMA during MRI, using the images obtained during investigations in 28 children to comment on the position of the device when inserted by residents in training.[29] Despite poor user skills (21% of attempts resulted in a failure to insert, 21% of the cases required more than one insertion attempt, 82% had a downward deflection of the epiglottis, and 7% had oropharyngeal misplacement), satisfactory ventilatory parameters were maintained in all of the children. The safety of the LMA, even in less than fully skilled hands, is a powerful argument for its use in areas remote from the operating room. Van Obbergh and colleagues, working in Brussels, Belgium, presented results from somewhat more experienced users.[30] The LMA was used during MRI in 100 consecutive procedures in children that were carried out using propofol. The position of the LMA was not recorded, but only 16% of the cases required more than one insertion attempt, there were no failures to insert, and oxygen saturation values of 99.1% or above were maintained in all of the children. Ventilation was manually assisted using an Ayre T-piece.

b. RADIATION THERAPY

Grebenik and coworkers were the first to describe the use of the LMA in pediatric radiation therapy in their study of 25 children who underwent a total of 312 courses of radiation therapy under anesthesia.[31] The children were between 3 weeks and 3 years old, and eight of them were anesthetized once daily for 20 or more consecutive days. In each case, the LMA was left in place until the protective reflexes returned. The absence of complications suggests that the LMA may be appropriate for procedures requiring frequent, repeated use of anesthetics in children.

Figure 22-6 Use of the laryngeal mask airway (LMA) in a child undergoing a series of radiation treatments at the University of Texas M.D. Anderson Cancer Center in Houston. **A,** Propofol is used to induce general anesthesia, and after the LMA is inserted, the child is placed in a prone position. **B,** Continuous intravenous infusion of propofol is used as the sole anesthetic agent during radiation treatment while the child is breathing spontaneously through the LMA. This allows more rapid turnover of patients and more efficient use of the radiation therapy suite.

A major advantage of the LMA over the ETT in children receiving radiation therapy on a daily basis during a 4- to 6-week course of treatment is that the LMA does not invade the trachea. The risk of tracheal ulcerations, granulation tissue, and subsequent tracheal stenosis associated with repeated intubations with an ETT is eliminated. The LMA causes much less stimulation than does an ETT; anesthesia requirements for the LMA are significantly lower. For example, at the University of Texas M.D. Anderson Cancer Center in Houston, all children undergoing radiation therapy receive an intravenous infusion of propofol as the sole anesthetic agent during their treatment. The LMA is frequently used for airway management, and spontaneous respiration is preserved (Fig. 22-6). This allows more rapid turnover of patients and more efficient use of the radiation therapy suite.

c. DIAGNOSTIC AND SHORT THERAPEUTIC PROCEDURES IN CHILDREN

The LMA can be very useful during short diagnostic, therapeutic, and minor surgical procedures performed in children in the hospital's procedure room or in the operating room. These procedures include spinal puncture with or without intrathecal therapy, bone marrow aspirations, insertion or removal of a central line or a Port-a-Cath, and minor biopsies (Fig. 22-7). Most children tolerate these procedures well under deep intravenous sedation with propofol and local anesthesia with maintenance of spontaneous respiration. However, some children develop respiratory depression or airway obstruction during deep sedation. In those children, the LMA can be an excellent and much less invasive alternative to endotracheal intubation, resulting in a clear airway without resorting to general anesthesia and muscle relaxation.

d. CARDIOLOGY

The LMA can be useful in patients undergoing transesophageal echocardiography (TEE). TEE is an invasive procedure, and many patients experience significant discomfort or are unable to tolerate TEE under topical anesthesia. In the cardiology clinic setting, TEE is usually performed with topical anesthesia consisting of spraying the oropharynx with a local anesthetic (e.g., 4% lidocaine or 20% benzocaine), with or without sedation.[32,33] However, a significant number of patients experience discomfort during the procedure, and many cannot tolerate the insertion of the probe, even after sedation.[34,35] Because topical anesthesia and light sedation do not completely abolish the gag reflex, deep sedation or general anesthesia may be necessary for patients with highly sensitive reflexes in the upper airway and pharynx. A possible solution for patients who cannot tolerate the

Figure 22-7 Lumbar spinal tap and intrathecal therapy performed on a small child at the University of Texas M.D. Anderson Cancer Center in Houston. Continuous infusion of propofol is used to achieve deep sedation. The laryngeal mask airway (LMA) is used to maintain the open airway, and the child is allowed to breathe spontaneously. The LMA is less invasive than the tracheal tube, and less medication is required to tolerate the device.

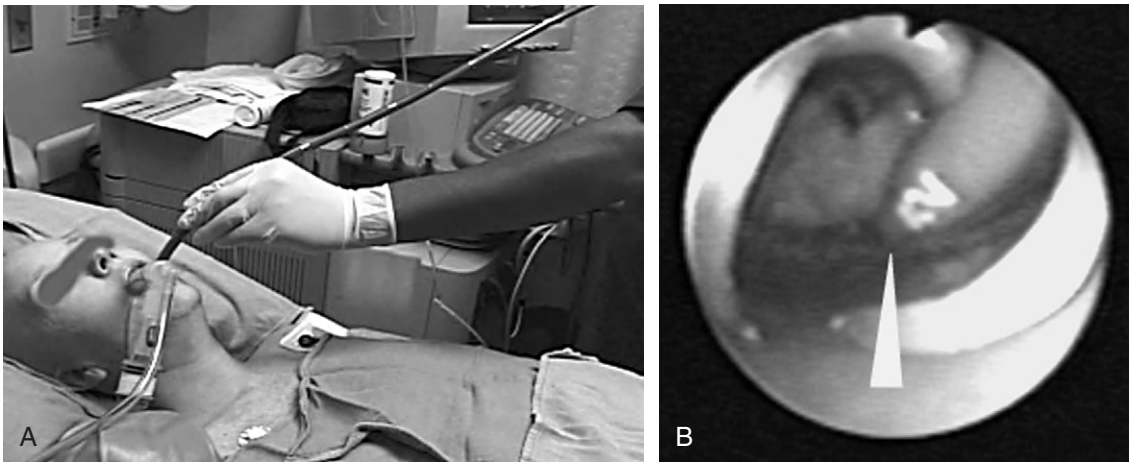

Figure 22-8 Use of the laryngeal mask airway (LMA) during transesophageal echocardiography (TEE) at the University of Texas M.D. Anderson Cancer Center in Houston. The LMA is inserted after TEE placement. **A,** The LMA does not interfere with TEE examination. **B,** Fiberoptic view through the LMA shows the TEE probe (arrowhead) inside the LMA bowl.

insertion of the TEE probe with topical anesthesia and light sedation is deep sedation with propofol. The LMA can be used to maintain the airway in patients undergoing TEE examination during deep sedation with propofol.[36] The LMA can easily be inserted with the TEE probe in place, and the presence of the LMA does not interfere with the manipulation of the probe (Fig. 22-8).

The LMA can be a better alternative than endotracheal intubation in patients undergoing cardioversion in whom face mask ventilation is difficult or inadequate. The minimal hemodynamic stimulation associated with insertion of the LMA, which contrasts with a significant hemodynamic response during endotracheal intubation, offers a great advantage in patients with cardiovascular disease.[37]

2. Head and Neck Surgery

Most of the applications of the LMA in procedures involving the head and neck are done with the FLMA. However, a unique advantage of using the LMA Classic in these patients is the access to the larynx that the device allows (Fig. 22-9), which is particularly useful for diagnostic evaluation of the larynx and trachea and during neodymium:yttrium-aluminum-garnet (Nd:YAG) laser surgery. It is difficult to manage the airway using an ETT in patients who require Nd:YAG laser treatment of lesions located in the vocal cords or the proximal part of the trachea because the ETT limits access to these lesions. There also is a high risk of a laser-induced airway fire when an ETT is used. In contrast, the LMA provides an unobstructed view of the surgical field and virtually eliminates the risk of airway fire (Fig. 22-10).

Head and neck surgery is associated with the risk of bruising or otherwise traumatizing nerves that control the motor functions of the larynx. The LMA can be useful in evaluating the function of the vocal cords at the conclusion of neck dissection and thyroid and parathyroid surgery.[38] While the patient is still under general anesthesia, the LMA is inserted behind the ETT and inflated. The anesthesiologist then removes the ETT, and

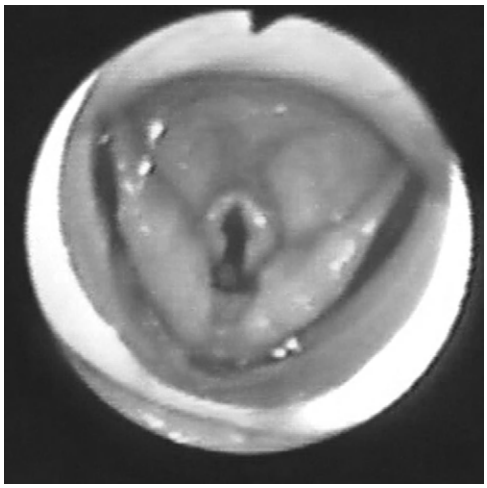

Figure 22-9 View of the larynx through a fiberscope placed coaxially through the optimally positioned laryngeal mask airway. The epiglottis is not downfolded, and the tip of the mask lies behind the larynx, occluding the upper esophageal sphincter.

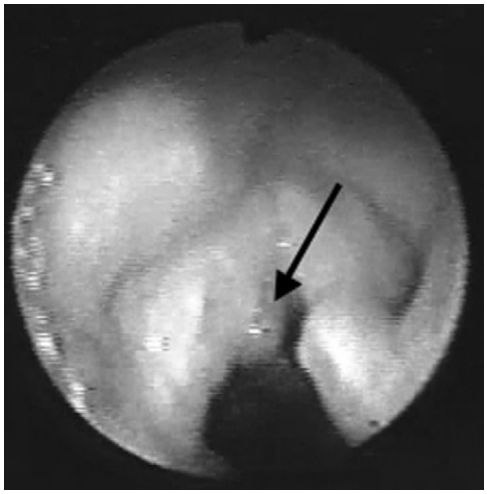

Figure 22-10 Fiberoptic view through the laryngeal mask airway of the left vocal cord lesion *(arrow)*. This type of lesion would be very difficult to treat with the Nd:YAG laser if an endotracheal tube were used.

Figure 22-11 A child was admitted to the intensive care unit after brainstem surgery at the University of Texas M.D. Anderson Cancer Center in Houston. Using deep sedation with propofol, the laryngeal mask airway (LMA) was inserted behind the endotracheal tube (ETT). After successful LMA insertion, the ETT was removed to allow visualization of the vocal cords and evaluation of their function in a spontaneously breathing child. This helped the intensivist and the surgeon determine whether the patient would be able to maintain the airway postoperatively.

the patient is allowed to breathe spontaneously. As the patient emerges from general anesthesia, a fiberoptic bronchoscope (FOB) is inserted through the lumen of the LMA to observe the function of the vocal cords. At M.D. Anderson Cancer Center, this technique has become an important diagnostic tool to detect the functional status of the nerves providing motor function to the larynx and has allowed the anesthesiologists and surgeons to make more informed decisions about the postoperative airway management of their patients. Similarly, patients undergoing brainstem surgery in the area that involves the lower cranial nerves, which control the pharynx and larynx, can be evaluated fiberoptically through the LMA in the intensive care unit. This helps the intensivist and the surgeon determine whether the patient will be able to maintain her or his airway postoperatively (Fig. 22-11).

3. Pulmonary Medicine and Thoracic Surgery

a. BRONCHOSCOPY IN CHILDREN AND ADULTS

Physicians in the fields of thoracic surgery and pulmonary medicine have shown interest in the LMA because of the unique access it provides to the larynx and respiratory tree. Diagnostic fiberoptic laryngoscopy and FOB can be performed readily through the LMA in patients under general anesthesia or under topical anesthesia with sedation.[39-41] Maekawa and colleagues, in a 1991 letter to *Anesthesiology* describing the use of a size 1 LMA as a conduit for FOB with a 3.6-mm flexible endoscope in two children (ages 2 and 8 months), listed four advantages. First, the LMA tube is much larger (5-mm internal diameter) than the corresponding ETT, permitting the use of a larger bronchoscope, which gives a better view than that obtained through the 2- to 2.5-mm bronchoscope normally required to fit through the ETT in this age group. Second, the use of the LMA permitted examination of the larynx, including vocal cord movement and the part of the trachea normally occupied by the ETT. Third, the larger-diameter LMA airway tube permits easy ventilation, which permits uninterrupted observation. Fourth, not using an ETT may be valuable in cases of laryngeal or tracheal stenosis that may be made worse by the passage of the ETT.[42]

In a letter to *Anesthesiology*, Theroux and associates described the use of the size 1 LMA as a conduit for intubation in a 2.5-kg baby with Schwarz-Jampel syndrome who could not be intubated by other means.[43] The uncuffed ETT was advanced over a 2.2-mm bronchoscope, which was easily passed into the trachea through the LMA. In 1997, Mizikov and coworkers reported their experience of using FOB through the LMA in 45 children: 15 diagnostic cases, 22 cases of lavage, 7 cases of foreign body removal, and 1 case of electrocoagulation of an adenoma.[44] Total intravenous anesthesia and PPV were used in all cases. Patients' ages ranged from neonatal to 15 years. They used the Olympus BF3C20 bronchoscope (3.6-mm diameter) with the size 1 LMA, and the Olympus BFP30 (5-mm diameter) was used with the size 2 LMA. The epiglottis was within the mask in 96.5% of cases but was not associated with significant airway obstruction in any case.

b. LASER SURGERY OF THE TRACHEA

In 1992, Slinger and colleagues provided a detailed account of a difficult case of palliative laser resection of a severely obstructing distal tracheal mass.[45] The airway was initially managed using a size 4 LMA, through which a 6-mm Olympus FOB was passed by a swivel connector to apply the laser. Spontaneous ventilation with propofol-isoflurane anesthesia was used. After 120 minutes, 50% of the tracheal lumen had been restored, at which point it was decided to convert to rigid bronchoscopy so that the surgeon could remove larger pieces of tissue by forceps, thereby facilitating the procedure. The physicians repeated this approach in two less severe cases without complications. They pointed out that the laser is not likely to burn the silicone LMA tube if it is switched on only when in the trachea. However, they stressed that use of the rigid bronchoscope remained the gold standard for such cases.

c. TRACHEOBRONCHIAL STENT PLACEMENT

Another advantage of using the LMA in patients with pathology involving the tracheobronchial tree is evident during stent placement using fiberoptic guidance.[46] The LMA's shaft permits use of a 6-mm FOB and provides a larger cross-sectional area than does a 9-mm ETT, which is usually employed during stent placement. The LMA allows better ventilation during stent placement than does an ETT in patients who already have compromised respiratory function. In patients who have an obstruction high in the trachea, the LMA is much better than an ETT because it allows placement of the stent without the risk of extubating the patient (Fig. 22-12).

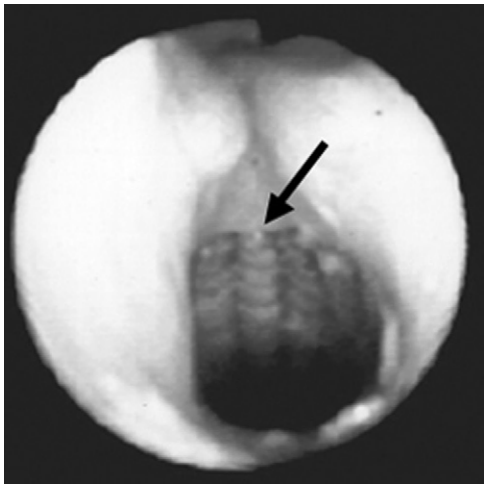

Figure 22-12 Fiberoptic view of the tracheal stent *(arrow)* placed high in the trachea (1.5 cm below the vocal cords) through the laryngeal mask airway (LMA). The LMA's shaft permits use of a 6-mm fiberoptic bronchoscope and provides a bigger cross-sectional area than a 9-mm endotracheal tube (ETT), allowing better ventilation during stent placement than the ETT in patients who already have compromised respiratory functions.

Figure 22-13 Insertion of the ProSeal laryngeal mask airway (PLMA) into a patient undergoing craniotomy with awake intraoperative speech mapping. The anesthesiologist is facing the patient and uses his thumb to insert the PLMA into the patient.

4. Neurosurgery

The hemodynamic stability associated with LMA use may be beneficial during induction in patients undergoing neurosurgical repair of an intracranial aneurysm and in patients with increased intracranial pressure. Silva and Brimacombe reported that hypertension, coughing, and bucking, all of which are common during emergence from general anesthesia with an ETT, were prevented in neurosurgical patients by replacing the ETT with the LMA at the end of the procedure.[47] The insertion and use of the LMA in patients under general anesthesia have been associated with minimal changes in intracranial pressure.[48] This characteristic may be particularly useful during ventriculoperitoneal shunt placement in children, adults, and patients who have suffered a traumatic brain injury.

Other uses for the LMA in neurosurgical patients include awake craniotomy and stereotactic procedures in children and adults. In an awake craniotomy, eloquent areas of the brain are mapped and monitored intraoperatively by stimulating the cerebral cortex with an electrical current. This direct electrical stimulation of the cerebral cortex greatly increases the risk of focal or generalized seizures. Airway management using a face mask and endotracheal intubation during generalized seizures can be very difficult because the patient is usually lying on her or his side, giving the anesthesiologist limited access to the airway, and the patient's head is fixed by metal pins and a frame to provide a stable surgical field and allow the use of modern intraoperative image guidance. However, an experienced and skilled anesthesiologist can easily insert the LMA into such patients, allowing ventilation and oxygenation in this potentially difficult clinical situation (Fig. 22-13).[49]

Stereotactic biopsies can be performed in children using the LMA. Anesthesia is induced with propofol in the radiology suite, and the LMA is inserted (Fig. 22-14). Local anesthetic is then injected to anesthetize the skin before pins for the stereotactic frame are applied. During continuous infusion of propofol, an MRI is obtained while the child breathes spontaneously through the LMA. While asleep, the child is transported to the operating room for the stereotactic biopsy. This technique provides optimal comfort for the children and excellent operating conditions for the radiologists and surgeons.

V. FLEXIBLE LARYNGEAL MASK AIRWAY

Many operations, particularly procedures performed on the head and neck, require the anesthesiologist and surgeon to share access to the airway. Traditionally, special ETTs that have a spiral coil built into them to increase the flexibility of the tube and to prevent kinking have been used to allow the surgeon to manipulate the ETT

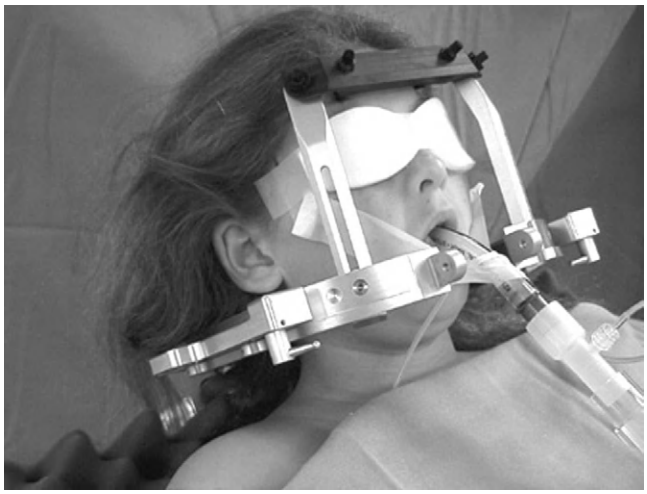

Figure 22-14 A young child undergoing stereotactic biopsy at the University of Texas M.D. Anderson Cancer Center in Houston. Anesthesia is induced with propofol in the radiology suite, and the laryngeal mask airway is inserted.

Figure 22-15 The flexible laryngeal mask airway (FLMA), which was introduced into clinical practice in 1994, has a spiral coil built into the shaft to increase the flexibility of the tube and to prevent kinking. This allows the surgeon to manipulate the FLMA's shaft during the surgery and to have good access to the operating field. The FLMA has been used successfully in patients undergoing a variety of head, neck, eye, and oral operations.

Figure 22-16 The flexible laryngeal mask airway (FLMA) was used in a patient undergoing oral surgery. Because the FLMA causes less hemodynamic stimulation than the endotracheal tube, it is safer to use in patients with severe atherosclerotic heart disease.

during surgery to gain access to the operating field. To make an LMA specifically for head and neck procedures, a similar spiral coil was incorporated into the LMA's shaft, creating the FLMA (Fig. 22-15), which was introduced into clinical practice in 1994. The FLMA has since been used successfully in patients undergoing a variety of head and neck procedures.

A. Tonsillectomy and Adenoidectomy

Several investigators have reported the successful use of the FLMA during tonsillectomies and adenoidectomies. The main advantages of using the FLMA for these procedures are better tolerance of the FLMA by the patients, fewer adverse airway events during emergence and on extubation, and less blood soiling of the airway because of the shielding of the larynx by the LMA's cuff. Williams and Bailey reported that when the FLMA was used in children during adenotonsillectomies,[50,51] there was little soiling of the trachea with blood. In contrast, when an uncuffed ETT was used, blood was almost always present in the trachea, causing coughing on emergence. At the end of surgery, there were also fewer episodes of airway obstruction in the FLMA group than in the ETT patients. This is probably because the FLMA was better tolerated by the patients, allowing extubation when the airway reflexes were less obtunded and the patients were able to maintain an open airway. Fiani and coworkers demonstrated in a randomized study of patients undergoing elective tonsillectomies that fewer complications such as laryngospasm, bleeding, bronchospasm, and desaturation occurred in the FLMA group than in the ETT group.[52]

The FLMA is useful during ear and nose surgery, such as tympanoplasty, myringoplasty, rhinoplasty, septoplasty, and nasal polypectomy.[50,53-58] As reported by Watcha and colleagues, the LMA provided better oxygen saturation and better surgical conditions in pediatric patients undergoing myringoplasties than did the face mask.[59] Although in other studies the FLMA and the ETT were equally effective in adult patients undergoing nasal surgery, there was less blood in the trachea and fewer airway events during emergence in the FLMA group.[54,59]

B. Dental and Oral Surgery

The FLMA has been useful during dental procedures and oral surgery in children and adults (Fig. 22-16).[60,61] For example, George and Sanders,[62] in a comparison of the FLMA with the nasal mask during dental procedures in children, reported significantly fewer instances of airway obstruction, oxygen desaturation, and cardiac dysrhythmias in children in the FLMA group. Other oral surgeries in which the FLMA has been used successfully include repair of a cleft palate,[63-65] glossopexy,[66] removal of a tongue tumor,[67] and fixation of mandibular fractures after failed endotracheal intubation.[68]

C. Ophthalmologic Procedures

Patients with increased intraocular pressure who are undergoing intraocular procedures are frequently at higher risk for injury from sudden pressure changes during laryngoscopy and endotracheal intubation.[69] Coughing and bucking on the ETT during emergence from general anesthesia can be detrimental and may cause suture rupture.[70] The benefits of using the FLMA for eye surgery include less change in the intraocular pressure during induction and emergence from general anesthesia and less hemodynamic stimulation.[71,72] The FLMA has been particularly useful during cataract surgery, trabeculectomy, and vitroretinal surgery.[73] Use of the device has also benefited children undergoing strabismus repair, gonioscopy, nasolacrimal duct probing, eyelid repair, scleral and conjunctival procedures, and foreign body removal.[74]

VI. LARYNGEAL MASK AIRWAY USE IN PATIENTS WITH DIFFICULT-TO-MANAGE AIRWAYS

One of the most important tasks of an anesthesiologist is to provide ventilation and oxygenation for the patient during surgery. This requires establishing and maintaining a patent airway during the course of anesthesia. As reported in 1990 in a closed claims study published by the ASA, airway-related problems were among the leading causes of major morbidity and mortality directly related to anesthesia.[75] This study laid the groundwork for the development of the ASA difficult airway algorithm, which established pathways for the care of patients with difficult-to-manage airways.[76] Although the algorithm provides an organized approach to airway management based on preoperative findings, it does not constitute a foolproof system. Many patients still prove difficult to intubate by means of conventional laryngoscopy, even when the preoperative interview and physical examination do not yield any signs of potential difficulty. Airway swelling may ensue quickly after multiple intubation attempts. Although face mask ventilation in these patients might have been adequate initially, it may soon become difficult, creating the very dangerous and potentially life-threatening situation of inadequate oxygenation.

During the past 10 years, the LMA has received much attention because it can be effective in patients who are difficult to intubate by conventional laryngoscopy and difficult to ventilate with a face mask. The success of the LMA in these patients results from its design. The LMA fits into the potential space of the pharynx much like a hand fits into a glove. In contrast to rigid laryngoscopy, insertion of the LMA does not rely on direct visualization of the larynx. Many factors that are associated with difficult rigid laryngoscopy (e.g., Mallampati class III and IV, Cormack-Lehane grade 3 and 4 views) do not affect the insertion of and ventilation through the LMA.[77,78]

A. Classic Laryngeal Mask Airway

The potential of the LMA for the emergency and nonemergency management of patients with difficult airways was appreciated shortly after its invention. In February 1983, an early prototype was used successfully by Brain in a 114-kg man undergoing laparotomy who could not be intubated. However, the first publication describing the LMA as a possible solution to airway management problems in emergency situations did not appear in the scientific literature until 1984.[79] By 1985, the LMA had been used successfully in five adults in whom difficult intubation was anticipated, and in October 1987, it was used for the first time in cases of failed pediatric intubation.[13] In 1989, Allison and McCrory used fiberoptic guidance for endotracheal intubations,[80] and in 1991, McCrirrick and Pracilio first reported an awake intubation through the LMA.[81] Numerous case reports appeared describing airway management with the LMA in several clinical situations, including adult and pediatric patients with cervical spine pathology, including cervical spine instability[12,81-84]; morbid obesity[85]; micrognathia and macrognathia[86,87]; Klippel-Feil syndrome[88]; Treacher Collins syndrome[89]; Pierre Robin syndrome[90]; Goldenhar's syndrome[91]; Hurler's syndrome[92]; Down syndrome[93]; or unexpected failed intubation associated with difficult face mask ventilation.[94,95]

A major step in recognizing the LMA's potential in the management of airway emergencies took place in 1993, when it was incorporated into the Practice Guidelines for Management of the Difficult Airway by the ASA Task Force on Management of the Difficult Airway.[76] Not enough data were available then to appreciate fully the LMA's role in difficult airway situations. By 1996, the reported experience with the LMA had substantially increased, and Jonathan Benumof, who participated in the development of the ASA algorithm, assessed the LMA's potential in a difficult airway scenario.[96] His recommendations were that the LMA should be considered as originally recommended in the emergency pathway of the algorithm and in four additional situations: during awake intubation as an aid to endotracheal intubation, as a definite airway in nonemergency situations, as an aid to tracheal intubation in anesthetized patients, and as an aid to tracheal intubation after the airway is established in emergency situations. In his review, Benumof concluded, "With multiple uses and multiple places of use, the LMA is an important option within the ASA difficult airway algorithm. More importantly, the clinical record of LMA use in 'cannot intubate, cannot ventilate' situations has been excellent, and in patients whose lungs cannot be ventilated because of the supraglottic obstruction and whose trachea cannot be intubated due to unfavorable anatomy (but not periglottic pathology), the LMA should be immediately available and considered as the first treatment of choice."[96] In 2003, Benumof's recommendations fully materialized in the Practice Guidelines for Management of the Difficult Airway that was updated by the ASA Task Force on Management of the Difficult Airway.[6] Essentially, depending on the user's level of expertise, the LMA can be used in any place in the algorithm.

B. Fastrach Intubating Laryngeal Mask Airway

In 1983, while developing the LMA, Brain conducted a fiberoptic investigation that revealed the LMA's potential as a guide for endotracheal intubation. The same year, he developed a prototype LMA and used it to intubate blindly three patients using a 9-mm ETT (Fig. 22-17). However, the development of an intubating LMA was not revisited by Brain until 1994. In response to clinicians' growing demands for a device that had the same ventilatory properties as the LMA Classic but would serve as a better conduit for intubation, he designed the Fastrach ILMA (LMA North America, San Diego, CA), which was introduced in 1997 (Fig. 22-18).

The ILMA is designed to facilitate blind or fiberoptically guided endotracheal intubations without the need to move the cervical spine during intubation. Available only in adult sizes, the ILMA consists of an anatomically curved, stainless steel tube with a 13-mm internal diameter that is connected firmly at its distal end to the laryngeal mask. The angle of the metal shaft was carefully

Figure 22-17 A prototype of the intubating laryngeal mask was built and used by Archie Brain in 1983. It was used to blindly intubate three patients who had a history of difficult intubation with a 9-mm-ID tracheal tube.

designed using measurements from sagittal MRI images to fit well into the oral and pharyngeal space while keeping the head and neck in a neutral position. Proximally, the metal shaft forms a standard 15-mm connector for the anesthesia circuit, and a rigid guiding handle serves to insert the device, eliminating the need to insert fingers into the mouth, and to stabilize and direct the device during intubation attempts. The two bars at the aperture of the LMA Classic have been replaced in the ILMA by a single, movable epiglottic elevating bar that pushes the epiglottis out of the way and allows smooth and unobstructed passage of the ETT as it emerges from the distal end of the ILMA's metal shaft (Fig. 22-19). This shaft can accommodate an ETT up to 8.5 mm in diameter. The shaft of the ILMA is shorter than that of the LMA Classic, eliminating the need for longer ETTs in patients with long necks.

The ILMA was first described by Brain and coworkers in 1997 in the *British Journal of Anaesthesia*.[97] In the same issue, there were two separate reports by Brain and Kapila and their colleagues[98,99] of early clinical experience with the ILMA. Unfortunately, Kapila's report described results obtained 3 years earlier using a more primitive prototype of the ILMA and created some confusion regarding the technique of intubation through the device. At the same time, early versions of the ILMA instruction manual included recommendations for use based on these early prototypes. Subsequently, the results from a large study that evaluated the effectiveness of the ILMA in patients with different types of difficult-to-manage airways rendered most of these earlier recommendations irrelevant by demonstrating that the only technique that improved the rate of blind intubation through the ILMA was Chandy's maneuver (Chandy Verghese, Royal Berkshire Hospital, Reading, England, personal communication, January 1998).[100]

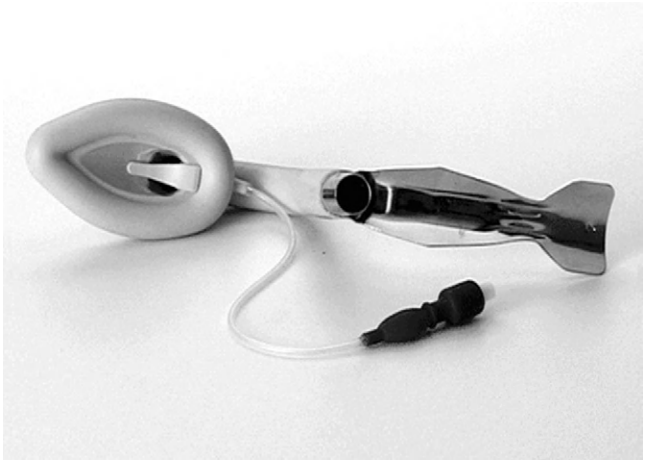

Figure 22-18 The intubating laryngeal mask airway (ILMA) was introduced in 1997. It consists of the mask, which has the same shape as the LMA Classic, and the 13-mm internal diameter, stainless steel shaft, which can accommodate an endotracheal tube with an internal diameter up to 8.5 mm.

Chandy's maneuver consists of two steps that are performed sequentially. The first step, which is important for establishing optimal ventilation, is to rotate the ILMA slightly in the sagittal plane using the metal handle until the least resistance to bag ventilation is achieved. The second step of Chandy's maneuver is performed just before blind intubation and consists of using the metal handle to lift slightly (but not tilt) the ILMA away from the posterior pharyngeal wall. This facilitates the smooth passage of the ETT into the trachea (Fig. 22-20). Ferson and colleagues assessed the effectiveness of the ILMA in 254 patients, including patients with Cormack-Lehane grade 4 views, immobilized cervical spines, and airways distorted by tumors, surgery, or radiation therapy and patients wearing stereotactic frames.[100] Insertion of the ILMA was accomplished in three attempts or fewer in all patients. The overall success rates for blind and fiberoptically guided intubations were 97% and 100%, respectively. This represents the largest analysis examining the use of the ILMA in patients with difficult-to-manage airways and demonstrates that the ILMA may be a particularly valuable tool in the emergency or elective airway management of patients in whom other techniques have failed and in the treatment of patients with immobilized cervical spines.

The ILMA can be used as an intubating tool in patients with normal airways. In a study conducted by Brain and colleagues, the hemodynamic response to the ILMA was similar to the response to the LMA Classic; in patients with compromised cardiovascular systems the ILMA could be a less stimulating alternative to rigid laryngoscopy for intubation of the trachea.[98,101] Using the ILMA in patients with normal airways allows clinicians to develop good skills and familiarity with the device before using it in emergency situations.

VII. PROSEAL LARYNGEAL MASK AIRWAY

The PLMA (LMA North America, San Diego, CA) (Fig. 22-21) was designed by Brain with the principal objective of providing a separate conduit to permit gastric fluids to bypass the glottis. He thought such a device was needed because even in fasted patients, the anesthesiologist can never be completely certain that the stomach is empty.

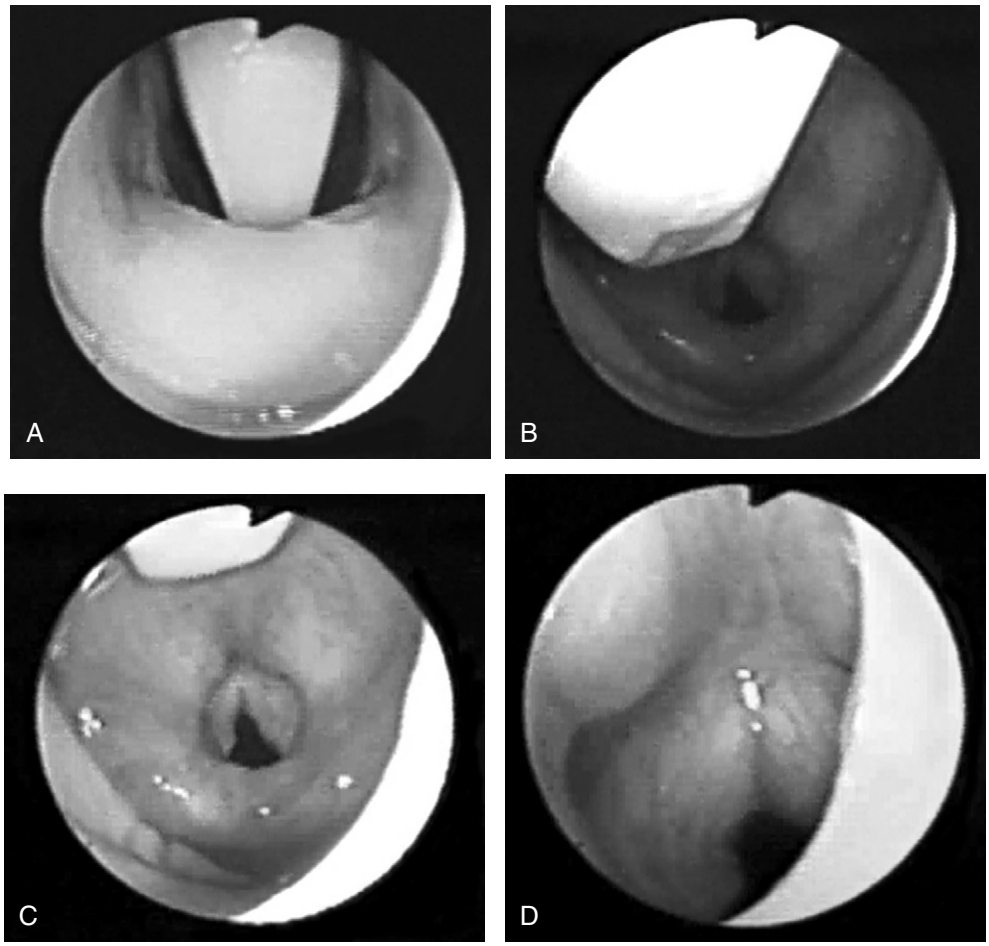

Figure 22-19 Fiberoptic view of intubation through the intubating laryngeal mask airway (ILMA). **A,** Epiglottic elevating bar (EEB) as seen from inside the shaft. **B,** The tip of the endotracheal tube (ETT), as it advances through the LMA Fastrach, pushes the EEB upward. **C,** This movement of the EEB lifts the epiglottis out of the way. **D,** It also provides a clear passage for the ETT through the vocal cords.

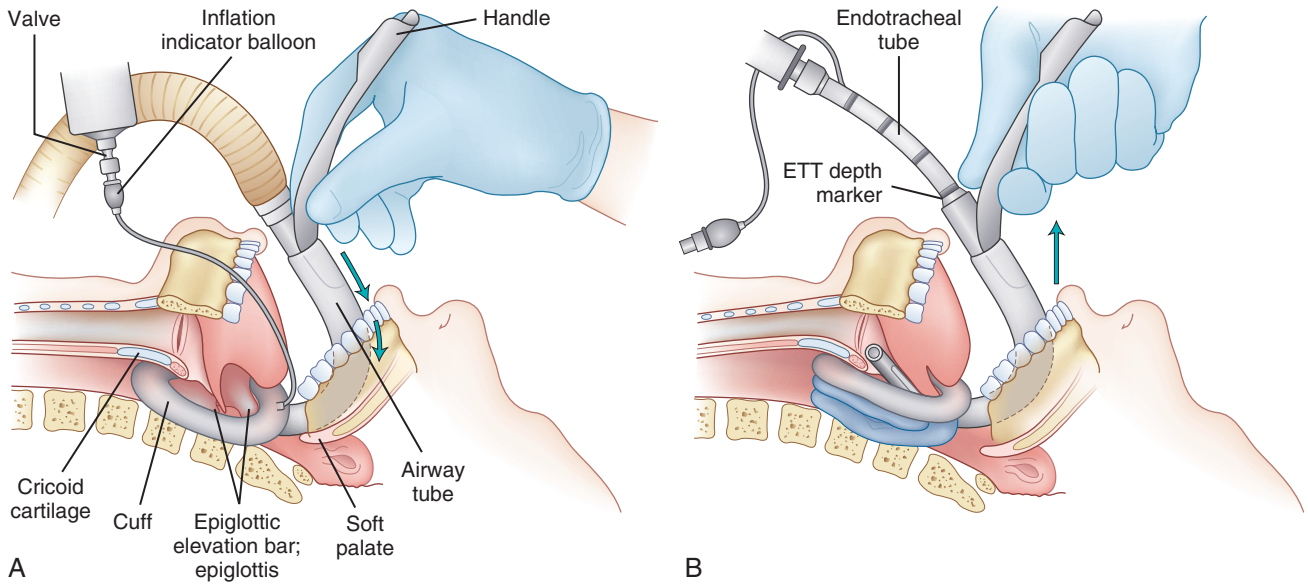

Figure 22-20 Chandy's maneuver consists of two steps that are performed sequentially. **A,** The first step is important for establishing optimal ventilation. The intubating laryngeal mask airway (ILMA) is rotated slightly in the sagittal plane using the metal handle until the least resistance to bag ventilation is achieved. **B,** The second step is performed just before blind intubation. The metal handle is used to lift slightly (but not tilt) the ILMA away from the posterior pharyngeal wall. This facilitates the smooth passage of the endotracheal tube *(ETT)* into the trachea.

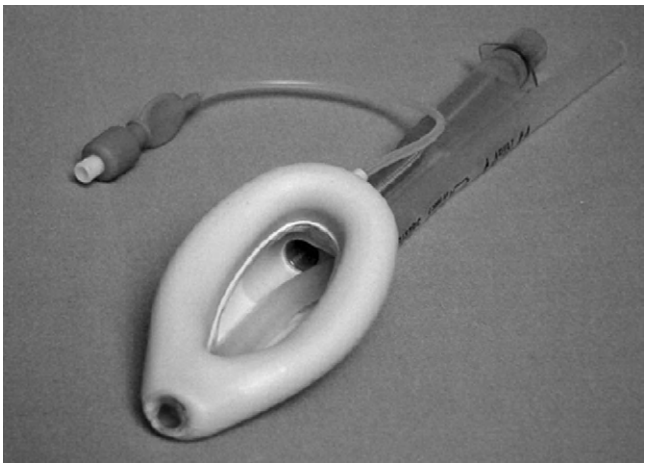

Figure 22-21 The ProSeal laryngeal mask airway (PLMA) was designed to separate the respiratory and gastrointestinal tracts and to provide a better seal around the glottis and allow positive-pressure ventilation in a more reliable manner than the LMA Classic.

The PLMA permits access to the stomach using standard gastric tubes, provides a more reliable seal around the glottis, reduces the leakage of inspired gases into the stomach, provides a more comfortable fit within the pharynx, facilitates the use of mechanical ventilation, and permits the diagnosis of incorrect LMA placement.

The LMA Classic may or may not block the esophagus, depending on how precisely it is positioned in the hypopharynx. Realizing this, Brain developed insertion and fixation techniques to ensure correct positioning, but these recommendations are widely ignored or unknown to most users, who continue to choose their own favored insertion techniques and methods of fixation. It therefore comes as no surprise that there are cases of aspiration in the LMA literature, although they are rare.[102] In the PLMA, the drain tube opening at the distal tip of the mask ensures that if the tip is not correctly placed against the UES, inflation of the reservoir bag causes some of the gas to be diverted back up the drain tube, providing measurable evidence of inadequate device placement. The PLMA instruction manual further details the diagnostic functions made possible by the drain tube.[103]

PLMA, which will soon be available in the same range of sizes as the LMA Classic (excluding size 6), has several important differences. The adult sizes are fitted with a posterior extension to the cuff that expands to a relatively small degree when inflated within the confined space of the pharynx, as demonstrated radiologically (Fig. 22-22). Similar images in which the cuff is inflated excessively demonstrate that the presence of the posterior cuff, although probably increasing the seal pressure by about 10%, introduces two dangers that must be guarded against. One is the possibility of herniating the cuff bowl forward toward the glottis, thereby causing partial or complete blockage of the delicate drain tube and compromising the airway (Fig. 22-23). Second, overinflation may cause the mask to slide proximally, reducing the efficacy of its seal against the UES. If the drain tube is blocked and its opening is simultaneously moved away from contact with the UES, the major advantages of the device are lost because there is no longer any guarantee that a seal exists against the UES, although the seal may appear to be excellent. The PLMA is therefore a more sophisticated device than the LMA Classic, and instructions for its use must be followed carefully.

Pediatric sizes of the PLMA feature the drain tube but no posterior cuff. The relatively larger airway and drain tube configuration required for optimal functioning in

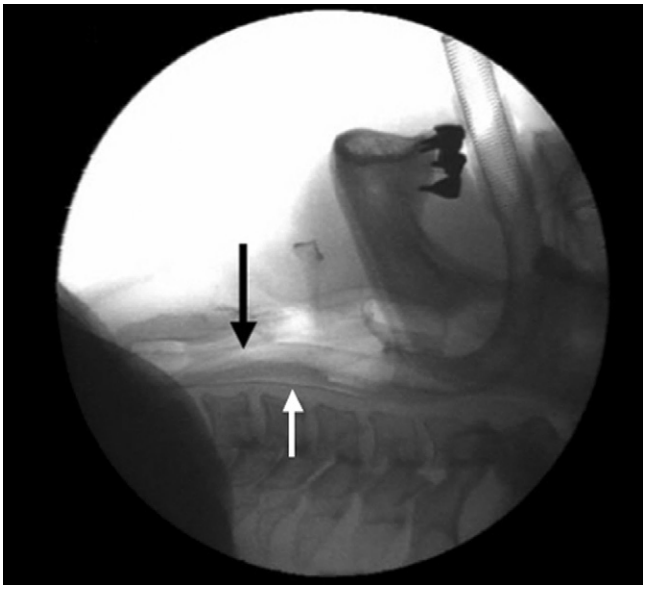

Figure 22-22 Lateral neck radiograph with the ProSeal laryngeal mask airway (PLMA) in place. When inflated correctly with a pressure up to 60 cm H_2O, the posterior cuff of the mask expands only slightly *(white arrow)*. This ensures the patency of the gastric drain tube *(black arrow)*.

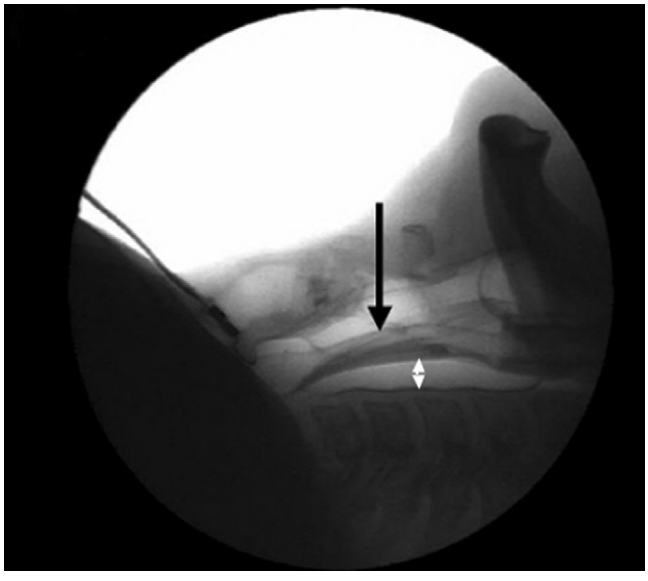

Figure 22-23 Lateral neck radiograph with the ProSeal laryngeal mask airway (PLMA) in place. If the cuff is inflated with excessive volume, exceeding a pressure of 60 cm H_2O, the gastric drain tube can be partially or completely occluded *(black arrow)* by the bowl of the mask that is pushed toward the glottis by the overinflated cuff *(white double arrow)*.

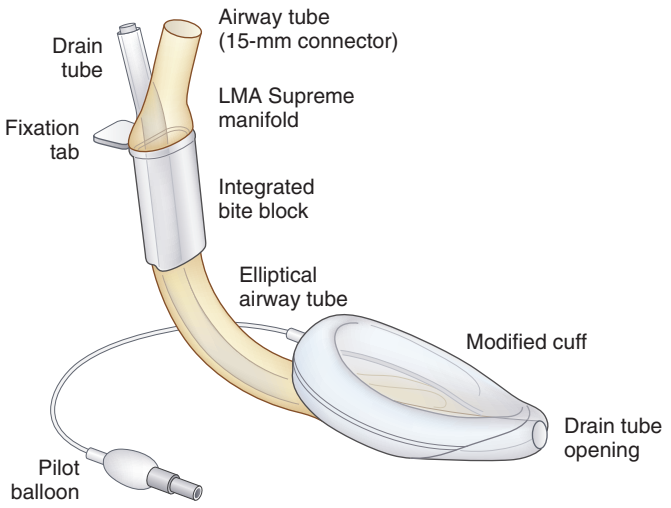

Figure 22-24 The LMA Supreme has a manifold with an integral bite block, an anatomically shaped airway tube enclosing a drain tube, a modified cuff through which the drain tube passes, and a cuff inflation line with pilot balloon.

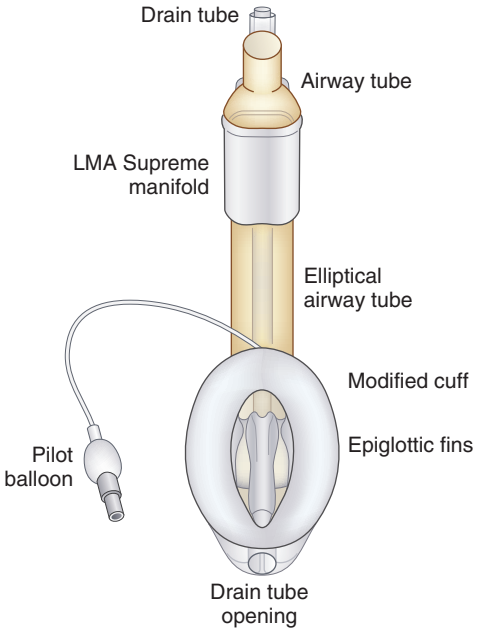

Figure 22-25 The LMA Supreme manifold and integral bite block is at the proximal end of the device. Two tubes project from the manifold. The 15-mm-diameter airway tube is designed to be connected to the airway circuit. The narrower tube is the proximal end of the drain tube.

the pediatric anatomy result in a wider device angle when viewed laterally. If a posterior cuff were added, the angle would become critically large, causing the device to slide proximally out of the pharynx as it is inflated. Halaseh and colleagues reported their experience with the PLMA in 3000 elective cesarean sections in a single center and using a method of insertion that allowed a rapid establishment of a patent airway together with gastric drainage.[104]

VIII. SUPREME LARYNGEAL MASK AIRWAY

After several years of continuous research, Brain designed the LMA Supreme (Intavent, Direct, Maidenhead, United Kingdom) as a single-use laryngeal mask airway device with gastric access. The intent was to combine some of the desirable features of the ILMA, such as ease of insertion, without the need for the insertion of the fingers into the oropharynx, and the PLMA, which offers higher seal pressures with a gastric tube access to permit drainage from and access to the stomach, and it provides confirmatory evidence of correct or incorrect device placement.

The LMA Supreme has a manifold with an integral bite block, an anatomically shaped airway tube enclosing a drain tube, a redesigned inflatable cuff (through which the drain tube passes), and a cuff inflation line with pilot balloon (Figs. 22-24 and 22-25). The LMA Supreme manifold and integral bite block is at the proximal end of the device. Two tubes project from the manifold. The standard 15-mm diameter airway tube is designed to be connected to the airway circuit. The narrower tube is the proximal end of the drain tube.[104,105]

The fixation tab is a rectangular structure molded onto the manifold at right angles, and it projects over the patient's upper lip. It is designed to facilitate easy insertion and fixation of the LMA Supreme after insertion and inflation of its cuff. The fixation tab was found in early pilot studies to act as a visual guide to correct size selection. After fixation of the device and inflation of the cuff to a pressure of 60 cm H_2O, the fixation tab should be 1.5 to 2 cm from the upper lip. If the fixation tab is less than this distance, the size chosen may be too small, and if it is more than 3.0 cm from the upper lip, the size chosen may be too large (see Figs. 22-24 and 22-25).

Extending distally from the manifold is the flattened, semirigid airway tube, which has an elliptical cross section and an integral bite block at its proximal end. The airway tube ends distally at the laryngeal inlet. The elliptical shape of the airway tube is intended to facilitate insertion in patients with reduced interdental space without requiring the insertion of fingers into the mouth. After it is in place, the flattened shape and stiffness of the airway tube also helps to minimize accidental rotation. The airway tube is much stiffer than that of the PLMA, but it is intended to bend with movements of the head and neck, unlike the completely rigid metallic airway tube of the ILMA. Patented lateral grooves on the airway tube of the LMA Supreme prevent it from kinking and occluding when bent, no matter how much it is flexed (see Figs. 22-24 and 22-25).

The drain tube runs from its rigid proximal end on the manifold through the middle of the airway tube and continues along the posterior surface of the cuff to the distal end of the cuff. At the distal end, it terminates as a centrally placed orifice designed to face into the opening of the UES, when the device is correctly inserted. The drain tube equalizes the pressure at the UES and atmosphere. In addition to venting gastrointestinal gases and liquids, the drain tube also serves as a conduit for the passage of a well-lubricated gastric tube (up to 16 F) into the stomach. The drain tube functions as a continuous clinical monitoring tool during PPV, indicating whether

the LMA Supreme is correctly positioned immediately after insertion and warning the user if the device becomes displaced from its optimal position during use. Incorrect positioning of the LMA Supreme results in a poor airway seal and an audible leak of delivered gases through the drain tube (see Figs. 22-24 and 22-25).

The modified shape and enlarged surface area of the inflatable cuff enhances the anatomic fit of the device into the pharynx, permitting higher glottic seal pressures than the LMA Classic and LMA Unique. The distal cuff is over-molded to strengthen the tip and prevent it from folding over during insertion. Two fin-shaped structures extend on either side of the drain tube where it passes through the bowl of the mask, designed to prevent the epiglottis from obstructing the airway (see Figs. 22-1 and 22-2). The cuff has a conventionally placed inflation line terminating in a pilot balloon and one-way valve for mask inflation and deflation.

The technique for LMA Supreme insertion described in the study by Balog and coworkers is similar to that recommended in the instruction manual.[74] The device was deflated to a vacuum using a 50-mL syringe and correctly shaped at the distal tip by compressing between finger and thumb during deflation to form a thin wedge. Insertion was performed with the head and neck in the semi-sniffing position. Complete extension is not required for successful insertion.[105,106]

In a prospective, descriptive study on the use of the LMA Supreme for airway management in 205 adult patients undergoing elective orthopedic surgery in the prone position, the investigators were able to demonstrate that first-pass success was achieved in 184 insertions.[107] Regurgitation of gastric contents through the LMA drainage tube was observed in 205 patients. There were no cases of clinically relevant aspiration. Sharma and colleagues concluded that the LMA Supreme was a useful device for airway management in patients anesthetized in the prone position and for possible airway management with PPV, with or without neuromuscular block.[107] No patient had to be turned to the supine position because of an airway problem during anesthesia. Brimacombe and coworkers demonstrated in 40 adult patients that maintenance of anesthesia is feasible in the prone position when the LMA Supreme was inserted by experienced users.[108]

The PLMA and LMA Supreme offer the additional advantages of higher glottic seal pressures than the LMA Classic, providing a separate conduit for passive passage of gastric contents and allowing the passage of a lubricated gastric tube through the drain tube to access liquid and gaseous gastric contents. The advantages of a higher glottic seal pressure, easy access to the stomach,[105] ease of insertion in the supine, lateral, and prone positions, efficacy for PPV, and as a reliable and noninvasive airway during the recovery phase from general anesthesia support its use in this form of surgery.

In a well-designed, randomized, prospective study comparing the safety and efficacy of the LMA Supreme with the PLMA in elective ambulatory procedures, Seet and associates included 99 patients and concluded that although the LMA Supreme has lower oropharyngeal leak pressures than the PLMA, the first attempt insertion success rate was higher for the LMA Supreme.[109] It is a safe, efficacious, and easy to use disposable supraglottic airway device suitable for elective ambulatory procedures.[109] The higher first-attempt success rate may make the LMA Supreme a more suitable choice as an airway rescue device.

The higher intracuff pressures demonstrated for the PLMA may be related to the cuff material. The PLMA is made from silicone, and the LMA Supreme is constructed from polyvinyl chloride.[106] Mucosal pressures are lower than pharyngeal perfusion pressure over the inflation range for the PLMA.[110]

Eschertzhuber and colleagues found a lower leak pressure with the size 4 LMA Supreme than with the size 4 PLMA in 93 healthy, female patients.[106] However, there was no significant difference in leak pressure with the LMA Supreme and PLMA in two other studies by Verghese and Ramaswamy[105] and Hosten and coworkers.[111] A literature review of the oropharyngeal leak pressure of the supreme LMA and the PLMA showed conflicting results. A prospective, randomized, crossover study of 36 female patients using a size 4 Supreme or the PLMA showed no difference in the oropharyngeal leak pressure (28.6 versus 28.5 cm H_2O, $P = 0.91$).[105] Hosten and associates conducted a prospective, randomized, controlled trial enrolling 60 patients (men and women) and comparing the Supreme with the Proseal.[111] Various LMA sizes (sizes 3 through 5) were used according to body weight. The leak pressures were also found to be similar for the Supreme and ProSeal groups at intracuff pressures of 60 cm H_2O (26.1 versus 26.9 cm H_2O).[111] However, muscle relaxants were given to 13 of 60 patients, which might have confused the results. The application of neuromuscular blocking agents can result in a decreased leak pressure of the PLMA and may have influenced the accuracy of measurement.[112] The lower oropharyngeal leak pressure for the LMA Supreme may be related to the less elastic properties of polyvinyl chloride.

Cuff pressures are not directly related to leak pressures. The materials play a major role in the compliance and elasticity of the device, as do the volume and elasticity of the patient's oropharyngeal anatomy, but it is also essential that the device is correctly located in the hypopharynx and that it remains securely fixed in position. The fact that leak pressures have been found by some to be lower in the LMA Supreme may be due to material differences, but it could also reflect positioning and subsequent movement of the airway after insertion.[113]

IX. DISPOSABLE LARYNGEAL MASK AIRWAYS

Infection is a perennial risk to health care workers and patients. The risk of infection in hospitals seems to be about as intractable a problem as iatrogenic disease. Newer antimicrobial agents encourage the emergence of resistant organisms just as more powerful therapeutic tools offer new opportunities for human error in their application. Although laryngeal masks have never been proved to be a source of infection transmission, the continuing uncertainty surrounding the size of the

population of Creutzfeldt-Jakob disease carriers and the risk of transmission of the infectious agent through the tonsillar bed, together with the difficulties in ensuring effective device sterilization against small virus-like particles, have led to increased interest in disposable airway equipment, particularly in some European countries. The U.K. Department of Health required surgeons and anesthesiologists to use disposable equipment for tonsillectomies but reversed this decision when the use of poorly designed disposable surgical instruments was implicated in the death of a patient. In London's main otolaryngologic hospital, the Royal Throat, Nose, and Ear Hospital, the reusable FLMA had for some years been used in approximately 90% of tonsillectomies (Paul Bailey, personal communication, March 2004), and substitution with the disposable ETT was believed to be a retrospective step. Accordingly, the Department of Health agreed to fund the cost of treating the reusable FLMA as a single-use item, pending the availability of a disposable version of the device.

The lessons learned from this experience were that we should be wary of rushing to embrace disposable forms of an established device until we are sure that their function is equivalent and that the avoidance of a theoretical risk of low probability (e.g., transmission of prion infection associated with tonsillectomy) should not take precedence over the avoidance of known risks (e.g., imposition of untried and unfamiliar equipment for an operation, the safety of which depends on skill, training, and well-established techniques).

All pediatric and adult sizes of the disposable LMA (LMA Unique; LMA North America) have been subjected to a rigorous series of tests to confirm that their function is equivalent to that of the reusable silicone device.[114,115] This has not been easy to accomplish because vinyl plastic materials lack the elasticity of silicone, and this tends to affect the insertion and seal characteristics of the LMA. It is likely that the plastic disposable LMAs will be found to be less appropriate for PPV than the LMA Classic. However, this limitation may be regarded as academic because the PLMA is specifically designed for use with positive pressure.

X. EXCHANGE USING THE AINTREE INTUBATION CATHETER

When an LMA is placed after a difficult intubation or difficult ventilation by face mask, the anesthesiologist must determine whether the airway should be secured by an ETT for the surgical procedure. The Aintree intubating catheter (AIC, Cook Critical Care, Bloomington, IN) is a semirigid, 560-mm-long tube with internal and external diameters of 47 and 70 mm, respectively.[116,117] It was designed to enable fiberoptically guided intubation of the trachea through a supraglottic airway device. The technique permits fiberoptic instrumentation of the airway while oxygenation and ventilation take place around the fiberscope through the airway device. Use of the AIC through the LMA Classic and the PLMA have been reported when conventional tracheal intubation has failed.[118-122]

The PLMA may offer additional benefits over the LMA Classic when using the AIC because of its larger airway bowl and the absence of aperture bars at the distal end of the airway tube. The deeper bowl of the PLMA and the absence of bars may allow improved access to the larynx compared with the LMA Classic and improve passage of the AIC during insertion.[123,124] The PLMA is not as easy to insert as the LMA Classic, and it has a slightly smaller internal diameter through which an AIC can easily pass.

Clinical studies have reported less than 30 intubations with the LMA Classic or the cuffed oropharyngeal airway (COPA). Both reports were executed by the inventors of the device and between them involved only three operators. On a manikin study comparing the use of AIC over the LMA Classic and the PLMA using the fiberscope, Blair and colleagues found no significant difference between the devices with regard to ease of advancement of the fiberscope or the view of the vocal cords with the AIC.[125] The study concluded that in a manikin, fiberoptically guided intubation through a PLMA was at least as easy and reliable as through the LMA Classic.[125] The technique of exchanging an LMA over an AIC has only been described in humans during difficult airway situations and found as case reports in the literature.

XI. PROBLEMS AND CONTROVERSIES

The occurrence of problems and complications associated with the use of the LMA appears to be inversely proportional to the experience and skill level of the operator. Most adverse events associated with LMA are probably the result of incorrect use of the device or inappropriate selection of patients. Some of the advanced clinical applications of the device (e.g., PPV with the LMA) have been considered controversial. However, as their experience and skill with the LMA advance, many clinicians find it to be a very useful tool in situations that they had previously considered to be problematic. The skill level and experience of the clinician, not the type of application, should guide the use of the LMA. In the following sections, we address the controversies regarding the LMA's use and discuss reported problems and complications and ways to manage them when they occur.

A. Oropharyngolaryngeal Morbidity

Any foreign body that comes into contact with airway structures can cause complications. The LMA passes through and occupies anatomic areas from the oral cavity to the hypopharynx. Structures that are at high risk for injury from supraglottic airways, including the LMA, are mucous membranes, soft tissues of the pharynx and larynx, salivary glands, nerves and blood vessels of the neck, laryngeal cartilages, and bones of the neck. When injury occurs, it usually manifests in minor complaints such as a dry mouth or sore throat.[126] These problems usually resolve quickly and have no long-term sequelae. However, more serious complications, such as hypoglossal and lingual nerve palsy, trauma to the epiglottis and larynx, dysarthria, dysphonia, and tongue cyanosis related to vascular compression, have been reported.[127-133]

1. Sore Throat

Sore throat, dry throat, pharyngeal erythema, and minor pharyngeal abrasions have been reported with the LMA. The published incidence of sore throat varies between 0% and 70%.[126,132] Initially, it was not clear why the incidence of sore throat varied so much. Factors that may affect the incidence include the insertion technique, duration of the procedure, type of lubricant, type of ventilation (i.e., spontaneous or controlled), and intracuff pressure.[134-137] Of these, the only variable that has been shown to reduce the incidence of sore throat reliably is lowering the intracuff pressure.[138] Overinflation of the LMA's cuff is a common practice when the size of the device is too small for a given patient and the practitioner encounters a significant leak while attempting assisted ventilation or PPV. The overinflated cuff becomes stiff and exerts high local pressure on tissues, especially those surrounding bony structures, such as the hyoid bone and cervical spine. Nitrous oxide diffuses through the silicone walls of the LMA, increasing the pressure inside the cuff.[139] This can be remedied by monitoring the intracuff pressure and periodically withdrawing the gas from the LMA's cuff. Based on Brain's unpublished research in awake volunteers, the maximum pressure inside the LMA's cuff should not exceed 60 cm H_2O because higher pressure causes discomfort, presumably because of stretching of the constrictor muscles. Appropriate LMA size selection combined with a good insertion technique and low intracuff pressure reduces significantly the incidence of postoperative sore throat.

2. Vascular Compression and Nerve Damage

Although rare, compression of the blood vessels of the tongue that leads to tongue cyanosis has been observed after LMA insertion.[130] This complication is likely to occur when the LMA is not inserted deeply enough or when the LMA's cuff is overinflated. The blood vessels of the tongue or the lingual nerve can be compressed by malpositioning of the LMA's shaft on the lateral side of the tongue, as found in cadaveric research. Similarly, if during LMA insertion the cuff is partially or fully inflated, the device frequently lies higher than when the correct insertion technique is used. Malpositioning of the LMA can compress the lingual or hypoglossal nerve, resulting in transient or prolonged nerve palsy. The hypoglossal nerve, which supplies all of the intrinsic and all but one of the extrinsic muscles of the tongue, is particularly vulnerable to injury at the point where the nerve loops anteriorly, close to the greater cornu of hyoid bone, and then runs along the lateral surface of the hyoglossal muscle and above the posterior border of the mylohyoid muscle before dividing into several branches that supply tongue muscles. To avoid these complications, the anesthesiologist should select the appropriate LMA size, use the standard insertion technique, and ensure that the intracuff pressure is no higher than 60 cm H_2O.

B. Risk of Aspiration

Aspiration during general anesthesia has an overall incidence of 1.4 to 6.5 per 10,000 cases and a mortality rate of 5%.[140-143] In a study of 215,488 anesthesia cases, Warner and coworkers reported that the incidence of aspiration was 2.6 per 10,000 patients undergoing elective surgery and 11 per 10,000 patients undergoing emergency procedures.[144] The mortality rate was 0.14 per 10,000 patients with an ASA physical status classifications III through V. The study by Warner and colleagues did not include patients whose airways were managed using the LMA.[144]

The LMA does not reliably protect against aspiration and should not be used electively in patients who are at high risk for this complication. However, most users do not adhere to the recommended insertion or fixation techniques when using the LMA, which are designed to optimize the seal of the distal end of the device against the UES. Nonetheless, a meta-analysis of the literature on the LMA by Brimacombe and Berry revealed that the overall incidence of pulmonary aspiration with the LMA is approximately 2 per 10,000 patients.[145] Eighteen cases of suspected pulmonary aspiration during LMA use have been found by meta-analysis, and only 10 of these were confirmed radiographically. In only three patients did the aspiration warrant ventilatory support, which lasted 1 to 7 days. None of the patients who aspirated through the LMA suffered any long-term effects. Most of these patients had one or more factors predisposing them to aspiration, including emergency surgery in an unfasted patient, a difficult airway, obesity, a steep Trendelenburg position with intra-abdominal insufflation, and previous gastric surgery. Although the meta-analysis study contained only reports published through September 1993, a subsequent analysis of 11,910 LMA anesthesia cases by Verghese and Brimacombe yielded an even smaller incidence of aspiration (0.84 per 10,000).[146]

A study by Bernadini and Natalini compared the risk of pulmonary aspiration in patients whose lungs were mechanically ventilated through an LMA airway (35,630 procedures) or ETT (30,082 procedures).[147] Three cases of pulmonary aspiration occurred with the LMA and seven with the ETT. No deaths were related to pulmonary aspiration. The incidence and outcome of pulmonary aspiration detected in this study were similar to those previously reported. The adjusted odds ratio (OR) for pulmonary aspiration with the LMA was determined to be 1.06 (95% confidence interval [CI], 0.20 to 5.62). Unplanned surgery (OR = 30.5; 95% CI, 8.6 to 108.9) and male sex (OR = 8.6, 95% CI, 1.1 to 68) were associated with an increased risk of aspiration and age younger than 14 years with a reduced risk (OR = 0.21; 95% CI, 0.07 to 0.64). There were contraindications and exclusions to the use of the LMA, but in this selected population, use of an LMA was not associated with an increased risk of pulmonary aspiration compared with an ETT.

Even allowing that critical events in anesthesia are frequently under-reported, the absence of admissions to intensive care units for ventilatory support indicates that aspiration with the LMA is rare. Nevertheless, the anesthesiologist must always be meticulous about selecting patients appropriately, using the correct insertion technique to obtain the optimal LMA position,

paying attention to the appropriate depth of anesthesia, and maintaining constant vigilance during surgery. If regurgitation or aspiration occurs despite all of these measures, the following plan of action should be implemented:

1. Do not attempt to remove the LMA because a significant amount of regurgitant fluid may be trapped behind its cuff. The cuff shields and protects the larynx from the trapped fluid, and removing the LMA may worsen the situation.
2. Temporarily disconnect the circuit to allow drainage of the fluid while tilting the patient's head down and to the side.
3. Suction the LMA, and administer 100% oxygen to the patient.
4. Ventilate the patient manually using low gas flows and small tidal volumes to minimize the risk of forcing fluid from the trachea into the small bronchi.
5. Use a large FOB to evaluate the tracheobronchial tree, and suction any remaining fluid.
6. If aspiration below the vocal cords is confirmed, consider intubating the patient with an ETT, and institute appropriate treatment protocols.

The risk of aspiration with an LMA is likely to be significantly reduced with the PLMA, which incorporates a drainage tube into the LMA design, warns of an inadequate UES seal, and permits more reliable PPV than does the LMA Classic.

C. Positive-Pressure Ventilation

When the first independent trial of the LMA was carried out, only a size 3 was available, and the correct fixation technique for ensuring an adequate seal against the UES had not been developed.[148] When used in large patients, the device was not very reliable for applying PPV. Because the LMA concept was new, it was prudent for clinicians initially to limit the use of the LMA to patients who were breathing spontaneously. Even now, PPV should be considered an advanced use of the LMA, and clinicians should practice and gain experience using the LMA in patients who are breathing spontaneously before attempting controlled ventilation. However, after the LMA was introduced commercially in a range of sizes, first for adults and then for children, many LMA users found that after they became experienced, the LMA could be effective during PPV.[73] Devitt and colleagues compared the effectiveness of the LMA with that of the ETT in 48 patients and demonstrated that PPV (range, 15 to 30 cm H_2O) through the LMA was adequate and comparable to that achieved through the ETT.[149] Epstein and associates studied the effectiveness of the LMA with controlled ventilation in children 3 months to 17 years old and concluded that the device performed effectively and reliably.[150] In another study, Epstein and coworkers established that the airway seal pressures (25.9 to 31.2 cm H_2O) were well maintained with the LMA in children.[151]

Two large clinical studies of more than 7000 patients led by Verghese and Van Damme established that the LMA was as effective as the ETT for controlled ventilation.[114,152] Van Damme's study also assessed the airway seal pressures and demonstrated that at 15 cm H_2O or less pressure, leaks occurred with the LMA in only 2.7% of patients. Subsequently, Verghese reported his experience of using the LMA successfully in 5236 patients undergoing a variety of surgical procedures under general anesthesia and PPV.[147]

The following principles should be considered when using the LMA with PPV:

1. *Selection of patients*: Most patients with normal lung compliance who have fasted can be mechanically ventilated effectively with the LMA.
2. *Size selection*: Select the largest LMA size appropriate for the patient, which prevents a tendency to compensate for inadequate seal pressure by overinflating the cuff.
3. *Insertion technique*: Carefully follow the correct insertion technique to ensure optimal positioning of the LMA in the airway.
4. *Fixation technique*: Use the correct method of taping the LMA. This ensures proper contact between the LMA's tip and the esophagus and prevents gastric insufflation.
5. *Auscultation*: Always auscultate over the stomach to ensure that gastric insufflation is not taking place.
6. *Ventilatory parameters*: Limit tidal volumes to 8 mL/kg, and control the end-tidal carbon dioxide by adjusting the respiratory rate.
7. *Treatment of inadequate tidal volume*: Maintain an adequate level of anesthesia for the particular surgical procedure.

If leaking occurs when using the LMA for PPV, investigate the cause, and try to correct the situation. If the device has been correctly fixed in place and remains correctly inflated, the problem usually is caused by the need for more relaxant or deeper anesthesia.

D. Use for Prolonged Procedures

The maximum duration for which the LMA can be safely used is not well established, but a limit of 2 hours was suggested soon after the LMA became widely available for clinical use.[82] This recommendation was based on the possible increased risk of aspiration or pharyngeal morbidity. Subsequent reports demonstrated that in the hands of experienced users, the LMA can be safely used during procedures lasting up to 8 hours.[153,154] In rare circumstances, the LMA has been used in the intensive care arena to provide effective respiratory support for 10 to 24 hours with no evidence of adverse effects.[155] The PLMA, which is designed for PPV and has a gastric drainage tube to minimize the risk of aspiration, may be best suited for prolonged procedures.[156] Regardless of the model used, clinicians must remain vigilant and provide adequate anesthesia to their patients, minimizing the risks of complications. If nitrous oxide is administered to the patient, the anesthesiologist should remember that this gas diffuses into the LMA's cuff, increasing intracuff pressure. During prolonged LMA use, close monitoring

of the intracuff pressure is recommended. To minimize the risk of mucosal ischemia associated with high intracuff pressures, hourly removal of a few milliliters of air from the cuff is considered a prudent practice.[157]

E. Use in Nonsupine Positions

Use of the LMA in patients in other than the supine position should be considered an advanced technique.[158-163] An alternative plan is necessary in case the device dislodges from its original position during the procedure. Because of the risk of LMA dislodgment in patients in nonsupine positions, consider inducing general anesthesia and inserting the LMA after the patient has been positioned for the procedure. This ensures the feasibility of inserting the LMA at any time during the procedure. If insertion cannot be performed successfully, reconsider whether the LMA should be used in that patient. The LMA insertion technique in patients in the lateral or prone position is significantly different from the insertion technique in supine patients. Using a thumb to insert the LMA may be the most useful method in patients positioned prone or laterally.[164] An advantage of using the LMA in patients in the prone position is that they are able to position themselves comfortably before induction of general anesthesia, potentially reducing the incidence of back problems.[165]

F. Device Problems

Before its clinical release, the LMA was subjected to rigorous testing to ensure compliance with the medical industry standards. However, some complications have been reported, including separation of the LMA cuff from the shaft,[166,167] fragmentation of the device inside the patient,[168] kinking of the LMA's shaft,[169] and failure to inflate or deflate the cuff.[170,171] Most of these complications are related to use of the device beyond the manufacturer's recommendations and to use of the wrong chemicals for sterilization and coating the device with silicone lubricants, which are not recommended for the LMA. Strict adherence to the manufacturer's instructions for cleaning, sterilization, and use should always be followed, including not exceeding the recommended 40 uses per device. Instructions from the manufacturer's manual should be followed if a malfunction occurs. With the introduction of the disposable LMA models, the number of device problems linked to overuse and wrong sterilization techniques may be eliminated, but all LMAs should be inspected and tested before use to ensure optimal performance and safety.

XII. CONCLUSIONS

When the LMA was first introduced, it was considered to be an alternative to the face mask. However, its clinical applications have exceeded the original recommendations and benefit patients undergoing operations in all surgical and anesthetic subspecialties. Modern surgical techniques often are much less invasive than traditional operations, and many patients undergo procedures in day surgical centers. The LMA is much less stimulating to patients than the ETT and is considered the first choice for diagnostic and minimally invasive surgical procedures. The LMA has been effective and frequently life-saving in patients with difficult-to-manage airways. A study by Combes and colleagues demonstrated that the ILMA and gum elastic bougie were the most frequently used and most successful techniques in patients with unexpected difficult intubation in the operating room.[172]

The LMA has unequivocally established the precedence that the supraglottic approach to airway management is feasible and preferred in many clinical situations. This has created an interest on the part of the medical industry in developing other supraglottic airways. Although this represents a healthy exploration of different clinical approaches to airway management, clinicians should be careful when inserting these devices into their patients because there are no separate standards or regulations guiding the safety and efficacy of supraglottic airways. The responsibility for any complications from these devices rests with the clinicians using them. The American Society for Testing and Materials and the U.S. Food and Drug Administration recently developed standards and regulations for supralaryngeal airways. These standards can guide the development of airway devices, which we hope will have the same record of safety as the LMA.

XIII. CLINICAL PEARLS

- Learn and follow the correct maneuvers for precise insertion and fixation of each of the LMA devices as thoroughly described by Brain. Extensive research has demonstrated that using the proper insertion and fixation techniques leads to higher success rates for insertion and less troubleshooting.
- Optimal results on placement of all LMA types are achieved when the tip of the LMA is delivered to the upper esophageal sphincter (UES).
- Anesthesiologists must understand the advantages and disadvantages of using the LMA.
- Ventilation through the LMA when intubation and face mask ventilation have failed may be a life-saving procedure.
- Proper patient population selection, appropriate LMA selection, adequate size selection, proper attention to the adequate depth of anesthesia (especially when the patient is not paralyzed), and maintenance of an intracuff pressure no higher than 60 cm H_2O (44 mm Hg) enhance the safety and efficacy of all LMAs.

VIII. **Conclusions**

IX. **Clinical Pearls**

I. INTRODUCTION

Nothing is more fundamental to the practice of general anesthesia than the maintenance of a clear upper airway. The choice of device depends on several factors, including access to the airway, duration of surgery, and risk factors for aspiration. After placement, the cuffed ETT provides a secure airway and protects against aspiration, but placement and removal of an ETT require training and judgment. Although ETTs typically are used without incident, complications ranging from trivial to life-threatening can occur.[1]

Advanced airway management depends on many airway devices, several of which have been included in the American Society of Anesthesiologists (ASA) difficult airway algorithm.[2] The Classic laryngeal mask airway (LMA Classic, LMA North America, San Diego, CA) was introduced into clinical practice in 1988. Since then and particularly in the past 10 years, there has been an explosion of supraglottic airway devices (SADs) designed to compete with the LMA Classic, especially single-use devices. The introduction of single-use devices has been driven by concern about the sterility of cleaned, reusable devices (e.g., elimination of proteinaceous material, risk of transmission of prion disease) and the inability to recycle the device enough to be cost-effective. More than 20 manufacturers produce single-use LMs. Other designs of SADs have been introduced, and they are the main focus of this chapter.

II. NOMENCLATURE

The term *supraglottic airway device* (SAD) is used to describe a group of airway devices designed to establish and maintain a clear airway during anesthesia. SADs have several roles, including maintenance of the airway during spontaneously breathing or controlled-ventilation anesthesia, airway rescue after failed intubation or out of the hospital, use during cardiopulmonary resuscitation, and use as a conduit to assist difficult tracheal intubation. Brimacombe recommended that the term *extraglottic airway* be used, because many of these devices have components that are infraglottic (i.e., hypopharynx and upper esophagus).[3] This textbook describes all airway devices that have a ventilation orifice or orifices above the glottis as *supraglottic* and those that deliver anesthetic gases or oxygen below the vocal cords (e.g., transtracheal jet ventilation, cricothyrotomy) as *infraglottic*. Other terms and acronyms include supraglottic airway (SGA), extraglottic airway device (EAD), and periglottic airway device (PAD), but SAD is more widely accepted and is used in this chapter.

Brimacombe and Miller suggested there should be a classification system for this increasingly complex family of devices. Miller[4] described three main sealing mechanisms: cuffed perilaryngeal sealers, cuffed pharyngeal sealers, and cuffless, anatomically preshaped sealers. Further subdivision can be made by considering whether the device is single use or reusable and whether protection from aspiration of gastric contents is offered. The practical value of this type of classification is uncertain. Chapters 22 and 27 review the LMA, its variants, and the Combitube.

The acronym *LMA* is a protected term and should be used to refer to any laryngeal mask airway produced by the manufacturers of the LMA Classic (LMA North America and associated international companies). The acronym *LM* refers to a laryngeal mask manufactured by anyone other than the original manufacturers.

First-generation SADs are devices that can be considered simple airway tubes. They include the LMA Classic, a flexible LMA (LMA Flexible), and all LMs. They also include the Laryngeal Tube and the Cobra perilaryngeal airway (CobraPLA). They may or may not protect against aspiration in the event of regurgitation, but they are not specifically designed to lessen this risk.

Second-generation SADs have been designed with safety in mind, and they incorporate design features that aim to reduce the risk of aspiration.[5] They include the ProSeal LMA (PLMA), i-gel, LMA Supreme, Laryngeal Tube Suction II (LTS-II), disposable version of the LTS (LTS-D), the Streamlined Liner of the Pharynx Airway (SLIPA), and the Baska mask. The efficacy of several of these designs has not been proven.

III. LIMITATIONS OF THE CLASSIC LARYNGEAL MASK AIRWAY

Prior to 1988, choices of airway devices essentially were limited to the face mask and endotracheal tube (ETT). The LMA Classic was designed by Archie Brain in the United Kingdom in the early 1980s, and it was introduced into anesthetic practice in 1988. Its introduction revolutionized airway management (Fig. 23-1). It was soon recognized to be a suitable device to use for many cases that previously were managed with a face mask or an ETT, because the LMA Classic had many advantages over both devices.[6] It has been used in approximately 200 million episodes of anesthesia globally. More than 2500

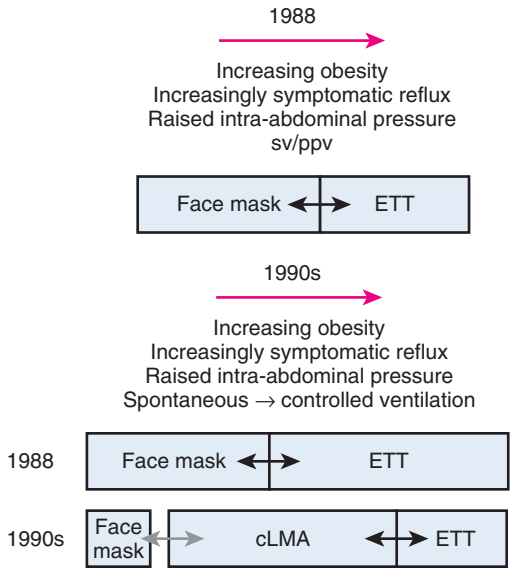

Figure 23-1 Evolution of airway choices before *(top)* and after *(bottom)* the introduction of the LMA Classic in 1988. *cLMA,* LMA Classic; *ETT,* endotracheal tube; *ppv,* positive-pressure ventilation; *sv,* spontaneous ventilation.

studies on the device have been published. The LMA Classic is considered the benchmark against which other SADs are judged. A 2008-2009 UK census found that 56% of all episodes of general anesthesia were delivered with a SAD as the primary airway,[7] and 90% of the devices were LMAs and LMs.

When correctly placed, the mask lies with its tip behind the cricoid cartilage at the esophageal inlet, with the airway orifice facing anteriorly and the cuff encircling the laryngeal inlet. The lateral cuff lies against the piriform fossa, and the upper cuff is located at the base of the tongue. The mask is held in a stable position by the hypopharyngeal constrictor muscles laterally and the cricopharyngeus muscle inferiorly. Inflation of the mask cuff produces a low-pressure seal around the larynx.

Limitations of the LMA include problems with controlled ventilation, airway protection, access through the airway for intubation, reusable design, and absence of a bite block. The first two limitations limit the case mix for which the LMA Classic is suitable.

A. Problems with Controlled Ventilation

The LMA Classic performs well during spontaneous ventilation, but it is so widely used during controlled ventilation that this is no longer considered an advanced use. The LMA Classic is an alternative to anesthesia with a face mask or an ETT. Its introduction has transformed the routine practice of anesthesia, and face mask anesthesia has become uncommon. However, the LMA Classic is not suitable for all cases, and good case selection is the key to successful use.

The LMA Classic usually seals the pharynx with a pressure of 16 to 24 cm H_2O, and this airway leak pressure is rarely above 30 cm H_2O. This relatively low- pressure seal means that when positive pressure is applied to the LMA Classic, gas leakage is common. Studies have shown a 5% failure rate for achieving an expired tidal volume of 10 mL/kg,[8] an audible leak in 48% of patients when ventilating to peak pressures of 17 to 19 cm H_2O, and a detectable leak rate as high as 90%, with an 8% failure rate for adequate ventilation.[9,10] Devitt and colleagues applied increasing peak airway pressures while ventilating through an LMA Classic. They found that as the airway pressure rose from 15 to 30 cm H_2O, the incidence of audible leak rose from 25% to 95%, and the leak fraction ([inspired minute volume–expired minute volume]/inspired minute volume) rose from 13% to 27%.[11] As the airway pressure increased, the incidence of airway leak into patients' stomachs rose from 2% to 35%. These findings indicate that the LMA Classic has a relatively low-pressure airway (pharyngeal) seal and that as higher airway pressures are applied, there is a risk of loss of ventilating gases and gastric inflation. Loss of ventilating gases is associated with hypoventilation, loss of anesthetic agent, and environmental pollution, and gastric inflation that may increase the risk of regurgitation.

B. Problems with Airway Protection

Several factors affect the risk of and protection against aspiration during use of a SAD. A device with a good pharyngeal seal minimizes the risk of air leak into the esophagus during positive-pressure ventilation, especially if airway pressures rise. A correctly positioned drain tube that is not obstructed by mucosa can vent gas entering the upper esophagus and minimize the risk of gastric inflation. If regurgitation does occur, a correctly positioned drain tube can vent liquid (and solids if large enough) so that it bypasses the oral cavity and alerts the anesthesiologist to the occurrence of regurgitation.

Several factors determine whether regurgitant fluid can enter the glottis: the seal between the tip of the SAD and the upper esophagus (i.e., esophageal seal), the bulk of the SAD in the hypopharynx and oral cavity, the pharyngeal seal, and perhaps the presence of a sump. Reliable placement of a gastric tube through a SAD enables stomach emptying and reduces the risk of regurgitation and aspiration. Many protective factors depend on correct positioning of the SAD. A device that is reliably placed in the correct position is likely to provide better protection. A malpositioned device likely disrupts the pharyngeal and esophageal seals, may displace or obstruct the drain tube, and may lead to high airway pressures during positive-pressure ventilation. The ability to check correct device position (e.g., PLMA) is another benefit. Among available SADs, the ProSeal LMA has the most evidence for protection against regurgitation and aspiration.

The LMA Classic is not regarded as providing protection against aspiration of regurgitated gastric contents and is contraindicated for patients who are not fasted or who may have a full stomach. The LMA Classic has a pharyngeal seal that is usually in the range of 16 to 24 cm H_2O. Its tip obturates the upper esophagus, and it has an esophageal seal of 40 to 50 cm H_2O, but it has no drain tube.[12] Despite this design, cadaver work shows the LMA Classic protects the glottis from regurgitant esophageal fluid considerably more efficiently than the unprotected airway.[13]

Soon after the introduction of the LMA Classic, several small studies raised concerns about the ability of the LMA Classic to protect the airway from regurgitant matter and therefore from pulmonary aspiration. Early concerns were raised that the LMA Classic, sitting at the back of the throat, might stimulate a swallowing reflex, especially during light planes of anesthesia, leading to relaxation of the upper and lower esophageal sphincters and increasing the risk of regurgitation and aspiration. A physiologic study recorded a fall in the lower esophageal barrier pressure of 4 cm H_2O during LMA Classic anesthesia, compared with a 2 cm H_2O rise during face mask anesthesia.[14] A study using swallowed methylene blue capsules demonstrated a 25% incidence of soiling of the inner portion of the LMA Classic on removal, and a small study reported a 2% incidence of aspiration, which occurred during spontaneous and controlled ventilation.[15,16]

As experience has accumulated, the evidence of a fundamental problem with aspiration has been reevaluated. Until 2004, 16 years after its introduction, there were no published reports of fatal aspiration during use of an LMA Classic. In 2004, Keller and colleagues published a series of three cases of serious morbidity, including one death from aspiration during LMA Classic

anesthesia.[17] Each case had risk factors for aspiration, and on reviewing all 20 published reports of aspiration during use of an LMA Classic, the investigators found identifiable risk factors in 19 of 20 cases. In the accompanying editorial, Asai listed more than 40 factors that increased the risk of aspiration.[18] Several large studies have shown a low rate of aspiration; Verghese and Brimacombe reported a series of 11,910 uses (40% with controlled ventilation, 19% during intra-abdominal surgery, and 5% with a duration longer than 2 hours).[19] Insertion success rate was 99.8%, the incidence of airway-related critical incidents was 0.16% during spontaneous ventilation and 0.14% during controlled ventilation, and there was one case of aspiration. Bernardini and Natalini reported three aspirations in a series of 35,630 LMA Classic uses for controlled ventilation (1 of 11,877).[20] In an editorial, Sidaras and Hunter[21] estimated an incidence of confirmed pulmonary aspiration during LMA Classic use of 1 in 11,000, and Brimacombe and Berry's meta-analysis calculated a risk during elective surgery of 1 case in 4300 operations.[6] This is similar to the rate of aspiration reported by Warner and colleagues in a study of 214,000 patients predating use of the LMA, in which aspiration occurred in 1 in 4000 elective operations.[22]

Although the risk of aspiration is relatively low in expert hands, this rate is achieved primarily by careful and appropriate case selection, expert insertion, and meticulous management of the airway after insertion. The Fourth National Audit Project of the Royal College of Anaesthetists and Difficult Airway Society (NAP4) in the United Kingdom studied major airway complications of 2.9 million episodes of general anesthesia and found that aspiration was the most common cause of airway-related deaths.[1] One third of these complications occurred during maintenance with a LM or LMA in place, and for many of the patients, the risk of aspiration made this unwise.

Aspiration remains a significant cause of morbidity and mortality during anesthesia, and all anesthesiologists should consider the patient's risk for aspiration before selecting the appropriate airway device. In making that selection, they should consider the degree of protection provided by the airway device, particularly when using a SAD.

C. Problems with Accessing the Airway for Intubation

The LMA Classic sits over the vocal cords in more than 90% of cases and may be used as a conduit for intubation, but several factors limit the ease of this application.[23] The internal lumen of the device is relatively narrow, limiting the size of ETT that can be passed. Size 4 and 5 LMA Classic devices accommodate most manufacturers' cuffed ETTs with internal diameters (IDs) of 6.0 and 6.5 mm, respectively. A tube of adequate length must be used to exit the LMA Classic and reach the midtrachea; an ETT of approximately 29 cm can be placed through a size 5 LMA Classic. Across the distal end of the airway tube are two flexible bars forming a grill that prevents the tongue from impeding insertion and the epiglottis from causing obstruction after placement; these bars may act as an impediment to intubation through an LMA Classic. The angle at which an ETT exits the mask of the LMA Classic means that blind insertion frequently leads to esophageal intubation. Brimacombe reported blind intubation with an ETT through the LMA Classic to have a first-time success rate of 52% and overall success rate of 59%.[24] Use of a bougie is less successful (32% of first attempts and 45% overall), and even fiberoptically guided techniques have a failure rate of 18%. After intubation has been achieved, removal of the LMA Classic without displacement of the ETT is cumbersome. Overall, direct intubation through the LMA Classic is a far from ideal technique.

The technique is dramatically improved if an Aintree intubation catheter (AIC, Cook Critical Care, Bloomington, IN) is used.[25] The hollow AIC (ID of 4.6 mm, external diameter [ED] of 7.0 mm, length of 46 cm) is placed over a fiberscope, the scope and AIC are negotiated through the LMA Classic into the midtrachea, and the fiberscope then is removed, followed by removal of the LMA Classic. Care must be taken to ensure the AIC is not advanced too far, especially if gases are passed through it, as this risks barotraumas. This technique can be performed with or without the use of a Bodai adapter (Sontek Medical, Lexington, MA). The Bodai adapter allows oxygen and gas administration through the attached breathing circuit during exchange of the LMA to an ETT. The AIC remains in place, and a suitably sized lubricated ETT is then advanced over the catheter. Although the AIC technique does not appear in current airway guidelines, its use is simple, has a high success rate, and is widely reported.[26,27]

D. Reusable Design

The LMA Classic is reusable and designed to be used up to 40 times. An in vitro study suggested that the LMA Classic and ProSeal LMA may be reused up to an average of 130 and 80 times, respectively, before showing signs of failing the preuse tests recommended by the manufacturer, and in vivo work supports use up to 60 times.[28,29]

After use, the LMA Classic is cleaned (decontaminated) before sterilization by autoclave (up to 137° C for 3 minutes with the cuff fully deflated), and it is stored in sterile packaging thereafter. A 2001 bench-top study demonstrated that routine decontamination and sterilization failed to remove all proteinaceous material from airway devices and from the LMA Classic in particular.[30] At the same time, there was increasing public awareness about variant Creutzfeldt-Jakob disease (vCJD), especially in the United Kingdom. Concerns grew that residual prions, the infective, misfolded proteins responsible for vCJD, might remain and be passed from patient to patient. Several national bodies recommended using single-use devices "wherever possible,"[31] even though the estimated risk of such cross-contamination was 1 to 10 cases in 100,000 patients.[32] Brimacombe and coworkers described the rush toward single-use LMs as "driven by fears of the unknown and scientific misinformation."[33] Since then, the risk of vCJD has fallen dramatically, and the risk of transmission is likely to be vanishingly small.[34]

This risk must be balanced against other risks introduced by alternative equipment.[35] Blunt and Burchett found that even a small deterioration in safety as a result of using a single-use device of poorer quality in place of a reusable device increased the overall risk to patients and went against the recommendation of the Spongiform Encephalopathy Advisory Committee (SEAC).[32]

E. Absence of a Bite Block

The LMA Classic lacks a bite block and is prone to obstruction by biting in the agitated patient during emergence. Use of a bite block (e.g., rolled gauze placed between the molar teeth) is recommended until the LMA Classic is removed, and failure to adhere to this recommendation can lead to airway obstruction, hypoxia, and postobstructive pulmonary edema.[36] The LMA Flexible also has no bite block, but the intubating LMA (ILMA), ProSeal, and Supreme LMA do.

IV. EFFICACY, SAFETY, AND EVALUATION OF SUPRAGLOTTIC AIRWAY DEVICES

The market for SADs is extensive, and in the United Kingdom, which represents only a fraction of the global market, estimated sales are in excess of $10,000,000 per annum. The LMA has five variations (i.e., Classic, Flexible, ILMA, ProSeal, and Supreme) or eight if single-use variants are included. At least 10 other SADs of different design to the LMA are on the market. In the past decade, production has ceased for at least six SADs, and it is inevitable that in the next decade more new devices will arrive and some currently in use will depart.

About 30 distinct single-use and reusable LMs are marketed. They are somewhat different from one another in design and in manufacturing materials and processes. If all variants are included, more than 40 SADs are available for nonintubated adult patients.

A small survey of SAD manufacturers in 2003 examined several devices introduced around that time[35] and found that the number of patients in whom the device had been used before marketing was less than 150 all in cases but one. In most cases, no trials were published in peer-reviewed journals before launching the product. One device launched in 2001 and remained without published data 18 months later. Only two of seven devices were compared with the LMA Classic in randomized, controlled trials before marketing, and the largest of them enrolled only 60 patients. This situation has not changed, and many later devices have been introduced with little or no trial evidence of their efficacy.

How does an anesthesiologist start using a new airway device? Typically, a company representative supplies a few anesthesiologists with samples of the new device and provides education in its use. The anesthesiologists try the device on a few patients and form an opinion. Hundreds of anesthesiologists may go through this process, exposing perhaps thousands of patients to relatively untested devices before a consensus is reached. The quality of each evaluation varies with the individual's practice, experience, and diligence. Companies may use informal comments from one user to encourage other users. Individual uptake may be swayed considerably by limited personal experiences, and new devices can be introduced without adequate evaluation of clinical efficacy or safety, or the devices can be rejected without due cause. Some companies restrict the distribution of new devices to a few hospitals or to experts in the field. Others attempt to collect an informal assessment of the device's performance each time it is used. Some perform extensive laboratory, model, and clinical evaluations before marketing, but these practices are far from universal.

This raises a question about whether it is acceptable to evaluate new devices in such an ad hoc manner. This process should be contrasted with the introduction of a new drug, which must go through laboratory and preclinical studies even before clinical trials are considered. Results of the three phases of clinical trials are reviewed before release of the drug to the market, and postmarketing surveillance is mandatory and extensive.

What regulations govern the introduction of new medical devices, particularly airway devices? In the European Union, the use of medical devices is controlled by three European Directives as part of European law.[36] Some directives are specifically applicable to airway devices, and adherence is overseen by a regulatory body in each member country. The statutory body has responsibility for ensuring that medical devices do not threaten patients' health and safety. Statutory requirements are largely harmonized throughout Europe, and compliance with one country's requirements allows distribution and marketing of a device throughout the European Union. Although many countries have mechanisms that are designed to critically examine the efficacy of new technologies (e.g., National Institute of Clinical Excellence [NICE] in the United Kingdom), these bodies often have specific conditions (e.g., for NICE, new technology for new procedures) such that new (airway) equipment designed to do an old job tends to fall outside their areas of inspection and regulation.

The statutory requirements of safety and quality do include a statement to the effect that the device should function as intended by the manufacturer. However, in practice, the statutory assessments focus on production quality control and manufacturing standards. A mixture of self-assessment and external assessment is obtained, depending on the risk that the device may pose to patients. These assessments must be passed to allow continued marketing of a device. Airway devices are considered to be of low or intermediate risk and are primarily subject to manufacturers' self-assessment. Performance of the desired function, efficacy, and cost-effectiveness are not a focus of these assessments. Passing the statutory requirements and obtaining a Conformité Européenne (i.e., European Conformity [CE]) mark allows marketing of the device throughout Europe, and member countries are not allowed to impose other barriers to trade after a CE mark is applied. The CE mark implies that the device is fit for its intended purpose, but assessment of performance, efficacy, and cost-effectiveness are left to the manufacturers, distributors, and end users in the postmarketing phase.

After a device is marketed, clinical trials are not required to demonstrate efficacy or quality of performance. Manufacturers are legally bound to report serious or potentially serious adverse incidents.[37] The statutory body requires reporting of incidences in which "malfunction of or deterioration in the characteristics and performance of a device" leads to "actual or potential patient harm."[37] There is also a mechanism for voluntary reporting of incidents by users. Whether these mechanisms lead to reliable reporting of such incidents and whether these schemes identify devices that are poorly designed or underperform is not clear. Formal assessment of performance may come from postmarketing cohort or comparative studies. However, these studies are uncommon, and they usually are published at some interval after a device has been marketed.

Lack of timely reporting creates another problem. In light of clinical experience and customer feedback, new devices are often redesigned after their initial release onto the market. These "improved" devices go through a similar process to that described earlier, and they are again brought to market. Second-, third-, and fourth-iteration devices may then appear, often under the same name as the original. For example, one SAD was modified three times (the four versions were named identically) in the 18 months after it was initially marketed. Publication delay compounds the confusion, because the unsuspecting reader of journals may not realize that a recently published paper relates to a device that has subsequently been modified. Performance of the old version may be very different from that of the current version. In one review of the SAD with four versions, one half of the cited papers related to previous versions of the device. Although this does not make trials of the previous version of each device completely redundant, it does make interpretation of the limited data more difficult. It would arguably be better to determine the desirable features of a new airway device and use these to assess the design and function of it before and after it is marketed.

A. Desirable Features of Supraglottic Airway Devices

Certain issues influence the anesthesiologist's choice of an airway for an individual patient. Should the anesthesiologist choose a single-use device, a device that can be reused most often, the cheapest device, or the device that causes the least trauma? Do all devices maintain the airway reliably? To what extent do any of them protect the airway from regurgitation and pulmonary aspiration? Which devices enable safe and effective positive-pressure ventilation? Will the device enable access to the airway for intubation if required? Are there differences in ease of insertion and ability to ventilate patients' lungs between the various devices? How often are manipulations needed to maintain a clear airway during anesthesia? Which devices are tolerated best during emergence? What are the relative incidences of airway trauma and postoperative pharyngolaryngeal morbidity? Unfortunately, in most cases, remarkably few of these data are available. The manner in which new medical devices are regulated contributes to this situation.

The characteristics of an ideal SAD include efficacy, versatility, safety, reusability, and cost. The device should be made of good-quality, nontoxic materials and have a long shelf-life. Reusable devices should be robust enough to allow many uses and cleaning cycles without damage or deterioration of performance, and other desirable features may reflect the preferences of anesthesiologists and their patients.

The anesthesiologist wants a device that is inserted reliably on the first attempt, producing a clear airway for spontaneous and controlled ventilation. It should enable maintenance of hands-free anesthesia in a variety of patients in various head and neck positions. Device performance should be consistent and predictable, and it should allow emergence without complications. The incidence of airway trauma and postoperative sore throat should be acceptably low. Design features or clinical evidence for protection against aspiration is highly desirable, and the ability to reach the trachea through the device may also be a factor in choosing a SAD. It should function reliably as a rescue device and for difficult airway management. The ideal device should not cause intraoperative complications, trauma, or pharyngolaryngeal morbidity for the patient.

The anesthesiologist should be able to insert the SAD despite a limited mouth opening (most require 2 to 3 cm) and using a light depth of anesthesia (dose range for different airways varies approximately twofold). SADs requiring a muscle relaxant for insertion are of limited use.

All SADs may cause airway obstruction from epiglottic downfolding. This problem can be reduced by ensuring correct insertion technique and by using devices designed with a slim leading edge and a large airway orifice. The slim profile of the deflated Laryngeal Tube (LT, King Systems, Noblesville, IN) and LMA Classic and the deflation device and tip flattener that are provided with the PLMA are examples of designs that minimize the tip size. The epiglottis may cause obstruction by entering the orifice of the airway device. Several design features are aimed at avoiding this problem, including epiglottic bars (e.g., LMA Classic, LMA Flexible, some newer LMs), a large orifice that is too big to become obstructed (e.g., PLMA, i-gel), multiple airway holes (e.g., Combitube, LT), and an orifice with protective fins (e.g., Supreme LMA).

The first-time insertion success rate should be high, and initial insertion should require a minimum of manipulations. With current devices, the first-time insertion success rate ranges from less than 70% to more than 95%. The average number of manipulations required for insertion ranges from less than one manipulation in 25 cases to more than one per case.

The anesthesiologist requires an airway that does not require manipulations after insertion or repositioning during anesthesia, enabling hands-free anesthesia. The most functional devices require an intervention in less than 1 in 25 cases, but others require intervention in two thirds of cases.

The airway should be stable when the head and neck position varies, such as during rotation to improve surgical access or when the head and neck are repositioned

for additional procedures. Limited evidence suggests that the stability of different SADs under these circumstances varies.

Intraoperative complications (e.g., airway obstruction, loss of airway, regurgitation, laryngospasm) should be uncommon. The published incidence of minor complications with existing devices ranges from less than 10% to 60%. Serious and minor repetitive complications or the need to perform repeated or continuous manipulations to maintain the airway may force early removal of the airway. This is the ultimate failure of the airway device, and it occurs with an incidence of less than 1 in 50 cases to more than 1 in 5 cases.

The ideal SAD should be reliable for spontaneous and controlled ventilation. Among the existing devices, several versions of one device function poorly during spontaneous ventilation, and another is designed specifically to facilitate controlled rather than spontaneous ventilation. Several devices that produce a low-pressure seal with the airway may be unsuitable during controlled ventilation because of the risk of gastric inflation and regurgitation. The role of second-generation SADs in protection of the airway is discussed later.

The ideal airway device causes no trauma to the airway. The incidence of trauma to the airway with the latest SADs, as evidenced by blood visible on the device, ranges from close to 0% to more than 50%. SADs commonly cause sore throat, dysphonia, and dysphagia, but these symptoms are usually minor, transient, and less common than after tracheal intubation. The possibility of nerve injuries is a greater concern. The ideal airway minimizes or eliminates both of these problems. However, the intracuff and mucosal pressures vary in intensity and location with different SADs. The overall incidence of sore throat varies from less than 10% to more than 40%. Clinically significant nerve injury is rare with all SADs, and the relative risks of individual devices are unknown.

In addition to maintaining the airway during anesthesia, a SAD may enable access to the airway. It is easy for this role to be overemphasized, because during routine anesthesia, it is rare that the SAD needs to be changed for an ETT, and when this exchange is required, the SAD usually can be removed before intubation is attempted conventionally. If the SAD is likely to be needed as a conduit for planned tracheal intubation or for management of a difficult airway, the device may be selected accordingly. The intubating LMA (ILMA) and Cookgas intubating laryngeal airway (ILA) are designed specifically for these roles, and several others (e.g., i-gel, PLMA) are likely to perform similarly well. Several techniques may be used, including blind use of an ETT or bougie and light-guided and fiberoptically guided techniques with an ETT or exchange catheter. Such techniques require the larynx to be visible from the airway orifice and the internal diameter of the SAD lumen and its orifice to be of adequate caliber. For various devices, the ability to view the laryngeal inlet from the airway orifice ranges from more than 90% to less than 40%. Variations in length and diameter limit the techniques that may be used with certain SADs. The proximal orifice of some SADs is too small to admit an ETT with an ID larger than 5.0 mm, whereas others accommodate ETTs with an 8.0-mm ID. At their distal end, grills, bars, small orifices, and difficult angles may impede or prevent access to the trachea.

Although most devices are used by anesthesiologists, SADs may be used by individuals with less experience for anesthesia, out-of-hospital rescue, or resuscitation. The ideal airway should therefore be intuitive to use, have a high success rate for the naive user, and be easy to learn. The few available data suggest that insertion and airway maintenance by nonanesthesiologists and by naive users varies considerably among devices.

Many assume that reusable devices may be replaced by cheaper, single-use devices, and some think that single-use devices are intrinsically preferable. However, many single-use devices differ from the reusable devices they seek to replace in design and in the materials used. Some modifications appear to be minor, but the implications for performance have generally not been evaluated. The work on single-use laryngoscopes and intubation bougies provides evidence that changes in product material may alter performance considerably.[38,39] Data on the current versions of the single-use LM and comparisons between these and the LMA Classic remain largely unavailable.

No single device meets all the criteria for the ideal SAD. Some criteria are incompatible with others. For instance, a device that is large enough to accommodate a standard-sized ETT and that incorporates an adequate-caliber drain tube is unlikely to be as easily inserted as a smaller device. Epiglottic bars reduce airway obstruction but hinder instrumental access to the trachea. A single-use device is less likely than a more expensive reusable device to be made of the best materials to optimize handling characteristics and minimize pharyngolaryngeal trauma. It is likely that several different airways will always be needed for use in different clinical situations.

B. Efficacy Versus Safety

SADs may have several roles, and different designs and performance characteristics may be required for each role. The LMA Classic was originally used almost exclusively to provide anesthesia for brief, peripheral operations that were performed in slim patients, usually during spontaneous ventilation. The popularity of the LMA Classic has led to an evolution in practice such that SADs have become increasingly used for longer, more complex operations and for obese patients. SADs are increasingly used for laparoscopic and open intra-abdominal surgery, and their use during controlled ventilation has become commonplace.

Many of these expanded indications can benefit patients, but they also raise questions about efficacy and safety. During spontaneous ventilation, the LMA Classic provides a clear airway and enables hands-free anesthesia in more than 95% of cases. Efficacy of the LMA Classic for controlled ventilation diminishes rapidly as lung resistance increases (e.g., obesity, laparoscopy), and rates of hypoventilation and gastric distention increase, raising concerns about the safety of its use in these situations.

In the past decade, more than 40 SADs have been introduced. Most are attempts to mimic and compete

with the LMA Classic to appeal to purchasers and managers. Anesthesiologists are more interested in SAD designs that improve performance (i.e., efficacy and safety) and thereby increase their clinical utility.

Many studies comparing SADs have been inadequately powered to determine efficacy, and none has addressed the issue of safety directly. Efficacy depends on several factors, including ease of insertion, manipulations required to maintain a clear airway throughout anesthesia, and tolerance during emergence. Efficacy during controlled ventilation requires the ventilation orifice of the SAD to be positioned over the larynx, and the SAD must seal well within the laryngopharynx (i.e., pharyngeal seal).

Safety encompasses avoidance of complications occurring at all stages of anesthesia and afterward. Prevention of aspiration requires a good-quality seal within the laryngopharynx and esophagus (i.e., esophageal seal) to prevent gas leaking into the esophagus and stomach and to prevent regurgitant matter passing from the esophagus into the airway. A functioning drain tube enables regurgitant matter to bypass the larynx and be vented outside, protecting the airway and giving an early indication of regurgitation to the anesthesiologist. Studies have shown that the extent of esophageal seal varies considerably among SADs. Those with a drain tube can effectively vent regurgitant fluid if the drain is not occluded.[12,40,41]

C. Structured Approaches to Evaluation of New Devices

New airway devices should undergo mandatory assessment of manufacturing quality and clinical performance before marketing. The characteristics of the ideal SAD outlined earlier provide a checklist against which function can be assessed. Several methods have been recommended.[35,42,43] Cook described a three-stage evaluation process[35]:

Stage 1. Bench evaluation using manikins or models designed to test function and basic safety
Stage 2. A rigorous cohort study to determine whether the device is effective and to further exclude major concerns about safety
Stage 3. A randomized, controlled trial against the current gold standard for the procedure for which the new device is expected to be used (e.g., LMA Classic, PLMA, ILMA)

In stage 1, the bench models include airway manikins and others, such as those specifically designed to test aspiration risk.[44] This stage is limited by lack of fidelity of available manikins.[45] With the increasing use of SADs during resuscitation, during out-of-hospital rescue, and by non-anesthesiologists, there is an urgent need to develop realistic manikins for testing and training. Data acquired from such studies require intelligent interpretation and knowledge of the relative performance of different manikins.[46-48] Results of manikins studies are considerably limited, and at best, they may be used to evaluate basic information on device performance and durability and to identify major conceptual or design problems. Appropriate bench testing may lead to further development of a device before starting clinical studies.

In stage 2, a cohort study may be used for the first assessment of clinical performance in patients. This approach enables full clinical evaluation of the new device under routine clinical conditions. Functions that can be tested include ease of insertion, pharyngeal seal, airway resistance, stability of the device in different head and neck positions, ease of passage of a gastric tube, positioning of the airway over the larynx, and suitability for fiberscopic or catheter exchange techniques. Learning curves can be examined. A cohort study also enables assessment of function during spontaneous and controlled ventilation and determination of airway trauma or pharyngolaryngeal morbidity. The cohort must be large enough to enable identification of common problems, but unless it is very large, it cannot detect uncommon or rare problems. For instance, for an event that does not occur in a cohort study of n cases, the 95% confidence interval (CI) for frequency of that event is approximately 1 in $\frac{3}{n}$.[49] For example, if no nerve injuries occur in a cohort study of 100 cases, the upper limit of the 95% CI for risk of nerve injury is 1 in 33. A cohort of at least 100 patients is a reasonable compromise between being large enough to identify important uncommon events and remaining a practical size.

Stage 3 employs a randomized, controlled trial. After successful completion of bench and cohort evaluations, the need for further modifications of the device should be considered. Significant modifications necessitate repetition of the early evaluations. On successful completion of the early evaluations, the new device should be compared with its best existing competitor. In many cases, this is the LMA Classic. The randomized, controlled trial must be of adequate size to identify clinically important differences in function. Studies may be designed to test the hypothesis that the devices perform differently (i.e., superiority-inferiority trials) or that the test device does not perform significantly less well than the benchmark device (i.e., noninferiority trials).[50] Power calculations can be based on data acquired from phase 2, but trials of at least 100 patients provide more comprehensive and clinically useful comparisons. Economic evaluation of cost-effectiveness of the new device may take place at this stage. Data from the three phases of evaluation can be used to determine what role the new airway device has in the market.

In an ideal world, a license for only one aspect of airway care (e.g., spontaneous breathing only, controlled ventilation in patients with good pulmonary compliance, airway maintenance when tracheal access is likely to be necessary) would be offered based on the results of research. License extensions could be granted in light of further research. Current legislation designed to encourage market competition means that no such limits are imposed, as they are in drug development.

Implementation of the suggested methodology would still result in only 200 to 300 uses of the device in patients before release to market. Because this number is not enough to identify uncommon or unexpected

problems, complications, and advantages, the proposed method of evaluation does not obviate the need for postmarketing surveillance or reporting of adverse incidents. A formal method of postmarketing evaluation could be developed. For instance, the first 5000 devices marketed could have evaluation cards attached, which would be returned after use. Some SAD manufacturers have used such a system in the past without making the resultant information available to the profession. Alternatively, the manufacturer could be required to seek reports of all adverse incidents for the first 2 years after release, similar to the Yellow Card system for new drugs that applies in the United Kingdom.

A second structured approach to evaluating and choosing new devices was made by Wilkes and colleagues.[43] In this proposal, a central body of experts would coordinate research to evaluate new devices, review available evidence and provide national recommendations on devices reaching standards of acceptability. Although potentially of value for a large population (e.g., a country), the barrier it may create to free trade and the likelihood of legal challenges are problems.

The UK Difficult Airway Society (DAS) has proposed a guideline whereby purchasers could adopt a minimum level of evidence before making a pragmatic decision about the purchase or use of an airway device.[42] This minimum level of evidence (i.e., level 3b: a case- or historical-controlled cohort study) would form the basis of a professional standard to guide those with responsibility for selecting airway devices.[51] Devices without this minimum level of evidence would not be purchased. The investigators argue that widespread adoption of this professional standard would lead to situations in which it was in the interests of manufacturers and purchasers to acquire such evidence and the DAS would support both parties in setting up research with this aim. The strength of this approach lies in purchasers driving the need to raise the evidence bar and manufacturers being encouraged to perform clinical trials at an early stage in device development. This approach is not anticompetitive because it creates no barriers to manufacturers bringing a device to market, but it does raise the level of expectation of the community of purchasers about what they wish to purchase.

Whether any of these methods of structured evaluation are officially adopted, each has potential advantages for the manufacturer, clinician, and patient. For successful devices, the manufacturer would have robust data to support performance claims and a clearer vision of the likely advantages and applications of the new device. This would enhance marketing and raise credibility. For devices that performed poorly, the manufacturer could avoid the expense of large-scale production and marketing of devices that would ultimately fail to achieve market share. The clinician would have better evidence on which to base medical decisions. Researchers would have clearer ideas about how a new device might be evaluated to define function further and investigate wider indications for use. The patient would be less likely to be exposed to unnecessary risk due to the use of an unevaluated device.

Anesthesiologists and patients expect equipment to be effective and safe during anesthesia. The relationship between manufacturer and clinician (acting for the patient) is symbiotic. Care of patients can improve only through a sustained effort by clinicians and manufacturers to improve the medical devices used during anesthesia. In this respect, much has been achieved in airway care in the past 20 years, and the practice of anesthesia has been transformed. Innovation is expensive, and much of the cost of advances or improvements accrues during research and development. This cost is borne entirely by the manufacturer. A more open relationship between interested parties and the early involvement of objective, structured evaluation of new airway equipment are recommended. This approach could prevent undertested or underdeveloped products from coming to market and thereby protect patients medically and manufacturers legally. An evaluation program should encourage and support equipment manufacturers to achieve these goals.

V. FIRST-GENERATION SUPRAGLOTTIC AIRWAY DEVICES

A. Generic Laryngeal Masks

Since 2005, many manufacturers have produced LMA-like devices designed to compete with LMAs. They included single-use (mostly polyvinyl chloride [PVC]) and reusable (PVC and silicone) devices. Because the term *laryngeal mask airway* (LMA) is registered, the newer devices are referred to as *laryngeal masks* (LMs). The manufacturers assert that the main driving force for the introduction of single-use devices has been the concerns about the sterility of cleaned, reusable devices. The financial opportunities of the SAD market are another reason for the increase in these devices.

For patent reasons, all LMs are different from the LMA Classic, and much variation exists between LMs. The patent on the basic design of the LMA Classic lapsed in 2005, but the patent for the epiglottic grills remained in place until 2008. All LMs designed before 2008, except those made by the original manufacturers of the LMA Classic, do not have the epiglottic bars at the distal end of the airway tube; some recent entrants into the market do. Some LMs have angulated stems, and others have enlarged masks. Some early LM designs featured more bulky masks and cuffs than the LMA Classic, and this design and the stiffer PVC material of which they were made impeded insertion. Particularly with the larger masks, there is a possibility of entrapping the tongue and drawing it backward during insertion (causing trauma) and downfolding the epiglottis after it is inserted (causing obstruction and trauma).

For cost reasons, most single-use LMs are made with a PVC cuff, which increases the rigidity of the device. PVC is cheaper than silicone and reduces the cost of these devices for the manufacturer and purchaser. PVC is less permeable to nitrous oxide than silicone, and during nitrous oxide administration, the increase in LM cuff pressure in the early phase of anesthesia is considerably less than when using a silicone device.[52,53]

PVC has two disadvantages. First, it is more rigid than silicone. Brain examined PVC as a material for LMA

construction in the mid-1980s but rejected it because of its rigidity.[54] The increased rigidity of PVC LMs may cause problems, such as increased trauma to the airway during use and an increase in pharyngolaryngeal morbidity postoperatively. The rigidity, especially in masks with thicker cuffs, may lead to folds and wrinkles in the partially inflated cuff, which may affect the airway seal or create channels that enable regurgitant fluid to reach the larynx, altering efficacy and safety. The impact of these effects is not known for many devices because of the lack of published evidence. Some manufacturers use a softer form of siliconized PVC, which may obviate the problems described.

The second concern is the toxicity of phthalates, such as di-2-ethylhexyl phthalate (DEHP) or dioctyl phthalate (DOP), which are used in the manufacturing process to render the PVC softer. These chemicals are not linked to the plastic matrix and leach out slowly during use. They are considered potentially carcinogenic, mutagenic, and reprotoxic,[55] and there is particular concern about phthalates in products that may be placed in the mouth (e.g., children's toys, airway devices). The issue has been considered important enough by some for bills banning PVC in some products to be brought before the legislatures of some U.S. states and the European Parliament. Phthalates are banned from use in cosmetics in Europe, and in May 2005, the European Parliament voted to make permanent a temporary ban on six phthalates (including DEHP) in PVC used in children's toys and called for investigation into health care equipment.[55] It is easy to overstate the importance of phthalates in the safety of PVC LMs, but the unquantified low risk they pose bears comparison with the unquantified low risk of transmission of prion disease when using a reusable device. Alternative plasticizers, such as no-DOP formulas and di-isononyl-cyclohexane dicarboxylate (Hexamoll DINCH) are available for use in PVC applications, although at considerably increased cost. In the past few years, an increasing number of low-cost silicone LMs designed for single use and reuse have been introduced.

The greatest concern about the profusion of LMs on the market is the lack of rigorous evaluation. Typically, there is no robust evidence to inform whether the single-use or reusable LMs perform similarly to equivalent LMAs or to inform which LM performs best. The limited evidence does show that all LMs and LMAs are not equivalent. Of the approximately 30 devices available, only 2 have substantial publications that compare their efficacy with that of LMAs: the AuraOnce LM (Ambu Inc., Glen Burnie, MD) and the Portex Soft Seal LM (SSLM, Smiths Medical ASD, Keene, NH). For the other devices, there appears to be a void of published evidence. A publication from the National Health Service (NHS) Centre for Evidence-Based Purchasing illustrates the difficulty in determining the relative merits and demerits of these competitors to the LMA Classic. The document listed more than 25 alternative standard LMs and reported a total of 18 comparative trials for the devices. Some of these studies were of poor quality. This publication record contrasts with the more than 2500 publications on the LMA Classic.[56]

B. Features of Laryngeal Masks

1. Indications, Advantages, and Disadvantages

LMs are intended for use for the same indications as the LMA Classic—as an alternative to the face mask for achieving and maintaining control of the airway during routine anesthesia in fasted patients. They may be used for critical anesthesia procedures (e.g., airway rescue after failed mask ventilation, after failed intubation). LMs also may be used to establish a clear airway during resuscitation in the profoundly unconscious patient with absent glossopharyngeal and laryngeal reflexes who may need artificial ventilation. LMs are not intended to replace all functions of the ETT and are best suited for use in fasted patients undergoing surgical procedures in which tracheal intubation is not deemed necessary. However, in certain circumstances, procedures previously requiring intubation because face mask anesthesia was not suitable (e.g., airway access, hand position) may be suitably performed using a LM or LMA.

The disadvantages and advantages of LMs are extrapolated from the extensive evidence for the LMA Classic to LMs because of their design similarities. However, equality of performance for the LMA Classic and many LMs has not been confirmed. For most standard LMs, the airway seal is modest (16 to 24 cm H_2O). There are no specific design features to prevent aspiration, although good technique and insertion can minimize this risk by ensuring the mask encircles the larynx and the tip obturates the upper esophageal inlet. Standard LMs may be used during spontaneous ventilation or controlled ventilation. If used for controlled ventilation, peak airway pressure should be limited to less than 20 cm H_2O to avoid airway leak and gastric inflation. LMs therefore may not be appropriate for patients with reduced lung compliance or increased airway resistance. Airway resistance during ventilation increases dramatically if the LM is poorly positioned over the larynx or if laryngeal closure occurs due to an inadequate depth of anesthesia. The major disadvantage of LMs is that they do not protect against aspiration and do not secure the airway as effectively as an ETT. A LM cannot prevent or treat airway obstruction at or beyond the larynx.

2. Laryngeal Masks Compared with Face Mask Ventilation and Tracheal Intubation

LMs reduce dead space ventilation compared with face mask ventilation. If reasonable airway pressures are used and the mask is correctly positioned, gastric inflation is unlikely. Use of a LM or any SAD enables anesthesiologists to have their hands free for other tasks. Compression of the eyes and facial and infraorbital nerves is avoided, and operating room pollution from anesthetic gases is reduced.

Compared with ETTs, LMs are easier to place, do not require laryngoscopy and its associated problems, and are less invasive. Insertion does not require the use of muscle relaxants. Insertion causes negligible cardiovascular stimulation, and increases in intraocular pressure are minimal at insertion and removal. Removal of LMs can be delayed until the patient is fully awake with the return of

protective airway reflexes. Coughing and hypoxia occur less frequently compared with removal of an ETT.

C. Single-Use Laryngeal Masks

Several single-use LMs and LMAs including flexible devices have been introduced in the past few years. Performance must be assumed because performance evaluations and comparative trials have not been performed.

In the United Kingdom, the Department of Health advises that all airway equipment used for tonsillectomy should be single use, and this recommendation is endorsed by the Royal College of Anaesthetists and other professional bodies. NICE did not consider LMAs when examining the risk of vCJD transmission. In this climate, the single-use LMA Flexible is likely to have a significant role. Two single-use LMs—the AuraOnce and the SSLM—have a significant body of published literature that allows a balanced analysis of their performance.

1. Ambu AuraOnce Laryngeal Mask

The Ambu AuraOnce LM was designed and produced between the fall of 2002 and February 2004, when it was launched by the Danish medical device manufacturer Ambu. Ambu offers a range of LMs. The Ambu AuraOnce is a single-use LM with a preformed curve. The Ambu Aura40 is a reusable version of the Ambu AuraOnce. The Ambu AuraSraight is a single-use device with a more conventional curve to the stem. The Ambu AuraFlex is a single-use, reinforced, flexible LM, and the Ambu Aura-i is a modification of the AuraOnce that is designed to facilitate intubation in a fashion similar to that of the ILMA.

The Ambu AuraOnce is the most investigated model. It is a sterile, single-use product made of PVC with a preformed curve designed to replicate human anatomy (Fig. 23-2). This angled curve is designed to ensure that the patient's head remains in a natural position when the mask is in use and to facilitate insertion without exerting force on the upper jaw. A reinforced tip reduces the risk of the device folding back during insertion. Reinforcing internal ribs built into the curve of the airway tube provide a degree of flexibility and enable the airway tube to conform to individual anatomic variations and adapt to a wide range of head positions without loss of function.

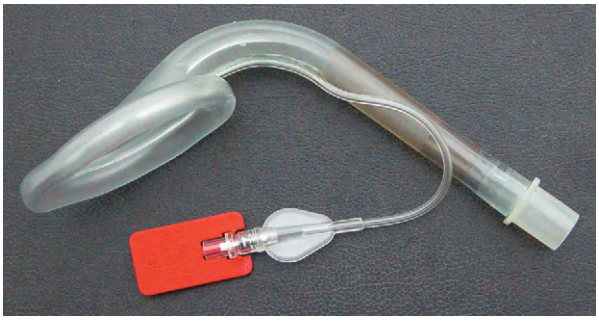

Figure 23-2 Ambu AuraOnce laryngeal mask as delivered. The red "tab" keeps the pilot balloon valve open so the cuff pressure is maintained at atmospheric pressure.

The Ambu AuraOnce is molded in one piece with an integrated inflation line and no epiglottic bars at the airway orifice. The cuff is elliptical and is shaped to lie in the hypopharynx at the base of the tongue. The absence of epiglottic bars means there is no barrier to flexible fiberoptic devices. The product is sterile and latex free and is available in adult and pediatric sizes 1 through 5. The recommended size is based on the weight and height of the patient.

The Ambu Aura40 is the reusable, silicone version of the Ambu AuraOnce.[40] Its built-in curve is designed o replicate the natural human anatomy and offers the same features as the Ambu AuraOnce. It can be steam autoclaved up to 40 times.

The Ambu Aura-i (Fig. 23-3) is a modification of the Ambu AuraOnce that is designed to facilitate intubation in a fashion similar to that of the ILMA. It has a shorter, wider, and more rigid airway tube than the Ambu AuraOnce, and proximally, a rigid plastic sleeve acts as a handle for insertion and as a bite block. It is designed for use during routine airway maintenance and as a device for airway rescue and fiberoptic intubation. Sizes 3, 4, and 5 accommodate ETTs up to sizes 6.5-, 7.5-, and 8-mm ID, respectively. Ambu has released a single-use videoscope that may be used with the Ambu Aura-i.

a. APPLICATION

Familiarity with the manufacturer's warnings, precautions, indications, and contraindications is necessary before use, and the patient should be at an adequate depth of anesthesia (or unconsciousness) before attempting insertion. Before insertion, the following guidelines should be observed:

- The size of the Ambu AuraOnce must be appropriate for the patient. Use the manufacturer's guidelines combined with clinical judgment to select the correct size. Always have a spare Ambu AuraOnce ready for use.
- Resistance or swallowing may indicate inadequate anesthesia or inappropriate technique, or both.

Figure 23-3 The Ambu Aura-i laryngeal mask with a tracheal tube passed through it illustrating its role as a conduit. Inset shows markings on posterior of stem.

Inexperienced users should choose a deeper level of anesthesia.

- The Ambu AuraOnce is inserted in a fashion similar to that described for the traditional LMAs in Chapter 22. Excess force must be avoided at all times. When the mask is fully inserted, resistance is felt. If the cuff fails to flatten or curls over as it is advanced, it is necessary to withdraw the mask and reinsert it. In case of tonsillar obstruction, a diagonal shift of the mask is often successful.

Intubation techniques through the Ambu AuraOnce are the same as those described earlier for the LMA Classic. The preformed curve may make this slightly less easy than in the more smoothly curved LMA Classic, but this difficulty is easily overcome with lubrication. The absence of bars at the end of the airway tube is an advantage over the LMA Classic.

The Ambu Aura-i is a single-use device that may be used in preference to the Ambu AuraOnce if intubation through the device is anticipated or planned.

b. INDICATIONS, ADVANTAGES, AND DISADVANTAGES

The Ambu AuraOnce has several features of potential advantage over some other LM designs. Its cuff is soft and flexible but has a reinforced tip; together with the preformed curve of the stem, these features facilitate insertion. Because it is molded in a single unit, it is free from ridges that may injure the airway during insertion, and component parts cannot separate during use.

Its disadvantages are those of all LMs. If used for controlled ventilation, the manufacturers recommend limiting peak airway pressure to 20 cm H_2O and the tidal volume to 8 mL/kg[2].

c. MEDICAL LITERATURE

Approximately 25 publications about the Ambu AuraOnce are listed on PubMed.

COHORT STUDIES. A multicenter study of the clinical performance of the Ambu AuraOnce was conducted by Hagberg and colleagues to evaluate ease of insertion, insertion success, airway seal, and ventilation.[57] Device placement was successful in all 118 nonparalyzed, anesthetized patients on the first or second attempt (92.4% and 7.6%, respectively). Adequate ventilation was achieved in all patients, and the vocal cords could be visualized by fiberoptic endoscopy in 91.5% of patients. Complications and patients' complaints were minor and were quickly resolved. The investigators reported that the curvature of the tube facilitated insertion and that the large, soft cuff allowed a higher oropharyngeal leak pressure than is commonly found in other LMs. The reinforced tip of the Ambu AuraOnce may avoid folding, which can lead to air leakage, a common problem with other LMs.

Genzwuerker and coworkers studied ventilation using the Ambu AuraOnce in different head positions in 30 patients.[58] Five different head positions were used: head on a standard pillow, head rotated 90 degrees to the left side, head rotated 90 degrees to the right side, head with chin lift on a standard pillow, and head flat on a table without a pillow. No changes in the performance of the device were observed in any position. The Ambu AuraOnce may be a useful SAD for cases in which head movement may be necessary during surgery.

RANDOMIZED, CONTROLLED STUDIES OF EFFICACY. Shariffuddin and Wang compared the Ambu AuraOnce with the LMA Classic during controlled ventilation in 40 patients in a randomized, crossover design.[59] The mean ± standard deviation oropharyngeal leak pressure was higher for the Ambu AuraOnce (19 ± 7.5 cm H_2O) than for the LMA Classic (15 ± 5.2 cm H_2O, $P = 0.004$). The Ambu AuraOnce also required fewer insertion attempts ($P = 0.02$) but more manipulations to achieve a patent airway ($P = 0.045$). Values for time to insert the device and intraoperative performance were similar.

Sudhir and associates performed a randomized, crossover study comparing the Ambu AuraOnce and LMA Classic in 50 patients.[60] Success rates for the first attempt success were similar (92% for the Ambu AuraOnce and 84% for the LMA Classic, $P = 0.22$). The volumes of air required to inflate the cuff to produce an effective airway seal were similar, but the cuff pressure was lower for the Ambu AuraOnce (median, 18 cm H_2O) compared with LMA Classic (27 cm H_2O, $P = 0.007$). Complications were similar in both groups.

Ng and coworkers compared the Ambu AuraOnce with the LMA Classic and reported the Ambu AuraOnce to be easier to insert, but they found no difference in time to insertion,[61] successful insertion on the first attempt, oropharyngeal leak pressure, hemodynamic response to insertion, or complications of placement.

Francksen and colleagues compared the performance of the Ambu AuraOnce and the LMA Unique in 80 patients undergoing minor routine gynecologic surgery.[62] They demonstrated that the time to insertion and failure rate were comparable and that oxygenation and ventilation variables were adequate with either device. Median airway leak pressures were slightly higher with the Ambu AuraOnce than with the LMA Unique (18 versus 16 cm H_2O, $P < 0.013$). No gastric inflation was observed with either device in this small study.

Francksen and coworkers also studied 120 patients scheduled for routine minor obstetric surgery who were randomly allocated to size 4 Ambu AuraOnce, LMA Unique, or SSLM.[63] The Ambu AuraOnce was fastest to insert by a few seconds. All three had high first-attempt insertion success rates (all >95%). Rates of subjectively rated excellent insertion were 75% for the LMA Unique, 70% for the Ambu AuraOnce, and 65% for the SSLM. All devices were judged acceptable.

Lopez and colleagues compared four single-use LMs (i.e., Ambu AuraOnce, Solus LM, LMA Unique, and SSLM) in 200 patients with ASA physical status class I, II, or III who were undergoing elective ambulatory surgery and for whom airway management was performed by inexperienced residents.[64] The Ambu AuraOnce (78%) and LMA Unique (80%) performed best in terms of ease of insertion, with the Solus requiring most reinsertions. Optimal ventilation was best with the LMA Unique (94%). Airway leak pressure was 27.3 mm Hg for

the SSLM, 23.7 mm Hg for the Ambu AuraOnce, 22.1 mm Hg for the LMA Unique, and 20.9 mm Hg for the Solus. Blood staining occurred most frequently with the SSLM (38%).

OTHER STUDIES. Gernoth and colleagues compared the performance of the Ambu AuraOnce with the LMA Classic in 60 patients whose cervical spines were immobilized with an extrication collar before elective ambulatory interventions.[65] Insertion time, number of insertion attempts, and airway leak pressures were comparable (25.6 ± 5.3 cm H_2O for the Ambu AuraOnce and 26.5 ± 6.5 cm H_2O for the LMA Classic). The investigators concluded that both devices were suitable for rapid and reliable airway management in patients with cervical immobilization.

Using an in vitro test, Zaballos and coworkers examined the Ambu AuraOnce, LMA Classic, PLMA, LMA Unique, and i-gel using magnetic resonance imaging (MRI).[66] The Ambu AuraOnce and i-gel did not lead to artifacts, whereas each of the LMAs did.

Maino and associates examined the effect of nitrous oxide exposure on intracuff pressure of PVC and silicone LMs and the LMA Classic in vitro.[67] All cuffs were initially inflated with air to a pressure of 60 cm H_2O. The findings were not surprising given the physicochemical properties of PVC and silicone. When exposed to 66% nitrous oxide, the cuff pressure rose considerably more in the silicone cuffs than in the PVC devices. Among the PVC devices, the lowest increases in cuff pressure after 60 minutes of exposure were found in the Solus and LMA Unique (13 and 15 cm H_2O, respectively), and the increases in the cuffs of the Ambu AuraOnce and SSLM were notably higher (28 and 31 cm H_2O, respectively).

LITERATURE SUMMARY. Overall, the published literature shows that the Ambu AuraOnce performs similar to the LMA Unique and similar to or better than some other single-use LMs. Studies comparing it with the LMA Classic usually report almost equivalent performance. Only one study compared the Ambu AuraOnce with second-generation SADs. There are few reports of adverse events with the Ambu AuraOnce.

2. Soft Seal Laryngeal Mask

The SSLM is a disposable device made of PVC. Like the Ambu masks, it is one of few LMs with a body of published evidence on which its performance can be judged. Product development for this mask began in November 1998. Several prototypes were tried with features designed to improve insertion and performance. Evaluation included construction of a model oropharynx and testing in this replica and cadaver models. The final product was commercially launched in Australia in May 2002 and in the United States in January 2003, making it one of the earliest LMs to come to market.

The SSLM is a tubular oropharyngeal airway with a mask and an inflatable peripheral cuff attached to the distal end (Fig. 23-4). It is designed to produce an airtight seal around the laryngeal inlet to provide a secure airway suitable for spontaneous or controlled ventilation during general anesthesia.

The SSLM is available in sizes 1 through 5. The appropriate size is based on the weight and size of the patient. For adults, mask sizes 3, 4, and 5 are suitable for patients weighing 30 to 50 kg, 50 to 70 kg, and more than 70 kg, respectively. In broad terms, size 3 is suitable for small female patients, size 4 for many male and female patients, and size 5 for larger male patients.

Smiths Portex introduced a single-use silicone LM that includes epiglottic bars. It is available only outside North America.

a. APPLICATION

Insertion technique for the SSLM is similar to that recommended for LMAs in terms of patient position, device checking, preparation, and lubrication. Although many insertion techniques are used, insertion with the cuff partially inflated is recommended for the SSLM. If a muscle relaxant is administered before device insertion, use of a triple airway maneuver (i.e., mouth opening, head extension, and jaw thrust) should decrease the incidence of epiglottic downfolding.[68] The cuff should be inflated with air until a "just-seal" pressure is obtained. A maximum intracuff pressure of 60 cm H_2O is recommended.

The SSLM may be used as an intubation conduit. As with other LMs, this can be performed blindly (using an ETT or a bougie) or under fiberoptic guidance. Due to high failure rates for the blind technique, a fiberoptically guided technique is recommended, and use of an Aintree Intubation Catheter, as described previously, is a recognized and successful technique. The SSLM has a wider ventilation orifice than the LMA Classic; larger SSLM sizes can accommodate up to a 7.5-mm ETT. This and the absence of aperture bars facilitate intubation.

b. INDICATIONS, ADVANTAGES, AND DISADVANTAGES

Indications for the SSLM are the same as for the LMA Classic, which include routine anesthesia in fasted patients. The device can be used as a rescue airway in the "cannot intubate, cannot ventilate" (CICV) or the "cannot intubate, difficult to ventilate" (CIDV) situation, or it can be used as a primary airway for rescue of an unconscious patient whose airway is compromised or at risk. In all circumstances, the clinician must balance the risk of pulmonary aspiration against the benefits of obtaining an adequate airway or oxygenation of the patient.

The limitations of use of the SSLM are the same as for other LMs. The large bowl of the device and its PVC construction have been found by some to inhibit easy insertion. These limitations affect many PVC LMs.

c. MEDICAL LITERATURE

There are approximately 27 publications about the SSLM in the medical literature.

RANDOMIZED, CONTROLLED STUDIES OF EFFICACY. Van Zundert and colleagues performed a randomized, controlled trial of the use of the size 4 SSLM and LMA Classic during spontaneously breathing anesthesia in 200 adult patients.[53] Insertion time, success, and fiberoptic position were equivalent. Further analysis of the cuff pressure change during nitrous oxide anesthesia, with the cuff pressure initially established at 45 mm Hg, showed that it increased in the LMA Classic to a mean of 100 mm Hg and that the mean final pressure in the SSLM was 47 mm Hg ($P < 0.001$).[69] There was a greater incidence of sore throat in the LMA Classic group at 2 hours postoperatively but not at 24 hours.

Similar to the low rates of trauma reported in the study by van Zundert's team, Hagberg and colleagues demonstrated that partial cuff inflation (30 mL of air) enhanced ease of insertion and minimized mucosal trauma.[70,71]

Shafik and associates performed a crossover comparison of the SSLM and LMA Classic in 60 patients.[72] The primary outcome measure was first-attempt insertion, for which success rates were equivalent (92% for the SSLM and 96% for the LMA Classic), as was ease of insertion.

Lopez and coworkers compared the SSLM with the LMA Classic in a randomized trial enrolling 60 patients.[73] Most performance characteristics were equivalent between devices, with the exception of a difference in airway seal (23 ±4 cm H_2O for the SSLM and 20 ±4 cm H_2O for the LMA Classic) and the fact that three patients in the SSLM group required the airway changed to an ETT.

Hanning and colleagues studied the SSLM and LMA Classic using a crossover design in a study of 35 healthy patients during paralyzed ventilation anesthesia.[74] The oropharyngeal leak pressure was higher with the SSLM than the LMA Classic (21 versus 16 cm H_2O).

In a crossover study, Brimacombe and colleagues compared the SSLM and LMA Unique in 90 healthy, paralyzed, anesthetized patients undergoing routine peripheral surgery.[75] The LMA Unique was superior to the SSLM in terms of ease of insertion, fiberoptic position, and mucosal trauma but similar in terms of oropharyngeal leak pressure and ease of ventilation.

In another randomized, crossover study, Paech and associates compared the SSLM and the LMA Unique in 168 anesthetized, spontaneously breathing patients.[52] The investigators reported that although both devices performed equivalently for first-time placement, the SSLM was subjectively rated more difficult to insert and more likely to cause mucosal trauma. However, the fiberoptic view of the larynx was better through the SSLM, and it more frequently provided a ventilation seal at 20 cm H_2O. In contrast to the LMA Unique, its cuff pressure did not increase during nitrous oxide anesthesia. In this study, there was a larger proportion of females, a smaller mask size was used for male and female patients, and the SSLM was inserted with a partially inflated cuff.

Cook and colleagues compared the SSLM with the LMA Unique in a randomized trial enrolling 100 patients.[76] The study was stopped early because of a high rate of airway trauma in the SSLM group. The investigators reported that the SSLM required more attempts for successful insertion ($P = 0.041$), more manipulations ($P < 0.0001$), failed more often ($P = 0.013$), and caused more complications ($P = 0.048$) than the LMA Unique. In 14% of SSLM uses, insertion or ventilation failed, and its use had to be abandoned. Leak pressure was higher with the SSLM (26.5 versus 20.5 cm H_2O, $P = 0.005$). Ventilation and fiberoptic view in those successfully inserted were not different for the two devices. The investigators also reported more complications during maintenance and sore throat postoperatively in recovery and at 24 hours for the SSLM. The SSLM was fully deflated before insertion in this study.

Francksen and coworkers studied 120 patients scheduled for routine minor obstetric surgery who were randomly allocated to the size 4 SSLM, Ambu AuraOnce, or LMA Unique.[63] The SSLM was slightly slower to insert than the Ambu AuraOnce and as fast as the LMA Unique. All three had high success rates (all >95%) for first-attempt insertions. Rates of subjectively designated excellent insertions were 75% for the LMA Unique, 70% for the Ambu AuraOnce, and 65% for the SSLM. All devices were judged acceptable.

Van Zundert and colleagues compared the SSLM with the LMA Unique and the CobraPLA in a study of 320 patients breathing spontaneously.[77] Insertion with the SSLM or LMA Unique was easier than with the CobraPLA ($P < 0.02$), but success rates and overall time to ventilation were similar. The SSLM and CobraPLA had higher airway seal than the LMA Unique ($P < 0.001$). Anatomic position was best with the CobraPLA, followed by the SSLM and LMA Unique. Blood staining occurred most frequently with the CobraPLA.

Hein and coworkers performed a crossover, randomized comparison of the SSLM and the SLIPA when inserted by trained medical students in 36 anesthetized patients.[78] Success rates for first-attempt insertions were similar (67% for the SSLM and 83% for the SLIPA), as were overall success rates (89% for the SSLM and 94% for the SLIPA). Time to ventilation with the SLIPA was faster, and there was an overall preference (67%) among participants for the SLIPA.

Tan and associates performed a randomized comparison of the SSLM, LMA Unique, and LMA Classic inserted by novice medical officers for anesthesia.[79] The novices had a total of five attempts with each mask. The SSLM was significantly slower to insert than the LMA Classic. The SSLM also had the lowest insertion success rate (80% for the LMA Classic, 77% for the LMA Unique, and 62% for the SSLM), although differences were not statistically significant. Although the SSLM achieved an airway seal of 4 to 5 cm H_2O higher than the other devices, blood on the airway was most common with the SSLM (32%) compared with the LMA Unique (9%) and the LMA Classic (6%), and sore throats were reported most frequently after use of the SSLM (42%) or LMA Classic (41%) compared with the LMA Unique (14%).

OTHER STUDIES. Boonmak and colleagues studied the use of the SSLM (sizes 3 and 4) for guiding fiberoptic intubation with a 6.0- or 6.5-mm ETT in 60 patients with normal airways.[80] The glottis was fully visible in 45% of patients after SSLM placement. Blind tracheal intubation succeeded in 5% of attempts, but with fiberoptic guidance, the success rate rose to 85%.

Danha and associates evaluated fiberoptically guided intubation through the SSLM and LMA Classic in 42 healthy patients with normal airways; a 6.0-mm, nasal, right-angle ETT was used for all evaluations.[81] Total intubation times and overall success rates were not different for the two devices. The success rate for first-attempt intubation through the SSLM was 76%.

Kuvaki and coworkers compared two insertion techniques for the SSLM in 100 patients randomized to different insertion techniques.[82] The SSLM was inserted in the two groups by a direct or a rotational technique, both without intraoral digital manipulation. The primary outcome measure was successful insertion at first attempt. The success rate for first-attempt insertion was higher with the direct technique (98%) than with the rotational technique (75%, $P = 0.002$), but insertion time was a few seconds faster with the latter method ($P = 0.035$). Final mask position over the larynx and airway morbidity were similar in both groups.

Keller and colleagues examined the pressure exerted in cadavers by the SSLM and LMA Unique on the larynx and pharyngeal wall during sequential inflation.[83] The SSLM had a lower elastance and lower intracuff pressure for a given inflation volume. Mucosal pressure increased with cuff inflation at most locations, and values were not different for the two devices at any site or cuff volume.

LITERATURE SUMMARY. A significant body of research has evaluated various aspects of the SSLM performance and compared it with other first-generation devices. Several studies comparing the SSLM with the LMA Classic and LMA Unique showed broadly equivalent performance, whereas others indicated the SSLM performed substantially less well. The airway seal of the SSLM is higher than that of the LMA Classic or LMA Unique. Insertion technique may be important. Some studies report the SSLM to be less easily inserted than the LMAs, and some report high rates of blood staining. Inflation with air before insertion appears to improve SSLM insertion and reduce trauma.

D. Intubating Laryngeal Airway

The Cookgas (St. Louis, MO) Intubating Laryngeal Airway (ILA) is distributed by Mercury Medical (Clearwater, FL). The ILA is a hypercurved intubating laryngeal airway invented by Daniel Cook. The ILA took more than 8 years to develop. In December 2004, it was introduced into clinical practice for airway management as a SAD or as a conduit for tracheal intubation. A single-use device has been launched.

The ILA is manufactured of medical-grade silicon and is latex free (Fig. 23-5). Ridges are located in the airway tube and the mask. The ridges below the airway connector were designed to improve the tube seal. They also allow easy removal of the connector during intubation through the device. The airway tube of the ILA is curved in a manner designed to mimic the anatomic curve of the upper airway; the design aims to eliminate the need to bend the tube further during use, which can lead to kinking.

The ILA tube accommodates large standard ETTs (≤8.5 mm for the larger ILA). The mask portion is large and cuffed, and it has a keyhole-shaped airway outlet designed to direct the ETT toward the laryngeal inlet. Three internal ridges located in the distal portion of the mask are designed to approximate the anatomic shape of the posterior pharynx and to create increased airway stability, smooth insertion, and improved airway alignment. When the ILA cuff is inflated, these ridges move against the posterior larynx and improve the anterior mask seal. The ILA was initially launched with three adult sizes available (2.5, 3.5, and 4.5), and two pediatric sizes were added (1.5 and 2). The increased range offers the possibility of use in small children and infants. The 2.5 is suitable for some children and adolescents 20 to 50 kg (smallest suitable ETT is 5.0 mm), the 3.5 is used in small adults (50 to 70 kg), and the 4.5 is used in large adults (70 to 100 kg). They are available in half-sizes to fit a broader range of patients.

After intubation, the ILA is removed using the Cookgas ILA Removal Stylet (Fig. 23-6), which is specifically designed for this use. The stylet stabilizes the previously inserted ETT and allows controlled removal of the ILA without dislodging the ETT from the trachea. The removal stylet consists of an adapter connected to a rod. The adapter is tapered from bottom to top and has horizontal ridges and vertical grooves. The ridges engage and grip the ETT, and the grooves create an airway passage for spontaneously breathing patients during removal of the ILA. The taper enables the stylet to accommodate standard ETTs in many sizes (5.0 to 8.5 mm). The stylet is manufactured from polypropylene and is reusable up to 10 times after washing in detergent, but cannot be autoclaved.

1. Application

After checking the patency of the device and integrity of the cuff by completely deflating and reinflating the cuff with the maximum recommended volume of air (Table 23-1), the device should be fully deflated before insertion. Performing this while pressing the anterior portion of the mask onto a sterile flat surface ensures an appropriately formed cuff for insertion. The posterior portion of the device should be prepared by applying a sterile, water-based lubricant just before insertion.

Insertion of the ILA is best performed with the patient's head and neck in the sniffing position, although other positions also may be used. The use of a jaw lift is recommended during insertion to lift the epiglottis off the posterior pharyngeal wall and increase pharyngeal space. The ILA is then inserted using a technique similar to that used for the LMA Classic, gently advancing the device while using the curvature of the ILA mask and airway tube as a guide. Some manipulation may be necessary to turn the corner into the upper pharynx. The

Figure 23-6 The Cookgas Removal Stylet is used with the Cookgas Intubating Laryngeal Airway.

TABLE 23-1
Intubating Laryngeal Airway Sizing

Mask Size	Patient Weight (kg)	Maximum Endotracheal Tube Internal Diameter (mm)
2.5	20-50	6.5
3.5	50-70	7.5
4.5	70-100	8.5

Courtesy of Tyco Healthcare, Schaffhausen, Switzerland.

device should be passed into the hypopharynx until resistance is met. The cuff should then be inflated with air (10 to 20 mL) until an effective seal is obtained or up to an intracuff pressure of 60 cm H_2O. Usually, cuff inflation with 10 mL of air is sufficient. The breathing system is then connected to the 15-mm connector, and adequacy of ventilation is assessed. If ventilation is inadequate, an up-down movement may be used to clear a downfolding epiglottis. The ILA may then be used as a SAD for airway management. A bite block should be inserted alongside the tube and taped in place in the usual fashion.

If tracheal intubation is necessary or desired, ILA positioning should be assessed for optimal ventilation (e.g., easy airflow, higher tidal volumes). Before intubation, the risk of glottic closure should be minimized by administration of a muscle relaxant or topical local anesthesia. The patient should be fully preoxygenated. An appropriately sized ETT should be selected and prepared by fully deflating the cuff and lubricating the outer surface.

The ILA connector should be removed (but not discarded) and the ETT inserted through the ILA to a depth of approximately 12 to 15 cm, depending on the ILA size. This places the distal tip of the ETT at or just proximal to the opening of the ILA airway tube within the mask cavity. Several acceptable methods can then be used to advance the ETT into the trachea, although the literature supports a fiberoptically guided technique.

- Fiberoptic technique. A fiberoptic bronchoscope is passed through the ETT and into the trachea. When the carina is seen, the fiberscope can be left in place and the ETT advanced over it using the fiberscope as a guide (i.e., railroading). The ETT cuff can then be inflated, the scope removed, and the ETT connector replaced.

- Bougie technique. An intubation bougie (e.g., Eschmann tracheal tube introducer, Frova intubation catheter) is passed through the ETT and into the trachea. By directing the angulated distal end of the bougie anteriorly, the success rate is likely increased. By gently placing fingers over the cricoid cartilage, the stylet may be felt as it passes through the cricoid ring. When the bougie has been placed in the trachea, the ETT is passed over the bougie, through the laryngeal inlet, and into the trachea.
- Blind technique. The ETT is slowly advanced through the ILA. For spontaneously breathing patients, the anesthetic circuit can be attached to the ETT connector, and capnography may be used as a guide to successful tracheal placement. The Beck Airway Airflow Monitor (Great Plains Ballistics, Lubbock, TX) can also be used to facilitate blind tracheal intubation. If resistance to further advancement is encountered, the ILA should be repositioned.

After successful tracheal intubation has been achieved with any of these techniques, the ETT cuff should be inflated, and adequate ventilation should be assessed by observation of bilateral chest movement, auscultation, capnography, or spirometry, as appropriate.

When the appropriate position of the ETT is confirmed, the 15-mm connector of the ETT should be removed and the ILA Removal Stylet used to enable removal of the ILA. The removal stylet is placed, tapered end first, into the proximal end of the ETT until the adapter fits snugly and then rotated in a clockwise direction while applying firm inward pressure until the adapter firmly engages the ETT. The cuff of the ILA is deflated to enable easier removal of the device. While stabilizing the position of the removal stylet, the ILA is slowly withdrawn outward and out of the patient's mouth, leaving the ETT with attached removal stylet in place. The removal stylet is then unscrewed from the ETT in the counterclockwise direction while applying outward tension to disengage it from the ETT. The 15-mm connector can then be replaced on the ETT and the correct position of the ETT in the trachea reconfirmed.

2. Indications, Advantages, and Disadvantages

The ILA was designed for airway management as a SAD or as a conduit for blind, stylet-guided, or fiberoptically guided tracheal intubation. The ILA has a theoretical advantage over many other SADs because it is specifically designed to facilitate tracheal intubation. Its larger bowl and curved tube are designed to enhance entry into the mouth and passage along the oropharyngeal curve. The curve of its leading edge is designed to facilitate passage behind the epiglottis and arytenoid cartilages and into the upper esophageal inlet without the need for special deflation techniques or insertion devices. Each ILA accepts routinely used PVC ETTs (see Table 23-1).

The ILA does not necessarily require removal when it has been used as a conduit. It can remain in place and later be used during emergence as a bridge to extubation. The ILA Removal Stylet is designed with grooves that enable spontaneous ventilation through the ETT during ILA removal, facilitating the performance of awake or asleep intubation during spontaneous ventilation.

The reusable ILA is nonsterile when delivered and requires cleaning and autoclaving before use. The nonsterile ILA Removal Stylet should be washed with soap and water and rinsed with alcohol before use. As with other first-generation SADs, the ILA does not provide protection against aspiration and should not be used in patients at risk of this complication. Due to the relatively low airway seal, the ILA is not suitable for patients with poor lung compliance, high airway resistance, or intraoral pathology.

3. Medical Literature

There is a limited but expanding literature on use of the ILA in adults.

a. COHORT STUDIES

Klein and Jones performed the first cohort study in 28 patients scheduled for gynecologic surgery; 22 of them were also intubated through the ILA.[84] The ILA was successfully placed (96.4%) on the first attempt in all but one patient. Leaks during manual ventilation were observed but were corrected with slight withdrawal of the device. The glottis was visible with the fiberscope in all patients, but a degree of epiglottic downfolding was observed in most cases. The investigators used the "Klein maneuver" to correct epiglottic downfolding: this involves jaw lift and withdrawal of the ILA, followed by reinsertion. Intubation through the ILA using fiberoptic guidance was 100% successful. The investigators reported that use of a flexible, reinforced ETT (Mallinckrodt) enhanced success during blind intubation.

Bakker and colleagues performed a cohort evaluation of controlled ventilation and tracheal intubation in 59 healthy patients undergoing elective surgery.[85] ILA insertion was successful in 100%, with a mean leak pressure of 19 ± 5 cm H_2O. Blind tracheal intubation was attempted in 19 patients. The first-attempt success rate was 58%, and the overall success rate for intubation was 74%. Postoperatively, 10% of patients had dysphagia, and one patient was diagnosed with bilateral lingual nerve injury, although this complication fully resolved after 4 weeks. The investigators concluded that the ILA was an adequate SAD for insertion and ventilation but that the proposed advantage of ease of tracheal intubation would require further investigation.

Joffe and associates reported a 70-patient cohort study of single-use and reusable ILAs.[86] The ILA insertion success rate was 100%, and in 57 patients, it was used as a primary airway only. The median airway leak pressures were 25 and 30 cm H_2O for the single-use and reusable devices, respectively. Fiberoptically guided intubation was successful in 12 (92%) of 13 attempts. Postoperatively, 26% of patients complained of mild sore throat.

Yang and coworkers studied 60 patients who were anticipated to be difficult to intubate and in whom the ILA was used for intubation; in one half, it was guided by a fiberscope and in one half by a Shikani Optical Stylet (SOS).[87] Insertion and ventilation through the ILA was

successful in all patients. With the fiberscope, all but two were intubated on the first attempt, and they were successfully intubated on the second or third attempt. In the SOS group, 18 patients were intubated on the first attempt and 7 on the second attempt. The five failures in this group were all successfully intubated with the fiberscope. The fiberscope enabled faster intubation with a higher success rate. The hemodynamic changes recorded during intubation were minimal.

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

Using a noninferiority approach, Karim and colleagues compared the ILA and single-use ILMA during attempts at blind intubation in 154 healthy adults undergoing elective surgery.[88] The primary outcome measure was successful intubation within two attempts. This was achieved with the ILA in 77% (60 of 78) and with the ILMA in 99% (75 of 76) of patients (95% CI for the difference, 12% to 32%; $P < 0.0001$). After two failed blind attempts, fiberoptic guidance was used. In the ILA group, this enabled successful intubation of another 14 patients, but it failed in 4 patients. The overall intubation success rate using the ILA with three attempts (one with a fiberscope) was 95%. The investigators concluded that the single-use ILMA appears to be superior to the ILA as a conduit to facilitate blind tracheal intubation. A notable feature of this study was that one half of the patients had a body mass index (BMI) of 30 to 40 kg/m^2 including one fourth who had a BMI of more than 35 kg/m^2. BMI did not appear to influence the success rate of the ILA.

Erlacher and associates compared the ILA, ILMA, and CobraPLUS (Engineered Medical Systems, Indianapolis, IN) for ventilation and blind intubation in 180 healthy adults.[89] Ventilation was excellent with all devices, and minor repositioning was required in no more than 5% of patients in any group. Blind intubation was successful using the ILMA in 95% of cases, the ILA in 57%, and the CobraPLUS in 47%. Fiberoptic intubation was possible in all but one patient. Standard measures for predicting difficulty during routine intubation were not useful for predicting difficulty during blind intubation through these SADs.

c. OTHER STUDIES

Wong reported the use of an ILA combined with a lighted stylet to achieve intubation in a patient with a potentially difficult airway.[90] The patient had Hallermann-Streiff syndrome with oculomandibulofacial dystocia (i.e., bird-like appearance, mouth opening of 4 cm, receding chin, and Mallampati class III score). The lighted stylet (with the introducer removed) was placed inside the ETT, and transillumination was used to identify tracheal intubation.

d. LITERATURE SUMMARY

The available evidence suggests the ILA is an effective SAD that is usually easily inserted and enables ventilation. Blind tracheal intubation is successful at a higher rate than with most SADs but not as high as the ILMA. Use of a fiberscope increases the success rate, but several studies report some failures with this addition. Studies comparing the ILA with other SADs would be of value, as would determination of the role of the ILA in difficult airway management.

E. Laryngeal Tube

The VBM Laryngeal Tube (VBM Medizintechnik, Sulz, Germany) and King Laryngeal Tube (King Systems, Noblesville, IN) are SAD devices that were introduced to the European market in 1999 and to the United States in February 2003.[91] Between 1999 and 2002, several modifications were made to the original version of the laryngeal tube (LT), including a softer tip, a change from cuff inflation by separate pilot tubes to a single pilot tube, and alterations to the ventilation orifices and proximal cuff. Among the several distinct LTs, some are first-generation and others second-generation SADs.

There are five versions of the LT: the reusable LT, the disposable LT (LT-D), the reusable Laryngeal Tube Suction II (LTS-II), a disposable version of the LTS-II (LTS-D), and the Gastro-Laryngeal Tube (Gastro-LT). The LTS-II, LTS-D, and LT-G are considered later in "Second-Generation Supraglottic Airway Devices." The LT is designed for use during spontaneous breathing, controlled ventilation, and airway rescue.

The LT consists of an airway tube with two inflatable balloons or cuffs designed to lie above and below the laryngeal inlet (i.e., pharyngeal and esophageal, respectively), and both cuffs are inflated through a single pilot tube and balloon (Fig. 23-7).[91,92] When the device is inserted, it lies along the length of the tongue and extends distally into the proximal esophagus. Proximal and distal cuffs sit in the oropharynx and esophageal inlet, respectively. Inflation creates a seal, and ventilation occurs through orifices between the cuffs. Proximally, a 15-mm standard male adapter enables connection to the anesthetic circuit, and distally, several small airway orifices lie between the balloons (Fig. 23-8). Three black lines proximally indicate approximately correct depth of insertion.

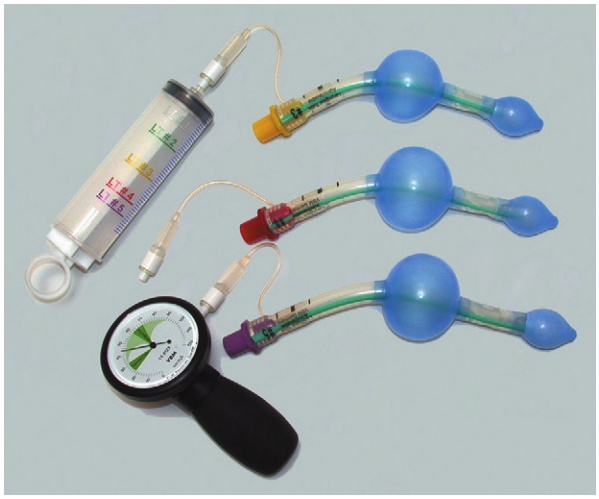

Figure 23-7 The VBM laryngeal tube (reusable versions, adult sizes shown). Also shown is a dedicated color-coded syringe *(top left)* for use with the LT and an inflation and cuff pressure monitor device *(bottom left)*.

The LT is made of silicon and is designed to be reused up to 50 times. The airway tube is slim, curved, and relatively short, with an average diameter of 11.5 mm and a blind tip. Seven sizes are available for use in neonates up to large adults (Table 23-2).[91,92] LT size selection should be based on the patient's weight for sizes 0 to 2 and on height for sizes 3 to 5. The disposable version (LT-D) is sold in sizes 2 to 5. Adult and child sizes (but not infant and newborn sizes) are supplied with a reusable, silicone bite block.

After correct device insertion, the proximal cuff lies in the hypopharynx and the distal cuff in the upper esophagus. Both cuffs have a high-volume, low-pressure design to avoid ischemic damage to mucosa and to achieve a good seal. The original version of the LT was designed with a single ventilation opening between the two cuffs in the ventral part of the tube. The current version has two main ventilation orifices.

The proximal cuff lies close to the proximal airway orifice, and there is a V-shaped dent in the pharyngeal cuff. As the cuff is inflated, soft tissue is deflected from the airway opening, helping to maintain a patent airway. The distal end of the airway tube slopes toward the distal ventilation orifice. The tip of the LT is a closed wedge shape, and it is surrounded by the distal cuff. Because there is a single inflation line, both cuffs inflate almost simultaneously.

In addition to the main ventilation orifices, there are two side eyelets, with one on either side of the main ventilation orifices. This design allows improved collateral ventilation if the epiglottis obstructs the main ventilation orifice. The latest version of the LT-D has three eyelets on each side. The efficacy of this design feature has not been formally tested. The LT-D is 1.0 cm longer than the LT to facilitate deeper placement of the device, aid correct positioning of the two main ventilation orifices, and improve the location of the proximal cuff beneath the tongue, so that the epiglottis is more likely to be raised with cuff inflation, in much the same manner as with a Macintosh laryngoscope blade.

1. Application

Before each use, the reusable LT must be cleaned and sterilized (by autoclaving) according to manufacturer's instructions. The device's general condition, tube patency, and integrity of both cuffs should be confirmed before use. Cuff integrity is tested by full deflation and inflation to check for leaks. The depth of anesthesia required before insertion is similar to that for other SADs: when the patient is unconscious, is apneic, and has no eyelash reflex or resistance to manipulation of the lower jaw. Muscle relaxants are unnecessary, but anesthesia should be deep enough to obtund airway reflexes. An appropriately sized LT should be chosen according to the selection criteria described previously. Before insertion, the cuffs must be fully deflated and lubricated. The LT may be inserted with a neutral head position or in the sniffing position; in the latter position, jaw lift may be needed to negotiate the angulation of the posterior pharynx.

The slim profile of the LT and easy insertion technique mean it can be inserted with either hand and with the anesthesiologist standing in a variety of positions. During routine use, the LT should be held in the dominant hand and inserted blindly along the midline of the tongue with the tip against the hard palate. It is passed smoothly along the palate into the hypopharynx until resistance is felt. If no resistance is felt, a thick, black line on the tube indicates the appropriate depth of insertion, and this line should lie at the incisors. After insertion, the cuffs should be inflated. As air is injected, the proximal cuff inflates first, stabilizing the device, followed by inflation of the distal cuff. A pressure gauge should be used to inflate the cuffs to a pressure of 60 cm H_2O. If a gauge is not available, a dedicated syringe can be used for cuff inflation. These 100-mL syringes have clear markings (in colors corresponding to the various LT color codes) indicating the approximate volumes of air needed for each size. The LT can then be connected to the breathing system. Indicators of correct LT placement are auscultation of bilateral lung sounds, bilateral chest excursion, absence of gastric insufflation, and an appropriate capnographic trace. When the LT is correctly positioned, the bite block, which is supplied with the device, can be attached to the tube.

After LT placement, manual, controlled, or spontaneous ventilation may be used. Initial use of positive-pressure ventilation may provide useful information about the correctness of LT placement. If ventilation is not ideal, the LT may be advanced or withdrawn slightly until ventilation is optimal. If controlled ventilation through the LT is problematic, spontaneous ventilation may also be difficult.

Correct placement of the LT may be verified using a test with a lightwand without the metallic stylet. The lightwand is inserted into the LT and advanced through it until a faint glow can be seen above the thyroid prominence. This indicates that the lightwand tip is just in front of the laryngeal inlet. When the LT is correctly positioned, the lightwand tip enters the glottic opening, and correct positioning is shown by a well-defined, circumscribed glow seen in the anterior neck slightly below the thyroid prominence. If transillumination shows a glow with a halo near the thyroid prominence, the test result is considered negative. This result may be caused by the lightwand tip lying against the epiglottis or the glossoepiglottic fold. A lateral glow indicates that the hole for ventilation is not in front of the laryngeal inlet, even if ventilation is effective.

At the end of anesthesia, the LT can be left in place until the return of the protective airway reflexes. Slight cuff deflation at this point improves tolerance of the oropharyngeal cuff. The device should be removed with the patient deeply anesthetized or totally awake; otherwise, laryngospasm, coughing, or gagging may occur. Before removal of the device, the cuffs should be completely deflated. Inadequate cuff deflation can make removal difficult, risking damage of the cuff and discomfort for the patient.

A well-lubricated ETT (up to 6.5 mm) can be inserted into the LT after the proximal connector has been removed. An attempt to intubate blindly through the LT is then possible, and success relies on alignment of the ventilation orifices and the glottis. The tip of the ETT is gently advanced until it passes through the glottic opening. Resistance may be caused by incorrect positioning of the LT, epiglottic obstruction of ETT passage, or inadequate lubrication of the ETT. A tube exchanger may be placed in this manner, and after removal of the LT, an appropriate ETT can be passed. Fiberoptic guidance is an alternative and likely a more successful technique. Alternative described methods include the use of a rigid video laryngoscope to view intubation from outside the LT during insertion and use of a Trachlight to guide and monitor intubation.

After intubation is achieved, the LT cuffs must be deflated before the device is removed. The shorter tube shaft of the LT compared with the LMA Classic allows the ETT to be inserted farther into the trachea and makes it possible to place the ETT cuff in the trachea without removing the LT. Unless indicated otherwise, there is an argument for leaving the LT in place with both cuffs deflated after tracheal intubation has been performed. It is possible to perform tracheal intubation through the LT with an Aintree intubation catheter (AIC, Cook Critical Care), but passage of the AIC through the ventilation holes is at the limit of what can fit.

There are disadvantages to using the LT as a conduit for intubation. The diameter of the ETT is limited by the LT size. The rather narrow LT airway orifice compared with many other SADs may cause problems because it does not lie opposite the glottis or because negotiating the fiberscope or tube into the glottis is difficult. The relatively narrow ventilation orifices of the LT, its narrow lumen, and the fact that axial rotation may lead to imperfect alignment of the airway and larynx mean that the LT is unlikely to be first choice if selecting a specific SAD for intubation.

2. Indications, Advantages, and Disadvantages

The LT is designed for use during spontaneous or controlled ventilation. Because the slim profile of the LT allows easy insertion through a narrow orifice, it can be considered for airway management in patients with restricted mouth opening. Insertion is relatively easy and provides a clear airway in most patients on the first attempt. Extensive training is unnecessary. Its insertion and performance characteristics have led to its being included as an airway device for use in the management of cardiac arrest in the 2010 guidelines of the International Liaison Committee on Resuscitation (ILCOR).[93]

Because of the design and length of the LT, inadvertent tracheal intubation is unlikely, although it has been reported with some versions of the device.[94] The LT is associated with a low incidence of minor traumatic sequelae, such as sore throat, hoarseness, or blood on the device after use. The slim design, soft materials used in construction, and high-volume, low-pressure cuffs offer advantages. These high-volume, low-pressure cuffs provide a good seal and reduce the risk of ischemic damage when used appropriately. Another advantage is the ability to insert the device from a variety of positions relative to the patient, making it useful in emergency situations.

The LT may be used to maintain ventilation during attempts at fiberoptic intubation. The fiberoptic bronchoscope and ETT can be advanced through the nose into the oral cavity without deflating the cuffs of the LT. After tracheal intubation has been accomplished, the cuffs of the LT can be deflated and the device removed.

Although the LT's distal cuff forms a good esophageal seal, the LT and LT-D do not have drain tubes, and the LT should not be used in anesthetized patients at increased risk of regurgitation or aspiration of gastric contents. As with other SADs, due to the relatively low-pressure airway seal, the LT may not be appropriate in patients with poor lung compliance, increased airway resistance, or lesions of the oropharynx or epiglottis.

As with any SAD, partial glottic closure or laryngospasm may lead to airway obstruction. This may occur if the LT is inserted at too light a depth of anesthesia or if there is excessive surgical stimulation without an appropriate depth of anesthesia. These changes may be identified by alterations in capnography, spirometry, or airway pressure during mechanical ventilation.

The slim LT can rotate within the airway along its longitudinal axis. When this happens, the airway orifices, which are smaller than those of some other SADs, become poorly aligned with the glottis, with the risk of increased airway resistance or airway obstruction. This risk is minimized by careful insertion and confirmation of correct positioning during initial placement and cuff inflation.

3. Medical Literature

There are more than 150 publications about the LT and its design variations. Because the LT was modified, studies

reporting before 2003 are likely to have evaluated an LT device that is no longer in use.

a. COHORT STUDIES AND STUDIES OF GENERAL PERFORMANCE

Using earlier versions of the LT, Asai,[95] Doerges,[96] and their colleagues determined that after blind insertion, the device provided a patent airway in most patients at the first attempt. The LT can be inserted quickly without extensive training; it is considered a suitable airway management device with a high rate of successful insertion requiring a mouth opening as limited as 23 mm.[97,98] Acceptance of the ease of LT placement is high among physicians, nurses, and paramedics, although correct positioning may require more adjustments in patients with an increased BMI.[99-101] Insertion time is reported to be comparable to that for the LMA Classic.[96]

Several studies confirmed the efficacy of controlled ventilation with the LT and found that its airway seal was modestly better than that of the LMA Classic, with some patients achieving a seal above 30 cm H_2O.[96,102-105] Although numerous studies have shown the LT can be effective during mechanical ventilation, some studies, most notably that of Miller (inventor of the SLIPA), have found the LT to be unsatisfactory for spontaneous ventilation.[106] The findings of Miller and colleagues were based on a frequent failure rate (7 of 17 patients) caused by loss of airway control during surgery.[106] The investigators assessed use of a first-generation LT that did not feature a second, large ventilation aperture and two lateral ventilatory openings that are part of the newer version.

In another study by Hagberg and colleagues, the LT was demonstrated to provide a reliable airway during elective surgery with spontaneous ventilation.[105] In this study, the mean depth of insertion was greater than expected for each size of the LT, and as a result, the company now manufactures this device 1 cm longer in the silicon version and 2 cm larger in the disposable version. The success rate for first-time placement was 86%, consistent with the rates of 85% to 95% found in previous studies.[96,102-104]

The dose of propofol required for LT insertion is approximately the same as for the LMA Classic.[107] Nitrous oxide diffuses into the cuffs, and cuff pressures should be monitored during use. During 30 minutes of nitrous oxide anesthesia, Asai and coworkers demonstrated an increase of 15 cm H_2O in the intracuff pressure.[104,108]

Because of the ease of insertion and a good airtight seal, the LT has been studied for airway management during cardiopulmonary resuscitation. There is considerable data on its use by medical staff and paramedics for primary airway management out of hospitals and for airway management during cardiopulmonary resuscitation.[109-113] The LT is included in the 2010 ILCOR resuscitation guidelines.[93] Dengler and associates reported some cases of massive pulmonary aspiration and one of gastric overinflation during use of the LT in the emergency setting.[114] This followed ventilation with high peak airway pressures, and the investigators questioned whether the LTS-II or LTS-D would have been a more appropriate device.

Langlois and associates performed a cohort study of the LT-D in 50 anesthetized patients.[115] Insertion was successful in 94%, and the median insertion time was 38 seconds. Insertion difficulty occurred in 25%. Mean oropharyngeal leak pressure increased from 26 cm H_2O (range, 22 to 32.5 cm H_2O) to 34 cm H_2O (range, 29 to 40 cm H_2O) at the end of surgery. No cases of gastric inflation, regurgitation, or hypoxia were reported. The incidence of moderate sore throat was 6% in the recovery room and 0% at 24 hours.

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

Amini and colleagues performed a study comparing the LT with the LT-D in 100 anesthetized, paralyzed patients.[116] Both devices showed similar clinical performance in terms of insertion success (90% for the LT-D and 96% for the LT) and insertion time (28.4 and 23.6 seconds, respectively). There were no differences in airway leak pressure, fiberoptic position, or postoperative sore throat and dysphagia.

Yilidz and associates compared the LT with the LMA Classic in 132 patients.[117] Oxygenation and ventilation were possible in all patients. Insertion success rates after the first, second, and third attempts were 84.8% ($n = 56$), 12.1% ($n = 8$), and 3% ($n = 2$) for the LT compared with 56.1% ($n = 37$), 25.8% ($n = 17$), and 18.2% ($n = 12$) for the LMA Classic ($P = 0.001$). Blood on the cuff was seen at removal in one patient with the LT and in 10 patients with the LMA Classic. Six patients in the LMA Classic group complained of hoarseness ($P = 0.012$). The success rates for LMA Classic insertion are markedly lower in this study than in many others, which may influence many of the results.

Noor and coworkers compared the LT and LMA Classic for ventilation during manual in-line stabilization in 40 healthy, anesthetized, and paralyzed patients.[118] Three attempts were allowed. The success rates (100%), adequacy of ventilation, and hemodynamic changes were not different for the two devices. The LT has a higher first-attempt success rate (100% versus 85%) and was significantly faster to insert (25 versus 36 seconds, $P = 0.001$).

Kurola and colleagues studied insertion of the LT, ILMA, and CobraPLA by paramedical students in 96 anesthetized, paralyzed patients.[119] The success rates for first-attempt insertion were 75% for the ILMA, 44% for the LT, and 22% for the CobraPLA. Overall success rates were 97% for the ILMA and 79% for the LT and the CobraPLA. In this small study, the numeric differences were not statistically significant.

c. OTHER STUDIES

No studies have been published examining whether the lower cuff protects against aspiration. Khazin and associates studied hypopharyngeal pH changes as a marker of regurgitation during anesthesia with several SADs (e.g., LT, CobraPLA, LMA Classic, ILMA, and PLMA) and with ETTs in 180 patients.[120] One to five patients in each study group of 30 had regurgitation episodes, but the rates were not statistically different between groups. The clinical relevance of the study, particularly its relevance to aspiration protection, is questionable. Bercker and coworkers designed a study to compare the seal of seven SADs in a cadaver model of elevated esophageal pressure. SADs included the LMA Classic, PLMA, ILMA, LT,

LTS-II, Combitube, and EasyTube.[40] All were inserted into unfixed human cadavers with an exposed esophagus that had been connected to a 130-cm water column. Slow and fast increases of esophageal pressure were performed, and the water pressure at which leakage appeared was documented. The Combitube, EasyTube, and ILMA withstood the water pressure up to more than 120 cm H_2O. The PLMA, LT, and LTS-II blocked the esophagus despite 72 to 82 cm H_2O of pressure. The LMA Classic leaked at 48 cm H_2O, but only minor leakage was found in the trachea. Devices with an additional esophageal drain tube removed fluid sufficiently without pulmonary aspiration. The LTS-II and LTS-D are likely to provide better protection than the LT.

Ulrick-Pur and colleagues examined the mucosal pressures exerted by several SADs in fresh cadavers.[121] Using maximum cuff volumes according to the manufacturers' guidelines, the highest pharyngeal pressures were found with the ILMA. The LMA Classic, ILMA, and PLMA induced significantly higher pharyngeal pressures than the LT, EasyTube, or Combitube at maximum inflation. The maximum esophageal pressures were significantly higher using the EasyTube than with the Combitube. Tracheal mucosal pressures were significantly higher using the Combitube compared with the ETT and the EasyTube.

Asai and coworkers reported successful use of the LT in three patients in whom insertion of the LMA had failed, and they suggested the relative width of the devices was responsible for failure or success.[122] In these cases, the pharyngeal space was narrowed by swollen tonsils, goiter, and redundant oropharyngeal tissue, and the investigators recommended that when LMA insertion is difficult or impossible because of a narrowed pharynx, insertion of the LT should be attempted before considering tracheal intubation. Reported side effects with the LT are few but do include tongue engorgement.[123]

d. LITERATURE SUMMARY

The LT is an easily inserted SAD. Alterations over the years have improved performance. Insertion by anesthesiologists and less-experienced practitioners can be performed with success rates exceeding 90%. Controlled ventilation may be more reliable than spontaneous ventilation. Airway seal is better than the LMA Classic but not as good as the PLMA. Protection against aspiration is undefined, and there are better alternatives when this is a factor in choosing a device. The LT-D appears to perform similar to the LT. The LT has an important role in out-of-hospital use.

F. Cobra Perilaryngeal Airway

The Cobra perilaryngeal airway (CobraPLA, Engineered Medical Systems, Indianapolis, IN) (Fig. 23-9) was designed by David Alfery. It was based on a modification of the Guedel oral airway and was marketed in 1997. The initial idea was to modify the Guedel airway to accomplish mask ventilation in the most difficult airways encountered. It has since been adapted to create a SAD. The proximal portion of the airway was modified to enable attachment to an airway circuit, a circumferential cuff was added proximal to the distal breathing hole, and the distal end of the device was modified to form a cobra head shape. Later refinements included a distal flexible tip (tongue) and an internal ramp inside the cobra head to help guide an ETT toward the glottis. A modification of the CobraPLA, the CobraPLUS, incorporates an integrated temperature probe and a distal gas-sampling port.

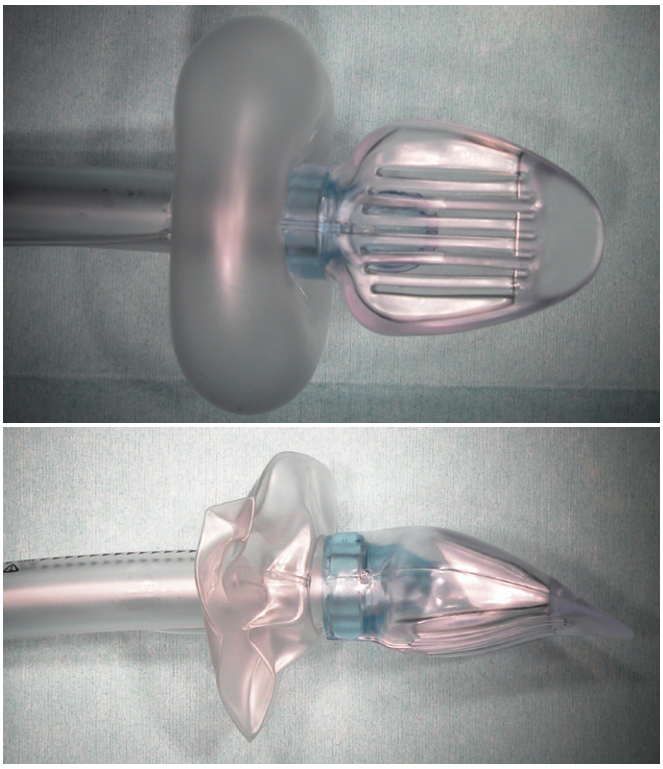

Figure 23-9 The Cobra perilaryngeal airway (CobraPLA) with cuff inflated *(top)* and deflated *(bottom)*.

The CobraPLA is made of PVC and polycarbonate. It consists of a breathing tube with a proximal, standard 15-mm adapter; a circumferential, inflatable cuff proximal to the ventilation orifice; and a distal, widened cobra-like head that surrounds the ventilation orifice. The anterior surface of the head consists of a grill of soft bars through which gas exchange takes place. The bars are soft enough to allow instrumentation of the larynx and upper airway if required. When in the proper position, the head lies in front of the laryngeal inlet and is designed to seal the hypopharynx. In this respect, it is different from many other SADs, because the distal tip lies proximal to the esophageal inlet. Internal to the head, there is a ramp to direct the breathing gas (or ETT) into the trachea. The head and anterior grill are designed to deflect the epiglottis off the head, preventing the epiglottis from obstructing the ventilation orifice. The cuff is circumferential and is designed to lie in the hypopharynx at the base of the tongue. When inflated, it raises the base of the tongue, exposing the laryngeal inlet, and it effects an airway seal, allowing positive-pressure ventilation to be carried out.

The device is named *Cobra* because of the shape of the distal part of the airway; when turned over and looked at on end, it appears similar to the head of a cobra snake.

This shape is designed to enable the device to pass more easily along the hard palate during insertion and to hold soft tissues widely away from the laryngeal inlet after the device is in place. *Perilaryngeal* describes its anatomic location and refers to the fact that the widened, distal Cobra end pushes soft tissues away from the laryngeal inlet.

The CobraPLA is available in eight sizes (1.5 through 6) designed to be used according to the weight and size of the patient. The recommended size is that which comfortably fits through the patient's mouth. Appropriate sizes are no. 3 for most female patients, no. 4 for most men, and no. 5 for larger men. When unsure about the appropriate size, especially when learning placement, use of the smaller of any two sizes under consideration is advisable. When a practitioner is comfortable with the insertion technique, especially when a muscle relaxant has been administered, use of a larger size may also be successful. The most important consideration is to choose a size that fits through the patient's mouth without undue difficulty, and the same device size may be appropriate for patients of considerably different weight, depending on their body habitus. The manufacturer suggests that two or more sizes may be acceptable for a particular height. Despite a relatively high weight, some patients may have a small mouth that necessitates a smaller CobraPLA.

Agro and colleagues suggested a modified method of size selection: no. 3 for less than 60 kg, no. 4 for 60 to 80 kg, and no. 5 for more than 80 kg.[100] In this study, relatively large CobraPLAs were used by skilled operators with techniques that included a combination of scissoring the mouth open and performing a jaw lift (i.e., Agro maneuver) in patients who had been given muscle relaxants. If using Agro's range or a relatively large CobraPLA, the cuff inflation volume can be reduced from the maximum recommended by the manufacturer. Use of the larger sizes achieves a higher degree of airway seal.

The CobraPLUS is a modified version of the CobraPLA which in its adult version has an integrated core temperature–measuring device and in its pediatric version also has a distal gas-sampling post within the device head. This is of particular interest in newborns and infants, in whom very rapid respiratory rates and low tidal volumes result in inaccurate gas-sampling values if using more proximal sampling sites.[124]

1. Application

The CobraPLA insertion technique is simple. After appropriate checks of integrity and patency, the cuff is fully deflated and folded back against the breathing tube. A lubricant is liberally applied to the front and the back of the Cobra head and to the cuff, with care taken to avoid obstructing the anterior grill. With the patient's head and neck in the sniffing position, the mouth is opened with a scissor maneuver using the nondominant hand and gently pulling the mandible upward. The CobraPLA tip should not be directed against the hard palate, as is often done when inserting an LMA Classic because this may increase the curve that the device tip must take at the back of the mouth and make insertion more difficult. The distal end of the CobraPLA is instead directed straight back between the tongue and hard palate. As the device is advanced into the mouth, an anterior jaw lift assists insertion. Pushing the jaw downward makes insertion more difficult. Modest neck extension (without a jaw lift) may aid passage of the device as it turns toward the glottis at the back of the mouth.

As the CobraPLA is advanced to the back of the mouth, it often turns caudally toward the larynx with minimal resistance as the flexible distal tip (tongue) guides the device downward. Sometimes, a gentle push past posterior resistance is needed. The CobraPLA is correctly seated when modest resistance to further distal passage is encountered as the device tip reaches the glottis. When the position is correct, the flexible tip lies under the arytenoids, the ramp-grill lifts the epiglottis, and the cuff lies in the hypopharynx at the base of the tongue.

After insertion, the cuff should be inflated initially with less than the maximum volume recommended until there is no leak with positive-pressure ventilation (i.e., minimal leakage technique). Providing an adequate depth of anesthesia is achieved, the cardiovascular response to CobraPLA insertion is similar to insertion of other SADs and therefore less than during laryngoscopy and tracheal intubation.

Manual ventilation assists the anesthesiologist in confirming correct placement and may determine the pressure at which an audible leak occurs. Indicators of correct placement are good lung ventilation, a normal capnographic trace, and no gastric insufflation.

Cuff inflation should be enough just to achieve a seal, and overinflation should be avoided. A cuff pressure gauge should be used to monitor intracuff pressure (approximately 60 cm H_2O). If adequate ventilation is not achieved, the CobraPLA may be inserted too far and should be withdrawn 1 to 2 cm. Spontaneous or mechanical ventilation can be used as indicated. Ventilation with an airway pressure above 25 cm H_2O should be avoided, even when testing for ventilation and cuff seal, because gastric insufflation may occur at pressures over this level. Low-pressure ventilation may be achieved by setting a low inspiratory flow rate and then adjusting the tidal volume. Pressure-controlled or pressure-limited modes of ventilation may also be useful to minimize peak airway pressure.

Some practical tips are worth considering. First, the patient should be at an adequate depth of anesthesia before insertion is attempted. Laryngospasm may occur during insertion if the patient is at too light a level of anesthesia. Second, if one CobraPLA is found to be unsuitable, an alternative size should be inserted before abandoning this technique. Third, if the CobraPLA is not inserted far enough, cuff inflation may cause tongue protrusion and a poor airway seal; the device should be advanced further or a smaller CobraPLA chosen. The cuff should not be visible at the base of the tongue when the mouth is opened. Fourth, if the CobraPLA is inserted too far, past the laryngeal inlet, ventilation is impossible. This may occur while learning the technique or if too small a CobraPLA is used. Pulling back the airway 1 to 2 cm usually resolves the situation. The CobraPLA is

considered to have a steep learning curve, and the technique can be mastered in 5 to 10 insertions.[100]

Removal should be performed as the patient regains consciousness. When the patient is able to respond to simple commands (e.g., "open your mouth"), the CobraPLA cuff may be partially deflated and the device gently withdrawn from the patient. Partial deflation of the cuff enables it to squeeze secretions up and out of the mouth as the CobraPLA is removed.

The CobraPLA may be used as an intubation conduit. Its internal diameter is larger than the corresponding LMA Classic, and the largest CobraPLA has a 12.5-mm ID. This means that intubation through a CobraPLA with a relatively large ETT without an intubation guide or exchange catheter is feasible. Provided the proximal connector is removed, because the CobraPLA is shorter than many other SADS, a standard ETT may be passed through it far enough that the cuff lies below the vocal cords. This potentially makes the procedure technically easier than through an LMA Classic, and it does not require an extra-long ETT.

A standard ETT may be used for intubation through a CobraPLA, ideally guided by a fiberscope. As the fiberscope and ETT exit the ventilation orifice, the soft bars of the grill separate easily without impediment to advancement. The internal ramp directs the fiberoptic bronchoscope anteriorly, and if the larynx is anterior to the ventilation orifice, this approach should enable prompt intubation. The large diameter of the CobraPLA permits the passage of an adequately sized ETT (Table 23-3). The CobraPLA can be left in place with its cuff deflated if desired.

An alternative technique involves use of a lightwand to guide intubation, as has been described for other SADs.[99,125,126] The technique is described in the "Laryngeal Tube" section. Blind intubation through the CobraPLA by advancing an ETT through it or by using a bougie guide may be successful, but it has a significant failure rate, and the preceding techniques are far preferable when the equipment is available.

2. Indications, Advantages, and Disadvantages

The indications for use of the CobraPLA are similar to those for other first-generation SADs. This device cannot be relied on to protect the upper airway from aspiration in anesthetized patients. Unlike many other SADs, the tip of the device does not enter and obturate the esophagus but is designed to lie above it. Elective use should be confined to patients not considered to be at risk for regurgitation of gastric contents.

TABLE 23-3
Sizing for Passage of an Endotracheal Tube in a CobraPLA

1½	4.5
2	6.5
3	6.5
4	8.0
5	8.0
6	8.0

ETT, Endotracheal tube; *PLA,* perilaryngeal airway.

The CobraPLA is designed for spontaneous and controlled ventilation. Like other SADs, the CobraPLA can be used as a rescue airway in CICV or CIDV scenarios, but it does not provide airway protection. If it is used to rescue the airway and regurgitation or aspiration is considered a risk, it is advisable to proceed to tracheal intubation if possible.

The relative ease of insertion is an advantage of the CobraPLA, which may make it suitable for use in airway emergencies even when it is used by personnel with little or no experience in the use of SADs. Some clinical evidence supports the efficacy of use by nonanesthesiologist physicians with minimal training in airway management.[127] Pediatric sizes of the CobraPLUS can monitor core body temperature and distal carbon dioxide levels.

As with many SADs, because airway pressures should be limited to no greater than 20 to 25 cm H_2O, the CobraPLA may not be appropriate for patients with reduced lung compliance or increased airway resistance. The major disadvantage of the device is that it does not protect against aspiration and does not secure the airway as effectively as the tracheal tube. Users should remember that the CobraPLA tip does not obturate the upper esophagus. Whether this increases the risk of aspiration compared with other SADs has not been determined definitively.

3. Medical Literature

Approximately 40 publications have described the CobraPLA or CobraPLUS. The CobraPLA was modified to aid insertion in 2006, as reported by the inventors, Alfery and Szmuk, in 2007.[128] The manufacturers modified the CobraPLA and the CobraPLUS by adding a distal bend in the breathing tube. It is likely that only publications after 2007 used the updated device, and this should be considered in interpreting these studies.

a. COHORT STUDIES

The first report of the use of the CobraPLA in a peer-reviewed journal was by Agro and coworkers in 2003; the study included 28 anesthetized and mechanically ventilated patients.[129] After mannequin training, the CobraPLA was inserted in patients within 10 ± 3 seconds with a 100% success rate. Immediate ventilation was achieved in 57% of patients, and 43% required a positioning maneuver (e.g., pulling back).

In a later study, Agro and colleagues studied 110 patients and reported 100% successful insertion in a mean time of 6.8 ± 2 seconds.[100] There were no adverse events or significant complications. Mean airway seal was 34 cm H_2O using very low cuff inflation volumes by choosing relatively large CobraPLAs.

In contrast, Cook and Lowe reported an aborted study with the CobraPLA.[130] During preparation for two studies, a total of 29 CobraPLAs were inserted, and two cases of significant aspiration were identified. The investigators raised concerns about the design of the CobraPLA and its safety in terms of aspiration protection. The manufacturers robustly rejected these assertions.[131-133]

Park and associates studied the effect of changing head and neck positions on SAD performance, including the CobraPLA, in 139 patients.[134] Oropharyngeal leak pressure and cuff pressure were evaluated in four head and neck positions: neutral, 45 degrees of flexion, 45 degrees of extension, and 45 degrees of right rotation. Adverse events such as difficult ventilation or gastric insufflation were assessed. Airway leak pressures were well maintained with the CobraPLA, but "gastric insufflations occurred before the oropharyngeal leak in 37 of 45 patients."[134] The investigators concluded that caution is warranted when changing the position of the head and neck while using the Cobra-PLA because gastric insufflation may occur.

Nam and coworkers reported a case series of 50 uses of the CobraPLA in paralyzed patients undergoing elective surgery.[135] The success rate for first-attempt insertion was 82%, with a mean insertion time of approximately 16 seconds. Airway leak pressure (22.5 cm H_2O) was lower than other reports. The point of leakage was recorded as the neck (52%), abdomen (46%), or both sites (2%). The glottis was visible in 88% of patients through the CobraPLA. Postoperative blood staining was seen in 22%, mild dysphonia in 6%, mild dysphagia in 10%, and mild and moderate sore throat in 44% and 4%, respectively.

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

Akça and colleagues compared the CobraPLA with the LMA Unique in a randomized series of 81 patients, and the insertion times, airway adequacy, number of repositioning episodes, and minor complications were similar in both groups.[136] However, the cuff leak pressure of the CobraPLA was significantly greater than that of the LMA Unique (23 versus 18 cm H_2O). The investigators found lower airway leak pressures than Agro did, most likely because the Akça study used smaller CobraPLAs.

Gaitini and others, including the inventor, compared the CobraPLA with the LMA Unique during spontaneous ventilation in 80 anesthetized patients.[137] They reported no statistically significant difference between the devices regarding ventilatory variables, number and type of airway interventions required for placement, fiberoptic view, or incidence of adverse events. Reported benefits of the CobraPLA were a significantly higher airway leak pressure (27 versus 21 cm H_2O) and higher oxygen saturation (98% versus 97%) than for the LMA Unique. Conversely time for insertion was significantly shorter for the LMA Classic (24 versus 27 seconds), and insertion was slightly easier than with the CobraPLA.

In a crossover study between the CobraPLA and LMA Classic during controlled ventilation, Nam and associates reported a faster median insertion time for the CobraPLA (15 versus 25 seconds) and a higher median airway seal (23 versus 15 cm H_2O).[138] Other aspects of performance were not different.

Schebesta and coworkers compared the CobraPLA with the LMA Classic in 60 anesthetized patients.[139] The study focused on airway sealing and gas leakage, and despite confirming a higher airway leak pressure with the CobraPLA (24 versus 20 cm H_2O), use of the CobraPLA was associated with higher environmental nitrous oxide (but not sevoflurane) levels during anesthesia. The study also reported the LMA Classic was associated with easier positioning and a lower peak airway pressure.

Galvin and colleagues studied the CobraPLA and LMA Classic for gynecologic laparoscopy.[140] Insertion characteristics, adverse events, and rates of throat morbidity were similar between devices. Peak airway pressures were higher with the LMA Classic than with the Cobra-PLA. Blood was observed on 40% of CobraPLAs after removal.

Turan and associates compared the CobraPLA with the LT and LMA Classic in 90 patients during short surgical procedures.[141] There were similar results for insertion times, number and type of airway interventions, and hemodynamic variables. Success rates for first-attempt insertion were highest in the CobraPLA group (95%) and lowest in the LMA Classic group (57%). However, blood staining was seen in 50% of cases using the CobraPLA and only 17% of cases using the LMA Classic or LT. The rate of sore throat was also higher in the CobraPLA group than with either of the other SADs.

c. OTHER STUDIES

Ben-Abraham and coworkers studied the ease of insertion of a CobraPLA in anaesthetized patients by residents in scrubs or in antichemical personal protective equipment (PPE).[127] Wearing PPE caused only a modest slowing of insertion time (i.e., median time increased 14 seconds) for anesthesia residents and nonanesthesia residents after training. After insertion, 42% of airway devices leaked, preventing adequate positive-pressure ventilation, and 13 devices (26% of the total) required replacement.

The CobraPLA has been used for difficult airway management in adults:

- For securing an obstructed airway and facilitating fiberoptically guided intubation after thyroidectomy[142]
- For rescuing the airway during cardiopulmonary resuscitation[143]
- For maintaining the airway during urgent percutaneous, dilatational cricothyroidotomy while enabling visualization of the procedure through a fiberscope[144]
- For a series of five percutaneous tracheostomies in a similar manner[145]
- For airway rescue followed by fiberoptically guided tracheal intubation in a "difficult to intubate, difficult to ventilate" patient undergoing rapid-sequence induction of anesthesia[146]

Complications reported during use of the CobraPLA include aspiration, hypoglossal nerve injury,[147] tube obstruction in a patient with a fixed flexed neck, and obstruction by incarceration of the epiglottis in the epiglottic bars.[148,149]

d. LITERATURE SUMMARY

The literature describes the positive and less positive aspects of the CobraPLA. The device usually is readily inserted and has a higher airway leak pressure than the LMA Classic and LMA Unique, although it is likely not higher than the PLMA and LMA Supreme. Some studies

report issues with airway trauma and leakage, but interpretation is complicated by a change in design that occurred in 2006 and 2007. Intubation through the CobraPLA is possible but likely requires fiberoptic guidance to make it a reliable technique, like many SADs. Further studies comparing performance of the CobraPLA with second-generation SADs and further evaluation of the ability of the CobraPLA to protect the airway during regurgitation be welcome additions to the literature.

G. Tulip Airway Device

The Tulip airway device (Marshall Medical, Bath, United Kingdom) is a first-generation single-use SAD. It was designed by a British anesthetist Amer Shaikh and brought to market in 2010. It was designed for easy placement by anesthesiologists and others who are trained in its use. Its novel feature is that one size is intended to fit all adults.

Like the CobraPLA, the Tulip was named to reflect its overall shape and appearance. It is a simple airway tube with a distal airway orifice and surrounding distal cuff (Fig. 23-10). The device has a proximal, 15-mm standard connector. It is made of PVC and is designed for single use. The distal cuff is described as an inflatable polyhedral beveled cuff, which is designed to inflate below the soft palate, behind the tongue, above the epiglottis, and within the oropharynx.

The Tulip's design is similar to that of a cuffed oropharyngeal airway (COPA), but it has a larger, more distal, asymmetrical cuff and a shorter, softer, more smoothly curved stem. The stem of the Tulip is curved, and proximally, it has depth markings in three colors to indicate the correct depth of insertion for small (green), medium (orange), and large (red) adults.

1. Application

For insertion, the cuff is deflated and lubricated, except for the front, and the patient placed in the sniffing position. The device is held like a pen and advanced along the hard and soft palates and into the pharynx until the appropriate depth is achieved (according to scale on the tube and the patient size). The cuff is then inflated with the appropriate volume of air to achieve a low-pressure ventilating seal. The device is delivered with 30 mL in the cuff, and 20 to 30 mL can be added. The cuff volume should not exceed 80 mL. As the cuff is inflated, the breathing tube rises out of the mouth.

2. Indications, Advantages, and Disadvantages

Because the device is new and untested, its clinical characteristics are difficult to determine. The manufacturers describe the device as suitable for operating rooms and emergency use because it bypasses the need for use of a Guedel oral airway and mask.

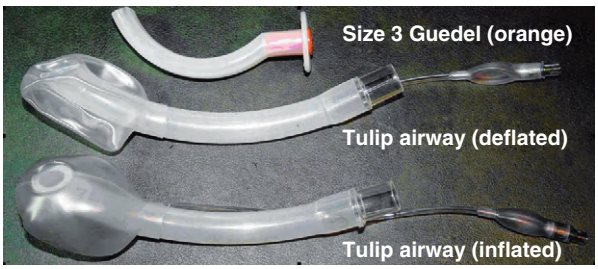

Figure 23-10 The Tulip airway device.

The main advantages of the Tulip are simplicity of size selection (i.e., one size fits all adults), a simple insertion technique, and low cost. The main disadvantage is the apparent lack of protection against aspiration. Because the device does not extend into the esophagus, it does not obturate the esophagus. In contrast to most other SADs, its design offers no protection against aspiration. If used for controlled ventilation at anything other than very low airway pressures, there is a risk of gastric inflation. Whether these concerns constitute a practical problem is unknown.

3. Medical Literature

The literature for the Tulip is limited to a single abstract, which describes very effective and swift deployment in a manikin with ventilation and positioning over the manikin's larynx as good as an i-gel and single-use LM.[150] The relevance of these provisional findings to clinical use are unknown. Early clinical experience confirmed its ease of use as a SAD, and clinical trials are being undertaken in the United Kingdom (Amer Shaikh, personal communication, 2009).

VI. SECOND-GENERATION SUPRAGLOTTIC AIRWAY DEVICES

When first introduced into anesthetic practice in 1988, the LMA Classic was greeted with a degree of skepticism. It was used almost exclusively for elective patients undergoing minor peripheral surgery while breathing spontaneously. The LMA Classic was avoided in all overweight patients and rarely used with controlled ventilation. Although this conservative approach was entirely appropriate, there has since been a gradual but inexorable widening of the applications and reduction in the contraindications to LMA Classic use. Whether the more laissez-faire approach to use of the device is appropriate is unknown, but the effect on routine anesthesia care that the LMA Classic has had is remarkable, as is its safety record. In 1993, a large study showed that 30% of all operations were performed with an LMA Classic. In 2009 in the United Kingdom, LMs were used for 56% of episodes of general anesthesia.[7]

First-generation devices that have appeared and disappeared from the market include the COPA, Airway Management Device (AMD), and the Pharyngeal Airway Xpress (PAXpress). Although several devices offered novel components of design, they had no clear advantages over other first-generation SADs, and some had several disadvantages. The main limiting factor to use of the LMA Classic and other-first generation SADs is a lack of protection against aspiration of gastric contents. A relatively low-pressure pharyngeal seal, leading to potential problems with efficacy and safety of controlled ventilation, is a secondary but important factor. In the past few years, newer SADs coming to market have offered the possibility of real technologic advances because they have design features intended to reduce the risk of aspiration, thereby increasing the safety of use. These

second-generation devices often create an increased pharyngeal seal, which ensures more effective and reliable performance during controlled ventilation. Second-generation devices overcome the main limitations of the LMA Classic and other first-generation devices and offer a genuine stride forward in the safety and effectiveness of SADs (Fig. 23-11).

Seven SADs have design features that are intended to reduce the risk of aspiration: the ProSeal LMA, LMA Supreme, LTS-II, LTS-D, i-gel, SLIPA, and Baska mask. The Combitube and EasyTube are crossover devices between ETTs and SADs, and they have characteristics of second-generation SADs, but they are rarely used for anesthesia (see Chapter 27).

All second-generation SADs except the SLIPA have drain tubes running from the tip of the device (correctly positioned in the upper esophagus) to the proximal end of the device (lying outside the mouth). If regurgitation occurs, the correctly functioning drain tube has two important functions. First, it enables the gastric contents to bypass the larynx, pharynx, and mouth completely. Second, even the smallest amount of gastric fluid visible in the drain tube can alert the anesthesiologist that regurgitation has occurred and trigger an appropriate response.

SADs are increasingly used in more obese patients, during laparoscopic surgery, during controlled ventilation, in the head-down position, and in those with minor gastroesophageal reflux. Although all second-generation SADs have features designed to lessen the likelihood of gastric inflation, regurgitation, and aspiration, in several cases, there is little or no evidence to support their performance (safety) benefits. Regurgitation and aspiration are uncommon events, but the UK NAP4, a year-long study of major airway complications in 2.9 million cases of general anesthesia in 2008 through 2009, identified aspiration as the most frequent cause of airway-related death during anesthesia.[1] Review of the individual cases identified numerous aspiration events when a first-generation SAD was used in patients with clearly identifiable risk factors for aspiration.[151] These events were not seen with second-generation SADs, although use of these devices is considerably less common than first-generation SADs in the United Kingdom, representing approximately 10% of SAD use.[7] Because harmful aspiration events occur infrequently, evidence proving better safety of one device compared with another can come only from formal studies of several million patients, and these studies are impractical. Instead, safety data must be acquired by analyzing the design features, appropriate bench models, surrogate measures of airway safety, and clinical experience.

The PLMA and LMA Supreme are discussed in Chapter 22, but it is worth noting that the PLMA is supported by a considerable body of data in terms of its efficacy as a SAD and regarding its safety profile in separating the respiratory and gastrointestinal tracts and preventing aspiration.[23] No other second-generation SAD has this body of evidence. The LMA Supreme is not a single-use PLMA. It has numerous design differences, is manufactured from a different material, and lacks the body of evidence underpinning the PLMA. The PLMA is therefore considered the benchmark against which other second-generation SADs should be judged.

A. Laryngeal Tube Suction II, Disposable Laryngeal Tube Suction, and Gastro-Laryngeal Tube

In 2002, the Laryngeal Tube Suction (LTS) was introduced. It had a drain tube running posterior to the airway tube to enable gastric tube placement and to prevent gastric inflation during ventilation. Although the design aimed to increase device safety (a similar design step to that from the LMA Classic to the PLMA), the change in design led to a much more bulky device, risking increased insertion difficulty and possible trauma and thereby losing two of the LT's major advantages. Several studies found similar performances for the LTS and PLMA, but one found marked differences in performance.[152-155] Comparing the LTS and PLMA, Dahaba and colleagues studied hemodynamic and catecholamine stress responses to their insertion in 36 patients.[156] Mean arterial pressure, heart rate, and epinephrine were significantly greater in the LTS group than in the PLMA group.

In late 2005, the LTS was replaced by a considerably modified LTS-II (Fig. 23-12). The LTS is no longer available. Like the PLMA, the LTS-II offers the potential for expansion of the role of the LT. The scant literature suggests that the LTS-II is much easier to insert than the LTS and that it provides a pharyngeal seal similar to that of the PLMA. Like the LT, the LTS-II is reusable after

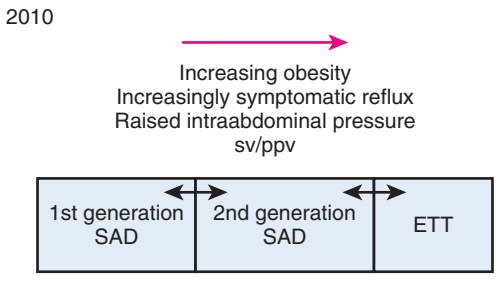

Figure 23-11 Second-generation supraglottic airway devices *(SADs)* available in 2010. *ETT,* Endotracheal tube. *ppv,* positive-pressure ventilation; *sv,* spontaneous ventilation.

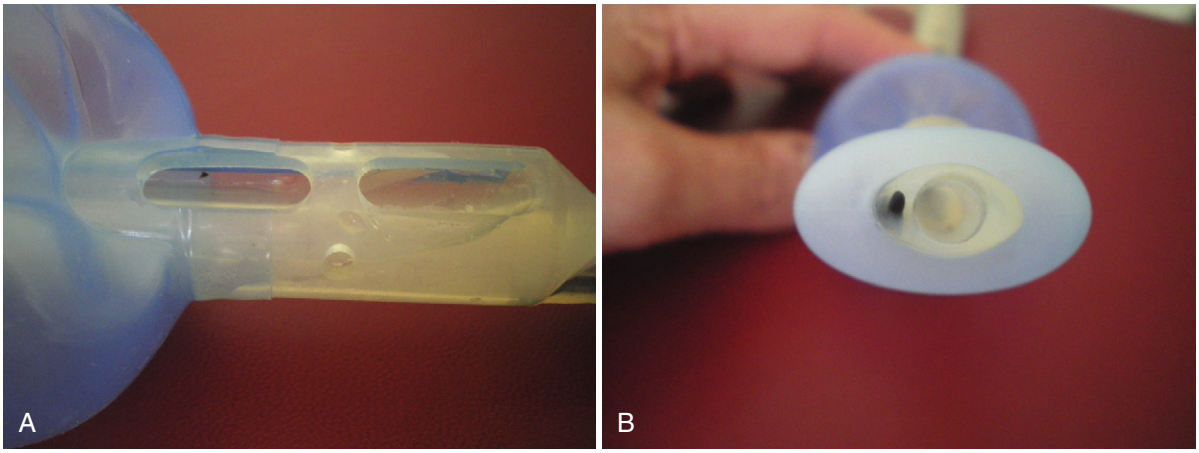

Figure 23-13 The Laryngeal Tube Suction II (LTS-II) airway orifices **(A)** and esophageal balloon **(B).**

sterilization up to 50 times. Size selection and insertion technique for the LTS-II are identical to those for the LT. A single-use version of the LTS-II, called the LTS-D, is marketed. The latest LT is the Gastro-LT. It is designed specifically for use in upper gastrointestinal endoscopic procedures. It also can be considered a specialized second-generation SAD.

The LTS-II is designed for maintaining the patency of the airway during anesthesia and in emergency airway management. It consists of a translucent, double-lumen silicone tube with two inflatable cuffs with anterior ventilation orifices lying between the cuffs (Fig. 23-13). Both balloons are inflated through a single pilot tube and balloon, through which the cuff pressure can be monitored. When in position with the cuffs inflated, the larger, proximal balloon lies behind the tongue and lifts it forward while stabilizing the tube and isolating the ventilation orifice from the oral and nasopharynx above. The smaller, distal balloon obturates the esophageal inlet and is designed to isolate the ventilation orifice from the esophagus below. A drainage tube runs posterior to the airway tube and extends well beyond its tip. In the original version (LTS), the drain tube was only a little longer than the airway tube, and it ended in a rounded and somewhat bulky tip. The LTS-II has a smaller, considerably longer, and markedly modified tip and a redesigned distal balloon that is ovoid to mimic the shape of the upper esophagus and to provide axial stability for the SAD (see Figs. 23-12 and 23-13). The LTS-II also incorporates minor changes to the airway orifices and to the pilot balloon. The drain tube is designed for passage of a gastric tube up to size 16 F.

The Gastro-LT has a dramatically expanded drain tube and reduced-caliber airway tube (the opposite of the conventional LTS-II) (Fig. 23-14). The basic design principles remain the same as for the LTS-II, but all features of the airway tube are smaller. The drain tube is large enough to allow insertion of a gastrointestinal endoscope up to a diameter of 13.8 mm. The Gastro-LT is made of silicone, has an integrated bite block, and is reusable after decontamination and autoclaving. The device is designed to be used in adults 155 cm tall or taller.

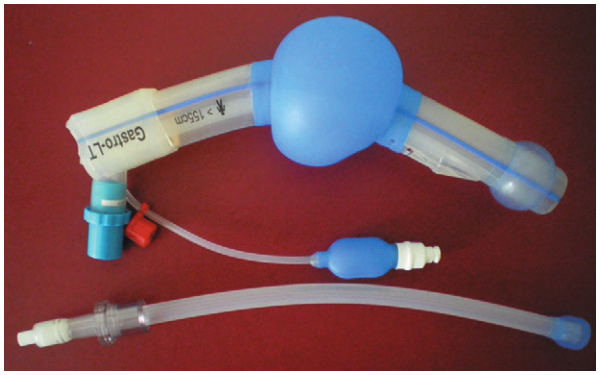

Figure 23-14 The Gastro-LT *(top)* and obturator *(bottom).*

1. Application

The possibilities and limitations for intubation through the LTS-II are similar to those for intubation through the LT. Insertion and removal techniques for the LTS-II are those described earlier for the LT.

The LTS-II is designed for blind insertion without laryngoscopy. The airway tube has a 15-mm connector (color coded for different sizes) and has a dental line mark to indicate the correct depth of insertion. A bite block is supplied with both devices. The LTS-II is available in the full range of seven sizes from size 0 (newborn <5 kg) to size 5 (large adults >180 cm high), whereas the LTS-D is available only in adult sizes 3, 4, and 5.

2. Indications, Advantages, and Disadvantages

Indications for the LTS-II (and LTS-D) are anesthesia with spontaneous or controlled ventilation, emergency use as a rescue device during difficult airway management, and as a primary emergency airway, in settings such as during management of cardiac arrest outside the hospital.

LTS-II advantages similar to those of the LT include its simple insertion technique, a short learning curve, a relatively slim profile enabling insertion even with limited mouth opening, and the ability to insert the device with

the patient's head and neck and the operator's body in a variety of positions. Compared with the LT, the LTS-II has a relatively large-caliber, noncompressible drain tube. This drain tube, which is semirigid and not prone to folding over or obstruction, enables access to the gastrointestinal tract (e.g., insertion of gastric tube) or egress of gastric contents (e.g., regurgitant gastric contents). It is large enough to accommodate small particles of food as well as liquids. Another advantage is that the asymmetrical distal balloon design anchors the device in the proximal esophagus, thereby reducing the likelihood of axial rotation, which has been observed with the LT.

The LTS-II forms a relatively high-pressure pharyngeal (airway) seal, enabling controlled ventilation in patients with reduced lung capacity, provided the airway orifice is correctly aligned with the glottis. The distal cuff forms an effective esophageal seal (approximately 72 to 82 cm H_2O).

Most attributes of the LTS-II described in the literature are assumed to be valid for the LTS-D. The design is identical, and materials are similar to those of the LTS-II. The cuffs of the LTS-D are made of thicker material. The Gastro-LT is designed to maintain the airway for upper gastrointestinal endoscopy during deep sedation or anesthesia with spontaneous or controlled ventilation.

Construction of the LTS-II is relatively rigid, and if used without due care, it can cause trauma to soft tissues. Adherence to manufacturer's guidance and well-practiced, careful technique should minimize this effect.

Despite the asymmetrical distal cuff, there is the possibility of axial rotation of the device leading to misalignment of the ventilation orifices and the glottis. Various rates have been reported for this complication. When it occurs, it may lead to airway obstruction during spontaneously ventilation, high airway pressures during controlled ventilation, and difficulty in accessing the trachea.

Because the airway orifice is a deficiency in the convex part of the curve of a semirigid device, poor insertion technique or undue force can flex the LTS-II at this point. Further advancement may lead to inadvertent tracheal intubation, which has been reported.[94] If inadvertent tracheal intubation occurs, the cuffs should not be inflated because the size of the distal cuff may damage the larynx.

3. Medical Literature

The medical literature should be interpreted with the knowledge that the LTS was replaced by the LTS-II in late 2005. Most studies before 2006 or 2007 studied the bulkier and less stable version of the device.

a. COHORT STUDIES

Mihai and coworkers reported an early cohort study of the LTS-II in 100 patients during controlled and spontaneous ventilation.[157] The success rates were 71% for first-attempt insertion and 100% for three attempts. Median insertion time was 15 seconds. Temporary airway obstruction occurred in six patients at insertion and in another eight during maintenance. Use of the device was abandoned once during insertion and once during maintenance. Median airway leak pressure was 29.5 cm H_2O. A gastric tube was passed through the drain tube in 97 of 99 patients. The glottis was visible during fiberoscopy in 51% of patients. Blood was visible on the device after removal in 12 patients. After the operation, 14 patients reported mild sore throat.

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

Genzwuerker and colleagues first compared the LTS-II and PLMA in 100 patients.[158] Overall performance was almost identical in terms of insertion success (96% for the LTS-II versus 98% for the PLMA), time to placement (25 versus 25.5 seconds), and airway seal (33 versus 32 cm H_2O). Similarly, rates of airway trauma and postoperative sequelae were equivalent in both groups.

Zand and associates randomized patients to the LTS-II or PLMA in a study of 100 anaesthetized patients undergoing minor surgery.[159] First- and second-attempt insertion success rates were comparable (86 versus. 88% and 96 versus 98%) in the LTS-II and PLMA groups, respectively); the two devices failed once after three attempts. The LTS-II was marginally favored over the PLMA in terms of insertion time (24.5 versus 28.8 seconds) and airway seal (20 versus 24.1 cm H_2O, $P = 0.04$). Of several postoperative pharyngeal morbidities, only hoarseness occurred more frequently in the LTS-II group.

Kikuchi and coworkers compared the LTS-II with the PLMA in 100 male patients.[94] Methods included assessing gas leakage with the cuff pressure reduced or when the device shaft was inclined and fluoroscopic examination of the position of the LTS-II. The LTS-II had a lower rate of successful placement than the PLMA (74% versus 96%), a lower tidal volume, and increased gas leakage. The airway seal lower in both groups compared with that reported elsewhere (16 cm H_2O for the LTS-II versus 21 cm H_2O for the PLMA). In 10% of uses, the LTS-II kinked and entered the trachea. Similar findings have not been published elsewhere.

Cavus and colleagues compared the LTS-II with the PLMA, EasyTube, and ETT in 88 patients.[160] Overall insertion success rates were 96% for the LTS-II and ETT, 91% for the PLMA, and 64% for the EasyTube. Time to first ventilation took significantly longer with the EasyTube. Airway leak pressure was highest with the LTS-II and lowest with the EasyTube (40 versus 19 cm H_2O). No major differences in objective or subjective performance were reported for the LTS-II, PLMA, and ETT.

Amini and associates compared the LTS-II and LTS-D in 60 healthy patients undergoing laparoscopic cholecystectomy.[161] First- and second-attempt success rates were similar (93% and 95% for the LTS-II and 86% and 93% for the LTS-D, respectively). After gas insufflation, tube replacement was required for one LTS-D and two LTS-II. Insertion times, success of gastric tube insertion, and postoperative complaints were similar for the two groups.

Thee and colleagues compared the LTS-II and ILMA with their respective disposable versions in 120 patients undergoing minor surgery.[162] Insertion success rates were 100%, except for one LTS-D failure. The LTS-D was faster to insert, had a higher airway leak pressure (40 cm H_2O), and was subjectively assessed to be easier to handle than the LTS-II.

c. OTHER STUDIES

A cadaver study of esophageal seal demonstrated a high-pressure seal (70 to 80 cm H_2O) for the LTS-II, similar to the PLMA seal and higher than the LMA Classic seal.[40]

Asai and colleagues demonstrated that the LT and LTS-II function less well with cricoid pressure applied before and during insertion.[163] Continuous cricoid pressure prolonged time to insertion, reduced the likelihood of successful ventilation, and decreased the airway seal.

Schalk and associates described modified insertion techniques for the LTS-D.[164,165] In the first variation, the LTS-D was inserted upside down (in the manner of a Guedel insertion) while a forced chin lift was performed with the other hand to create sufficient retropharyngeal space.[164] After insertion of one third of its length, the LTS-D was rotated by 180 degrees and pushed down the pharynx. The technique, performed by novices, almost halved insertion time and increased successful insertion within 45 seconds by threefold. When the LTS-D was inserted with the operator in front of the patient and by applying jaw thrust, insertion in patients with an immobilized neck was faster, and the success rate increased more than twofold.[165] Further evaluation suggested that a forceful jaw thrust was an important part of the success of the technique. In both studies, the baseline success rates for insertion were lower than in many other studies.

There is an emerging literature about use of the LTS-II and LTS-D in prehospital airway management, particularly in central Europe. Dengler and colleagues reported one case of massive pulmonary aspiration and one case of gastric overinflation during use of the LT.[114] In both cases, peak airway pressure had been high, and the investigators questioned whether the LTS-II or LTS-D would have been more appropriate. Shalk and colleagues reported 57 attempts with the LTS-D over a 40-month period by paramedics or medics, most of whom had limited prior experience.[166] The use was successful in all but one case, and most devices were inserted in less than 45 seconds. In a subsequent report, Shalk and coworkers described[167] use over 24 months with a 97% success rate; most users were relative novices with the LTS-D.[113] Its use was approximately equally spread between primary airway procedures and airway rescue after failed tracheal intubation. Three fourths of insertions took less than 45 seconds.

Park and colleagues studied the effect of changing the patient's head and neck position on SAD performance, including the LTS-II.[134] Leak pressure was well maintained with the LTS-II, but neck flexion led to ventilation difficulty in approximately 15% of patients.

The LTS-II has been used successfully in a patient with a cervical spine injury.[167] Scheller and associates reported emergency use of the LTS-II or LTS-D in eight patients with difficult airways.[168] In all cases, the device was successfully used as a bridge until a secure airway was established; in six, this was accomplished by cricothyroidotomy or surgical tracheotomy.

Reported complications of the LTS-II are few. In addition to the cases of inadvertent tracheal intubation, there are cases of pilot balloon obstruction by the bite block and a case of ulceration of the tongue and uvula after apparently uneventful use.[169,170]

A single publication described use of the Gastro-LT in 30 patients undergoing general anesthesia for endoscopic retrograde cholangiopancreatography.[171] The study reported 100% insertion success (90% at first attempt), and the mean time to achieve an effective airway was 26 seconds. Tidal volumes were well maintained, and the mean airway leak pressure was 34 cm H_2O.

d. LITERATURE SUMMARY

The LTS-II appears to be easy to insert, and it achieves a high airway seal. It has the advantages of a high-pressure esophageal seal and a drain tube. Ventilation is highly successful, and complications are few. Several studies suggest equivalence to the PLMA. The LTS-D appears to perform at least as well as the LTS-II. Neither device is ideally suited as a conduit for intubation. There is emerging literature on its role in prehospital care.

B. The i-gel

The i-gel (Intersurgical, Wokingham, United Kingdom) is a CE-marked, single-use device. Over several years, numerous prototypes of the i-gel were designed by Muhammed Nasir, a British anesthetist. It was marketed in 2007 and has not been modified since its introduction. In 2009, a full range of pediatric sizes was introduced.

The i-gel is a cuffless, single-use SAD made of a medical-grade thermoplastic elastomer gel (i.e., styrene-ethylene-butadene styrene) and designed for use during anesthesia and airway rescue. It is constructed with a stem and an anatomically designed mask portion; because of the absence of a cuff, inflation is not required after insertion (Fig. 23-15). To seal the airway, the i-gel relies on creating an anatomic seal with pharyngeal, laryngeal, and perilaryngeal structures.

Proximally, the device has a firm tube section that is rigid and noncompressible, acting as an integral bite block. The i-gel stem is elliptical and curved in cross section. Its large caliber lessens the likelihood of displacement or axial rotation after insertion. The mask portion is relatively large—similar to the size of an inflated cuffed SAD (e.g., LMA Classic, PLMA)—enabling the mask to occupy the whole hypopharynx and laryngopharynx. The mask has a relatively blunt tip. The airway tube has a wide bore and ends in a large ventilation orifice with no bars of grills. A ridge at the proximal end of the mask

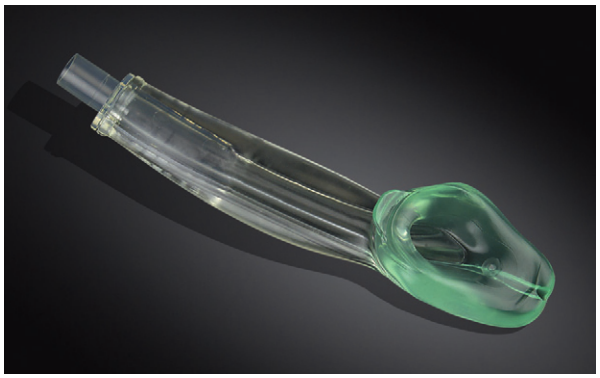

Figure 23-15 The i-gel.

bowl is designed to sit below the tongue base to prevent the i-gel from moving upward and out of position. A black line near the proximal end of the stem acts as a guide to the approximate correct depth.

The i-gel is included among the second-generation SADs because it incorporates throughout its length a drain tube running from the center of the mask tip to the proximal end of the stem. The drain tube is narrower than in some second-generation SADs (e.g., PLMA, LMA Supreme, LTS-II); the size 5 i-gel accommodates a 14-F gastric tube, and sizes 3 and 4 accommodate a 12-F gastric tube.

1. Application

The i-gel is supplied in a plastic cradle that maintains the stem's preformed curve and indicates the device size by its color. Seven sizes of i-gel are available (Table 23-4) and suitable for use in patients from neonates to large adults. Size selection is based on the patient's weight, but the manufacturers advise users to consider individual anatomic variations in selecting a size. For example, patients with long necks and wide thyroid and cricoid cartilages may require a larger size, and patients with central obesity may require the device size to be chosen on the basis of their ideal body weight.

The device should be inspected and checked for defects and obstructions before use. The back, sides, and front of the mask should be lubricated with a thin layer of water-soluble lubricant immediately before use. Excessive lubricant that may be aspirated, particularly from the anterior surface, should be avoided. The patient should be placed in the sniffing position and adequately anesthetized (i.e., to a level suitable for LMA Classic insertion). The patient's mouth should be opened and the i-gel advanced along the roof of the mouth and into the pharynx until resistance is met, indicating it is in position with the tip of the device sitting at the entrance to the esophagus.

Care should be taken to avoid catching the tongue in the bowl of the mask by ensuring the mouth is well open and that the mask tip is directed to the hard palate as it enters the mouth. If the tongue is caught, it may impede insertion and risk tearing the frenulum. Difficulty in negotiating the angle of the pharynx may be minimized by choosing the correct size of i-gel, lubricating as instructed, and extending the patient's head. A jaw lift or rotation of the device during insertion may also ease its passage. Alternatively, a rotatory technique may be chosen in which the device is inserted laterally and rotated into place as resistance is felt on reaching the posterior pharyngeal wall. If insertion is difficult or an adequate seal is not achieved, another device size should be tried.

After insertion, the i-gel should be held in place and secured with tape from "maxilla to maxilla." The anesthetic circuit should be attached to the 15-mm connector, and ease of ventilation should be confirmed with gentle manual ventilation. In most cases, the pharyngeal seal is approximately 20 to 30 cm H_2O. Although the manufacturers describe the use of muscle relaxants during controlled ventilation with the i-gel, many practitioners do not find this to be necessary if an adequate depth of anesthesia is maintained.

For most patients, the i-gel may be left in place after routine anesthesia until consciousness is regained and airway reflexes have returned. Gentle suction may be applied around the i-gel before removal, which should be performed when the patient is able to open his or her mouth in response to commands. The manufacturers describe removal under deep anesthesia and replacement with a Guedel airway for patients with a heightened gag reflex (e.g., smokers, asthmatics, patients with chronic obstructive pulmonary disease).

The i-gel has several features that make it suitable for use as a conduit for tracheal intubation, including a large-diameter lumen, relatively short airway tube, absence of bars or grills across the distal airway tube or airway orifice, and the large dimension of the mask bowl. The epiglottis is rarely folded over within the large mask bowl, and the glottis is usually easily visible. In this respect, the i-gel is similar to the PLMA. During endoscopy through the i-gel, the glottis usually is visible almost as soon as the endoscope exits the stem part of the airway tube, and the fiberscope can easily be negotiated to the glottis even if some manipulation is required. In some other SADs, such as the LMA Classic and LT family of devices, there is less space for manipulation. Table 23-5 shows the sizes of lubricated ETTs that can be passed through each size of i-gel.

Two high-quality studies compared the performance of the i-gel as a conduit for intubation with intubation through a single-use ILMA.[172,173] The first study found that the i-gel was a poor device for use with blind intubation (as are many SADs). The overall success rate for the first attempt was 15% through the i-gel and 69% through the ILMA ($P < 0.001$). In the second study, in which fiberoptic guidance was used, the i-gel performed very well and at least as well as the ILMA; the first-time success rate was 96% for the i-gel and 90% for the ILMA

TABLE 23-4
Sizing Guidelines for the i-gel Supraglottic Airway

i-gel Size	Patient Size	Guide Weight (kg)
1	Newborn	2-5
1.5	Infant	5-12
2	Small child	10-25
2.5	Large child	25-35
3	Small adult	30-60
4	Medium adult	50-90
5	Large adult	90+

($P = 0.21$). The findings support the use of the i-gel as a conduit for intubation as an elective technique and after airway rescue, but they strongly indicate that a fiberoptically guided technique should be used when possible.

2. Indications, Advantages, and Disadvantages

The i-gel is designed primarily for use during anesthesia and is suitable for spontaneous and controlled ventilation. The ease of insertion allied with a steep learning curve has led to recognition of its role in airway rescue. Its wide airway tube and large bowl reduce airway resistance and make it suitable for use as a conduit for intubation as an elective technique or after airway rescue. Because of its insertion and performance characteristics, it has been included as an airway device for use in management of cardiac arrest in ILCOR's 2010 guidelines.[93]

The i-gel has several design and performance advantages. Absence of a cuff may make insertion quicker and easier than many other SADs. Its remarkable slipperiness after lubrication and moderate rigidity increase ease of insertion. Its relatively large size and elliptical shape reduce the risk of displacement or rotation after insertion. The large, short, unobstructed airway lumen leads to low airway resistance during use and enables easy endoscopic access to the glottis if required. The drain tube and airway seal, which is usually a higher-pressure seal than that of the LMA Classic, indicate a degree of protection against aspiration and enable early identification of regurgitation (i.e., gastric contents seen in drain tube), although this advantage is largely unproven. Despite its size, it is well tolerated on emergence and may be removed with the patient fully awake. The incidence of sequelae after use of the i-gel (e.g., sore throat, dysphagia, dysphonia) appears to be low and perhaps as low as for any SAD.

The material the i-gel cuff is filled with is a thermoplastic gel. When warmed, its properties alter slightly, and several investigators have reported that the pharyngeal (airway) seal improves over time after insertion. Only limited evidence supports this effect, which has not been widely explored in other SADs. Alternative explanations include stress relaxation of pharyngeal muscles after distention, which may lead to improved airway seal sometime after insertion of the i-gel and other SADs. Although the clinical relevance of this feature remains undefined, the other features of the i-gel make it a useful and versatile device.

The i-gel is a suitable alternative to the LMA Classic and LMs during routine use, and it may have advantages over them. It is less well suited for some head and neck operations (suitable for the LMA Flexible) due to the bulky, rigid stem. Despite its soft feel, the relatively large size of the i-gel and its noncompressible design mean that care is required during insertion and removal to avoid injury, particularly to at-risk dentition and the frenulum of the tongue. There have been sporadic reports of congestion of the tongue, perhaps due to an incompletely inserted i-gel interfering with venous drainage. Good technique with full insertion and the device secured in place should minimize this risk.

In some series of i-gel uses, only a very-low-pressure airway seal can be achieved in a minority of patients. In about 2% to 5% of cases, manual ventilation may not be possible due to a gas leak. A change of size of device may resolve the problem.

One feature of the i-gel design may be an advantage and a disadvantage. The tip of the bowl of the i-gel is somewhat truncated. During the design phase, the inventor reduced the size of the tip to minimize disruption of the cricopharyngeus with the intention of reducing postoperative sore throat (Muhammed Nasir, personal communication, 2009 or 2010). Observational data suggest this modification has been successful in reducing postoperative sequelae, but a cadaver study has indicated that the esophageal seal of the i-gel is rather low (13 to 21 cm H_2O); this is less than one half of the equivalent seal of the LMA Classic (30 to 50 cm H_2O) or PLMA (50 to 80 cm H_2O) and less than one third of the seal achieved by the laryngeal tubes (70 to 80 cm H_2O).[12,40] The same studies demonstrate that regurgitant fluid is effectively vented by the i-gel drain tube, unless it is blocked. The drain tube may obviate the need for a high-pressure esophageal seal in protecting the pharynx from regurgitation, although the clinical importance of these findings remains uncertain. On the available evidence, it appears that an orogastric tube should not remain in the drain tube during use, because if the drain tube is occluded, the esophageal seal may not protect the airway; if inserted to drain the stomach, it should be used after suctioning. Cases of protection from aspiration with the i-gel are reported, as is one case of partial aspiration.

Overall, the increased protection against aspiration of the i-gel is supported by several design features but not formally proved by a clinical study. However, several million i-gel uses attest to the fact that the i-gel is a safe device.

3. Medical Literature

Despite the relatively new introduction of the i-gel, there are already more than 60 publications describing the device. This reflects the great interest in the device. Only the most important can be summarized here.

a. COHORT STUDIES

The first published i-gel study evaluated a series of 73 uses in 63 cadavers to determine its anatomic positioning after insertion using fiberscopic, radiologic, and dissection methods.[174] The full glottis was visible after 44 of 73 insertions, with only three epiglottis-only views. After eight reinsertions, more than half of the glottis was visible in all cadavers. In each of the 16 neck dissections and on eight radiographs, the bowl of the i-gel covered the laryngeal inlet.

Richez and colleagues reported use of the i-gel in 71 women.[175] Insertion success rate was 97%, and was rated easy in all cases. Mean airway leak pressure was 30 ± 7 cm H_2O, and peak airway pressure was 11 ± 3 cm H_2O. Gastric tube insertion was successful in 100% of cases. One case of coughing and one mild sore throat occurred.

Asai and Liu reported i-gel use in 20 patients breathing spontaneously.[176] In 19 patients, insertion was successful on the first attempt, and the mean insertion time was 12 seconds. The success rate for gastric tube insertion

was 100%. No complications occurred during anesthesia, removal was uneventful, and no blood was detected on any device.

Kannaujia and colleagues performed a study of 50 i-gel uses, including assessment of stability during head and neck movement.[177] The success rate at first attempt was 90%, and 100% after two attempts, with a median insertion time of 11 seconds. Manipulations needed to achieve an effective airway were deeper insertion in 8% and jaw thrust or chin lift in 4%. Mean airway leak pressure was 20 cm H_2O. Gastric tube insertion was successful when attempted. There were no significant adverse events.

Gatward and coworkers evaluated 100 i-gels during controlled and spontaneous ventilation.[178] First-attempt insertion was successful in 86%, second-attempt in 11%, and third-attempt in 3% of patients. Fifty-three manipulations were required in 26 patients (median, 1) to achieve a clear airway. Median insertion time was 15 seconds. During ventilation, an expired tidal volume of 7 mL × kg^{-1} was achieved in 96% of patients. Median airway leak pressure was 24 cm H_2O. On fiberoptic examination, the vocal cords were visible in 87 patients (91%). There was one episode of regurgitation without aspiration. Other complications and side effects were mild and few.

In the largest cohort series of 1658 cases, insertion of the i-gel failed in 1.3% of cases, and 90% were judged to be an easy or very easy insertion.[179] Mean airway seal was 25 ± 8 cm H_2O, and 93% of cases were completed with the i-gel. Complications included laryngospasm or bronchospasm (0.8%), glossopharyngeal nerve injury (0.6%), glottic hematoma (0.6%), bilateral tip of the tongue paresthesia (0.6%), and bradycardia requiring cardiopulmonary resuscitation (0.6%).

Wharton and coworkers examined i-gel use by inexpert medical and paramedical users in 40 patients after manikin training.[180] The success rate was 82.5% (33 of 40) on the first attempt and 15% on the second attempt (6 of 40). After three attempts, there were no failures. Median insertion time was 17.5 seconds. Median airway seal was 20 cm H_2O (range, 13 to –40 cm H_2O). One case of regurgitation and partial aspiration occurred. Performance by these novices using the i-gel compared well with performance using other SADS, and it was remarkably similar to the performance by experienced anesthesiologists reported by the same group.[178]

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

In a small study, Uppall and associates compared leak volume (i.e., inspired volume – expired volume) during pressure-controlled ventilation (15, 20, and 25 cm H_2O) through the i-gel and cuffed ETT in 25 patients.[181] Leak volume did not vary at 15 or 20 cm H_2O, but at 25 cm H_2O, the i-gel leaked more than the ETT. No gastric inflation was detected.

Two studies compared the LMA Classic and i-gel and reported opposing findings. Janakiraman and colleagues compared the i-gel and LMA Classic in 50 healthy patients who were breathing spontaneously.[182] The investigators reported a much lower first-attempt insertion success rate (54%) for the i-gel than many other investigators and found this rate significantly lower than for the LMA Classic (86%, $P = 0.001$). After two attempts and with a change in size, the insertion rates were similar (84% for the i-gel and 92% for the LMA Classic). Leak pressure was higher for the i-gel (median [IQR], 20 cm H_2O; 14 to 24 cm H_2O) than for the LMA Classic (17 H_2O; 12 to 22 cm H_2O; $P = 0.023$), and the fiberoptic view was statistically significantly better. The manufacturer suggested that the high failure correlated with a lack of lubrication of the front of the mask during this study.[183]

Helmy and coworkers also compared the i-gel and LMA Classic during spontaneous ventilation.[184] Neither device caused significant hemodynamic disturbance during insertion, and there was no difference in insertion attempts. The i-gel had a faster mean insertion time (15.6 ± 4.9 seconds versus 26.2 ± 17.7, $P < 0.1$), and it produced a higher leak pressure (25.6 ± 4.9 versus 21.2 ± 7.7 cm H_2O, $P = 0.016$). Gastric inflation was detected in 23% of LMA Classic uses and 5% of i-gel uses ($P = 0.016$).

Several studies have compared the i-gel with single-use LMs. Cattano and associates compared the i-gel and LMA Unique in 50 healthy patients.[185] There were no significant differences in the ease of insertion, leak pressures, or fiberoptic view. The i-gel was favored by faster insertion (21.0 ± 12.6 versus 30.0 ± 14.1 seconds, $P = 0.02$), but it required a second attempt at insertion more frequently, and in three patients, the i-gel was replaced by an LMA Unique. Patients weighing 80 to 90 kg were more likely to experience postoperative symptoms, such as sore throat and dysphagia. The investigators suggested the larger size might be restricted to patients who weighed more than 90 kg.

Uppal and colleagues conducted a study of 39 patients during controlled ventilation with the i-gel or LMA Unique. They reported similar insertion success, leak pressures (median, 25 cm H_2O for the i-gel versus 22 cm H_2O, for the LMA Unique) and leak volumes for both devices.[186] The i-gel was a few seconds faster to insert.

Francksen and coworkers compared the i-gel and LMA Unique in a study of 80 patients.[187] Overall performance measures were similar, but the i-gel had a higher leak pressure (29 versus 18 cm H_2O) and better fiberoptic view of the larynx. Postoperative symptoms were similar for the two devices.

Amini and Khoshfetrat compared the i-gel with the Solus LM (from the same manufacturers) in 120 patients.[188] The leak pressure was significantly higher in the Solus group (mean ± SD, 22.7 ± 7.7 versus 19.3 ± 7.1 cm H_2O, $P = 0.02$). The Solus provided a better fiberoptic view of the larynx and required less airway manipulation to maintain a clear airway. Both devices were considered to perform well.

Keijzer and associates studied postoperative symptoms in 218 patients whose airways were managed with the i-gel or La Premiere single-use LM.[189] The incidence of sore throat was significantly lower with the i-gel than with LM at three time points (1, 24, and 48 hours), with up to 40% of La Premiere uses leading to sore throat. The i-gel was also associated with less dysphagia and neck pain.

Heuer and colleagues compared the performance of the Ambu AuraOnce, LMA Classic, PLMA, and i-gel during ambulatory surgery; each group contained 40 patients.[190] The Ambu AuraOnce and LMA Classic were placed on the first attempt most often (both, 92.5%; PLMA, 85%; i-gel, 82.5%; $P < 0.05$).[190] Mean insertion times for the four devices were all within 2.5 seconds of each other. The investigators measured the proportion of cases in which the pharyngeal seal was above 15 and 20 cm H_2O; the respective rates were highest for the Ambu AuraOnce (97.5% and 67.5%), then for the PLMA (90% and 60%), the LMA Classic (85% and 62.5%), and the i-gel (72.5% and 50%); for both series, $P > 0.05$. More patients complained of a sore throat after using the LMA Classic ($P < 0.05$). The rather low airway leak pressures with the PLMA and i-gel and low insertion success rates with the i-gel are not consistent with the bulk of the literature.

Comparing the i-gel with the PLMA in 60 healthy patients, Singh and colleagues reported a somewhat higher first-time insertion success rate with the i-gel (29 of 30 versus 25 of 30 patients) and a lower leak pressure (25 versus 30 cm H_2O).[191] The i-gel group had fewer episodes of minor trauma, and the device was associated with more reliable gastric tube insertion.

Shin and associates compared the i-gel with the LMA Classic and the PLMA in a study of 167 healthy patients.[192] The airway leak pressures for the PLMA (30 cm H_2O) were higher than for the i-gel (27 cm H_2O) and LMA Classic (25 cm H_2O). Rates of insertion success and adverse events were similar, although there were more sore throats in the LMA Classic group.

Fernández Díez studied the i-gel and LMA Supreme in 85 patients.[193] First-attempt insertion success for the LMA Supreme (95%) was higher than for the i-gel (86%), and the time to insertion (27 versus 32 seconds) was not significantly different. The rate for passing a gastric tube on the first attempt was better for the i-gel (98%) than the LMA Supreme (86%). Leak pressure and compliance were similar in the two groups at the start of surgery and at 10, 30, and 60 minutes. Complications during surgery and at 90 minutes were not significantly different.

Theiler and colleagues compared the i-gel and LMA Supreme in a crossover study of 60 patients with simulated difficult airways through neck immobilization.[194] Insertion success was similar for the i-gel (93%) and LMA Supreme (95%, $P = 1.0$), as were tidal volumes and airway leak pressure (27 versus 26 cm H_2O, $P = 0.4$). The difference in success rates was 1.7% (95% CI, −11.3% to 7.6%). Insertion time was shorter for the LMA Supreme (34 versus 42 seconds, $P = 0.024$). The fiberoptic view through the i-gel showed less epiglottic downfolding. Two major studies comparing the i-gel with the single-use ILMA for intubation, blindly or with fiberoptic guidance, were described earlier.[172,173]

c. OTHER STUDIES

A U.K. national census of airway device use conducted from 2008 through 2009 recorded that 56.2% of all instances of general anesthesia are delivered with a SAD as the primary airway.[7] Most were LMs (including the LMA Classic, LMA Flexible, and other LMs). Only 10% of SAD uses in this census were second-generation SADs, and the ratio of uses of i-gels to PLMAs was 2.5:1. The i-gels were used for 4% of all episodes of general anesthesia, and PLMAs were used for 1.7%.

Schmidbauers and coworkers' cadaver study showed the i-gel's esophageal seal to be lost at lower pressures than many others SADs.[12] During a slow increase in pressure, the i-gel lost its seal at 13 cm H_2O; 1 minute after maximum pressure had been applied, the device withstood a sustained pressure of 21 cm H_2O. Despite the lost seal, the i-gel drain tube vented liquids rapidly. The LMA Classic and PLMA created esophageal seals at considerably higher pressures (37 to 46 versus 58 to 59 cm H_2O). The clinical relevance of these findings is debated and requires further exploration.

Ismail and associates studied the changes in hemodynamics and intraocular pressure in 60 patients scheduled for nonophthalmic surgery with the i-gel, LMA Classic, or ETT.[195] Insertion of the i-gel did not increase intraocular pressure, whereas the ETT increased it 5 mm Hg, and the LMA Classic increased it marginally. Tracheal intubation led to a rise in all hemodynamic measures (i.e., heart rate, systolic blood pressure and diastolic blood pressure), but the increases were less with the LMA Classic. The i-gel led to significantly fewer changes. The perfusion index was decreased for 5 minutes by the ETT, 2 minutes by the LMA Classic, and not at all by the i-gel. Jindal and colleagues also examined the hemodynamics of insertion of the i-gel, LMA Classic, and SLIPA.[196] The i-gel produced the least hemodynamic changes. Zaballos and colleagues observed that the i-gel in vitro had no effect on MRI, whereas the LMA Classic, PLMA, and LMA Unique (but not the Ambu AuraOnce) did.[66] Novel applications of the i-gel include use for awake craniotomy with the head in a rotated position,[197] use in the prone position,[198] use for a patient with subglottic stenosis,[199] and use during placement of a bronchial blocker for single-lung ventilation in 25 patients without incident.[200]

The i-gel has been used in difficult airway management, including during rescue of an obstructed airway,[201,202] as an intermediate airway during difficult intubation,[203] as a conduit after failed intubation, and as a conduit for elective intubation in patients with predicted difficult airway.[204-206] All of these intubations use fiberoptic guidance.

Reported complications of i-gel use include tongue trauma,[207] severe laryngeal hemorrhage requiring intensive care unit admission,[208] regurgitation and aspiration,[178,209] and a variety of minor nerve injuries.[179,180,209-211]

d. LITERATURE SUMMARY

The i-gel is acquiring a reputation for ease of insertion, minimal stimulation, good performance during spontaneous or controlled ventilation, and excellent tolerance during emergence. Access to the glottis for intubation is reliable but requires fiberoptic guidance. Limitations are its occasional very poor seal and its moderate bulk. There is some uncertainty about the esophageal seal and drain tube capacity and therefore a degree of uncertainty about the additional protection against aspiration that the i-gel offers in the event of regurgitation.

TABLE 23-6
SLIPA Size Selection

SLIPA Size	Patient	Median Height (cm)	Height Range (cm)
47	Very small female	152	145-160
49	Small female	160	152-168
51	Medium female	168	160-175
53	Large female to small male	173	163-182
55	Medium male	180	173-193
57	Large male	190	180-200

SLIPA, Streamlined Liner of the Pharynx Airway.

C. SLIPA: Streamlined Liner of the Pharynx Airway

The SLIPA (Curveair, London, United Kingdom), which looks somewhat like a slipper, was developed by Donald Miller, a U.K.-based anesthetist.[212] The airway lines the pharynx and thereby controls it and provides an enlarged cavity (i.e., sump) for trapping regurgitated liquids and preventing pulmonary aspiration. The design does not require an inflatable cuff to achieve airway seal and such a cuff would also reduce storage capacity. A simpler device without a cuff makes manufacturing less expensive and the device suitable for single use. There were several iterations of the SLIPA before its commercial launch in Europe in June 2004.

The SLIPA is a cuffless single-use SAD made from firm plastic with a preformed shape designed to match the anatomy of the pharynx. Its hollow, blow-molded chamber is shaped like a pressurized pharynx and somewhat like a boot with a toe, a bridge that seals at the base of the tongue, and a heel that anchors the device in a stable position between the esophagus and nasopharynx (Fig. 23-16).[44] The anterior surface of the SLIPA has a series of bulges and indentations whose positions are designed to mimic human anatomy and enable close matching of the shape of the device and the patient's airway. For example, toward the toe side of two lateral bulges of the bridge are smaller, secondary lateral bulges that leave an indentation; the positions of the bulges were extrapolated from a study on cadavers to coincide with the tips of the hyoid bone. This design is intended to relive pressure at this vulnerable anatomic site and thereby reduces the risk of damage to the hypoglossal and recurrent laryngeal nerves.[213]

Because the device is hollow, a limited volume of pharyngeal secretions or regurgitated liquids can pass through the anterior airway orifice and be retained within the airway, potentially providing some protection from aspiration. The chamber has a considerably higher capacity than several other SADs (up to 70 mL for the SLIPA and less than 5 mL for a size 4 or 5 LMA Classic).[44] This design feature of the SLIPA is intended to reduce the risk of aspiration and is the reason it is classified as a second-generation device.

The SLIPA has six adult sizes (47, 49, 51, 53, 55, and 57) and no pediatric sizes. Many sizes are needed to closely match the SLIPA to the pharyngeal dimensions. Sizes 47, 49, and 51 are suitable for small, medium, and large female patients, and sizes 53, 55, and 57 are suitable for small, medium, and large male patients, respectively. The numbers refer to the widest transverse diameter (in millimeters) at the level of the bridge of the device. Matching this dimension to the distance between left and right cornu of the thyroid cartilage is one method of choosing the correct size. Guidance for sizing the device is shown in Table 23-6. Size selection is arguably more important for the SLIPA than other SADs because the lack of a cuff means that the airway seal and the ability to provide controlled ventilation depend on correct sizing. When there is doubt, the manufacturers recommend initially using the larger of two possible sizes.

1. Application

The insertion technique for the SLIPA is different from that of the LMA Classic, and it is not helpful to try pushing it against the hard palate. The device is lubricated, and the patient, who must be adequately anaesthetized, is positioned in the sniffing position. The device is advanced toward the esophagus until the heel of the device spontaneously locates itself in the nasopharynx. It usually passes the oropharyngeal curve with ease. The toe of the SLIPA may be used to lift the base of the tongue in a manner similar to a laryngoscope. As with most SADs, it is helpful if an assistant lifts the jaw forward during insertion. Alternatively, the anesthesiologist can lift the jaw forward with the thumb and finger. As the device moves into position, the angle between stem and shoe portion increases to be almost perpendicular. When it is in position, further pressure on the stem leads to clear resistance, indicating it is fully inserted. Because the heel enters the nasopharynx and anchors the device's position, the manufacturers indicate it is unnecessary to tie the device in place.

The SLIPA's plastic is relatively rigid at room temperature, and this may facilitate insertion. During use, the plastic softens as it warms, reducing the risk of airway trauma. After insertion, the toe of the device sits at the level of the cricopharyngeus (i.e., upper esophageal sphincter), the heal lies in the nasopharynx, and the stem lies over the tongue. The crescent shape of the toe is designed to lower the risk of obstructing the airway during insertion by folding the epiglottis down or causing laryngospasm. The bridge in the center of the chamber

TABLE 23-7
Fluid Retention by SLIPAs in Horizontal and 10-Degree Head-Down Positions

SLIPA Size (mm)	Horizontal Position (mL of Fluid)*	Head-Down Position (mL of Fluid)*
47	29 ± 0.3	45 ± 0.3
49	30 ± 1.0	48 ± 0.7
51	32 ± 1.3	54 ± 0.7
53	36 ± 1.0	62 ± 0.6
55	45 ± 1.2	68 ± 1.1
57	54 ± 0.8	72 ± 1.2

with its two lateral bulges is designed to fit into the piriform fossa at the base of the tongue and displace it from the posterior pharyngeal wall, thereby preventing the epiglottis from closing on the glottis. The anterior opening in the SLIPA has a wider portion and a narrower, distal portion, which is designed to minimize the risk of obstruction by an elongated epiglottis. For patients with limited mouth opening (as little as 1 cm), the hollow chamber may be flattened to facilitate insertion.

The SLIPA can be removed while the patient is still anesthetized, in which case a bite block is not recommended for routine use. Removing the SLIPA requires dislodgement of the heel from its anchoring in the nasopharynx. The device should be gently pulled anterior and caudal at the same time as opening the mouth. If the intention is to remove the SLIPA after the return of airway reflexes, a bite block is recommended.

If regurgitation is suspected, the chamber can be emptied by passing a suction catheter into it. Directing the catheter laterally during insertion minimizes the risk of it passing through the ventilation orifice. Alternatively, the SLIPA can be removed and then the pharynx suctioned. The head-down position enlarges the capacity that a given SLIPA can accommodate (Table 23-7).

The SLIPA has not been evaluated as an intubation conduit. The instructions for use state that "the SLIPA is not recommended for pulmonary endoscopic procedures."

2. Indications, Advantages, and Disadvantages

The SLIPA is a simple, inexpensive, disposable SAD with design features intended to minimize the risk of aspiration during use. It can be used during anesthesia with spontaneous or controlled ventilation. Proposed advantages over first-generation SADs include simplicity of construction and use because of lack of a cuff, ease of insertion, ability to compress and insert when there is a reduced mouth opening, a shape designed to minimize pressure on at-risk nerves, no need to be secured, and the ability to capture regurgitant fluid. The limited amount of published literature on the SLIPA means that many of these proposed advantages remain unexamined and therefore unproven.

The SLIPA is recommended for patients who are fasted and is not recommended for use in patients with gastric volumes that are likely to exceed normal fasting gastric volumes or in patients with gastroparesis. Because it relies on the chamber lying below the larynx, it is not recommended for use in positions such as prone or when the head and neck may be rotated. As with other SADs, use of the SLIPA does not require paralysis or laryngoscopy.

Because the SLIPA must be closely matched to the size of the pharynx to seal it effectively, many sizes are needed to ensure a correct fit for adult patients. Although patient height is an acceptable method for sizing the SLIPA, matching the width of the thyroid cartilage to the SLIPA's dimension aids in making the appropriate choice of device size. This range of sizes is not required for other SADs, and it may be considered an additional complexity, with an increased risk of selecting the wrong size.

The SLIPA is not designed to be used with the head rotated to the side, which may lead to loss of the seal. In the lateral or prone position, the utility of the SLIPA chamber to capture regurgitant fluid is reduced or lost.

3. Medical Literature

The literature on the SLIPA is complicated by several changes in its design over the years, which not all publications make clear. Many early studies were led or contributed to by the inventor. Later versions of the device have become more stable, and there have been more independent evaluations.

Fewer than 20 publications have described study of the SLIPA.

a. COHORT STUDIES

Miller and Lavelle reported an early cohort of 22 patients and a 91% success rate for use of the SLIPA.[212] Hein and colleagues performed a study of 60 insertions in patients undergoing minor surgical procedures.[214] Twenty SLIPAs were inserted by the experienced study lead and 40 by medical officers and anesthesiologists with various degrees of experience. Median time to ventilation was 20.4 seconds for the study lead and 24.8 seconds in the other group. The overall success rate for insertion was 100% for the study lead and 92.5% for the less-experienced group. Incidences of blood or sore throat score of more than 3 (scale of 0 to 10) were 23% and 7%, respectively. The less-experienced group reported the SLIPA to be easy to insert in 92% of cases.

Zimmermann and coworkers reported use of the SLIPA in 36 patients undergoing ophthalmic surgery.[215] Insertion was successful in 100% of patients, with 16% requiring manipulation to achieve a good seal. Four devices were replaced for other sizes. Ventilation was good, with no gastric inflation or regurgitation. In 17% of patients, blood was seen on removal of the device, and 22% reported slight pharyngeal discomfort.

b. RANDOMIZED, CONTROLLED STUDIES OF EFFICACY

In a study enrolling 120 patients, the inventor compared an early version of the SLIPA with the LMA Classic, with three sizes to choose from.[44] In overall performance (i.e., insertion success rate, airway seal, stress response to placement, postoperative trauma and sore throat), both devices were comparable. Insertion was successful for the

SLIPA and the LMA Classic in 59 of 60 patients. The airway leak pressure was higher with the LMA Classic, but the difference was not statistically significant.

Lange and associates compared the SLIPA with the LMA Classic in 124 patients undergoing ophthalmic surgery during general anesthesia.[216] SLIPA insertion failed in 2% and was easy in 88% of patients, and LMA Classic insertion failed in 0% and was easy in 90%. Airway leak pressure was not different between groups. Gastric inflation occurred in 19% of patients in the SLIPA group and 3% in the LMA Classic group ($P < 0.05$). No regurgitation was observed. Blood traces were more common in the SLIPA group (20% versus 11%, not statistically significant), as was postoperative sore throat (14% versus 2%).

In an early study by Miller and Camporota, the SLIPA was compared with the PLMA and ETT during 150 gynecologic laparoscopies.[217] The SLIPA and PLMA were comparable regarding ease of insertion, oropharyngeal leak (30 versus 31 cm H_2O), seal quality, systolic pressure in response to insertion, and time saved compared with tracheal intubation. There were fewer sore throats with the PLMA.

Woo and colleagues compared the SLIPA and PLMA in 101 patients undergoing gynecologic laparoscopy with controlled ventilation.[218] Insertion success rate, gastric insufflation, perilaryngeal leakage, anatomic fit, airway sealing pressure, respiratory mechanics, severity of sore throat, and incidence of blood and regurgitated fluid on the device were similar for the two groups. When the patient's head and neck position was changed, perilaryngeal leakage was less frequent with the SLIPA than with the PLMA (3 of 50 versus 11 of 51, $P = 0.026$). During peritoneal insufflation, perilaryngeal leakage did not occur with the SLIPA, but it occurred in four cases with the LMA ProSeal ($P = 0.045$).

Choi and coworkers reported a study of the SLIPA and PLMA in 60 patients.[219] Success rates for first-attempt intubation were 93% for the PLMA and 73% for the SLIPA, and the mean insertion times were 7.3 and 10.5 seconds, respectively. There was a greater hemodynamic response to SLIPA insertion than the PLMA. There was no statistically significant difference in the airway leak pressure, ventilation measures, postoperative sore throat, or other complication between the two groups. Blood stain on the device's surface was seen in 40% with the SLIPA and in 6.7% with the PLMA.

Puri and associates reported a high incidence of blood on the SLIPA at removal (40% versus 12% for the LMA Classic).[220]

c. OTHER STUDIES

Miller and Light used a lung model to study aspiration into the lungs, which could be quantitatively modeled in relation to regurgitation volumes during positive-pressure ventilation.[44] The model design had morphologic similarity to the SLIPA and was used to examine the SLIPA, LMA Classic, and PLMA. The SLIPA and PLMA compared favorably with the LMA Classic. Aspiration occurred after as little as 3.5 mL with the LMA Classic, whereas aspiration was prevented with the SLIPA until volumes of approximately 50 mL.

Hein and colleagues studied SLIPA and SSLM insertion in 36 anaesthetized patients by medical students trained on a manikin.[78] Rates of first-attempt insertion favored the SLIPA over the SSLM (83% versus 67%), as did the overall insertion success rate (94% versus 89%), but neither difference was significant. Median time to ventilation was shorter with the SLIPA (41 versus 67 seconds, $P = 0.004$) but only when it was used as the first device. Sixty-seven percent of the students expressed a preference for use of the SLIPA.

Fluid dynamic studies of various SADs revealed that there was less resistance to gas flow in the SLIPA than in other devices.[221] A surprising amount of the literature on the SLIPA examines hemodynamic changes in response to insertion. Xu and Zhong compared the SLIPA with the LMA Classic and ETT in 90 healthy patients scheduled for gynecologic laparoscopy.[222] Hemodynamic changes were greatest with the ETT. Puri and associates studied the hemodynamic response to insertion of the SLIPA and the LMA Classic in 100 patients.[220] Before SAD insertion, the Bispectral index was titrated to 40, a value indicating an appropriate level of general anesthesia. Both airway devices elicited hemodynamic changes, but they were greater and more prolonged in the SLIPA group. Both devices produced a similar increase in the Bispectral index after insertion. Similarly, Jindal and colleagues reported the SLIPA produced greater hemodynamic changes than the i-gel.[196] Choi and coworkers reported a greater hemodynamic response to the SLIPA than the PLMA.[219]

d. LITERATURE SUMMARY

There are too few studies to determine the efficacy of the SLIPA and whether the chamber does reduce the risk of aspiration. There is no substantial clinical evidence to support this claim. Although several studies have indicated adequate insertion and ventilation performance, including performance equivalent to the PLMA, several studies have indicated a high rate of airway trauma and sore throat. Clinical benefits of the SLIPA over other modern SADs require verification.

D. Baska Mask

The Baska mask is the newest entrant in the SAD market. It incorporates many features of the second-generation SADs with several novel features, which the inventor reports offer further advantages. It has been designed and developed over 11 years by Kanag Baska, an Australian anesthetist. The device came to market in Europe in 2011.

The Baska mask is a single-use, cuffless, silicone SAD. All parts that were deemed unnecessary were removed during design to minimize the bulk in the mask portion (Fig. 23-17). The stem, which has a 15-mm standard connector and an integrated, rigid bite block, has an oval cross section to provide axial stability. Two drain tubes run laterally on either side of the airway tube toward the mask portion. A soft, oval airway orifice at the distal end is surrounded by a soft, malleable mask portion. To either side of and posterior to the mask, the drain tubes open and extend to the mask tip (Fig. 23-18). The drainage

system, incorporating one conventional drain tube and one active pharyngeal suction port, is intended to reduce the rate of aspiration. Proximally, an attachment enables suction to be attached to one of the ports to achieve continuous suction during insertion. Between the proximal anterior part of the mask and the distal stem is a strap designed to assist insertion.

The soft structure of the mask is compliant enough to change shape when pressure is applied. The manufacturers describe that as positive pressure is applied, the mask distends, increasing the pharyngeal seal, and as that pressure is released, the mask partially deflates, limiting any pressures applied to the pharyngeal tissues. Four sizes are available for small to large adults.

1. Application

The Baska mask is first sealed at both ends with fingers and compressed to assess its integrity. The posterior and sides of the mask should be lubricated with a water-soluble lubricant. The device may be inserted with the patient in several head and neck positions, but the neutral position is favored. The device is held in the dominant hand with the thumb, forefinger, and middle finger grasping the base of the mask and with the index and middle fingers exerting pressure on the mask in a posterior and downward direction. The device is inserted into the mouth and along the hard palate. On reaching the soft palate, the device is advanced into place by advancing the stem of the device. If difficulty is encountered in negotiating the pharyngeal corner, the anterior strap is pulled to flex the device tip and ease it around the corner. The device is fully inserted when resistance to advancement is felt. There is no cuff to deflate. Gentle manual ventilation is used to confirm the correct position of the device. Difficulties in ventilation may be resolved by minor advancement or withdrawal of the device. When this is not successful, a different size of Baska mask may be tried.

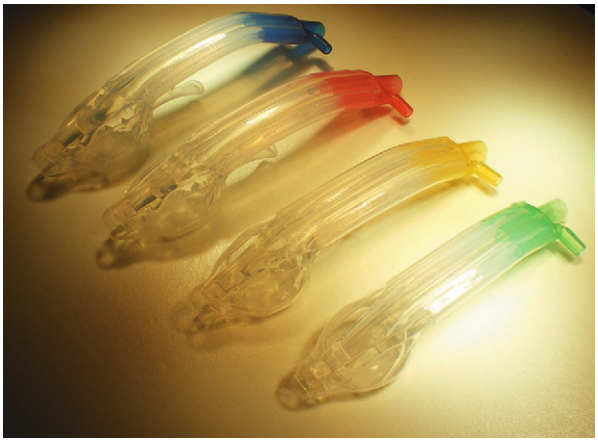

Figure 23-17 The Baska mask is a novel type of supraglottic airway device. Colors differentiate the different sizes of the device.

Continuous pharyngeal suction may be applied through one of the drain tubes during insertion to clear secretions in the pharynx. After insertion, the other drain tube may be used to insert a gastric tube and empty the stomach. At the end of surgery, the patient should be allowed to emerge until able to follow simple commands. At this point, the Baska mask may be removed by recovery staff or the patient.

The Baska mask has a wide lumen and a moderately large airway orifice without grills or impediments to the passage of tubes. Although it might be anticipated that the Baska mask performs similarly to other SADs as a conduit for fiberoptic-guided intubation (e.g., PLMA, i-gel), this depends on the ventilation orifice lying over the larynx and ease of passage of a fiberscope and tube. No reports or studies are available.

2. Indications, Advantages, and Disadvantages

The Baska mask can be used with spontaneous or controlled ventilation. It is new, and there are no publications reporting details of its routine use or defining the breadth or limits of its safe use. Specific disadvantages have not been determined due to a lack of experience.

3. Medical Literature

No published literature is available for this device, although at least two clinical studies are being conducted.

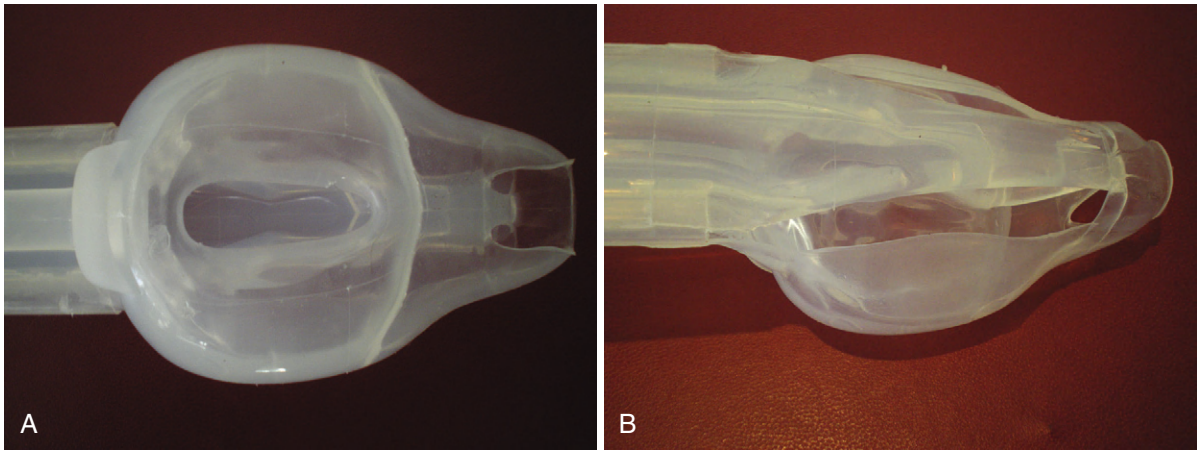

Figure 23-18 The mask portion of the Baska mask. **A,** View from anterior; **B,** view from posterior.

VII. PEDIATRIC SUPRAGLOTTIC AIRWAY DEVICES

SAD technology in pediatrics lags several years behind adult practice. In the past few years, some of the newer first-generation and second-generation SADs have become available in the full range of pediatric sizes. This represents an opportunity and a potential risk if not managed with care. There is an emerging selection of SADs for pediatric use and a supporting literature.

A. Ambu AuraOnce, Soft Seal Laryngeal Mask, and Other Laryngeal Masks

Monclus and associates studied the Ambu AuraOnce in 121 pediatric patients during MRI to look for a correlation between clinical measures such as insertion ease, leak pressure, and radiologic positioning.[223] Patients were between 4 months and 17 years old. Clinical data were collected, and saggital MRI cuts were reviewed to calculate neck flexion, LM position, and the device's relation to the trachea. The success rate for first-attempt insertion was 96%, and the rate for second-attempt insertion was 4%. Leak pressures ranged from 22.1 to 23.8 cm H_2O for different mask sizes, and values rose with patient age. Anomalous placement was seen on MRI for 23.5% of size 1.5, 10.9% of size 2, and 13.8% of size 2.5. No correlation was identified between anomalous LM position and leak pressure or ease of introduction.

Baker and coworkers studied several single-use LMs and the LMA Classic as conduits for pediatric flexible bronchoscopy in 100 patients.[224] Five devices (i.e., LMA Classic, Ambu AuraOnce, SSLM, LMA Unique, and Boss LM) were studied. Evaluation was based on subjective assessment of resistance to bronchoscopic manipulation within the SAD, laryngeal view, and measurement of time from starting insertion to visualizing the right upper lobe bronchus. Resistance to bronchoscopic manipulation was higher using PVC devices. The LMA Unique and Ambu AuraOnce were judged clinically inferior to the LMA Classic. The Boss Systems' single-use LM was as effective as the LMA Classic.

Glaisyer and Yule studied the use of the SSLM in 40 infants and children.[225] The SSLM was deemed a satisfactory airway in all patients. Insertion was achieved at the first attempt and was quick and easy. Repositioning during anesthesia was required in four cases.

B. Intubating Laryngeal Airway

Jagannathan and colleagues reported a 1-year, retrospective series of 34 uses of the ILA in children as a conduit for intubation.[226] Eight of these cases were emergencies. Patients were between 0.3 and 202 months old, and they weighed between 3.9 and 86 kg. Difficult airways (mostly craniofacial syndromes) were anticipated in 31 patients, and three difficult airways were unanticipated. The success rate for first-attempt intubation was 97% (33 patients), and the overall intubation rate was 100%; a fiberscope was used in 25, and a Shikani optical stylet in 7 patients. In two patients blind intubation succeeded and in one it failed. The investigators suggest that visualized techniques offer a greater degree of success because of the potential for epiglottic downfolding when using the ILA in children.

In another prospective study, size 1.5 and 2.0 ILAs were studied in 100 healthy children with normal airways who were between 6 months and 8 years old.[227] ILA placement, fiberoptic tracheal intubation, and ILA removal were successful in all patients. The size 1.5 ILA cohort had a significantly higher rate of epiglottic downfolding compared with the size 2.0 ILA cohort ($P < 0.001$) despite adequate ventilation variables. A moderate negative correlation was found between weight and fiberoptic view ($r = -0.41$, $P < 0.001$), indicating that larger patients tended to have better fiberoptic grades. Compared with size 2.0, the size 1.5 ILA cohort took a significantly longer time for tracheal intubation, although this was of questionable clinical significance.

A few reports describe use of the ILA for management of difficult airways in children under anesthesia,[228-230] during extensive bleeding, and in an awake patient.[231,232] Several modifications of technique have been made for use in children. They include use of an airway exchange catheter or esophageal dilator to facilitate removal of the SAD after intubation.[233,234]

C. Laryngeal Tube and Laryngeal Tube Suction II

Genzwuerker and coworkers reported a comparative trial of the LT or LMA Classic with controlled ventilation in children between the ages of 2 and 8 years, who were scheduled for elective surgical interventions.[235] Insertion success was high for the LT group (30 of 30) and for the LMA Classic group (29 of 30). The LT was inserted slightly quicker than the LMA Classic (19 versus 23 seconds, $P < 0.05$) and achieved a higher airway leak pressure (19.2 versus 26.3 cm H_2O, $P < 0.001$). Peak airway pressure was slightly lower in the LMA Classic group.

Bortone and associates compared the LT and LMA Classic in 30 healthy children younger than 10 years.[236] Eleven children with an LMA Classic and two with an LT had adequate spontaneous or assisted ventilation after initial positioning ($P < 0.01$). Head positioning improved adequate ventilation in 15 of 15 with the LMA Classic and 11 of 15 with the LT ($P < 0.05$). Fiberoptic inspection revealed the vocal cords in 11 through the LMA Classic and none through the LT ($P < 0.001$).

Kaya and colleagues compared performance of the LT, LMA Classic, and CobraPLA in 90 healthy children undergoing short procedures with controlled ventilation.[237] Insertion times were similar for the LMA Classic (19 seconds), LT (21 seconds), and CobraPLA (18 seconds), as were the rates of successful insertion at first attempt for the LMA Classic (67%), LT (70.0%) and CobraPLA (73%). The number and type of airway interventions required and the hemodynamic, ventilation, and oxygenation variables throughout surgery were similar. Blood traces were seen on 20% of the LMA Classics, 20% of the CobraPLAs, and 10% of the LTs.

In a study of 24 children, Kim and associates reported that two methods of insertion—until resistance was felt and by inserting to a previously measured depth of the curved distance between the cricoid cartilage and the upper incisor—were more successful than the standard method of insertion (i.e., until the thick teeth mark on the tube was aligned with the upper incisors).[238] All children weighed between 12 and 25 kg, and a size 2 LT was used. Both alternative methods led to better ventilation and increased ability to identify the vocal cords with fiberoscopy (62.5% by the first method and 75% by the second) compared with standard method (12.5%).

Lee and colleagues compared complications of LT removal during anesthesia or after emergence in 70 healthy children between the ages of 1 and 12 years.[239] Anesthesia was induced and maintained with sevoflurane. In the anesthesia group, sevoflurane was maintained at 2%. Cough (37% versus 3%), hypersalivation (29% versus 6%), and desaturation (20% versus 0%) occurred more frequently in the awake group ($P < 0.05$), whereas airway obstruction (easily resolved by chin or jaw lifting) was more frequent in the anaesthetized group. The same group studied the optimal concentration of sevoflurane for removal of an LT (and LMA Classic) in children.[240] Forty unpremedicated children between the ages of 8 months and 12 years were studied during sevoflurane anesthesia. An up-down method was used to determine the optimal concentration for device removal (i.e., absence of coughing, teeth clenching, gross purposeful movement, breath-holding, laryngospasm, and desaturation). The end-tidal concentration of sevoflurane to achieve successful LT removal in 50% of children was 1.83%, and for a 95% success rate, it was 2%. For the LMA Classic, the concentrations were 1.9 %, and 2.15%. For both devices, this represents a minimum alveolar concentration (MAC) of 0.8 to 0.9.

The bulk of publications on the LTS-II in children describe its use in difficult airway management. Kim and associates reported on the effect of changes in head and neck position in LTS-II performance in 33 children scheduled for elective surgery.[241] The ventilation score (i.e., no leakage with an airway pressure of 15 cm H_2O, bilateral chest excursion, and a square wave capnogram, with each item scored 0 or 1 point) was measured in various positions. Leak pressure was reduced to 22 cm H_2O in the extended position, but ventilation was good without a leak at tidal volumes of 10 mL/kg.[99] In the neutral, extended, and rotated positions, the median ventilation scores were better (3 points each) than that with the head and neck flexed (1 point). Peak inspiratory pressure significantly increased in the flexed position. During fiberoptic examination, the vocal cords were more easily seen in extension and right rotation compared with the neutral position and flexion. The flexed position usually should be avoided.

Scheller and coworkers described the use of the LTS-II in 10 neonates and infants during difficult airway management, including failed mask ventilation, failed SAD ventilation, or failed intubation.[242] Use of the LTS-II was associated with a high level of success, securing the airway when other techniques had failed. The investigators support the use of the LTS-II over the LT in part because the drain tube enables gastric tube placement and can be used as an indirect indicator of correct placement. A modified insertion technique using an Esmarch maneuver was recommended. A single case report described use of the LTS-II to facilitate fiberoptic intubation in an infant.[243]

D. Cobra Perilaryngeal Airway

Passariello and coworkers studied the CobraPLA size 1.5 and 2 during controlled ventilation in 40 anesthetized children aged 1-10 years, weighing 10-35 kg.[244] The first-attempt insertion success rate was 90%, the median leak pressure was 20 cm H_2O, and the vocal cords were visible by fiberoscopy in 90% of patients. In 21% of patients, gastric inflation was observed at a peak inspiratory pressure of 20 cm H_2O or less.

Kaya and colleagues' study of the LT, LMA Classic, and CobraPLA in 90 healthy children undergoing short procedures with controlled ventilation was described earlier.[237]

Gaitini and coworkers compared the CobraPLA with the LMA Unique in 80 children undergoing elective general surgery of short duration during volume-controlled ventilation.[245] Time for and ease of insertion were similar. The CobraPLA needed more frequent jaw lifts, and the LMA Unique required more frequent head and neck adjustments. Fiberoptic scores were excellent with both devices. Respiratory variables were similar, except that plateau and peak pressures were higher in the CobraPLA group. Gas exchange was similar for both groups. Airway leak pressure was higher for the CobraPLA than the LMA Unique (27 versus 21 cm H_2O). There was a low rate of blood mucosal staining of the devices.

Szmuk and associates compared the CobraPLA with the LMA Unique in 200 children during positive-pressure ventilation.[246] The CobraPLA performed better in terms of airway seal, device stability, and gastric inflation. Capnography values (measured at the head of the CobraPLA) were higher than those of the Y piece of the circle circuit. This implies a greater accuracy, and the feature is incorporated in the CobraPLUS.

Szmuk and others have described the use of the CobraPLA as a conduit to facilitate tracheal intubation in two cases of known or predicted difficult airway.[247, 248] In a third case, a size 0.5 CobraPLA was used to maintain the airway of a neonate with airway difficulty (i.e., hypoplastic midfacies and subluxation of C5-C6) when intubation proved impossible.[249]

E. The i-gel

In the first published study of the i-gel in children the device was used in 50 healthy children weighing more than 30 kg who were undergoing short-duration surgery.[250] All devices were inserted on the first attempt. Mean airway leak pressure was 25 cm H_2O. There was no gastric inflation, and gastric tube insertion was achieved in all cases.

The i-gel was compared with the Ambu AuraOnce in 208 children up to 17 years old.[251] Insertion success was

equivalent for the Ambu AuraOnce group (98%) and the i-gel group (93%), but i-gel insertion was slower (27 versus 24 seconds). Airway leak pressure was higher with the i-gel (23 versus 19 cm H_2O). Gastric tube placement was successful in 97% of the i-gel group. The fiberoptic view was good and equivalent between groups, and there were few side effects in either group. Almost one half of the i-gels needed taping to maintain the airway seal, especially in smaller children.

A study of 120 smaller children (<35 kg; median weight, 19 kg) reported insertion success on the first, second, or third attempt in 110, 8, and 1, respectively, with one failure.[252] Manual ventilation was possible in all cases, although excess leak precluded a tidal volume above 7 mL/kg in three children. Fiberoptic inspection through the i-gel showed a clear view of the vocal cords in 40 of 46 inspected cases. Median leak pressure was 20 cm H_2O. One child regurgitated without aspirating, and other complications and side effects were uncommon. The i-gel was inserted without complications, establishing a clear airway and enabling spontaneous and controlled ventilation in 113 (94%) children.

Initial findings suggest the pediatric i-gel requires careful insertion to avoid displacement: an inward force must be created by bimandibular taping. The stem of the device is unnecessarily long. The depth of insertion marker routinely lies some distance outside the mouth with the device correctly positioned, particularly for smaller size devices.

VIII. CONCLUSIONS

Since the introduction of the LMA into clinical practice, numerous alternative SADs have been developed. They have different sizes and shapes, and some are reusable, whereas others are designed only for single use. They have various intended uses. No single device meets all the criteria for the ideal SAD. Fortunately, use of these devices is easy to learn, and they can be used by experienced anesthesiologists and novice airway providers alike. Second-generation SADs are likely to provide better airway protection, and their use is increasing in clinical practice. Nonetheless, there are situations in which such devices should not be used (e.g., full-stomach patients) unless as a rescue device.

It is likely that several different airways will always be needed for use in different clinical situations. Airway providers should be skilled with several devices and techniques, including various SAD devices, to be considered competent in airway management. Clinical judgment born from experience is necessary to determine which of these devices is indicated in any situation.

IX. CLINICAL PEARLS

- Supraglottic airway devices (SADs) have several roles, including maintenance of the airway during spontaneously breathing or controlled-ventilation anesthesia, airway rescue after failed intubation or out of the hospital, use during cardiopulmonary resuscitation, and use as a conduit to assist in the mangement of a difficult tracheal intubation.
- The risk of aspiration with SADs is considered to be relatively low in expert hands, which is achieved primarily by careful and appropriate case selection, expert insertion, and meticulous management of the airway after insertion.
- About 30 single-use and reusable laryngeal masks (LMs) are on the market. Each is different from other LMs in design and in manufacturing materials and processes.
- The greatest concern about the profusion of LMs on the market is the lack of rigorous evaluation. The limited evidence available shows that all LMs and LMAs are not equivalent.
- LMs are not intended to replace all functions of the ETT and are best suited for use in fasted patients undergoing surgical procedures when tracheal intubation is not deemed necessary.
- Airway devices are considered to be of low or intermediate risk and are primarily subject to manufacturers' self-assessment. Performance of the desired function, efficacy, and cost-effectiveness are not a focus of these assessments.
- The desirable features of an ideal SAD are efficacy, versatility, safety, reusability, and reasonable cost.
- Although most devices are used by anesthesiologists, SADs may be used by individuals with less experience in anesthesia, out-of-hospital rescue, or resuscitation.
- Familiarity with the manufacturer's warnings, precautions, indications, and contraindications is necessary before use, and the patient should be at an adequate depth of anesthesia or unconsciousness before attempting insertion.
- There is an emerging selection of SADs for pediatric use and a supporting literature.

VII. Clinical Pearls

I. INTRODUCTION

Laryngoscopy performed for the purpose of tracheal intubation has historically involved a direct line-of-sight to the larynx. Newer fiberoptic and video imaging can visualize around the anatomic difficulties associated with difficult or impossible direct laryngoscopy. However, most intubations are still performed with direct laryngoscopy. Most direct laryngoscopy in adults is performed with a curved Macintosh blade, and less often, the narrow-lumen, straight Miller blade is used. Straight blades typically are used in pediatrics. This chapter reviews the evolution of the laryngoscope, some blades of historic interest and innovative designs, and subtleties of Macintosh and Miller blades. Major modifications have occurred in blade materials and illumination, and there has been a dramatic increase in the use of disposable laryngoscope blades for single cases.

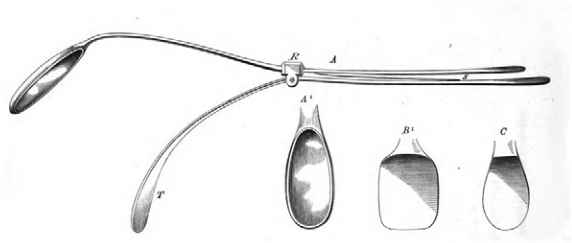

Figure 24-1 British physician Benjamin Babington combined a mirror and spatula. (From Mackenzie M: *Use of the laryngoscope in diseases of the throat*, ed 2, Philadelphia, 1869, Lindsay & Blakiston.)

II. HISTORY

Benjamin Babington first described mirror-based indirect laryngoscopy in 1829,[1] although it is often erroneously attributed to Manuel Garcia, a singer who described visualization of his own vocal cords in 1855.[2-8] Babington also hinged a tongue depressor to his initial mirror design, but he subsequently abandoned the depressor and focused on the mirror alone (Fig. 24-1). In 1844, John Avery combined a reflective speculum with an external light source to view the larynx (Fig. 24-2).[4] Mirror laryngoscopy for the investigation of laryngeal pathology was pioneered by

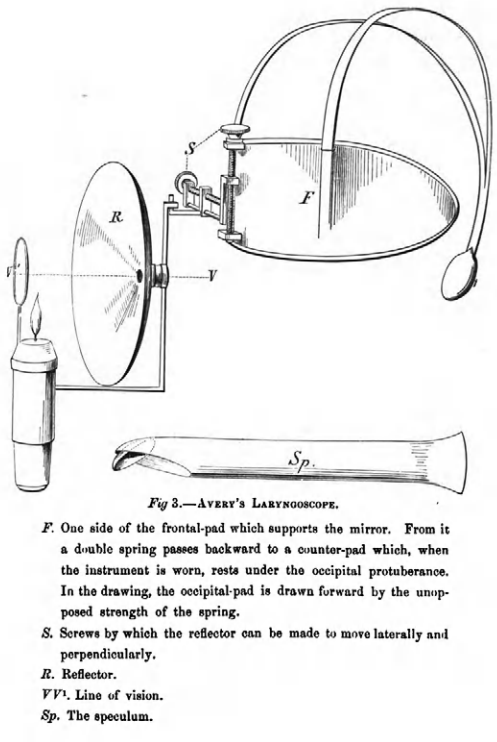

Figure 24-2 Avery's reflective speculum. One side of the frontal pad *(F)* supports the mirror. From it, a spring passes backward to a counter-pad, which when the instrument is worn, rests under the occipital protuberance. As shown here, the occipital pad is drawn forward by the unopposed strength of the spring. The reflector *(R)* can be moved laterally and perpendicularly by screws *(S)*. *Sp*, Speculum; *V-V1*, line of vision. (From Mackenzie M: *Use of the laryngoscope in diseases of the throat*, ed 2, Philadelphia, 1869, Lindsay & Blakiston.)

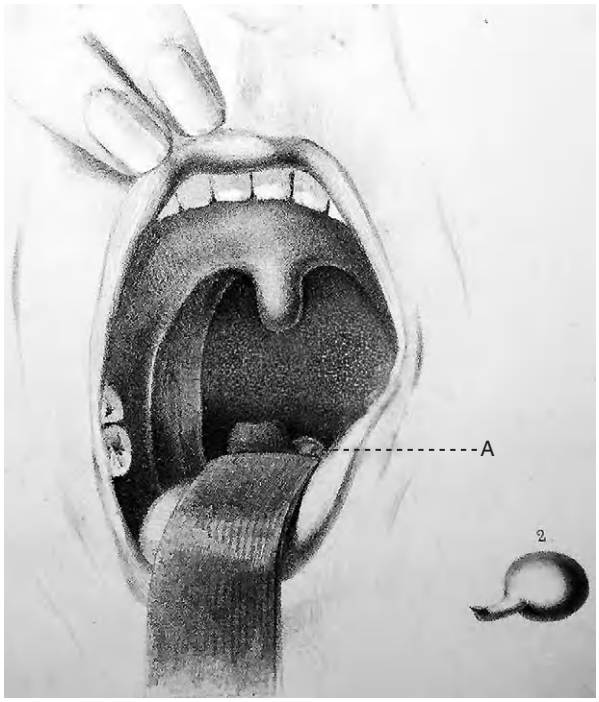

Figure 24-3 1845, Horace Green removed a laryngeal polyp *(2)* using a bent tongue spatula *(A)* to expose the larynx and polyp to direct vision. (From Green H: Morbid growths within the larynx. In Green H, editor: *On the surgical treatment of polypi of the larynx and oedema of the glottis*, New York, 1852, GP Putnam.)

Johann Czermak, who used instruments designed by Ludwig Turck in the late 1850s.[5-8] Czermak subsequently applied an external light source and a head-mounted mirror to improve visualization.[7]

Horace Green, widely considered to be America's first laryngologist, used tongue spatulas and probangs to examine and treat diseases of the larynx and trachea in the mid-1800s. In 1845, Green performed transoral removal of a laryngeal polyp in an 11-year-old girl using a bent tongue spatula to expose the larynx and polyp to direct vision (Fig. 24-3).[7,9] Green's technique[9] is remarkably similar to the indirect elevation of the epiglottis described almost 90 years later by Macintosh:

> *I drew forward and depressed the tongue, so as to enable me to see the condition of the epiglottis.… Whilst making this examination, and at the very moment the tongue was depressed, and the epiglottis in full view, the patient gave a sudden and rather violent cough, when a round white fibrous looking polypus appeared, momentarily, at the opening of the glottis, and then seemed as quickly to be drawn into the larynx.*

Green goes on to describe the use of a hook and knife passed "nearly an inch into the glottis" to extract the polyp. Despite Green's accomplishments in direct laryngeal exposure, laryngeal surgery, and intubation, the first publication on direct laryngoscopy is credited to Alfred Kirstein in 1895, who called the new procedure *autoscopy* and devised techniques for use with the patient in sitting and supine positions.[10,11] Kirstein's 1896 treatise on the procedure presages the development of laryngoscopy

Figure 24-4 Alfred Kirstein performed autoscopy in the 1890s. (From Kirstein A, Thorner M: *Autoscopy of the larynx and the trachea (direct examination without mirror)*, Philadelphia, 1896, FA Davis.)

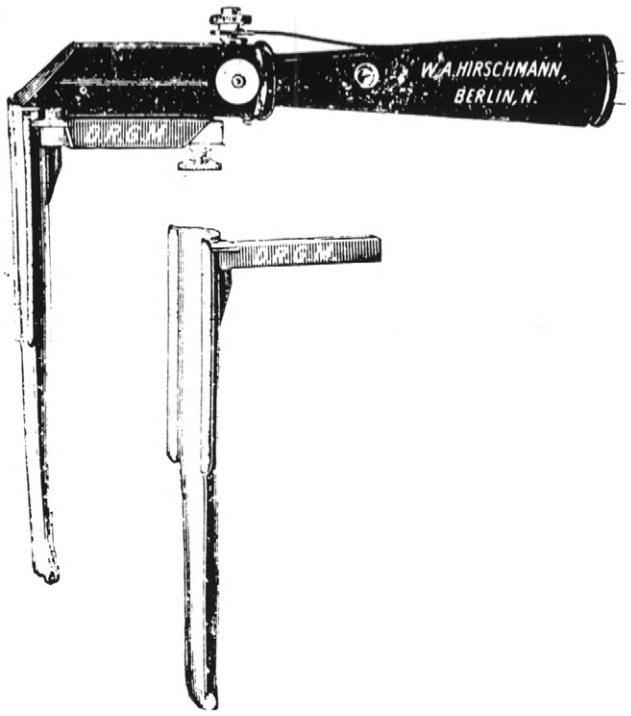

Figure 24-5 Kirstein's modified autoscope. A standard blade is attached to the handle, and an intralaryngeal blade is shown separately *(bottom)*. (From Hirsch NP, Smith GB, Hirsch PO: Alfred Kirstein—Pioneer of direct laryngoscopy. *Anaesthesia* 41:42, 1986.)

blades used in the modern era.[11] He observes that the tongue must be drawn forward and downward (with the patient sitting in front of the operator): "To get this position of the tongue, a tongue depressor is necessary (i.e., spatula)—which, however, unlike the ordinary spatula, must not be placed in front of the circumvallate papillae but must be applied behind the same to the root of the tongue" (Fig. 24-4). The epiglottis can be elevated *directly* by an instrument that projects over the epiglottis (e.g., the tip of the spatula introduced behind the epiglottis) or *indirectly* by a method described by Reichert in 1879 and promulgated by Kirstein[11]:

> *Pressure upon the base of the tongue and the median glosso-epiglottic ligament produces an elevation of the epiglottis on account of its close attachment to the tongue. As the first method requires previous cocainization, it should be reserved for exceptional cases; autoscopy must depend, in general, on the principle enunciated by Reichert—a principle which is already involved in the necessary instrumental depression of the base of the tongue.*

Kirstein developed two spatulas (Fig. 24-5). One had a distal, bent, bifid tip, which he called the *standard spatula*, that was designed for placement in the valleculae and pressed on the median glossoepiglottic ligament. Kirstein's intralaryngeal, perfectly straight spatula was designed to be introduced behind the epiglottis and press it against the root of the tongue. His descriptions of these instruments and intended uses portray exactly the functioning of modern curved- and straight-blade laryngoscopes.[11]

Chevalier Jackson, a professor of laryngology at Jefferson Medical College in Philadelphia (after Jacob de Silva Solis-Cohen, another Jefferson pioneer), refined laryngoscopy techniques in supine patients and established the principles of modern laryngoscopic exposure. Jackson created a tubed *glottiscope* in 1903 and was the first to apply enclosed distal lighting using a tungsten bulb that was connected to a large battery.[5-9,12] Subsequent versions of Jackson's tubular laryngoscope incorporated a removable, sliding floor that facilitated tube insertion, and he reported on the routine insertion of tracheal tubes using direct laryngoscopy in 1913 (Fig. 24-6).[12,13] In the same year, Henry Janeway, an anesthesiologist at Bellevue Hospital in New York City, described a smaller and more portable laryngoscope powered by batteries located in the handle (Fig. 24-7).[14] It featured a straight blade with a slight distal curve.[14] Janeway's blade did not achieve commercial success, but similar large, C-shaped, straight-blade designs created by Flagg, McGill, and Guedel became widely adopted.[15,16]

Laryngoscope blade design and laryngoscopy technique underwent little apparent evolution until Robert Miller's 1941 narrow-lumen, D-shaped, straight-blade design and Robert Macintosh's 1943 publication about a new curved-blade laryngoscope (Fig. 24-8, *A*).[17,18] The Macintosh and Miller blades have become universally adopted and the benchmarks against which all direct laryngoscope blades are compared. Although innumerable modifications of these standard designs have been described in the past 70 years, only a few alternative designs have achieved widespread use. In the 1970s, the

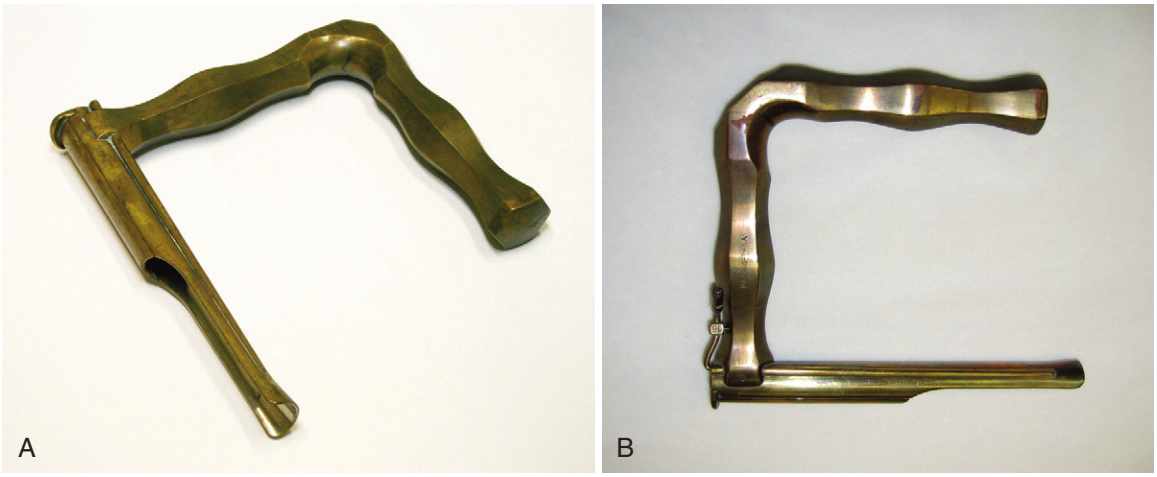

Figure 24-6 **A** and **B,** Chevalier Jackson's tubular laryngoscope incorporated a removable, sliding floor, which facilitated tube insertion.

flexible fiberoptic bronchoscope offered another option for use in difficult situations, and rigid fiberoptic devices such as the Bullard laryngoscope were first introduced in the late 1980s. The 1990s saw the introduction of additional rigid fiberoptic laryngoscopes and commercially available fiberoptic stylets. In the 21st century, video-assisted devices have been added to clinical practice.

III. DIRECT LARYNGOSCOPE DESIGN

A. Components of a Direct Laryngoscope

A laryngoscope consists of a handle, a blade, and a light source. There are marked variations in blade shape, tip design, and the mechanism and location of illumination systems (i.e., bulbs, or light-conducting fibers). The section of the blade that contacts the tongue is the *spatula*, and the left edge of the blade (from the operator's perspective) is the *flange*. (see Fig. 24-8, *B*). The proximal vertical flange is sometimes called the *vertical step*. At the base (or *heel*) of the blade is the *block*, which interacts with the top of the handle. The connection between the blade and handle causes the light to come on when the blade is opened. Blades are designed to attach and detach from the handle with a standardized fitting (engaged at 45 degrees) that connects a *hook* on the blade to a small rod at the top of the handle.

Most laryngoscope blades are made from steel and most are chrome plated. Plastic blades have been produced by different manufacturers for approximately

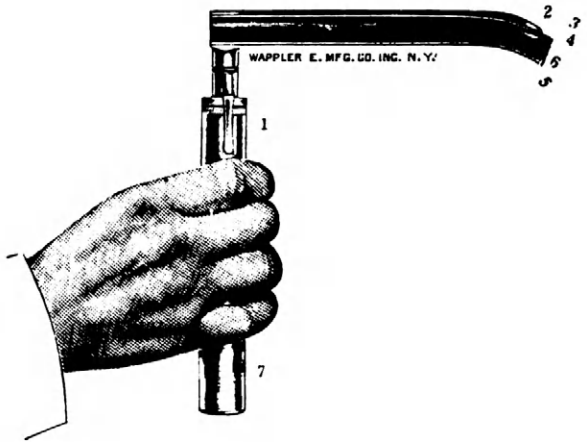

Figure 24-7 Henry Janeway produced a portable laryngoscope powered by batteries located in the handle.

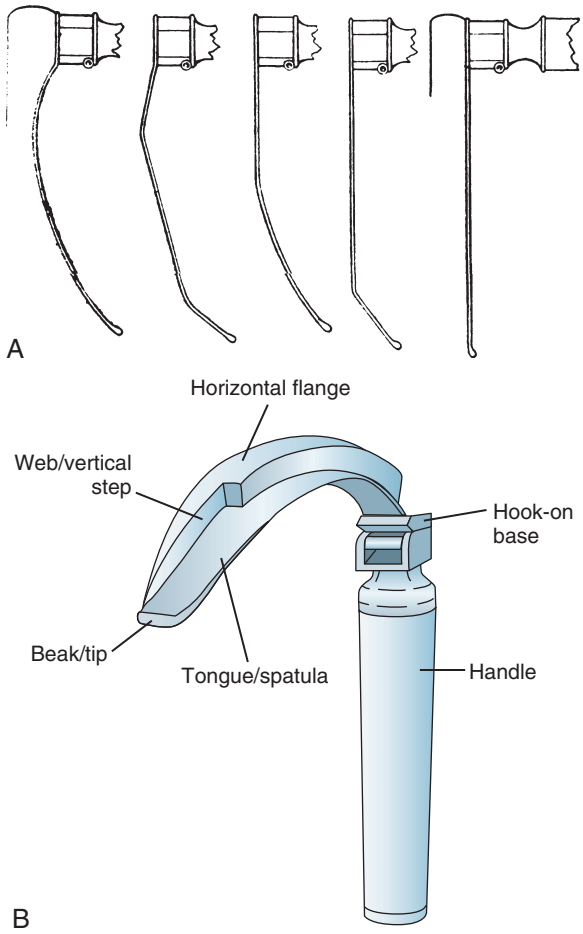

Figure 24-8 **A,** Macintosh experimented with various blade shapes for the laryngoscope. **B,** The components of a direct laryngoscope with a Macintosh blade. (**A,** From Macintosh RR: Laryngoscope blades. *Lancet* 1:485, 1944; **B,** Courtesy of Anne Law,)

20 years. Plastic blades can be made very inexpensively, especially fiber-lit blades that use an acrylic rod for light conduction. The initial plastic blades had some flex and wobble; later designs have overcome these problems, and some are sturdy enough to be reusable.

The heel of a laryngoscope blade is a critical mechanical element. Many manufacturers decrease production costs using plastic heels on a metal blade, and some use metal fittings for the hook and base, even though the bulk of the heel is plastic. A potential problem with plastic-heeled blades is loosening of the paired ball bearings on either side of the heel. Some plastic blades have plastic flanges instead of bearings. A relatively new feature of some blades is a mechanism on the hook to prevent the blade from touching the handle when closed. This keeps a sterile blade from contacting the presumably dirty handle, although there is no requirement for laryngoscope blades to be supplied sterile.

B. Direct Laryngoscope Lighting

Visualization of the laryngeal inlet during direct laryngoscopy depends on adequate illumination of airway structures by the laryngoscope. Illumination is a function of the intensity and color of the supplied light and the area over which it falls. These factors depend on the nature of the laryngoscope blade's light source and the potential of the power source applied to it. Light can be measured in several ways: at its source (i.e., luminous flux, measured in lumens), at its receiving surface (i.e., illuminance, measured in lux), or by the amount of light re-emitted from a surface in a given direction (i.e., luminance, measured in candela per square meter [cd/m^2]).[19,20] During direct laryngoscopy, perception of the surface brightness of the larynx depends on light transmitted back to the laryngoscopist's eyes from the surface of the larynx; this is luminance.

A significant variable in the perception of adequate lighting during laryngoscopy is the operator. As clinicians age, they develop presbyopia (beginning in the fourth decade, regardless of visual acuity), and the amount of light needed for a given visual task increases. This is especially significant in performing direct laryngoscopy because the larynx is sighted with only one eye due to the severe visual restrictions of the procedure.[21] The procedure is visually analogous to looking down a 1-inch pipe at a target 12 to 18 inches away; visual restrictions include the mouth, teeth, tongue, blade, and epiglottis. Because the right and left eye are separated in the skull by 4 to 5 inches, the two views are disparate and cannot be merged into a stereoscopic view of the larynx. Subconsciously, we suppress the nondominant image through a phenomenon known as binocular suppression. It is not known what component of difficult laryngoscopy is related to inadequate lighting, but adequate illuminance is especially important when landmarks are obscured by secretions, blood, and vomitus and when the epiglottis causes shadowing of the larynx.

Historically, there was no standard for laryngoscope light, but the International Organization for Standardization recently agreed on a standard of 500 lux after 10 minutes of operation.[22] The illuminance of a laryngoscope light at the distal tip of the blade is a function of the distance from the light source to the tip of the blade, the type of bulb or fiberoptic-conducting system, and the battery type and charge status.[23] The light-to-tip distance is important because the amount of illuminance at a target is governed by the inverse square law (i.e., if the distance from the light source is doubled, one fourth of the amount of light lands on the target). Across different clinical settings, there may be dramatic differences in the illuminance of blade and handle pairs. Marked variation and poor light performance of laryngoscopes is widespread in anesthesia and emergency departments.[23,24] In a study of many emergency departments in Philadelphia, there was a 500-fold difference in the illuminance produced by different blade and handle pairs, ranging from 11 to more than 6000 lux.[24]

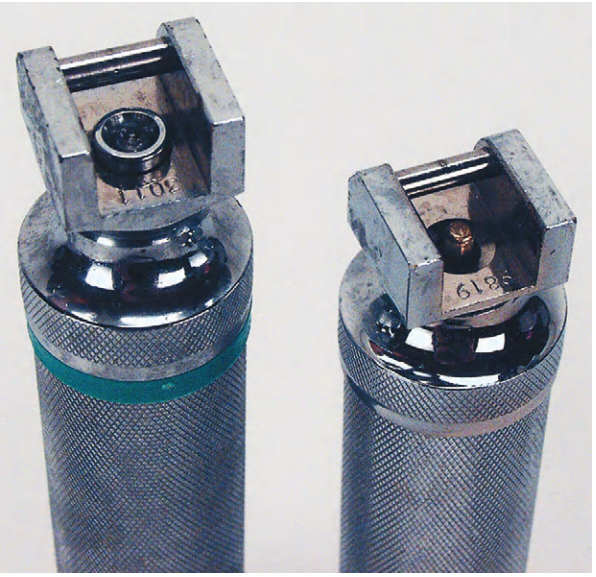

Figure 24-9 The conventional laryngoscope and fiber-lit laryngoscope use different, non-interchangeable fittings. In the United States, fiber-lit blades have a green dot on the base, and the handles have a green ring near the top *(left)*.

Bulb-on-blade laryngoscopes (called *conventional blades*) and fiber-lit laryngoscopes (in the United States, called *green-line scopes*) use different, non-interchangeable fittings (Fig. 24-9). Bulb-on-blade laryngoscopes have a simple electrical connection between the handle and blade. The electrical circuit is completed by opening the blade, providing power to the bulb, which is mounted on the distal aspect of the blade. Halogen and xenon bulbs are used by many manufacturers, but within the past 5 years, super-bright LED bulbs have become available. LED bulbs have tremendous advantages compared with other bulbs. They use a fraction of the energy of xenon or halogen bulbs, and they operate at much lower temperatures. The light they produce is much whiter, which may improve the discrimination of landmarks. The more yellow color of standard bulbs can be especially poor for distinguishing reddish yellow mucosal structures (e.g., epiglottis from the posterior pharyngeal wall). The primary reason LED lights will become standard on all instruments in the future is cost; as LEDs become much more commonly used on laryngoscopes and other

Figure 24-10 Examples of all-steel laryngoscope blades with LED bulbs on them. (Courtesy of SunMed, Largo, FL.)

portable medical instruments, the cost of the bulbs will continue to decrease. Some manufacturers already offer inexpensive, single-use, all-steel, LED-bulb blades (Fig. 24-10). Another advantage of LED bulb-on-blade designs is that they do not require expensive handle-battery systems because of their low energy requirements. This extends the operational and shelf life of the handle-battery pair dramatically, an important feature when stocking laryngoscopes in code carts and other settings.

An alternative illumination system uses light-conducting fibers in the blade with a bulb mounted in the top of the laryngoscope handle. In the United States, these blades have a green dot on the base, and the handles have a green ring on the top. Different types of fiber-lit blades and handles are not interchangeable. Fiber-lit systems depend on a good fit between the base of the blade and the top of the handle. A spring-loaded mechanism depresses the light at the top of the handle, making an electrical connection with the batteries. Problems with the spring may cause erratic performance, and a poor fit can allow light to escape between the bulb source in the handle and the fiberoptic bundle in the blade. The best light-conducting material is glass fiber, and the best designed of the glass fiber–lit blades use large arrays of fiber bundles (Fig. 24-11). There is significant variation in the size and quality of these glass fibers among manufacturers. Glass fiber is relatively expensive, and its light conduction deteriorates over time, depending on sterilization techniques.[25] Fast deterioration in light conduction, erosion of the bond between the glass and blade, and rusting of the blade occurs with lower-quality glass fiber blades.

Figure 24-11 Large, glass-bundle blade (Emerald fiberoptic blade, Rüsch, Duluth, GA). Fiber-lit laryngoscopes use glass or acrylic fiber bundles to conduct light from the handle, along the blade, and to the distal tip.

Figure 24-12 Disposable, fiber-lit blades are available in stainless steel with acrylic stems (SunMed Healthcare, Largo, FL).

Acrylic can be used for light conduction, and although it is not as effective a light conductor as glass, it is inexpensive and easy to integrate onto a laryngoscope blade (Fig. 24-12). Glass fibers must be wrapped in a steel rod and then attached to the blade or threaded through a channel that runs the length of the blade, but an acrylic rod can be easily attached as a separate component. Better acrylic fiber–lit blades enclose part or all of the acrylic rod to minimize light loss (Fig. 24-13). Acrylic fiber–lit blades usually are designed as single-use blades; they are inexpensive to produce, and their light conduction deteriorates significantly with sterilization. The inferior light-conducting performance of acrylic can

Figure 24-13 **A,** Wrapped acrylic rod (Truphatek International Ltd., Netanya, Israel). **B,** Heine XP disposable, fiber-lit blade (Heine Optotechnik, Herrsching, Germany).

Figure 24-14 LED laryngoscope handle (General Electric, Fairfield, CT).

Figure 24-15 Rechargeable handle. (Courtesy of Heine Optotechnik, Herrsching, Germany)

be compensated by super-bright bulbs (LED is best) and powerful handles, but these features necessitate relatively expensive lamps, reflectors, and battery systems (Fig. 24-14).

A major variable in laryngoscope lighting involves the battery source. Standard handles use two C-sized batteries, and most pediatric handles or stubby handles use AA batteries. Several companies offer small handles that use a single, 3-volt, CR123 lithium battery (i.e., camera type). Compared with alkaline batteries, lithium batteries (regardless of size) have a flatter discharge curve, and they slowly diminish in power output over a long time. When lithium batteries start to fade, they die quickly; but during operation, they maintain a much more steady power output. Alkaline battery–powered handles continue to turn on even though light output has diminished dramatically. This phenomenon contributes to delayed battery replacement, because few clinical settings monitor blade and handle pairs using light meters. Many manufacturers offer rechargeable fiber-lit handles using nickel–metal hydride or nickel-cadmium batteries; combined with LED bulbs and special reflectors, these handles create brilliant white light that is far superior to older illumination technology (Fig. 24-15).

C. Direct Laryngoscope Blade Design

Laryngoscope blade design has evolved through trial and error and by sophisticated technical analysis. Macintosh published a series of blade design drawings with which he had experimented; models varied from the curved blade so widely accepted subsequently to entirely straight blades[18,26] (Fig. 24-16). Some investigators have made use of lateral head and neck fluoroscopy and radiography during laryngoscopy to help elucidate relationships of the tongue, hyoid bone, epiglottis, and laryngoscope blade during laryngoscopy.[27,28]

The scientific evaluation of laryngoscope blades has been impeded by the visual restrictions inherent to laryngoscopy; for example, the target is seen monocularly and therefore cannot be simultaneously viewed by two operators.[21] Although a head-mounted direct laryngoscopy video system was invented in 1998 that allowed routine recording of the procedure from the operator's perspective, few studies of laryngoscope blade design have used this objective tool.[29] Most studies have relied on subjectively reported laryngeal view (i.e., visualization of the larynx by the laryngoscopist for a few seconds). The standard reporting system of laryngeal view (i.e., Cormack-Lehane classification) has poor interobserver reliability and is not very sensitive because up to 99% of direct laryngoscopies involve Cormack-Lehane grade 1 or 2 views.[30] This grading system does not allow detection of differences between blade designs without a very large number of patients because of the relative scarcity of grade 3 and 4 views. The combination of restricted visualization, subjective reporting of the view, and lack of a sensitive means of reporting has historically retarded rigorous research on laryngoscopy blade design. As observed by McIntyre in a 1989 review article on blade design, "detailed evaluations of the performance of any particular laryngoscope blade are extremely rare and critical analysis virtually nonexistent." [31]

IV. DIRECT LARYNGOSCOPY BLADES

A. Macintosh and Related Curved Blades

1. Macintosh Laryngoscope Blade

Macintosh's 1943 publication of his curved-blade laryngoscope design defined a new blade and emphasized a

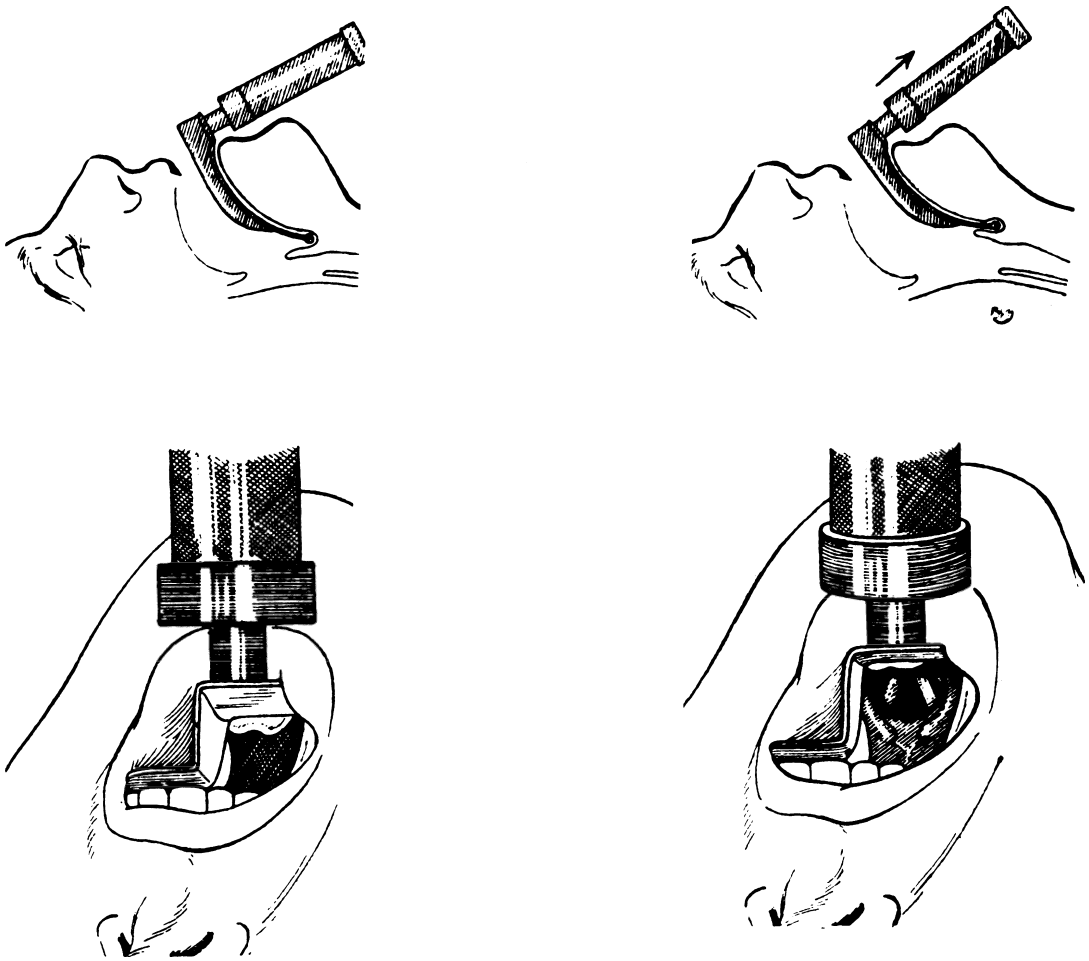

Figure 24-16 The drawings, which appeared in the original Macintosh paper, show the blade tip location and view obtained before *(left)* and after *(right)* lifting the laryngoscope. (From Macintosh RR: A new laryngoscope. *Lancet* 1:205, 1943.)

novel technique of laryngeal exposure for anesthesiologists (i.e., indirect elevation of the epiglottis) (see Figs. 24-8A and 24-16).[18] Although the pioneers of laryngology, including Green and Kirstein, were familiar with indirect elevation of the epiglottis, this technique was not widely appreciated in the new clinical discipline of anesthesiology. Macintosh stumbled into the design by accidentally exposing the larynx indirectly after inserting a Boyle-Davis mouth gag to keep the mouth open and depress the tongue during a tonsillectomy case: "Opening the mouth with the [Boyle-Davis] gag, I found the cords perfectly displayed.… Before the morning had finished, I had Richard Salt [senior technical assistant of his anesthesia department] … [solder] the Davis blade onto a laryngoscope handle, and this functioned quite adequately as a laryngoscope."[32] The Crowe-Davis gag had been in use for several decades (Fig. 24-17); Boyle popularized the use of this mouth gag in England during World War II.[33]

Macintosh's classic article in *The Lancet* described using his shorter, curved blade by placing its tip in the vallecula between the epiglottis and the base of the tongue, with subsequent indirect elevation of the epiglottis.[18] Macintosh contended that he could use the blade at a lighter plane of anesthesia because of the predominant glossopharyngeal nerve innervation of the base of tongue area rather than the superior laryngeal nerve innervation of the dorsal surface of the epiglottis. This was important before the widespread use of neuromuscular blockers. He also mentioned the need to insert the blade to the right of the tongue, with a sweep to the left to displace and control the tongue.[18] In this original communication,

Figure 24-17 Davis blade. (Courtesy of the University of Melbourne Museum Image Archives, Melbourne, Australia.)

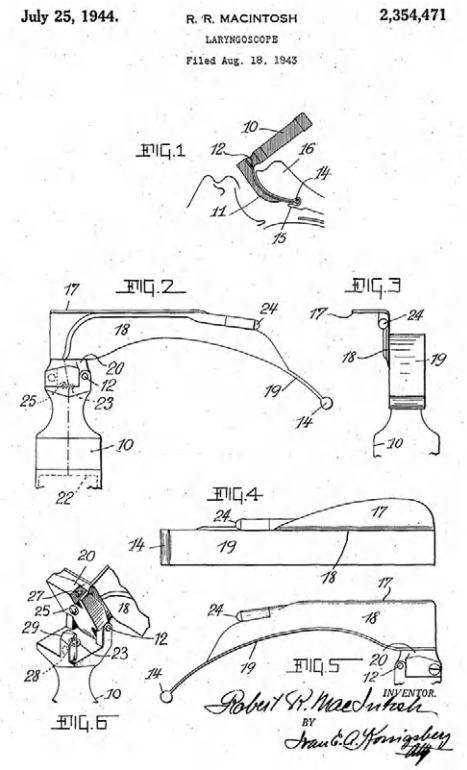

Figure 24-18 Macintosh's patent images for the American version of the Macintosh blade were filed by the Foregger Company (with a misspelled MacIntosh signature).

Macintosh stated and later reiterated that "the precise shape or curve of the blade does not seem to matter much provided that the tip does not go beyond the epiglottis."[18] However, numerous modifications of the Macintosh blade have been reported.

The specific design of the Macintosh blade has a circuitous history. Macintosh, a New Zealander, invented the blade while working in England. Richard Foregger, the son of Richard von Foregger, a manufacturer of early anesthesia devices, was stationed briefly in England during the Second World War. Macintosh gave his new blade to Foregger's son to bring to America, and he also gave blades to two English manufacturers (Medical Industrial Equipment and Longworth Scientific Instruments).[34] Macintosh did not pursue patents or royalties on his design. The U.S. patent application by the Foregger company shows Macintosh's name spelled incorrectly (with a capital I in the middle), and this incorrect spelling persists on many labels[34] (Fig. 24-18). The American and English Macintosh blade designs are descendants of the blades initially produced by the Foregger and Longworth companies, respectively.[34] Macintosh thought that one size would fit all adults, but the blade was initially used in obstetrics cases (i.e., only in women). Eventually, a larger size was devised, which evolved into the modern Macintosh 4, whereas the original design approximates what became the Macintosh 3. Although manufacturers have produced a Macintosh 2 and Macintosh 1, these sizes were not endorsed by Macintosh, and direct laryngoscopy in small children and infants usually is done with straight blades.

Figure 24-19 The English Macintosh blade *(top)* with its more accentuated curve and continued step and flange to distal blade is compared with the standard Macintosh blade *(bottom)*.

2. English Macintosh Blade

The English Macintosh laryngoscope, initially produced by Longworth in the United Kingdom, is continuously curved along the entire spatula, the flange runs to the tip of the blade, and the proximal flange is smaller[34-36] (Fig. 24-19). In contrast, many versions of the American Macintosh are straight in the distal portion, have a distal tip without a flange, and have a very large proximal flange. The bulb on an English Macintosh is closer to the distal tip, increasing illuminance measured at the tip. Although not standardized across all English-labeled Macintosh blades, most English designs use a clear bulb, whereas American Macintosh designs usually come with a frosted bulb. English blades and American Macintosh blades are also offered with fiber-lit illumination systems, which typically use smaller (2- to 3-mm), round bundles.

Asai and colleagues conducted a randomized crossover study of the English blade, comparing it with the standard Macintosh in 300 patients.[35] They found that the view with the English blade was better than the view with the standard blade in 34%, no different in 54%, and worse in 11% of patients. For the 42 patients with a Cormack-Lehane grade of 3 or worse with one blade, the view was rated better with the English blade than the standard blade in 60%, worse in 7%, and no different in 33% of patients.[35] Yardeni and colleagues, in performing an in vitro technical analysis of various blades, concluded that the English Macintosh 4 provided the best results, surpassing those delivered by the American size 4 and English Macintosh 3 blades, even at shallow insertion depths.[36] The flange heights on English Macintosh 4 and 3 blades are similar, but on the American Macintosh, the proximal flange on the 4 is much larger than the 3, and the larger size confers a significant risk of dental injury in some patients.

Levitan advocates the use of a narrow-flange-height Macintosh 4 German or English design on all adult emergency cases; if the full depth of the blade is not required, the flange height with these blades does not cause a problem (its height is the same as a Macintosh 3), but if more blade is needed, the depth can be increased without the need to switch the blade.[37] As stressed originally by Chevalier Jackson, epiglottoscopy must always be performed to find the epiglottis before making any effort to

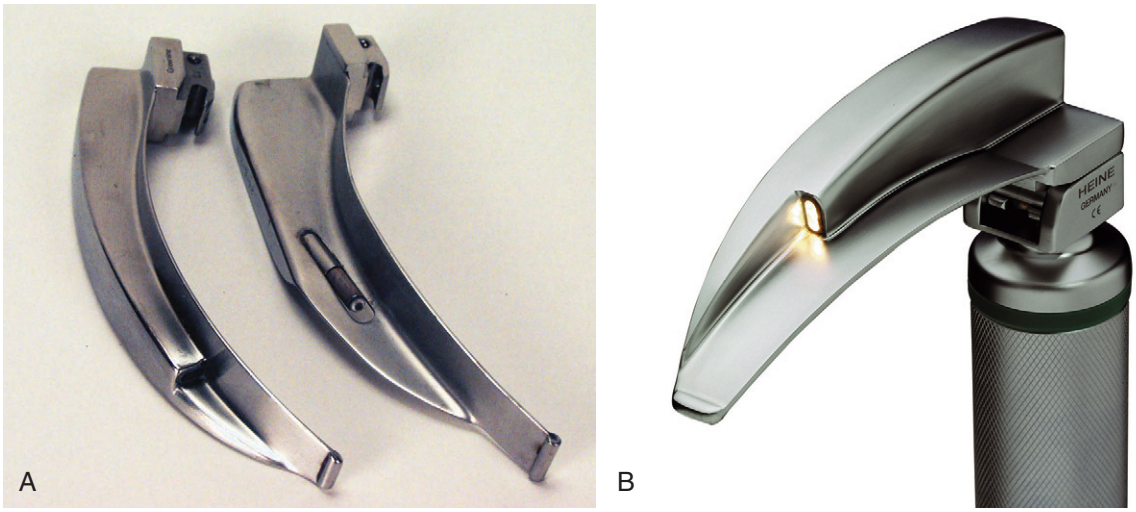

Figure 24-20 German Macintosh (i.e., German design) fiberoptic laryngoscope blades: Rüsch Emerald **(A)** and Heine **(B).**

expose the larynx; otherwise, a large blade can be inserted too deeply and fail to identify landmarks.[38]

3. German Macintosh Blade

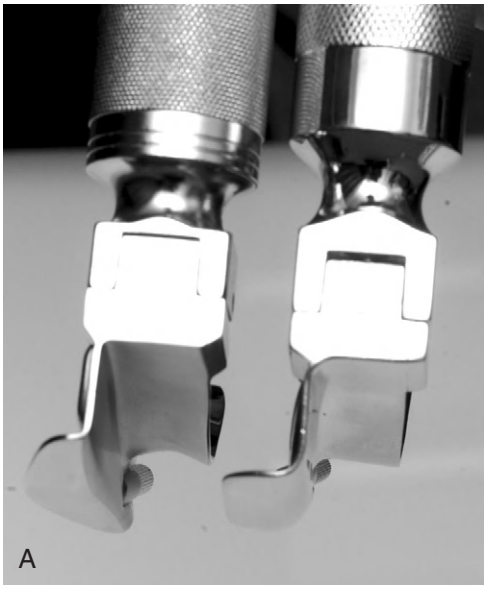
Heine, the German medical instrument company, pioneered incorporation of a rectangular, large (4.3-mm), glass-fiber bundle combined with a small flange height and full-length flange similar to that of an English Macintosh (Fig. 24-20). Like the English Macintosh, it has a small light-to-tip distance. When paired with rechargeable batteries and especially with an LED bulb, this large fiber bundle provides an extremely intense, white light. This design is easy to clean because it has no irregular surfaces. Other manufacturers have copied this design, with some labeling it a *German Macintosh*.

4. Improved-Vision Macintosh Blade

In Macintosh's original 1943 report of his curved-blade laryngoscope, the accompanying photograph of the blade showed a subtle flattening of the curve midblade. This disappeared early in the blade's history, probably because of manufacturing considerations.[32] In 1984, Gabor Racz described a modification in which the midportion of the Macintosh blade spatula was made concave (dorsally) in cross section, and the slight flattening of the midblade was reintroduced while the vertical step and flange were left intact (Fig. 24-21).[39] The combined modifications should help to reduce the crest-of-hill effect whereby the midblade convexity can encroach on the direct line of sight from eye to laryngeal inlet. Racz reported that the blade had been used successfully in several cases in which conventional laryngoscopy had failed.[39] The improved-view Macintosh is commercially available in multiple sizes from several manufacturers.

5. Bowen-Jackson Blade

Recognizing that curved and straight blades had advantages and disadvantages, Ronald Bowen and Ian Jackson attempted to create a blade that could be used in all difficult situations. The resulting blade is almost straight, but it has a fairly marked distal curve (Fig. 24-22). The distal beak of the blade is bifid to allow straddling of the glossoepiglottic fold. The maximum depth of the vertical step is substantially less than that of the Macintosh blade, and it occurs midblade and tapers proximally to allow its use in patients with limited mouth opening or prominent teeth. When attached to the handle, the blade forms an angle of 100 degrees to help avoid contact with the chest.[40]



6. Left-Handed Laryngoscope

A mirror-image version of the Macintosh blade exists for use with the right hand. Inappropriately referred to as the left-handed laryngoscope, it is identical to the regular Macintosh blade except for the reversed configuration of the flange. Potential uses include laryngoscopy of patients in the right lateral decubitus position, procedures in those with right-sided facial or oropharyngeal abnormalities, and procedures in which the endotracheal tube (ETT) should be located on the left side of the mouth.[41,42]

7. Curved Blades with Exaggerated Distal Curvature

Several blades have been described with a more acute curvature of the distal spatula than that of the Macintosh. Of historical interest, the Gubuya-Orkin blade, described in 1959, was unique in having an S-shaped blade with a malleable distal 3 cm. The investigators described bending it through a range of 15 to 45 degrees, with an optimal position thought to be 35 degrees from the horizontal for indirect lifting of the epiglottis (Fig. 24-23).[43] Found to be effective in some cases in which Macintosh laryngoscopy had failed, the Gubuya-Orkin blade can be considered a forerunner of other blades with marked fixed or variable distal curvature.

Unlike the Macintosh blade, the Blechman blade has an accentuated curve at its distal tip. Its reverse-Z vertical step and flange begin distal to the block of the blade and extend only to within 5 cm of the blade tip. The curved Fink laryngoscope blade similarly has a sharper curve at the distal spatula and reduced vertical step proximally compared with the Macintosh. The ULX Macintosh

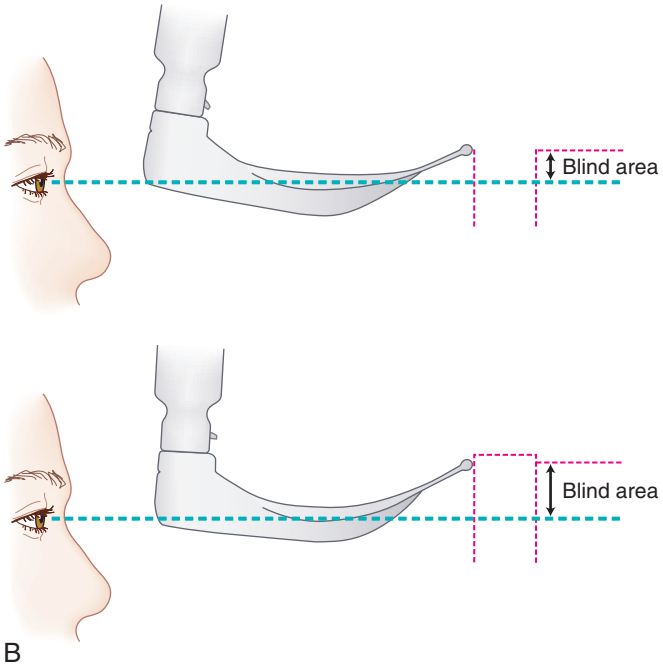


Figure 24-21 **A,** Cross section of the Improved Vision version of the Macintosh blade *(left)* compared with the standard blade *(right)*. Notice the concave, downward cross section of the midblade, potentially reducing the crest-of-hill obstruction to visualization that occurs with the standard Macintosh. **B,** The line of vision is improved and the blind area reduced by the redesigned blade *(top)* compared with the regular Macintosh blade *(bottom)*. (From Racz GB: Improved vision modification of the Macintosh laryngoscope (letter). *Anaesthesia* 39:1249–1250, 1984.)

(Upsher Laryngoscopy Systems, Mercury Medical, Clearwater, FL) blade has a more pronounced curve throughout the entire blade length than the standard Macintosh. The Wiemers or Freiburg blade, marketed in Europe, has less initial curvature than a Macintosh and has an acutely curved tip (Fig. 24-24).[44] As a group, these blades may have utility in patients with limitations of mouth opening, impaired head and neck mobility, or prominent upper incisors, in whom the tip of a Macintosh blade may fail

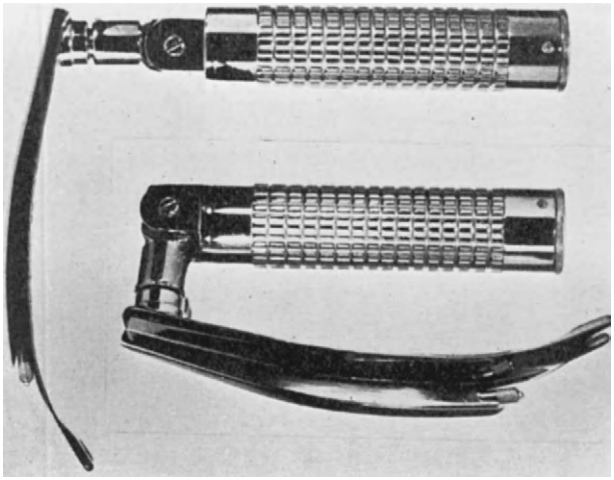

Figure 24-22 The Bowen-Jackson laryngoscope blade. (From Bowen RA, Jackson I: A new laryngoscope. *Anaesthesia* 7:254–256, 1952.)

to engage the glossoepiglottic fold at the appropriate angle. More specific indications for these blades await scientific evaluation.

B. Miller and Related Straight Blades

1. Miller Laryngoscope Blade

The use of straight blades, with entrapment and direct lifting of the epiglottis, was the common laryngoscopic technique when Miller introduced his modification of the straight laryngoscope blade in 1941. The blade he described was longer than the medium-sized blades available at the time, had a comparatively smaller flange height, was narrower at the tip, and featured a gradual curve starting 2 inches (5 cm) from the distal end (Fig. 24-25).[17] Miller contended that the smaller flange height would allow less mouth opening (permitting freer anterior movement of the mandible) and less potential for damage to the teeth. Although Miller's original design could accept a 38-F tube down the barrel, the flange height of modern Miller blades has become substantially smaller, and an adult-sized tracheal tube cannot fit down a Miller size 3 blade. Miller warned that the lumen should not be used for this purpose in his original description of the design.[17] With a smaller degree of mouth opening, Miller conceded that available room for tube manipulation would be less and that a stylet would be desirable.[17] In 1942, Cassels echoed Miller's contention that a greater distal curvature of the straight blade would facilitate exposure of the laryngeal inlet, accompanying his report with an elegant diagram to help illustrate his theory.[45] For a given position of the base of a straight blade between the teeth, especially when the mouth opening is limited, a curved distal tip can enable the laryngoscopist to visualize a more anterior aspect of the laryngeal inlet (Fig. 24-26). The Miller laryngoscope blade continues to be a commonly used straight blade.

2. Magill, Flagg, and Guedel Blades

Three older straight blades that warrant mention are the Magill, Flagg, and Guedel blades, which all predate the

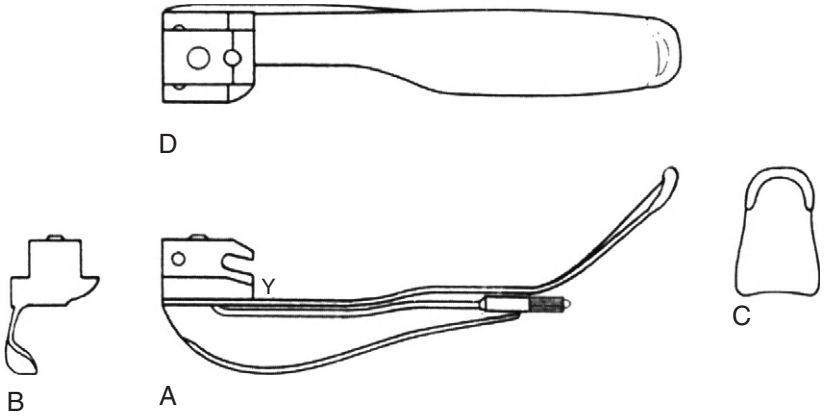

Figure 24-23 Schematic of the Gubuya-Orkin blade: side view **(A),** fitting view **(B),** end view of the tip section **(C),** and top view **(D).** (From Gabuya R, Orkin LR: Design and utility of a new curved laryngoscope blade. *Anesth Analg* 38:364–369, 1959.)

Miller. Miller developed his lower-profile, smaller-flanged straight blade partly in response to the perceived shortcomings of these relatively larger blades. Nonetheless, all three blades continue to be marketed in adult and pediatric sizes, attesting to their ongoing popularity.

The Magill blade, first marketed in 1921, is mainly straight, with a U-shaped step and flange concave to the right. The step and flange continue to within an inch of the end of the blade. The Flagg blade is straight with a very slight curve at the distal tip and was originally designed for use with Flagg catheters and tubes. With a light source placed quite distally, the C-shaped cross section tapers gradually from its proximal to distal end (Fig. 24-27).[46] The Guedel has an extremely large spatula and U-shape flange that is concave to the right. Its distal tip has slightly more curve than the Flagg, and the blade is angled on its base to result in a 72-degree angle with the handle to help promote a lifting action instead of using the teeth as a fulcrum.

3. Soper Blade

The straight Soper blade originally was described in 1947. When he was Wing Commander in the Royal Air Force Medical Division, Robert Soper developed the blade in response to the Macintosh's occasional failure to elevate a long, "flabby" epiglottis.[47] Although described as a modification of the Macintosh blade, it is largely straight except for a slight distal curvature. It retains the reverse-Z-shaped vertical step and flange of the Macintosh blade. A small, transverse slot cut into the blade a few millimeters from the tip is designed to help prevent the epiglottis from slipping off the blade (Fig. 24-28). The Soper blade is still commercially available in adult and pediatric lengths.

Figure 24-24 The Wiemers blade has a reduced initial curvature and sharply curved tip. (From Maleck WH, Koetter KP, Lentz M, et al: A randomized comparison of three laryngoscopes with the Macintosh. *Resuscitation* 42:241–245, 1999.)

Figure 24-25 Original Miller blades. The original Miller design had a light on the right side of the flange when looking down the blade *(far right)*. Poorly designed Miller blades *(far left)* have the light on the leading edge of the left flange. The light embeds in the tongue and produces inadequate illumination.

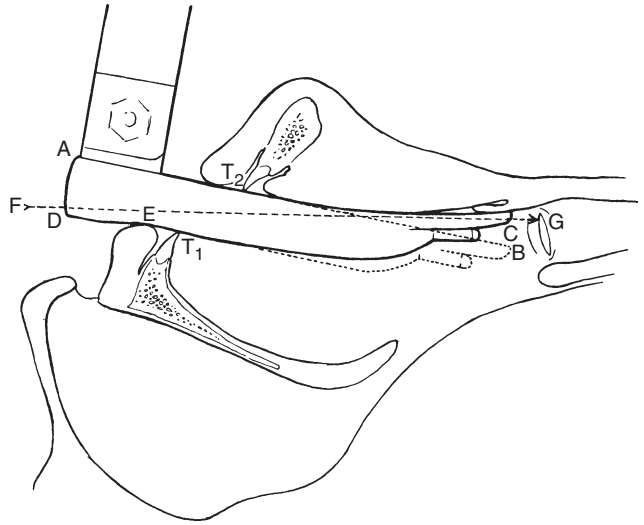

Figure 24-26 Cassels' 1942 diagram shows the advantages of a distal curve to an otherwise straight blade. With a compromised interincisor opening (T_1 to T_2), the limited upward angulation of a straight blade (*A* to *B*) may afford a view of only the posterior laryngeal inlet. Curving the distal blade (*A* to *C*) permits a more anterior view from point D looking along the line from *F* to *G*. (From Cassels WH: Advantages of a curved laryngoscope. *Anesthesiology* 3:580–581, 1942.)

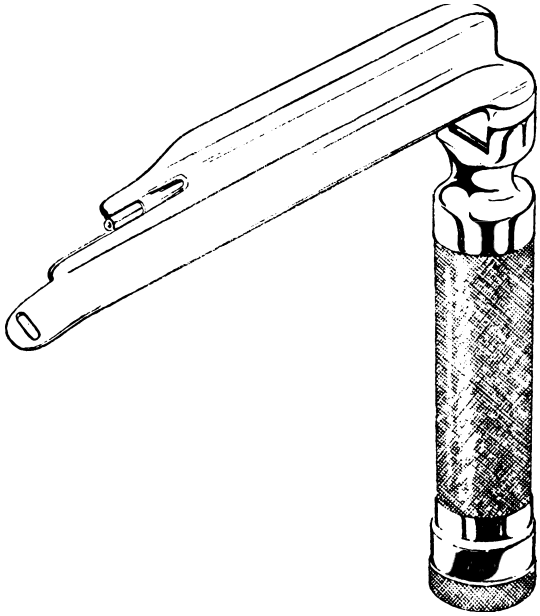

Figure 24-28 The Soper laryngoscope. (From Soper RL: A new laryngoscope for anaesthetists. *Br Med J* 1:265, 1947.)

Figure 24-27 The Flagg blade.

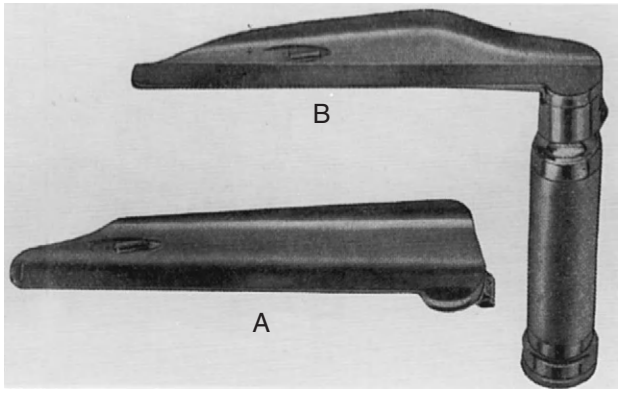

Figure 24-29 The Gould blade **(B)** is slightly longer, with a flattened vertical step proximally compared with the parent Soper blade **(A).** (From Gould RB: Modified laryngoscope blade. *Anaesthesia* 9:125, 1954.)

4. Gould Blade

Gould, in 1954, modified a Soper blade by (1) lining the flange with rubber and reducing the proximal vertical step and (2) lengthening and blunting the distal end of the blade (Fig. 24-29). He made a similar modification to a Macintosh blade, although neither version attained widespread use.[48]

5. Wisconsin Blades

The Wisconsin blade is a large, straight blade with a circular flange. The original design had a slightly flared distal flange. The Whitehead modifications—the Wis-Foregger and Wis-Hipple blades—are variations of the original Wisconsin design with slightly modified flanges, bulb locations, and spatulas (Fig. 24-30).[46]

6. Snow Blade

In 1962, Snow recognized the advantages of a straight blade in certain difficult situations, but finding difficulty with epiglottic entrapment with the Wis-Foregger and problematic ETT passage with the Miller, he modified a straight blade by slightly curving the distal tip beginning

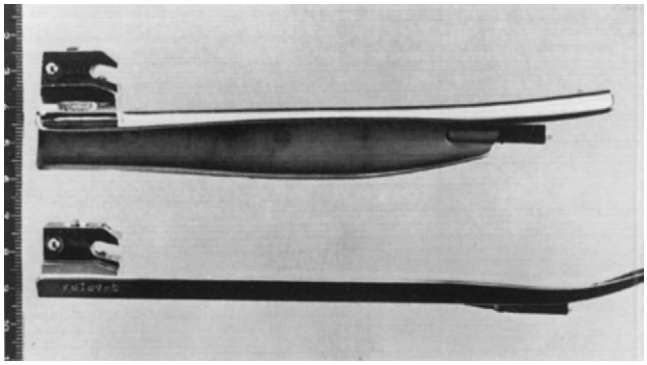

Figure 24-30 The Schapira blade *(bottom)* with minimal vertical component is compared with the Wis-Foregger blade *(top)*. (From Schapira M: A modified straight laryngoscope blade designed to facilitate endotracheal intubation. *Anesth Analg* 52:553–554, 1973.)

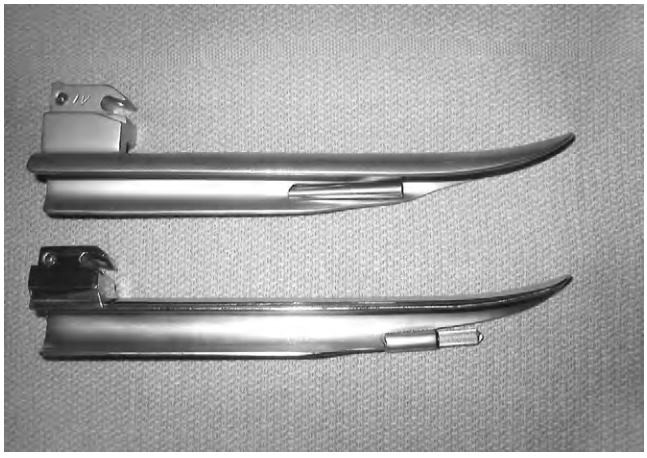

Figure 24-32 Two versions of the straight Phillips blade with a light tip that is protected *(top)* behind the vertical step and unprotected *(bottom)*.

1 inch (2.5 cm) from its semirounded beak. He also increased the vertical step and flange combination to create a C-shaped groove that was concave to the right, which allowed a better view and easier tube passage (Fig. 24-31).[49]

7. Phillips Blade

Otto Phillips developed a blade similar to the Snow blade. In 1973, Phillips described it as a combination of the shaft of the Jackson blade and curved tip of the Miller blade. He thought that the Jackson shaft offered a good conduit for ETT passage and reasoned that the curved tip of the Miller would help to lift the hyoid bone and attached structures, affording good visualization of the glottis.[50] The light bulb is located on the left side of the blade, and in some versions of the blade, it may be unprotected from the tongue, although other versions use a fiberoptic carrier shielded by the vertical step (Fig. 24-32). The C-shaped vertical step and flange are less complete than a Wisconsin arc, are concave to the right, and extend to within 5 cm of the end of the blade. Phillips conducted an observational study of the use of the blade in the hands of experienced and inexperienced users in more than 1000 patients and found that successful intubation was achieved on the first attempt with the Phillips blade in 84% of cases.[50] The Phillips blade is produced in size 1 for pediatric patients and size 2 for adult patients. It is available commercially and has relatively widespread use.

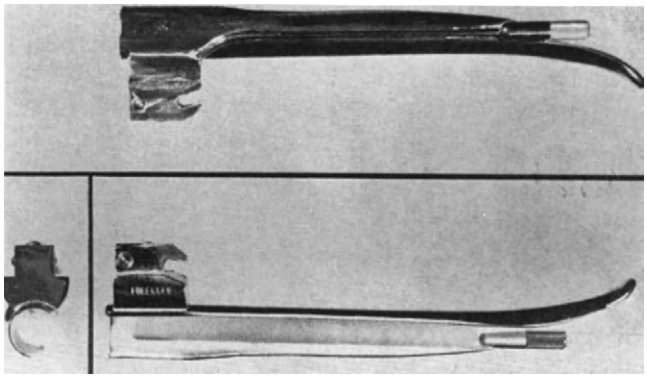

Figure 24-31 The Snow blade predates and is similar to the Phillips blade (see Fig. 24-32), with distal curve and C-shaped channel for endotracheal tube delivery. (From Snow JC: Modification of laryngoscope blade. *Anesthesiology* 23:294, 1962.)

8. Schapira Blade

Max Schapira described a blade that is straight with a slight distal anterior curvature but with a minimal vertical component and no horizontal flange (see Fig. 24-30).[51] The blade remains available commercially.

9. Henderson Laryngoscope

The Henderson laryngoscope blade (Karl Storz, Tuttlingen, Germany) is a modification of the straight blade. It was introduced by John Henderson of Glasgow, an enthusiastic proponent of straight-blade laryngoscopy in anesthesia practice.[52,53] The Henderson blade is straight over its entire length and has a semicircular vertical step and flange, resulting in a wide slot that permits easy ETT entry, passage, and exit. The step, flange, and light carrier continue to within 2.5 cm of the blade tip, which with the straight blade is designed to maximize light delivery. The fiberoptic light carrier is shielded from the tongue within the lumen of the blade (Fig. 24-33). The distal tip of the blade has a rounded, knurled edge, which can be seen when viewing down the barrel. Having a visible distal tip makes it easy to determine whether the blade has been advanced far enough to lift the epiglottis; when using a Miller blade or others with a distal upturned tip, repeated rounds of advancing and lifting are often required until the epiglottis is controlled.

The Henderson blade is available in small and large sizes. The 148- and 192-cm-long blades have lumens sufficiently large to accommodate passage of ETTs with 7- and 8-mm inner diameters (IDs), respectively. Henderson evaluated the blade in 300 patients and reported easy positioning of the blade in 91%, a grade 1 view in 93%, and successful direct ETT passage on the first attempt in 97% of patients.[53] He published a case series

Figure 24-33 The Henderson blade features a completely straight spatula, protected light source, semicircular channel, and Macintosh-type beak. (Courtesy of John Henderson, MD, Glassow, UK.)

documenting successful glottic exposure and intubation using paraglossal straight blade laryngoscopy in situations in which the Macintosh blade had failed.[52]

10. Dörges Universal Blade

The Dörges universal laryngoscope blade has been described as an effort to create a single blade with utility in many situations.[54] The blade is mainly straight with a slightly curved distal end, enabling its use by direct or indirect elevation of the epiglottis. It tapers gradually from the heel to 11 mm at its tip, corresponding to the width of a Macintosh 2 blade tip. The working length of 125 mm, however, is between those of Macintosh 3 and 4 blades. The angle of the blade tip with the handle is 76 degrees, as opposed to the usual 58 degrees of the Macintosh blade, potentially facilitating blade insertion into patients with a prominent sternal area. Similarly, the lower profile, 15-mm, reverse-Z-shaped vertical step and flange may facilitate the blade's insertion in patients with limited mouth opening. Two marks corresponding to a patient weight of 10 or 20 kg on the front and rear of the blade serve as a rough guide for insertion depth when using the blade in a pediatric patient (Fig. 24-34).

11. Grandview Blade

The Grandview laryngoscope blade (Hartwell Medical, Carlsbad, CA) was designed by a paramedic in the United States, and it has achieved widespread use in U.S. Emergency Medical Systems.[55] It has a curvature somewhat similar to that of a Dörges blade, in that it is mostly straight but has a slightly bent distal tip. Its primary unique feature is its massive proximal spatula, and it is advertised as "the tongue tamer" (Fig. 24-35). Another feature of the Grandview is its use of a super-bright LED bulb. It comes in two sizes and in a reusable or single-use version. Its reusable version has a gold-colored tip to make tip visualization easier. There are no published clinical case series validating the Grandview blade as superior to a conventional Macintosh, although anecdotally, the manufacturer has received very positive feedback, and it has been successful commercially. Inadequate tongue control is a frequent error among novice intubators, and the larger spatula blade may be valued by those who intubate less frequently. Conversely, a larger blade volume may make it harder to reach the larynx in patients with a small displacement space (i.e., thyromental distance) and a large tongue-to-pharynx ratio.

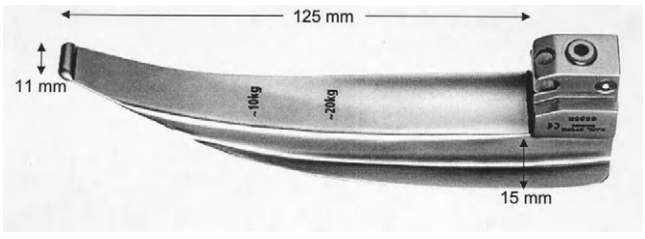

Figure 24-34 The Dörges universal laryngoscope blade has markings that indicate appropriate insertion depths for pediatric use. (From Gerlach K, Wenzel V, von Knobelsdorff G, et al: A new universal laryngoscope blade: A preliminary comparison with Macintosh laryngoscope blades. *Resuscitation* 57:63–67, 2003.)

C. Blades with Fixed and Various Degrees of Acute Angulation

1. Belscope

a. DESCRIPTION

The Bellhouse laryngoscope, or Belscope, is a straight blade bent 45 degrees at its midpoint.[56] The blade comes off the handle at a slightly offset angle and has a vertical step less than that of a Macintosh blade and no horizontal flange (Fig. 24-36). The Belscope is available in three lengths from tip to angle: 6.7, 8, and 9.3 cm. Because the blade typically is used to elevate the epiglottis directly, less compression and anterior displacement of the tongue may be needed to obtain a view of the larynx. The

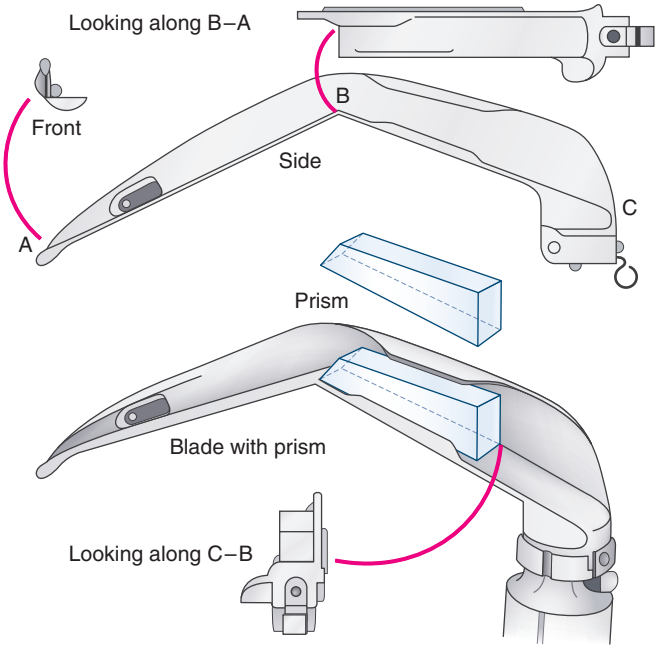

Figure 24-36 The Belscope angulated laryngoscope. The view *(top)* obtained from the blade angle along the distal blade *(line B-A)* is shown. Failing this, indirect visualization is possible with a prism *(line C-B)*. (From Bellhouse CP: An angulated laryngoscope for routine and difficult tracheal intubation. *Anesthesiology* 69:126–129, 1988.)

Belscope may be useful when poor atlanto-occipital extension, a large tongue, or a short mandible hinder optimal positioning of a Macintosh laryngoscope blade. If visualization remains suboptimal with the Belscope, a prism can be attached proximal to the angulation to provide an indirect view of the glottic opening.

b. BLADE USE

Without the prism, the Belscope can be used in a fashion similar to a straight blade. Displacing the tongue to the left, the blade may be inserted into the proximal esophagus and then withdrawn to expose the laryngeal inlet. Retraction of the upper lip may be advantageous. Because of the blade's 45-degree angulation, there may be less chance of the proximal blade applying pressure to the upper teeth. In the event that the larynx is not primarily visualized with the blade, use of the prism (suitably defogged) rotates the image of the larynx by 34 degrees (Fig. 24-37). Often, a styleted tracheal tube curved anteriorly is necessary for advancement through the glottis.[56]

c. CLINICAL EXPERIENCE

Bellhouse reported his experience of 3500 intubations in which he used the Belscope without failure.[56] The report included a subseries of 12 patients in whom the Belscope successfully exposed the glottis after the Macintosh had failed. Bellhouse emphasized the need for practice in the use of the blade because its feel was different from that of other blades.[56] Separately, Mayall reported a second series of 12 patients with Cormack-Lehane grade 3 laryngoscopies with the Macintosh blade, all of whom were converted to a "good view of the cords" with the Belscope without use of the prism.[57] In a crossover study by Sultana and colleagues comparing Macintosh and Belscope laryngoscopy, of 22 grade 3 views obtained, 19 were with the Macintosh blade. Tube passage using the Belscope required lip retraction by an assistant more frequently than with the Macintosh.[58]

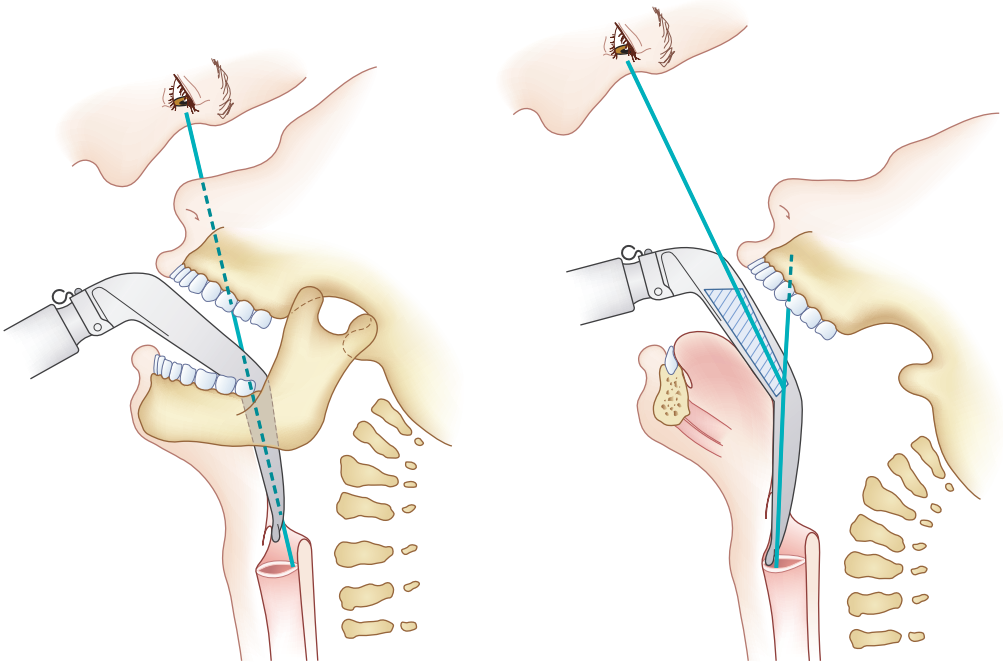

Figure 24-37 When using the Belscope by the right paraglossal route *(left)*, the view is assisted by retraction of the lip. Occasionally, use of the prism may be required for indirect visualization of the larynx *(right)*. (From Bellhouse CP: An angulated laryngoscope for routine and difficult tracheal intubation. *Anesthesiology* 69:126–129, 1988.)

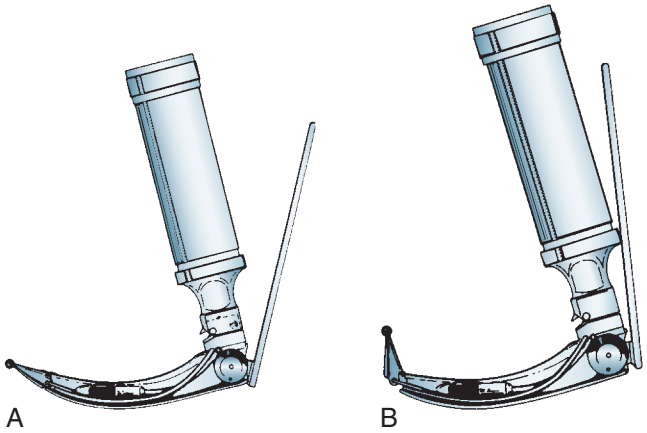

Figure 24-40 The Corazzelli-London-McCoy blade in the default position **(A)** and activated with the tip elevated **(B).** (From McCoy EP, Mirakhur RK: The levering laryngoscope. *Anaesthesia* 48:516–519, 1993.)

2. Choi Double-Angle Laryngoscope

In 1990, Choi described a double-angled blade with the spatula incorporating two incremental angles—the proximal (20 degrees) and the distal (30 degrees) (Fig. 24-38).[59] The spatula and beak are wide and flat for tongue or epiglottis control, and there is no vertical step or flange. The light source lies along the left edge of the blade between the two angles, with the bulb pointing toward the center of the glottis. The blade can be used with direct or indirect lifting of the epiglottis. It is commercially available in one adult and one pediatric size.[59]

3. Orr Laryngoscope

The Orr blade was developed to help eliminate contact with the upper teeth. Two right-angle bends (Fig. 24-39) are designed to enable the blade to sit down inside the mouth, shifting the fulcrum into the pharynx and away from the teeth. It typically is used to elevate the epiglottis directly, and the ETT is advanced from the right side of the mouth. Rarely used now, the Orr blade was available in two lengths.[60]

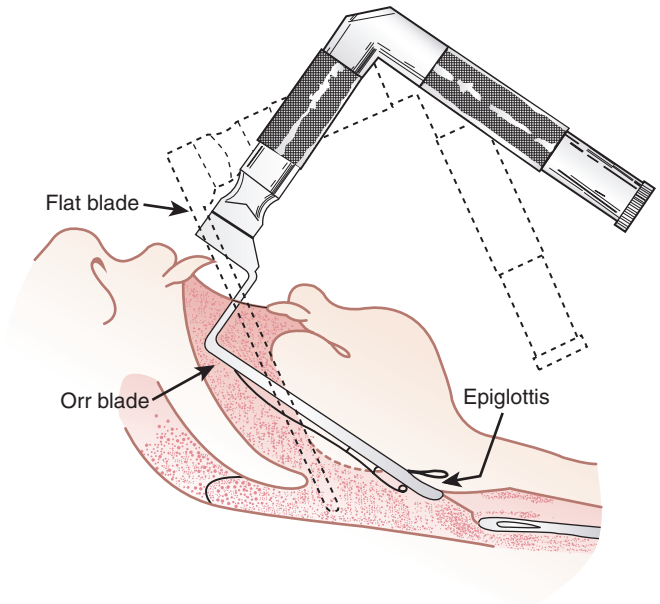

Figure 24-39 The Orr laryngoscope blade. (From Orr RB: A new laryngoscopy blade designed to facilitate difficult endotracheal intubation. *Anesthesiology* 31:377–378, 1969.)

4. Levering Tip Laryngoscope

a. DESCRIPTION

The levering tip or articulating laryngoscope (Corazzelli-London-McCoy [CLM] blade, Mercury Medical, Clearwater, FL) is a modification of standard curved (and straight) laryngoscope blades. A curved blade first described in 1993 is marketed by several manufacturers (e.g., the Flipper, Rüsch, Duluth, GA; Heine Flex Tip, Heine Optotechnik, Herrsching, Germany). These laryngoscope blades have a hinged distal tip activated by a lever that lies adjacent to the handle of the laryngoscope. Depressing the lever toward the handle elevates the tip, located 25 mm from the end of the blade, by approximately 70 degrees (Fig. 24-40).[61] The lever acts on the tip through a spring-loaded drum on the proximal end of the blade, which pushes a shaft linking with the distal hinge. In the resting position, the blade looks and acts like a standard blade, with the vertical step of the distal adjustable tip locking with that of the rest of the blade. The blade-lever assembly can be used with any compatible standard handle. When activated, the levering tip laryngoscope may have the advantage of having a fulcrum at a point lower in the pharynx, helping to provide an optimal tip angle and contact with the hyoepiglottic ligament in situations such as limited mouth opening, a large tongue, or prominent or overriding upper teeth.

b. BLADE USE

The curved levering tip blade is most often used by placing the tip in the vallecula, although the tip can be placed beneath the epiglottis. If glottic visualization is poor, the lever can be depressed, activating the distal tip upward. This may help the blade tip make contact with the hyoepiglottic ligament, helping to lift the epiglottis and improve glottic visualization. Endotracheal intubation is then performed in a standard fashion. The lever is

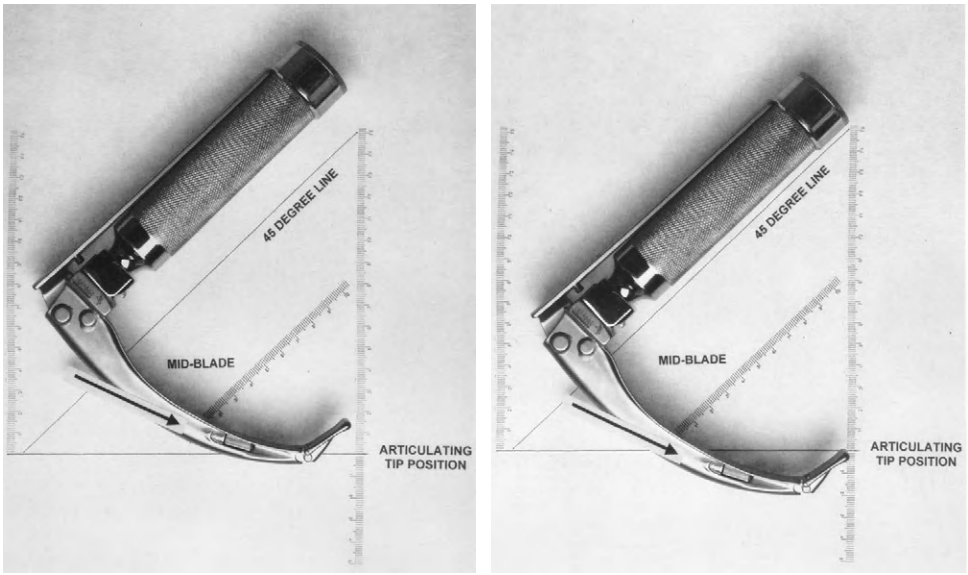

Figure 24-41 When the Corazzelli-London-McCoy blade improves the view *(left)*, the tip elevates the base of the tongue and the vallecula. However, if these structures are already maximally elevated, tip activation forces the blade posteriorly into the line of sight *(right)*, possibly worsening the view. (From Levitan RM, Ochroch EA: Explaining the variable effect on laryngeal view obtained with the McCoy laryngoscope (letter). *Anaesthesia* 54:599–601, 1999.)

released, and the blade is removed with the tip in the neutral position.

c. CLINICAL EXPERIENCE

Since the introduction of the CLM, several case reports have attested to its value in difficult situations.[62-69] Subsequent prospective series have confirmed the CLM's utility in some difficult situations and confirmed clinical suspicions that its use in otherwise easy situations may worsen the view. Studies have been consistent in their findings that without cervical spine precautions, improvement with the use of blade tip activation from Cormack-Lehane grade 3 views to grade 2 or better is significant, occurring in 44% to 91% of cases.[44,62-69] In most studies, the CLM blade has failed to meaningfully improve Cormack-Lehane grade 4 views.

The levering tip blade is less useful in otherwise easy laryngoscopies. Although one report documented a 66% improvement in 38 patients (arytenoids only) with Cormack-Lehane grade 2 laryngoscopic views, the same report revealed a 22% overall incidence of a worsening view obtained with tip activation, all in patients with Cormack-Lehane grades 1 and 2.[69] In easy laryngoscopic situations, the blade tip easily engages and can lift the hyoepiglottic ligament and hyoid bone at the appropriate angle. With no potential for further upward travel, blade tip activation instead forces the midportion of the blade downward and into the direct line of sight, potentially obscuring the view (Fig. 24-41).[70] The better the view before tip activation, the more likely this phenomenon appears to be.

Several studies have documented that the improvement in laryngoscopic view obtained with tip activation of the CLM is less than that obtained by external laryngeal pressure,[67,68,70] although application of external laryngeal pressure and tip activation has an additive effect.[67] McCoy and colleagues found that the force incurred when using the levering tip blade was significantly less than that needed to visualize the larynx with the Macintosh blade.[62] There was no increase in heart rate, mean arterial pressure, or plasma norepinephrine levels with use of the levering tip blade,[62] possibly because there was less need to provide forward displacement of attached structures while elevating the epiglottis.

The CLM blade may be useful in patients requiring cervical spine precautions. In three studies simulating cervical spine precautions with use of manual in-line stabilization or application of a cervical collar, activation of the levering tip improved the Cormack-Lehane laryngeal view by at least one grade in 45% to 74% of patients, and in the patients with a grade 3 view, conversion to a grade 2 or better view occurred in 83% to 92% of cases.[71-73] In the 319 patients enrolled in these three studies, the view was worsened by use of the activated CLM blade in only one case. A separate study looking at head extension using external anatomic markers during CLM laryngoscopy demonstrated that 6 to 8 degrees less head extension was necessary for arytenoid-only and full-glottic exposure compared with Macintosh blade use.[74] MacIntyre and colleagues, using lateral radiographs to look at cervical spine movement with Macintosh and CLM blade use, could not demonstrate a significant difference in the degree of extension occurring between C0 and C3.[75] In a cadaver series with surgically induced lesions at C5-C6, Miller, Macintosh, and McCoy blade laryngoscopy use was assessed fluoroscopically. The Miller was superior to the Macintosh or the CLM blade at minimizing axial distraction, but no significant difference in anteroposterior displacement or angular rotation at the level of the lesion was demonstrated between blades.[76]

The CLM has been well studied since its introduction and appears to be useful in some difficult situations while not helping or worsening the view in easy cases of direct laryngoscopy. Published evidence suggests that it may be

particularly useful when Cormack-Lehane grade 3 views have been induced by cervical spine precautions.

5. Flexiblade

a. DESCRIPTION

The Flexiblade (Arco Medic, Omer, Israel) incorporates a flexible component into a rigid blade. This direct laryngoscope is flexible in the intermediate portion of the blade. Activation of the trigger, which, unlike that in the CLM, lies along the front of the handle, results in variable flexion of six intermediate segments located 3.5 to 10 cm from the blade's tip. This adjusts the blade's curvature through a 20-degree arc, going from a shape similar to that of a Miller blade to that of a Macintosh blade (Fig. 24-42).[77] The Flexiblade can be attached to a standard laryngoscope handle or a remote light source by a fiberoptic cable. It is available in three sizes that correspond roughly to Macintosh 2, 3, and 4 blades.

b. MODIFIED HANDLES

Use of the Flexiblade is similar to the technique used with the CLM blade. With the tip of the blade located in the vallecula, activation of the trigger increases the amount of blade flexion, which may help with glottic visualization. ETT passage follows in the usual fashion.

c. ADAPTERS

Perera and coworkers evaluated the Flexiblade in 200 patients.[78] In patients with an initial Cormack-Lehane grade 3 view with the Flexiblade in the neutral position, blade activation converted the view to grade 2 or 1 in 84% of cases. In this series, blade activation worsened the view in only four patients, and as with the CLM blade, all of those patients had grade 1 or 2 views before blade flexion. Yardeni and colleagues[77] performed an in vitro technical analysis of the blade after the technique described by Marks and associates[28] and confirmed that the Flexiblade behaves in fashion similar to that of a Miller or Macintosh blade in the neutral and fully elevated positions, respectively.[78]

Figure 24-42 The Flexiblade has a flexible blade that can assume many positions. (Courtesy of Arco Medic, Omer, Israel.)

D. Blades Designed for Other Anatomic Variants

1. Blades with Reduced Vertical Step

Several blades have been designed with a reduced vertical step. In theory, this should help with blade insertion in patients with limited mouth opening and pose a lower risk to the upper teeth. The risk is increased if the laryngoscopist levers on the teeth, but studies have demonstrated that the horizontal flanges of well-used Macintosh blades show significant signs of wear at the level of the upper teeth, suggesting frequent contact with the blade, and other studies have demonstrated that even experienced clinicians generate significant axial force on the upper incisors.[79,80] Although these findings may suggest that one of the functions of the vertical step is to maintain mouth opening through contact with the upper teeth, most clinicians prefer to minimize contact with the upper teeth. To address the issue of step or flange contact with the upper teeth, several modifications to blades have been made.

a. BIZZARRI-GIUFFRIDA BLADE

The Bizzarri-Giuffrida blade was developed in response to the problem of the Macintosh blade's vertical step and flange proximally touching the upper teeth, causing difficulty in rotation of the blade into the hypopharynx and full insertion into the valleculae, particularly in patients with limited mandibular mobility. The blade is curved in fashion similar to that of the Macintosh blade and omits the vertical step, with the exception of a minimal amount at midblade, where it is needed to protect the light carrier (Fig. 24-43). The experience of several hundred patients was "complete satisfaction," particularly by those with buckteeth, a receding jaw, bull neck, or an anterior larynx. The investigators reported successful use of the blade during awake direct laryngoscopy.[81]

b. CALLANDER-THOMAS BLADE

In 1987, Callander and Thomas described a blade incorporating a reduction in the proximal portion of the vertical step and flange of the Macintosh blade (Fig. 24-44).[82] The reduction in the step height was postulated to improve the blade's utility in patients with limited mouth opening and to decrease the risk of dental damage.[82]

c. BUCX BLADE

A modification similar to the Callander-Thomas blade was made by Bucx and colleagues after technical analysis suggested it to be a good model.[83] This blade had a Macintosh-style curve and had the vertical step and flange reduced to a minimum from blade base to 8 cm

Figure 24-43 The Bizzarri blade has an almost no vertical step.

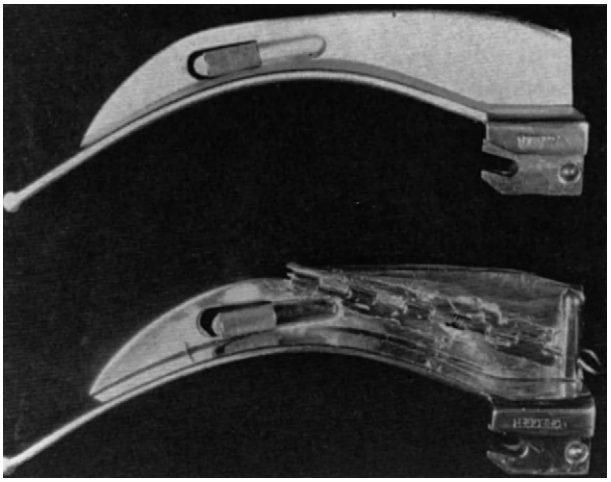

Figure 24-45 The Onkst blade *(bottom)* has a hinged vertical component compared with the standard Macintosh blade *(top)*. (From Onkst R: Modified laryngoscope blade. *Anesthesiology* 22:846, 1961.)

from the blade tip. Bucx and coworkers clinically evaluated the blade, randomly assigning 46 patients to two groups for laryngoscopy and intubation with a regular Macintosh or the modified blade.[84] Although the mean force exerted on the maxillary incisors was significantly reduced in the modified-blade group, there was a decided tendency toward anteflexion of the head during laryngoscopy with the modified blade and an increased need for the assistant to retract the upper lip to aid with intubation. Although the accepted purpose of the vertical step of laryngoscope blades is control of soft tissue, especially the tongue, this study suggests the possibility that the vertical step and flange at the level of the upper teeth may help to maintain mouth opening and counteract the tendency of the head to anteflex during laryngoscopy.

d. ONKST BLADE

In 1961, Onkst modified a Macintosh 3 blade to help avoid undue pressure on the upper incisors. The proximal portions of the blade's vertical step and flange are hinged and, although normally kept in the upright position by a weak spring, allow the vertical step and flange to fold down in response to pressure on the teeth, theoretically avoiding dental damage (Fig. 24-45).[85]

e. RACZ-ALLEN HINGED-STEP BLADE

The Racz-Allen blade has a hinged step and flange.[86] The vertical step of this modified straight blade is maintained in position by a spring. During laryngoscopy, any pressure on the vertical step from the upper teeth causes an upward and lateral deflection of the hinged portion. The main blade is convex in cross section to a greater extent than the Miller blade to help maintain vision when the concave, hinged portion is displaced. A threaded shaft is removable, allowing disassembly of the two portions of the blade for cleaning (Fig. 24-46).[86] The blade length is intermediate between a Miller 2 and 3. Racz and Allen reported more than 2000 successful intubations at their institution with the blade.[86]

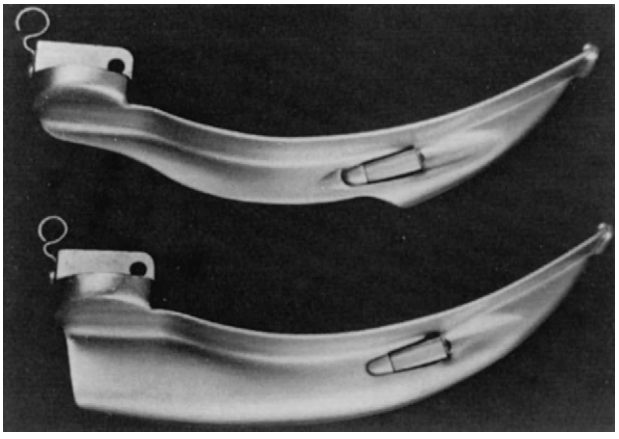

Figure 24-44 The Callander-Thomas blade *(top)* has a reduced vertical step proximally compared with the Macintosh blade *(bottom)*. (From Callander CC, Thomas J: Modification of Macintosh laryngoscope for difficult intubation (letter). *Anaesthesia* 42:671, 1987.)

Figure 24-47 The Polio blade is a standard Macintosh blade that fits onto a standard handle at a very obtuse angle.

2. Blades and Devices That Avoid Chest Impingement

Several adaptations have been made to help avoid unwanted impingement of a laryngoscope's handle during laryngoscopy. This had been particularly important in morbidly obese patients, parturients with mammomegaly, and patients in an iron lung and during the application of cricoid pressure, when an assistant's hand is present. Equipment solutions have included shortened handles and making the angle between the laryngoscope handle and blade more obtuse by means of modifications to the blade or the handle or by insertion of adapters. However, appropriate positioning of the patient (e.g., ear-to-sternal notch horizontal alignment, head elevation relative to the chest) often renders these devices unnecessary.

a. MODIFIED BLADES

The Polio blade was introduced by Foregger in 1954 and designed for use during intubation of patients in iron lung respirators. It features a Macintosh-style blade that attaches to a battery handle at an obtuse angle of 170 degrees (Fig. 24-47).[87] It may still be used when a regular handle attachment setup encounters forward impingement (e.g., obesity, kyphosis with barrel chest deformity, mammary gland hypertrophy, a short neck),[87] although the extremely obtuse angle of the blade to the handle may make it difficult to generate an adequate lifting force. For obstetric cases, Kessell modified a Macintosh blade's block so that the blade comes off the handle at an angle of 110 degrees instead of the usual 90 degrees (Fig. 24-48).[88] Beaver described a straight blade with a handle set at 25 degrees to facilitate intubation of patients in "box" respirators.[89]

b. MODIFIED HANDLES

Handles with one half of the length of regular laryngoscope handles have been used to help avoid chest or breast impingement (Fig. 24-49). Patil and colleagues described a shortened, adjustable-angle laryngoscope handle incorporating a blade-lock device that allows blade positioning at 180, 135, 90, or 45 degrees to the handle (Fig. 24-50). When there is potential impingement of a laryngoscope handle on a patient's chest, the instrument can be inserted at 180 degrees; the angle of the blade to handle then can be reduced to 135 or 90 degrees, allowing laryngoscopy to be performed.[90]

Figure 24-48 The Kessell blade. (From Kessell J: A laryngoscope for obstetrical use: An obstetrical laryngoscope. *Anaesth Intensive Care* 5:265, 1977.)

c. ADAPTERS

The Jellicoe adapter was described to overcome the true angle between the Macintosh blade tip and handle of 58 degrees. The adapter increases this angle to 90 degrees (Fig. 24-51), facilitating blade entry into patients' oral cavities in some situations.[91] In 1991, Dhara and Cheong described a multiple-angle laryngoscope adapter that fits between the handle and blade and that provides working angles of 65, 90, 110, 130, 150, and 180 degrees between blade and handle.[92] The Yentis adapter is a 2.5-cm cube block that fits between a standard handle and laryngoscope blade (Fig. 24-52). It allows insertion of the blade into the patient's mouth with the handle swung 90 degrees to the right. After the blade is inserted, the handle can be swung back to the normal position for laryngoscopy.[93]

3. Blades for a Small Infraoral Cavity

a. BAINTON BLADE

The Bainton blade is unique in this collection of blades because it is designed specifically for pathologic conditions that obliterate the hypopharynx. The very large and long straight blade is compatible with regular laryngoscope handles. The distal 7 cm of the blade has a squared,

Figure 24-49 Shortened handles *(left)* help to avoid chest impingement during laryngoscopy.

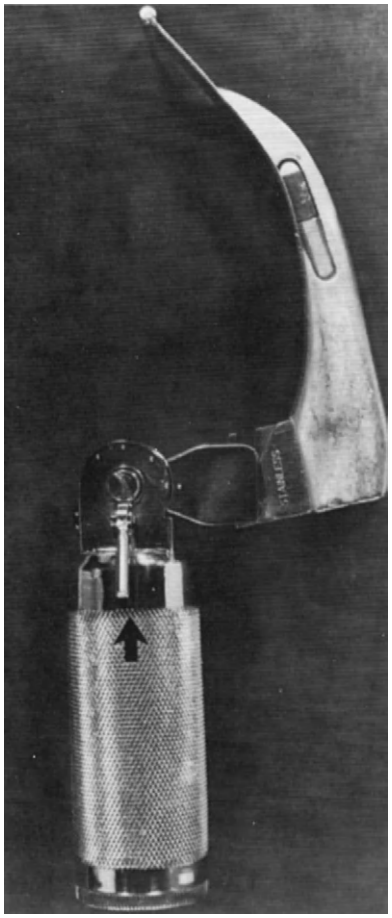

Figure 24-50 The shortened Patil handle allows positioning of the laryngoscope blade at an angle of 45, 90, 135, or 180 degrees. (From Patil VU, Stehling LC, Zauder HL: An adjustable laryngoscope handle for difficult intubations (letter). *Anesthesiology* 60:609, 1984.)

tubular design to help create a hypopharyngeal space where there may be none (Fig. 24-53). The lumen accepts an ETT up to size 8.0, and an intraluminal light source ensures that lighting is not compromised by tissues crowding the bulb. Bainton successfully tested his prototype in dogs with artificially induced hypopharyngeal swelling and in a small series of 12 patients with edematous conditions of the pharynx (one with a friable, bleeding tumor).[94]

b. DIAZ PEDIATRIC TUBULAR LARYNGOSCOPE

The Diaz pediatric tubular laryngoscope features a U-shaped handle and blade assembly. With a gradual distal curve, the blade is composed of two halves that are held together with a removable screw. A tubular scope with a straight blade design results when the two halves are attached (Fig. 24-54). The enclosed channel houses two light sources (one on each side) that are powered from an external fiberoptic light source. Endotracheal intubation is accomplished through the lumen of the scope, which must be disassembled by removal of the screw before the scope's removal from the patient.[95]

E. Pediatric Laryngoscopes

Macintosh and Miller blades are available in pediatric sizes. A size 1 in both blades is appropriate for an infant and a size 2 for a child. Additional Miller sizes 0 and 00 are available for the premature and small premature infant, respectively. Other pediatric blades are available commercially.

1. Oxford (Bryce-Smith) Blade

The Oxford, or Bryce-Smith, blade, was intended for neonates but is applicable for infants up to age 3 months. Primarily a straight blade, it tapers gradually from its proximal width of 1.8 cm to 1 cm distally. The step and flange are U-shaped, and although the distal 2.5 cm is open, a slight distal step remains for tongue control. The horizontal flange is quite broad proximally, helping to

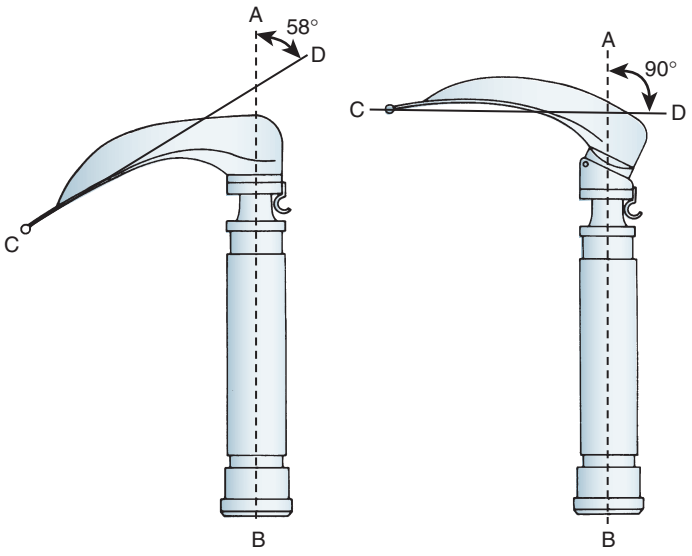

Figure 24-51 There is a 58-degree functional angle between the standard Macintosh blade tip and handle *(left)* and a 90-degree angle with the interposed Jellicoe adapter *(right)*. (From Jellicoe JA, Harris NR: A modification of a standard laryngoscope for difficult tracheal intubation in obstetric cases. *Anaesthesia* 39:800–802, 1984.)

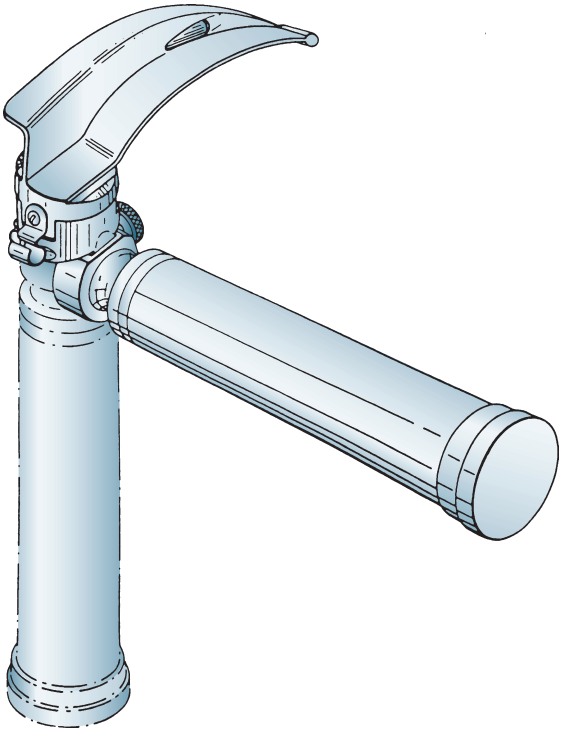

Figure 24-52 The Yentis adapter allows lateral pivoting of the laryngoscope handle to aid blade insertion. (From Yentis SM: A laryngoscope adaptor for difficult intubation. *Anaesthesia* 42:764–766, 1987.)

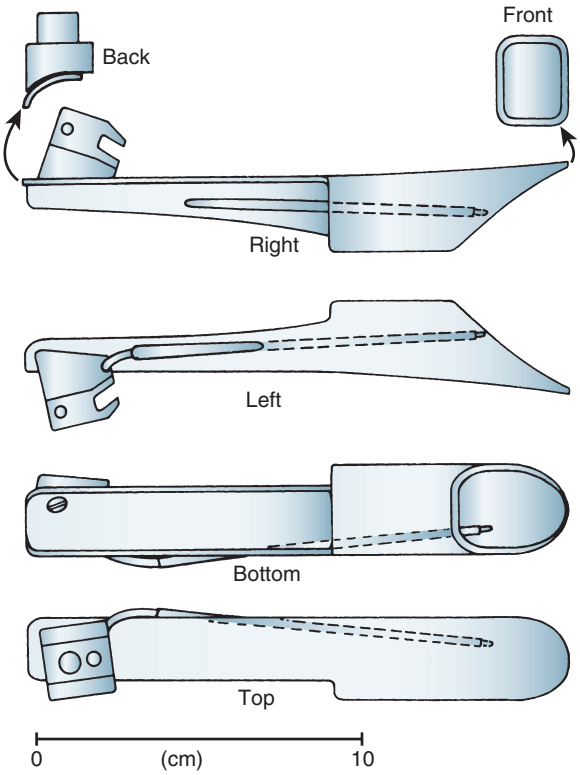

Figure 24-53 The Bainton laryngoscope blade is tubular distally to help overcome pharyngeal obstruction. (From Bainton CR: A new laryngoscope blade to overcome pharyngeal obstruction. *Anesthesiology* 67:767–770, 1987.)

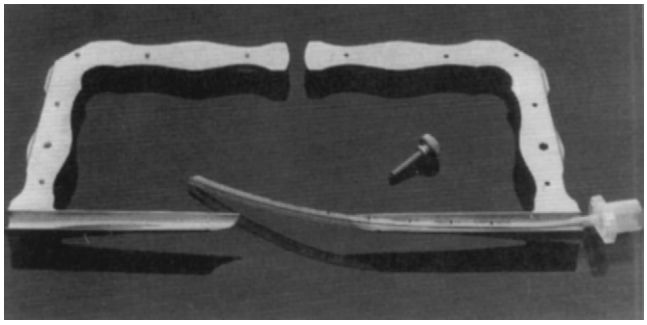

Figure 24-54 A tubular pediatric laryngoscope results when the two halves are attached by a removable screw. (From Diaz JH, Guarisco JL, LeJeune FE: A modified tubular pharyngolaryngoscope for difficult pediatric laryngoscopy. *Anesthesiology* 73:357–358, 1990.)

prevent the upper lip from obscuring the view and potentially helping in difficult cleft-palate situations (Fig. 24-55).[96]

2. Seward Blade

The Seward blade was created for use in the neonate, but additional sizes allow it to be used in children up to age 5 years. The primarily straight blade is 10.5 cm long, has a mild distal angulation and sharply tapering width, and ends in a thickened beak. The adult bulb is protected from the tongue on the inside of the reverse-Z-shaped step and flange (Fig. 24-56).[97]

3. Robertshaw Blade

Robertshaw originally modified a baby Soper straight blade by slightly curving the distal end while modifying the step and flange from the Soper's reverse-Z to a slight C shape. The light source was well protected from the tongue inside the vertical step. A subsequent modification exhibited additional leftward bending of the vertical step, creating a wider channel for visualization (Fig. 24-57).[98]

4. Other Blades

The Propper, or Heine, blade is straight with a slightly curved tip. The horizontal flange is in the reverse-Z configuration, curving away from the blade.[46] Other

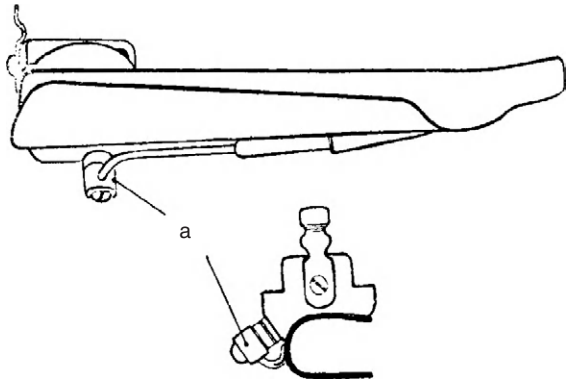

Figure 24-55 The Oxford, or Bryce-Smith, blade was intended for neonates but can be used for infants up to 3 months old. *a,* Light carrier. (From Bryce-Smith R: A laryngoscope blade for infants (letter). *Br Med J* 1:217, 1952.)

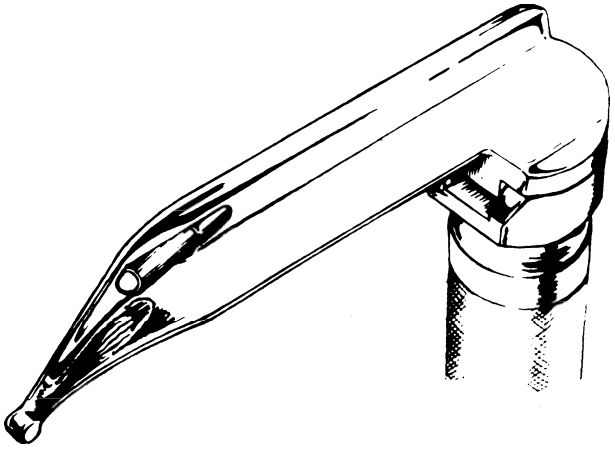

Figure 24-56 The Seward newborn laryngoscope blade. (From Seward EH: Laryngoscope for resuscitation of the newborn. *Lancet* 2:1041, 1957.)

modifications have been made for pediatric use. Matsuki described a widened, thin blade attached to the handle at a slightly obtuse angle to aid in control of the infant's tongue.[99] Rokowski and Gurmarnik described a modification of the standard Miller 0 blade in which the distal portion of the blade was widened to a triangular configuration for neonates or to a circular configuration for infants.[100] The width of the flange was reduced by 2 mm without modifying the height of the step to improve the area available for ETT manipulation and laryngeal visualization. Diaz combined several of the improvements in pediatric blades into one unit by modifying a Miller 1 blade to include an attached oxygen insufflation port, a corrugated lingual surface, and outward bending of the C-shaped flange to widen the cross-sectional area.[101] No formal evaluation has been published.

F. Laryngoscope Blades with Accessory Devices

1. Blades with Integrated Oxygen Delivery Channels

Some blades, mainly in pediatric sizes, are available with integrated channels designed for the insufflation of oxygen during direct laryngoscopy. The concept has evolved from earlier reports of oxygen insufflation through feeding tubes taped to blades during laryngoscopy in neonates and infants.[102,103] Hencz described permanently affixing a wide-bore aspirating needle for the same purpose.[104] Todres and Crone formally described the Oxyscope laryngoscope, which incorporates a built-in oxygen insufflation channel.[105] It was originally made available in Miller 0 and 1 blades and subsequently in Macintosh blades. Studies during laryngoscopy in spontaneously breathing, anesthetized infants have demonstrated higher oxygen tensions with oxygen administration through these blades.[105,106] They continue to be marketed under various brand names, mainly in the Miller configuration.

2. Blades with Integrated Suction Channels

Some adult and pediatric blades have an integrated suction channel or blades that allow suction through an oxygen administration port.[107-109] The modified blades allow suctioning during ongoing laryngoscopy and may be useful in patients with copious secretions or emesis or in situations such as bleeding after tonsillectomy. The Khan blade has a 1.75-mm-ID tube welded to a straight blade with a proximal hub angled so that the laryngoscopist's thumb can occlude a port to control the amount of suction applied.[108] Tull suction blades, available in Miller and Macintosh versions, have a finger-controlled valve lying next to the laryngoscope handle to enable the laryngoscopist to apply suction at will.[46]

3. Blade with a Secondary Ultraviolet Light Source

In 2009, Intubrite introduced a new concept in laryngoscope blade illumination that combined a white LED light with a second ultraviolet (UV) or black light.[110] The UV light is a higher frequency (wavelength) than white light that lies in the invisible part of the electromagnetic spectrum. It overpowers the lower end of the white light spectrum, where reds and yellows cause a whitewash effect. According to Intubrite, the UV light reduces the scatter from standard white light and improves visualization of the airway. The ligamentous vocal cords contain high levels of phosphorus that, when struck by the black light (UV), phosphoresce (Fig. 24-58). The company claims that by varying the wavelength of UV light and adding a spectrally specific white LED light, this illumination system better outlines the texture and structure of the airway and diminishes the reflectivity from fluids within the passage.

The Intubrite blade requires 4.5 volts and is designed for use with unique, high-powered, ergonomic handles that have a conventional handle-blade connection. Intubrite blades cannot be used on the standard handles of conventional laryngoscopes because of their power

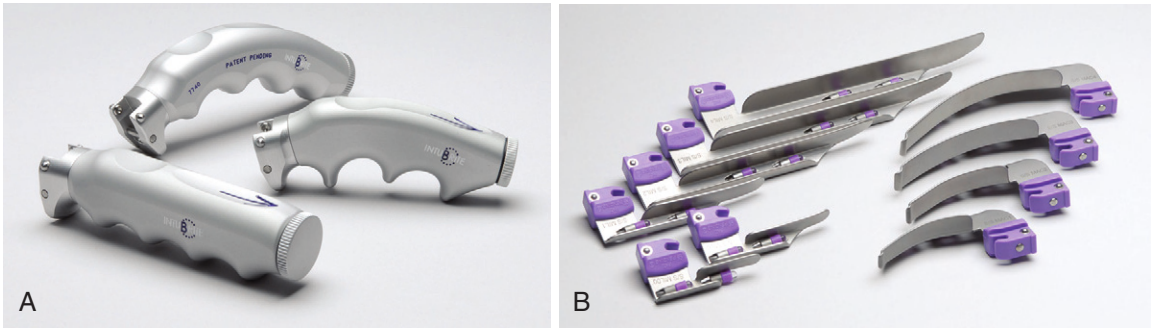

Figure 24-58 Intubrite handles **(A)** and laryngoscope blades **(B).** (Courtesy of Intubrite, Vista, CA.)

requirements; traditional handles using 2 C batteries generate only 3.0 volts.

Intubrite blades come in sizes from neonatal to large adult, and they are offered in Macintosh and Miller designs. Blades are offered in single-use and reposable (i.e., limited multi-use) versions; the latter can be resterilized 20 times using a low-temperature sterilization process (e.g., Sterrad). No clinical studies have been published comparing the performance of these blades with that of standard illumination blades.

4. Ultra-lightweight Tactical Laryngoscope

The TruLite (Truphatek International Ltd., Netanya, Israel) is a single patient–use laryngoscope, which combines a low-profile Macintosh or Miller metal blade hinged to a small plastic handle (Fig. 24-59).[111] With two AA batteries, the laryngoscope blade and handle weighs only 120 g. The LED light provides a bright white light. The preconfigured and attached metal blade, extreme light weight, and small overall size and packaging make it ideal for tactical settings and use in aircraft medical operations. It is offered in three Miller sizes (1 to 3) and four Macintosh sizes (1 to 4), all of which have small, narrow flange heights.

Figure 24-59 The Trulite (Truphatek International, Ltd., Netanya, Israel) is a disposable laryngoscope that combines handle and blade.

V. RIGID INDIRECT LARYNGOSCOPES WITH OPTICALLY ASSISTED VIEWS

Rigid indirect laryngoscopes enable a view of the laryngeal inlet indirectly through a fiberoptic bundle, video camera, or other optical aid. Examples of optically aided laryngoscopes include the Siker blade with its built-in mirror, blades using attachable prisms (e.g., Huffman, Belscope), and the Viewmax and EVO2 blades, which have integrated optical rods. Other indirect rigid laryngoscopes deliver an image endoscopically through a fiberoptic bundle or using video technology. The ensuing discussion is limited to mirrored blades and those that use prisms or optical rods. Fiberoptic instruments and video laryngoscopes are covered in Chapters 19 and 25, respectively.

A. Siker Laryngoscope

In 1956, Siker described an angled laryngoscope with an incorporated reflecting surface. The portion of the blade distal to the mirror is angulated at 135 degrees from the proximal section (Fig. 24-60). The stainless steel mirror is attached to the blade by means of a copper jacket to facilitate conduction of heat from the patient, thereby minimizing fogging of the mirror.[112] After blade insertion, if the laryngeal inlet cannot be directly visualized, the mirror can be used to indirectly identify the epiglottis and then the cords. Facility with the use of this blade takes some experience because the mirror inverts the reflected image. A styleted tube is essential; as the tube enters the larynx, it appears to move in a posteroinferior direction. In his original publication, Siker described the blade's use in 100 unselected patients. Laryngoscopy failed in just one patient because of excessive blade length. In three other patients with failed laryngoscopy and intubation with standard blades, the Siker succeeded. He emphasized the need for practice in the use of the blade.[112]

B. McMorrow-Mirakhur Mirrored Laryngoscope

McMorrow and Mirakhur described a modification of the levering tip laryngoscope that incorporates an adjustable

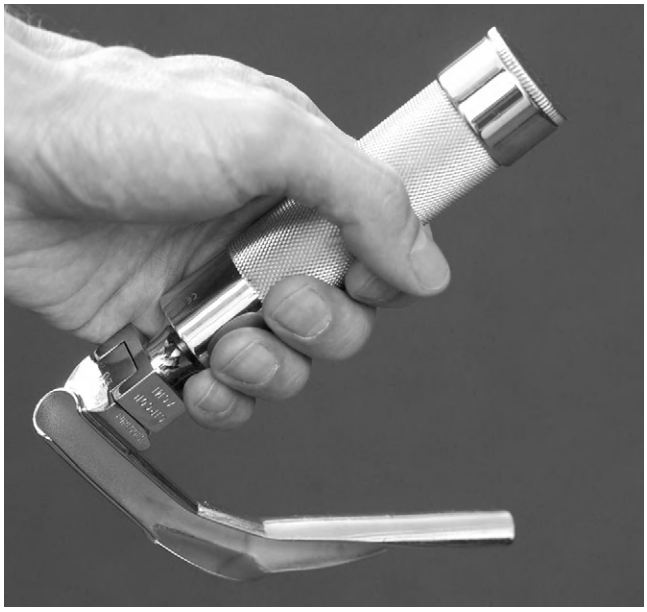

Figure 24-60 The Siker blade has a reflecting mirror located inferiorly at midblade.

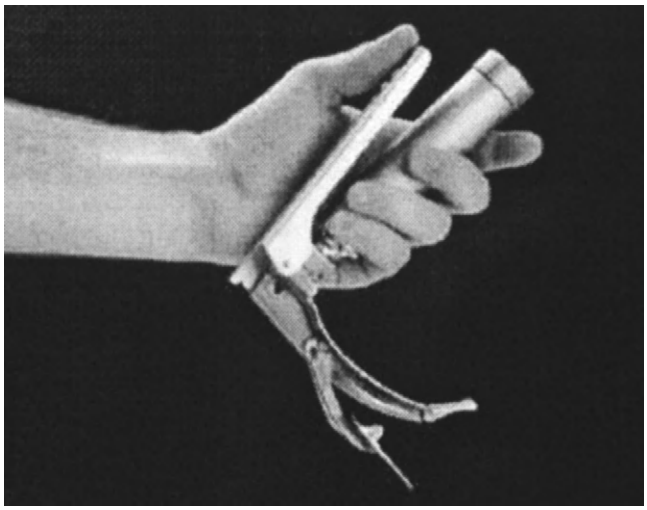

Figure 24-62 The McMorrow-Mirakhur laryngoscope is in the half-deployed position. The levering tip is activated, and the mirror is ignored. (From McMorrow RCN, Mirakhur RK: A new mirrored laryngoscope. *Anaesthesia* 58:998–1002, 2003.)

mirror.[113] Looking like a regular CLM (McCoy) laryngoscope in the resting position (Fig. 24-61), the McMorrow-Mirakhur laryngoscope can be operated as both a regular Macintosh blade or levering tip blade, as previously described. The difference is that it has a mirror lying posteriorly on the blade. As the levering tip is activated by moving the control lever toward the laryngoscope handle (Fig. 24-62), the mirror is deployed posteriorly and inferiorly with respect to the blade. If necessary, further depression of the control lever toward the handle changes the mirror pitch to a usable angle (Fig. 24-63), ultimately providing an additional 60-degree field of view compared with the Macintosh alone. If intubation is performed between the blade and the mirror, the scope has to be removed in its activated state. The blade should be heated or the mirror defogged before each use.

McMorrow and Mirakhur tested the laryngoscope in 15 patients presenting for elective surgery and compared it with the Macintosh and McCoy blades. Manual in-line neck stabilization was used to create difficult conditions for laryngoscopy, and all patients had Cormack-Lehane grade 3 views with the Macintosh blade. Using the McMorrow-Mirakhur blade with mirror deployment, the view was improved from grade 3 to grade 1 in 50% of patients and to grade 2 in 21%. The view was considered worse in 7%, and no change was seen in 21% of patients.[113]

C. Huffman Prism

Although a prism had been described by Janeway in 1913, Huffman revisited the concept in 1968. He attached

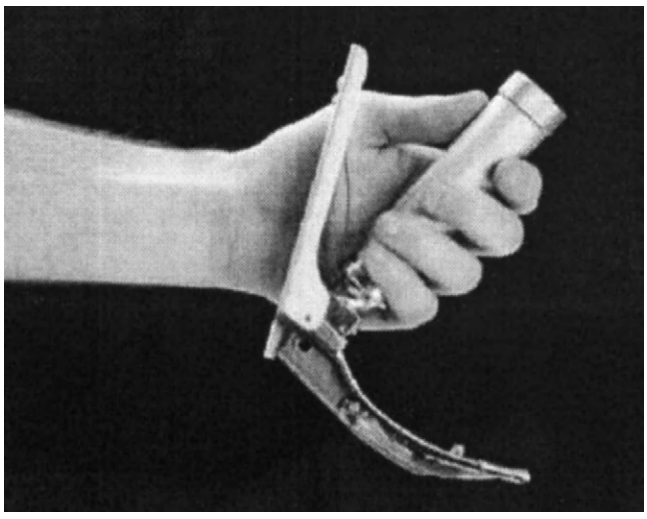

Figure 24-61 The McMorrow-Mirakhur laryngoscope in the resting position. (From McMorrow RCN, Mirakhur RK: A new mirrored laryngoscope. *Anaesthesia* 58:998–1002, 2003.)

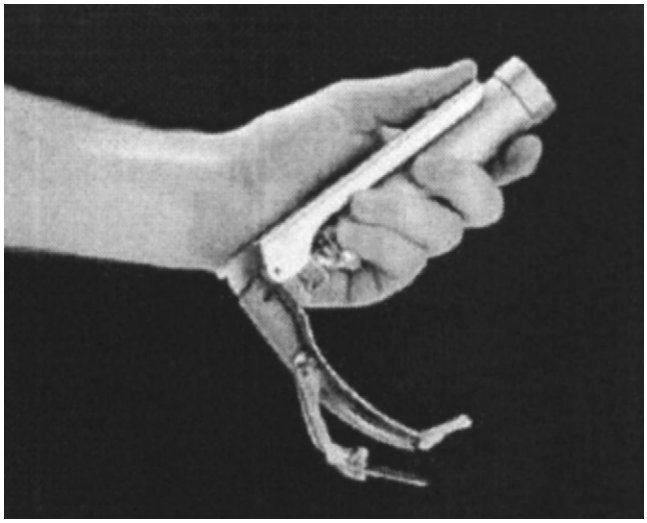

Figure 24-63 The McMorrow-Mirakhur laryngoscope is in the fully deployed position, with the distal mirror providing an additional 60 degrees of visual field. (From McMorrow RCN, Mirakhur RK: A new mirrored laryngoscope. *Anaesthesia* 58:998–1002, 2003.)

Figure 24-64 A Huffman prism is attached to a Macintosh 3 blade.

Figure 24-65 The lens system of the Rüsch Viewmax blade refracts the distal image by 20 degrees. (Courtesy of Rüsch, Duluth, GA.)

a Plexiglas prism to a Macintosh 3 blade by means of a steel clip. Because the image of the cords is deflected by approximately 30 degrees, Huffman theorized that less force on the tongue and hypopharynx would be needed to achieve laryngeal inlet visualization (Fig. 24-64).[114] Subsequently, he affixed a second prism distal to the first to achieve a total refraction of 80 degrees. He used the resulting instrument to inspect the larynx at light planes of anesthesia, but he speculated that it would be a useful tool for difficult laryngoscopy.[115] Huffman prisms continue to be available in various sizes for Macintosh blades.

D. Rüsch Viewmax Laryngoscope

1. Description

The Viewmax (Rüsch, Duluth, GA) laryngoscope blade is similar in shape to a Macintosh, but it incorporates a removable lens system (i.e., Viewscope) ending in a proximal eyepiece, which can refract the distal image 20 degrees from the horizontal (Fig. 24-65). This has the potential to improve laryngeal inlet visualization compared with that obtained by direct vision. The blade of the Viewmax is wider than that of a standard Macintosh, and although the lens system provides some vertical component, the blade otherwise has little formal vertical step. With the resultant lessened ability to sweep the tongue to the left, the blade can be used midline in the patient's mouth. The Viewmax is available in an adult and a pediatric size, corresponding to Macintosh size 3½ and 2 blades, respectively. (The name *Viewmax* is also applied to another company's [Timesco, London, England] version of the improved-view Macintosh blade.) The Viewmax has received limited investigation in manikins and cadavers with mixed results compared to a standard Macintosh blade.[116-118]

2. Truview EVO2

The Truview EVO2 uses an optical rod similar to the Viewmax, but it has an angulated shape (Fig. 24-66). The EVO2 is made by Truphatek International, which also manufactures the Viewmax, a product distributed by Rüsch. The EVO2 has a 42-degree refraction angle to its

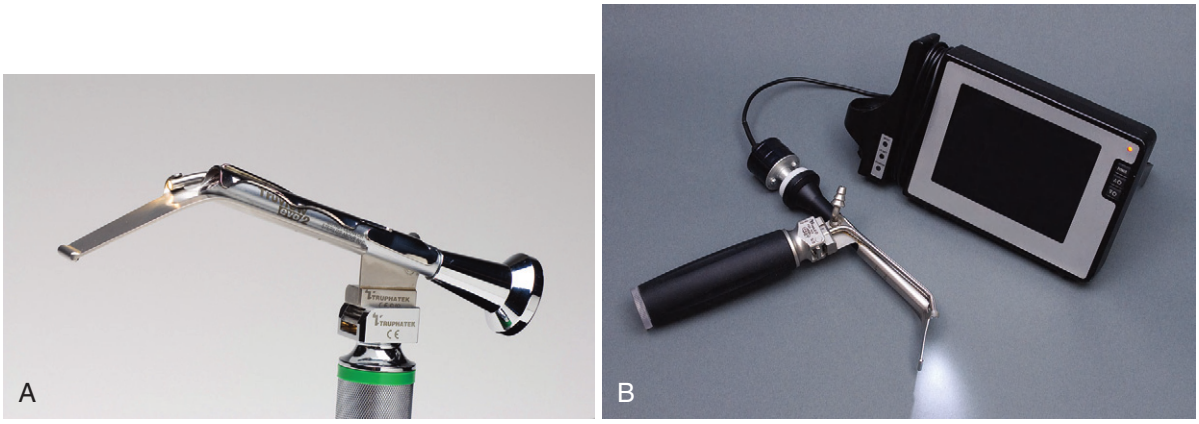

Figure 24-66 **A** and **B,** Truview EVO2 laryngoscope. (Courtesy of Truphatek International, Ltd., Netanya, Israel.)

optical system. Instead of a gently curved shape like the Viewmax, the EVO2 is an angulated blade; the proximal two thirds of the blade are straight, although it has a wide spatula, and the last third of the blade has a steep upward angle and a flat tip like a standard Macintosh blade. The optical lens system runs straight along the proximal two thirds of the blade.

A distinguishing feature of the EVO2 is an integrated oxygen port that allows delivery of up to 10 L/min of flow during laryngoscopy. The EVO2 is powered by a rechargeable fiber-lit handle (C or A battery sizes), and illumination is provided by a round, glass-fiber bundle. It comes in five sizes, from premature infant (0) to large adult (4). A 32-mm endoscopic coupler can be attached to the eyepiece, transforming the blade into a video laryngoscope system. The company offers a camera and monitor with the EVO2 (Truphatek PCD).

3. Clinical Experience

In pediatric and adult patients, the EVO2 has provided much improved laryngeal views compared with the standard Macintosh and Miller blades, although some studies have found slightly longer intubation times.[119-125] In adult patients with anticipated difficult laryngoscopy, the EVO2 has significantly improved the laryngeal view. In a small case series of cervical spine patients intubated while in a cervical collar, the EVO2 provided full glottic visualization, whereas the standard Macintosh blade provided very poor or nonexistent views.[120]

VI. CONCLUSIONS

Direct laryngoscopy for intubation confers the advantages of simplicity, direct glottic visualization, cost-effectiveness, equipment availability, and an overall success rate that is matched by few procedures in medicine. Although there is dramatically increased use of video laryngoscopes for many valid reasons, direct laryngoscopy is faster, and it is the most common means of rescuing failed video laryngoscopy. Direct laryngoscopy remains especially appropriate in emergency situations in which video or other imaging can be compromised by blood, vomitus, and secretions and in critical care scenarios in which there are very brief or nonexistent safe-apnea times. Clinicians should have redundant methods of intubation and ventilation immediately available to minimize the risk of failed intubation and to ensure patient safety.

VII. CLINICAL PEARLS

- Laryngoscope blades are not identical, and even within same designs (e.g., Macintosh and Miller), there is considerable variation among manufacturers. Depending on blade design, light source, battery type, and battery charge status, there can be a 500-fold difference in illuminance among blades in different clinical settings.
- With curved-blade laryngoscopes, design variables that are important to consider include the height of the proximal flange and the distance from the light source to the tip of the blade. Typically, a small flange is advantageous, and a shorter light-to-tip distance creates more light at the target.
- Low-profile Macintosh 4 blades (German or English designs) can be used in all adults, by varying the depth of insertion. When using a blade with more length than may be needed, the practitioner should identify the epiglottis on insertion and avoid passing by this critical landmark. Starting with a longer blade eliminates the need for switching out to a larger blade in emergency situations. A smaller flange permits insertion even in small-mouthed persons.
- Whiter, brighter light is provided by LED and fiber-illuminated systems than with traditional bulb-on-blade devices. Battery status and battery type are important to ensure good light output. Lithium, nickel-hydride, and other battery types have better discharge profiles (i.e., more uniform output) for high-drain devices such as laryngoscopes than alkaline batteries, which have long run times but very diminished output over time.
- Fiber-lit laryngoscopes have light sources in the handle and use glass or acrylic rods to transmit light from the base to the tip of the blade. Conventional blades have an electrical connection at the top of the handle and base of the blade. There is wide variation in bulb types, and LED, xenon, and halogen bulbs are available in both systems.
- LED bulbs have several major advantages over other bulb types. They produce a very white light that may improve discrimination of the epiglottis edge against the mucosa of the hypopharynx, and they use markedly less energy than filament bulbs. They have become so inexpensive that many companies offer disposable conventional blades with an LED bulb on the blade.
- Considerations in straight-blade design include the flange height, spatula shape, and location of the light source. A light source on the left flange may embed in tissue and provide poor illumination. Large-flange and large-spatula designs provide easier tube delivery but have to displace more tissue to get to the larynx. The shape of the distal tip (e.g., slightly upturned distal tip of the Miller design) affects how the blade is advanced to lift the epiglottis directly.

V. Fields of Application

VI. Difficult Airway

VII. Teaching

VIII. Documentation

IX. Conclusions

X. Clinical Pearls

I. INTRODUCTION

Although the use of video laryngoscopy for teaching the routine laryngoscopic technique of endotracheal intubation and for managing a difficult airway have been known for some years, anesthesiologists have been slow to recognize these advantages. Video-assisted techniques have been successfully used for decades in many surgical disciplines and have largely replaced open approaches in areas such as arthroscopy and laparoscopy (Box 25-1). The magnified and detailed view of the surgical site on a monitor makes it easier to coordinate the work of the surgical team and provides an effective teaching tool for novices. Anesthesiologists have observed this development with interest but without realizing its potential for their own specialty. For years, anesthesiologists have applied video technology almost exclusively for imaging in bronchoscopy and fiberoptic intubation, but the past decade has witnessed some important innovations in the field of video-assisted airway management.

In 1996, Levitan introduced a video camera attached to a head ring (Airway Cam). With this technique, intubation performed with a standard laryngoscope is displayed on a video monitor so that it can be observed by other personnel in the room. The view of the glottis matches the visual field of the intubating physician and does not improve visualization of the glottic plane.

Box 25-1 Important Indications for Video Laryngoscopy

Airway pathology, difficult airway (e.g., trauma, tumor, previous surgery)
Immobilization of the cervical spine
Limited spatial conditions
Education, teaching
Documentation

Another principle forms the basis for development of modern video laryngoscopes (VLs). By integrating optical image guides and video cameras into standard laryngoscopes, a magnified and detailed view can be displayed on an external monitor while conventional direct laryngoscopy is performed. Various investigators made an effort to advance this principle and integrated rigid or flexible fiberoptics into laryngoscopes with different shapes, such as the WuScope,[1] Bullard,[2] and UpsherScope.[3] Henthorn and coworkers reported the combination of a flexible fiberoptic cable with a conventional Miller laryngoscope blade,[4] which they used for student education. Instructors and trainees found this forerunner of modern VLs to be helpful in identifying the anatomy of the upper airways and successfully performing the intubation.

In 2001, Weiss and associates described a Macintosh laryngoscope, the angulated video-intubation laryngoscope (AVIL), in which a thin fiberoptic cable can be advanced through a guide channel in the laryngoscope handle and blade to a point very close to the blade tip.[5] Adapters can be used to connect the fiberoptic cable to an external video unit, enabling a close-up view of the larynx to be displayed on an external monitor. Another option is to introduce the video scope into the endotracheal tube (ETT). However, there have been no other publications on this device from other users, and it apparently has not found wide application.

The X-Lite (Rüsch, Duluth, GA) was introduced in 2001 in Vienna. This commercially available VL has an image guide built into the blade and a video camera installed in the handle. It was the first design to offer interchangeable blade shapes and sizes that could be connected to the camera handle. Two fairly bulky and heavy cables (i.e., light and image guides) emerge from the end of the handle. These characteristics made the device more cumbersome than a conventional laryngoscope, made the device less rugged and more susceptible to technical flaws, and hampered cleaning and disinfection.

In 2004, Kaplan and Berci introduced a further improvement of a Macintosh VL, a direct coupled interface VL (DCI, Karl Storz, Tuttlingen, Germany), also known as the VMS or V-MAC.[6] The DCI has an integrated camera and connectable blades equipped with a fiberoptic light and image guide, and the handle and blade are combined in a fixed unit.

Miniaturization of camera chip technology; improved, rechargeable battery power and light output; and affordable, small liquid crystal display (LCD) monitors made video laryngoscopy a booming technology, which led to the introduction of different types of VLs. Because VLs have different shapes, technical equipment, and applications, further classification of these devices is justified.[7] The main difference in VLs arises from the type of blade that is incorporated into the system. VLs that are based on a conventional, established blade shape, such as the Macintosh blade, have the option of visualizing the glottic entrance by direct laryngoscopy. Users are familiar with the handling of this blade type. Other VLs are designed with highly curved or angled blades that pass around the tongue and allow a "look around the corner" to the glottic opening. These VLs allow the best visualization of the glottis, although a direct view of the glottic entrance usually is impossible (i.e., obligatory indirect visualization). Because of the high degree of blade angulation, they must be used with a malleable or rigid styletted tube in most cases.

A subcategory of obligatory indirect laryngoscopes has a tube-guiding channel incorporated in the curved blade. This design obviates the use of a tube stylet to guide the tube to the glottic entrance, but it also does not allow correction of the direction of the tube.

For hygienic purposes, all VL systems are available in disposable forms. Compared with the reusable, stainless steel designs that allow lower blade profiles, the disposable versions mainly use a plastic blade sheath, which causes slightly larger blade profiles.

VL systems are available with an external or internal monitor. The larger external monitor allows better orientation for the laryngoscopist and operating staff, who may actively help with the intubation process (e.g., extralaryngeal maneuvers, suction). In systems with integrated monitors, visual orientation is more difficult on the smaller monitors. Others cannot easily follow the intubation process on the small monitor; this limitation may be aggravated by adverse space or light conditions. Picture or video documentation that can be obtained with external monitors usually is not available with the compact design of the smaller monitor. The greatest advantages of the systems with integrated monitors are their unrestricted mobility and minimal light and space requirements, which make them valuable for use in the prehospital setting. Because all these devices are battery operated, attention should be paid to the battery capacity to prevent a system blackout during intubation.

II. VIDEO LARYNGOSCOPES USING MACINTOSH-BASED BLADES

A. A.P. Advance

1. Description

The A.P. Advance (Venner Medical, Kiel, Germany) is a mobile VL that consists of a battery-containing handle, a blade core, and a 3.5-inch LCD monitor that connects to the handle magnetically. The size of the integrated monitor is bigger than in competitive VLs; using National Television System Committee (NTSC) video output, the monitor signal can be exported to an external screen. The monitor has an integrated, rechargeable battery, which provides the monitor screen and handle with power. The light source of the blade receives power from a battery

integrated in the handle, and the handle and blade may be used without a monitor attached (i.e., conventional direct laryngoscopy).

2. Instrument Use

The blade core can be used with three types of disposable blade sheaths. Two blades are adapted to the classic Macintosh shape (sizes 3 and 4), and one, the difficult airway blade (DAB), has been developed for use in the difficult airway. The DAB has a specific distal angulation and houses a tube-guiding channel in the distal one third of the blade, providing an obligatory indirect glottic view. For blade types with a guiding channel, the epiglottis should be lifted directly by the blade tip of the DAB, similar to the straight blade technique employed with a Miller blade.

3. Clinical Experience

No clinical experience has been published for the A.P. Advance, but in two mannequin studies, medical professionals used it in normal and difficult airway scenarios and reported good visualization and intubation success.[8,9] In another mannequin study, paramedics who had not previously used video laryngoscopy achieved earlier intubation and fewer unplanned advances of the tube compared with use of the GlideScope Ranger.[10]

B. Direct Coupled Interface (DCI) Video Laryngoscope System

1. Description

The DCI video laryngoscope was designed using a modified Macintosh blade with the same curvature as the original 1943 version and a laryngoscope handle. The batteries in the handle are replaced with a small video camera (i.e., DCI camera) and a combined image-light bundle that inserts into the Macintosh blade.[6] The DCI video laryngoscope system allows interchange of different devices, such as laryngoscopes (e.g., Macintosh, Dörges, Miller, D-Blade) and rigid (e.g., Bonfils intubation endoscope) and flexible fiberscopes (Fig. 25-1); however, mobility of the fiberoptic-based system is limited. The DCI system has been displaced by the mobile C-MAC video intubation system.

Figure 25-1 The DCI video laryngoscope system.

2. Instrument Use

Component of the DCI video laryngoscope system are assembled, and an antifog solution is applied to the tip of the image-light bundle. If a regular Macintosh blade is used, conventional direct laryngoscopy may be performed. On insertion of the scope into the patient's mouth, the image can be viewed on the video monitor. Even if the familiar Macintosh blade technique is used with this device, the distal viewing bundle may necessitate less anterior lift on the blade and may permit a view of part or all of the glottic opening in otherwise difficult laryngoscopies.

3. Clinical Experience

Kaplan and associates reported a series of 235 patients in whom they used the DCI video laryngoscope system.[6] Of these cases, 217 were predicted to be straightforward, and in all but one, the DCI video laryngoscope system was successfully used, with 10% requiring external laryngeal manipulation. A second group of 18 patients had anatomic predictors of difficult laryngoscopy; all in this group required external laryngeal manipulation but were successfully intubated with the DCI video laryngoscope system. In another study, Kaplan and colleagues compared the view obtained using DCI by direct vision with that obtained on the monitor and found that the image on the monitor was the same as or better than the direct line-of-sight view in most patients undergoing routine anesthesia.[11] Hagberg and colleagues describe the successful use in a patient who previously had an unexpected difficult laryngoscopy and impossible intubation and who was subsequently intubated with the DCI system after the first attempt.[12]

C. C-MAC Video Laryngoscope System

1. Description

The C-MAC (Karl Storz, Tuttlingen, Germany) video laryngoscope system is a modification of the Storz DCI system. The C-MAC VL can provide a useful alternative during routine induction of general anesthesia and in securing a difficult airway. The C-MAC is based on a modified Macintosh blade that has the same curvature as the original 1943 version,[13] but it is different from the original Macintosh blade in its thinner profile (maximum of 14 mm) and its beveled shoulder, which reduces the risk of oral and dental injury and facilitates insertion in patients with limited mouth opening. Optionally, the blade may be equipped with a guide channel for introducing a suction catheter to help maintain a clear visual field during laryngoscopy. The C-MAC system is compatible with various blades. The electronic module

(E-module) fits into the blade handle and allows a rapid exchange of Macintosh stainless steel blade sizes 2, 3, and 4, Miller sizes 0 and 1, and the D-Blade. A clip-on camera (C-CAM) can link the C-MAC system with rigid or flexible fiberoptics. The combined optical system of the C-MAC consists of a complementary metal-oxide semiconductor (CMOS) chip set (320 × 240 pixels), an optical lens with an aperture angle of 80 degrees, and a high-power, light-emitting diode (LED) at the distal third of the blade with effective antifogging properties. The blade handle with the E-module and the external, 7-inch LCD color monitor have push buttons that allow the operator to capture images from the screen and record video sequences, which are storable on standard SD memory cards, which have a 2-GB capacity. In the rare case that visualization of the glottic opening is still difficult, the D-Blade may be attached to the system within seconds. The higher curvature of the D-Blade allows a better look around the corner, and the low blade profile may permit use even in patients with limited mouth opening (e.g., 15 mm); however, direct laryngoscopy is not possible in most cases.

Other parts of the C-MAC system include the C-MAC pocket monitor (PM), which is a 2.4-inch LCD monitor combined with a lithium-ion battery–equipped E-module that fits in all available blades of the C-MAC system (e.g., Miller 0 and 1, Macintosh 2-4, D-Blade). The rechargeable battery supplies the monitor and the LED light source of the blades with 1 hour of energy without recharging, so that the VL is fully portable and can be used wireless. Power is turned on by a magnetic switch when lifting the monitor. Because this system is designed for mobile use, there are no other switches or connections for picture or video recording and exportation. To save battery capacity, the monitor turns off after 10 minutes automatically.

2. Instrument Use

For portable use, the monitor and blade handles can be packed separately in a rugged carrying bag, which permits use of all monitor buttons through the bag, even under difficult ambient conditions (e.g., prehospital settings). The C-MAC PM uses the identical blades, and the laryngoscopic technique is the same as with the conventional C-MAC system. However, successful handling of the device with the small monitor needs to be tested in clinical trials.

3. Clinical Experience

Several investigators showed superior visualization of the glottis with the C-MAC compared with conventional direct laryngoscopy.[14-17] Even if the application of a stylet cannot be eliminated completely, most intubations using a C-MAC VL can be performed without stylet use.[18,19] In a preliminary study by Cavus and associates of patients in whom conventional Macintosh laryngoscopy failed, use of the C-MAC D-Blade provided better glottic visualization and intubation success in all patients.[20] An observational study of 80 patients with the need for out-of-hospital emergency intubation (e.g. trauma, cardiopulmonary resuscitation) performed by physicians showed good handling and intubation success with the C-MAC VL. In a few cases, video laryngoscopic intubation was impossible due to VL problems such as bright surrounding light, and only direct laryngoscopy with the same device resulted in fast, successful intubation.[17]

D. McGrath MAC Video Laryngoscope

1. Description

The McGrath MAC (Aircraft Medical, Edinburgh, United Kingdom) is a slim-profile, mobile VL that consists of a battery-containing handle, a steel blade core (CameraStick), and a 2.5-inch LCD monitor fixed to the handle. The proprietary lithium-ion battery pack provides approximately 250 minutes of power. The McGrath MAC is fully immersible for high-level disinfection. As in the McGrath Series 5 VL, there is no connection port to transfer the image to an external monitor.

2. Instrument Use

The McGrath MAC may be used with disposable Macintosh blades (sizes 3 and 4); there are no blades with higher angulation (as in the McGrath Series 5 VL) available for this VL. Because of the Macintosh blade shape, direct and indirect laryngoscopy can be performed.

3. Clinical Experience

The McGrath MAC has been used for double-lumen tube insertion and compared with conventional direct laryngoscopy. Glottic visualization and ease of double-lumen tube intubation were improved using the McGrath VL.[21]

E. GlideScope Direct

1. Description

The GlideScope Direct (Verathon Medical, Bothell, WA) is a stainless steel Macintosh blade that adds to the existing GlideScope system (see "Video Laryngoscopes Using Highly Curved Blades"). The purpose of this blade is to expand the system with the option to teach conventional laryngoscopy because the GlideScope Direct allows direct and indirect (video laryngoscopic) glottic visualization.

2. Instrument Use

The GlideScope Direct is primarily designed as an intubation trainer, but may also be used for clinical use. Due to the Macintosh shape, the GlideScope Direct provides both direct and indirect laryngoscopic view. It is available as a reusable and single-use device. In cases that need a more highly curved blade (e.g., GlideScope AVL, GVL), the whole blade including the cable has to be changed.

3. Clinical Experience

No clinical experiences have been published.

F. Truview Picture Capture Device

1. Description

The Truview picture capture device (PCD) VL (Truphatek International Limited, Netanya, Israel) has an integrated optical lens (optical view tube), a unique 42-degree blade

tip angulation, and a view through a 15-mm eyepiece. The LED light source is stored in the handle, and the light is transmitted to the blade tip by fiberoptic strands. It is available in five blades sizes, and all of them allow direct laryngoscopy.

The blades are equipped with an integrated oxygen jet cleaning and insufflation system, which can connect to an external oxygen flow meter and provide oxygen at a rate of 4 to 6 L/min. The video properties of the optical Truview blade can be achieved by magnetic connection of the eyepiece to the camera of the Truview PCD screen.

2. Instrument Use

The Truview may be used like a conventional laryngoscope. Additional defogging maneuvers should be performed. The blade has an integrated channel that may allow apneic oxygenation of the patient during laryngoscopy.

3. Clinical Experience

The glottic view may be improved by use of the Truview compared with conventional laryngoscopy with a Macintosh blade, and this may result in a higher intubation success rate in difficult-to-manage airways.[22-25] Compared with conventional laryngoscopy with a Macintosh laryngoscope, intubation with the Truview may take more time, but intubation success rates may be comparable; however, rates of airway morbidity related to laryngoscopy may be lower.[23] In a study by Carlino and colleagues using the Truview as a teaching tool for anesthesiology residents, intubation success after the first attempt was almost doubled compared with that for conventional Macintosh laryngoscopy.[26] In patients with cervical spine immobilization, Malik and colleagues experienced inferior visualization and intubation compared with other VLs. The handling may be cumbersome, and fogging may impair visualization process.[22]

III. VIDEO LARYNGOSCOPES USING HIGHLY CURVED BLADES

Alignment of the oropharyngolaryngeal axis is not necessary using highly curved blades. With a look around the corner, optimal visualization of the glottis can be achieved without further manipulation (e.g., flexion or extension of the cervical spine). This may be important in patients with cervical immobilization, severe micrognathia, a fixed temporomandibular joint, or limited regional access.

High curvature of the blade typically makes it impossible to perform direct laryngoscopy; tracheal intubation requires indirect visualization. To follow the high curvature of the blade with an ETT, a tube guide or malleable stylet is necessary.[18,19] Although there is a tendency to focus on the video monitor, it is important to directly visualize the tube going into the mouth and advancing beyond the tongue before it becomes visible on the monitor. Perforations of the pharynx and hypopharynx have occurred with the GlideScope and the McGrath when operators have blindly inserted styletted tubes while focusing only on the video monitor.[27,28] Highly curved, indirect VLs can be used with almost no forces applied to tongue and pharyngeal structures, and these devices can be used in awake video laryngoscopic intubation as an alternative to awake fiberoptic intubation, assuming that attention is paid to possible contraindications for video laryngoscopy (e.g., mouth opening <15 mm, subglottic stenosis, tumor masses). Several case reports describe safe application of this technique.[29-35]

A. GlideScope

1. Description

The GlideScope is the prototype of modern, obligate indirect video laryngoscopes that display an image of the laryngeal inlet on an accompanying monitor. Made of medical-grade plastic, the laryngoscope is available in different sizes for fitting small children to morbidly obese patients. A high-power LED and miniature CMOS video camera are embedded posteriorly midway along the blade, resulting in a vertical profile up to 16 mm. Angulation of 60 degrees at midblade permits laryngeal inlet visualization with little tissue manipulation. An antifogging mechanism effectively maintains the view. The video image is transmitted to a 7-inch LCD monitor through a video cable; an integrated USB port allows recording of captured images and videos. A disposable version is available (GlideScope Cobalt AVL), which combines a nonsterile, reusable video baton and a sterile, single-use blade sheath. The monitor can be affixed to a mobile stand or be stored in a portable case. The GlideScope Ranger has been developed especially for mobile use in emergency situations (e.g., out of the hospital). The blade shape has been adapted to fit in the monitor box, and the size of the monitor screen has been reduced. A Macintosh-based steel blade (GlideScope Direct) has been added as an intubation trainer for educational purpose (see "Video Laryngoscopes Using Macintosh-Based Blades").

2. Instrument Use

Preparation for use of the GlideScope is limited to ensuring that the power is connected and turned on. After the instrument has been on for a few minutes, no additional defogging maneuver is needed. A styletted ETT is needed with distal curvature of 60 to 90 degrees to aid access to the glottic opening (i.e., "hockey-stick" formation). The blade is inserted as done with a Macintosh blade, although in this indirect technique, the blade tip does not need to be advanced to the vallecula, and a lift does not need to be performed to the same extent as with a conventional Macintosh blade. When the best view of the glottis is achieved on the video monitor with or without external laryngeal manipulation, the ETT is advanced alongside and posterior to the blade. Because advancement of the styletted tube cannot directly be observed due to the blade curvature, caution is needed during advancement of the tube to avoid injury of pharyngeal structures.[27,36-38] Intubation can be achieved by positioning the ETT at the glottic opening and then advancing it off the stylet through the cords. If tube passage is difficult, relaxation of any upward tongue lift should be attempted; alternatively, backing away slightly from the laryngeal inlet with the scope may help. Good

visualization of the process should be available throughout on the monitor.

3. Clinical Experience

The GlideScope is the prototype of modern obligate indirect VLs. Since its introduction in 2001, it has been studied in the operating room,[39-43] used in normal and difficult intubation scenarios,[38,44-49] and compared with other VLs.[16,18,22,50-55] In most patients, use of the GlideScope resulted in improved glottic visualization according to the Cormack-Lehane classification,[56] and it has provided successful intubation of difficult airways.[48,57] Aziz and colleagues analyzed 2004 GlideScope intubations and reported an overall intubation success rate of 97%. However, 3% could not be intubated with the GlideScope, and the investigators concluded that maintenance of competency with alternative methods of intubation was mandatory.[38] Intubation difficulties have changed from impaired visualization to difficult tube advancement. Despite optimal glottic visualization, the most difficult part of indirect video laryngoscopy is placing the curved tube in the glottic entrance and advancing it into the trachea.[58]

Use of the portable GlideScope Ranger has been studied predominantly in out-of-hospital settings and in emergency departments.[59-62] GlideScope Ranger use in an emergency setting improved glottic visualization and reduced the number of intubation attempts compared with conventional laryngoscopy.[57,63] However, Choi and colleagues reported some cases of unsuccessful intubation despite excellent visualization, which highlights the need for training on the device outside of emergency situations.[64]

B. McGrath Series 5

1. Description

One of the first fully portable and wireless devices with higher blade angulation and an integrated monitor is the McGrath Series 5 VL (Aircraft Medical Edinburgh, UK). It combines a steel blade with a length that may be adjusted according to the patient's body size and a single-size, disposable blade sheath. The low-profile blade has a disarticulating handle that can accommodate patients with limited mouth opening and severely limited neck mobility. There is no connection port for transferring the image to an external monitor. Two versions of the VL are available: a basic version with limited water protection and an improved version that is submersible in liquids, which may be essential for cleaning and disinfection purposes and for use in prehospital emergencies.

2. Instrument Use

The length of the blade can be adjusted before insertion into the patient's mouth. The McGrath Series 5 VL has three sizes, comparable in length to size 3, 4, and 5 Macintosh blades. After the instrument's power has been turned on for a few minutes, no additional defogging maneuver is needed. Similar to the GlideScope, a highly angulated, styletted ETT is needed to aid access to the glottic opening. Blade insertion is the same as for a Macintosh blade, although in this indirect technique, the blade tip does not need to be advanced to the vallecula, and a lift need not be performed to the same extent as with the Macintosh blade.

3. Clinical Experience

Most clinical data show improved visualization and intubation success compared with conventional laryngoscopy with the Macintosh and Henderson straight blades.[65-68] Similar to the GlideScope, advancement of the styletted tube cannot directly be observed because of the blade's shape, and caution is needed during advancement of the tube to avoid injuries.[28]

C. A.P. Advance Difficult Airway Blade and the C-MAC D-Blade

The curved blades for use in difficult airways, the A.P. Advance DAB and C-MAC D-Blade, are additional components of the corresponding Macintosh-based video laryngoscopy systems.

IV. VIDEO LARYNGOSCOPES WITH TUBE-GUIDING CHANNELS

Some video laryngoscopes with high blade curvatures have integrated tube-guiding channels to improve tube passage without the use of a tube stylet. The VL and tube are directed together to the glottic entrance. Because of the surrounding channel, the tube cuff is reasonably protected from damage.

A. King Vision

1. Description

The King Vision (King Systems, Noblesville, IN) is a fully portable and wireless VL with high blade angulation. It has a reusable-battery–operated monitor and a disposable blade that also includes a CMOS video camera. The disposable blade is available with or without a tube-guiding channel, and one blade size is provided for adult use (tube sizes 6.0 to 8.0 mm). The King Vision's video output allows bystanders to view the images on an external medical monitor.

2. Instrument Use

The tube should be preloaded in the tube-guiding channel before insertion of the laryngoscope into the patient's mouth. The VL should be advanced toward the glottis, so that it barely lifts the epiglottis with the blade tip. With the channeled blade, better intubation conditions may be achieved if the VL is placed into the vallecula without uploading the epiglottis directly. When the glottic entrance is in the center of the screen, the tube can be advanced into the trachea under direct observation on the video screen. Because the monitor is attached to the blade without articulation, it may be necessary in obese or busty patients to connect the monitor first after introduction of the blade.

3. Clinical Experience

Clinical data for the use of the King Vision VL have not been published.

B. Pentax Airway Scope AWS-S100

1. Description

The Pentax Airway Scope (AWS-S100, Pentax Medical, distributed by AMBU, Inc., Glen Burnie, MD) is a fully portable, battery-operated, and wireless VL that is available in one size only. The AWS-S100 has a portable, transparent blade (PBlade) equipped with a port through which a suction catheter can be passed. It uses an LED light and flexible wire for a charge-coupled device (CCD) camera, rather than the CMOS camera chip used in other VLs.

2. Instrument Use

The AWS is the prototype of modern VLs that provide a blade-integrated channel for guiding a tube to the larynx. The standard technique for using the Pentax AWS involves direct elevation of the epiglottis for exposure of the vocal cords; however, it may also be used without elevating the epiglottis. A target symbol on the monitor assists in directing the tube to the glottic entrance. The AWS video output (NTSC composite) allows bystanders to view the images on an external medical monitor. According to the manufacturer, antifogging substances should be applied to the camera before use of the VL.

3. Clinical Experience

Because of the high angulation of the blade, the AWS has shown superior glottic visualization and intubation success compared with conventional laryngoscopy in patients with immobilization of the cervical spine.[22,69] In contrast, in a study of morbidly obese patients, Abdallah and colleagues showed faster intubation and higher first-pass success rates with a conventional Macintosh size 4 blade compared with the Pentax-AWS, despite inferior glottic visualization.[70] Several case reports describe the Pentax AWS VL for successful intubation of awake, spontaneously breathing patients.[31-33]

In morbidly obese patients, the relatively bulky design may cause difficulties during insertion in the mouth.[71] Problems with the guiding channel may arise if the cervical spine has a fixed rotation[72] or if otherwise the tube may not be redirected from the channel.[73] In principle, these problems may arise with all channeled-blade VLs.

C. Airtraq

1. Description

The Airtraq (Prodol Meditec, Guecho, Spain) is a single-use, indirect laryngoscope that incorporates two channels. One transfers the image to a proximal viewfinder through a series of prisms and lenses, and the other acts as a conduit for the ETT. A clip-on camera can transfer the image from the viewfinder to an external monitor. The Airtraq is available in different sizes for pediatric and adult patients. Nasal and double-lumen versions are available.

2. Instrument Use

Similar to the King Vision VL, the Airtraq tube should be preloaded in the tube-guiding channel before insertion of the laryngoscope into the patient's mouth. The laryngoscope should be advanced toward the glottis, so that it barely lifts the epiglottis with the tip of the blade.

3. Clinical Experience

Compared with conventional Macintosh laryngoscopy, the Airtraq has demonstrated promising results in patients at low or higher risk for difficult tracheal intubation and in patients with immobilization of the cervical spine.[74-76] McElwain and colleagues found that the Airtraq laryngoscope performed better than the C-MAC (with a Macintosh blade) and conventional Macintosh laryngoscopes in patients undergoing tracheal intubation with manual in-line stabilization of the cervical spine.[77] However, Trimmel and colleagues showed that the Airtraq laryngoscope had no benefit over conventional direct laryngoscopy in the prehospital setting if used by untrained physicians, and they could not recommend it in the prehospital setting without significant clinical experience obtained in the operation room.[78]

V. FIELDS OF APPLICATION

As more VLs are introduced into clinical practice and as airway managers become more skillful with the application of video laryngoscopy, it could become a standard part of management for patients with known or suspected difficult airway. However, because video laryngoscopic devices have different designs, technical issues, indications, and applications, it may take some time before a VL system is used for routine intubations.

VLs are available with external and integrated monitors. External monitors can provide optimal visualization of the intubation process to the entire team, who may anticipate actions such as extralaryngeal manipulations or suctioning. Captured images and videos can be recorded by external units. The smaller integrated monitors offer the greatest portability, which will be improved when wireless technology is implemented.

Video laryngoscopy has many nontraditional but useful applications in anesthesiology (Table 25-1). Suitable devices should be available when anesthesia is administered, and all airway practitioners should be skilled in their use. Although VLs can provide important savings in time and decreased patient morbidity, equipment cannot substitute for clinical proficiency, and traditional intubation skills should be maintained.

VI. DIFFICULT AIRWAY

At one time, the use of video laryngoscopy for managing the unexpected difficult airway was limited by restricted mobility and extended preparation time. This is no longer the case because current VLs are mobile and quick to set up. Serocki and colleagues found that video laryngoscopy was helpful in many clinical conditions with an expected difficult airway, including limited neck mobility, reduced thyromental distance, reduced inter-incisor distance, and retrognathia.[48] Their data confirmed that the DCI VL with a Macintosh blade and the GlideScope enhanced glottic visualization in patients with difficult conventional laryngoscopy.

Video laryngoscopy cannot replace awake fiberoptic intubation in many cases of predictable difficult airway. Nonetheless, in an expected difficult airway, video laryngoscopy may be a worthy addition as an awake intubation technique.[32,34,79] Although the American Society of Anesthesiologists (ASA) difficult airway guidelines highlight the approach of awake intubation as the preferred method to manage expected difficult airways, video laryngoscopy under general anesthesia should be considered for intubation if difficulty with intubation, but not mask ventilation, is expected.[80] Video laryngoscopy has successfully been applied for the management of the difficult airway in otonasolaryngologic and maxillofacial surgery,[48] neurosurgery,[81] obstetrics,[82] traumatology, pediatrics,[83] the intensive care unit,[84] the emergency department,[64] and in physician-based, out-of-hospital emergency medicine.[17]

VL systems may be advantageous over direct laryngoscopy for the exchange of one airway device for another. A case report demonstrated the use of video laryngoscopy to exchange a Combitube, which was placed by paramedics after failed direct vision intubation, for an ETT to establish a definitive airway.[12] It is not unusual for a supraglottic airway device, such as a Laryngeal Tube or Combitube, to be placed in the prehospital setting when direct laryngoscopy is unsuccessful and the patient's airway is difficult; exchanging this device for an ETT may be demanding. Anesthesiologists use VLs in routine cases without any suspicion of difficult airway management or before any attempt of direct laryngoscopy is performed, because VLs are simple to use and have a high rate of intubation success.

VLs have the advantage in the unanticipated situation because their rigidity facilitates rapid control of the position of the laryngoscope tip, and they can be ready for immediate use. These devices allow retraction of soft tissues so that there is a line of sight from the lens to the distal structures, without the necessity of aligning the oral and laryngotracheal axes with the naked eye. Even with a Macintosh VL that is used in the traditional Macintosh fashion (i.e., tip of blade in vallecula), the epiglottis may be directly elevated; the straight-blade technique offers improved viewing. This type of positioning is often performed for difficult airways. In a study of 60 patients by Cavus and associates,[15] a size 4 rather than a size 3 C-MAC blade was used in three patients with unexpected intubation difficulties. The Macintosh size 4 blade is more curved than the size 3, resulting in a higher angulation with a wider view of the glottis. In all three of these patients, the Cormack-Lehane score improved by two classes using this technique. Some practitioners position the tip over the dorsum of the tongue, proximal to the epiglottis, achieving indirect elevation of the epiglottis without conventional tensioning of the hyoepiglottic ligament.

Because of their optics, these devices allow the operator to visualize structures that may not be seen with the direct line-of-sight view available to the naked eye. When glottic visualization is difficult despite the use of a Macintosh-based VL, an obligate indirect VL such as the GlideScope or the C-MAC D-Blade may be used.[20,39] A direct view on the glottis is impossible with an obligate indirect VL in most patients. If secretions (e.g., blood, vomit), surrounding light, and battery failure impede the glottic view on the monitor, direct glottic visualization can be an important fall-back strategy.[17]

It may be advantageous to use a system in which different types of blades can be changed with minimal delay, such as C-MAC system or A.P. Advance.[9] In a stepwise approach, airway management can be changed from direct laryngoscopy by video laryngoscopy with a Macintosh blade to obligate indirect video laryngoscopy with a more highly curved blade (Fig. 25-2). Most VLs provide an output socket to an external monitor. Some offer video capture capabilities to record airway procedures for educational or documentation purposes (e.g., C-MAC, GlideScope). Control buttons are located on the handle or the monitor for recording videos and captured images.

The use of VLs has some restrictions. A training period outside an emergency situation is necessary to use the system correctly and obtain its full benefit. Additional training is also necessary for correct handling of the ETT while viewing the monitor instead of direct visualization of the larynx.

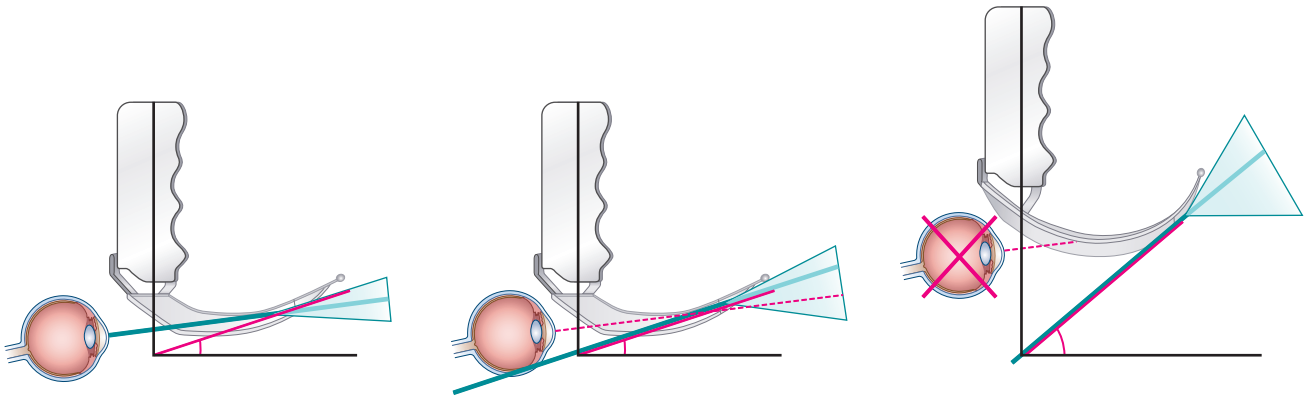

Figure 25-2 Stepwise approach to video laryngoscopy using interchangeable blades for conventional direct laryngoscopy, indirect video laryngoscopy, and obligate indirect video laryngoscopy.

VII. TEACHING

All VLs provide optimal visualization of the glottis on a video screen. The video presentation may be used to provide a "what to see during intubation" tutorial. Video laryngoscopy enables the supervising faculty member to directly observe the actions of the trainee, reducing the anxiety associated with allowing the trainee to perform the intubation. However, because the application of some devices varies significantly and only obligate indirect laryngoscopy may be possible, a limited number of VLs may be used in training for conventional laryngoscopy and intubation.

The demands for adequate clinical experience with airway management are increasing in training programs because providing acute airway management is often accomplished in high-stress settings. Allowing the trainee to manage the airway is a crucial decision by the faculty member, who must always consider the patient's level of acuity, the clinical circumstances, and the perceived confidence in the trainee who will be afforded the clinical experience.

VLs based on Macintosh blades offer the possibility for conventional direct laryngoscopy attempts by the trainee, and at the same time, the faculty member is able to analyze the airway on the monitor and make better-informed decisions about the prudence of allowing the trainee to continue. A study using video laryngoscopy to provide feedback for instructor showed that the student's success of intubation is increased and the rate of esophageal intubations was markedly decreased compared with instructor assistance based on standard cues.[85] In the absence of a VL system, the faculty member is more likely to take over the procedure earlier if a problem is encountered, reducing the experience afforded to the trainee.

VIII. DOCUMENTATION

VLs with external monitors can record and save video sequences and image captures from the screen. Video recordings of professional laryngoscopic attempts can be educational, and recordings of intubation attempts by students can be used as a teaching tool. Airway pathologies such as edema of the glottic opening and erythema after a burn injury can be documented. In newborns, the enlarged panoramic view and recordings of video laryngoscopy have assisted in correctly diagnosing vocal cord paralysis.[83]

Direct visualization of tube insertion with video recording can confirm correct tube placement and can detect esophageally misplaced ETTs quickly. Use of video laryngoscopy for routine intubations in the operating room, intensive care unit, emergency department, and prehospital emergency settings can increase intubation success rates and reduce the incidence of critical situations in airway management.[86]

IX. CONCLUSIONS

Direct laryngoscopy for intubation confers the advantages of familiarity, direct glottic visualization, cost-effectiveness, equipment availability, and a steep learning curve. However, the prevalence of Cormack-Lehane grade 3 views at direct laryngoscopy is stubbornly persistent. Adjunctive maneuvers such as external laryngeal manipulation and head lift, together with accessories such as ETT introducers (bougies), remain crucial to the success of unexpected difficult direct laryngoscopy. Alternative intubation techniques such as video laryngoscopy applied in a timely fashion are essential to achieving success in challenging situations. Because VLs are mobile and quick to set up, they play an important role in the management of an unexpected difficult airway. Use of a VL also may be considered in a predicted difficult airway if mask ventilation and oxygenation are warranted or in situations in which blind techniques are contraindicated (e.g., anatomic abnormalities of the airway) and video documentation is needed. However, the gold standard for management of predicted airway difficulties when oxygenation after induction of anesthesia cannot be ensured is the use of a flexible fiberoptic device in an awake, spontaneously breathing patient.

As more video-aided devices become available, clinicians must become familiar with some of them in elective cases to expect them to be useful in difficult situations. Teaching programs must ensure that excellent skills in direct laryngoscopy and flexible fiberoptics are taught and maintained and that anesthesiologists attain competence with different direct laryngoscopy blades.

X. CLINICAL PEARLS

- The main indication for video laryngoscopy is an unpredicted difficult intubation.
- If oxygenation of the patient can be ensured (e.g., by bag-mask ventilation), video laryngoscopy may be considered for some cases of predicted difficult intubation.
- Video laryngoscopes (VLs) have different technical requirements and handling conditions. Training with each device in elective situations is mandatory before use in airway emergencies.
- VLs with highly curved blades provide obligate indirect glottic visualization. In most cases, a tube stylet must be used. Despite optimal visualization of the glottic entrance, tube advancement into the trachea may be difficult due to the steep angle of the styletted, curved tube.
- VLs with Macintosh-type blades provide direct and indirect glottic views. The option of direct visualization may be particularly important in airway emergencies outside of the hospital.
- Ideally, VLs are available to cover a broad range of applications in patients of different ages and sizes (e.g., newborns, obese patients).
- Reusable, stainless steel blades have lower blade profiles, but disposable blades also should be available for hygienic reasons. Disposable blades are mandatory in some countries.
- Video laryngoscopy allows for image capture and video documentation that may be useful in a variety of

settings (e.g., oropharyngeal pathologies, correct tube placement).

- Video laryngoscopy may be used for awake orotracheal intubation, but awake fiberoptic intubation remains the gold standard for patients with a predicted difficult airway, and skill in performing fiberoptic intubation must be maintained.
- Because VLs, especially those with interchangeable blades for direct laryngoscopy and obligate indirect laryngoscopy, aid education in conventional laryngoscopy and reduce patient morbidity, they may become the standard for routine intubation in the operating room, intensive care unit, emergency department, and prehospital emergency settings.

I. INTRODUCTION

The physiology, indications, and techniques of lung isolation and single-lung ventilation (SLV) are discussed in this chapter. Lung isolation is most commonly used during thoracic and cardiovascular procedures; however, it can often be useful and potentially life-saving in other situations. Newly designed double-lumen tubes (DLTs), single-lumen tubes (SLTs) with built-in endobronchial blockers (also called bronchial blockers), new bronchial devices, and enhanced fiberoptic technology are making lung isolation and SLV easier and safer to perform. Knowledge of these topics is requisite for a consultant anesthesiologist.

II. PHYSIOLOGY

The most common physiologic problem with SLV is the creation of a large intrapulmonary shunt. This shunt may result in hypoxia with severe irreversible end-organ damage. Most anesthesiologists aim to maintain arterial oxygen tension (Pa_{O_2}) at greater than 60 mm Hg as hemoglobin saturation drops sharply below this value.

In most surgical cases, patients are placed in lateral decubitus position with the ventilated lung dependent. The physiologic goal is to promote blood flow to the nonsurgical, dependent lung. By reducing the pulmonary vascular resistance (PVR) of the dependent lung to minimal levels, improved ventilation-perfusion ($\dot{V}/\dot{Q}$) matching may occur. Excess positive end-expiratory pressure (PEEP), airway pressures, hypoxia, hypercapnia, and hypovolemia may contribute to an increase in PVR of the dependent lung, thereby increasing the shunt fraction. Improvement of the shunt fraction can be accomplished by decreasing blood flow or supplying O_2 to the nondependent lung.

Hypoxic pulmonary vasoconstriction is a powerful reflex that increases the PVR of the hypoxic lung and the atelectatic lung, diverting blood to the well-oxygenated areas of lung. It is useful to limit agents that inhibit hypoxic pulmonary vasoconstriction, such as nitrates and high concentrations of volatile agents.

Supplementation of O_2 to the nondependent lung may also alleviate hypoxia. This can be accomplished by the application of an external continuous positive airway pressure (CPAP) circuit to the nondependent lung or simply by trapping partial inflations of the nondependent lung. The goal is to allow enough O_2 into the nondependent lung to reverse hypoxia while not obscuring the surgical field.

III. INDICATIONS FOR LUNG SEPARATION

A. Absolute Indications

Absolute indications for lung separation (Box 26-1) include protective isolation of the normal lung, establishment of adequate gas exchange when there is a change in pulmonary compliance or lung pathology, and unilateral bronchopulmonary lavage.

Accumulation of blood or any contaminant in the noninvolved lung can lead to severe atelectasis, pneumonia, sepsis, and death. Lung isolation may be life-saving by simply preventing immediate drowning of the ventilated lung or by preventing further deterioration of overall pulmonary function.

Several unilateral lung conditions lead to inadequate ventilation. A large bronchopleural or bronchocutaneous fistula can lead to little or no ventilation of the nonoperative, healthy lung. In this situation, the increased compliance of the diseased lung results in direction of most of the positive-pressure ventilation (PPV) toward the diseased lung, minimally ventilating the normal lung and producing inadequate gas exchange. Conversely, a relatively noncompliant transplanted lung cannot compete with the better compliance of the native lung, and as a result, the healthy transplanted lung can be severely underventilated. Another scenario involves a lung with bullous or cystic disease or a lung with tracheobronchial disruption.[1] Tension pneumothorax or tension mediastinum could result during these scenarios from elevated airway pressures that are often observed with SLV in the lateral decubitus position.

Patients with alveolar proteinosis may require unilateral bronchopulmonary lavage, which involves multiple instillations of large fluid volumes into the target lung with subsequent drainage of the effluent fluid.[2-4] Lung separation is mandatory to avoid lung cross-contamination and drowning caused by the large volume of fluid required to perform the lavage.

Box 26-1 Indications for Separation of the Two Lungs or One-Lung Ventilation

Absolute Indications

Isolation of one lung from the other to avoid spillage or contamination
1. Infection
2. Massive hemorrhage

Control of the distribution of ventilation
1. Bronchopleural fistula
2. Bronchopleural cutaneous fistula
3. Surgical opening of a major conducting airway
4. Giant unilateral lung cyst or bulla
5. Life-threatening hypoxemia related to unilateral lung disease

Unilateral bronchopulmonary lavage
1. Pulmonary alveolar proteinosis

Relative Indications

Surgical exposure—high priority
1. Thoracic aortic aneurysm
2. Pneumonectomy
3. Thoracoscopy
4. Upper lobectomy
5. Mediastinal exposure

Surgical exposure—medium (lower) priority
1. Middle and lower lobectomies and subsegmental resections
2. Esophageal resection
3. Procedures on the thoracic spine

Pulmonary edema after cardiopulmonary bypass

Hemorrhage after removal of totally occluding, unilateral, chronic pulmonary emboli

Severe hypoxemia related to unilateral lung disease

B. Relative Indications

Relative indications for lung isolation involve facilitating surgical exposure, avoiding lung trauma, and improving gas exchange. Operations such as repair of thoracic aneurysms, pneumonectomy, pulmonary lobectomies (especially of the upper lobe), video-assisted thoracoscopic surgery, esophageal surgery, and anterior spinal surgery all benefit from the optimized surgical exposure afforded by SLV (see Box 26-1). Lung isolation further improves recovery by minimizing lung instrumentation and trauma to the nonventilated, nondependent lung. In cases of unilateral lung trauma, oxygenation and recovery may be optimized with SLV by improving $\dot{V}/\dot{Q}$ matching.

Additional indications for SLV are bronchopleural and bronchocutaneous fistulas because they offer a low-resistance pathway for the delivered tidal volume during PPV. Another example is bronchopulmonary lavage for alveolar proteinosis or cystic fibrosis, because protection of the contralateral lung is necessary during separation. All other indications for SLV can be considered as the need for lung separation in which there is no risk of contamination of the dependent lung. This includes all relative indications that are necessary for surgical exposure, such as video-assisted thoracoscopy (VAT) for diagnostic and therapeutic procedures. Most procedures in which SLV is used are for lung separation; few require lung isolation. This distinction is important when selecting the method to provide SLV. In cases of lung isolation, DLTs are preferable to endobronchial blockers because they provide a superior protective seal to prevent contamination of the dependent lung.

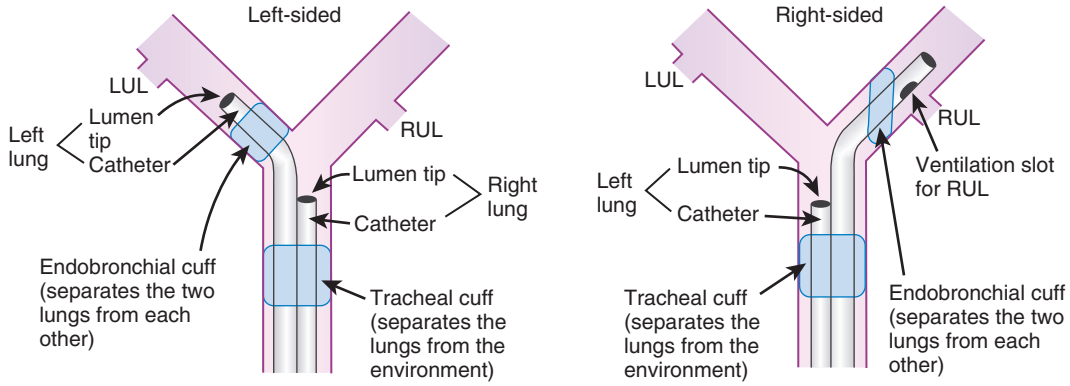

Figure 26-1 Essential features and parts of left-sided and right-sided double-lumen tubes. *RUL,* Right upper lobe; *LUL,* left upper lobe. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

IV. TECHNIQUES

A. Double-Lumen Tubes

1. Anatomy

DLTs are essentially two tubes bonded together with a design that allows each tube to ventilate a specified lung. DLTs are right-sided or left-sided devices. Left-sided DLTs have a bronchial port that extends into the left main stem bronchus and a tracheal port that is designed to sit above the carina. In right-sided DLTs, the bronchial port extends into the right main stem bronchus, and the tracheal port sits above the carina. The cuff of the right-sided DLT may be at an oblique angle to facilitate ventilation of the right upper lobe bronchus at the Murphy eye (Fig. 26-1).

The original DLTs were reusable, red rubber tubes with high-pressure cuffs that became stiff and brittle over time, making placement more difficult and traumatic. Newer DLTs are made of nontoxic plastic (the Z-79 marking) and are disposable. As the plastic warms up from the surrounding body temperature, the DLT conforms to the anatomy of the patient. This increased malleability, however, makes it more difficult to reposition the same tube. Current DLTs employ high-volume, low-pressure, color-coded cuffs. The bronchial cuff and its pilot balloon/connector are blue. The tracheal cuff and its pilot balloon/connector are clear or white. Cuff inflation pressure requires a balance between preserving an adequate seal and maintaining mucosal perfusion. Measured cuff pressures between 15 and 30 mm Hg achieve these goals.[5-8] In cases involving the use of nitrous oxide, the cuff pressures should be checked periodically.

DLTs come in various French (F) sizes: 28, 32, 35, 37, 39, and 41, and 1 F equals an approximately 0.33-mm measurement of the outer diameter (OD). In most adult men, a 39-F DLT fits well, having adequate length and appropriate diameter, while providing the capability of suctioning or fiberoptic bronchoscopy (FOB), and a 37-F DLT fits most adult women. A radiopaque line may be seen at the end of each lumen to allow for radiographic positioning. A Y-adapter for the proximal end allows ventilation of both lumens through a single circuit. The cross section of the DLT is designed as one round bronchial lumen and one crescent-shaped tracheal lumen. Left- and right-sided DLTs are curved at the distal end to enable advancement into the respective main stem bronchus. DLTs from different manufacturers have their own characteristic feel and slight modifications to the basic design described. The depth required for insertion of the DLT correlates with the height of the patient. For any adult 170 to 180 cm tall, the average depth for a left-sided DLT is 29 cm. For every 10-cm increase or decrease in height, the DLT is advanced or withdrawn 1.0 cm.[9]

2. Advantages

The DLT has inherent advantages. When properly positioned, the DLT allows independent ventilation of each lung in unison or separately. This is a great advantage in cases in which each lung needs to be ventilated using different modalities. Treatment and prevention of desaturation is also easier with DLTs, because CPAP or partial lung inflation is easy to perform on the surgical lung while the opposite lung is ventilated normally. Suctioning and FOB are facilitated by the relatively large luminal accesses into each main stem bronchus. Access beyond each main stem bronchus also allows for egress of gases and lung deflation for surgical exposure. Other advantages include the solid structure and improved cuff seals of the DLTs, which prevent easy dislodgment after proper positioning.

3. Disadvantages

The most significant disadvantages of the DLT are related to its size. Intubation with a DLT is often more difficult than with an SLT.[6] Intubation is even more complex in patients with difficult airway anatomy.[10] In cases of a distorted or compressed tracheobronchial tree, placement of a DLT can be impossible due to its size and rigidity. DLT size can contribute to airway damage during placement and when the device is left in place for a long period. Because of some difficulty managing DLTs in the ICU with regard to weaning and pulmonary toilet, they are often exchanged for SLTs. The process of exchanging a DLT for an SLT can be dangerous, especially after procedures in which airway edema has occurred. Although DLT lumens are relatively large, FOB may be cumbersome due to the extended length of each tube and the

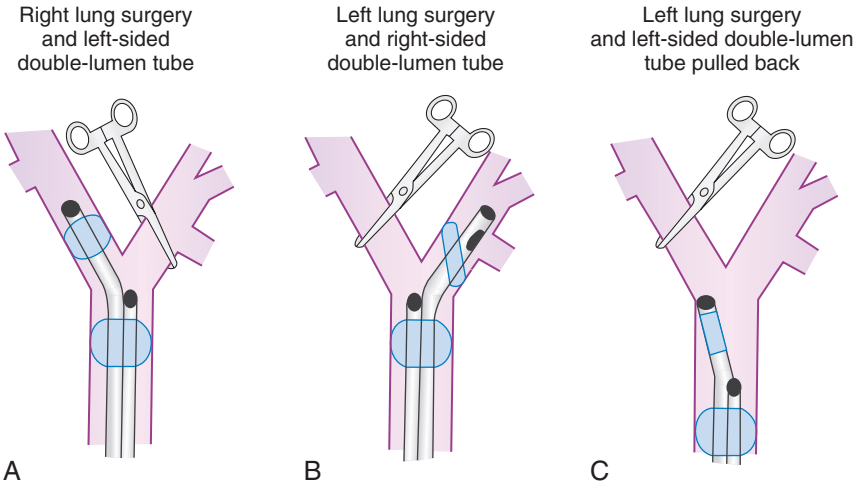

Figure 26-2 Use of left-sided and right-sided double-lumen tubes (DLTs) for left and right lung surgery is indicated by the clamp. When surgery is performed on the right lung, a left-sided DLT should be used **(A).** When surgery is performed on the left lung, a right-sided DLT may be used **(B).** However, because of uncertainty about the alignment of a right upper lobe ventilation slot to the right upper lobe orifice, a left-sided DLT can be used for left lung surgery **(C).** If left lung surgery requires a clamp to be placed high on the left main stem bronchus, the left endobronchial cuff should be deflated, the left-sided DLT pulled back into the trachea, and the right lung ventilated through both lumens (using the DLT as a single-lumen tube). (From Benumof JL: *Anesthesia for thoracic surgery*, Philadelphia, 1987, Saunders.)

narrowed crescent shape of the tracheal lumen. Multiple ports and connections further require a good working knowledge of the DLT anatomy to prevent errors in ventilation and management.

4. Selection

a. RIGHT-SIDED VERSUS LEFT-SIDED DOUBLE-LUMEN TUBES

To minimize tube displacement, it may be recommended that the nonoperated bronchus be intubated (i.e., using a left-sided DLT for a patient undergoing right lung surgery) (Fig. 26-2).[11] However, controversy exists in regard to left lung procedures because of the anatomic variability of the right upper lobe. The bronchial port of a right-sided tube may be difficult to position for adequate lung isolation and ventilation of the right upper lobe bronchus. This can result in difficulties during surgery, including severe hypoxia during isolated right lung ventilation.[12]

Many anesthesiologists prefer to use left-sided DLTs for all lung surgeries (see Fig. 26-2); however, there are insufficient data to support actual increased safety, as opposed to the perception of safety when intraoperative hypoxia, hypercapnia, and high airway pressures are used as criteria.[13,14] If manipulation of the left main stem bronchus is required, the left-sided DLT is withdrawn and repositioned with the bronchial port above the carina. For operations on the left main stem, including sleeve resection, it may be preferable to use a right-sided DLT (Fig. 26-3).

Contraindications for use of a DLT include anatomic barriers that make positioning improbable or dangerous, such as carinal or bronchial lesions, strictures, vascular compression by aortic aneurysm, and aberrant

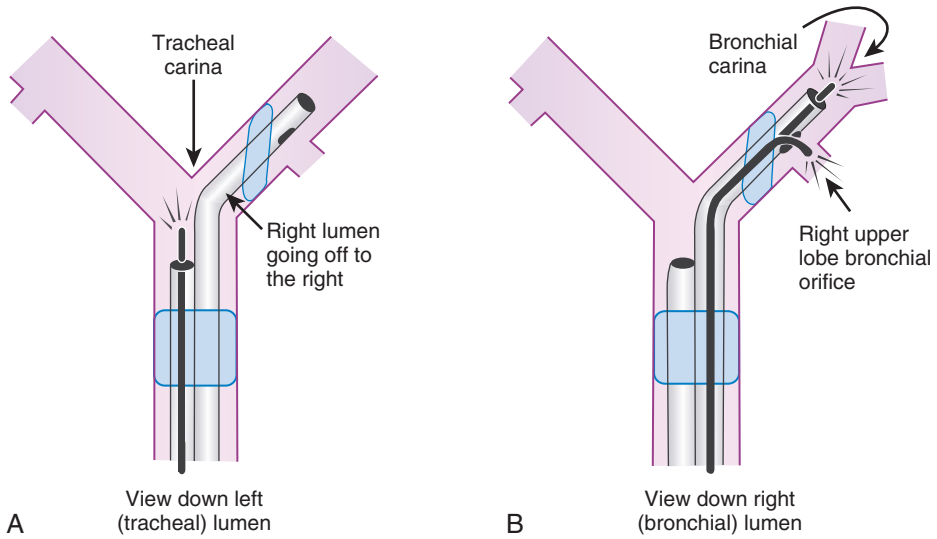

Figure 26-3 Schematic diagram portrays use of a flexible fiberoptic bronchoscope (FFB) to determine the precise position of a right-sided double-lumen tube. **A,** When the FFB is passed down the left (tracheal) lumen, the endoscopist should see a clear, straight-ahead view of the tracheal carina and right lumen going off into the right main stem bronchus. **B,** When the FFB is passed down the right (bronchial) lumen, the endoscopist should see the bronchial carina in the distance; when the FFB is flexed laterally and cephalad and passed through the ventilation slot of the right upper lobe, the bronchial orifice of the right upper lobe should be visible. (From Benumof JL: *Anesthesia for thoracic surgery*, Philadelphia, 1987, Saunders.)

TABLE 26-1
Relation of Flexible Fiberoptic Bronchoscope Size to Double-Lumen Tube Size

FFB OD Size (mm)	DLT Size (F)	Fit of FFB inside DLT
5.6	All sizes	Does not fit
	41	Easy passage
	39	Moderately easy passage
4.9	37	Tight fit, needs lubricant,* hand push
	35	Does not fit
3.6-4.2	All sizes	Easy passage
Approximately 2.0	All sizes	Most operating rooms need special arrangements to obtain this size FFB

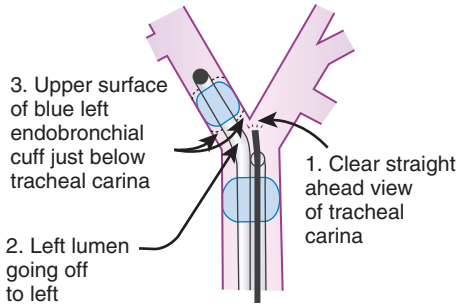

Figure 26-4 Use of a flexible fiberoptic bronchoscope down the right lumen to determine precise position of a left-sided double-lumen tube. The endoscopist should see a clear, straight-ahead view of the tracheal carina (1); the left lumen going off into the left main stem bronchus (2); and the upper surface of the blue left endobronchial cuff just below the tracheal carina (3). (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

bronchus.[6,15,16] Right-sided DLTs may be indicated in cases with tortuosity and compression of the trachea or left main stem bronchus, which can make placement of a left-sided DLT impossible. Newly designed DLTs may be applicable for patients with special conditions including those with unusual anatomic variability.[17]

b. DOUBLE-LUMEN TUBE SIZE

The ideal size of a DLT is one that results in a near-complete seal of the bronchial lumen without inflation of the cuff. The high inflation pressures of a small tube can cause as much mucosal damage as forcing too large a tube into a small bronchus.[18] Even when height- and weight-based size estimates are used, it is impossible to choose the correct size of tube every time.[15,19] Commonly, a 39-F or 41-F DLT is selected for men and a 37-F or 39-F DLT for women of average height and build. The intentional use of smaller DLTs has not had significant clinical benefits.[20] A flexible fiberoptic bronchoscope (FFB) may be passed through the bronchial lumen to assess appropriate diameter and length of the DLT during placement (Table 26-1).

5. Positioning

Malposition of the DLT can lead to life-threatening consequences. Ventilation can be severely impaired, leading to hypoxia, gas trapping, tension pneumothorax, cross-contamination of lung contents, and interference with surgical procedures. Multiple studies have shown that DLTs are often malpositioned.[15,19] On the basis of these studies, indirect visualization with a FFB may be used routinely for confirmation of positioning. Various techniques using a FFB are discussed in the following sections.

a. PLACEMENT OF THE DOUBLE-LUMEN TUBE

DLTs are placed similar to SLTs but with some additional maneuvers and considerations. DLTs are larger in diameter and longer than SLTs, making them more difficult to place. It is important never to force a DLT into position. For laryngoscopy, the shoulder of a Macintosh blade provides better tongue displacement and more space through which to insert the tube. The use of a video laryngoscope has also been described as effective and potentially time-saving.[21] The bronchial tip of the DLT is placed through the cords, and the stylet is then removed to prevent trauma. After the bronchial portion has passed the cords, the DLT must be rotated 90 degrees toward the selected side of the bronchial lumen to sit properly. If resistance is encountered on rotating or advancing the tube, the use of a smaller tube needs to be considered. The average depth of insertion is 29 cm for a 170-cm individual. For each 10-cm increase or decrease in height, the tube depth is increased or decreased by 1 cm, respectively.[15] When the tube depth is reached, the tracheal cuff is inflated, and the patient is connected to the ventilator. Care must be taken not to tear or puncture the tracheal cuff during intubation. For example, covering the teeth with an unopened alcohol swab can minimize cuff damage.

After confirmation of CO_2 return and initiation of ventilation, an FFB is placed through the tracheal lumen (Fig. 26-4). The FFB is advanced, and the carina is identified. The bronchial lumen of the tube must be visualized entering the appropriate main stem bronchus (i.e., the bronchial lumen should be in the left main stem bronchus for a left-sided DLT). The balloon of the bronchial lumen should be inflated under direct vision and should lie just distal to the carina. The tube may have to be repositioned to visualize the balloon. Direct visualization of the balloon inflation helps to confirm tube position and size. Some DLTs have an indicator line just proximal to the bronchial cuff that should sit at the level of the carina. Direct visualization may be necessary to ensure that the bronchial balloon does not herniate over the carina or that the tracheal portion of the DLT does not encroach on the carina (Fig. 26-5).

Determination of right versus left main stem bronchus is done by visualization of the anterior and posterior aspects of the trachea. The anterior of the trachea is identified by the tracheal rings, which extend throughout the anterior two thirds of the trachea. Posteriorly, the trachea consists of the membranous component with longitudinal striations. After the anterior and posterior

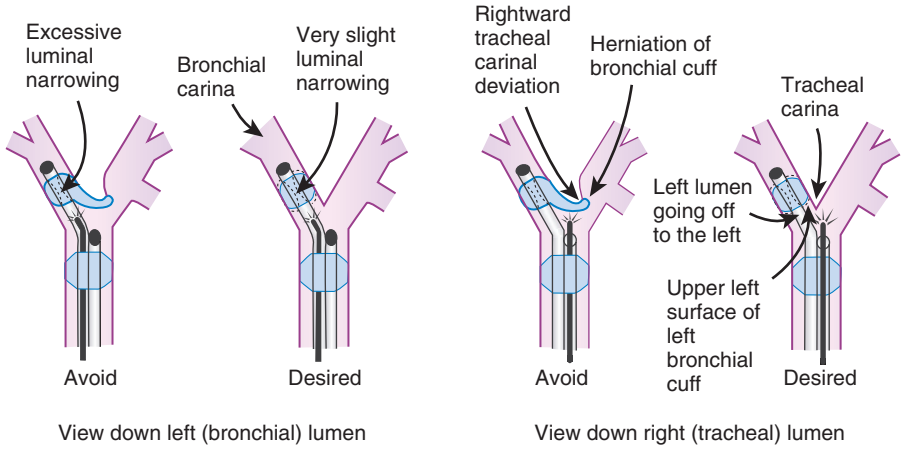

Figure 26-5 Desired views and views to be avoided when using a fiberoptic bronchoscope (FOB) to determine the position of a left-sided, double-lumen tube (DLT). *Left,* When an FOB is passed down the left lumen of a left-sided DLT, the endoscopist should see a slight, left luminal narrowing and a clear, straight-ahead view of the bronchial carina in the distance. Excessive left luminal narrowing should be avoided. *Right,* When the flexible FOB is passed down the right lumen of the left-sided DLT, the endoscopist should see a clear, straight-ahead view of the tracheal carina; the left lumen going off into the main stem bronchus; and the upper surface of the blue, left endotracheal cuff just below the tracheal carina. Excessive pressure in the endobronchial cuff, as manifested by tracheal carinal deviation to the right and herniation of endobronchial cuff over the carina, should be avoided. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

aspects of the trachea are identified, right and left orientation is obvious. It may be necessary to suction the DLT before insertion of the FFB. Lubrication and antifogging agents applied to the FFB can facilitate manipulation and visualization. The appropriate use of antisialagogues can also be useful in limiting secretions before DLT placement.

An alternative method of DLT placement is to use the FFB as an intubating stylet to guide the bronchial tip of the DLT directly into the correct main stem bronchus (Fig. 26-6). This is accomplished by inserting the FFB through the bronchial port of the DLT after the bronchial tip has passed the vocal cords. The FFB is then advanced down the trachea while identifying the anterior-posterior and right-left orientation. The FFB is advanced further to identifying the carina and the right and left main stem bronchi, then advanced into the appropriate bronchus. The DLT is advanced over the FFB. It is then necessary to remove the FFB after confirming that the bronchial tip is not obstructed and is proximal to the secondary bronchial branches. The FFB is then placed in the tracheal lumen to confirm the position of the bronchial cuff and to ensure that the tracheal lumen is not encroaching on the carina. This technique allows for assessment of the carina and tracheal rings and allows placement in tortuous airways. However, it takes more time to perform, and in some patients with poor pulmonary reserve, this extra time can lead to desaturation.

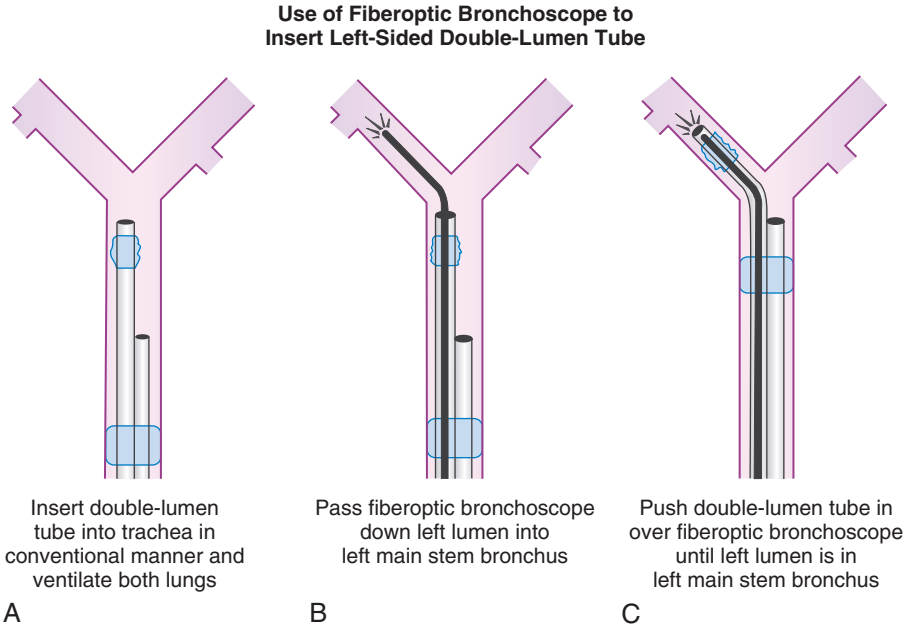

Figure 26-6 A double-lumen tube (DLT) can be put into the trachea in a conventional manner, and both lungs can be ventilated by both lumens **(A).** A flexible fiberoptic bronchoscope (FFB) may be inserted into the left lumen of the DLT through a self-sealing diaphragm in the elbow connector to the left lumen; this allows continued positive-pressure ventilation of both lungs through the right lumen without creating a leak. After the FFB has been passed into the left main stem bronchus **(B),** it is used as a stylet for the left lumen **(C);** the FFB is then withdrawn. Final precise positioning of the DLT is performed with the FFB in the right lumen (see Figs. 26-19 and 26-20). (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

b. CONFIRMATION OF PROPER PLACEMENT

Many maneuvers have been described to assess the proper position of a DLT,[22,23] including visualization of chest excursion while alternately clamping and unclamping the tracheal and bronchial ports, auscultation of lung fields while alternately clamping and unclamping the tracheal and bronchial ports (Fig. 26-7), and radiographic confirmation.[24,25]

The most important advance in checking for the proper position of a DLT is the FFB (Fig. 26-8). Smith and colleagues[26] demonstrated that when the disposable DLT was thought to be in the correct position by auscultation and physical examination, subsequent FOB showed that 48% of the tubes were malpositioned. Malpositions may not be clinically significant and may be missed by the clinician. When using a left-sided DLT, the bronchoscope is usually first introduced through the tracheal lumen to visualize the carina and to ensure that the bronchial cuff is not herniated. The upper surface of the blue endobronchial cuff should be just below the tracheal carina; the blue bronchial cuff of the disposable DLT is easily visualized. The bronchoscope is then passed through the bronchial lumen to identify the left upper lobe bronchial orifice. When a right-sided DLT is used, the carina should be visualized through the tracheal lumen, and the orifice of the right upper lobe bronchus should be identified when the bronchoscope is passed through the right upper lobe ventilating slot of the DLT.

Pediatric FOBs are available in several standard sizes: 5.6-, 4.9-, and 3.6-mm OD. The 4.9-mm OD bronchoscope can be passed through DLTs that are 37 F or larger. A 3.6-mm or smaller diameter bronchoscope is easily passed through all sizes of DLTs.[27-29]

DLT placement must be rechecked when the patient is repositioned, because movement of the tube is common. Training in the use of FFBs may be achieved during evaluation of any SLT-intubated patient and through the use of airway simulation and mannequins.[30]

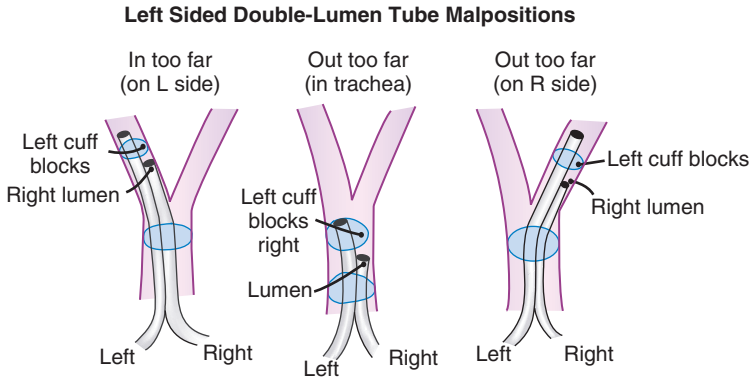
6. Malpositioning and Complications

Use of a DLT is associated with a number of problems, the most important of which is malpositioning (see Fig. 26-7).[26,31] The tube can be malpositioned in several ways.

The DLT may be accidentally directed to the side opposite the desired main stem bronchus. In this case, the lung opposite the side of the connector clamp will collapse. Inadequate separation, increased airway pressures, and instability of the DLT usually occur. Because of the morphology of the DLT curvatures, tracheal or bronchial lacerations may result. If a left-sided DLT is inserted into the right main stem bronchus, it obstructs ventilation to the right upper lobe. It is essential to recognize and correct such a malposition as soon as possible.

The DLT may be passed too far down into the right or the left main stem bronchus. In this case, breath sounds are greatly diminished or not audible over the contralateral side. The tube should be withdrawn until the opening of the tracheal lumen is above the carina.

The DLT may not be inserted far enough, leaving the bronchial lumen opening above the carina. In this position, good breath sounds are heard bilaterally when ventilating through the bronchial lumen, but no breath sounds are audible when ventilating through the tracheal lumen because the inflated bronchial cuff obstructs gas flow from the tracheal lumen. The cuff should be deflated and the DLT rotated and advanced into the desired main stem bronchus.



A right-sided DLT may occlude the right upper lobe orifice. The mean distance from the carina to the right upper lobe orifice is 2.3 ± 0.7 cm in men and 2.1 ± 0.7 cm in women. With right-sided DLTs, the ventilatory slot in the side of the bronchial catheter must overlie the right upper lobe orifice to permit ventilation of this lobe. However, the margin of safety is extremely small and varies from 1 to 8 mm.[32] It is difficult to ensure proper ventilation to the right upper lobe and avoid dislocation of the DLT during surgical manipulation.

The left upper lobe orifice may be obstructed by a left-sided DLT. Traditionally, the take-off of the left upper lobe bronchus was thought to be at a safe distance from the carina and that it would not be obstructed by a left-sided DLT. However, the mean distance between the left upper lobe orifice and the carina is 5.4 ± 0.7 cm in men and 5.0 ± 0.7 cm in women.[33] The average distance between the openings of the right and left lumens on the left-sided disposable tubes is 6.9 cm. An obstruction of the left upper lobe bronchus is possible while the tracheal lumen is still above the carina. There is also a 20% variation in the location of the blue endobronchial cuff on the disposable tubes because this cuff is attached to the tube at the end of the manufacturing process.

Bronchial cuff herniation may occur and obstruct the bronchial lumen if excessive volumes are used to inflate the cuff. The bronchial cuff has also been known to herniate over the tracheal carina and, in the case of a left-sided DLT, to obstruct ventilation to the right main stem bronchus.

A rare complication with DLTs is tracheal laceration or rupture from the stiff tip of the bronchial lumen (Fig. 26-9). Overinflation of the bronchial cuff, inappropriate positioning, and trauma due to intraoperative dislocation that resulted in bronchial rupture have been associated with use of the Robertshaw tube and the disposable DLT.[34] The pressure in the bronchial cuff should be assessed and decreased if the cuff is overinflated. If lung isolation is unnecessary, the bronchial cuff should be deflated and then reinflated slowly to avoid excessive pressure on the bronchial walls. The bronchial cuff should also be deflated during any repositioning of the patient unless lung separation is absolutely required during this time.

In a prospective trial, 60 patients were randomly assigned to two groups. SLV was achieved with an endobronchial blocker or a DLT. Postoperative hoarseness and sore throat were assessed at 24, 48, and 72 hours after surgery. Bronchial injuries and vocal cord lesions were examined by bronchoscopy immediately after surgery. Postoperative hoarseness occurred significantly more frequently in the double-lumen group than the blocker group (44% versus 17%). Similar findings were observed for vocal cord lesions (44% versus 17%). The incidence of bronchial injuries was comparable between groups.[35]

Procedure	Breath sounds heard		
Clamp right lumen; both cuffs inflated	Left	Left and right	Right
Clamp left lumen; both cuffs inflated	None or faint right	None or very	None or faint left
Clamp left lumen; deflate left cuff	Left only or left and faint right	Left and right	Right only or right and faint left

Figure 26-7 Three major malpositions involving a whole lung are possible for a left-sided, double-lumen tube. The tube can be in too far on the left (i.e., both lumens are in the left main stem bronchus), out too far (i.e., both lumens are in the trachea), or down the right main stem bronchus (i.e., at least the left lumen is in the right main stem bronchus). In each of these malpositions, the left cuff, when fully inflated, can completely block the right lumen. Inflation and deflation of the left cuff while the left lumen is clamped creates a breath sound differential diagnosis of tube malposition. *L,* Left; *R,* right. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

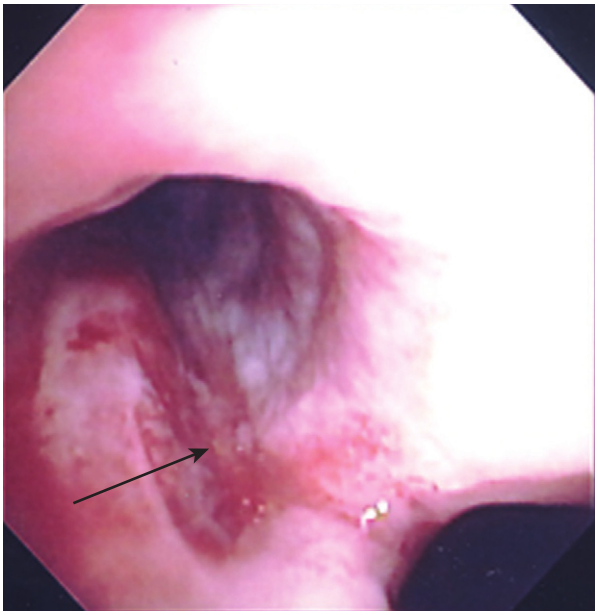

Figure 26-9 Injury *(arrow)* to the main left bronchus.

The most common minor complication is sore throat and temporary hoarseness. Other complications include laryngeal and bronchial injury, tracheobronchial tree disruption,[36] inadvertent suturing of the DLT to thoracic structures, and direct vocal cord injury.[37] Although most of the complications, except malpositioning, have been reported in the older-style DLTs (e.g., Carlens, Robertshaw), the newer designs can also pose risks.[38-40]

7. Exchanging the Double-Lumen Tube for a Single-Lumen Tube

a. PROCEDURE

It is often desirable to replace the DLT with an SLT at the end of the surgical procedure if the patient is to remain intubated postoperatively.

Replacement of a DLT with an SLT can be life-threatening and must be performed with great caution. Before changing out a DLT, the anesthesiologist must ensure that the patient is prepared for reintubation, well preoxygenated and paralyzed. An SLT with stylet, face mask, and suction must be readily available. Individual bronchial suctioning may be considered, followed by bronchial cuff deflation and suctioning of the oropharynx.

Direct laryngoscopy is then performed, preferably with a Miller blade to allow control of the epiglottis. If the DLT and larynx are well visualized, the blade can be passed into the larynx just past the vocal cords. After the laryngoscope is positioned, an assistant deflates the tracheal cuff of the DLT on instruction, and the DLT is retracted under constant direct vision. When the DLT is removed, the assistant hands off the SLT, which is placed directly into the larynx. It is vital not to lose sight of the larynx and not to reposition the laryngoscope blade. Advancement of the Miller blade beyond the vocal cords may not be necessary, and the use of a Macintosh blade may also be adequate; however, the advantages of the techniques described here should be considered. When the SLT is beyond the cords, the cuff is inflated, the patient is ventilated, and CO_2 confirmation is obtained. If, on initial laryngoscopic inspection of the airway, the vocal cords are too edematous, bloody, or difficult to visualize, the tube exchange should be aborted.

b. AIRWAY EXCHANGE CATHETERS

Alternative techniques of tube exchange involve the use of airway exchange catheters (AECs). Of those available, the Cook AECs (CAECs; Cook Critical Care, Bloomington, IN) are easy to use and allow ventilation if the need arises. The technique involves placing an AEC through the existing DLT and then removing the DLT. The tracheal or bronchial port may be used. Although the bronchial port may provide more stability, it requires full extraction of the DLT to get hold of the AEC distally. Care must be taken to keep the AEC in place as the DLT is removed. After the DLT is removed, the SLT is guided over the AEC into the trachea. Then the AEC is removed while the SLT is kept in place. The cuff is inflated, and ventilation with confirmation of CO_2 is then obtained.

AECs are easy to dislodge at any point during the attempted exchange. The fit between the exchanger and the SLT is often such that the SLT becomes caught at the level of the vocal cords. Rotating the SLT with a corkscrew maneuver can overcome this obstruction, but it can also cause dislodgment of the endotracheal tube (ETT) and the AEC.

A combination technique using a tube exchanger under direct vision may be a safer approach. With this technique, the larynx and the DLT are visualized while an AEC is inserted through the DLT. The CAEC is seen passing into the distal airway; then, under direct vision, the DLT is withdrawn and the AEC position is confirmed. The SLT is advanced over the AEC while the larynx is visualized. The tube is guided under direct vision into the larynx, and the AEC is removed. Proper placement is determined by CO_2 detection and bilateral lung auscultation.

Several tube exchangers are commercially available from Cook Critical Care (Bloomington, IN) and Sheridan Catheter Corporation (Argyle, NY). On these tube exchangers, the depth is marked in centimeters. They are available in a wide range of ODs and easily adapted for oxygen insufflation or jet ventilation. The size of the tube exchanger and the size of the tube to be inserted should be tested before use in a patient. The 11-F tube changer can pass through a 35- to 41-F DLT, whereas the 14-F tube exchanger does not pass through a 35-F DLT.

To prevent lung laceration, the tube exchanger should never be inserted against resistance. Because the first generation of tube exchangers was very stiff, there was a risk for tracheal or bronchial laceration. A tube exchanger with a soft flexible tip was released by Cook Critical Care that is safer to use and is less likely to cause airway laceration. A laryngoscope should always be used to facilitate passage of a tube over the airway guide and past the supraglottic tissues.

8. Contraindications

Not all patients requiring lung separation are candidates for a DLT. Contraindications to placement of a DLT can be separated into four categories: (1) known or anticipated technical difficulty in DLT placement, (2) dangerous anatomy, (3) difficult or small airways or small patient, and (4) unstable patient. For these patients, alternative means of lung separation are discussed later.

B. Single-Lumen Tubes

In some situations, lung isolation is required, but the use of a DLT is not practical. In these instances, the use of a modified SLT with integrated blockers (i.e., Univent tube [Fig. 26-10]) or the use of blockers in conjunction with a standard SLT is appropriate.

1. Indications

a. DIFFICULT AIRWAYS

Patients presenting with difficult airway anatomy can be a particular challenge for lung isolation, because the placement of a conventional DLT can be impossible in such patients.[41] Use of an SLT or a Univent tube (Fuji Systems, Tokyo, Japan) is advised, because these devices may be more easily placed than DLTs.[42]

For patients who have an SLT in place and have developed significant airway edema or are in the prone or lateral position and then require lung isolation, use of a bronchial blocker device is the safest technique to invoke lung isolation. Similarly, in patients who have an SLT and develop traumatized or bloodied airways, the insertion of a DLT is very difficult because of inability to visualize the airway anatomy properly through an FOB. The use of an SLT or Univent tube allows large-bore airway suctioning and improved safety for lung isolation.

Postoperative airway edema is inevitable in some cases, and the prospect of changing a DLT to an SLT postoperatively poses too great a risk to the patient. It is worth considering the use of an SLT with a bronchial blocker or a Univent tube. The bronchial blockers can be withdrawn after they are no longer required, without removal of the ETT, and the patient may be transported to the ICU and weaned from the ventilator.

In patients with small airways anatomy, it is often not possible to place a DLT. The use of an SLT (with or without a bronchial blocker) or a Univent tube is the only method of isolating the lung without manual surgical compression of the lung. ETTs as small as 5.0 mm can accommodate blockers. With ETTs that are smaller than a 5.0-mm inner diameter (ID), it is not possible to pass the bronchial blocker and the FFB through the tube. In cases requiring a very small ETT (<5.0 mm), the technique of "main stemming" the ETT to achieve lung isolation can be used.

b. SEGMENTAL LOBE ISOLATION

Selective blockade of lung segments is sometimes desired. In these cases, a bronchial blocker device can be advanced into the desired lung segment.[43] For example, a patient with a left lung pneumonia and right lower lobe and right middle lobe bronchocutaneous fistulas would likely fail this method because of profound desaturation from inability to ventilate the healthy right upper lobe. Selective lobar blockade is considered an advantageous technique to avoid total lung collapse and improve oxygenation.[44] An SLT with a bronchial blocker isolating the right lower lobe and right middle lobe allows adequate saturation while the patient recovers from the pneumonia and the sealing of the bronchocutaneous fistula. It is very difficult to isolate lung segments with a DLT; combined use of a DLT and bronchial blocker devices would likely be required.

2. Disadvantages

a. LUNG DEFLATION

When bronchial blockers are used to isolate the lung, deflation of the blocked lung is slow because the gas trapped in the isolated lung cannot escape and must be reabsorbed. Deflation of the lung with the Univent tube is somewhat faster because of a small lumen extending through the blocker. It is also possible to administer suction to the blocker lumen of the Univent tube and facilitate lung deflation. To accelerate lung deflation, the patient should be ventilated with 100% O_2 for several minutes before bronchial cuff inflation. This accelerates deflation because O_2 is reabsorbed more rapidly than air. If the patient's pulmonary function permits, the patient can be temporarily disconnected from the ventilator circuit and both lungs allowed to deflate spontaneously. The bronchial blocker cuff is then inflated, and the patient is reconnected to the ventilator for SLV.

b. SECRETION REMOVAL

The relatively large lumens of DLTs allow passage of small suction catheters and good removal of blood or secretions. The same is not true of SLTs with bronchial blockers or Univent tubes; suctioning beyond the blockers is not possible during lung isolation. Suctioning of the nonblocked lung is possible, although care must be taken not to dislodge the bronchial blocker from its position.

c. BRONCHIAL MUCOSAL DAMAGE

Unlike DLTs, which use high-volume, low-pressure tracheal and bronchial cuffs, bronchial blockers and Univent tube blockers have low-volume, higher-pressure cuffs. Prolonged inflation of the bronchial balloons can result in mucosal ischemia and irreversible damage. For this reason, it is necessary to deflate the bronchial cuff at the earliest opportunity after lung isolation is no longer required.

Some practitioners advocate techniques of "just-seal" bronchial cuff inflation volumes to minimize mucosal ischemia and damage.[5,8] These techniques may be of little or no value, however, because most of those described are cumbersome and require specialized connectors between the ETT, the blocking device, and the circuit. The cuff pressure required for the bronchial blocker can change because of compliance changes of the ventilated lung.

d. TREATMENT OF DESATURATION

In all cases of SLV and desaturation, it is necessary to ensure that the patient is receiving 100% O_2, ensure adequate ventilation and perfusion, and verify tube and blocker placement. After these issues are resolved, the desaturation can be further treated.

With DLTs, desaturation with SLV can be treated by several maneuvers. The nondependent lung can have CPAP applied, the nondependent lung can be partially expanded, PEEP to the dependent lung can be altered, and if necessary, both lungs can be ventilated temporarily or throughout the procedure. Not all of these options are readily available for SLTs and Univent tubes. Because of the fully obstructive nature of the bronchial blockers, the nondependent lung cannot receive CPAP. Because of the lack of stability of the bronchial blocker line, deflation of the blocker results in shifting of its location, requiring FFB position confirmation each time. Intermittent partial or intermittent full inflation of the isolated lung may be cumbersome.

C. Univent Tubes

1. Anatomy

The Univent tube is a Silastic SLT with a built-in chamber that allows advancement of the integrated blocker (see Fig. 26-10).[41,45,46] The integrated blocker has a small lumen along its entire length that facilitates lung deflation and allows very limited suctioning. At the distal tip of the blocker is a small balloon, and the proximal end of the blocker section contains a lumen cap. This cap needs to be engaged when the blocker balloon is deflated during full lung ventilation. Failure to engage the cap when the blocker balloon is deflated results in a circuit leak. Univent tubes are available in many sizes (Table 26-2), all designated by internal lumen size. Because of the thickness of the tube wall and the integrated blocker chamber, the outer size of these devices is much larger than that of a similarly designated SLT. For example, a 7.5-mm Univent tube has an 11.2-mm OD, compared with the 10.2-mm OD of a 7.5-mm SLT. Despite the larger size, these tubes are very useful.

TABLE 26-2
Comparative Tube Sizes

Univent ID (mm)	Univent Gauge (F) of Single Main Lumen*	Univent OD (mm) Lateral/ AP†	Equivalent SLT OD (mm)	Equivalent DLT (F)
7.5	31	11.0/12.0	9.6	35
8.0	33	11.5/13.0	10.9	37
8.5	35	12.0/13.5	11.6	39
9.0	37	12.5/14.0	12.2	41

*Marked on the tube.

2. Positioning

Before the Univent tube is placed, it must be prepared. Preparation involves removal of the distal and proximal tension wires that help keep the Univent's shape during storage. The cuffs of the bronchial blocker and the main tube should be checked and deflated. After the tip of the bronchial blocker is bent to the shape of a hockey stick, it is retracted into the blocker chamber so that its distal tip is flush with the main tube. The tube is then inserted into the trachea with the tracheal balloon just distal to the cords. The main tube cuff is then inflated and secured at a distance of at least 2 to 3 cm between the distal tip of the main tube and the carina (Fig. 26-11) so that the curved shape of the blocker can be maintained and manipulated as it is advanced beyond the tip of the main tube. Failure to provide this adequate distance between the tip of the main tube and the carina makes directional control of the bronchial blocker very difficult.

Because the material of the Univent tube makes passage of a nonlubricated FFB difficult, the scope should be well lubricated before it is inserted into the main segment of the tube. It is often helpful to attach some type of self-sealing diaphragm device between the Univent tube and the elbow connection of the circuit. This allows continuous ventilation while the blocker is being positioned with the FFB. The FFB is advanced beyond the distal tip of the tube, and the anterior tracheal rings are identified, allowing proper orientation of the right and left main stem bronchi. The blocker portion of the tube is then visually advanced while the main tube position is maintained (see Fig. 26-11).

Placement of the blocker into the desired main stem bronchus is achieved by advancing the blocker with a clockwise or a counterclockwise rotation. If this maneuver is not sufficient to align the blocker into the desired bronchus, the entire Univent tube may be rotated in the desired direction to assist blocker orientation. The blocker is advanced into the correct location, and the locking cuff at the proximal end of the blocker is secured. It is useful

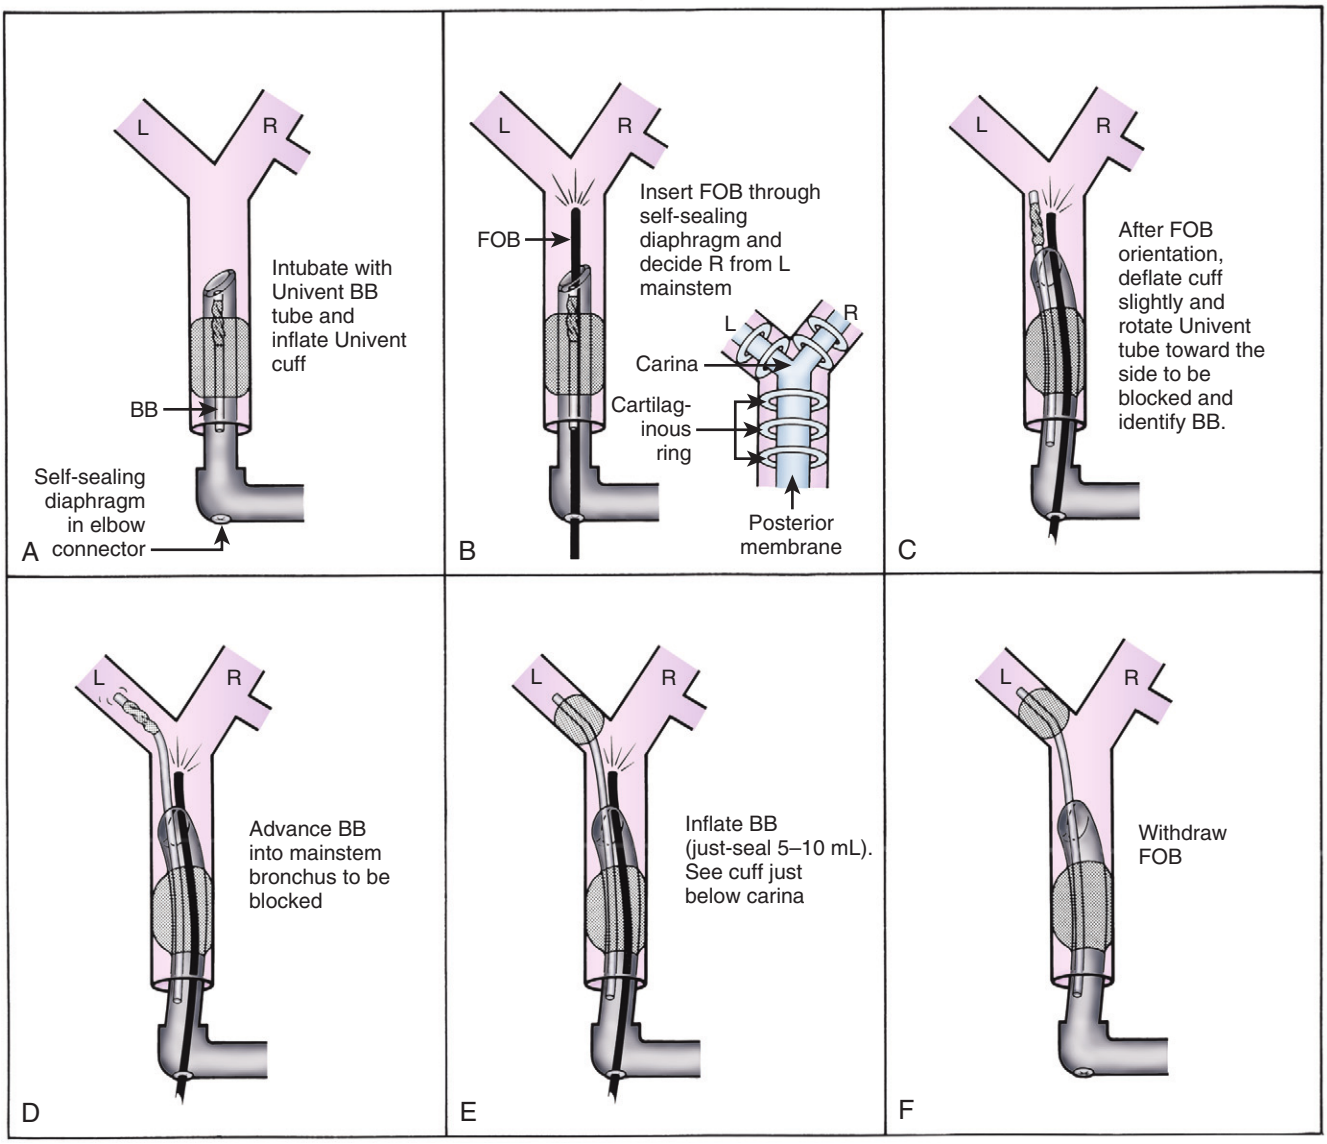

Figure 26-11 Sequential steps of the fiberoptically aided method of inserting and positioning the Univent bronchial blocker *(BB)* in the left main stem bronchus. Ventilation of one or two lungs is achieved by inflating or deflating, respectively, the bronchial blocker balloon. *FOB,* Fiberoptic bronchoscope; *L,* left; *R,* right. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

to note the distance marker on the blocker. If lung isolation is desired, the blocker cuff is inflated (best performed under direct FFB visualization), and the proximal cap of the blocker may be disengaged to enhance lung deflation (see Fig. 26-11). Blind placement of the blocker is often unsuccessful. Blind placement may result in trauma to the tracheobronchial tree, resulting in complications including bleeding or even tension pneumothorax. Limitations of the Univent tube shown in Table 26-3. The solutions related to Univent blocker issues may be applicable to other types of bronchial blockers.

D. Endobronchial Blockers

In modern thoracic anesthesia, lung separation can be achieved with a reusable bronchial blocker.[47] Inflation of the cuff at the distal end of the blocker blocks ventilation to that lung. All modern blockers have a lumen that permits suctioning of the airway distal to the catheter tip, and depending on the clinical circumstance, oxygen can be insufflated through the catheter lumen. The main advantage of these blockers is that they can be placed through a conventional SLT. When a blocker is placed in the right main bronchus, it usually is positioned close to the carina to block the right upper lobe. Because the blocker balloon requires a high distending pressure, it easily slips out of the bronchus into the trachea because of changes in position or surgical manipulation. That movement can result in obstructing ventilation and losing the seal between the two lungs. The loss of lung separation can be a life-threatening situation if it was performed to prevent spillage of pus, blood, or fluid from bronchopulmonary lavage. Bronchial blockers are rarely used for these types of cases in which lung isolation is required.

TABLE 26-3
Univent Bronchial Blocker Tube: Limitations and Solutions

Limitation	Solution
Slow inflation time	Deflate the bronchial blocker cuff, and administer a positive-pressure breath through the main single lumen. Then carefully administer one short, high-pressure (20-30 psi) jet ventilation.
Slow deflation time	Deflate the bronchial blocker cuff, and compress and evacuate the lung through the main single lumen. Then apply suction to the bronchial blocker lumen.
Blockage of bronchial blocker lumen by blood or pus	Suction, use a wire stylet, and then suction.
High-pressure cuff	Use a just-seal volume of air.
Intraoperative leak in bronchial blocker cuff	Ensure the bronchial blocker cuff is positioned below the carina. Increase the inflation volume, and rearrange the surgical field.

1. Indications

Indications for the use of a bronchial blocker are shown in Box 26-2. Because the blocker is placed through an SLT, it avoids the use of a DLT in a patient with a difficult airway. The use of a bronchial blocker also eliminates the need to change a DLT to an SLT at the conclusion of the procedure. This is important, because the airway at the conclusion of the procedure may be different from that in the initial period due to secretions and edema. In the past, Fogarty vascular embolectomy catheters were used for lung separation, but there is no indication for their use in the current practice of thoracic anesthesia. The balloon of the Fogarty is high pressure and low volume, and there is no lumen to allow egress of gas from the lung to facilitate deflation. The characteristics of bronchial blockers are summarized in Table 26-4.

Box 26-2 Indications for the Use of Endobronchial Blockers

Lung isolation versus lung separation
Video-assisted thoracoscopy, increased number of patients who require one-lung ventilation
To avoid the need for tube exchange
Patients with difficult airways
1. Patients after laryngeal or pharyngeal surgery
2. Patients with a tracheotomy
3. Patients with distorted bronchial anatomy (e.g., aneurysm compression, intraluminal tumor)
4. Patients who require nasotracheal intubation
5. Patients with an immobility or kyphoscoliosis

Surgical procedures not involving the lung
1. Esophageal surgery
2. Spinal surgery that requires a transthoracic approach
3. Minimally invasive cardiac surgery

Special management circumstances
1. Video-assisted thoracoscopy in which a quick look or wedge resection of the chest is planned
2. Possible segmental blockade in a patient unable to tolerate one-lung ventilation
3. Morbidly obese patients
4. Small adult or pediatric patients
5. Patients who require intraoperative lung isolation
6. Patients who arrive in the operating room intubated from the intensive care unit

2. Coaxial Stand-Alone Endotracheal Blockers

a. ARNDT ENDOBRONCHIAL BLOCKER

A snare-guided bronchial blocker, the Arndt Endobronchial Blocker (Cook Critical Care), was introduced to address the previously described problems. It is a wire-guided catheter with a loop snare (Fig. 26-12). A fiberscope is passed through the loop of the bronchial blocker and then guided into the desired bronchus. The

TABLE 26-4
Characteristics of Endobronchial Blockers

Characteristics	Arndt Blocker	Cohen Blocker	Uniblocker	EZ-Blocker
Size	9 F, 7 F, 5 F (pediatric)	9.0 F	9.0 F, 5.0 F (pediatric)	7.0 F
Guidance feature	Wire loop to snare the FB	Deflecting tip	Prefixed bend	Double-lumen bifurcated tip
Recommended ETT size (mm)	9-F 8.0 ETT 7-F 7.0 ETT 5-F 4.5 ETT	8.0 ETT	8.0 ETT	8.0 ETT
Central lumen	1.8 mm	1.8 mm	2.0 mm	1.4 mm (divided in half)
Murphy eye	Only in the 9-F device	Yes	No	No
Disadvantages	BB not visualized during insertion	Expensive	No steering mechanism; prefixed bend	Each lumen is too small; impossible to suction

BB, Bronchial blocker; *ETT,* endotracheal tube; *FFB,* flexible fiberoptic bronchoscope.

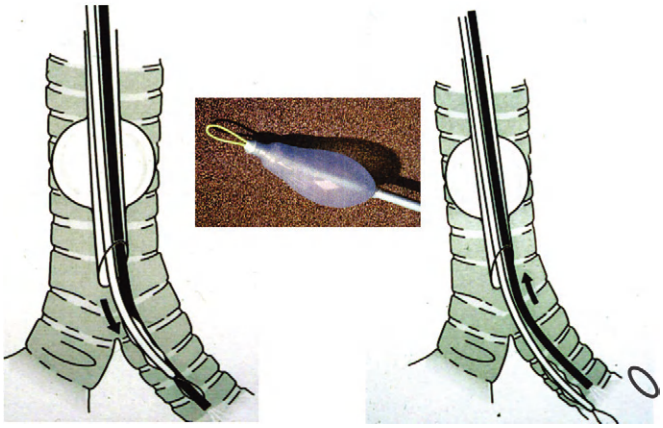

Figure 26-12 Arndt endobronchial blocker.

blocker is then slid distally over the fiberscope and into the selected bronchus. Bronchoscopic visualization confirms blocker placement and bronchial occlusion (Fig. 26-13).

This balloon-tipped catheter has a hollow lumen of 1.6 mm, which allows suction to facilitate the collapse of the lung and insufflation of oxygen to the nondependent lung. The balloon is available in a spherical or elliptic shape. The set contains a multiport adapter (Fig. 26-14) that allows uninterrupted ventilation during positioning of the blocker. The wire may then be removed, and a 1.6-mm lumen may be used as a suction port or for oxygen insufflation. In the first generation of this device, it was not possible to reinsert the string after it had been pulled out, losing the ability to redirect the bronchial blocker if necessary. External reinforcement of the wire allows its reintroduction through the lumen. The OD necessitates a large SLT (at least 8.0 mm) to accommodate the bronchial blocker. The Arndt blocker is available in a 7-F size for adults and in a 5-F pediatric size. A disadvantage of the Arndt blocker is that it is advanced blindly over the FFB into the desired main bronchus. In some cases, the tip of the blocker may get caught at the main carina or at the Murphy eye of the SLT.

b. COHEN FLEXITIP ENDOBRONCHIAL BLOCKER

The Cohen Flexitip Endobronchial Blocker (Cook Critical Care) is designed for use through an SLT with the aid of a small-diameter (4.0-mm) FOB (Fig. 26-15).[48] The blocker has a rotating wheel that deflects the soft tip by

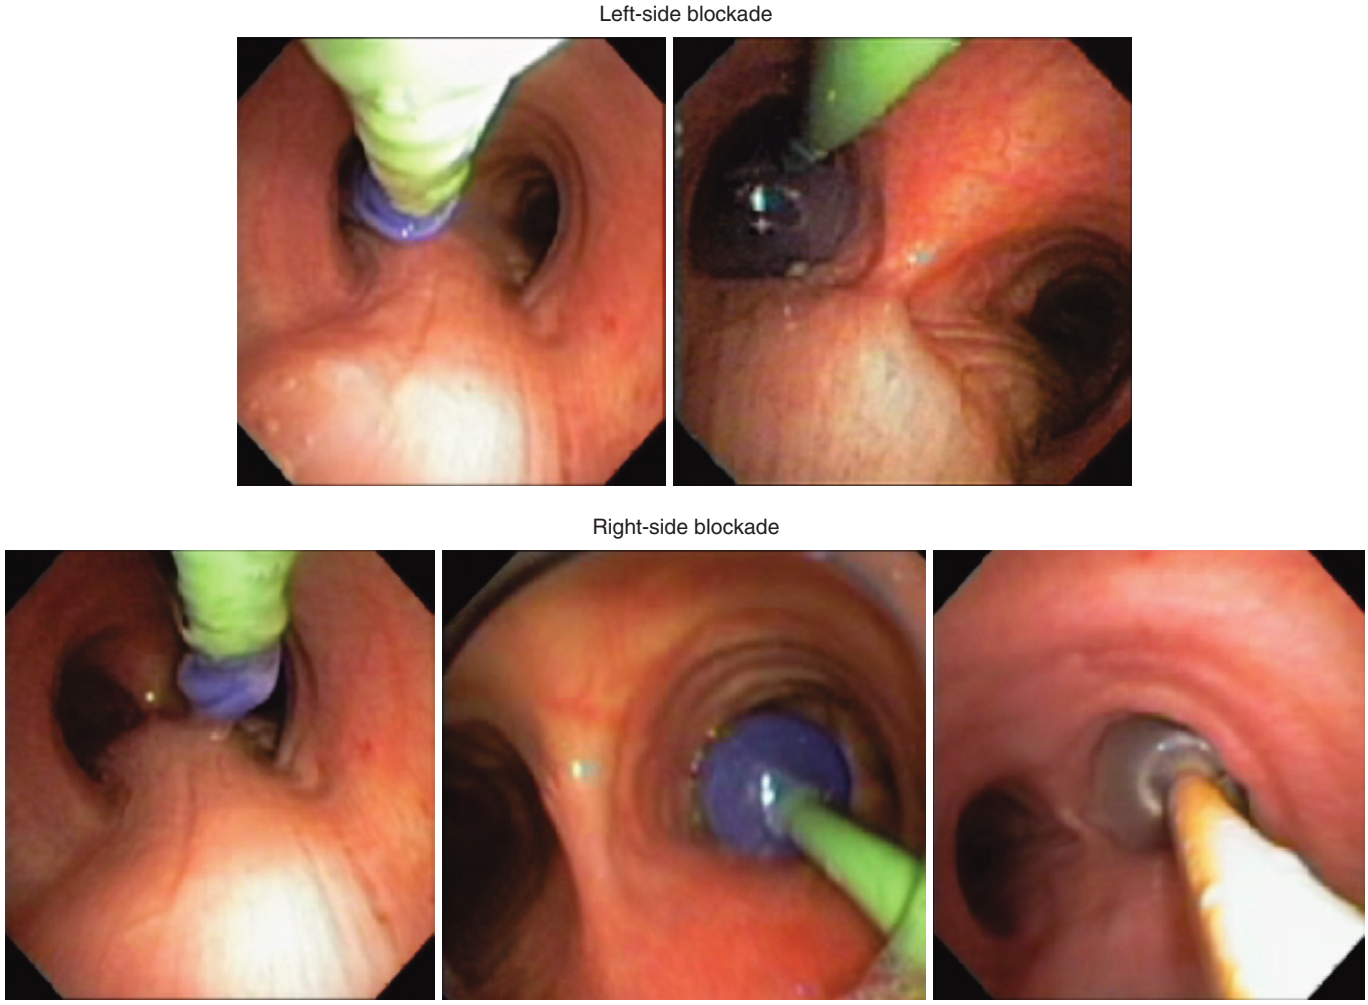

Figure 26-13 *Top,* Left main stem bronchus bronchial blocker in position before *(left)* and after *(right)* "just-seal" inflation. *Bottom left,* Right main stem bronchus bronchial blocker in the entering position. *Bottom center,* Bronchial blocker is too deep, occluding only the bronchus intermedius. *Bottom right,* Bronchial blocker in the right main stem bronchus with a just-seal inflation.

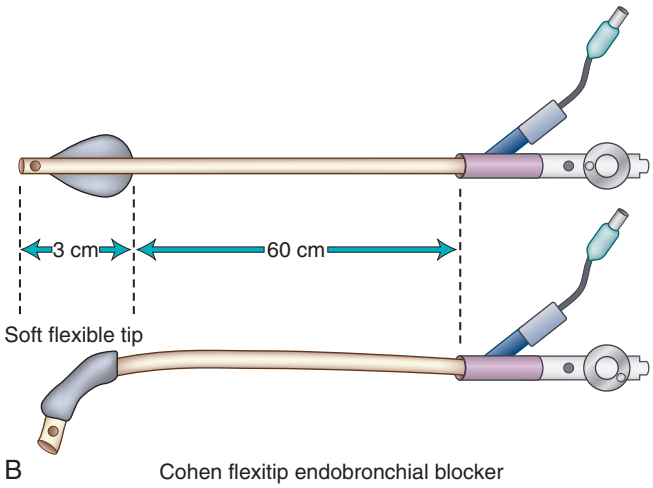

Figure 26-15 Cohen Flexitip endobronchial blocker. **A,** Equipment. **B,** Diagram.

more than 90 degrees and easily directs it into the desired bronchus. The blocker cuff is a high-volume, low-pressure balloon inflated through a 0.4-mm lumen inside the wall of the blocker. Its pear shape provides an adequate seal of the bronchus. It takes 6 to 8 mL of air to seal the bronchus with the cuff. The distinctive blue cuff is easily recognizable by FOB. It is best to inflate the cuff under direct vision by FOB, which is particularly important during right-sided blockade. In this case, the cuff is inflated near the carina, and proper position and cuff inflation are critical. The 9-F blocker has a central main lumen (1.6 mm) that allows limited suctioning of secretions and insufflation of oxygen to the collapsed lung.

c. UNIBLOCKER

Fuji Systems introduced a 9-F, balloon-tipped, angled blocker with a multiple-port adapter that is essentially the same design as the Univent tube blocker, but it can be used as an independent blocker passed by means of a special connector through a standard ETT (Fig. 26-16). It has a prefixed bend to facilitate insertion into the desired bronchus. This blocker is also available in a 5.0-F size for the pediatric population.

d. EZ-BLOCKER

The latest addition to the endobronchial blocker design is the EZ-Blocker (IQ Medical Ventures, Rotterdam, The Netherlands). It is a 7-F, four-lumen, 75-cm, disposable endobronchial blocker used to facilitate selective lung ventilation (Fig. 26-17). It has a symmetrical, Y-shaped bifurcation, and both branches have an inflatable cuff on each arm and a central lumen. The bifurcation resembles the bifurcation of the trachea. During insertion through a standard ETT, each of the two distal ends is placed into a main stem bronchus. The selected lung is isolated by inflating the blocker's balloon to the least volume necessary to occlude the main stem under bronchoscopic visualization. This device should offer an advantage during bilateral procedures, because each lung can be deflated without the need for repositioning the blocker. The clinical experience with this device is limited.

The effectiveness of lung isolation with three devices—the left-sided Broncho-Cath DLT, the Univent torque-control blocker, and the wire-guided Arndt—has been compared in a prospective, randomized trial. There was no significant difference in tube malpositions for the three devices, but it took longer to position the Arndt

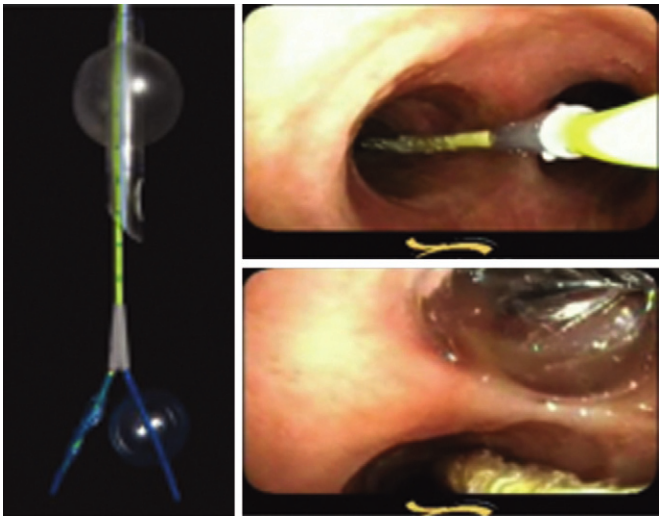

Figure 26-17 EZ-Blocker: device, insertion, and deployment.

blocker (86 versus 56 seconds) than the left-sided DLT and the Univent. Excluding the time for tube placement, the Arndt group also took longer for the lung to collapse (26 minutes), compared with the DLT group (18 minutes) or the Univent group (19.5 minutes). Unlike the other two groups, most of the Arndt patients required suction to achieve lung collapse. After lung isolation was achieved, overall surgical exposure was rated excellent for the three groups (Fig. 26-18). One minute longer to position a bronchial blocker or 6 minutes longer to collapse the lung with the bronchial blocker is insignificant considering the length of the thoracic procedure. The risk-benefit ratio and the patient safety profile for each patient and the clinical experience of the anesthesiologist should be considered when choosing the method for lung isolation.[49,50]

Another study evaluated the use of the Cohen blocker, the Arndt blocker, the Uniblocker, and a DLT in four groups of 26 patients in each group. The investigators found no differences among the groups in the time taken to insert these lung isolation devices or in the quality of the lung collapse.[51] The grading was done by the operating surgeons, who were blinded to which device was used. The number of cuff dislocations was higher among

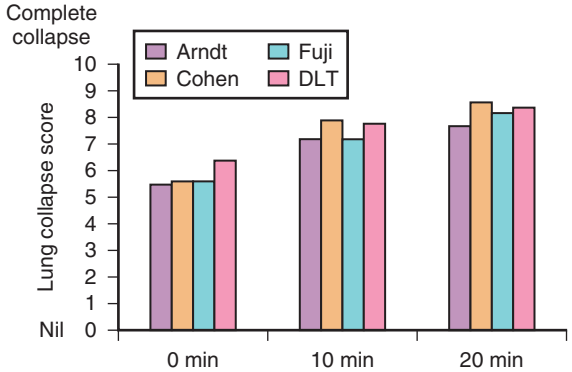

Figure 26-18 Comparison of lung collapse times for three bronchial blockers and a double-lumen tube.

the bronchial blocker groups, which was highest with the Arndt blocker, possibly because the study protocol used the elliptical cuff. Regardless of the type of bronchial blocker or DLT selected to provide SLV, the choice of technique depends on the clinical circumstances and the physician's experience and comfort with a particular device. However, the clinician should not limit his or her practice to the use of only one device but rather be versatile and comfortable in the use of several.

It is possible to perform lung isolation without the use of specialized tubes. In these cases, a bronchial blocking device is inserted through the lumen of an SLT (Fig. 26-19) or outside the SLT between the tracheal cuff and the trachea (Fig. 26-20). Placement is confirmed by FOB.

Any device that has a balloon-tipped catheter can be used as a bronchial blocker (see Fig. 26-19).[52] The most common devices used are Fogarty embolectomy catheters and the Cook bronchial blockers.[53]

a. FOGARTY CATHETERS

The Fogarty catheters come with a rigid wire stylet in place. This allows the creation of a hockey-stick curve at the distal end of the catheter, facilitating directional control of the blocker tip. After the catheter is positioned by FFB, the stylet is removed and a stopcock is placed over the balloon port. Under FFB visualization, the balloon is inflated until the desired lumen is occluded. The Fogarty is then secured to the ETT. The main disadvantage of this device is the inability to suction or insufflate distal to the high-pressure, low-volume cuff.

b. ARNDT AND COHEN BRONCHIAL BLOCKERS

Cook Critical Care has produced two specialized bronchial blockers, the Arndt and Cohen bronchial blockers. Each blocker uses a high-volume, low-pressure cuff and is introduced through a multiport airway adapter. This adapter has a sealing diaphragm that allows passage of blockers of different sizes and incorporates a separate port for introduction of the FFB. The multiport adapter can be used with any stand-alone bronchial blocker.

The Arndt bronchial blocker comes in various sizes and has a small central lumen to allow minimal insufflation and suctioning. It has a monofilament guide loop through which an FFB can be passed. On placement of the FFB in the desired tip position, release of the loop snare and advancement of the blocker to the tip of the FFB places the bronchial blocker in position while releasing the FFB from the loop. The Cohen bronchial blocker also comes in various sizes and employs a directional tip, which potentially makes placement of this device easier than placement of the Arndt bronchial blocker.

The main disadvantage of these commercial blockers is that their ODs are greater than those of the Fogarty catheters, making placement in ETTs with an ID smaller than 6.0 mm difficult to impossible. When a small ETT (<6.0-mm ID) is used, a Cook multiport adapter with a small Fogarty catheter may be preferred.

3. Para-axial Endotracheal Blockers

The advantage of placing the bronchial blocker device outside the SLT is that this method allows blocker placement with smaller ETTs because the blocker does not

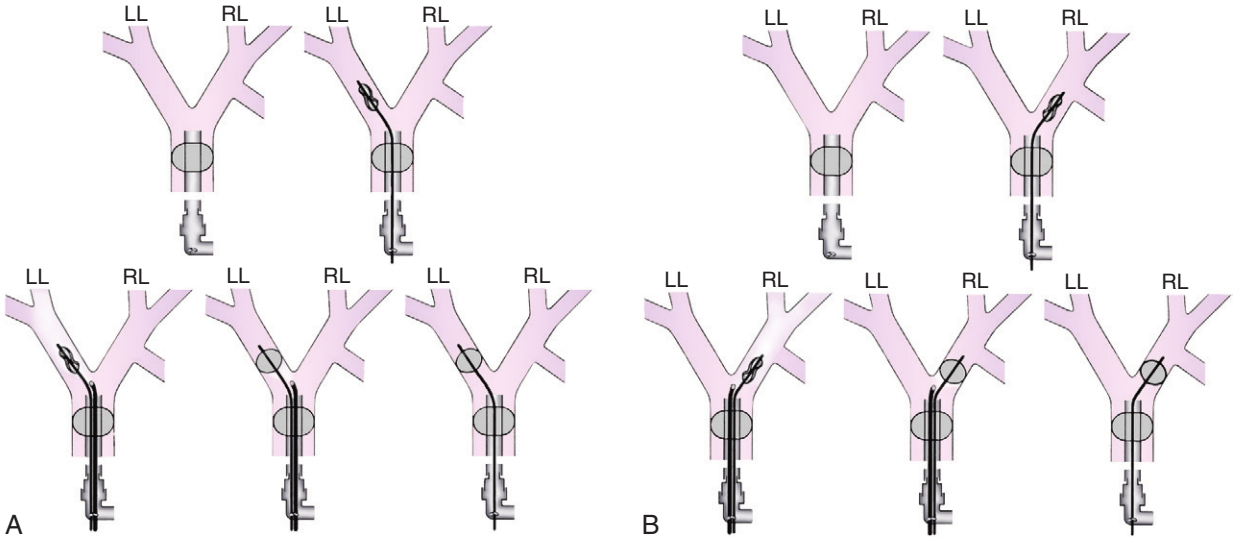

Figure 26-19 Sequence for lung separation with a single-lumen tube (SLT) and a bronchial blocker within the SLT. **A,** Left lung *(LL)* bronchial blocker. **B,** Right lung *(RL)* bronchial blocker. The bronchial blocker (Fogarty embolectomy catheter) is placed in the correct main stem bronchus under fiberoptic vision. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

share the ETT lumen (see Fig. 26-20). It is often easier to position the bronchial blocker with this method, because the blocker and the FFB do not become caught up with each other within the ETT lumen. Disadvantages of this para-tube technique include the need to perform laryngoscopy to place the bronchial blocker into the trachea, the need to deflate the tracheal cuff while positioning the bronchial blocker, and the potential of rupturing the ETT cuff while manipulating the bronchial blocker. Because of these disadvantages, a coaxial placement may be advised, provided ETT lumen size is not an issue.

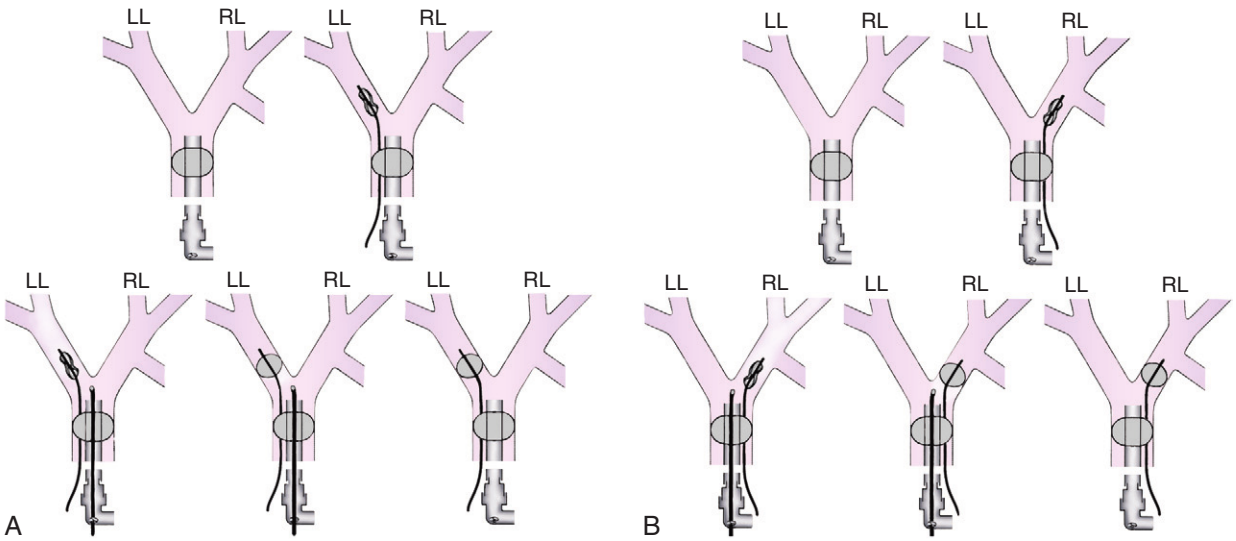

Figure 26-20 Separation of two lungs with a single-lumen tube (SLT), flexible fiberoptic bronchoscope (FFB), and a left lung **(A)** and a right lung **(B)** bronchial blocker that is outside the SLT. The SLT is inserted, and the patient is ventilated (*upper left diagrams*). The bronchial blocker is passed alongside the indwelling endotracheal tube (*upper right diagrams*). The FFB is passed through a self-sealing diaphragm in the elbow connector to the endotracheal tube and is used to place the bronchial blocker into the appropriate main stem bronchus under direct vision (*lower left diagrams*). The balloon on the bronchial blocker is inflated under direct vision and is positioned just below the tracheal carina (*lower middle diagrams*). During insertion and use of the FFB *(lower panels),* the self-sealing diaphragm allows the patient to continue to receive positive-pressure ventilation around the FFB but within the lumens of the ETT. *LL,* Left lung; *RL,* right lung. (From Benumof JL: *Anesthesia for thoracic surgery,* Philadelphia, 1987, Saunders.)

V. PEDIATRIC LUNG ISOLATION

A. Ventilation-Perfusion During Thoracic Surgery

Ventilation is normally distributed preferentially to dependent regions of the lung so that there is a gradient of increasing ventilation from the most nondependent to the most dependent lung segments. Because of gravitational effects, perfusion normally follows a similar distribution, with increased blood flow to dependent lung segments. Ventilation and perfusion are normally well matched. During thoracic surgery, several factors act to increase the $\dot{V}/\dot{Q}$ mismatch. General anesthesia, neuromuscular blockade, and mechanical ventilation cause a decrease in functional residual capacity (FRC) of both lungs. Compression of the dependent lung in the lateral decubitus position can cause atelectasis. Surgical retraction or SLV, or both, can result in collapse of the operative lung. Hypoxic pulmonary vasoconstriction, which acts to divert blood flow away from the underventilated lung, thereby minimizing the $\dot{V}/\dot{Q}$ mismatch, may be diminished by inhalational anesthetic agents and other vasodilating drugs. These factors apply to infants, children, and adults. The overall effect of the lateral decubitus position on $\dot{V}/\dot{Q}$ mismatching is different in infants than in older children and adults.

In adults with unilateral lung disease, oxygenation is optimal when the patient is placed in the lateral decubitus position with the healthy lung dependent and the diseased lung nondependent.[54] Presumably, this is related to an increase in blood flow to the dependent, healthy lung and a decrease in blood flow to the nondependent, diseased lung resulting from the hydrostatic pressure (or gravitational) gradient between the two lungs. This phenomenon promotes $\dot{V}/\dot{Q}$ matching in the adult patient who is undergoing thoracic surgery in the lateral decubitus position.

In infants with unilateral lung disease, on the other hand, oxygenation is improved when the healthy lung is nondependent.[55] Several factors account for this discrepancy between adults and infants. Infants have a soft, easily compressible rib cage that cannot fully protect the underlying lung. The FRC is closer to the residual volume, making airway closure likely to occur in the dependent lung even during tidal breathing.[56] When the adult is placed in the lateral decubitus position, the dependent diaphragm has a mechanical advantage because it is "loaded" by the abdominal hydrostatic pressure gradient. This pressure gradient is reduced in infants, reducing the functional advantage of the dependent diaphragm. The infant's small size also results in a reduced hydrostatic pressure gradient between the nondependent and dependent lungs. Consequently, the favorable increase in perfusion to the dependent, ventilated lung is reduced in infants.

The infant's increased O_2 requirement, coupled with a small FRC, predisposes to hypoxemia. Infants normally consume 6 to 8 mL of O_2/kg/min, compared with a normal O_2 consumption in adults of 2 to 3 mL/kg/min.[57] For these reasons, infants are at increased risk for significant O_2 desaturation during surgery in the lateral decubitus position.

B. Indications and Techniques for Single-Lung Ventilation in Infants and Children

Before 1995, almost all thoracic surgery in children was performed by thoracotomy. In most cases, anesthesiologists ventilated both lungs with a conventional ETT, and surgeons retracted the operative lung to gain exposure to the surgical field. During the past decade, the use of video-assisted thoracoscopic surgery (VATS) has dramatically increased in both adults and children. Reported advantages of VATS include smaller chest incisions, reduced postoperative pain, and more rapid postoperative recovery compared with thoracotomy.[58-60] Advances in surgical technique as well as technology, including high-resolution microchip cameras and smaller endoscopic instruments, have facilitated the application of VATS in smaller patients.

VATS is being used extensively for pleural débridement in patients with emphysema, lung biopsy, or wedge resections for interstitial lung disease; mediastinal masses; or metastatic lesions. More extensive pulmonary resections, including segmentectomy and lobectomy, have been performed for lung abscess, bullous disease, sequestrations, lobar emphysema, cystic adenomatoid malformation, and neoplasms. In selected centers, more advanced procedures have been reported, including closure of patent ductus arteriosus, repair of hiatal hernias, and anterior spinal fusion.

VATS can be performed while both lungs are being ventilated with the use of CO_2 insufflation and placement of a retractor to displace lung tissue in the operative field. However, SLV is extremely desirable during VATS because lung deflation improves visualization of thoracic contents and may reduce lung injury caused by the use of retractors.[11] There are several different techniques that can be used for SLV in children.

C. Single-Lumen Tube

The simplest means of providing SLV is to intubate the ipsilateral main stem bronchus with a conventional SLT.[61] When the left bronchus is to be intubated, the bevel of the ETT is rotated 180 degrees and the head is turned to the right.[62] The ETT is advanced into the bronchus until breath sounds on the operative side disappear. An FFB may be passed through, or alongside, the ETT to confirm or guide placement. When a cuffed ETT is used, the distance from the tip of the tube to the distal cuff must be shorter than the length of the bronchus, so that the cuff is not entirely in the bronchus.[63] This technique is simple and requires no special equipment other than an FFB. This may be the preferred technique of SLV in emergency situations such as airway hemorrhage or contralateral tension pneumothorax.

Problems can occur when using an SLT for SLV. If a smaller, uncuffed ETT is used, it may be difficult to provide an adequate seal of the intended bronchus. This may prevent the operative lung from adequately collapsing or fail to protect the healthy, ventilated lung from contamination by purulent material from the contralateral lung. One is unable to suction the operative lung

using this technique. Hypoxemia may occur because of obstruction of the upper lobe bronchus, especially when the short right main stem bronchus is intubated.

Variations of this technique have been described, including intubation of both bronchi independently with small ETTs.[64-67] One main stem bronchus is initially intubated with an ETT, after which another ETT is advanced over an FFB into the opposite bronchus.

D. Balloon-Tipped Bronchial Blockers

A Fogarty embolectomy catheter or an end-hole, balloon wedge catheter may be used for bronchial blockade to provide SLV.[52,68-70] Placement of a Fogarty catheter is facilitated by bending the tip of its stylet toward the bronchus on the operative side. An FFB may be used to reposition the catheter and confirm appropriate placement. When an end-hole catheter is placed outside the ETT, the bronchus on the operative side is initially intubated with an ETT. A guidewire is then advanced into that bronchus through the ETT. The ETT is removed, and the bronchial blocker is advanced over the guidewire into the bronchus. An ETT is then reinserted into the trachea alongside the blocker catheter. The catheter balloon is positioned in the proximal main stem bronchus under fiberoptic visual guidance. With an inflated bronchial blocker balloon, the airway is completely sealed, providing more predictable lung collapse and better operating conditions than with an ETT in the bronchus.

A potential problem with this technique is dislodgment of the bronchial blocker balloon into the trachea. The inflated balloon blocks ventilation to both lungs and prevents collapse of the operated lung. The balloons of most catheters currently used for bronchial blockade have low-volume, high-pressure properties, and overdistention can damage or even rupture the airway.[71] One study, however, reported that bronchial blocker cuffs produced lower ratios of cuff to tracheal pressure than DLTs do.[72] When closed-tip bronchial blockers are used, the operative lung cannot be suctioned, and CPAP cannot be provided to the operative lung if needed.

Adapters have been used that facilitate ventilation during placement of a bronchial blocker through an indwelling ETT.[73,74] A 5-F endobronchial blocker that is suitable for use in children with a multiport adapter and FFB has been described (Cook Critical Care).[75] The risk of hypoxemia during blocker placement is diminished, and repositioning of the blocker may be performed with FFB guidance during surgery. Even with an FFB with a 2.2-mm OD, the indwelling ETT must have an ID of 5.0 mm or larger to allow passage of the catheter and FFB. This technique typically is limited to children older than 18 months to 2 years.

E. Univent Tube

The Univent tube is a conventional ETT with a second lumen containing a small tube that can be advanced into a bronchus.[45,76,77] A balloon located at the distal end of this small tube serves as a blocker. Univent tubes require an FFB for successful placement. Univent tubes are available in sizes as small as 3.5- and 4.5-mm ID for use in children older than 6 years of age.[78] Because the blocker tube is firmly attached to the main ETT, displacement of the Univent blocker balloon is less likely than when other bronchial blocker techniques are used. The blocker tube has a small lumen, which allows egress of gas and can be used to insufflate O_2 or suction the operated lung.

A disadvantage of the Univent tube is the large amount of cross-sectional area occupied by the blocker channel, especially in the smaller tubes. Smaller Univent tubes have a disproportionately high resistance to gas flow.[79] The Univent tube's blocker balloon has low-volume, high-pressure characteristics, and mucosal injury can occur during normal inflation.[80,81]

F. Double-Lumen Tubes

All DLTs are essentially two tubes of unequal length molded together. The shorter tube ends in the trachea and the longer tube in the bronchus. Marraro described a DLT for infants that consists of two separate uncuffed ETTs of different length attached longitudinally.[82] This tube is not available in the United States. DLTs for older children and adults have cuffs located on the tracheal and bronchial lumens. The tracheal cuff, when inflated, allows PPV. The inflated bronchial cuff allows ventilation to be diverted to either or both lungs and protects each lung from contamination from the contralateral side.

Conventional plastic DLTs, previously available only in adult sizes (35, 37, 39, and 41 F), are now available in smaller sizes. The smallest cuffed DLT is 26 F (Rusch, Duluth, GA) and may be used in children as young as 8 years of age. DLTs are also available in sizes 28 and 32 F (Mallinckrodt Medical, St. Louis, MO), which are suitable for children 10 years of age or older.

DLTs are inserted in children by the same technique as is used in adults.[83] The tip of the tube is inserted just beyond the vocal cords, and the stylet is withdrawn. The DLT is rotated 90 degrees to the appropriate side and then advanced into the bronchus. In the adult population, the depth of insertion is directly related to the height of the patient.[84] No equivalent measurements are yet available in children. If FOB is to be used to confirm tube placement, an FFB with a small diameter and sufficient length must be available.[85]

A DLT offers the advantage of ease of insertion as well as the ability to suction and oxygenate the operative lung with CPAP. Left-sided DLTs are preferred to right-sided instruments because of the shorter length of the right main bronchus.[19] Right-sided DLTs are more difficult to position accurately because of the greater risk of right upper lobe obstruction.

DLTs are safe and easy to use. There have been very few reports of airway damage from DLTs in adults and none in children. Their high-volume, low-pressure cuffs should not damage the airway if they are not overinflated with air or distended with nitrous oxide while in place.

There is significant variability in overall size and airway dimensions in children, particularly in teenagers. For average-sized children 8 to 10 years of age, a 26-F DLT may be appropriate. However, in patients 11 to 14 years of age, appropriate DLT size may range from 26 to 32 F.

Estimation of the appropriate-sized cuffed-ETT may be used to correlate outer diameter measurements for proper DLT selection in these age groups. Difficulty in selection of DLT size contributes to use of other SLV techniques. Ultimately, proper evaluation of the patient with knowledge of anesthetic and surgical procedure requirements will determine proper modality selection and patient safety.

VI. CONCLUSIONS

The anesthesiologist caring for patients who require SLV and lung isolation faces many challenges. An understanding of the primary underlying lesion, as well as associated anomalies that may affect perioperative management, is paramount. A working knowledge of respiratory physiology and anatomy is required for the planning and execution of appropriate intraoperative care. Familiarity with a variety of techniques for SLV suited to the patient's needs allows maximal surgical exposure while minimizing trauma to the lungs and airways.

VII. CLINICAL PEARLS

- Lung isolation should be performed by well-trained and experienced practitioners who should understand the significant risks and benefits to such techniques.
- Absolute indications for lung separation include isolation of infection, contamination, or hemorrhage; control of ventilation distribution; and unilateral bronchopulmonary lavage.
- Relative indications for lung separation include surgical exposure and severe hypoxemia related to unilateral lung disease.
- Double-lumen tubes (DLTs) come in sizes 28, 32, 35, 37, 39, and 41 F, and the appropriate length is based on height, build, and airway examination. Positioning should be confirmed by flexible fiberoptic bronchoscopic (FFB) visualization, selective ventilation auscultation, or radiographic studies.
- DLTs are advantageous because they provide the capability of independent bilateral lung ventilation, bronchial suctioning, lung deflation, and stability, but they have the disadvantage of large size, rigidity, and difficulty in management for prolonged ventilation.
- For patients with difficult airways, anatomic anomalies, tracheal obstructions, tracheal-vascular distortions, or need for segmental lung isolation, the use of single-lumen tube (SLT) isolation devices should be strongly considered.
- Disadvantages to SLT isolation techniques include difficulty with lung deflation, difficulty suctioning the isolated lung, difficulty with stability and positioning, and inability to independently ventilate the isolated lung portion.
- Univent tubes are SLTs with an external bronchial blocker attachment; they can be used as an effective device for lung isolation, including large segmental-lobar isolation.
- Bronchial blockers come as stand-alone devices and can be used with SLTs or DLTs that have a low-volume, high-pressure cuff system; they may be used paraaxially or axially for whole or segmental lung isolation.
- Pediatric lung isolation techniques are similar, if not identical, to those used for adults, although SLT techniques are often used; however, pediatric anatomy and physiology differs from that of adults in regard to positioning and ventilation.

I. COMBITUBE

A. Use of the Endotracheal Tube for Intubation and Ventilation

Rapid establishment of a patent airway to facilitate adequate ventilation during cardiopulmonary resuscitation (CPR) is the primary task of the rescuer. Mouth-to-mouth ventilation carries the disadvantages of possible gastric insufflation and the danger of aspiration. Endotracheal intubation remains the gold standard in airway maintenance, but this skill is acquired only after intensive training and requires constant practice. The people performing resuscitation procedures often are untrained in intubation, which is sometimes difficult or impossible even for skilled personnel.[1] It requires good exposure of the patient's airway, a skilled endoscopist, and equipment or facilities for intubation. Because the main objectives of airway management are ventilation and oxygenation, the need arises for a simple and efficient alternative to endotracheal intubation.[2]

B. Use of the Esophageal Obturator Airway as an Alternative Airway Adjunct

The esophageal obturator airway was constructed by Don Michael and colleagues as an alternative to using the

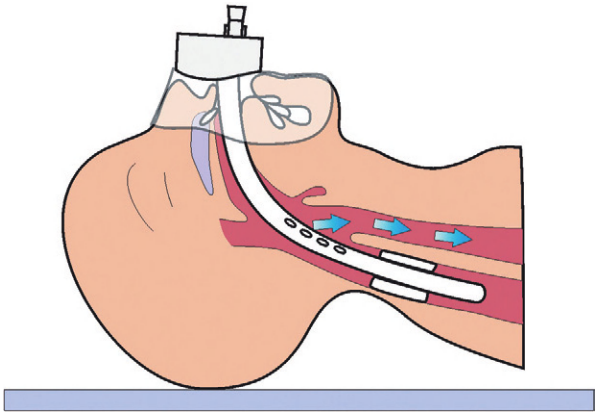

Figure 27-1 Esophageal obturator airway. Air is blown through the proximal port and travels through perforations into the hypopharynx *(arrows)* and trachea, because the mouth and nose are sealed by the mask and esophagus by the balloon.

endotracheal tube during emergency intubation.[3] The esophageal obturator airway is a 34-cm-long tube with a balloon at its distal tip (Fig. 27-1). The balloon should lie below the level of the tracheal bifurcation after insertion. The distal end is blocked. Proximal to the balloon, there are 16 holes that are positioned in the region of the hypopharynx after positioning the airway. At the proximal end, a face mask is connected to the airway, sealing the mouth and nose during ventilation.

The esophageal obturator airway is inserted by first grasping the back of the patient's tongue and the lower jaw with the thumb and index finger and then guiding the airway gently into the esophagus. The distal balloon is inflated to occlude the esophagus while the mask is pressed against the patient's face. Air enters the proximal end and then enters the hypopharynx through perforations because the distal end is blocked. From there, air is forced over the opened glottis into the trachea because the mouth and nose are sealed by the mask and the esophagus by the balloon (see Fig. 27-1).

1. Testing and Trials of the Esophageal Obturator Airway

Subsequent physiologic testing and field trials of the esophageal obturator airway have been performed. Schofferman and colleagues evaluated the airway in 18 patients suffering from cardiac arrest,[4] in whom resuscitation was performed by paramedics. Arterial blood gas analysis was obtained during ventilation with the esophageal obturator airway and subsequently with the endotracheal tube (ETT). There was little or no improvement in oxygenation after endotracheal intubation, implying that failure to oxygenate some patients did not result from the esophageal obturator airway.

Shea and associates compared two similar groups of patients during cardiopulmonary arrest with ventricular fibrillation[5]; 296 patients were intubated with an ETT or esophageal obturator airway. Survival rates and neurologic sequelae of survivors showed no statistically significant difference for the two groups. Hammargren and colleagues compared both devices after standardizing the method of oxygen delivery and ensuring true sampling of arterial blood.[6] In 48 victims who had prehospital cardiac arrest, blood gases were sampled during ventilation with the esophageal obturator airway and subsequent ventilation with the ETT. There was no statistically significant difference between the two devices for the Pa_{O_2} and Pa_{CO_2} values. The investigators concluded that the esophageal obturator airway was an effective means of airway management, with the ventilation achieved equal to that of an ETT. Nevertheless, it soon became apparent from studies in the controlled environment of the operating room that considerable technical difficulties were associated with the esophageal obturator airway.[7]

2. Disadvantages of the Esophageal Obturator Airway

In the literature, the esophageal obturator airway remains controversial because of several possible complications:

1. There are significant difficulties in obtaining a tight face mask seal and maintaining the seal during transportation. Effective use requires at least two hands to seal the mask. Obtaining an adequate mask fit is particularly difficult in edentulous or bearded patients.[6,7]
2. Inadvertent or unrecognized tracheal intubation may occur.[8] The patient's airway is completely obstructed, and attempts at repositioning are usually unsuccessful.
3. Esophageal or gastric ruptures have been reported.[9-12] Ruptures of the esophagus or the stomach may be due to the length of the esophageal obturator airway. Because many cardiac arrest patients exhibit left atrial dilatation with subsequent lateral deviation of the lower half of the esophagus, the esophageal obturator airway may be forced in a left lateral direction in addition to the curved sagittal direction, which can lead to ruptures.

C. Development of the Combitube Esophageal-Tracheal Double-Lumen Airway

The previously described disadvantages and the idea that both tracheal and esophageal intubation allow ventilation and oxygenation led to the development of the Combitube. It was devised by Michael Frass in cooperation with Reinhard Frenzer and Jonas Zahler in Mödling and Vienna, Austria.[13-17]

The Combitube design was intended to deal effectively with the problem of managing the airway with the greatest success possible. Studies in large populations demonstrate that the Combitube provides a much better chance of ventilation and oxygenation than other devices[18-21] by isolating and protecting the airway from digestive regurgitation and aspiration.[22] The Combitube can be used when airway management is difficult independent of the cause, such as anatomic factors, the patient's position with respect to the operator, space and illumination restrictions, and presence of a full stomach. The Combitube does not need special equipment, energy, or complex techniques to be properly used. Because the Combitube is available in only two sizes (37 and 41 F),

Figure 27-2 The Combitube has a large syringe for inflation of the oropharyngeal balloon and a small syringe for inflation of the distal cuff.

no time is lost in selecting the proper size among many alternatives.

D. Technical Description

The Esophageal Tracheal Combitube (Combitube; Tyco Healthcare, Mansfield, MA) is a device for emergency intubation that combines the functions of an esophageal obturator airway and a conventional ETT (Fig. 27-2). The Combitube is a double-cuff and double-lumen tube (Fig. 27-3). The oropharyngeal balloon is located at the middle portion of the tube and the tracheoesophageal cuff is located at the distal end.[23] The lumens are separated by a partition wall. Proximally, both lumens are opened and linked by short tubes with universal connectors. Distally, the pharyngeal lumen is blocked and has eight perforations at the level between the cuffs, and the tracheoesophageal lumen is open. This design allows ventilation when the Combitube is positioned in the esophagus through the perforations of the pharyngeal lumen and in the trachea through the opened distal end of the tracheoesophageal lumen. The pharyngeal balloon seals the oral and nasal cavities after inflation. Printed ring marks proximal to the oropharyngeal balloon indicate the limit of insertion.

The 37-F Small Adult (SA) Combitube may be used in patients 4 to 6.5 ft tall.[18,24,25] The 41-F model is used in patients taller than 6 ft (with some overlap with the SA model). The 37-F SA Combitube usually is the preferred model because it works well in patients up to 6.5 ft tall.

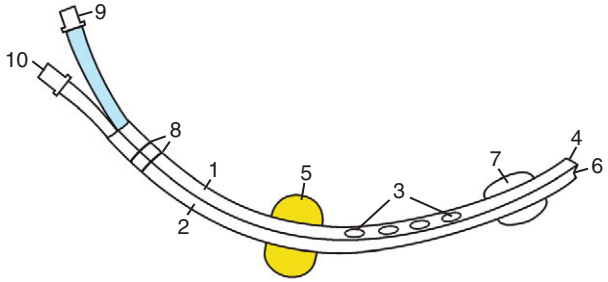

Figure 27-3 Cross-sectional view of the Combitube: *1,* pharyngeal lumen (i.e., longer tube with a blocked distal end); *2,* tracheoesophageal lumen (i.e., shorter tube with open distal end); *3,* perforations of esophageal lumen 1 in the pharyngeal section; *4,* blocked distal end of esophageal lumen 1; *5,* oropharyngeal balloon *(yellow); 6,* open distal end of tracheal lumen 2; *7,* distal cuff for obturating the esophagus or trachea; *8,* printed ring marks for indicating the depth of insertion between the teeth or alveolar ridges; *9,* connector for *(blue)* the tube leading to esophageal lumen 1; *10,* connector for *(transparent)* the tube leading to tracheal lumen 2.

E. Insertion Techniques

The Combitube can be successfully inserted independently of the patient's position with regard to the operator. The patient's head is preferably in the neutral position, or a small cushion may be used. The sniffing position may impede Combitube insertion.

1. Conventional Technique

With the operator behind the patient's head, the lower jaw and tongue are lifted by the thumb and index finger. The tongue is pressed forward by the thumb, and the tube is inserted in a curved downward movement until the printed ring marks lie between the teeth or the alveolar ridges in edentulous patients (Fig. 27-4A). The insertion should be performed along the tongue to avoid potential damage of the posterior pharyngeal mucosa. Sometimes, a rocking motion may alleviate problems encountered with insertion. Next, the oropharyngeal balloon is inflated with up to 85 mL of air for the 37-F SA Combitube (or up to 100 mL for the 41-F Combitube) through port no. 1 with the blue pilot balloon using the large syringe with the blue color code (see Fig. 27-4B). When the minimal-volume technique is used, enough air is added to inflate the balloon and obtain a seal (see "General Anesthesia"), or a cuff pressure gauge may be used to achieve a seal of 60 mm Hg. If sufficient sealing of the mouth and nose cannot be accomplished, the oropharyngeal balloon may be filled with an additional 50 mL of air, up to a total amount of 150 mL.[26]

During inflation, the tube may move slightly out of the patient's mouth because of the self-positioning properties of the balloon. A useful sign indicating malposition due to insufficient insertion is that the inflated pharyngeal balloon can be seen when looking into the patient's mouth (Fig. 27-5). If this occurs, the pharyngeal balloon should be deflated, and the tip's position should be reevaluated. The Combitube may become kinked during placement, and reinsertion may be necessary. The anatomic relationships of the oropharyngeal balloon have been demonstrated radiologically.[26] The balloon protrudes in an oral direction after overinflation so that it does not close the epiglottis. Figure 27-6 shows a cross-sectional magnetic resonance imaging (MRI) view of the Combitube in the esophageal position. It displays anterior movement of the larynx, a situation that can often be observed clinically. Knowledge of this may facilitate subsequent location of the larynx for endotracheal intubation.

The distal balloon is then inflated with 10 mL of air through port no. 2 with the white pilot balloon and using the small syringe.[27] With blind insertion, there is a high probability that the tube will be placed into the esophagus. Test ventilation is recommended through the longer, blue no. 1 tube leading to the esophageal lumen (see Fig. 27-4C). Air passes into the pharynx and then through the glottis into the trachea because the mouth, nose, and

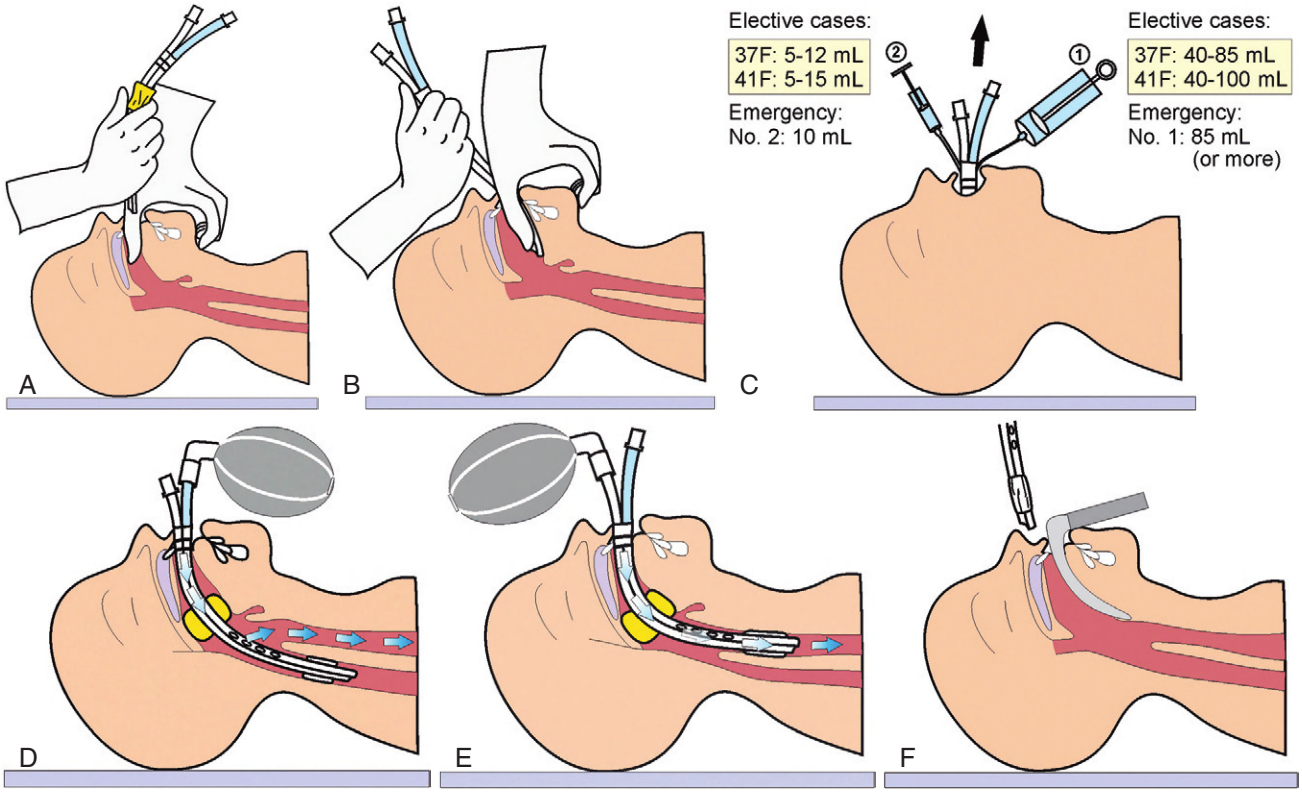

Figure 27-4 Guidelines for introduction of the Combitube. **A,** Insertion begins by lifting the chin and lower jaw. **B,** The Combitube is inserted in a downward, curved movement along the tongue. **C,** The oropharyngeal balloon is inflated with 85 mL of air, and the distal cuff is inflated with 5 to 10 mL of air. **D,** With the Combitube in the esophageal position, ventilation is performed through the longer no. 1 tube *(blue)*. Air flows through the holes into pharynx the and from there into the trachea *(arrows)*. **E,** With the Combitube in the tracheal position, ventilation is performed through the shorter no. 2 tube *(transparent)*. Air flows directly into the trachea *(arrows)*. **F,** The Combitube is inserted using a laryngoscope.

esophagus are blocked by the balloons. Auscultation of breath sounds in the absence of gastric insufflation confirms adequate ventilation when the Combitube is in the esophagus. Ventilation is then continued through this lumen. In this position, the Combitube allows closed suctioning and active decompression of the stomach.[28] Closed suctioning provides the advantage of reduced cross contamination between the bronchial system and gastric juices.[29] Gastric contents can be suctioned through the unused tracheoesophageal lumen with the help of a small suction catheter (10 or 12 F) included in the kit.

Figure 27-5 Seeing the inflated oropharyngeal balloon in the patient's mouth indicates malposition of the Combitube.

The most common cause of failed ventilation through the blue connector is a tracheal position of the distal tip (see Fig. 27-4D). Without changing the position of the Combitube, ventilation is changed to the shorter, transparent no. 2 tube leading to the tracheoesophageal lumen, and the position is again confirmed by auscultation. Ventilation is then carried out through the tracheoesophageal lumen directly into the trachea. The oropharyngeal balloon may be deflated in case of regurgitation to allow suctioning with a conventional catheter. Otherwise, the balloon should remain inflated to stabilize the Combitube.

If no breath sounds are heard over the lungs or a capnographic curve is absent while ventilating through the blue connector, the second most common cause is that the Combitube has been inserted too deeply, and the oropharyngeal balloon lies just opposite the laryngeal aperture and occludes the airway.[30] In this situation, both balloons should be deflated and the Combitube pulled back about 2 to 3 cm out of the patient's mouth and then fixed in this position.

The third most common cause of failed ventilation is a phenomenon (e.g., laryngospasm, bronchospasm, pulmonary edema) leading to high airway pressure. In this situation, cause should be identified and treated. Unlike other airway devices, the Combitube allows ventilation

Figure 27-6 Cross-sectional MRI view of a patient intubated with Combitube in the esophageal position. (Courtesy of B. Panning, MD, Department of Anesthesiology, and C. Ehrenheim, MD, Department of Nuclear Medicine and Special Biophysics, Hannover School of Medicine, Hannover, Germany.)

against high airway pressure, and administration of inhaled bronchodilators[28,31] and proper treatment of the spastic phenomenon can be started immediately after full inflation of the balloon to ensure high-pressure ventilation.

An investigation by Wafai and coworkers was designed to test the reliability of the self-inflating bulb in identifying the location of the Combitube and facilitating its proper position in anesthetized patients.[32] In group 1 ($n = 26$), the Combitube was introduced blindly. In group 2 ($n = 20$), the tube was placed in the trachea (8 patients) or once in the trachea and once in the esophagus randomly (12 patients) under direct vision rigid laryngoscopy by the anesthesiologist performing the intubation. In both groups, the efficacy of the self-inflating bulb in identifying the location of the Combitube was tested by a second blinded anesthesiologist. In group 1, blind insertion of the Combitube resulted in esophageal placement in all patients, and in each case, it was correctly identified. The second anesthesiologist reported no reinflation when the compressed self-inflating bulb was connected to the distal lumen. When the compressed self-inflating bulb was connected to the proximal lumen, instantaneous reinflation was observed in 23 patients, delayed reinflation (2 to 4 seconds) in 2, and no reinflation (>4 seconds) in 1. Instantaneous reinflation occurred in these three patients after repositioning the Combitube. In group 2, the second anesthesiologist correctly identified the location of the Combitube in all cases. The results confirm previous findings that blind introduction of the Combitube leads to esophageal placement and yields adequate ventilation. The self-inflating bulb can quickly identify the location of the Combitube and facilitate its positioning with the use of a simple algorithm. This can be important if the Combitube is used in a patient whose lungs cannot be ventilated by mask and whose trachea cannot be intubated.

2. Alternative Insertion Technique

Another way of inserting the Combitube has been described by Urtubia and colleagues.[33] This insertion technique (Fig. 27-7A and B) consists of grasping the upper teeth or the upper alveolar ridge with the index finger while pushing the chin with the middle finger. To avoid contact of the tip of the Combitube with the posterior oropharyngeal wall, Urtubia recommends keeping the Combitube bent as long as possible before blind insertion.[33] Similarly, Urtubia and associates describe a modification of the Lipp maneuver for blind insertion of the Combitube.[34]

For patients in sitting and prone positions or when the operator is facing the patient, a similar technique can be useful. The index finger grasps the lower teeth or alveolar ridge while the middle finger pushes the cheek (see Fig. 27-7C). The enlarged interincisor distance allows easier insertion of the Combitube, especially in partially edentulous patients and in patients with a limited oral opening (Fig. 27-8A and B). As with the original technique, it does not require any cervical movement, which makes it suitable for patients with cervical spine trauma.

The Combitube may be inserted blindly or with the aid of a laryngoscope. Use of a laryngoscope is recommended during the initial training period when endotracheal intubation using laryngoscopy fails (i.e., insert the Combitube with the laryngoscope still in place) and when blind insertion of the Combitube fails.[28]

F. Indications, Advantages, and Complications

1. Out-of-Hospital Emergency Intubation

The Combitube is especially suitable for emergency intubation in and out of the hospital when endotracheal intubation is not immediately possible. It may be used in the following three situations. First, in patients with difficult anatomy (e.g., bull neck, lockjaw, small mouth opening), the Combitube can be inserted in those with an interincisor distance (i.e., oral aperture) as small as 15 mm.[35] Second, the Combitube can be inserted in difficult spatial circumstances, such as limited access to a patient's head when the patient lies on the floor in a small room, when the patient is lying with his head close to the wall in the general ward or in the intensive care unit (ICU) with many lines at the side impeding quick access to the head, or when a patient is trapped in a car after an accident. Third, the Combitube can be inserted despite challenging illumination, such as bright light, massive bleeding, or regurgitation that can inhibit direct laryngoscopy. The Combitube prevents aspiration, which may occur with repeated suction maneuvers or vomiting.[22,24,36]

BOX 27-1 Suggested Indications for Use of the Combitube in Anesthesia and Emergencies

I. Face abnormalities
  A. Congenital (e.g., micrognathia, macroglossia)
  B. Facial trauma[8,54,80]
  C. Lockjaw[14,35,41]
  D. Small interincisor distance[14,76]
II. Cervical spine abnormalities
  A. Bull neck[76]
  B. Bechterew's disease
  C. Klippel-Feil syndrome
  D. Fractures and luxations[7,80,84,87]
  E. Rheumatoid arthritis with subluxation of the atlantoaxial joint[36]
  F. Morbidly obese patients[76,140]
III. Further indications
  A. Preoperative evaluation indications
    1. Previous difficult intubation
    2. Mallampati oropharyngeal classification class III or IV[93]
    3. Cormack-Lehane laryngoscopic grade 3 or 4
  B. Emergency situation
    1. Accidental extubation in patients undergoing surgery in a prone or sitting position
    2. Cervical hematoma after inadvertent puncture of the carotid artery[78]
    3. Unexpected upper airway bleeding or continued vomiting[22,90]
    4. Cesarean section[102-106]
    5. Intubation in circumstances of limited space
    6. Failed rapid sequence intubation[73,80]

2. Elective and Emergency Surgery

a. GENERAL ANESTHESIA

Use of the Combitube is indicated in routine surgery in patients for whom conventional intubation is not mandatory, such as singers and actors who may be afraid of damage to the vocal cords by endotracheal intubation, or in patients with rheumatoid arthritis with atlantoaxial subluxation. The main advantages of the Combitube in elective and emergency surgery are higher insertion and ventilation rates, reliable protection of the airway against regurgitation and aspiration of gastric contents (e.g., patients with a full stomach, gynecologic laparoscopy), and ventilation and oxygenation against high airway pressures (e.g., obesity, laryngospasm, bronchospasm). As with emergency intubation, it is especially suitable in patients with difficult anatomic conditions. When endotracheal intubation cannot be performed immediately, the Combitube should be considered (Box 27-1). The main advantage in the case of failed intubation or ventilation is immediate esophageal insertion of the Combitube under direct vision without removing the laryngoscope.

Some special considerations apply to the use of the Combitube by anesthesiologists who are expert in endotracheal intubation.

1. The patient's head does not have to be placed in the traditional sniffing position, as recommended for conventional endotracheal intubation. The patient's head should remain in a neutral position that allows free movement of the lower jaw. Depending on the situation, the chin may be pushed toward the patient's chest. Some clinicians prefer to extend the head or to use a small cushion. In patients with a cervical spine injury, the Combitube allows airway management while avoiding mobilization of the neck.
2. The position of the operator (Fig. 27-9) may be behind the patient, especially when a laryngoscope is used (see Fig. 27-9A); to the side of the patient's head (see Fig. 27-9B); or face to face, when the operator stands beside the patient's thorax and faces the patient (see Fig. 27-9C). In all three positions, it is necessary to insert the Combitube with a curved downward-caudal movement.
3. During elective surgery, it is always necessary to achieve an adequate depth of anesthesia, with or without additional relaxation. One half of the intubating dose of a neuromuscular blocking agent may be enough to ensure a smooth insertion.[18] Gaitini and colleagues have used the Combitube in patients with controlled mechanical ventilation and in spontaneously breathing patients without relaxation.[18] However, grasping and elevating the epiglottis with the fingers during insertion may reduce the need for relaxation.
4. Recommended induction agents are propofol or sevoflurane, with or without opioids.[37] In a study of 50 female patients undergoing gynecologic laparoscopy, Urtubia and associates successfully inserted the Combitube in 100% of cases using inhalational induction with sevoflurane as the sole agent,[38] without opioids or neuromuscular blockade. Use of a laryngoscope is recommended to avoid damage to the oral and pharyngeal mucosa. Nevertheless, with a well-performed blind insertion technique and an adequate level of anesthesia, the risk of damage is comparable to that with the laryngeal mask airway (LMA) or the ETT in terms of postoperative sore throat (16% to 25%).[18,24,27] With the laryngoscope, the Combitube is then intentionally introduced into the esophagus. When endotracheal intubation fails, a Combitube can be placed under direct visualization with the laryngoscope still in the patient's mouth.
5. Another method that may facilitate Combitube insertion and minimize insertion trauma is warming the Combitube in a bottle of warm saline or water, similar to the procedure performed with an ETT for nasal intubation. This technique also allows Combitube insertion without additional application of lubricant.
6. The minimal-volume technique should be applied in elective cases and in emergencies after stabilization of the patient. Studies have shown that adequate sealing of the oropharyngeal balloon can be achieved with 40 to 85 mL of air for the SA Combitube.[18,24,27,38-41] Gaitini and colleagues reported that the mean inflation volume of the oropharyngeal balloon at which an air leak was first observed was 45.5 ± 12.3 mL for the 37-F Combitube and

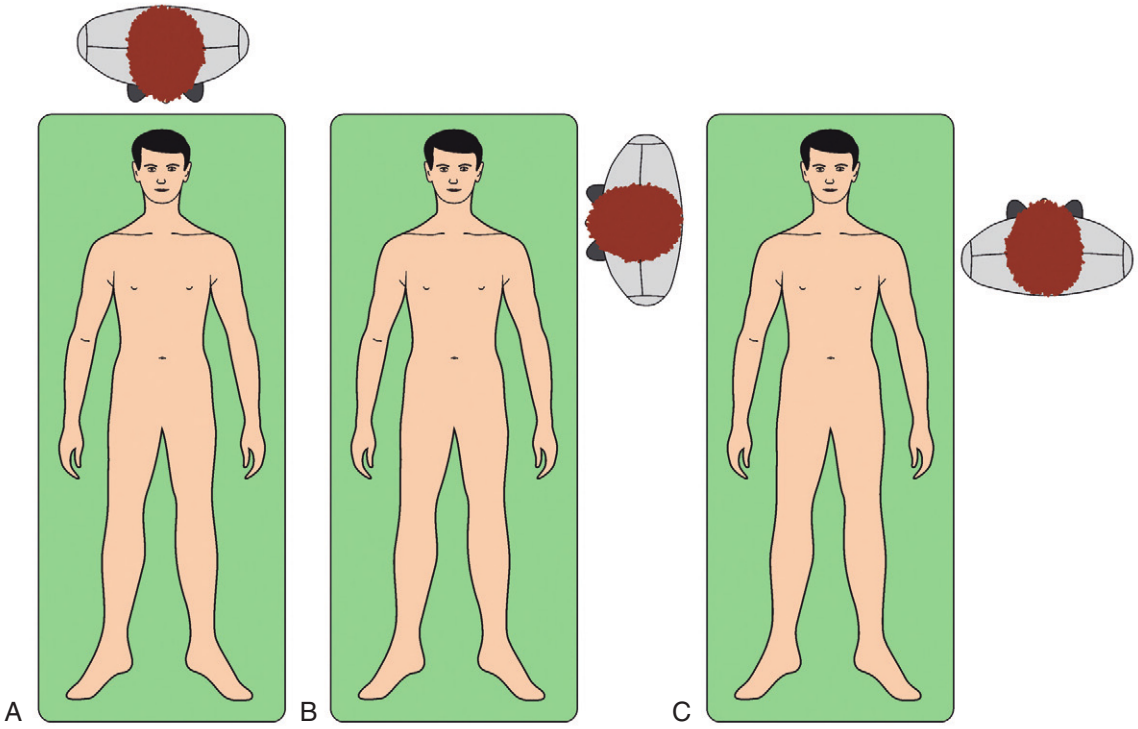

Figure 27-9 Position of the operator during insertion of the Combitube. **A,** The operator stands behind the patient, especially when using a laryngoscope. **B,** The operator stands to the side of the patient's head. **C,** The operator stands beside patient's thorax so that they are positioned face to face.

48.1 ± 12.1 mL for the 41-F Combitube.[40] The balloon should be initially filled with 40 mL of air only. If a tight seal can be achieved as evaluated by auscultation, comparable to inspiratory and expiratory tidal volumes and the flow-volume curve, the volume is not increased. If a leak is observed, additional increments of 10 mL of air each are added into the balloon until a tight seal is confirmed. The volumes of the oropharyngeal balloon also must be adjusted with the use of nitrous oxide and volatile anesthetics.

b. AWAKE INTUBATION

In an experiment on himself, Panning showed that the Combitube can be inserted easily with local pharyngeal anesthesia.[42] Keller and coworkers inserted the Combitube in four awake volunteers with topical anesthesia.[43] Nevertheless, unless an urgent insertion is required, the Combitube should always be inserted when gag reflexes are suppressed because of the risk of mucosal damage or vomiting.

c. REPLACEMENT OF THE COMBITUBE

The Combitube may be left in place for up to 8 hours.[44] Although emergency and routine surgical procedures may be successfully carried out during this period, the Combitube is not intended for long-term ventilation, because the pressure on the pharyngeal mucosa may be harmful. We recommend replacing the Combitube after a maximum duration of 8 hours. Replacement of the Combitube in the esophageal position by an ETT can be performed in several ways with no danger of aspiration:

1. While the distal cuff remains inflated, deflate the oropharyngeal balloon completely, with the Combitube remaining in the esophagus. Displace the Combitube to the left corner of the mouth, and insert an ETT by laryngoscopy or fiberoptic intubation.[45] After successful placement of the ETT, insert a suction catheter through the tracheoesophageal lumen into the esophagus, and during continuous suctioning, deflate the distal cuff, and remove the Combitube. If ETT insertion is impossible, push the Combitube back into its original midline position, reinflate the oropharyngeal balloon, and continue ventilating through the longer no. 1 lumen (blue) of the Combitube until the next endotracheal intubation attempt or until a surgical airway is established.
2. Gaitini and associates described another method.[46] The oropharyngeal balloon is partly deflated according to the minimal-volume technique so that the least amount of air allows adequate sealing of the oral and nasal cavities. During continued ventilation through the no. 1 lumen, a fiberoptic bronchoscope mounted with an ETT is introduced through the patient's mouth. Without a time limit, the bronchoscope may be advanced into the trachea. The unique feature of this method is that ventilation is not interrupted during the entire replacement procedure. All the patients in this study had Mallampati class III or IV oral cavity anatomy.

3. The Combitube may be replaced by surgical means, such as cricothyrotomy or tracheostomy.[47] These were the first surgical procedures performed with the Combitube. An advantage of this method is that the trachea is not occupied by an ETT, and ventilation can be continued while the surgical airway is established. A disadvantage is that the trachea is not protected against aspiration of blood generated during the surgical procedure.
4. If there is no danger of aspiration, the Combitube may be removed and replaced by conventional means (e.g., laryngoscopy, bronchoscopy). This approach may be advantageous because intubation around the Combitube can be difficult. In a cadaver study, the laryngeal view with and without the Combitube in place has been compared and the difficulty of intubation around the device evaluated.[48] Nine participants in an airway workshop placed 37-F Combitubes in eight non-embalmed cadavers. The pharyngeal balloon was deflated and laryngoscopy attempted with the Combitube in place. Each operator assessed the percentage of glottic opening (POGO) score and tried to pass a tracheal tube around the device. Difficulty of tube passage was rated by the operator. The Combitube was then removed and laryngoscopy (and POGO scoring) repeated without the device. POGO scores with and without the Combitube averaged 61% (95% confidence interval [CI], 49% to 73%) and 92% (CI, 89% to 95%), respectively. Fourteen (19%) of 72 intubation attempts with the Combitube failed. Major difficulty was reported for 22 (31%) of 72 attempts, and minor difficulty for 34 (47%) of 72. The investigators concluded that a previously placed Combitube significantly worsened the laryngeal view at laryngoscopy and prevented intubation in 19% of cases in this cadaver study. They suggest that removal of the Combitube is warranted if any difficulty with laryngoscopy is anticipated or encountered.
5. Harrison and colleagues described the successful replacement of the Combitube with an ETT by retrograde intubation.[49] The retrograde intubation was successfully performed without removing an in situ Combitube.
6. A Combitube in the tracheal position can be replaced by an ETT. After lubrication, a pediatric (8-F) tracheal tube exchanger (Cook Critical Care, Bloomington, IN) is introduced into the tracheoesophageal lumen through the shorter no. 2 lumen (transparent) into the trachea, the Combitube is removed, and an ETT is advanced using the tube exchanger as a guide.[50,51] If not contraindicated, laryngoscopy should be performed, to facilitate advancement of the ETT through the glottis.

d. EXTUBATION

Extubation after surgery in the awake patient is possible, and the patient will not show signs of significant distress. It begins by deflating the oropharyngeal balloon, allowing communication with the patient. Deflation of the distal cuff and final extubation during continuous suctioning through the shorter no. 2 lumen should be performed only after recovery of protective reflexes.

After deflation of the oropharyngeal balloon, the pharyngeal structures may occlude the ventilating perforations of the Combitube. It is advisable to deflate the balloon up to the point at which breathing is normal. After spontaneous ventilation fully resumes, the Combitube can be withdrawn with a curved movement out of the patient's mouth in a fashion similar to insertion.

3. Advantages

The Combitube has a wide range of applications and advantages (Box 27-2). Those benefiting from its use include anesthesiologists and physicians in emergency departments,[18,19,23] paramedics and emergency medical technicians,[19,50,52-57] combat medics,[58] parkmedics,[59] and physicians in private practice (e.g., responding to anaphylactic reactions).[28,31] Cardiac arrests usually do not occur under ideal circumstances, and CPR often is performed in awkward locations, poorly lighted areas, and with limited access to the patient's head. Because the Combitube can be inserted without a laryngoscope, establishment of a patent airway is not hampered by adverse environmental factors or staff unskilled in endotracheal intubation.[27] It is safe against aspiration, and high ventilatory pressures may be applied.

There is no need for additional fixation of the Combitube after inflation of the oropharyngeal balloon,

BOX 27-2 Advantages of the Combitube and EasyTube

- Noninvasive compared with cricothyrotomy
- Universal size (37-F Small Adult Combitube fits patients 4 to 6.5 ft)[18,23,104]
- Universal model (one type only)
- Easy to learn, even by untrained personnel[58,68,110,129,130]
- No preparations necessary; tube and syringes are ready to use
- Helpful under difficult conditions of space and illumination
- Blind insertion technique
- Neck extension unnecessary
- Simultaneous fixation after inflation of the oropharyngeal balloon
- Works in the tracheal or esophageal position
- Active decompression of the esophagus and stomach
- Minimized risk of aspiration[22,36,38,57,101,106]
- Controlled mechanical ventilation possible at high ventilation pressures (≤50 cm H_2O)[19,24,27,36,51,93,101]
- Independent of power supply (e.g., batteries of laryngoscope)
- Well suited for obese patients[76,140]
- May be used in paralyzed patients who cannot be intubated or mask ventilated
- Only device for insertion in patients with trismus and limited mobility of cervical spine and those with combined pathologic conditions, such as trismus plus limited mobility of the spine and trismus plus tongue edema[129]
- Fast, safe, and easy to use with successful skill retention[129,130]

because the anterior upper wall of the oropharyngeal balloon lies just behind the posterior end of the hard palate, thereby guaranteeing strong anchoring during ventilation and transportation. Providing a more secure airway is an attractive advantage of the Combitube compared with other devices used during transportation of emergency patients. Studies have shown that the Combitube is easy to learn and that the skills are retained over time.[57]

4. Disadvantages

A potential disadvantage of the Combitube is that suctioning tracheal secretions is impossible in the esophageal position. However, studies of use of the esophageal obturator airway in cardiac arrest patients have shown that the outcome of those cases is not statistically different compared with cases in which endotracheal intubation is used.[5,6] The Combitube is designed to bridge the short gap between the prehospital setting and admission of the patient to the emergency department. If prolonged ventilation is required, glycopyrronium bromide may be administered to suppress tracheal secretions (e.g., during surgery). Krafft and colleagues have described a redesigned Combitube in which two proximal anterior holes are replaced by one large hole, allowing a bronchoscope to pass for inspection and suctioning of the trachea and as a means for replacing the Combitube using a guidewire.[60]

5. Contraindications

The Combitube is contraindicated for use in patients with the following: intact gag reflexes (irrespective of the level of consciousness), height less than 6 ft (41-F Combitube) or less than 4 ft (37-F SA Combitube), central airway obstruction, ingestion of caustic substances, and known upper esophageal pathology (e.g., Zencker's diverticulum).

6. Complications

Ovassapian and coworkers observed livid discoloration of the tongue during ventilation with the Combitube in a few patients without further sequelae.[45] Tongue engorgement was described after 4 hours of Combitube use.[61] In an out-of-hospital study with paramedics as rescuers, two lacerations of the esophagus were found in autopsies of cardiac arrest patients ventilated with the Combitube.[62] However, the investigators found that the distal cuff was overfilled with 20 to 40 mL of air (instead of 10 ± 1 mL). As outlined in the instructions, the Combitube should not be advanced with use of force. Klein and associates reported an esophageal rupture after insertion of a Combitube, stiff suctioning catheter, LMA, laryngoscope, and ETT.[35] A traumatic procedure with one or more of these devices probably caused the complication.

Overinflation of the esophageal balloon was described in a case reporting airway obstruction secondary to tracheal compression. In this case, the esophageal balloon was inflated with 22.4 mL according to the computed tomography (CT) measurement.[63] Richards reported a case of piriform sinus perforation during the insertion of the Combitube.[64] This patient presented with cardiorespiratory arrest due to angioedema, probably caused by treatment with angiotensin-converting enzyme inhibitors. Another case of piriform sinus perforation during Combitube placement was reported by Moser.[65]

Oczenski and coworkers reported a very high number of complications for cases of elective surgery.[66] The total complication rate found by Oczenski's group[66] was fourfold that found in the studies led by Gaitini,[18] Hartmann,[27] and Urtubia.[24] This unexpectedly high rate of complications probably was caused by traumatic maneuvers during airway management, which is in accordance with an 8% rate of pharyngeal hematoma associated with the LMA. Vezina and colleagues retrospectively reviewed medical records of patients with cardiac or respiratory arrest.[67] The study was performed in the Quebec City Health Region, where paramedics use the Combitube as a primary airway device for patients with cardiorespiratory arrest. A high incidence of complications was reported.

The study of Oczenski and coworkers demonstrates that all precautions should be considered when there are obvious handling problems.[66] When facing difficulties during insertion, a laryngoscope should be used immediately to insert the Combitube intentionally into the esophagus under direct vision.

G. Medical Literature

1. Combitube in Cardiac Arrest Patients

a. IN-HOSPITAL STUDIES

Application of the Combitube during CPR has been investigated.[14-16,21] The first study consisted of two parts.[15] The first part considered the blood gas analyses of 19 patients after 15 minutes of ventilation with the Combitube. In the second part, the blood gas analyses of samples taken from 12 patients during ventilation with the Combitube were compared with those taken during subsequent ventilation with a conventional ETT. Blood gas analyses showed higher arterial oxygen pressures with the Combitube than with an ETT (124 ± 33 versus 103 ± 30 mm Hg; $P = 0.001$). Carbon dioxide pressure was not significantly different.

A second study reported the use of the Combitube during in-hospital CPR.[14] In a randomized sequence, the Combitube or a conventional ETT was used in 43 patients. After stabilization of the patients, each tube was replaced with the other type of tube. Blood gas analyses revealed increased oxygen tensions during Combitube ventilation, and the intubation time was significantly shorter with the Combitube.

Another study evaluated the safety and effectiveness of the 41-F Combitube as used by ICU nurses under medical supervision compared with an ETT established by ICU physicians during CPR.[68] The intubation time was shorter for the Combitube, and results of blood gas determinations for each device were comparable, although arterial oxygen tension was slightly higher during ventilation with the Combitube. The study suggests that the Combitube as used by ICU nurses is as effective as the ETT as used by ICU physicians during CPR.

b. OUT-OF-HOSPITAL STUDIES

Atherton and Johnson investigated the ability of paramedics in a nonurban emergency medical setting to use the 41-F Combitube.[52] Fifty-two cases of prehospital Combitube insertion by paramedics were examined, and 11 paramedics were evaluated for skill retention. Combitube insertion was attempted in 52 cardiac arrest patients in a prehospital setting, and 69% of them were intubated successfully. Paramedics recognized esophageal versus tracheal placement in 100% of cases. The Combitube was inserted successfully in 64% of patients who could not be tracheally intubated by direct visualization. The Combitube was inserted successfully in 71% of cases when used as a first-line airway adjunct. Fifteen months later, a follow-up study of 9 of 11 randomly selected paramedics demonstrated inadequate skill retention (e.g., improper insertion angle resulting in resistance and inability to insert the tube, inappropriate inflation of the balloons, insertion too deep or not deep enough). After this reevaluation and retraining, the success rate rose to almost 100%.[69] These results demonstrate that as with every device, there is a necessity for a reevaluation of skills after initial training. A study of emergency medicine residents suggests that they can learn and retain these airway skills.[70]

In a prehospital setting, three alternative airway devices and an oral airway were compared in a modified, randomized, crossover study by emergency medical assistants who were not trained in advanced life support (ALS) techniques.[20] The pharyngeal-tracheal lumen (PTL) airway, the LMA, and the 41-F Combitube were compared objectively for success of insertion, ventilation, and arterial blood gas and spirometry measurements performed on arrival at the hospital. Subjective assessment was carried out by emergency medical assistants and receiving physicians. Operating room training was performed only with the LMA. Autopsy findings and survival to hospital discharge were analyzed. The study took place in four non-ALS communities over 4.5 years and involved 470 patients in cardiac or respiratory arrest, or both. Emergency medical assistants had automatic external defibrillator training but no endotracheal intubation skills. Successful insertion and ventilation was highest for the Combitube (86% versus 82% with PTL airway and 73% with LMA, $P = 0.048$). Differences in subjective evaluation were significant. The Combitube was associated with the fewest problems with ventilation, and it was preferred by most emergency medical assistants. Unlike LMA use, no aspirations were found in autopsies after use of the Combitube.

A retrospective study was designed to determine the choice of airway devices used for nontraumatic,[21] out-of-hospital cardiac arrest patients and to evaluate the success and failure of insertion and airway control or ventilation by three airway adjuncts—the 41-F Combitube, the esophageal-gastric tube airway (EGTA), and the LMA—which were used in conjunction with the bag-valve-mask ventilation by emergency life-saving technicians in Japan. A survey of 1079 technicians was performed to identify the type of airway devices, the success rates of airway insertion, the effectiveness of airway control/ventilation, and associated complications in 12,020 cases of cardiac arrest. The choice of airway devices included bag-valve-mask ventilation for 7180 cases, EGTA for 545 cases, Combitube for 1594 cases, and LMA for 2701 cases. Successful insertion rates on the first attempt were 82.7% for EGTA, 82.4% for Combitube, and 72.5% for LMA ($P = 0.0001$). Rates of failed insertion were 8.2% for EGTA, 6.9% for Combitube, and 10.5% for LMA ($P = 0.0001$). Successful ventilation rates were 71.0% for EGTA, 78.9% for Combitube, and 71.5% for LMA ($P = 0.0004$). Six cases of aspiration were reported in the LMA group, whereas nine cases of soft tissue injuries, including one esophageal perforation, were reported in the 41-F Combitube group; 17.8% had vomited before or during airway placement. The Combitube appears to be the most appropriate choice among the airway devices examined.

The ability to train emergency medical technicians with defibrillation capabilities (EMT-Ds) to effectively use the 41-F Combitube for intubations in the prehospital environment was evaluated in a prospective field study lasting for 18 months.[71] Indications for use of the Combitube included unconsciousness without a purposeful response, absence of the gag reflex, apnea or a respiratory rate of less than 6 breaths/min, age older than 16 years, and height of at least 5 ft. Twenty-two EMT-D provider agencies involving approximately 500 EMT-Ds were included as study participants. Combitube insertions were attempted in 195 patients in cardiorespiratory arrest in a prehospital setting. An overall successful intubation rate of 79% was observed, with identical success rates for medical and trauma patients. The device was placed in the esophagus in 91% of cases. Resistance during insertion was the major reason for unsuccessful Combitube intubations. The overall hospital admission rate was 19%. No complications were reported. The study confirmed that EMT-Ds could be trained to use the Combitube as a means of establishing an airway in patients in the prehospital setting.

Rural EMTs were educated in selected advanced skills, and the safety and effectiveness of practice were evaluated.[55] After a minimum of 72 hours of training, EMTs employed three skills (i.e., Combitube insertion, glucometry, and automated external defibrillation) and seven medications (i.e., albuterol, nitroglycerin, naloxone, epinephrine, glucagon, activated charcoal, and aspirin). Congruence between prehospital assessment and emergency department diagnosis was assessed, along with correct use of airway skills (18 of 36 months). The Combitube functioned satisfactorily in 15 (79%) of 19 cases, and EMTs always correctly found the correct lumen to ventilate.

The purpose of another study was to assess the feasibility, safety, and effectiveness of the Combitube when used by EMT-Ds in cardiorespiratory arrest patients of all causes.[72] The EMTs had automatic external defibrillator training but no prior advanced airway technique skills. The prehospital intervention was reviewed using the EMTs cardiac arrest report, the automatic external defibrillator tape recording of the event, and the assessment of the receiving emergency physician. Hospital records and autopsy reports of 831 adult, cardiac arrest patients were reviewed in search of complications. Placement was successful in 725 (95.4%) of the 760 patients in whom

Combitube insertion was attempted, and ventilation was successful in 695 (91.4%) patients. An autopsy was performed in 133 patients, and no esophageal lesions or significant injuries to the airway structures were observed. Results suggest that EMT-Ds can use the Combitube for control of the airway and ventilation in cardiorespiratory arrest patients safely and effectively. In other field studies investigating the best time for postshock analysis after out-of-hospital defibrillation with automated external defibrillators, 86 (93.7%) of 96 patients were successfully intubated with the Combitube.[53,73] Similar results were found in a study by Cady and Pirrallo, who found a success rate of 89.4% for 860 Combitube insertions performed by paramedics experienced in endotracheal intubation.[74]

Mort reviewed an emergency intubation database to determine what airway devices were used as a backup to rescue the primary rescue device failures.[75] The bougie and the LMA have intrinsic failure rates. In each of the 18 patients, the Combitube was placed in the esophagus with no tracheal insertions identified. Carbon dioxide detection confirmed tracheal air exchange in each case. Minor adjustments were required to optimize the air exchange with the Combitube in nine cases and involved moving the Combitube distally (deeper) or proximally (shallower). Four of the 18 patients required a second attempt of Combitube placement when ventilation was obstructed despite repositioning (i.e., presumed epiglottic impingement by Combitube). After Combitube placement, effective ventilation and life-sustaining oxygen saturations (>92%) were established and maintained in each case until further steps were taken to secure the airway. Steps required to secure the airway (tracheal intubation) after successful placement of the Combitube varied. Eleven patients were tracheally intubated with the Combitube maintained in the esophageal position (i.e., direct laryngoscopy alone in four patients and direct laryngoscopy and bougie-assisted tracheal intubation in seven patients). Because of the poorly recognized periglottic anatomy with the Combitube in place, two patients had the Combitube exchanged to a Fastrach LMA as a successful intubation conduit. Five patients had unrecognizable periglottic anatomy due to excessive edema, significant secretions, and tissue trauma and therefore had a surgical airway created with the Combitube supporting ventilation and oxygenation (i.e., four cases in the emergency department and one general ward patient transported to the operating room for surgical airway procedure). The Combitube, commonly used in the emergency prehospital setting, appeared to be a useful secondary rescue device in the hospital setting when the bougie and LMA failed.

c. CASE REPORTS

Liao and Shalit reported a case of successful Combitube treatment of an acute respiratory arrest caused by an acute asthma exacerbation.[59] A level II EMT (National Park Service Parkmedic) used this device.[59] The female patient was successfully intubated and ventilated and was flown by helicopter for more than 2 hours. Despite repeated episodes of vomiting, no aspiration occurred in this patient. The Combitube was replaced by an ETT, and the patient was extubated 2 days later and discharged on day 3 after the initial event.

The Combitube was helpful in a bull-necked patient when movement of the neck and opening of the mouth were impossible and in the case of a rapidly enlarging cervical hematoma,[76,77] which caused upper airway obstruction and required immediate intubation after endotracheal intubation had failed because the epiglottis could not be visualized with a laryngoscope.[78]

In Chile, a 65-year-old woman with chronic renal insufficiency and atrial fibrillation experienced sudden respiratory arrest during the dialysis procedure at an out-of-hospital dialysis center. Ventilation with a face mask was impossible. As the patient's condition rapidly deteriorated, a nonskilled nurse reestablished her oxygenation by blind insertion of a Combitube.[79]

For a patient with acute respiratory failure,[22] attempts at endotracheal intubation failed due to continued vomiting that rendered fiberoptic visualization of the vocal cords impossible. Blind insertion of the Combitube led to successful ventilation, and replacement by an endotracheal airway was performed without danger of aspiration.

2. Combitube in Trauma Patients

a. STUDIES

Blostein and colleagues have prospectively studied use of the Combitube in trauma patients in whom orotracheal rapid-sequence intubation (RSI) failed.[80] Flight nurses were trained in the use of the Combitube by mannequin simulation, videotape review, and didactic sessions. Combitube insertion was attempted after failure of two or more attempts at orotracheal RSI. Over a 12-month period, 12 patients had successful Combitube insertion, and 10 cases qualified for review. Injuries, number of failed orotracheal RSI attempts, definitive airway control, initial arterial blood gas results, and outcome were recorded. Combitube insertion was successful in all 10 patients in whom placement was attempted. Definitive airway control was achieved by conversion to orotracheal intubation in seven patients, emergency department cricothyroidotomy in one patient, and operative room tracheostomy in two patients. No patient died because of failure to control the airway. Seven patients requiring Combitube had mandible fractures, four had traumatic brain injuries, two had facial fractures, and one had hemopneumothorax. Data suggest that Combitube insertion is an effective method of airway control in trauma patients who fail orotracheal RSI. It may be particularly useful in the patient with maxillofacial trauma and offers a practical alternative to surgical cricothyroidotomy in difficult airway situations.

The ability of paramedic RSI to facilitate intubation of patients with severe head injuries in an urban out-of-hospital system was evaluated by Davis and colleagues.[73] Adult patients with head injuries were prospectively enrolled over a 1-year period by using the following inclusion criteria: Glasgow Coma Scale score of 3 to 8, transport time greater than 10 minutes, and inability to intubate without RSI. Midazolam and succinylcholine were administered before laryngoscopy, and rocuronium

was given after tube placement was confirmed by means of capnometry, syringe aspiration, and pulse oximetry. The Combitube was used as a salvage airway device. Outcome measures included intubation success rates, oxygen saturation values before and after intubation, arrival arterial blood gas values, and total out-of-hospital times for patients intubated en route versus on scene. Of 114 enrolled patients, 96 (84.2%) underwent successful endotracheal intubation, and 17 (14.9%) underwent Combitube intubation, with only 1 (0.9%) airway failure. There were no unrecognized esophageal intubations. On arrival at the trauma center, median oxygen saturation was 99%, mean arrival Pa_{O_2} was 307 mm Hg, and mean arrival Pa_{CO_2} was 35.8 mm Hg.[73,81]

Mercer and Gabbott considered the influence of neck position on ventilation with the Combitube, which was inserted in 40 patients undergoing general anesthesia.[77] A rigid cervical collar was then used to immobilize the neck of each patient. In all 40 subjects, adequate ventilation of the lungs was possible in this position as assessed by chest movement and auscultation, measurement of expired tidal volume, and maintenance of satisfactory arterial oxygen saturation. In 18 (45%) of 40 patients, small traces of blood were present on the Combitube after removal. Reducing the volume of air injected into the proximal balloon of the Combitube appeared to reduce the incidence of airway trauma during insertion.

In another study, a rigid cervical collar was used to immobilize the neck in 15 American Society of Anesthesiologists (ASA) physical class I or II patients under general anesthesia.[82] Insertion of the Combitube was then attempted. In 10 (66%) of 15 patients, blind insertion was impossible. In 5 (33%) of 15 successful blind insertions, the Combitube was in an esophageal position on each occasion. In 8 of 10 of the failures, reinsertion of the Combitube was attempted with the aid of a Macintosh laryngoscope. In 6 (75%) of 8 cases satisfactory placement was then possible, with the Combitube entering the esophagus on each occasion. Ventilation was satisfactory in all patients when insertion was successful. Blood staining of the Combitube was present in 7 (47%) of 15 patients. The investigators state that the Combitube cannot be recommended for use in patients whose necks are immobilized in rigid cervical collars. The alternative insertion technique may improve the rate of successful insertion in this group of patients, because it provides a larger oral aperture than the classic maneuver. However, in cases of suspected or evident cervical spine injury, manual in-line traction before intubation and application of a cervical collar is recommended.

In a 4-year, prospective study, Timmermann and colleagues followed the airway interventions performed by anesthesia-trained emergency physicians.[83] The Combitube or LMA was used in 2% of cases of failed intubation, with a success rate of 85% and 89%, respectively.

b. CASE REPORTS

A 14-year-old boy had been hit by a motorcycle while riding his bicycle. He suffered severe oronasal bleeding associated with craniofacial injury.[84] Computed tomography (CT) at admission indicated multiple craniofacial fractures (i.e., left frontal bone, maxilla, mandible, sphenoid bone, zygomatic bone, nasal bone, and ethmoid bone) with an epidural hematoma of the frontal lobe. His face was depressed about the nose. To keep the airway from oronasal bleeding, an emergency tracheostomy was performed after endotracheal intubation. Nasal and oral packing using Foley balloon catheters was performed but failed to control oronasal bleeding. Bradycardia appeared with ventricular fibrillation during the course because of marked hypovolemia. To get tighter packing, a Combitube was inserted. When the pharyngeal cuff of the Combitube was inflated, the blood pressure rose from 105/60 to 140/90 mm Hg, and the heart rate immediately decreased from 145 to 95 beats/min. Stable circulation was realized by this method during angiography. Embolization produced hemostasis. The Combitube was removed the next day. Surgery for facial fractures was conducted on the 16th hospital day, and the patient was discharged on the 70th hospital day. The Combitube was used in this case to effectively control severe oronasal bleeding before performing angiography. This method was easy to perform, and the investigators recommend the Combitube for oronasal bleeding before embolization.

In another case, an 18-year-old driver lost control of his car and crashed into a tree standing beside the street.[85] On arrival of the ambulance, the patient required immediate intubation, but he was trapped in the car. When the car struck the tree, the windshield was broken. Intubation was performed with the Combitube through the broken windshield with one hand only, and ventilation was performed successfully. The patient was then extracted and was intubated by an endotracheal airway. The patient survived and passed high school examinations soon after the accident.

A similar situation occurred for a 24-year-old man who was trapped in his jeep after a motor vehicle collision.[86] During his rescue, immediate intubation became mandatory. Because access to the patient's head was limited, a Combitube was inserted while standing in front of him, and ventilation was easily accomplished. The patient was admitted to the hospital and weaned from the ventilator 3 days later. After 4 weeks, he was discharged from the hospital without any neurologic sequelae. The Combitube appeared to be a valid alternative to endotracheal intubation in cases of difficult access to the patient's head.

Deroy and Ghoris described a case of elective anesthetic airway management in a patient with a cervical spine fracture.[87] In several unusual cases, the Combitube has proved superior to conventional endotracheal intubation. The Combitube proved to be useful in the case of neck impalement with a large, wooden splinter entering at the left angle of the mandible, traversing the pharynx and soft palate, and entering the right maxillary cavity below the floor of the orbit.[88]

Mercer reported a patient with a difficult airway who was in a halo frame for cervical immobilization.[89] The Combitube was successfully used after difficult bag-mask-valve ventilation and failed LMA ventilation.[89] Bhagwat and coworkers described the successful use of the Combitube to control oral cavity bleeding.[90] The

patient had uncontrollable, torrential bleeding caused by the rupture of a right cheek and mandible arteriovenous malformation. The Combitube was used to ensure the airway and to control bleeding through the tamponade effect exercised by the pharyngeal balloon while performing external carotid artery ligation.

3. Anesthesiologic Studies

a. GENERAL ANESTHESIA

Function and effectiveness of the Combitube were first tested in animal experiments and subsequently in humans.[13,14] The effectiveness of ventilation with the Combitube was compared with ventilation with an ETT during routine surgery in a crossover study.[17] Twenty-three patients were ventilated first with the Combitube and then with an ETT (group 1). In group 2, application of the tubes was performed in a reversed order in eight patients. After 20 minutes of ventilation with each airway, arterial blood samples were analyzed. In all cases, patients were ventilated with the Combitube without problems, comparable to ventilation with an ETT. Arterial oxygen pressure was higher during ventilation with the Combitube (142 ± 43 mm Hg with the Combitube versus 119 ± 40 mm Hg with the ETT in group 1, P =.001; 117 ± 16 mm Hg with the endotracheal airway versus 146 ± 13 mm Hg with the Combitube in group 2, P =.001), whereas the differences in arterial carbon dioxide tension and pH were not significant.

The reasons for increased oxygen tension during ventilation with the Combitube were investigated in another study.[91] In 12 patients undergoing general anesthesia during routine surgery, a thin catheter was placed with its tip 10 cm below the vocal cords. Patients were then ventilated by mask, by the Combitube in the esophageal position, and by an ETT in a randomized sequence. Pressures were recorded in the trachea and at the airway openings. Blood gas analysis showed a higher arterial oxygen tension with the Combitube than with the ETT (151 ± 37 mm Hg versus 125 ± 32 mm Hg, $P < 0.05$) and a higher arterial carbon dioxide tension (36 ± 4 mm Hg versus 33 ± 4 mm Hg, $P < 0.05$). This slightly higher carbon dioxide tension with the Combitube may in part reflect integration of the hypopharynx into the physiologic dead space. Compared with mask ventilation, carbon dioxide tension was lower with the Combitube.

Several differences in intratracheal pressures were found. The rising pressure during inspiration was highest with the ETT (19 ± 6 mm Hg/sec with the ETT versus 14 ± 6 mm Hg/sec with the Combitube, $P < 0.05$). The smaller rising pressure with the Combitube may lead to a more favorable distribution of ventilation. Expiratory flow time was prolonged during ventilation with the Combitube (2.0 ± 1.0 seconds versus 1.3 ± 0.6 seconds with the ETT). This effect probably results from increased expiratory resistance because of the double-lumen design, and it may favor formation of a small, intrinsic, positive end-expiratory pressure (auto-PEEP). Auto-PEEP may also be caused by integration of the vocal cords into the airway with the Combitube, whereas they are bypassed by the ETT. The auto-PEEP does not exceed 2 mm Hg and therefore does not influence cerebral perfusion during CPR. The smaller rising pressure, prolonged expiratory-flow time, and auto-PEEP are responsible for the improved conditions for alveolar-arterial gas exchange.

Although peak pressures at the airway openings may be high due to the resistance of the double-lumen airway, intratracheal pressures were comparable for the two tubes. The peak endotracheal pressure was 10 ± 4 mm Hg with a Combitube and 12 ± 6 mm Hg with an ETT (P was not significant [ns]). The endotracheal-plateau pressure was 8 ± 2 mm Hg with the Combitube and 8 ± 4 mm Hg with the ETT (P = ns).[14] The Combitube may also be used for prolonged ventilation.[39] In seven patients in the ICU, the Combitube was used over a period of 2 to 8 hours during mechanical ventilation. Results showed adequate ventilation compared with subsequent endotracheal ventilation. Lipp and associates had an average time for insertion of the Combitube of 12 to 23 seconds.[92] In 3 of 50 patients, the Combitube had to be withdrawn 1 to 2 cm.

Urtubia and coworkers studied the proper use of the Combitube.[24] Although the manufacturer recommends that the SA Combitube be used in patients between 122 and 152 cm tall, the aim of this study was to evaluate whether ventilation was effective and reliable in patients taller than 152 cm with the Combitube in the esophageal position. They investigated whether airway protection was adequate and whether direct intubation of the trachea with the Combitube inserted in the esophagus was possible. Urtubia and colleagues studied 25 anesthetized, paralyzed, adult patients who were 150 to 180 cm tall.[24] Methylene blue was given orally to all patients before anesthesia induction. Under direct vision, an SA Combitube was inserted in the esophagus of all patients. The pharyngeal balloon inflation volume was titrated to air leak, and cuff pressures were measured. During surgery, a laryngoscope was inserted into the pharynx with the pharyngeal balloon deflated, and the laryngoscopic view was evaluated by using the Cormack-Lehane scale. The presence of methylene blue in the hypopharynx was investigated by direct laryngoscopy. Ventilation was effective and reliable in all 25 patients who were 150 to 180 cm tall (average, 169 ± 7 cm). A direct relationship between the pharyngeal balloon volume and patient height was established ($P < 0.05$) by using linear regression models, suggesting that the 37-F SA Combitube can be used in patients up to 6 feet (185 cm) tall and implying that the SA Combitube is the preferred size for most patients. The laryngoscopic view of the glottis was adequate to allow direct tracheal intubation. No trace of methylene blue was detected in the hypopharynx. The investigators concluded that the SA Combitube may be used in patients 122 to 185 cm tall. The trachea could be directly intubated with the Combitube in the esophageal position in patients with normal airways, and airway protection appeared to be adequate.

Gaitini and coworkers investigated the effectiveness of the Combitube in elective surgery during mechanical and spontaneous ventilation.[18] Two hundred ASA physical status I or II patients with normal airways who were scheduled for elective surgery were randomly allocated to two groups: nonparalyzed, spontaneously breathing

($n = 100$) or paralyzed, mechanically ventilated ($n = 100$). After induction of general anesthesia and insertion of the Combitube, SpO_2, Et_{CO_2}, isoflurane concentration, systolic and diastolic blood pressure, heart rate, and breath-by-breath spirometry data were obtained every 5 minutes. In 97% of patients, it was possible to maintain oxygenation, ventilation, respiratory mechanics, and hemodynamic stability during mechanical or spontaneous ventilation for the duration of surgery, which was between 15 and 155 minutes. The results of this study suggest that the Combitube is an effective and safe airway device for continued management of the airway in 97% of elective surgery cases.

Walz and colleagues tested the smaller SA Combitube in patients exceeding 5 feet tall.[25] They studied 104 patients (66 men and 38 women between 3.93 [120 cm] and 6.5 ft [198 cm]) who received the SA Combitube during general anesthesia, most often during implantation of an automatic implantable cardioverter defibrillator. The duration of the procedures ranged from 45 to 360 minutes. In each case, the investigators were able to document with the use of pulse oximetry, capnometry, and ventilation parameters that the patients could be oxygenated and ventilated adequately. The oropharyngeal cuff volume of 85 mL, recommended by the manufacturer, was sufficient in 71 patients (68%). The remaining 33 patients required an additional insufflation volume of 25 to 50 mL in the oropharyngeal balloon to prevent air leakage. The group concluded that the SA Combitube could be used without restriction in patients exceeding 5 feet tall. Because of its smaller size, the SA Combitube is easier to use and seems to be less traumatic to soft tissues. Walz and colleagues preferred to use a laryngoscope during insertion of the SA Combitube, which resulted in less trauma and reduced the number of intubation failures.[25]

Evaluation of safety, efficacy, and maximum ventilatory pressures during routine surgery was investigated by Frass and coworkers.[93] Five hundred patients receiving general anesthesia were enrolled in the study. Type of surgery, duration of surgery, ease of airway insertion, and potential complications were recorded, along with maximum ventilatory pressures and leaks. The Combitube worked well in all but two patients. Duration of surgery varied between 30 and 360 minutes. The Combitube was placed in the esophagus in 97% of patients. More than 95% of the blind Combitube insertions were successful on the first attempt, with an average intubation time of less than 15 seconds. Efficacy of oxygenation and ventilation with the Combitube was evaluated by pulse oximetry and Et_{CO_2}. An SpO_2 greater than 95% was documented in all cases, and the Et_{CO_2} was 35 to 45 mm Hg. Leak, expressed as a fraction of the inspired volume, did not increase more than 5%, up to a ventilation pressure of 50 cm H_2O. Data suggest that the Combitube is safe, easy to insert, and useful during routine surgery. The device may be used when ETT placement is not immediately possible.

Schreier and associates studied the 37-F SA Combitube in 20 children.[94] The average age was 9.3 ± 2.4 years, height was 137.3 ± 10.5 cm, and weight was 35 ±10.8 kg. The Combitube worked well in all cases. This study shows that the 37-F SA Combitube can be used in "cannot intubate, cannot ventilate" (CICV) cases for children taller than 122 cm.

A 46-year-old, obese, white woman with a short neck was scheduled for excision of a thyroid goiter.[95] One hour after extubation, a hematoma was identified in the right anterior neck. Immediate intubation was mandatory. Fiberoptic intubation failed, but a blind attempt at inserting an ETT resulted in an esophageal intubation. An interincisor distance of 13 mm prevented insertion of a no. 3 LMA. An SA Combitube was then inserted blindly. Oxygen saturation rapidly improved and was maintained at 97% with an F_{IO_2} of 1.0. General anesthesia was completed, and after evacuation of the hematoma, ventilation improved as peak airway pressures declined. The Combitube was superior to the LMA in this case because of its slim design. The Combitube should be considered as an additional tool for managing patient airways in difficult circumstances.

Hagberg and colleagues reported successful use of the Combitube in a 50-year-old patient who had a severe contracture of the mouth and significant tracheal stenosis after prolonged intubation following a burn injury to the face.[96] His airway evaluation revealed a Mallampati class IV airway, one-finger-breadth mouth opening, and full range of neck mobility. Because of the patient's airway examination and concern about endotracheal intubation causing further subglottic tracheal stenosis, a Combitube was chosen for airway management. The otorhinolaryngology surgeons were present in the room when the patient's neck was prepared and draped and equipment was set up for a tracheostomy, if necessary. A fiberoptic bronchoscope was prepared for use. The investigators found the Combitube to be a very advantageous airway device in establishing an airway in this case and thought it should be considered for elective use in patients with limited mouth opening. They also recommended more extensive use of the Combitube in the operating room so that physicians are familiar with the device when it is needed emergently.[97,98]

The ease of learning to use the Combitube has been assessed. Enlund and associates reported a case in which conventional endotracheal intubation failed.[99] The patient was ventilated by a face mask in the sitting position while the Combitube was brought to the operating room. Although the surgeons were inexperienced in Combitube use, they read the manufacturer's instructions in the operating room and successfully inserted the Combitube. The device worked well throughout the entire surgical procedure.

Because tracheal suctioning is impossible with the Combitube placed in the esophageal position, the Combitube was redesigned.[60] The two anterior, proximal perforations of regular Combitubes were replaced by a larger, ellipsoid hole. Twenty patients with normal airways (Mallampati class I or II) were studied. During general anesthesia, patients were esophageally intubated with the Combitube. A flexible bronchoscope was inserted and guided through the modified hole and glottic opening down the trachea. For the replacement procedure, a J-tip guidewire was introduced through the bronchoscope. The bronchoscope and the Combitube were removed,

and a standard ETT was advanced over a guide catheter. Bronchoscopic evaluation of the trachea and guided replacement of the Combitube by an ETT was successful in all 20 patients. The average time needed to perform airway exchange was 90 ± 20 seconds. Arterial oxygen saturation and Et_{CO_2} levels remained normal in all patients. No case of laryngeal trauma was observed during intubation or the airway exchange procedure. The redesigned Combitube enables fiberoptic bronchoscopy, fine-tuning of its position in the esophagus, and guided airway exchange in patients with normal airways. Further studies are warranted to demonstrate the value of this redesigned Combitube in patients with abnormal airways. This version is not commercially available.

b. LAPAROSCOPIC SURGERY

Airway management during laparoscopy is complicated by intraperitoneal carbon dioxide inflation, Trendelenburg position, increased airway pressures, and increased risk of pulmonary aspiration. The Combitube was used in 25 cases of laparoscopic cholecystectomy. Gastric insufflation could not be observed on the video film at the beginning or end of surgery.[100] Hartmann and coworkers investigated whether the SA Combitube was a suitable airway during gynecologic laparoscopy.[27] One hundred patients were randomly allocated to receive the SA Combitube (n = 49) or ETT (n = 51). Esophageal placement of the Combitube was successful at the first attempt (16 ± 3 seconds). Peak airway pressures were 25 ± 5 cm H_2O. An airtight seal was obtained using air volumes of 55 ± 13 mL (oropharyngeal balloon) and 10 ± 1 mL (esophageal cuff). Significant correlations were observed between the patient's height and weight and the volumes necessary to produce a seal. Similar findings were recorded for the control group; tracheal intubation was difficult in three patients. The SA Combitube provided a patent airway during laparoscopy. Nontraumatic insertion was possible, and an airtight seal was provided at airway pressures of up to 30 cm H_2O.

Exposure to sevoflurane and nitrous oxide (N_2O) during ventilation using an SA Combitube was compared with waste gas exposure using a conventional ETT.[101] Trace concentrations of sevoflurane and N_2O were assessed using a direct-reading spectrometer during 40 gynecologic laparoscopic procedures performed under general anesthesia. Measurements were made at the patients' mouths and in the anesthesiologists' breathing zones. Mean (±SD) concentrations of sevoflurane and N_2O measured at the patients' mouths were comparable in the SA Combitube group (0.6 ± 0.2 ppm of sevoflurane; 9.7 ± 8.5 ppm of N_2O) and ETT group (1.2 ± 0.8 ppm of sevoflurane; 17.2 ± 10.6 ppm of N_2O). These values caused comparable contamination of the anesthesiologists' breathing zones: 0.6 ± 0.2 ppm of sevoflurane and 4.3 ± 3.7 ppm of N_2O for the SA Combitube group, compared with 0.5 ± 0.2 ppm of sevoflurane and 4.1 ± 1.8 ppm of N_2O for the ETT group. Use of the SA Combitube during positive-pressure ventilation was not necessarily associated with increased waste gas exposure, especially when air conditioning and scavenging devices were available. The Combitube functioned satisfactorily in 22 patients scheduled for elective laparotomy.[91]

c. OBSTETRIC ANESTHESIA

Airway-related problems represent the most frequent cause of death among women who die of a complication of general anesthesia for cesarean delivery.[102] The Combitube has been included in algorithms for managing an unexpected difficult airway during general anesthesia for cesarean delivery.[102,103]

Urtubia and colleagues reported two cases of emergency cesarean delivery under general anesthesia in which an SA Combitube was used for first-line management of the airway.[104] Acute, severe fetal bradycardia in a 17-year-old, obese, pregnant girl did not allow time to perform spinal blockade. General anesthesia was induced, and the airway was maintained through a face mask while applying the Sellick maneuver. After delivery, an SA Combitube was blindly inserted into the esophagus while maintaining cricoid pressure. Ventilation and oxygenation were adequate. For a 27-year-old, deaf-mute, pregnant woman, emergent cesarean delivery was performed because of fetal distress under spinal anesthesia. Soon after surgery began, the patient demonstrated clear signs of pain, and general anesthesia was induced and ventilation performed through the SA Combitube inserted in the esophagus under laryngoscopic guidance. No postoperative pharyngeal symptoms and no respiratory complications were detected in both cases. The Combitube allowed adequate ventilation and airway protection for emergency cesarean delivery in these patients. The Combitube was quickly inserted blindly and with laryngoscopic guidance.

The Combitube was used as a rescue device in a CICV situation during induction of general anesthesia for a cesarean delivery. This case was followed by transient dysfunction of cranial nerves IX and XI, which was attributed to excessive pressure exerted on the pharyngeal mucosa.[105] This problem can be avoided by using the minimal inflation technique.[40]

Wissler used the Combitube in obstetric anesthesia.[106] He found that the Combitube was most easily and atraumatically inserted into the esophagus under direct vision using a laryngoscope. In his practice of obstetric anesthesia, the Combitube is his first choice for the anesthetized parturient who cannot be intubated or mask ventilated with cricoid pressure. He thinks it provides a better barrier against regurgitation and aspiration than the LMA.

In a pilot study performed by Hagberg and colleagues, the Combitube was determined to be comparable to the LMA regarding the incidence of gastroesophageal reflux (GER) and tracheal acid aspiration as detected by pH monitoring.[36] Fifty-seven patients were randomly assigned to receive an LMA or a Combitube for their elective surgical procedures. All patients were paralyzed and received positive-pressure ventilation. Two monocrystalline antimony catheters were used for pH monitoring of the trachea, oropharynx, and esophagus. One episode of GER occurred with the Combitube in place on extubation, but there were no pH changes reflected in the oropharyngeal or tracheal regions. Three patients in the LMA group met the pH criterion for aspiration (pH < 4.0 lasting at least 15 seconds), compared with only one patient in the Combitube group, but no patient

TABLE 27-1
Comparisons of Emergency Airway Equipment

Function	EasyTube or Combitube	Laryngeal Mask Airway or Laryngeal Tube	Esophageal Obturator Airway	Esophageal Gastric Tube Airway	Pharyngotracheal Lumen Airway
Provides barrier to minimize regurgitation of gastric contents	Yes	No	Yes	Yes	Yes
Allows buildup in esophagus of pressure and gastric contents during use	No	No	Yes	No	No
Functions when blindly passed into esophagus	Yes	NA	Yes	Yes	Yes
Functions when blindly passed into trachea	Yes	NA	No	No	Yes
Requires effective mask fit on face	No	No	Yes	Yes	No

developed any clinical signs of aspiration. By providing reliable airway protection, the Combitube provides another alternative in managing a difficult airway.

Ideal insertion conditions for the LMA include lubrication and a special method of cuff deflation, whereas the Combitube is ready to use in its package. In an obstetric patient with increased oxygen consumption, decreased functional residual capacity, and airway obstruction, these differences in preparation time may be clinically important.

d. COMBITUBE COMPARED WITH ALTERNATIVE AIRWAY TECHNIQUES

The design of the Combitube has several advantages over other devices, including an open distal tip that allows decompression and suctioning of the esophagus and stomach in the esophageal position and ventilation in the tracheal position (Table 27-1).[106] Compared with other devices, the double-lumen design of the Combitube prevents lumen occlusion if the patient bites the tube, which avoids ventilation emergencies during the awakening period.

Compared with the LMA, the VBM Laryngeal Tube (LT; VBM Medizintechnik, Sulz, Germany), and other similar devices, the Combitube provides a decompression barrier (i.e., tracheoesophageal lumen) to minimize regurgitation of gastric contents and allows controlled mechanical ventilation with ventilation pressures higher than 20 cm H_2O.[91,107] Because the Combitube is safe against aspiration and avoids gastric insufflation during positive-pressure ventilation, use of the LMA is recommended only in elective cases without danger of aspiration. The LT is a device that simulates the design of the Combitube. Although the LT bears no lumen for active decompression, the VBM Laryngeal Tube Suction (LTS) does allow decompression of gastric contents. However, the device is very bulky and may be difficult to place in patients with a small interincisor distance. Another disadvantage is that analogous to the LMA, several sizes should be available to meet the needs of different sizes of patients.

In a training course for emergency care physicians, Winterhalter and associates compared emergency intubation with the Magill tube,[108] LMA, and Combitube in mannequins. The Combitube was rated highest with regard to effectiveness and ease of placement. In another comparative study involving nonanesthesia house officers, ventilation by face mask and LMA in a model led to gastric insufflation, but there was none with the Combitube.[109]

H. Recommendations for the Combitube

The Combitube has gained worldwide interest as an adjunct to standard airway equipment in many anesthesiology departments and ambulance services.[110-113] The Combitube has been recommended in the ASA practice guidelines for management of the difficult airway; the difficult airway algorithm calls for using the Combitube when an anesthetized patient can be neither intubated nor mask ventilated. Since 1992, it has been included in the guidelines for cardiopulmonary resuscitation and emergency cardiac care of the American Heart Association (AHA) as the first alternative airway, replacing the esophageal obturator as an alternative to the ETT.[114-117] The AHA has described the Combitube as a valuable tool for emergency intubation.[116]

In 2000, the Combitube was upgraded by the AHA to a class IIa device.[117] Recommendations for use of the Combitube have been included in the guidelines of the European Resuscitation Council, the Difficult Airway Society guidelines for management of unanticipated difficult intubations, and in many national guidelines.[118-121] The Combitube is included in the Street-Level Airway Management (SLAM) Emergency Airway Flowchart, a guideline created for advanced airway practitioners in anesthesiology, emergency medicine, and prehospital care.[113]

The Combitube is cited in many review articles as an alternative method for artificial ventilation, and it is recommended for patients with massive regurgitation or airway hemorrhage when visualization of the

vocal cords may be impossible.[28,31,50,51,111,122,123] Gaitini and coworkers described the Combitube as an easily inserted, double-lumen/double-balloon supraglottic airway device.[18] The major indication for the Combitube is as a backup device for airway management. It is highly recommended for rescue ventilation in in-hospital and out-of-hospital environments and in situations of difficult ventilation and intubation, especially in patients with massive airway bleeding or limited access to the airway and those in whom neck movement is contraindicated.

Continued airway management with a Combitube that has been placed is a reasonable option in many cases. After securing the airway, it may not be necessary to abort the anesthetic or to continue with further airway management efforts. The Combitube is the perfect solution in places where a fiberoptic device is not available or when fiberoptic intubation fails.

Agró and colleagues emphasized that the Combitube is an easily inserted and highly efficacious device to be used as an alternative airway whenever conventional ventilation fails.[28] The Combitube allows ventilation and oxygenation whether the device is located in the esophagus (common) or the trachea (rare). Their review of the literature found the Combitube described as a valuable and effective airway in the emergency and prehospital settings, in cardiopulmonary resuscitation, in elective surgery, and in critically ill patients in the ICU. Some studies demonstrated the superiority of the Combitube over other supraglottic ventilatory devices in resuscitation as assessed by success rates for insertion and ventilation. Unlike the LMA, the Combitube may help in patients with limited mouth opening. It may especially benefit patients with massive bleeding or regurgitation, and it minimizes the risk of aspiration.

Because the Combitube is one of the three alternatives approved by the ASA for managing the CICV situation, its continued use is highly advisable, especially for trainees, to promote familiarity with it and allow its successful use during an emergency.

II. EASYTUBE

A. Development of the EasyTube Esophageal-Tracheal Double-Lumen Airway

The EasyTube (Rüsch EasyTube, Teleflex Medical, Research Triangle Park, NC) was developed to improve the standard of the Combitube. The outer appearance and handling are similar to those features of the Combitube.[124]

B. Technical Description and Insertion Technique

The EasyTube has a pharyngeal lumen that provides a supraglottic ventilation outlet ending just below the oropharyngeal balloon, which allows passage of a bronchoscope for inspection of the trachea, suctioning of tracheal secretions, or replacement, if necessary (Fig. 27-10). Because of this design, the longer tracheoesophageal lumen has a smaller outer tube diameter together and a larger inner diameter, and it ends like an ETT, decreasing the chance of injury to the pharyngeal and tracheal mucosa.

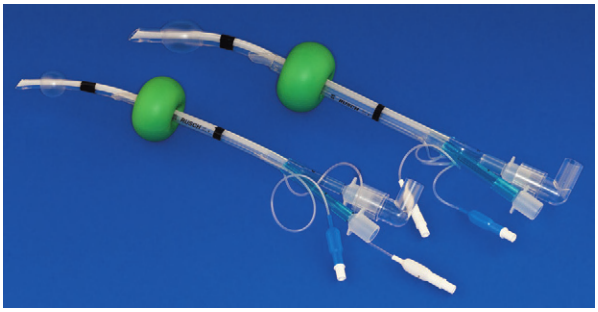

Figure 27-10 Two sizes of the EasyTube: 41 F (large) and 28 F (small).

The distal end of the EasyTube is designed like that of a standard tracheal tube, with a tip diameter of 7.5 mm (41 F) or 5.5 mm (28 F). The device has kink-resistant outer tubes. It is a latex-free, sterile, single-use, double-lumen tube, and it is available in two sizes: 41 F for adult patients who are taller than 130 cm and 28 F for pediatric patients 90 to 130 cm tall. It provides sufficient ventilation when placed in the esophagus or the trachea.

The EasyTube may be positioned blindly or with the help of a laryngoscope. Laryngoscopic insertion is similar to that used for a standard tracheal tube. After placing the patient's head in a sniffing position and performing direct laryngoscopy, the trachea is intubated with the EasyTube. A black mark at the distal end of the tube indicates correct depth of insertion just below the vocal cords. Ventilation is performed through the transparent no. 2 lumen. In a CICV situation, the EasyTube can be inserted in the esophagus using a laryngoscope. Ventilation is then performed using the colored no. 1 lumen. The EasyTube also may be inserted blindly, as health care providers usually perform it, especially in the prehospital setting. While the patient's head is kept in a neutral position, the tube is inserted in a straightforward movement, parallel to the frontal axis of the patient, until the proximal black ring mark is positioned at the level of the upper incisor teeth. In the esophageal position, the no. 2 lumen may be used to drain gastric contents or allow insertion of a gastric tube. The pharyngeal and the distal cuffs are inflated with 80 and 10 mL of air, respectively, using the two prefilled syringes in the package (Fig. 27-11).

C. Indications, Advantages, and Complications

Indications for use of the EasyTube are the same as for the Combitube (see Box 27-1). It is designed for emergency intubation and for use in patients undergoing general anesthesia. It has been especially useful in various CICV situations. The 28-F pediatric size may be advantageous, because advanced airway management in children can be challenging, and the potential for morbidity is increased by failed attempts.[125] Nagler and Bachur posit that supraglottic rescue devices, including the LMA,

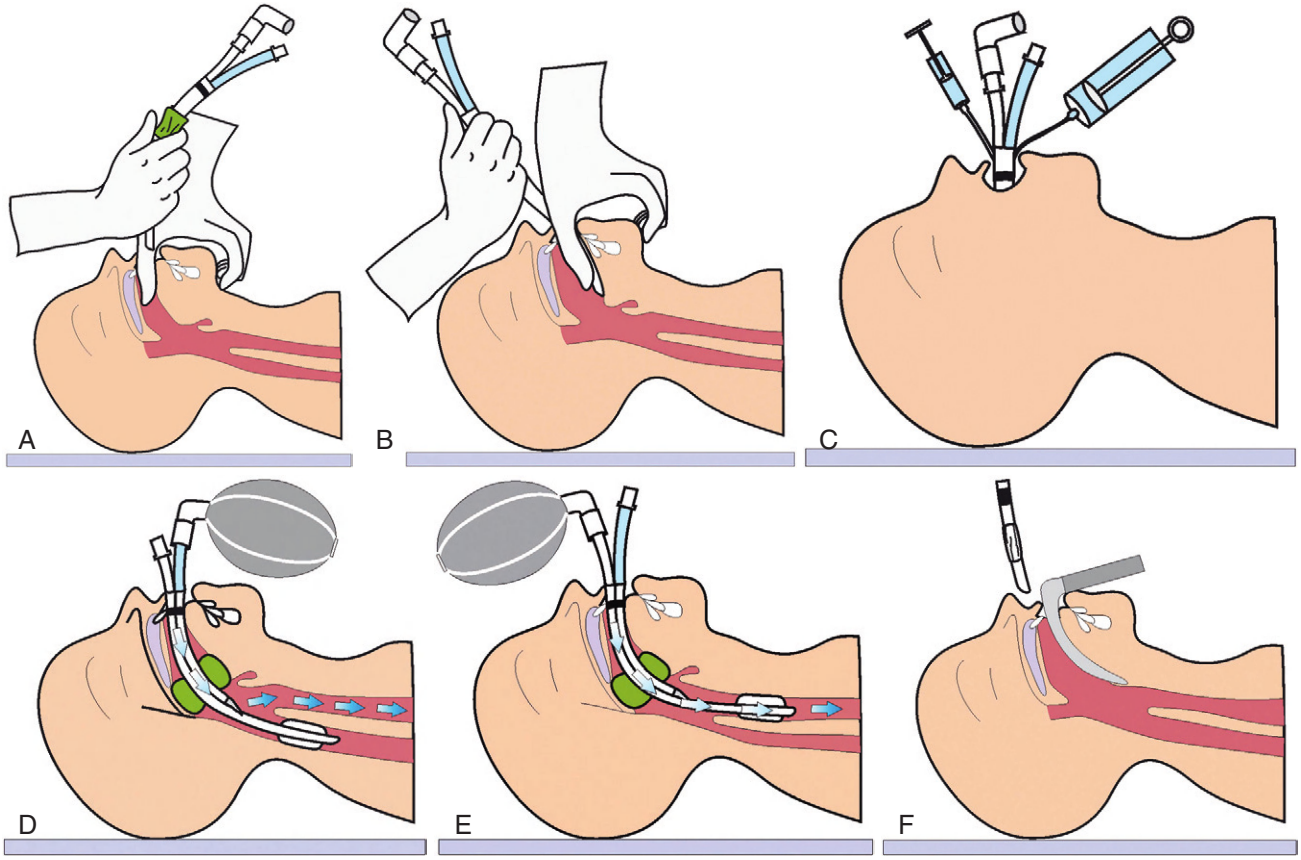

Figure 27-11 Guidelines for insertion of the EasyTube. **A,** Insertion begins by lifting the chin and lower jaw. **B,** The EasyTube is inserted in a downward, curved movement along the tongue. **C,** The oropharyngeal balloon is inflated with 80 mL of air and the distal cuff with 10 mL of air using the two prefilled syringes in the package. **D,** With the EasyTube in the esophageal position, ventilation is performed through the longer no. 1 tube *(blue)*. Air flows through the ventilation aperture into the pharynx and from there into the trachea *(arrows)*. **E,** With the EasyTube in the tracheal position, ventilation is performed through the shorter no. 2 tube *(transparent)*. Air flows directly into the trachea *(arrow)*. **F.** The EasyTube is inserted using a laryngoscope.

esophageal–tracheal double-lumen tube, and laryngeal tube, offer suitable ventilation strategies after failed intubation and in arrest scenarios.[125] They encourage pediatric providers to develop familiarity with emerging rescue ventilation devices and with advances in the practice of RSI and laryngoscopy.

1. Out-of-Hospital Emergency Intubation

Ease of use of the EasyTube makes it especially suitable for emergency intubation, which can be performed with the patient in almost any position. The dual lumens allow ventilation in the esophageal or tracheal position. Oral anchoring of the EasyTube is another feature that can be valuable during ventilation and transportation.

2. Elective and Emergency Surgery

a. GENERAL ANESTHESIA

The EasyTube was developed for use in general anesthesia cases. The dual system may be used to insert the EasyTube intentionally in the esophagus or the trachea. The ring mark below the distal cuffs enables correct positioning in relation to the vocal cords.

b. REPLACEMENT OF THE EASYTUBE

Analogous to the Combitube, the EasyTube can be replaced through a cricothyrotomy or tracheostomy or with the help of a video laryngoscope. Replacement also can be achieved with a bronchoscope and a guidewire inserted through the EasyTube working channel.

c. EXTUBATION

Similar to the Combitube, the oropharyngeal balloon of the EasyTube is deflated to allow communication with the patient. After recovery of protective reflexes, deflation of the distal cuff and final extubation during continuous suctioning through the shorter no. 2 lumen is performed. After full resumption of spontaneous ventilation, the EasyTube can be removed.

3. Advantages

The EasyTube provides several advantages over the Combitube:

1. The pharyngeal lumen of the EasyTube ends just below the oropharyngeal balloon. The tracheoesophageal lumen is thinner than that of the

Combitube, which carries the two lumens down to the end. The thinner distal lumen of the EasyTube decreases the chance of injury to the pharyngeal and tracheal mucosa.
2. The oropharyngeal balloon is latex free.
3. The EasyTube is available in two sizes. The 28-F version is designed for pediatric patients 90 to 130 cm tall. The 41-F EasyTube is designed for patients taller than 130 cm, which includes most patients.
4. A fiberoptic scope can be passed through the pharyngeal lumen, because it is open at the distal end. This feature allows inspection of the trachea and offers one way to replace the EasyTube using a guidewire.
5. A larger suction catheter can be passed through both lumens (e.g., 16-F suction catheter in the 41-F EasyTube).
6. The eight small holes or ventilation apertures of the terminal oropharyngeal lumen of the Combitube may be responsible for a greater resistance, leading to larger differences in peak airway pressure measurements.[126] The EasyTube has only one supraglottic ventilation aperture.

The slim design allows insertion of the EasyTube in patients with an interincisor distance as small as 12 mm. As in the Combitube, the oropharyngeal cuff of the EasyTube prevents aspiration of blood or secretions from the oral or nasal cavity, and the distal cuff seals the esophagus preventing aspiration of esophageal or gastric secretions. This has been confirmed in a cadaver study.[107] Bercker and colleagues designed a study to compare the seal of seven supraglottic airway devices in a cadaver model of elevated esophageal pressure.[107] The Classic laryngeal mask airway (LMA-Classic), ProSeal laryngeal mask airway (PLMA), Fastrach intubating laryngeal mask airway (ILMA-Fastrach), Laryngeal Tube Suction (LTS), Laryngeal Tube Suction II (LTS II), Combitube, and EasyTube were inserted in unfixed human cadavers with an exposed esophagus that had been connected to a water column 130 cm high. Slow and fast increases of esophageal pressure were performed, and the water pressure at which leakage appeared was registered. The Combitube, EasyTube, and ILMA-Fastrach withstood water pressure up to more than 120 cm H_2O. The PLMA, LTS, and LTS II were able to block the esophagus until 72 to 82 cm H_2O. The LMA-Classic showed leakage at 48 cm H_2O, but only minor leakage was found in the trachea. Devices with an additional esophageal drainage tube drained fluid sufficiently without pulmonary aspiration. The investigators thought that the use of devices with an additional esophageal drainage lumen might be superior for use in patients with an increased risk of aspiration.[107] The Combitube, EasyTube, and ILMA-Fastrach showed the best capacity to withstand an increase of esophageal pressure.

Based on a review of the literature and his own experience as a paramedic and anesthesiologist, Bollig suggests that the Combitube and the EasyTube should be recommended in the Scandinavian guidelines for prehospital airway management.[127] He argues that the Combitube has been recommended as an alternative airway device in the ALS guidelines of the European Resuscitation Council and in the ASA guidelines for CICV situations.[114,116] A review of the literature revealed the following advantages of the Combitube and EasyTube:

1. Insertion time is shorter for these devices than for endotracheal intubation.
2. The double-lumen airways offer better protection against aspiration than a laryngeal mask.
3. Insertion is possible despite a smaller mouth opening and in patients with massive bleeding or regurgitation.
4. Blind insertion is possible in patients who are trapped in a sitting position (e.g., car crash).
5. Epinephrine and lidocaine can be applied through the Combitube.
6. Mechanical ventilation in intensive care is possible for several hours using the Combitube.

4. Disadvantages

Long-term ventilation through the pharyngeal lumen of the EasyTube is limited to 8 hours. However, this time appears to be adequate for bridging the gap in managing a difficult airway situation.

5. Contraindications

Similar to the Combitube, any obstruction of the upper airways may be a relative or absolute contraindication for insertion of the EasyTube.

6. Complications

Possible complications comprise any damage, bleeding, or perforation of the oral, pharyngeal, or esophageal mucosa. However, because of the slimmer distal outer diameter of the tracheoesophageal lumen, the danger of injury is minimal. No major complications have been reported with the use of the EasyTube.

D. Medical Literature

1. Mannequin Studies

Based on the results from a mannequin study, the use of an impedance threshold valve for ventilation during CPR is possible in combination with the Combitube, EasyTube, or other supraglottic airway device.[128] Robak and coworkers reported the superiority of Combitube and EasyTube for controlling the airway in a mannequin under simulated pathologic airway conditions.[129] Fifty medical students assessed the success rate and insertion time for seven supraglottic airway devices: LMA Unique, LMA Fastrach single use, LMA Supreme, King LTS disposable (LTS-D), i-gel, Combitube, and EasyTube. All airways were inserted without problems, but only the Combitube and EasyTube were successfully inserted in simulated trismus, limited mobility of the cervical spine, and in cases of combined pathologic conditions such as trismus plus limited mobility of the spine and trismus plus tongue edema.

In another mannequin model, Ruetzler and colleagues studied the performance and skill retention of intubation by paramedics using seven airway devices: ETT, LMA

Unique, PLMA, LTS-D, i-gel, Combitube, and EasyTube.[130] After 3 months, 100% successful skill retention was reported for five of six supraglottic airway devices (i.e., LMA Unique, LTS-D, i-gel, Combitube, and EasyTube), and a rate of 58% was reported for endotracheal intubation.

2. In-Hospital Studies

Bollig and colleagues determined the difference in the rate of and time to successful airway placement and ventilation using tracheal intubation compared with use of the esophageal-tracheal Combitube or EasyTube. Twenty-six paramedics, who were trained in tracheal intubation, received additional training in the use of the Combitube and the EasyTube.[131] Each participant performed all three methods twice in a random order on a manikin. Time to successful ventilation (presented as the mean and standard deviation) and the success rate were recorded. Mean time to successful ventilation was significantly longer for tracheal intubation (45.2 ± 15.8 seconds) than for the Combitube (36.0 ± 8.6 seconds, $P = 0.002$) and the EasyTube (38.0 ± 15.3 seconds, $P = 0.023$), with no difference between the latter two methods ($P = 1.000$). The combined success rate for the Combitube and EasyTube (103 of 104 attempts) was significantly higher than for tracheal intubation (45 of 52 attempts) (odds ratio [OR] = 16.0; 95% confidence interval [CI], 1.9 to 134; $P = 0.002$). For the paramedics tested on manikins, the placement success rate was higher and less time was required for the Combitube and EasyTube than for tracheal intubation, with no differences identified between the Combitube and EasyTube.

In a study by Thierbach and Werner, 30 adult patients (ASA physical status I or II, Mallampati class I and II, and weight between 50 and 80 kg) undergoing minor surgery were randomly allocated to the esophageal EasyTube insertion group using a blind or laryngoscopically guided technique.[132] Data were collected for number of attempts, time taken to provide an effective airway, blood staining, and postoperative airway morbidity. The time to obtain an effective airway was measured from removal of the face mask to confirmation of normal ventilation and evaluated by bilateral chest movement and a normal capnography curve. There were no failures on inserting the device with either technique. First attempt and second attempt insertion rates were 86% and 14% for the blind insertion technique and 93% and 7% for the laryngoscopically guided technique, respectively. Time to achieve an effective airway was 31 ± 4 seconds for the blind technique and 33 ± 6 seconds for the laryngoscopically guided technique. After removal of the device, blood stains were observed in eight patients, with four patients in each group. The rate of sore throat in the postanesthesia care unit was 20% for both groups, and no patient required treatment. Data suggest that insertion of the EasyTube has the same success rate with or without using a laryngoscope. A study determined that pressures exerted on the oropharyngeal mucosa were lower than with laryngeal masks.[133]

Lorenz and associates studied the effectiveness, safety, and ease of placement of the EasyTube compared with an ETT in 200 patients randomized to one of these two groups.[134] Even though the number of insertions was equal in both groups, the insertion time was shorter with the EasyTube. (15.5 ± 3.6 seconds for the EasyTube versus 19.3 ± 4.6 seconds for the ETT, $P = 0.0001$). Ease of insertion was greater in the EasyTube group, and there was no difference in the incidence of sore throat, dysphagia, and hoarseness.

Gaitini and colleagues evaluated the ease of use of the EasyTube compared with the Combitube in 80 patients randomized to one of these two groups.[135] All patients were intubated blindly in the esophagus. Less time was required to achieve an effective airway using the EasyTube (19.4 ± 5.3 seconds) compared with the esophageal-tracheal Combitube (30.6 ± 4.1 seconds, $P < 0.001$). EasyTube insertion was rated significantly easier than Combitube insertion ($P = 0.008$) by anesthesiologists participating in the study. EasyTube insertion was rated easy in 36 cases and moderately difficult in 4 cases. Combitube insertion was rated easy in 26 cases and moderately difficult in 14 cases. No insertion in either group was rated difficult or impossible.

3. Out-of-Hospital Studies

In a prehospital setting, Chenaitia and coworkers evaluated the effectiveness and safety of use of the EasyTube in cases of difficult airway management by emergency physicians with minimal training with the device.[136] They performed a prospective, multicenter, observational study of patients requiring airway management conducted in a prehospital emergency setting in France by three mobile ICUs from October 2007 to October 2008. Data were available for 239 patients who needed airway management and were classified in two groups: the easy airway management group (225 patients [94%]) and the difficult airway management group (14 patients [6%]). All patients had a successful airway management. The EasyTube was used in eight men and six women; the mean age was 64 years. It was used for ventilation for a maximum of 150 minutes, and the mean time was 65 minutes. It was positioned successfully at first attempt, except for two patients; one needed an adjustment because of an air leak, and in the other patient, the EasyTube was replaced due to complete obstruction during bronchial suction. The investigators concluded that emergency physicians could use the EasyTube safely and effectively with minimal training in cases of difficult airway management. Because of its very high success rate for ventilation, the possibility of blind intubation, the low failure rate after a short training period, they thought it should be introduced in new guidelines for managing difficult airways in prehospital emergency settings.[133]

4. Study of the EasyTube in Emergencies

A preliminary study was undertaken by Thierbach and colleagues to assess early experiences with the EasyTube in prehospital and in-hospital emergency airway management procedures.[137] All airway management procedures with the EasyTube were recorded for a period of 18 months. The EasyTube was successfully used in 15 patients with unanticipated airway difficulties during anesthesia induction or prehospital airway management.

In all patients, the EasyTube was positioned successfully at the first attempt, with a median time of 31 seconds until start of ventilation. Effective supraglottic ventilation and oxygenation were achieved within 25 to 40 seconds. In three patients, the EasyTube needed one additional repositioning maneuver. On removal of the EasyTube, no blood was observed on the surface of the device, and no injuries were observed in the patients' mouth, pharynx, or esophagus. The investigators concluded that the device successfully established sufficient ventilation and oxygenation.[137]

5. Study Results and Applications

Studies demonstrate that the Combitube and EasyTube are effective alternatives to traditional intubation techniques. Both devices have been shown to be as effective as an endotracheal tube in emergency situations. The wide range of applications and ease of insertion make them valuable pieces of equipment in wards, operating rooms, and prehospital conditions, and the Combitube may be reused.[138] Operators involved in airway management should be familiar with the techniques described for these rescue devices to successfully manage an emergency and to avoid using the Combitube or EasyTube for the first time during a crisis.

Data suggest that the Combitube can be inserted successfully during microgravity (e.g., parabolic flights).[135,139] These results may aid in developing protocols for managing airway emergencies during space missions.

Studies show that double-lumen airways such as the Combitube and EasyTube are superior to other supraglottic devices in emergency situations.[20,21,75] Further study of these devices is recommended because they require less training than endotracheal intubation and are easier to insert than an endotracheal airway.[66]

III. CASE EXAMPLES OF AIRWAY MANAGEMENT WITH COMBITUBE, EASYTUBE, AND OTHER DEVICES

A 54-year-old, morbidly obese woman was admitted to the ICU because of respiratory failure.[140] Her neck was short and rigid, with thick, subcutaneous fat pads. Anatomic landmarks such as thyroid and cricoid cartilages were impossible to identify. Her tongue was very large, and the Mallampati score was class IV. Tracheal intubation by flexible fiberoptic bronchoscope (FOB) was performed under local anesthesia. Four days later, extubation was uneventful, and continuous positive airway pressure (CPAP) was initiated with the patient in the sitting position. Oxygen saturation ranged from 95% to 97%, but the patient was uncooperative and did not tolerate the CPAP mask. After removing the CPAP mask, supplemental oxygen (8 L/min) was given by an open face mask. Oxygen saturation decreased to 85%, she became rapidly cyanotic and dyspneic, and a severe bronchospasm was identified by direct thorax auscultation. Immediate tracheal intubation using the FOB was attempted under topical anesthesia, but respiratory parameters rapidly deteriorated. During intubation, the patient developed severe laryngeal spasm, which made passage of the FOB through the vocal cords impossible. Oxygen saturation dropped to 60%, and the patient became unconscious and bradycardic. Three-handed mask ventilation was established with 100% supplemental oxygen and an oropharyngeal and two nasopharyngeal cannulas. Oxygen saturation increased to 80%. An expert anesthesiologist made one attempt at laryngoscopy, but only the tip of the epiglottis could be seen under direct vision. Laryngoscopy was immediately stopped because oxygen saturation dropped to 60% and the patient did not tolerate apnea. Cricothyrotomy was considered but excluded because it was impossible to identify the anatomic landmarks of the cricothyroid membrane. In view of the CICV situation, a 41-F Combitube was considered. Insertion was easy, and after checking the esophageal position by auscultation, ventilation was obtained using the device's pharyngeal tube. Inflation pressure appeared to be high, but oxygen saturation returned quickly to 95%. A 50-mg dose of atracurium was administered intravenously, and the patient was connected to a mechanical ventilator. Peak pressure was 45 cm H_2O. Residual bronchospasm was treated with 750 mg of aminophylline. The patient was transferred to the operating room for a tracheotomy while she was ventilated through the Combitube. The next day, the patient was fully awake and responsive, and she had no symptoms of neurologic damage. She was weaned from the ventilator 10 days after the tracheostomy and discharged from the ICU on day 22 after admission without neurologic sequelae.[140]

A female motor cyclist was hit by a truck and thrown onto the side of the street. On arrival of the ambulance, the patient was lying in a prone position. Because moving the body appeared to be dangerous, a 41-F EasyTube was inserted with the patient still in the prone position. Insertion and ventilation worked well.

A 45-year-old patient was scheduled for a neurosurgical procedure. Preoperative evaluation revealed a Mallampati score of class II. Endotracheal intubation was performed uneventfully, and the patient was moved into a prone position for surgery of the spine. Because of unintended movement of the ventilation tubes during surgery, extubation occurred. Immediate reintubation was mandatory, but insertion of a PLMA by an experienced anesthesiologist failed. An EasyTube was inserted without difficulty and remained in place during the 5-hour operation.

A 40-year-old man was scheduled for revision of scars caused by facial burns due to a gas explosion. The initial injury occurred 14 months before this procedure, and the patient had received a tracheostomy during his stay in the ICU. Preoperative evaluation revealed a reduced glottic opening and tracheal stenosis. Because of the existing airway pathology and the impossibility of using tapes, the EasyTube was elected for airway management. The EasyTube was inserted under direct vision with a laryngoscope into the esophagus and successfully used throughout the 130-minute surgical procedure.[141]

Paramedics failed to intubate a 51-year-old patient who was found unresponsive, but they successfully placed a Combitube. On arrival in the emergency department, it was decided to exchange the Combitube for an ETT. Three attempts to exchange the Combitube with an ETT

using direct laryngoscopy failed. After deflation of the proximal cuff of the Combitube, an 8-mm ETT was advanced over a gum elastic bougie into the trachea under visualization of the oropharynx using a Direct Coupled Interface video intubating system.[142]

IV. CONCLUSIONS

The Combitube and EasyTube have proved to be valuable tools, especially in emergency and unexpected difficult airway situations. Compared with alternative supraglottic airways, these devices appear to be superior with respect to prevention of aspiration and application of high ventilatory pressures. Both airways can be inserted easily in patients with small interincisor distances.

The EasyTube has several advantages over the Combitube. First, the pharyngeal lumen of the EasyTube ends just below the oropharyngeal balloon. The tracheal-esophageal lumen is thinner than that of the Combitube, in which the two lumens continue to the distal end. Because the distal single lumen of the EasyTube is significantly thinner, the danger of mucosal damage is minimized. Second, the oropharyngeal balloon of the EasyTube is latex free. Third, the EasyTube is available in two sizes: 28 F for patients between 90 and 130 cm tall and 41 F for patients taller than 130 cm. Fourth, a fiberoptic scope can be passed through the pharyngeal lumen because it is open at the distal end. This feature allows inspection of the trachea and possible replacement of the EasyTube using a guidewire. Fifth, a larger suction catheter can be passed through both lumens of the EasyTube. Both airway devices can be considered for use in nonemergent or emergent situations, in patients with normal or difficult airways, and as a primary method of airway management or as a rescue device, as outlined in the ASA difficult airway algorithm.

V. CLINICAL PEARLS

- Train practitioners in alternate airways using manikins and intraoperatively
- Take care of aspiration risks
- Always have always a plan "B" available

I. INTRODUCTION

Invasive airway management is relegated to the category of rescue techniques that one must know but hopes never to use. Students may be able to witness a surgical cricothyrotomy, and possibly to assist in the performance of an elective tracheostomy, but most anesthesiologists have successfully avoided incorporating these procedures into their practice. Although the modern airway armamentarium has made resorting to invasive procedures a rare event, the "cannot intubate, cannot ventilate" (CICV) scenario still occurs.[1] By equipping the clinician with an alternative to routine upper airway management, the potential for rescuing a failed airway and preventing devastating adverse outcomes is substantially increased.

Multiple studies have indicated that the incidence of the CICV scenario is between 0.01 and 2.0 cases per 10,000 anesthesias.[1–3] Although the root cause of this dire apneic or obstructive state may be fully or partially related to the patient's disease, it often has an iatrogenic component, being recognized at the time of anesthetic induction or as a result of other interventions. The American Society of Anesthesiologists (ASA), The Difficult Airway Society, and The Advanced Trauma Life Support guidelines, as well as the opinions of other expert organizations, concur that, although invasive airway access is rarely practiced or prepared for, this capability must be at the fingertips of any operator who is charged with airway management.[4-6] The conditions that commonly require the use of invasive airway access include facial fractures (32%), blood or vomit in the airway (32%), traumatic airway obstruction (7%), and failed intubation in the absence of other indications (11%).[7] A completely obstructed airway state does not have to exist for a patient to be at jeopardy. Any time the clinician cannot ensure adequate, life-sustaining gas exchange by virtue of a problem within the conveyance portions of the respiratory tract, further actions (noninvasive or invasive) are mandatory.

Although surgical cricothyrotomy has long been a standard of emergency invasive airway rescue, its use has declined, in part because of advances in noninvasive airway devices such as supralaryngeal airways (SLAs) and video laryngoscopes, the adoption of pharmacologic agents for rapid-sequence intubation in the emergency department, and increased requirements for trainee supervision.[8]

There is widespread agreement in the literature that percutaneous translaryngeal jet ventilation (PTJV),[5] using a small-bore catheter placed through the cricothyroid membrane (CTM), is a simple and effective treatment for the desperate CICV situation.[8,9] Compared with surgical cricothyrotomy and tracheostomy, the establishment of PTJV is ordinarily quicker, simpler, and

therefore more efficacious for most anesthesiologists, who may not be practiced in more formal surgical techniques.[8,10] This may not hold true for the infant or small child, however. Although PTJV was faster to achieve than a surgical airway, it had an exceedingly high failure rate (83%) in a swine model of the juvenile population.[11] This is likely due to the lack of circumferential support offered by the immature cricoid cartilage.

The goal of this chapter is to present a clinically applicable discussion of the technique of PTJV. This will give the clinician the tools to perform PTJV rapidly and safely, but only if he or she is prepared. It is important that the clinician give advanced consideration to the technique—such as ensuring the immediate availability of appropriate cannulas, oxygen conveyance devices, and a high-pressure O_2 source—and to the situations that may call for its use.

A. A Note on Nomenclature

Although the acronym PTJV is used for this discussion, there are a number of names and acronyms in the literature that might be just as adequate but do not completely describe the current technique. Terms such as percutaneous (versus trans), tracheal (versus laryngeal), jet (versus insufflation), and oxygenation (versus ventilation) may all be appropriate, and at times one descriptor will fit better than another. The acronym PTJV is commonly used and describes most clinical situations in which it is likely to be used successfully.

The literature is replete with descriptions of PTJV techniques and of a number of devices, both commercial and "operating room [OR] rigged."[12-16] As discussed here, many of these OR-rigged PTJV setups have not undergone objective testing; although they are easy to construct, they may not be practical, robust, or life-sustaining.

Although the term "small-bore catheter" may be encountered in some texts and primary literature, authors use this term as a comparison to "surgical" options, which involve percutaneous cricothyrotomy and tracheostomy devices with an internal-bore diameter (ID) of 3 mm or greater. It should also be noted that the term "cannula-over-needle" is used in this text to refer to a device similar to the common intravenous catheter: a hollow, elongated plastic catheter with an inner coaxial sharp-beveled needle that is removed after in vivo positioning.

II. INCORPORATING PERCUTANEOUS TRANSLARYNGEAL JET VENTILATION INTO THE DIFFICULT AIRWAY PLAN

The 2003 ASA difficult airway (DA) algorithm lists three techniques that should be employed when circumstances are encountered in which one cannot intubate (i.e., via direct laryngoscopy) and cannot ventilate, either by bag-mask or with the use of a laryngeal mask airway (LMA; LMA North America, Inc., San Diego, CA). These techniques are insertion of an esophageal-tracheal Combitube (ETC; Ambu, Copenhagen, Denmark), use of PTJV, and provision of an emergency surgical airway. Because the LMA and ETC are familiar to most anesthesiologists, both of these noninvasive airways should be considered first in cases of supraglottic obstruction, unfavorable anatomy, or other CICV situations. Both have been demonstrated to be highly effective in this setting and are generally considered atraumatic.[4,17,18] Though other SLAs are likely to be as applicable, they are not mentioned in the 2003 practice guidelines. Whether or not future guideline revisions call for other devices or refer to generic SLAs, operator experience and comfort should guide choice. The preferred device should be immediately available whenever the possibility of a CICV situation might arise.[17]

If insertion of an SLA does not affect gas exchange quickly, the ASA DA algorithm recommends that the clinician move to an invasive airway access maneuver without hesitation or delay. Of the maneuvers suggested, PTJV may be the most familiar to the anesthesiologist. A distinct advantage of PTJV over surgical cricothyrotomy is that it can be practiced in nonemergency clinical care. The anesthesiologist who is practicing elective, awake intubation may choose to make the percutaneous transtracheal injection of lidocaine a routine technique, thereby practicing laryngeal catheter placement, and some have advocated the placement of prophylactic transtracheal catheters in high-risk airway situations or for elective laryngeal surgery.[19] It should be noted that severe subcutaneous emphysema is a rare complication of translaryngeal lidocaine injection, even in otherwise uncomplicated cases.[20]

III. INCIDENCE AND COMPLICATIONS

Barotrauma with resultant pneumothorax and hemodynamic changes has been reported with both emergent and elective use of PTJV.[8,19,21-31] In a retrospective chart review, Patel and associates described a 53-month experience with patients in acute respiratory failure in the intensive care unit.[21] Of the 352 patients requiring endotracheal intubation, 29 emergent PTJV attempts were made. The procedure was performed by house staff (n = 5) and attending physicians (n = 24). Successful cannulation of the airway was achieved in 79% of patients. Subcutaneous emphysema occurred in 2 of these patients. Orotracheal intubation was subsequently required in 22 patients, with 1 requiring a surgical tracheostomy. PTJV failed in 6 patients. These failures were attributed to recent thyroid surgery (n = 1), obesity (n = 2), kinking of the PTJV cannula (n = 2), and misplacement of the cannula (n = 1). Subcutaneous emphysema was seen in only 1 patient for whom PTJV failed. The other patient who suffered subcutaneous emphysema experienced severe pneumomediastinum treated with bilateral chest tubes. Of the 6 patients with failed PTJV, 2 were subsequently orally intubated with the aid of a bougie, and the remaining 4 died.

Smith and colleagues reported a 29% incidence of complications in 28 patients managed with PTJV to provide an emergency airway.[22] These complications included subcutaneous emphysema (7.1%), mediastinal emphysema (3.6%), exhalation difficulty (14.3%), and arterial perforation (3.6%), none of which were fatal.

Other complications, such as esophageal puncture, bleeding, hematoma, and hemoptysis, have been also reported after PTJV.[23]

In a review of 265 elective PTJV and other forms of jet oxygenation/ventilation for otolaryngologic surgery, Jaquet and colleagues wrote that PTJV was associated with hemodynamic instability (8 patients), subcutaneous emphysema of the neck (3 patients), posterior tracheal mucosa tear (1 patient), catheter kinking (3 patients), severe mediastinal/cervical subcutaneous emphysema (1 patient), unilateral pneumothorax (1 patient), and bilateral pneumothorax (1 patient).[19] The last 3 events were considered major complications, and all were associated with cough or laryngospasm during PTJV. Damage to the tracheal wall, witnessed by this group, was also demonstrated in a large-animal model of PTJV in which full-thickness erosion and hemorrhage of posterior tracheal mucosa was seen in all specimens.[29] Subcutaneous emphysema has been associated with cannula shaft lacerations in the absence of frank cannula misplacement.[30]

In another series of elective PTJV cases, there was an overall minor complication rate of 3%.[22] These complications (minor bleeding, subcutaneous emphysema) were typically seen when multiple attempts had to be made during cannula placement. The authors recommended that no more than two attempts should be made.

The site of PTJV access may also influence complications. In a swine tracheal model, Salah and coworkers studied trans-CTM versus transtracheal cannulation. With some percutaneous techniques, traumatic injury (including posterior wall tears or frank penetration and cartilaginous fractures) were more common when the PTJV cannula was inserted into the trachea.[31]

Complete or near-complete airway obstruction during PTJV may also contribute to hemodynamic instability.[24] In a controlled trial employing graded airway obstruction in dogs undergoing PTJV with 45 psi inflation pressures through a 13-G catheter, intratracheal pressures of 24 cm H_2O were associated with decreasing blood pressure and increased central venous pressure, even in the absence of pneumothorax. In complete upper airway obstruction simulated in dogs, intratracheal airway pressure rose precipitously as soon as the total lung capacity was exceeded. This was accompanied by a fall in systolic blood pressure and eventual rupture of the pulmonary system (pneumothoraces, pneumomediastinum, subcutaneous emphysema, cardiac fibrillation) when an intratracheal pressure of 250 cm H_2O was achieved.[25]

In one canine study, methylene blue instilled into the oral cavity was less readily aspirated into the trachea during PTJV, compared with controls.[26,27] The authors reasoned that the retrograde egress of gas from the larynx reduced oral content aspiration. A similar phenomenon has been noted in humans during O_2 insufflation through an endotracheal tube (ETT) exchange catheter.[28]

A. Mechanism of Barotrauma and Other Forms of Airway Trauma

Striving to verify the intraluminal position of a percutaneously placed cannula is mandatory during PTJV. Though cannula misadventures are responsible for many of the complications related to PTJV, complete upper airway obstruction during O_2 insufflation is likely responsible for most episodes of barotrauma. During involuntary obstruction of the upper airway (e.g., due to laryngospasm) intraluminal pressures, generally remaining in the safe range of 18 to 25 cm H_2O during PTJV, rise precipitously. In an artificial lung model, upper airway obstruction (airway resistance 200 cm H_2O/L/sec) resulted in an intratracheal pressure of 60 cm H_2O. Intraluminal pressures between insufflations did not rise above minimal levels (3 cm H_2O) until maximal airway resistance was produced, at which time there was an equilibration to maximal pressure.[32] In an adult sheep model, complete airway obstruction during constant tracheal insufflation of O_2 at 15 L/min resulted in a pressure of 96 cm H_2O in 12 seconds. When intermittent jet ventilation (JV) was used (inspiratory-to-expiratory [I:E] phase ratio, 3:5), a pressure of 108 cm H_2O was reached in 33 seconds.[25]

IV. CANNULA SIZE AND OXYGENATION

A wide variety of cannula-over-needle devices have been described in the PTJV literature in both in vivo and mechanical model trials and in case reports. Trials of cannulas smaller than 3 mm in diameter (equivalent to 8 G) have typically demonstrated the need for a high-flow regulator/conveyance apparatus. Although flow through cannulas of various diameters and lengths has been measured during simulated PTJV, actual flow varies with the clinical situation and is affected by factors such as airway resistance and pulmonary compliance. Table 28-1 lists experimental data on flow rates through cannulas of various sizes with the use of a 50 psi gas supply.[14,33,36]

TABLE 28-1
Flow Rates Through Cannulas in Various Models

Cannula Gauge	Internal Diameter (mm)	Flow (mL/sec)	Model	Reference
18*	1.4	50	Sheep (46-54 kg)	14
15*	2	150	Sheep (46-54 kg)	14
13*	2.5	250	Sheep (46-54 kg)	14
12*	3	340	Sheep (46-54 kg)	14
9*	4	800	Sheep (46-54 kg)	14
20	0.89*	400	Lung model	33
16	1.65*	500	Animal	
14	2.1*	1600	Lung model	33

*Approximate conversion.

Neff and colleagues insufflated gas through cannulas of various diameters in a sheep model.[25] Marginal oxygenation was achieved with a 1.4-mm-diameter (15-G) cannula using 15 L/min constant and 50-psi "pulsed" O_2 flow. Use of low-pressure systems, such as resuscitator bags and anesthesia machine circuits, which provide 1 to 2 psi, was futile for catheters smaller than 3 mm in diameter. However, Zornow and colleagues were able to produce "delayed" reoxygenation in a hypoxic swine model with a 14-G cannula and "vigorous" ventilation with an anesthesia machine circuit.[25,29] O_2 resuscitation was significantly faster when 50-psi supplies were used (15 versus 120 seconds).[25]

Some authors have speculated that entrainment of room air via a Venturi effect produced by the high velocity of the gas injected into the larynx during PTJV might add as much as 40% or 50% to the volume of inspired gas.[33-35] This hypothesis has been contradicted by the findings of arterial blood gas studies in both animals and healthy patients undergoing jet ventilation, which demonstrated O_2 tensions consistent with the insufflation of 100% O_2 (no entrainment of room air).[36-38]

Whereas complete upper airway obstruction has been associated with ineffective ventilation and barotrauma, partial obstruction may enhance both oxygenation and ventilation by driving gas flow toward the lower bronchial tree, facilitating tidal volume (V_T) and improving alveolar oxygen tension (Pa_{O_2}).[24]

In summary, cannulas smaller than 3 mm in diameter (8 G) are unreliable for oxygenation and ventilation unless high-pressure regulator systems are used and there is an egress for exhaled gas. Catheters smaller than 14 G are unreliable even with the use of high-flow regulators.

V. VENTILATION

Effective ventilation during PTJV requires a pathway for gas egress. Fortunately, most patients who present with life-threatening airway failure (e.g., laryngeal edema, epiglottitis, laryngeal tumor) have isolated inspiratory obstruction with no or partial expiratory obstruction.[39] This is true during spontaneous breathing as well as controlled ventilation through a face mask or SLA, and it is related both to the extrathoracic position of the upper airway and to the architecture of laryngeal and supralaryngeal structures. Complete obstruction to gas escape is a contraindication for PTJV and may be dependent on the devices used.

Because removal of CO_2 is dependent on sufficient volumes of gas entering and exiting the lung, low-pressure systems (e.g., resuscitation bags) are generally inadequate for ventilation, as they are for oxygenation. Zornow and colleagues, using a 14-G transtracheal cannula in a swine model, was able to effectively ventilate with a 50 psi O_2 source but could not reduce arterial CO_2 despite "vigorous" ventilation with an anesthesia machine circuit.[29] Whereas gas escaping from an in vivo ETT could be measured when PTJV was performed with the high-pressure source, no gas movement was appreciated with use of the low-pressure system.

Ward and coworkers examined no, partial, and complete upper airway obstruction during PTJV in dogs, using 13-G catheters and a high-flow regulator delivering 45 psi of pressure.[40] With no or partial upper airway obstruction, CO_2 levels decreased during PTJV. Partial airway obstruction improved CO_2 removal, possibly by promoting improved alveolar expansion during the O_2 injection phase of PTJV.

A. Airway Rescue in Complete Upper Airway Obstruction

Although controversial and based on animal models, low-flow insufflation of O_2 into the pulmonary circuit has been proposed as a mechanism for maintaining oxygenation, although not effective ventilation, in the patient with a completely obstructed airway.[24,41,42] Several alternative techniques have been studied in the model of complete upper airway obstruction.

Frame and associates, using a canine model (20 to 29 kg), found that with complete airway obstruction, O_2 flows of 5 to 7 L/min through 10-G and 12-G catheters could maintain oxygenation with I:E phases of 1:4 seconds and provided reasonable ventilation (Pa_{CO_2} <75 mm Hg).[41] When lower flow rates (3 L/min) were used, CO_2 tension increased rapidly after 5 to 20 minutes. Although this study demonstrated the successful use of low-pressure O_2 flow in complete airway obstruction (in an effort to avoid barotrauma), it must be cautioned that small animals and large insufflation catheters were used.

Low-flow translaryngeal rescue insufflation of oxygen (LF-TRIO) of as little as 2 L/min has been shown to maintain oxygenation in a large animal model (34-kg swine) for upwards of 60 minutes.[5] LF-TRIO recovered the animals from O_2 saturation nadirs of 50% in an average of 23 seconds. Cardiovascular parameters were stable in all animals for a minimum of 15 minutes. Although the animals experienced hypercapnia, the authors argued that this may be well tolerated if there are no specific comorbidities that may be aggravated by increasing CO_2 (e.g., head trauma). Although imaging in this study was limited to a small number of animals, there was no evidence of microatelectasis after 1 hour of LF-TRIO. LF-TRIO was considered by these authors to be a short-term rescue option when definitive surgical airway control is anticipated.

More recently, the concept of an active expiratory phase has been applied to PTJV (Fig. 28-1). In a series

Figure 28-1 The Ventrain device uses a Venturi valve to apply negative pressure during the expiratory phase of percutaneous transtracheal jet ventilation. (Courtesy of Dolphys Medical BV, The Netherlands.)

of large-animal studies, Enk and Hamaekers described using the O_2 flow from a standard flowmeter to create a negative-pressure, transcatheter expiratory phase.[32] Bernoulli's principle, application of which is familiar to anesthesiologists in the functioning of the Venturi valve, states that when a fluid in a vessel passes through a constriction, dynamic energy (speed of flow) is increased, whereas static pressure (potential energy) exerted on the vessel side-wall is diminished. This setup can be manipulated to produce a subatmospheric pressure during an expiratory phase of PTJV. In an initial bench model, a prototype expiratory ventilation assistance (EVA) device reduced by half the time required for a 1000-mL injected V_T to be expired via a 2-mm ID cannula and also increased the effective minute ventilation by 33%.[32] In another large-animal study by the same group that included a complete obstruction of the upper airway, EVA restored oxygenation within 10 seconds and limited hypercarbia over 15 minutes.[42] However, EVA was less effective when the upper airway was unobstructed, possibly due to preferential entrainment of ambient air into the PTJV catheter via the lower-resistance upper airway path and, consequently, reduced removal of alveolar gases.[43]

B. Percutaneous Translaryngeal Jet Ventilation in Relief of Upper Airway Obstruction

The introduction of PTJV may encourage partial relief of upper airway obstruction. In a controlled study, Okazaki and colleagues demonstrated that induced airway obstruction (by simple neck flexion) was partially relieved by the insufflation of 10 L/min O_2, although not as well as by the chin lift–jaw thrust maneuver.[44] This finding implies a potential utility of transtracheal insufflation in patients who are at high risk for airway obstruction during postanesthesia recovery.[44,45]

VI. ELECTIVE INDICATIONS

A. To Facilitate Operations of the Upper Airway

There have been several reports and various recommendations for the elective use of PTJV in surgical procedures to avoid tracheostomy, provide an unobstructed surgical field, or facilitate safe ETT. Singh and coworkers reported on 1500 cases of PTJV for diagnostic and surgical procedures of the upper airways, including bronchoscopy and esophagoscopy (n = 1257) and endolaryngeal surgery (n = 135).[46] PTJV support was continued for 24 to 48 hours into the postoperative period in 108 cases. Spoerel and Greenway, describing ventilation techniques during endolaryngeal surgery, similarly found adequate pulmonary ventilation with excellent conditions for microscopic surgery.[47] Smith and colleagues reported on elective transtracheal ventilation in children undergoing surgical procedures involving the head and neck.[48] They described the use of this technique in two children, one undergoing an operation for laryngeal stenosis and one who became obstructed and cyanotic in the recovery room. $PaCO_2$ measurement at the end of the procedures indicated that the patients were moderately hyperventilated. Similarly, because PTJV leaves the entire airway from the vocal cords to the face accessible for surgical manipulation, it is not surprising that its elective use has been described for a large variety of procedures on these structures in adults.[49] In addition, Wagner and coauthors described a case in which high-frequency JV was used with success (thus avoiding tracheostomy) in a patient with a partial upper airway obstruction caused by a hypopharyngeal foreign body with sharp appendages.[50]

Dhara and colleagues reported on two cases in which a triple-lumen central venous catheter was placed through the CTM before induction of anesthesia.[51] Making use of all three lumens, this unique approach allowed the clinicians to measure tracheal CO_2 and intra-airway pressure, as well as providing jet oxygenation. In both cases, an upper airway egress for insufflated O_2 was maximized by use of a nasopharyngeal airway (NPA) or tongue retraction.

Depierraz and associates investigated the elective use of PTJV in pediatric patients (aged from less than 1 to 12 years) with significant upper airway obstruction.[52] They recited the major advantages of this technique: improved surgical exposure of the upper airway obstructive lesion, reduced manipulation of the lesion, reduced operative field movement during laser surgery, reduced danger of airway fire, and reduced risk of blowing particles into the distal airway.

B. To Permit Safe Intubation of the Trachea

In situations in which there is a significant risk of airway management failure, PTJV has been used electively to preclude the CICV situation. One report described the use of prophylactic PTJV to provide oxygenation in a patient who was known to be difficult to intubate.[53] PTJV enabled the patient to be anesthetized, muscle relaxed, and intubated in a safe, nonemergent manner. In another report of a 13-year-old girl with ankylosis of the temporomandibular joint resulting from a prior fracture, PTJV was electively instituted before the induction of anesthesia, and the trachea was subsequently intubated with the aid of fiberoptic bronchoscopy.[54] In a third report, PTJV was used to supplement spontaneous ventilation via the natural airway in a patient with a massive upper tumor so that the airway could be secured in a nonemergent manner.[55]

C. To Facilitate Training

Another benefit of the elective use of transtracheal techniques not to be ignored is training of students and anesthesiology residents as well as critical practice for attending physicians themselves. As discussed earlier, the 2003 ASA DA algorithm suggests four alternatives in the CICV situation: LMA, ETC, PTJV, and surgical airway.[4] The first two techniques can be practiced electively (the cost of the single-use ETC may be decreased by reprocessing).[56] Although a surgical airway can be electively practiced in appropriate patients, such as in a case of upper airway pathology when a tracheostomy is surgically planned and an otolaryngologist is available as a

supervising physician, transtracheal catheter placement has definite clinical indications that can be employed for training purposes (e.g., awake intubation procedures, retrograde intubation). Many authors agree with this approach, especially because total airway obstruction may not be relieved by the SLA devices.[22,57,58] However, elective use of translaryngeal needle placement is not without its complications, as reviewed earlier.[20]

VII. EQUIPMENT

The literature is replete with manufactured and OR-rigged devices for delivering O_2 to a translaryngeal catheter. The great advantage of using a preassembled, commercially made PTJV system is the quality assurance that is built into a commercial product and the freedom from having to assemble the system. In addition, because low-pressure systems (e.g., anesthesia breathing circuit, self-inflating resuscitation bag) are typically ineffective when coupled with percutaneous catheters and because the anesthesia machine manufacturers limit the utility of the common gas outlet (CGO) for PTJV, commercial systems offer specifically designed components and joints for use with high pressure.[25] Many of the OR-rigged devices remain untested, and although they may resemble working systems, performance in a true clinical emergency is unknown.[59] In addition, a working system should be prepared or made available before the need for it arises. In the CICV situation, small delays contribute to devastating effects. Not only can it take many seconds to minutes to assemble a device, not all anesthetizing or resuscitative locations contain uniform equipment. Basic characteristics of a PTJV system are listed in Box 28-1.

A study testing four different OR-rigged devices arrived at the conclusion that only devices employing high pressure were capable of delivering adequate transcannula flows and maintaining oxygenation, although adequate ventilation was not consistently assured.[15]

Several of the described OR-rigged devices rely on intermittent occlusion of a port of a three-way stopcock with the intent of allowing diversion of the O_2 supply flow through the unoccluded port during the expiration phase (expired gas is meant to be removed via the upper airway, if it is unobstructed).[60-62] Hamaekers and colleagues showed that three-way stopcocks act as flow splitters.[63] Unoccluding the open limb of the stopcock does not halt all flow into the transtracheal catheter; this results in continuous O_2 flow into the trachea, possibly hindering CO_2 removal and contributing to hemodynamic instability. In the case of total upper airway occlusion, continued flow from these devices can contribute to barotrauma.[63]

By comparison, a relatively simple manufactured device is the Enk Flow Modulator (Fig. 28-2; Cook Critical Care, Bloomington, IN). Unlike many OR-rigged devices, forward gas flow in the PTJV catheter is minimal when the five 4-mm holes of the Enk Flow Modulator are released. This reduces positive end-expiratory pressure (PEEP) and other consequences of continued flow during the expiratory phase.[63,64] Some flow through the catheter during the expiratory phase may be desirable (when there is not complete upper airway occlusion). This flow may aid in elimination of CO_2 from the unoccluded airway, as well as enhancing oxygenation.[64]

In two studies, investigators surveyed their colleagues to determine what OR-rigged devices were preferred. In Morley and Thorpe's survey,[14] three different configurations were described, and the survey by Ryder and colleagues[15] described seven different configurations. In these studies, 5% and 10% of anesthesiologists, respectively, could not assemble any device, and only 5% and 40% of the devices, respectively, were considered adequate for PTJV. When clinicians were asked to assemble a device of their own choosing, they needed between 20 and 365 seconds (mean, 90 seconds) to produce a functional device, again raising doubts about the practicality of depending on unmanufactured systems.[15] Industrial-grade valves, which may mimic the function of the devices manufactured specifically for JV, typically contain lubricants and should not be used for medical indications.

The most critical element in the system employed for PTJV may be the availability of pressurized O_2, typically supplied at 45 to 60 psi. Central supply ("wall oxygen") is ubiquitous in ORs, intensive care units, and other areas of hospitals. Portable O_2 tanks are also fitted with regulators that are adjusted to deliver 50 psi. A variety of

BOX 28-1 Characteristics of an Ideal Transtracheal Jet Ventilation Device

- Validated in clinical or laboratory studies
- Minimum cannula size, 14 G
- Low-compliance tubing, fixed component joints
- Ability to connect to a high-pressure (50 psi) O_2 source
- Ability to connect to anesthesia circuit, self-inflating bag (if ≥3 mm ID)
- Kink resistant
- Intratracheal pressure measurable
- Et_{CO_2} measurable
- Flow controllable
- Pressure regulation provided
- Available preassembled
- Available sterile

indexed systems may be used to prevent mismatching of gas sources and clinical devices (Fig. 28-3). When purchasing new equipment for PTJV use, the specific indexing system, as well as the male versus female configuration, must be specified to the vendor. Many anesthesia machine manufacturers provide an outlet that is tied to the high-pressure gas supply and is accessible by Diameter-Index Safety System (DISS) fittings (see Fig. 28-3A). Although the anesthesia machine CGO was previously employed as a source of high-pressure O_2, its use is discouraged, and to this end, manufacturers have downregulated the available pressure when the machines' O_2 flush valve is activated (Fig. 28-4).[33]

All systems used to convey O_2 from high-pressure sources to the patient must have adjustable governors that limit static pressure or continuous flow in order to minimize barotrauma, and they must contain a mechanism for halting or diverting flow to produce an expiratory phase during PTJV. Two such systems are commonly used in PTJV: high-flow regulators (with manual triggers) and low-flow regulator-flowmeters (with flow diversion). High-flow regulator systems, such as the Manujet III (VBM Medizintechnik, Sulz, Germany) (Fig. 28-5), allow the user to preset the pressure delivered to the PTJV catheter (0 to 50 psi) during a no-flow state. Manual activation of a trigger starts the flow of O_2 to the translaryngeal catheter; release of the trigger halts gas flow. A disadvantage of this system is that it is closed—there is no path for gas escape during the expiratory phase. This may increase the risk of barotrauma or encourage more hypercapnia. Although these systems are capable of delivering 50 psi to the translaryngeal catheter, intratracheal pressures do not rise above 25 cm H_2O.

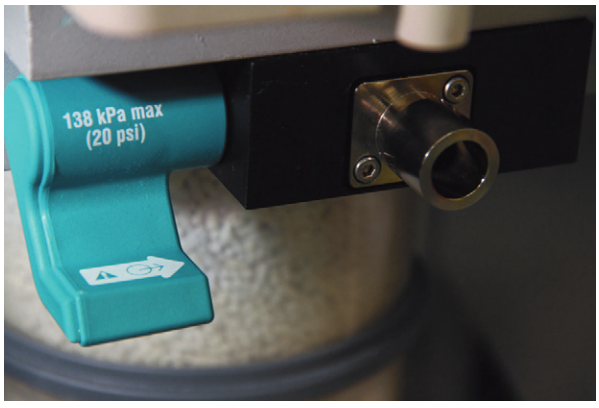

Figure 28-4 Accessory common gas outlet on an Asteva Anesthesia Machine from Datex-Ohmeda (Madison, WI). The maximum pressure from this outlet is downregulated by the manufacturer, who also supplies an accessory Diameter-Index Safety System (DISS) fitting on the rear of the machine.

The second commonly studied system for O_2 conveyance is the low-flow regulator, which limits continuous flow from 0 to 15 L/min (Fig. 28-6). Low-flow regulators are commonly available on small (E-cylinder) O_2 transport tanks, on some anesthesia machines, and attached to central supply O_2.[34] Several studies have demonstrated the utility of these devices. When 15 L/min is delivered satisfactory V_T with 16- and 14-G PTJV catheters may be achieved within the first 0.5 seconds.[34] Low-flow regulators are ubiquitous in hospitals. Inexpensive systems have been developed to convey O_2 from low-flow regulators to the patient.

A study by Preussler and colleagues compared the two aforementioned conveyance systems.[65] This group compared a high-flow regulator (Manujet III) attached to a 50 psi O_2 source and low-flow, 15 L/min regulator-flowmeter fitted with an Enk Oxygen Flow Modulator.[66] Both systems were tested in anesthetized pigs using a specialized 15-G transtracheal cannula. The upper airway of the pigs was kept patent with an ETT and a 20-cm H_2O PEEP valve in order to simulate a clinical partially

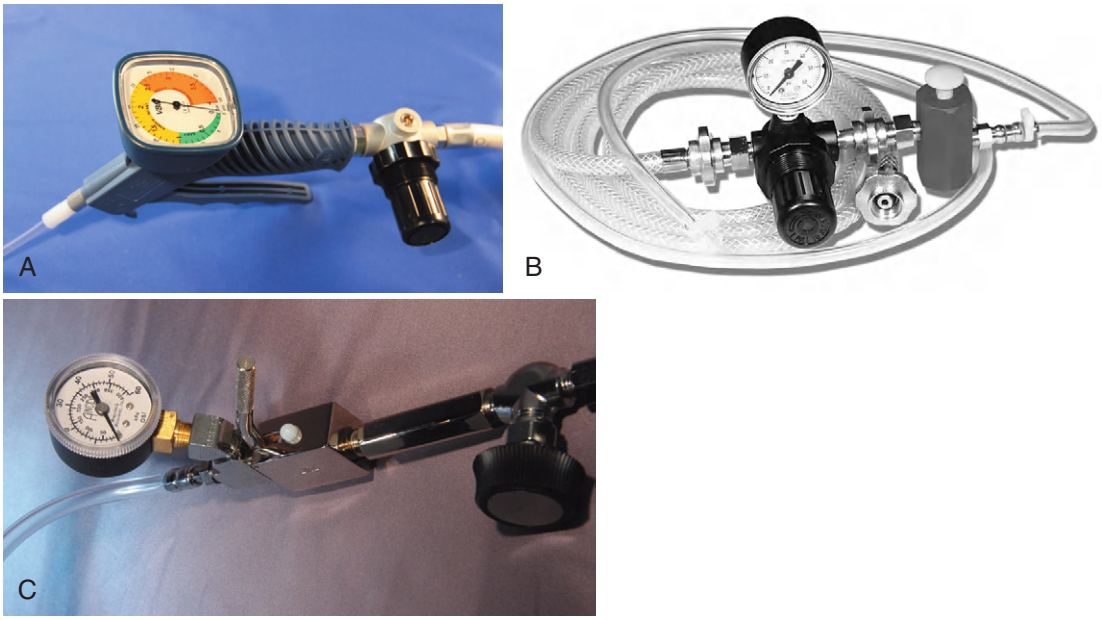

Figure 28-5 Three high-flow regulator-powered manual jet ventilators: **A,** Manujet III (VBM, Medizintechnik, Sulz, Germany); **B,** manual jet ventilator (Instrumentation Industries, Bethel Park, PA); **C,** jet ventilator (Anesthesia Associated, San Marco, CA). (**B,** Courtesy of Instrumentation Industries.)

obstructed airway. The investigators found that both device setups performed equally well, maintaining Et_{CO_2}, P_{CO_2}, and Pa_{O_2} in acceptable ranges. The Enk Flow Modulator includes a Luer-Lok syringe port for administration of drugs into the trachea without interruption of ventilation or oxygenation. The Manujet III has a variable-pressure regulator and pressure gauge. Other bench models have shown that close-circuit gas injectors, such as the Manujet III, achieve higher peak flows, greater V_T (650 mL), and higher intra-airway pressures, compared with the Enk Flow Modulator (240 mL).[64]

During total expiratory pathway occlusion in a bench model, intra-airway pressure rises precipitously with closed-circuit gas injectors (e.g., Manujet III) that have no facility for gas release during the expiratory phase via the transtracheal catheter. Lenfant and colleagues showed

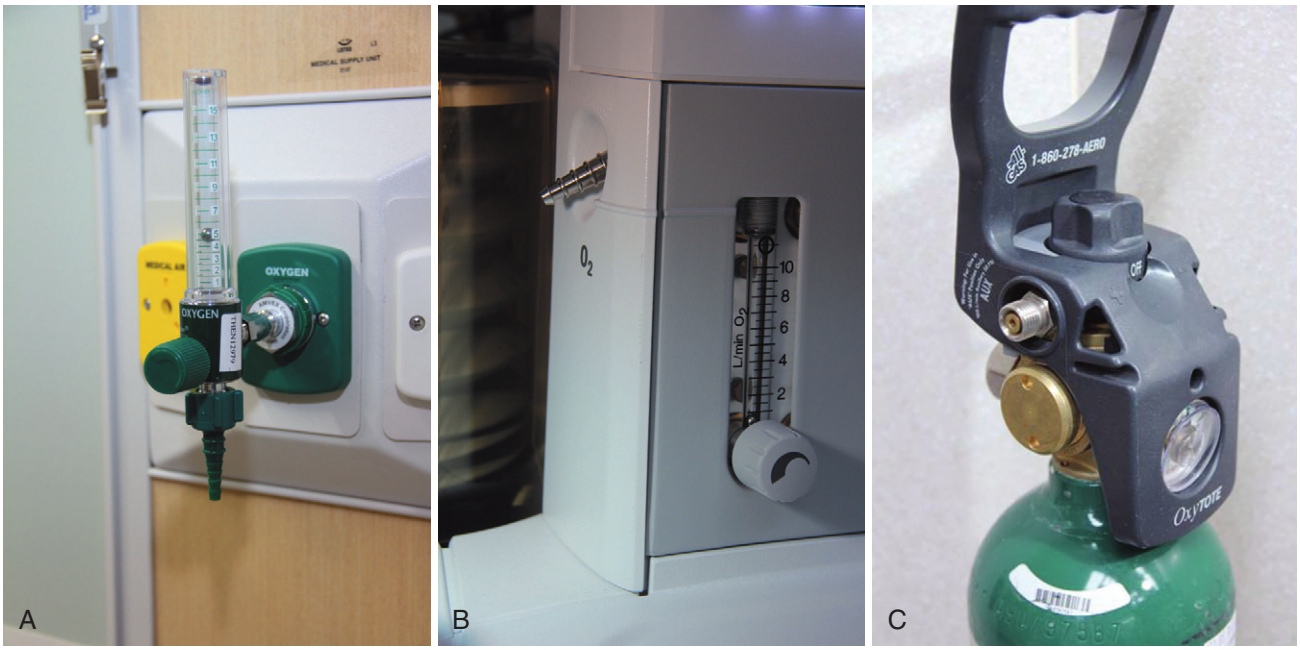

Figure 28-6 Three types of low-flow regulator-flowmeters: **A,** wall mounted; **B,** incorporated into an anesthesia machine (Datex-Ohmeda Avance model; Datex-Ohmeda, Madison, WI); **C,** incorporated into an E-cylinder tank regulator.

that when 3-bar pressure was applied via the Manujet in a completely occluded airway, intra-airway pressures of 136 cm H_2O were measured after two inspirations.[64] In contrast, systems that use flow diversion by allowing gas escape during the expiration phase (e.g., Enk Flow Modulator with 15 L/min gas flow) generated significantly lower intra-airway pressures after multiple breaths. In the completely occluded airway scenario, these systems may have an advantage, providing a pressure release pathway. The authors caution, however, that aggressive insufflation with any device can be dangerous in the completely occluded airway. The Enk Flow Modulator is not immune to producing high pressures in this situation.[64] In most cases of CICV, total airway occlusion does not occur. In situations in which high peak pressure is of concern, the driving pressure can be reduced. In the emergency clinical situation, close attention to chest rise (and fall, between insufflations) can guide adjustment.[64]

The last critical device in the PTJV setup is the translaryngeal cannula. Historically, a variety of intravenous catheter-over-needle devices have been employed.[22,55,67,68] Others have attempted to measure expired CO_2 and intratracheal pressure using alternative devices, such as triple-lumen central venous catheters.[51] Garry and colleagues used a needle-in-needle catheter assembly (a 14 G or 16 G catheter fitted within a 3-mm ID catheter).[69] O_2 was insufflated in the central needle while suction and CO_2 monitoring were applied to the annular space. Newer catheters constructed from kink-resistant materials have a preformed tip angulation, Luer-Lok connectors, 15-mm circuit adapters, or securing rings (Fig. 28-7).

VIII. TECHNIQUE OF PERCUTANEOUS TRANSLARYNGEAL JET VENTILATION

Emergent need for PTJV may be anticipated but is rarely expected. No clinician is likely to induce anesthesia when complete loss of airway control is a probable outcome. Conversely, most patient airways are managed without critical incident, and it is the job of the anesthesiologist to envisage the scenario in which invasive airway access could become necessary. Preparation for the use of PTJV may be the single most important aspect of its application. Table 28-2 lists the minimal materials and resources that must be available if PTJV is anticipated; my own opinion is that these should be accessible in any anesthetizing situation in a health care setting.

Willingness to use PTJV is the next step of preparation. Most anesthesiologists, by the nature of their training, prefer noninvasive methods. The tendency (and trend) is to reduce the use of even well-established invasive procedures (e.g., adoption of ultrasound guided nerve block versus nerve stimulation techniques). Given the proliferation of SLA devices and endotracheal intubation techniques during the last 20 years, it is unsurprising that surgical and percutaneous airway rescue procedures, even when performed adequately, are often applied too late in the lost-airway scenario to effect a change in outcome and prevent death or brain death.[70] Dogged perseverance with laryngoscopy and unsuccessful SLA ventilation must be avoided—evidence attests that this not only is futile but also contributes to a worsening outcome.[70,71]

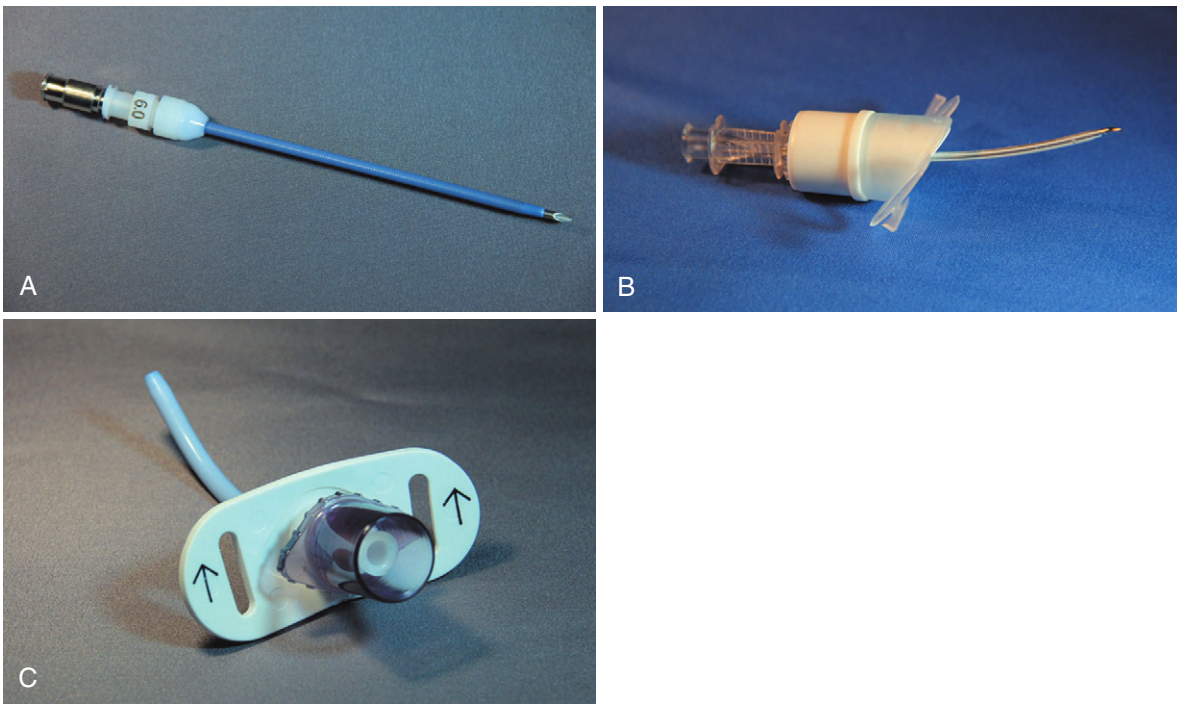

Figure 28-7 **A,** The Cook transtracheal jet ventilation catheter (Cook Critical Care, Bloomington, IN) is a 15-G, 5- or 7.5-cm, wire-reinforced, kink-resistant cannula. The proximal end has a female Luer-Lok type of adapter. **B,** The Ravusin 13- or 14-G jet cannula (VBM, Medizintechnik, Sulz, Germany) has rings for securing the cannula to the patient, both Luer-Lok and 15-mm proximal adapters, and a preformed curve. **C,** The Ardnt Emergency Cricothyrotomy Catheter (Cook Critical Care) is made of a precurved, kink-resistant material; unlike the other catheters, it is inserted with the use of an over-the-wire Seldinger technique.

TABLE 28-2
Equipment and Resources for Percutaneous Translaryngeal Jet Ventilation

	Description	Example
Minimal Resources		
Oxygen source	Wall or regulated tank, 50 psi	Indexed central supply or regulated tank O_2
	Low-flow O_2 flowmeter, 15 L/min minimal flow	Wall outlet or tank flowmeter
Needle catheter (specialized)	13-G ID or greater diameter	Cook Transtracheal Catheter* Ravusin catheter†
Conveyance device	Regulated and adjustable, hand-triggered valve with indexed O_2 source connection	Manujet III†
	O_2 flowmeter-powered, hand-regulated O_2 outlet	Enk Flow Modulator* Ventrain‡
Personal protective equipment	Protects operator from bloodborne acquired antigens	Gloves, face mask
Other	Syringe, Luer-Lok	5 or 10 mL
Preferred Accessories		
Skin-marking pen	To mark the location of the cricothyroid membrane	
Antiseptic solution, sterile drapes	For preparation of sterile field	
Scalpel	For small vertical skin incision	
Fluid	Helps to appreciate needle entrance into larynx	Saline, local anesthetic with epinephrine (1:200,000 dilution)
Fine-gauge needle	For local injection of anesthetic, epinephrine	22-25 G

A. Insertion of the Transtracheal Catheter

The right-hand–dominant operator stands on the left hand side of the patient. The CTM is palpated with the neck of the patient extended, unless an absolute contraindication exists (Fig. 28-8). The rate of misplacement of PTJV due to misidentification of the CTM is high, with one study showing that only 30% of clinicians were able to identify the overlying surface landmarks.[72] The literature is replete with methods of identifying the CTM (Box 28-2). When airway management difficulty is anticipated, it is not unreasonable (and is often encouraged) for the clinician to identify the CTM before the start of any airway procedures such as anesthetic induction or preparation for awake management (see Fig. 28-8).[4] The DA Taskforce of the ASA encouraged assessing the feasibility of invasive airway use in any patient whose airway is to be controlled. Preanesthesia palpation and marking draws attention to the potential futility of attempting invasive management (e.g., in the patient with super-obesity) and may lead to an early change in the anesthesia plan.[1]

The CTM is the accepted entrance point for PTJV.[31] Insertion of a cannula-over-needle or surgical airway in the vicinity of the cricoid cartilage has several advantages. First, several landmarks have been described for CTM identification. Second, it is the only completely circumferential cartilage in the airway. The mature cricoid cartilage lends rigidity to the larynx, making it resilient to the anteroposterior pressure of an inserted cannula-over-needle, resulting in reduced trauma.[31] Third, the posterior wall of the cricoid cartilage extends from the trachea inferiorly to the inferior border of the thyroid cartilage. This provides a solid "backstop" for the probing PTJV cannula-over-needle placed through the CTM. Several reports have described intentional and unintentional tracheal PTJV cannula placement when the CTM was

Figure 28-8 The location of the cricothyroid membrane is identified and marked. When difficulty is anticipated, this may be done in anticipation of percutaneous transtracheal jet ventilation.

BOX 28-2 Methods for Identifying the Cricothyroid Membrane

difficult to identify. Salah and colleagues, in a swine cadaveric airway study, noted increased trauma to the tracheal anatomy with some, but not all, percutaneous techniques, emphasizing the preference for CTM access.[9]

If time permits, a local anesthetic with epinephrine can be injected into the skin to reduce bleeding, thus improving visualization in the event that a surgical technique must be pursued. In the emergent situation, analgesia at the site of airway access is not an objective. Combined local anesthetic-epinephrine solutions are often used by surgeons for skin vasoconstriction because of their safe and reliable dilutions. An antiseptic solution can be rapidly applied, if time permits.

The previously identified translaryngeal cannula-over-needle is readied with a 5- to 10-mL syringe, with or without fluid. If it is not already preshaped by the manufacturer, a small-angle bend (15 degrees) can be placed 2.5 cm from the distal end.[73] This angulation helps prevent intratracheal cannula kinking or cephalad travel. The needle punctures the skin in the midline over the lower third of the surface landmarks of the CTM. The CTM is a relatively avascular structure, although blood is occasionally drawn into the syringe (this should not deter the intubator from completing this life-saving procedure). The cricothyroid artery and vein can be avoided by performing the puncture in the midline of the neck in the lower third of the CTM, just above the cricoid cartilage.[74,75] Initially, the axis of the cannula-over-needle is oriented at a 90-degree angle to the imagined location of the cervical spine. As downward pressure is exerted, constant negative pressure is applied to the syringe plunger. It is practically mandatory that the intralaryngeal position be identified by aspiration of gas. Except in the case of drowning or pulmonary hemorrhage, the larynx and trachea should be gas filled. Under no circumstance should the intubator assume that the larynx or trachea has been entered based on surface landmarks or tactile sense alone. Not only is the injection of pressurized O_2 into the subcutaneous tissue, the mediastinum, a large vessel, the pleural space, or other inappropriate location futile, but it may lead to rapid death and may obscure the anatomic planes needed to complete a surgical airway.

As bore diameter increases, passage of the cannula-over-needle through the skin becomes increasingly difficult. The requirement that large-gauge cannula be used for PTJV is counterbalanced by percutaneous insertion difficulty. If this is encountered, a small vertical incision through the skin can be made with a scalpel blade. Resistance to needle advancement may otherwise be caused by contact with the cricoid or thyroid cartilage, and the landmarks of the airway should be rapidly reassessed.

If a constant negative pressure is applied to the syringe, entrance into the larynx is heralded by air aspiration. The few bubbles that may be detected with needle exploration should not be construed to indicate airway entry. A 13-G or larger needle entering the airway will allow the effortless aspiration of voluminous air. Once air is aspirated from the larynx, the syringe is oriented 30 degrees cephalad, and the cannula is advanced off the needle and into the airway. When the hub of the cannula reaches the skin line, and the needle has been fully removed and safely discarded, air should once again be aspirated from the in situ cannula to reconfirm the intralaryngeal location. From the moment the cannula is inserted into the trachea, a human hand should be dedicated to holding the transtracheal cannula in place until a definitive airway is established.

After reverification of the intra-airway cannula location, the available O_2 conveyance system is attached via its Luer-Lok connections. Initial insufflations of O_2 should be titrated to chest excursion. When a high-flow, hand-triggered regulator is used, a 1 second or less inspiratory time has been emphasized by several authors.[34,64] Though 50 psi may be needed to cause chest excursion, commencing PTJV with more modest pressures (25 to 30 psi) may be prudent to preclude the devastating complications of cannula misplacement. The ability to designate precise insufflation pressures may not be available on all high-flow regulators, underscoring the recommendation that equipment be prepared or adjusted before the need arises. The maximum and midrange output settings on the available high-flow regulator should be determined during equipment preparation.

A variety of I:E phase ratios have been suggested without absolute advantages being established, in part because of the wide variety of artificial and animal models that have been studied. In general, low respiratory rates (e.g., 4 breaths/min) result in improved ventilation, especially if partial airway obstruction exists. Respiratory rates as high as 12 breaths/min (e.g., a phase ratio of 1:4) have been studied.[64] Adhering to the principle of ensuring adequate chest wall recoil to guide the respiratory rate is of singular importance. Inadequate recoil may be caused by poor maintenance of upper airway patency, a shortened expiratory phase, or a fixed obstruction. Maneuvers to open the upper airway (e.g., oropharyngeal airways [OPAs], NPAs, SLAs, chin lift-jaw thrust) may be reassessed, and lengthening of the expiratory phase may be attempted. If the clinical history and course are consistent with a fixed upper airway obstruction, the strategies discussed earlier may be in order. As previously discussed, complete upper airway obstruction is a contraindication to the use of high-flow regulators.

When a low-flow regulator and conveyance system is in use (e.g., O_2 flow meter, Enk Flow Modulator), V_T will be reduced, yet the same oxygenation/ventilation strategies are applied.[64] The low-flow regulator should be set to 15 L/min; inspiratory time should be based on observation of chest wall excursion, although 1 second may be used as the initial standard. The phase ratio should be based on observations of chest fall but has been studied in ranges similar to those noted earlier for high-flow regulators. The use of active expiratory valves (e.g., EVA) should improve ventilation by allowing faster respiratory rates and by reducing, but not eliminating, the dangers of barotrauma and hypoventilation during complete upper airway obstruction.

IX. MAINTENANCE OF THE NATURAL AIRWAY

Unless an advanced EVA device such as the Ventrain (Dolphys Medical BV, The Netherlands) is in use, the driving pressure for the expiratory phase of PTJV is the

elastic recoil of the chest wall and abdominal contents (10 to 20 cm H_2O). The hazards of an obstructed upper airway, apart from inadequate ventilation, have already been discussed. During PTJV, all efforts should be made to maintain a patent upper airway in order to avoid excessive intrathoracic pressure and to aid ventilation. Chin and jaw thrust maneuvers or use of an OPA, NPA, or SLA should be employed throughout the PTJV procedures.

X. CONCLUSIONS

The incidence of the CICV situation is 1 per 10,000 patients presenting to the OR, and it is higher in the emergency department. The degree to which SLA devices have reduced the occurrence of this critical circumstance, although dramatic, has yet to be defined. In most cases, the possibility of failed upper airway management can be anticipated and avoided. PTJV is a simple, easily mastered procedure that offers a remedy for this dire situation. The lungs of both healthy and critically ill patients have been successfully oxygenated and ventilated by this method, and it has a place in every anesthetizing situation. The systems of choice are dependent on the clinical situation, the physical plant in which the operator works, and the available conveyance devices. Translaryngeal ventilation systems using the anesthesia circle system (with reservoir bag), self-inflating resuscitation bags, and OR-rigged conveyance devices perform poorly in this dire clinical situation and may be helpful only if very large (>3 mm) cannulas are used.

Because there are a number of serious PTJV complications, this life-saving procedure should be undertaken only in desperate emergencies or in carefully thought-out elective situations. However, because desperate CICV emergencies continue to occur in association with the practice of anesthesia, I recommend that every anesthetizing location have PTJV equipment immediately available and that anesthesiologists become familiar with the technique.

XI. CLINICAL PEARLS

- Translaryngeal insufflation of O_2 requires a high-pressure O_2 source unless catheters 3 mm or larger in diameter are used. Anesthesia circuits and air-mask-bag units cannot provide adequate pressure.
- Before contemplating translaryngeal insufflation of O_2, the clinician should ensure that all materials and an O_2 source are available. This requires planning prior to the event.
- Only medical-grade devices should be used for these life-salvaging techniques. Jerry-rigged devices should not be used.
- Dedicated translaryngeal catheters, 14 G or larger, and not angiocatheters should be used.
- Translaryngeal insufflation of O_2 requires some degree of upper airway patency. If the airway is completely occluded, devices that allow exhalation of gas (passive or active) must be used. In any case, these patients demand a surgical airway as soon as possible.
- Whenever translaryngeal insufflation of O_2 is undertaken, an oropharyngeal device (e.g., supralaryngeal airway [SLA], oropharyngeal airway [OPA], nasopharyngeal airway [NPA]) should be in place to promote gas escape.
- Apart from and earlier than recovering O_2 saturation, chest recoil (not expansion) is the best monitor of well-performed translaryngeal insufflation.

I. Historical Background
II. Indications and Contraindications
III. Instrumentation
IV. Preoperative Considerations
V. Anesthesia for Bronchoscopy
VI. Surgical Technique
VII. Complications
VIII. Foreign Body Removal
IX. Conclusions
X. Clinical Pearls

I. HISTORICAL BACKGROUND

Rigid bronchoscopy is an invasive surgical technique that is used to visualize the oropharynx, larynx, vocal cords, trachea, and proximal pulmonary branches. The origins of rigid bronchoscopy, like many aspects of modern medicine, can be traced back to Hippocrates (460-370 BC), who advised introducing a pipe into the larynx in a suffocating patient to assess the airways.[1] Because of limitations with lighting, the field was largely dormant until the 1800s, when incandescent light bulbs were invented. The development of local anesthesia in 1880 also made bronchoscopy more tolerable. In March of 1897, Gustave Killian passed an endoscope through the larynx and removed a piece of pork bone from the right main stem bronchus using cocaine anesthesia.[1] Chevalier Jackson further advanced the field of rigid endoscopy by developing improved lighting, auxiliary instrumentation for removal of foreign objects, and rigid bronchoscopy training programs.[2] He is recognized as the father of contemporary rigid endoscopy.[3] Since Jackson's time, many changes have been made to the bronchoscope, so that current rigid instrumentation and ventilation systems allow for more precise and accurate assessment of the aerodigestive tract.[3] H.H. Hopkins of England invented the first conventional lens system by using glass rods instead of small lenses, which produced a significantly brighter image, occupied less space, and allowed for greater visualization of an object in a single field.[1] This provided the basis for fiberoptic and modern rigid bronchoscopy.

II. INDICATIONS AND CONTRAINDICATIONS

The tracheobronchial tree can be directly observed with either rigid or flexible bronchoscopy. Although the advent of flexible bronchoscopy has given physicians improved access to more distal portions of the tracheobronchial tree with a more rapid learning curve and less patient discomfort compared with rigid bronchoscopy,[2] there are still several situations in which rigid bronchoscopy is more appropriate. The larger working port and rigid structure make rigid bronchoscopy useful for surgical interventions within the airway, such as the removal of foreign bodies or polyps (see "Foreign Body Removal").[4] At the same time, the bronchoscope can be used in establishing and maintaining airway control in patients with difficult ventilation, such as those with an acute airway obstruction or massive hemoptysis.[4] The major advantage of the rigid bronchoscope compared to the flexible one is that it has a ventilation port that can be directly connected to the anesthesia ventilator, allowing for maintenance of an airway and external ventilation while airway procedures are performed. In fact, the latest practice guidelines for the management of a difficult airway (DA) include the use of rigid bronchoscopy because it "reduces airway-related adverse outcomes."[5]

Other instances in which rigid bronchoscopy is indicated include deeper diagnostic biopsies when a fiberoptic specimen would be inadequate; dilatation of strictures; bronchial stenting; fracture reduction; application of laser therapy or cryotherapy; tumor removal; and diagnosis of vascular rings. Some of the indications for pediatric rigid bronchoscopy are listed in Box 29-1.

There are few contraindications to rigid bronchoscopy. In practice, most of the factors limiting rigid bronchoscopy are related to the general anesthesia used, such as an unstable cardiovascular or respiratory status.[6] One absolute contraindication to rigid bronchoscopy is an unstable cervical spine, because of the hyperextension of the head required during the procedure. In this instance, flexible bronchoscopy is indicated to avoid any further spinal injury during bronchoscopy. Other contraindications include laryngeal stenosis that prevents passage of the bronchoscope; limited range of motion of the mandible; severe kyphoscoliosis; uncontrolled coagulopathy; and extreme ventilatory/oxygenation demands.[7,8]

BOX 29-1 Indications for Rigid Bronchoscopy

Stridor
Tracheostomy surveillance
Foreign body evaluation and management
Interval evaluation after laryngotracheal reconstruction
Chronic cough
Severe hemoptysis
Management of severe laryngotracheal infections
Airway trauma
Assessment of toxic inhalation or aspiration
Evaluation of laryngeal pathology
Management of mass lesions of the airway, including recurrent respiratory papillomatosis
Placement of stents
Assisting in laser therapy

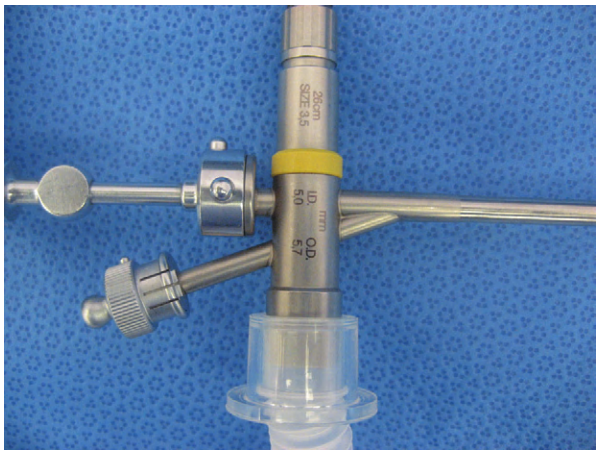

Figure 29-2 Close-up view of ventilating bronchoscope. The anesthesia circuit attaches inferiorly, the prismatic light source superiorly, and the suction port at an angle.

III. INSTRUMENTATION

The Storz endoscope with the Hopkins rod-lens optical system, introduced in 1966, is the most widely used rigid bronchoscope and has largely replaced the Jackson and Holinger endoscopes.[9] As described earlier, the rod-lens system provides better illumination, greater visualization, and angled views. The bronchoscope is a hollow, rigid metal tube that is tapered and beveled on the distal end and has a series of different-sized ports on the proximal end that serve different purposes. There are side holes at the end of the bronchoscope to allow for ventilation proximal to the tip.[10] The beveled edge of the tip is used to facilitate introduction of the bronchoscope into the airway and for resection of tumors. The inferior port is usually the ventilating port connected to the anesthesia circuit. The superior port connects to the prismatic light deflector and the light source (Figs. 29-1 and 29-2). The main port is the working channel for aspiration and for insertion of instruments such as telescopes, biopsy forceps, laser fibers, balloon devices, cryotherapy probes, and stents. The port can be left open to allow room air into the system or it can be closed to prevent leakage of air or anesthetic gases, depending on the ventilation and type of anesthesia being used.

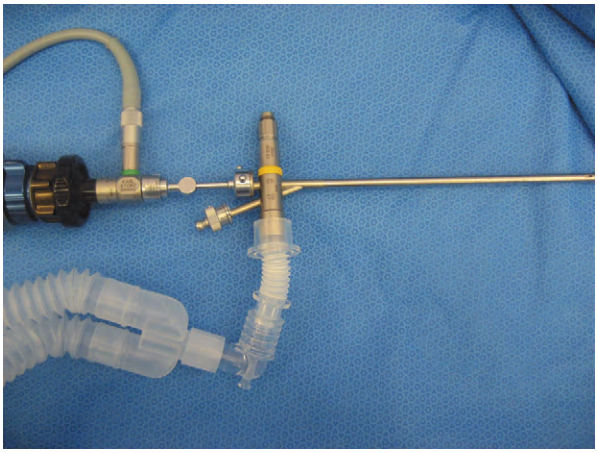

Figure 29-1 Bronchoscope with attachments to anesthesia circuit.

Bronchoscopes vary in size, in length, and in internal and external diameter. Table 29-1 depicts the different sizes of Storz bronchoscopes used by patient age, although this choice needs to be tailored to the individual patient. The size chosen should maximize the surgeon's view while causing the least trauma to the airway.[9] Telescopes with different angles (0, 30, and 70 degrees), lengths, and diameters can be inserted through the main working port to visualize areas that are difficult to see with the rigid bronchoscope alone, namely the right and left upper bronchial orifices and the right middle bronchial orifice.[9] Illumination can be provided either through a light carrier rod that goes down a channel in older endoscopes, through the telescope, or by means of a port that attaches to a prismatic light deflector which subsequently attaches to a light source in newer endoscopes (Figs. 29-3 and 29-4). The last configuration has the advantage that it provides both proximal and distal illumination.

Rigid bronchoscopy should be performed either in an operating room (OR) or an endoscopy suite. As with all procedures that require general anesthesia, the room should be equipped with equipment for oxygen (O_2) saturation monitoring, carbon dioxide (CO_2) monitoring, blood pressure monitoring, and electrocardiography. A

TABLE 29-1
Suggested Bronchoscope Sizes (Karo Storz Brand) According to Patient Age

Size	Length	ID (mm)	OD (mm)	Age
2.5	20	3.5	4.2	Premature
3.0	20, 26	4.3	5.0	Premature, newborn
3.5	20, 26, 30	5.0	5.7	Newborn-6 mo
3.7	26, 30	5.7	6.4	6 mo-1 yr
4.0	26, 30	6.0	6.7	1-2 yr
5.0	30	7.1	7.8	3-4 yr
6.0	30, 40	7.5	8.2	5-7 yr
6.5	43	8.5	9.2	Adult

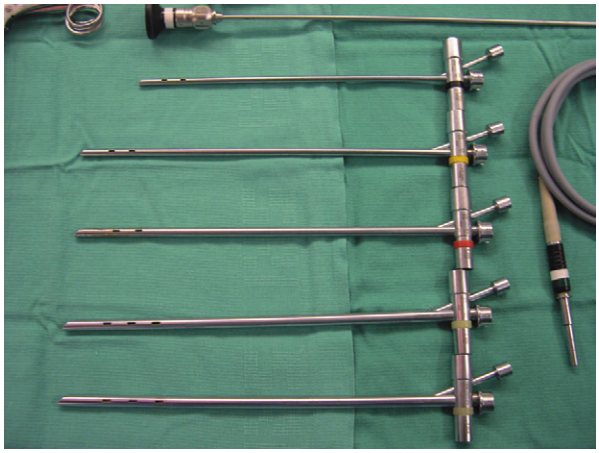

Figure 29-3 Bronchoscopes of varying sizes in example setup.

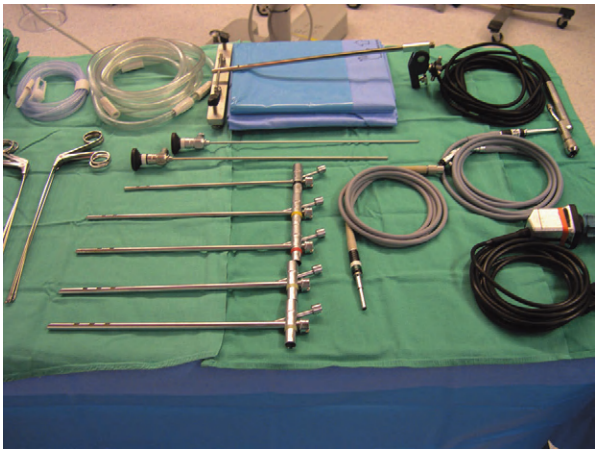

Figure 29-5 Additional setup including graspers and suction

full set of ventilating bronchoscopes (see Table 29-1 for sizes) and a backup light source should be available. The standard adult size rigid bronchoscopy is 8 mm in diameter and 40 cm long. Other instruments such as graspers, biopsy forceps, optical forceps, and suction devices should also be available to the surgeon (Fig. 29-5). Optional items include a flexible bronchoscope that can be passed through the rigid bronchoscope for further examination of the lower tracheobronchial tree. Video capability is also desirable but not required (Fig. 29-6).

IV. PREOPERATIVE CONSIDERATIONS

A thorough history should be taken to assess previous cardiac disease, such as a recent myocardial infarction or any documented dysrhythmias, or pulmonary disease (e.g., asthma) that may require bronchodilators before bronchoscopy.[4] To minimize the risk of bleeding, the patient should have a normal platelet count, prothrombin time, and partial thromboplastin time. Unless a bleeding history is known, a preoperative coagulation workup is not necessary. Because patients with uremia have qualitative platelet abnormalities that can predispose to excessive bleeding, creatinine and blood urea nitrogen values should be relatively normal.[4] Patients should also be questioned about aspirin or anticoagulant use and timing of the last intravenous dose. Additional laboratory studies and tests may be ordered depending on the history.

A 12-lead electrocardiogram is required for patients with cardiac risk factors such as smoking, diabetes mellitus, arterial hypertension, or hypercholesterolemia and for those with a significant cardiac history. A chest radiograph may provide information regarding congestive heart failure, pulmonary consolidations, or the presence of chronic obstructive pulmonary disease (COPD). Arterial blood gas analysis can be performed to evaluate the patient's acid/base status in the setting of pulmonary disease.

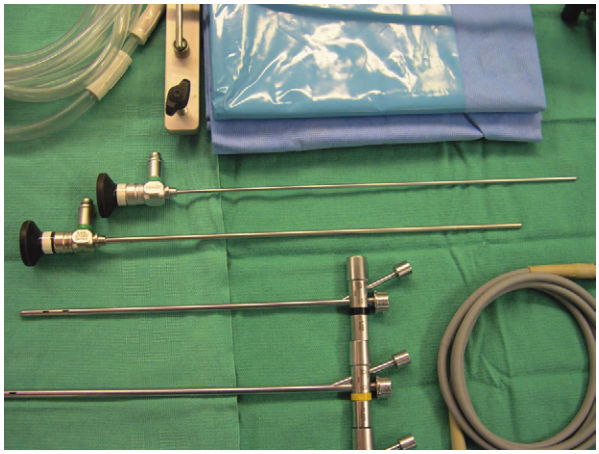

Figure 29-4 Optical telescopes for visualization through bronchoscopes.

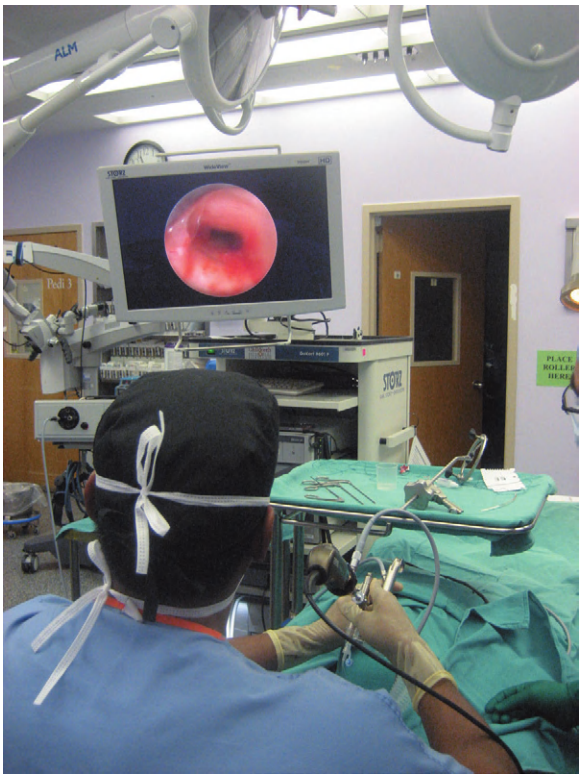

Figure 29-6 Bronchoscopist's view during a procedure. The monitor is shared so that it may be viewed simultaneously by the bronchoscopist and the anesthesiologist.

Pulmonary function tests are no longer indicated as routine preoperative assessment of respiratory disease but may be useful for determining the postoperative plan.[11] For example, patients with a forced vital capacity (FVC) of less than 20 mL/kg is at an increased risk for pulmonary complications postoperatively and may benefit from extended postoperative monitoring.[10] Also, patients with forced expiratory volumes of less than 50% are at risk for hypercarbia and hypoxia.[12] The clinical predictors of cardiac complications perioperatively or postoperatively with major risk are unstable or severe angina, decompensated congestive heart failure, significant dysrhythmias, and severe valvular disease.[13] Cardiac conditions should be evaluated and the medical therapies optimized before the surgery. Perhaps the simplest way to assess the patient's overall cardiopulmonary status is to inquire about exercise tolerance.

Often, rigid bronchoscopy is performed emergently with limited preoperative evaluation or testing in order to secure an airway, and knowledge and assessment of risk factors for cardiopulmonary mortality, difficult intubation (DI), and difficult mask ventilation (DMV) may be of importance for perioperative and postoperative management. DI may be predicted by weight, head and neck movement, jaw movement, receding mandible, "buck" teeth, Mallampati classification, thyromental distance, sternomental distance, and a history of DI.[5,14,15] There are five independent risk factors for DMV: age greater than 55 years, body mass index greater than 26 kg/m^2, presence of a beard, lack of teeth, and a history of snoring.[14] A careful evaluation of the patient's jaw and neck mobility should be made, because severe cervical spine disease is a contraindication to rigid bronchoscopy.

V. ANESTHESIA FOR BRONCHOSCOPY

Because of the nature of the procedure and sharing of the airway, the anesthesiologist and the surgeon must be in constant communication during a rigid bronchoscopy procedure. The goals for anesthesia during bronchoscopy are to provide anesthesia and analgesia, to provide sufficient relaxation, to diminish the reactivity and reflexes of the respiratory tract, to maintain adequate oxygenation, and to achieve prompt awakening at the conclusion of the procedure. General anesthesia is typically used to prevent unnecessary patient movement and possible unintentional damage to the airway. This can be accomplished with deep inhalational anesthesia, total intravenous anesthesia, or a combination of inhalational and intravenous anesthesia with or without neuromuscular blocking (NMB) agents depending on the specifics of the procedure and the preferences of the surgeon and anesthesiologist.

There are several different ventilation techniques that can be used with rigid bronchoscopy. The rigid bronchoscopes have ventilating ports that can be attached to the anesthesia circuit directly, allowing the anesthetic gases to flow concomitantly during the procedure. This is the most common and straightforward manner in which to keep a patient adequately ventilated during rigid bronchoscopy, although ventilation can also be achieved by the use of spontaneous ventilation, positive-pressure ventilation (PPV), apneic oxygenation, jet (Venturi) ventilation, or negative-pressure ventilation (NPV).

Traditionally in the pediatric population, inhalational anesthesia with spontaneous respiration has been used during rigid bronchoscopy, often with switching to a total intravenous anesthetic technique after induction. Disadvantages of inhalational anesthesia with spontaneous respiration include difficulty in maintaining an adequate plane of anesthetic depth and the anesthetic pollution of the surgical environment from a gas leak around the bronchoscope.[16] Malherbe and colleagues proposed total intravenous anesthesia with propofol and remifentanil and spontaneous respiration as a reasonable alternative to deep inhalational anesthesia that carries no major complications.[16] In the spontaneous respiration technique, the patient is not given an NMB agent and is allowed to breathe spontaneously. The ventilating port of the bronchoscope is attached to the anesthesia circuit with 100% O_2 flow (see Fig. 29-1). The advantage of spontaneous ventilation is that it allows for *continuous* ventilation during the procedure; the main disadvantage is that the depth of anesthesia required for the procedure itself may suppress both cardiac output and the respiratory drive, making spontaneous respirations difficult.[17] Another potential disadvantage is that the instrumentation required for the procedure itself provides increased airway resistance and may reduce the efficacy of spontaneous respirations.[18]

When PPV is used, it is typically achieved by first relaxing the patient with an NMB agent and subsequently connecting the ventilating port of the bronchoscope to the anesthesia circuit. Positive pressure is administered by squeezing the bag or by using the anesthesia ventilator, forcing gas pressure through the rigid bronchoscope.[19] Advantages include the prevention of atelectasis, improved oxygenation, and the ability to overcome the increased airway resistance caused by the instrumentation within the rigid bronchoscope.[18] A disadvantage to PPV is that a proximal eyepiece must be in place, which hinders the use of suction or other instrumentation during ventilation.[20] There is also usually some gas leak during PPV due to the absence of a tight seal, decreasing efficiency. Finally, the size of the bronchoscope and the presence of a telescope in the lumen increases resistance to airflow and increases dead space ventilation, making ventilation more difficult.

In apneic oxygenation, there are periods of time when the anesthesiologist withholds ventilation during which the surgeon works. The patient is first hyperventilated to produce a profound hypocarbia. Under direct visualization, a catheter is then passed to the carina, and the flow rate of O_2 is set. The period of time in which the surgeon can work is determined by the rise in CO_2, after which the patient is allowed an equivalent amount of time during the next ventilation cycle to return to baseline. The partial pressure of CO_2 (P_{CO_2}) is expected to rise continuously at a rate of 3 mm Hg per minute.[10] This technique is risky when it is used in patients who have a history of CO_2 retention (e.g., COPD), and intraprocedural awareness is also reported more frequently with this technique.

Jet ventilation is usually used during laser procedures, and it is provided by use of a jet-ventilator with a jet injection cannula (JIC), also known as a Saunders injector.[21] This technique is used to overcome the hypoventilation caused by air leaks during PPV.[22] The cannula has three lumens, two of which open proximally and deliver the jet ventilation; a distal lumen measures airway pressure.[21] The JIC is 3 mm in diameter, can have various lengths, and is made of stainless steel and therefore has a lower risk of endotracheal ignition.[21,22] The JIC is usually introduced distal to the lesion being accessed to provide optimal ventilation. High-pressure O_2 (50 psi) is delivered to the airway at high velocities, creating a negative pressure and causing a Venturi effect.[16] The negative pressure caused by the high velocity of air entering the airways induces a column of air from outside the injector to flow into the airways and expand the lungs. Exhalation is passive and relies on the collapse of the airway once the pressure is removed. Sufficient time must be allotted for air egress during this technique to prevent stacked breaths and progressive hyperinflation. This method is contraindicated during foreign body removal, because the high-flow air may dislodge the foreign body and cause a complete obstruction.[18] Of note, jet ventilation does not prevent acidemia or hypercarbia and may increase the risk of air embolism, pneumothorax, and particle dissemination into the lungs and distal airways.[20] Also, in patients with poor lung compliance, ventilation may be inadequate with this technique.[10]

NPV, compared with spontaneous assisted ventilation, reduces the administration of opioids, shortens recovery time from anesthesia, and prevents hypercarbia.[20] It can be accomplished by a poncho-wrap connected to a negative-pressure ventilator, with a 2-L/min O_2 flow, negative pressure of –25 hectopascals (hPa), a respiratory rate of 15 breaths/min, and an inspiration/expiration ratio of 1:1. NPV may be safer in patients with poor tolerance to hypercarbia, such as patients with myocardial ischemia.[20]

Intravenous and topical medications can be used provided the patient's history reveals no prior adverse reactions or if the potential benefit outweighs the expected risks. Opioids are often used for analgesia, for sedation, and to decrease the cough reflex. However, because they depress the respiratory drive, they should be withheld from patients who have signs of airway obstruction or a foreign body. A recent study by Yoon and colleagues comparing propofol sedation to a combination of both propofol and alfentanil showed that the propofol-only group had a higher average oxygen saturation as measured by pulse oximetry (SpO_2; 97.8 ± 1.6 versus 96.4 ± 1.1, $P < 0.01$). The degree of cough (measured using a 100 mm visual analogue scale), however, was not different between the groups (73.4 ± 22.7 versus 72.2 ± 18.5, respectively). This may be partially attributed to the intrinsic antitussive properties of propofol. Therefore, narcotics may not be required if the patient is being induced with propofol.[23]

Anticholinergics are often used to reduce airway secretions and have been shown to enhance the absorption and prolong the analgesic action of topical analgesics such as lidocaine which are administered to the airways to reduce reactivity, prevent bronchospasm, and dampen the systemic reaction to airway manipulation.[24] Intravenous anticholinergics are also commonly used to prevent the parasympathetic-mediated bradycardia and hypotension that can occur during rigid bronchoscopy.[11] Their routine use remains debated.[25] A steroid such as dexamethasone can be used to decrease intraoperative and postoperative edema that can result from airway instrumentation.

For emergence from anesthesia, all anesthetic gases are turned off, NMB agents are reversed, and the patient is ventilated until spontaneous respirations resume. Topical lidocaine may again be administered to prevent laryngospasm and diminish coughing.[12]

VI. SURGICAL TECHNIQUE

The surgeon should ensure that the necessary instrumentation is available before rigid bronchoscopy is initiated. In pediatric bronchoscopy, the size of the bronchoscope needed can be approximated by the patient's age, or by size of an appropriate endotracheal tube (see Table 29-1). In all patients, bronchoscopes one or two sizes smaller than the preselected one should be available in case the airway encountered is smaller than anticipated.[9] The surgeon should also select the appropriate size of instruments that will be used during the procedure, such as laryngoscopes, telescopes, endotracheal tubes, forceps, and suctions, and ensure that they are functioning properly. Teeth should be protected with rubber guards or with damp gauze, and the eyes should be protected with lubricant and tape.[4,12]

After informed consent for the procedure is obtained, the patient is taken to the OR or endoscopy suite. In pediatric bronchoscopy, the child should be positioned with the neck flexed on the body and the head extended at the neck.[9] This position is sometimes called the "sniffing" position, and is used to position the trachea anteriorly.[4] A shoulder roll to elevate the shoulders and a foam donut to stabilize the head are usually placed in older children; in younger children, a small donut for the head is sufficient. The goal is to align the oral, pharyngeal, and tracheal axes to facilitate insertion of the bronchoscope.

The anesthesiologist may induce anesthesia with either mask ventilation or intravenous agents, after which the surgeon begins the endoscopy by examining the oral cavity, oropharynx, and supraglottic larynx.[12] The vocal cords are identified and may at this point be sprayed with a topical agent such as lidocaine to diminish airway reactivity and laryngospasm. In pediatric bronchoscopy, especially in cases of airway obstruction due to a foreign object, a slotted laryngoscope can be used in combination with a telescope to examine the larynx and the airway before the rigid bronchoscope is inserted, because there is a possibility of dislodging the foreign object and causing a complete obstruction during the introduction of instruments.[12] O_2 can also be insufflated via a flexible large-bore catheter into the laryngeal inlet during the preliminary examination to allow the surgeon additional time to work in the airway (Fig. 29-7).[12]

Whereas in older children and adults the bronchoscope may be advanced directly into the trachea without laryngoscopic assistance, in younger children it is easiest

Figure 29-7 Bronchoscope in position for ventilation during a procedure.

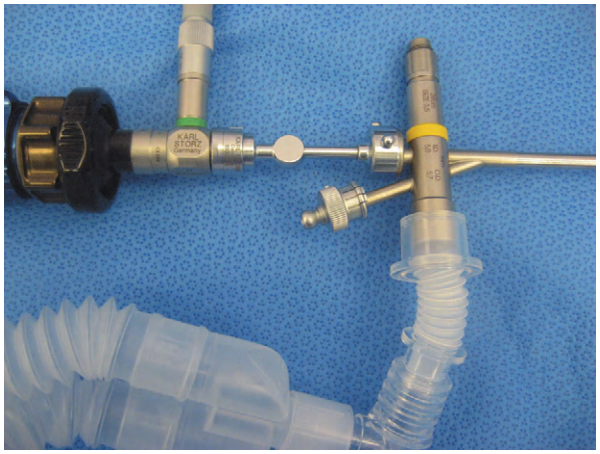

Figure 29-8 Rigid ventilating bronchoscope with telescope attached to camera posteriorly.

and safest to use a laryngoscope to guide the rigid bronchoscope.[9] The laryngoscope is introduced in the usual fashion into the vallecula until the glottis is in the field of vision. The rigid bronchoscope is then introduced within or adjacent to the lumen of the laryngoscope down to the level of the true vocal cords.[9] If the vocal cords are not open, then the patient is not sufficiently relaxed, and additional intravenous anesthetic or NMB agent should be given.[3] The rigid bronchoscope is then rotated 90 degrees to align the leading edge with the axis of the vocal cords as the bronchoscope passes through the glottic opening into the subglottis. This provides the path of least resistance and minimizes the risk of glottic damage.[7] A simple twisting motion may be required to advance the bronchoscope into the subglottic area.[9] Once it is distal to the glottis, it can be rotated back 90 degrees to its original orientation. Although the beveled tip of the rigid bronchoscope is conventionally directed anteriorly, some surgeons advocate placing the tip along the posterior wall of the trachea to prevent damage to the membranous trachea.[8]

In older children, adolescents, and adults, laryngoscopy is not always required. The patient's maxilla is grasped with the left hand while at the same time support is provided for the rigid bronchoscope, and the dentition is protected by the thumb of the surgeon's nondominant hand.[4,9] The bronchoscope is passed into the oral cavity in a plane perpendicular to that of the patient, and the posterior pharynx can be visualized. The bronchoscope is then rotated to a plane parallel with the airway axis. After visualization of the epiglottis, the tip of the bronchoscope is used to displace the epiglottis and tongue anteriorly. This maneuver requires gentle rocking of the bronchoscope on the thumb (*not on the teeth*) and brings the vocal cords into the field of vision.[4] Once the vocal cords are in view, the glottis can be approached and the subglottis may be entered, as previously described.[9]

For the intubated patient, the rigid bronchoscope may be advanced alongside the tube and then passed through the glottic opening as the tube is removed under direct visualization. If the patient has had the larynx surgically removed or closed, the rigid bronchoscope should be placed only through the laryngostoma.[8]

Once the bronchoscope has been successfully introduced into the trachea, the "sniffing" position can be converted to cervical hyperextension by removing the supporting pillow and donut from under the head and by lowering the headboard to extend the neck.[4,26] This maneuver is typically used in adults. The nondominant hand then holds the bronchoscope while the dominant hand is used for instrumentation of the airway for the duration of the procedure.[4] If any resistance is felt during the procedure, the surgeon should always reevaluate the patient's head and positioning, jaw opening, and bronchoscope size as well as ensuring that the patient's lips are not caught. At this point, the anesthesia circuit can be attached to the bronchoscope through the side port, and the catheter with O_2 flow can be removed (Fig. 29-8). Unless total intravenous anesthesia is being used, the lens cap to the main working port should be on to prevent leakage of anesthetic gas through the proximal end of the bronchoscope.

Before any intervention, an initial examination of the airway is performed. The subglottis and trachea are examined, and any masses or mucosal discolorations should be thoroughly investigated.[9] Even after premedication with an anticholinergic agent, secretions are frequently encountered during the bronchoscopy and can be suctioned by introducing a rigid or flexible suction cannula into the main working port. This or any other rigid instrumentation of the airway allows for escape of anesthetic gases into the OR environment and results in a loss of the closed anesthesia circuit. Flexible suction catheters can be used through a smaller side port to prevent the loss of the closed anesthesia circuit.[12]

Care must be taken not to suction the airways excessively, because this may lead to mucosal edema and inflammation and worsen the respiratory status of the patient. This effect can be mitigated by premedicating the patient with a steroid such as dexamethasone. The bronchoscope is then advanced to the level of the carina. The appearance and movement of the carina are noted during respirations. Decreased movement of the carina can be an indicator of hilar lymphadenopathy.[9] In order to advance the rigid bronchoscope to the main stem bronchus, the head should be slightly turned to the side

opposite the intended bronchus. The distal airways may be evaluated by inserting different-angled telescopes to view the tracheobronchial tree. The 30- and 90-degree telescopes are especially useful to examine the segmental orifices of the upper lobes, in particular the right upper lobe, which is in a difficult location.[3,7] The distal tracheobronchial tree can also be examined by inserting the flexible bronchoscope through the rigid bronchoscope.[7]

After the preliminary evaluation of the airway is completed, the planned procedure is performed (see later discussion). For diagnostic bronchoscopy, the bronchial brushings, washings, and biopsies are performed, in that order.[3] If any bleeding is encountered, it can be controlled with electrocautery or local application of epinephrine, oxymetazoline, or phenylephrine.[3] Phenylephrine may result in pulmonary edema or cardiac depression and should be used very cautiously. This emphasizes the need for constant communication between the anesthesiologist and the surgeon during rigid bronchoscopy. The procedure must be paused periodically and the working port sealed to minimize leakage of anesthetic gases into the OR environment and to allow for adequate ventilation. After the procedure is completed, the secretions should be thoroughly suctioned to prevent atelectasis.[12] Once the anesthesiologist has prepared for postbronchoscopy ventilation, the bronchoscope can be removed under direct vision if O_2 saturation is greater than 90%.[3,12] Bronchospasm and temporary hypoxia are not uncommon after withdrawal of the bronchoscope, and the anesthesiologist must be ready to support ventilation via mask ventilation or endotracheal intubation until spontaneous ventilation resumes.[3,12]

VII. COMPLICATIONS

The complications that may occur during or after rigid bronchoscopy can often be avoided by a thorough preoperative evaluation and proper technique.[3] These include damage to dentition, arytenoid dislocation, respiratory depression, laryngospasm, bronchospasm, subglottic edema, hypoxia, dysrhythmias, mucosal or parenchymal bleeding, perforation, pneumothorax, pneumomediastinum, and death.[3,9,27] In pediatric rigid bronchoscopy, the complication rates range from 1.9% to 4%.[27] In adults, Lukomsky and associates reported a complication rate of 5%,[28] whereas Drummond and coworkers reported a rate of 13.4%.[29] Patients with an increased preoperative risk, neoplastic disease, presence of a foreign body, or carinal involvement should be monitored closely, because these conditions are particularly associated with an increased complication rate in adults.[29] The three risk factors identified by Hoeve and colleagues for an increased complication rate in children are a history of tetralogy of Fallot, need for biopsy or drainage of a lesion during bronchoscopy, and a history of foreign body aspiration.[27]

It is imperative that patients be evaluated preoperatively for poor dentition, because loose teeth are at risk for damage or dislodgement during the procedure. If cervical spine disease with a contracted neck is present, rigid bronchoscopy may not be safely performed; a limited range of cervical motion precludes safe advancement of the scope into the airway, resulting in complications ranging from dental injury to perforation of the posterior pharynx, membranous trachea, or distal airway.[26] Such perforation of the airway may result in pneumomediastinum or pneumothorax but can be avoided by choosing an alternative method for examining the airway (e.g., flexible bronchoscopy) in susceptible patients.[16]

Hemorrhage can occur during bronchoscopy, especially during deep tissue biopsies. It may be controlled by use of the bronchoscope to apply pressure to the bleeding site, thorough suction, local application of epinephrine, or intravenous vasopressin. The patient's greatest danger when this occurs is aspiration rather than hemorrhagic shock.[27]

Bronchospasm and laryngospasm occasionally occur intraoperatively. Their incidence can be reduced by maintaining an adequate anesthetic plane and by the topical application of a local anesthetic, such as lidocaine. Other agents, including opioids and beta-blockers, can be used to blunt the hemodynamic response to airway stimulation.[16]

Late complications include airway edema, pneumothorax, and atelectasis.[12] Laryngeal edema is usually more serious in children, because their airway lumen is smaller and resistance increases exponentially with any airway swelling.[12] This condition can be improved with the administration of humidified O_2, racemic epinephrine, and steroids. If the patient does not respond to medical management, endotracheal intubation may be necessary. Laryngeal edema may be reduced by premedicating the patient with intravenous steroids.[16] In cases of Venturi ventilation or high ventilation pressures, pneumothorax may result from barotrauma.[10,12]

Rigid bronchoscopy requires excellent communication between the anesthesiologist and the surgeon. Failure to communicate may lead to inadequate control of the airway and can result in hypercarbia, hypoxemia, or death, especially in patients with impending complete airway obstruction.[26] This can be prevented by having all parties involved in the surgery familiarize themselves with the procedure before starting. A contingency plan must be in place in the event the airway is lost. This may entail preparation for tracheostomy or ventilatory bypass in an absolute emergency.

VIII. FOREIGN BODY REMOVAL

The removal of aspirated foreign bodies remains one of the main indications for rigid bronchoscopy, especially in children, in whom the use of flexible bronchoscopy is comparatively risky. In 2006, the total number of deaths caused by aspiration or ingestion of foreign objects, including food, totaled 3981.[30] Most deaths resulting from foreign body aspiration occur before hospital arrival.[31] The incidence of foreign body aspiration peaks in older infants and toddlers, with 74% of cases occurring in children younger than 3 years of age.[32] The male-to-female ratio is about 2:1 in children.[32] In adults, the peak incidence occurs in the sixth decade of life.[33]

The clinical progression of foreign body aspiration occurs in three stages. The initial stage is usually characterized by a choking episode followed by coughing,

gagging, and even obstruction of the airway.[32] In a series of 100 cases published by Barrios and coworkers, the history of a choking crisis was the clinical parameter with the highest sensitivity (97%) and also had a fair specificity (63%).[34] Chest radiographs may appear normal, and symptoms can be minimal.[31,34] In cases of suspected foreign body aspiration, rigid bronchoscopy remains the gold standard for both diagnosis and treatment. Whereas atelectasis is more common in adults, air trapping is more common in children.[33] The location of the foreign object also differs between adults (right bronchial tree) and pediatric patients (central airway). The second stage is usually asymptomatic, because the initial symptoms resolve due to a fatigued cough reflex.[32] As many as 50% of initial presentations of foreign body aspiration go undiagnosed for longer than 7 days,[29] and this is more likely to occur in an adult.[33] The third stage indicates a complicated foreign body aspiration, which can be associated with pneumonia, hemoptysis, bronchiectasis, chronic cough, lung abscess, fever, or malaise.[32]

Radiographic evaluation includes anteroposterior and lateral views of the extended neck and chest. It is imperative that both inspiratory and expiratory views be obtained whenever possible to evaluate for unilateral air trapping.[32] The four main types of obstruction at a bronchial orifice are bypass valve obstruction, check valve obstruction, stop valve obstruction, and ball valve obstruction.[32] In bypass valve obstruction, the obstruction is incomplete and will result in a normal radiographic evaluation. In check valve obstruction, commonly seen acutely, the foreign body permits air flow into the lung segment but blocks the air flow out of the lung segment. This results in a mediastinal shift *away from* the obstruction on an expiratory film. Stop valve obstruction is seen when a foreign body has been present for an extended period; it is characterized by no airflow into, and subsequent collapse of, the affected lung segment. The rarest type of obstruction, the ball valve type, permits airflow out of the lung segment but not into it. This phenomenon results in atelectasis and a mediastinal shift *toward* the obstructed segment on an expiratory film. Other studies (e.g., fluoroscopy, videofluoroscopy) have been used when the diagnosis is uncertain.[31,32]

The management of an aspirated foreign body depends on the clinical picture. If an acute complete obstruction is suspected, rigid bronchoscopy must be performed promptly. More frequently, however, the patient presents in the second or third stage, when there is adequate time to plan a successful and safe bronchoscopy. If possible, the procedure should be scheduled when experienced personnel are available, the instruments have been appropriately selected, and the child is fasted appropriately to prevent aspiration of gastric contents.[19,32] Advanced planning for the procedure includes determining the nature of the foreign object to guide the selection of instruments for its retrieval.

Controversy remains regarding the anesthetic approach during bronchoscopy for foreign body aspiration. Those who advocate spontaneous ventilation argue that PPV may precipitate an acute obstruction with clinical deterioration,[18,32] whereas others advocate controlled ventilation with NMB to prevent the patient from moving and decrease the probability of airway trauma. A retrospective series of 94 cases showed no difference in adverse events with either ventilatory management approach,[18] whereas a prospective study by Chen and colleagues consisting of 384 children found that patients managed with total intravenous anesthesia and spontaneous ventilation had increased intraoperative body movement, longer duration of emergence from anesthesia, lower percentage of successful foreign body removal, and more postoperative laryngospasm.[35] Chen's study also identified five risk factors for intraoperative hypoxemia ($SpO_2 \leq 90\%$): younger age, plant seed as the type of foreign body, longer operative time, presence of pneumonia before procedure, and spontaneous ventilation. Manual jet ventilation was found to decrease the risk of intraoperative hypoxemia. The factors associated with postoperative hypoxemia were plant seed as the foreign object and prolonged emergence from anesthesia. Patients with these characteristics should be closely monitored after the procedure.

If the foreign body is small enough, it can be removed through the lumen of the main working port. However, the objects are usually larger and need to be removed with the bronchoscope as a unit. Once the object is within the forceps, it is dislodged from the airway and the bronchoscope is advanced to cover the foreign object, preventing it being stripped off the forceps during withdrawal.[32] Removal of the bronchoscope may compromise the airway, so, again, communication during withdrawal is critical. Vegetable foreign bodies should be grasped lightly to avoid fragmentation of the foreign body into the distal airways.[32] After removal of the object, bronchoscopy should be repeated to ensure that no residual foreign body is left and to assess the patency of the airway distal to the previous obstruction. Bleeding is usually controlled with thorough suctioning and vasoactive agents. If residual granulation tissue is present and is the source of bleeding or residual obstruction, it may be resected at the repeat endoscopy.[32]

IX. CONCLUSIONS

Despite the advances that have expanded the applications for flexible bronchoscopy, rigid bronchoscopy remains a valuable tool in a surgeon's armamentarium. Rigid bronchoscopy is preferred when the airway is in peril and for procedures in which direct manipulation of the airway is needed. The two most common indications are foreign body aspiration or ingestion and massive hemoptysis, and rigid bronchoscopy is also often used to secure or assess an otherwise unstable airway. The wide lumen of the bronchoscope allows for instrumentation of the airway, which is required for endoscopic airway procedures such as biopsies and laser therapy. The procedure is performed with the patient under general anesthesia, although there are many different ventilation techniques.

The risk for complications increases significantly with inexperienced personnel, and the American College of Chest Physicians recommends that trainees perform at least 20 procedures under supervision to obtain basic competency and at least 10 procedures per year to

maintain competency.[7] The importance of communication between the bronchoscopist and the anesthesiologist cannot be overstated. When applied appropriately, rigid bronchoscopy can be a life-saving intervention in airway management.

X. CLINICAL PEARLS

- Open communication between the surgeon and the anesthetist is of highest importance during rigid bronchoscopy.
- Inspect the equipment prior to the patient's arrival; ensure that the bronchoscopes, light sources, light carriers and connectors are all in working order.
- Check that instruments (suctions, graspers, telescopes) are appropriate length for the selected bronchoscope.
- Have a backup set that is a size smaller than what you plan to use.
- For pediatric patients, calculate the safe maximum dose of each topical medication (e.g., lidocaine), and restrict their presence in the operative field.
- Place dental/gingival protection, and never leave the bronchoscope on the teeth.
- Advance the scope only when there is an identifiable lumen.

I. DEFINITIONS AND CLASSIFICATIONS OF PERCUTANEOUS CRICOTHYROTOMY AND TRACHEOSTOMY

A. Cricothyrotomy and Percutaneous Dilational Cricothyrotomy

Cricothyrotomy is a technique for providing an opening in the space between the anterior inferior border of the thyroid cartilage and the anterior superior border of the cricoid cartilage for the purpose of gaining access to the airway. This area is considered to be the most accessible part of the respiratory tree below the glottis.[1-6]

Cricothyrotomy can be classified in several ways. Based on the urgency of the clinical situation, the procedure has been classified as emergent or elective. Emergent cricothyrotomy may be done in the prehospital setting, emergency room, intensive care unit (ICU), or operating room. Elective cricothyrotomy is usually done before surgery in the operating room. It also may be performed in critically ill patients in the ICU at the bedside.[7] Depending on the technique used, the procedure may also be classified as nonsurgical or surgical. The

Figure 30-1 Cook cricothyrotomy catheter needle. (Courtesy of Cook Medical, Bloomington, IN.)

nonsurgical approach can be achieved by needle puncture or percutaneously over a guidewire, with or without a cricothyroid membrane (CTM) incision.[8]

A practical and clinical classification of cricothyrotomy techniques includes three categories. The first category includes techniques that use a needle or over-the-needle catheter placed directly into the cricothyroid space. The needle technique is used for transtracheal catheter ventilation or, more properly, transcricoid ventilation.[9] The cricothyrotomy needle (Fig. 30-1) and the Ravussin cannula (Fig. 30-2) are examples of these devices. Transtracheal catheter ventilation cannulas are also available, but they are inserted as described for the second category (Fig. 30-3).

The second category includes techniques requiring the introduction of a guidewire that is inserted through a needle or catheter and followed by dilation of the cricothyroid space. The needle or catheter placement can be preceded by an incision of the skin and of the CTM. An airway catheter is also introduced over the dilator threaded over the guidewire. These techniques allow insertion of an airway considerably larger than the initial needle or catheter, often of sufficient internal diameter (ID) to allow ventilation with conventional ventilation devices, suctioning, and spontaneous ventilation. These techniques may properly be classified as percutaneous dilational cricothyrotomy (PDC).

The third category is surgical cricothyrotomy, which involves the use of a scalpel and other surgical instruments to create an opening between the skin and the cricothyroid space. It is discussed in Chapter 31.

B. Tracheostomy and Percutaneous Dilational Tracheostomy

1. Open Tracheostomy

Surgical tracheostomy, as described by Chevalier Jackson,[10] is a surgical procedure that provides an airway through the cervical trachea. It remains the standard against which all other procedures with the same aim must be compared in terms of success and complications rates. Classically, the procedure is performed in the operating room under general or local anesthesia, as dictated by the clinical situation. An open tracheostomy may be performed at the bedside in the ICU or in the emergency room in urgent situations. After an initial skin incision, sharp dissection is carried out to the thyroid isthmus, which is divided. The cervical trachea is then incised and a tracheostomy tube inserted.

2. Percutaneous Tracheostomy

Percutaneous tracheostomy is performed by means of a skin puncture into the trachea that is subsequently dilated to form a stoma, rather than creating a stoma by surgical incision.[11] Although there are many techniques for performing a percutaneous tracheostomy, the initial part of the procedure always involves a puncture through the skin into the trachea, which is then enlarged by dilation or with forceps to spread the puncture to a size that allows placement of an appropriate tracheostomy tube. These techniques are typically used in patients with an

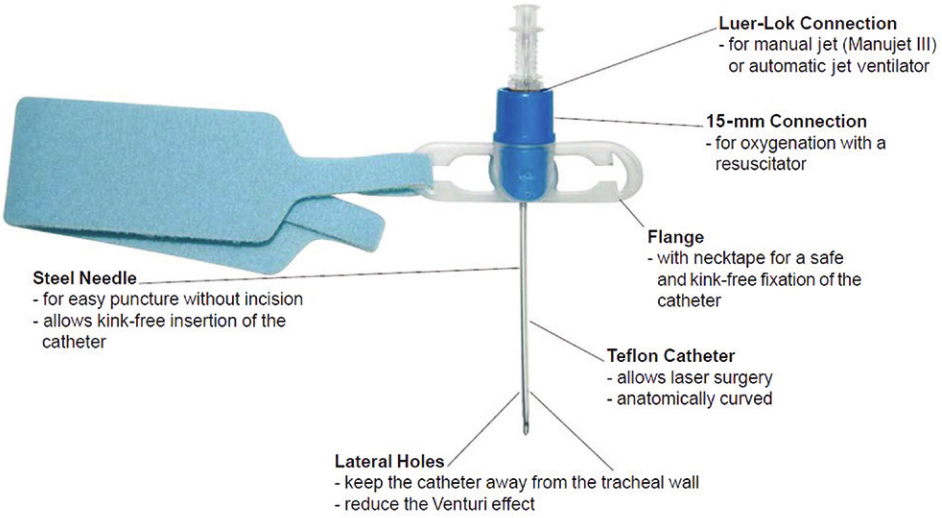

Figure 30-2 Ravussin cannula. (Courtesy of VBM Medical, Noblesville, IN.)

Figure 30-3 Arndt cannula for cricothyrotomy. (Courtesy of Cook Medical, Bloomington, IN.)

established airway (i.e., endotracheal tube [ETT] or laryngeal mask airway [LMA]) and are mostly used for intubated ICU patients.

Emergency situations were traditionally considered absolute contraindications to the use of this technique, but in the past few years, some reports have supported its safety and feasibility in selected emergent cases.[12,13] The Ciaglia technique, first described in 1985, is the original technique now described as percutaneous dilational tracheostomy (PDT). It involves making a very small skin incision, introducing a needle into the trachea, and dilating the opening with sequentially larger dilators to allow insertion of a tracheostomy tube of the selected size. As originally described, this procedure was performed blind, but it is increasingly performed under continuous endoscopic guidance.

Other modifications of the Ciaglia technique include the use of lower tracheal rings interspaces (originally performed in the interspace between the cricoid cartilage and the first tracheal ring) and the use of a single, curved dilator to replace the original multiple dilators. Of the percutaneous approaches described, the Ciaglia technique with continuous endoscopic visualization and use of a single dilator is considered by many to be the safest, and it is the most widely used in North America.

The Griggs guidewire dilating forceps technique involves placing a guidewire through an initial puncture site. The area is forcibly enlarged with the use of a dilating forceps (i.e., grooved Howard-Kelly forceps) to obtain a stoma of the desired size. One advantage of this technique is the reduced amount of compression on the airway by the forceps compared with other dilational methods. The procedure as originally described is performed blind and subject to complications such as false passage and subcutaneous emphysema. Concurrent endoscopic visualization reduces these risks, although bleeding may be a problem because of tearing of adjacent structures when inserting and opening the forceps.

The Fantoni technique is based on retrograde dilation of an initial tracheal puncture. During this procedure, a needle is inserted between the tracheal rings (i.e., first and second or second and third) and directed cranially. A guidewire is then passed through the needle and directed toward the oral cavity. Dilation is carried out by means of a conic cannula inserted over the guidewire through the oral cavity. Ventilation at this stage is maintained by means of a special, small ETT that allows passage of the conic cannula alongside the ETT. The tracheostomy tube is ultimately brought out in a retrograde fashion through the cervical trachea and skin. This technique is used primarily in Italy, where it originated, but it has found little applicability in North America, because it is lengthy to perform and involves potential loss of the airway due to the many airway manipulations necessary to perform the procedure and secure the cannula in its final position.

3. Percutaneous Dilational Cricothyrotomy and Tracheostomy in Airway Control

a. THE PROBLEM OF AIRWAY CONTROL

Adverse outcomes related to respiratory events account for one of the two largest classes of injury in the American Society of Anesthesiologists (ASA) Closed Claims Project. As reported by Caplan and colleagues and Cheney and associates, the two major categories of anesthesia-related events or mechanisms causing death or brain damage between 1975 and 2000 were respiratory and cardiovascular difficulties, which together made up 68% of damaging events.[14,15] Three mechanisms of injury were responsible for most of the adverse respiratory events: difficult ETT placement (23%), inadequate ventilation (22%), and esophageal intubation (13%).

In an analysis of claims against the National Health System in England between 1995 and 2007,[16] airway and respiratory claims accounted for 12% of anesthesia-related claims, 53% of deaths, 27% of cost, and 10 of the 50 most expensive claims in the dataset. These claims most frequently described events at induction of anesthesia, involved airway management with a tracheal tube, and typically led to hypoxia and the patient's death or brain injury.

In the operating room, in the ICU (or in other hospital areas), and in the prehospital setting, three difficult scenarios have been repeatedly observed during attempts to control the airway: (1) the airway can be easily controlled by mask ventilation, but endotracheal intubation is not possible; (2) the airway cannot be mask ventilated but can be intubated; and (3) rarely, the airway cannot be mask ventilated or intubated. It is every anesthesiologist's nightmare to encounter a true difficult airway as depicted in the third scenario.[17] Five to 35 of 10,000 patients (0.05% to 0.35%) reportedly cannot be endotracheally intubated, and approximately 0.01 to 2.0 of 10,000 patients are difficult to mask ventilate and intubate.[18,19]

ASA guidelines provide a difficult airway algorithm and suggest strategies for evaluating, preparing for, and intubating the difficult airway. They also consider the relative merits and feasibility of alternative management choices, such as nonsurgical versus surgical techniques for the initial approach to ventilation, awake intubation versus intubation after induction of general anesthesia, and preservation versus ablation of spontaneous ventilation. The algorithm describes emergency and nonemergency pathways for managing the airway if intubation fails. The ASA guidelines also suggest that equipment suitable for "emergency surgical airway access" be among the contents of a portable storage unit readily available

in the operating room. The algorithm suggests that emergency invasive airway procedures are "surgical or percutaneous tracheostomy or cricothyrotomy."

ASA guidelines offer a stepwise approach to the patient with a difficult airway, primarily focusing on difficulties encountered in the operating room, and offer strategies to anticipate and treat a difficult airway in this environment. However, the anesthesiologist is often called on to manage the airways of critically ill patients in other hospital environments, such as the emergency department, wards, diagnostic areas (e.g., radiology), or ICUs. In all settings, it is important that anesthesiologists are trained and prepared to recognize and manage situations in which cricothyrotomy or percutaneous tracheostomy, or both, are considered as preferred options.

b. ROLES OF THE ANESTHESIOLOGIST, OTOLARYNGOLOGIST, AND EMERGENCY MEDICINE PHYSICIAN

The anesthesiologist may be called immediately or after other physicians have attempted unsuccessfully to secure the airway or failed to recognize the futility of standard intubation techniques. In rare instances, the availability of a physician skilled in the technique of cricothyrotomy or percutaneous tracheostomy may be life-saving. This individual should be the anesthesiologist. Appropriate equipment for cricothyrotomy should be available throughout the hospital or as part of an emergency airway kit. No data exist regarding how frequently anesthesiologists are called to secure an airway outside the operating room, but in many hospitals, this responsibility seems to be handled more frequently by other physicians.[20-23]

Each institution should have a clear plan for alerting qualified individuals when emergency airway support is required in different areas of the hospital.[24] Many publications describe the use of various types of advanced airway equipment, report the availability of such devices, and explain the use of simulators to teach difficult airway management skills, and many articles identify the need to educate residents in advanced airway techniques.

Organizing resources and staff to manage a difficult airway and maintaining appropriate training are important for patient safety and clinical quality.[25,26] In 2000, Showan and Sestito proposed that the components of a successful airway management system include personnel, training, an emergency response system, an oversight process, standardized equipment, and patient education. As with any type of emergency, preparedness is the key when planning for response.[27-30]

In 1996, a comprehensive airway program was introduced at Johns Hopkins.[26] The core components of the comprehensive difficult airway program were communication and electronic medical record information (including airway documentation), equipment, personnel, and education. Investigators based their implementation on the causes that required a surgical airway and the inability of an anesthesiologist to intubate and ventilate. The causes were an inability to access the written medical record, resulting in a lack of preoperative information about the patient's airway; lack of immediate access to equipment and supplies necessary to manage a difficult airway; and lack of availability of trained personnel to help manage and secure the airway.

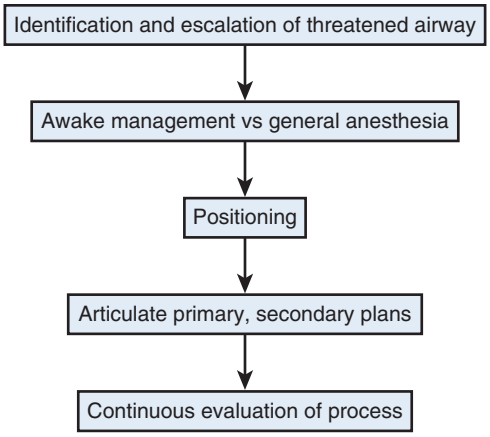

Figure 30-4 Progressive escalation sequence for a threatened airway.

Continuing medical education is essential to maintain skills in performing emergent cricothyrotomy, and standardized simulation alone may not be sufficient to warrant optimal training. Individual skills, availability of devices, and training in specific techniques may deviate from standard guidelines, making "at site, ad hoc" guidelines necessary.

A threatened airway protocol has been proposed for implementing an escalation-based model at The University of Texas Medical School at Houston.[31] The model is based on seven general principles to guide physicians in the identification and management of situations in which hospitalized patients may have rapid deterioration of a condition affecting the upper airway that requires immediate intervention to maintain or reestablish ventilation and oxygenation. These seven principles are concerned with appropriate communication among providers, maintenance of oxygenation, avoidance of sedation until the patient is in a safe environment, complete airway assessment, maintenance of spontaneous ventilation as long as possible, and avoidance of rapid-sequence induction (i.e., administration of a muscle relaxant without a prior attempt to ventilate), unless an easy airway and a full stomach are expected. Four main features constitute the cornerstones of management of a patient with a threatened airway: identification of the airway emergency and escalation of the approach to management, choice of appropriate sedation or anesthesia technique, positioning, and articulation of plans for intervention. A progressive algorithm (Fig. 30-4) that guides the progression of the necessary steps has been inspired by others' work.[31,32] The use of specific airway devices or tools is mandated in the primary and secondary plans by the success in securing the airway or depending on changes in airway viability (Fig. 30-5).

The otolaryngologist plays a critical role in airway management by contributing a skill set that is different from but complementary to that of the anesthesiologist. Circumstances may range from well-controlled elective situations to near-panic, last-ditch attempts to establish an airway when all else has failed.[33] The otolaryngologist possesses an excellent knowledge of the three-dimensional anatomy of the upper aerodigestive tract and the

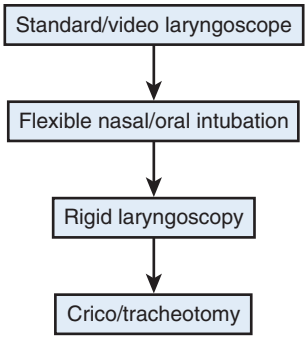

Figure 30-5 Airway approach algorithm for a threatened airway.

variations encountered in pathologic circumstances. This knowledge and expert endoscopy skills can assist the anesthesiologist in determining a difficult airway.

II. HISTORICAL PERSPECTIVE

Surgical manipulation of the trachea for emergent airway control is one of the oldest invasive procedures documented. It was performed in ancient Egypt and India more than 3000 years ago. Tracheostomy was mentioned in the writings and illustrations of the great Greek physician Galen (130 to 200 AD). He provided anatomic drawings of the airway and favored a vertical rather than horizontal incision in emergencies. He based his anatomic knowledge on dissections of animals and assumed that the structures were identical in the human body. Galen also stated that Asclepiades (124 to 56 BC), who practiced in Rome, recommended opening the trachea in its upper part to prevent suffocation. Antyllus (approximately 150 AD) described the indications for and technique of tracheostomy, advocating a transverse incision between two rings. Galenic teaching persisted for more than 1300 years, until Andreas Wesele Vesalius (1515 to 1564 AD) published *De Humani Corporis Fabrica*, detailing the first correct description of human anatomy. Vesalius secretly conducted extensive dissection of human cadavers and, at age 28, published his landmark work in seven volumes. Included was a detailed description of tracheostomy—control of the airway with the use of a cane or reed and assisted ventilation of the lung. He allegedly performed a tracheostomy and experimentally inflated the lungs of a dead Spanish nobleman, whose heart was reported to beat again. His action outraged the medical and clerical communities.

During the next 300 years, very few reports were published regarding the surgical control of the airway, and they were primarily limited to experimental control of breathing in laboratory animals. In *Respiratory Changes of Intrathoracic Pressure*, published in 1892, Samuel Meltzer described insertion of breathing tubes through a tracheostomy and successfully controlling ventilation in curarized animals. In France, Armand Trousseau recognized the importance of emergency tracheostomy in airways compromised by upper airway obstruction, diphtheria, and massive infection in the oropharynx and neck.

In 1909, Chevalier Jackson,[10] a laryngologist at the Jefferson Medical School in Philadelphia, described the technical details of surgical tracheostomy and standardized the procedure. Jackson's technique was for years considered the preferred method of surgical airway management. Jackson later published the results of 30 years' observation of his own tracheotomized patients and reported a very high incidence of laryngeal and subglottic stenosis in patients who underwent a procedure that he referred to as *high tracheostomy*, involving division of the cricoid or thyroid cartilage.[34] As a consequence, the high tracheostomy technique was abandoned for many decades.

In 1969, Toye and Weinstein described a technique for percutaneous tracheostomy based on the premise that a functional tracheal airway could be more rapidly and safely achieved percutaneously than with Jackson's method of surgical dissection.[35] The technique involved inserting a needle into the trachea and dilating the resultant needle tract to allow placement of a breathing catheter.

Cricothyrotomy, which differed from high tracheostomy because it involved opening of the CTM instead of dissection of the cricoid cartilage, was proposed again in 1976 by two Denver cardiothoracic surgeons, Brantigan and Grow. They published the results of 655 consecutive cricothyrotomies in which there were minimal complications and no reported incidence of subglottic stenosis. Subsequently, other clinical and experimental series have been reported, and cricothyrotomy has become generally accepted. The procedure was found to be faster, simpler, less invasive, and less likely to cause bleeding than tracheostomy. It is associated with lower morbidity and mortality rates than emergency tracheostomy, making it desirable as an emergency technique for gaining immediate airway control. Various modifications of the original technique have been developed. The use of the Seldinger technique for insertion, as described by Corke and Cranswick in 1988, enhances the safety of the procedure.[8]

Using a guidewire and passing a dilator to create a channel reduce the chance of incorrect placement and damage to surrounding blood vessels. Interest in cricothyrotomy as an alternative to endotracheal intubation is largely the result of the development of emergency medicine as a distinct specialty and the frequent treatment of patients with difficult airways in the prehospital and emergency department environments. Emergency physicians and prehospital providers often encounter patients with life-threatening injuries who cannot be intubated by conventional routes and who need immediate and definitive treatment. Most reports of the use of cricothyrotomy in emergent situations appear in the emergency medicine literature. For anesthesiologists, interest in PDT and PDC increased as part of a trend toward less invasive surgical procedures.

The Ciaglia technique, first described in 1985, is the original technique now described as PDT. In this technique, insertion of the guidewire is followed by serial dilations performed with multiple, progressively larger dilators.[36] The Rapitrach method, proposed in 1989 by Schachner and coworkers, entails the use of dilating forceps and a single-step dilating technique.[37]

In 1990, Griggs and colleagues presented the guidewire dilating forceps method, which was similar to the

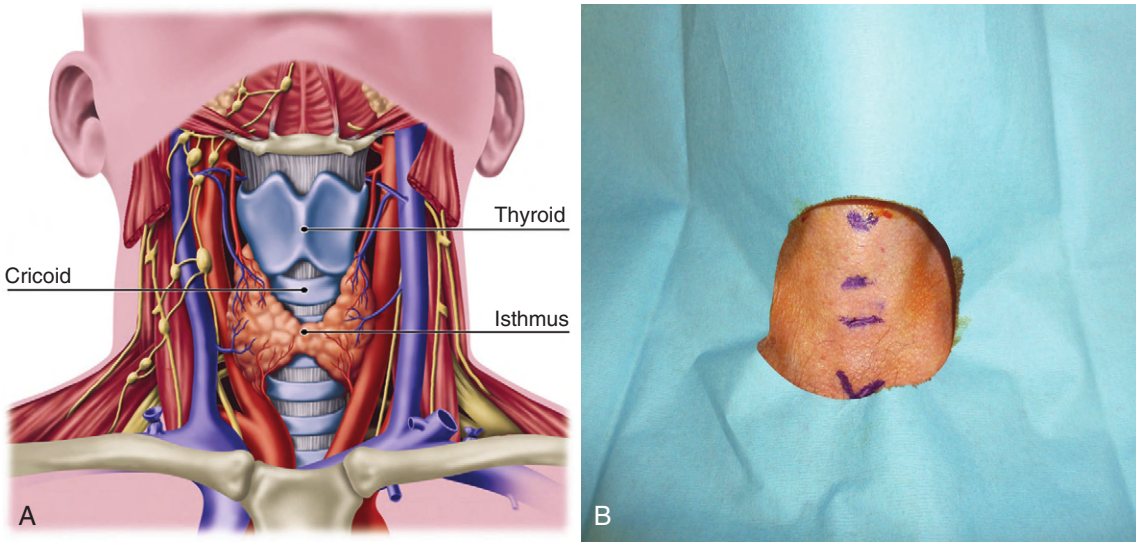

Figure 30-6 **A,** Dissection anatomy. **B,** External landmarks. (**A,** From De Leyn P, Bedert L, Delcroix M: Tracheotomy: Clinical review and guidelines. *Eur J Cardiothorac Surg* 32:412–421, 2007.)

Rapitrach method and based on a one-step dilating techinque[38] that used a modified forceps. In 1997, Fantoni proposed the translaryngeal tracheostomy technique based on retrograde dilation of an initial tracheal puncture by means of a conic cannula inserted through the oral cavity.[39]

The Ciaglia Blue Rhino, a modified version of the Ciaglia technique, was introduced by Cook Medical (Bloomington, IN) in 2000.[40] In this technique, the series of sequentially larger dilators of the original Ciaglia technique is replaced by a single, curved dilator with a hydrophilic coating, the Blue Rhino, that progressively dilates the stoma in one step.

In 2002, Frova and Quintel described the Percutwist tracheostomy technique. A "rotating dilation" is performed in a single step by means of a screwlike, rotating device.[41] In 2008, a further development of the Ciaglia technique was presented by Cook Medical: the Ciaglia Blue Dolphin balloon percutaneous tracheostomy introducer. This device combines balloon dilation and tracheal tube insertion into one step.

Many of the techniques proposed for PDC and PDT are performed over guidewires. Although anesthesiologists are familiar with the Seldinger technique for the insertion of vascular catheters, many are unacquainted with airway management techniques that use airway devices based on the same technology and concept.[27,42]

III. ANATOMY AND PHYSIOLOGY

Safe and rapid performance of cricothyrotomy requires a thorough knowledge of cricothyroid space anatomy (Fig. 30-6) and its relation to other structures in the neck.[1,6,43-47] The CTM ligament is 10 mm long and 22 mm wide and is composed mostly of yellow elastic tissue. It covers the cricothyroid space and is located in the anterior neck between the thyroid cartilage superiorly and the cricoid cartilage inferiorly. The cricothyroid space can be readily identified by palpating a slight dip or indentation in the skin immediately below the laryngeal prominence.

The CTM consists of a central anterior triangular portion (i.e., conus elasticus) and two lateral parts. The thicker and stronger conus elasticus narrows above and broadens below, connecting the thyroid to the cricoid cartilage. It lies subcutaneously in the midline and is often crossed horizontally in its upper third by the superior cricothyroid vessels. To minimize the possibility of bleeding, the CTM should be incised at its inferior-third portion. The two lateral parts are thinner, lie close to the laryngeal mucosa, and extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords. On either side, the CTM is bordered by the cricothyroid muscle. Lateral to the membrane are venous tributaries from the inferior thyroid and anterior jugular veins. Because the vocal cords usually lie 1 cm above the cricothyroid space, they are not commonly injured, even during emergency cricothyrotomy.[48] The anterior jugular veins run vertically in the lateral aspect of the neck and are rarely injured, but tributaries may occasionally course over the cricothyroid space and be damaged during the procedure. Characteristically, the CTM does not calcify with age and lies immediately underneath the skin.

Variations in the anatomy and dimensions of the CTM are common. The anterior cricothyroid space is trapezoidal and has a cross-sectional area of approximately 2.9 cm^2. The mean distance between the anterior borders of the inferior thyroid cartilage and the superior cricoid cartilage is 9 mm (range, 5 to 12 mm), whereas the width of the anterior cricothyroid space ranges from 27 to 32 mm. The cricothyroid space is not much larger than 7 mm in its vertical dimension, and that space may be narrowed further by contraction of the cricothyroid muscle. The vertical distance between the undersurface of the true vocal cords and the lower anterior edge of the thyroid cartilage is between 5 and 11 mm. The vertical height of the CTM from the superior border of the cricoid cartilage to the inferior border of the thyroid cartilage in the midline varies from 8 to 19 mm (mean, 13.69 mm), a somewhat greater distance that can

probably be explained by the fresh rather than fixed state of specimens.

The arterial and venous vessel patterns in the neck area surrounding the CTM vary considerably. Although the arteries always lie deep to the pretracheal fascia and are easily avoided during a skin incision, veins may be found in the pretracheal fascia and between the pretracheal and superficial cervical fascia. Vascular structures may cross vertically and anterior to the CTM, predisposing them to damage during cricothyrotomy. A small cricothyroid artery, which is a branch of the superior thyroid artery, commonly crosses the upper portion of the CTM, anastomosing with the artery on the other side. External visible and palpable anatomic landmarks are used to locate the CTM. The laryngeal prominence (i.e., thyroid cartilage or Adam's apple) and the hyoid bone above it are readily palpable. The CTM usually lies one to one and a half finger breadths below the laryngeal prominence. The cricoid cartilage is usually felt below the CTM. The importance of these landmarks is emphasized because it is disastrous to place the cricothyroid tube into the thyrohyoid space instead of the cricothyroid space.

Conscious effort to identify these landmarks reduces the possibility of committing this preventable error (see Fig. 30-6B). When the normal anatomy is distorted, identification of these landmarks is difficult. In these cases, the suprasternal notch may be used as an alternative marker. The small finger of the right hand should be placed in the patient's suprasternal notch, followed by placement of the ring, long, and index fingers adjacent to each other in a stepwise fashion up the neck, with each finger touching the one below it. When the head is in the neutral position, the index finger is usually on or near the CTM.

IV. INDICATIONS AND CONTRAINDICATIONS FOR PERCUTANEOUS DILATIONAL CRICOTHYROTOMY AND TRACHEOSTOMY

A. Cricothyrotomy

Cricothyrotomy is considered by many to be the standard approach to airway management when orotracheal or nasotracheal intubation and fiberoptic approaches have failed.[5,18,49] In the emergency room or prehospital setting,[50,51] cricothyrotomy is indicated for immediate airway control in patients with maxillofacial, cervical spine, head, neck, and multiple trauma and in patients in whom endotracheal intubation is impossible to perform or contraindicated. It is also used for the immediate relief of upper airway obstruction. In the operating room and in the ICU, the technique is indicated when conventional methods of intubation fail, such as in patients with traumatic facial injuries in whom other techniques of airway access are difficult or impossible to perform. Cricothyrotomy can also be used as an alternative to tracheostomy in patients with recent sternotomy who need airway access because the incision does not communicate with the mediastinal tissue planes. A needle-size cricothyrotomy with a Luer-Lok connection (for jet ventilation) or an anesthesia circuit–size connection is used for thoracic and other procedures involving the airways, especially the trachea, larynx, epiglottis, and base of the tongue.

Emergency cricothyrotomy has largely replaced emergency tracheostomy in the emergency department because of its simplicity, rapidity, and minimal morbidity, and percutaneous techniques are replacing surgical approaches.[52,53] Use of emergency tracheostomy is limited and indicated only when laryngeal trauma may be accompanied by local edema, hemorrhage, subcutaneous emphysema, and damage to the thyroid or cricothyroid cartilage, precluding the performance of cricothyrotomy.

Cricothyrotomy is difficult to perform in pediatric patients because the larynx is smaller and their airways contain less fibrous supporting tissue and have only loose mucous membrane attachments in the airway inlet. Absolute and relative contraindications to cricothyrotomy are rare. Patients who have been intubated translaryngeally for more than 3 days (7 days according to many investigators) should not undergo cricothyrotomy because of the propensity to develop subglottic stenosis. Those with preexisting laryngeal diseases, such as cancer, acute or chronic inflammation, or epiglottitis, have a higher morbidity rate when cricothyrotomy is performed. Distortion of the normal neck anatomy by disease or injury may render the technique impossible. Normal anatomic landmarks may be distorted, making identification of the CTM difficult. Bleeding diathesis and a history of coagulopathy predispose the patient to hemorrhage, making the procedure extremely dangerous.

Cricothyrotomy is technically problematic to perform in the pediatric population and should be performed with extreme caution in children younger than 10 years. It should not be performed at all in children younger than 6 years unless a wire can be placed in the cricothyroid space and placement within the trachea can be verified.[54] Emergency tracheostomy under controlled conditions is the preferred choice.[55] Physicians who are unfamiliar or inexperienced with the technique are discouraged from performing the procedure without adequate supervision from a more senior or knowledgeable member of the medical team. Inexperience has been implicated as the most important factor contributing to cricothyroid complications.[56-58] Accuracy in identifying anatomic landmarks significantly depends on the physician's experience but is poor overall, justifying the percutaneous technique in emergency conditions but supporting the use of ultrasound or video-enhanced visualization during elective procedures.

B. Percutaneous Dilational Tracheostomy

PDT is mainly indicated in adult intubated patients (Box 30-1). In this patient population, the main indications for performing a PDT are the same as those for surgical tracheostomy:

- Preventing upper airway damage due to prolonged intubation
- Facilitating pulmonary toilet

Box 30-1 Indications and Contraindications to Percutaneous Tracheostomy in Intubated Adults in the Intensive Care Unit

Indications

Prevention of upper airway damage due to prolonged intubation
Facilitating pulmonary toilet
Providing a stable airway in patients requiring long-term mechanical ventilation and oxygen support

Contraindications

Inability to palpate cricoid
Midline neck mass or large thyroid gland
High innominate artery
Uncorrected coagulopathy (relative contraindication)
Unprotected airway (rare exceptions in acute setting)
Children
Positive end-expiratory pressure ≥15 cm H_2O

Controversies

Use for emergent airway access in trauma or acute obstruction
Use in obese patients

- Providing a stable airway in patients requiring long-term mechanical ventilation and oxygen support

Several benefits of performing a tracheostomy in patients who require prolonged ventilation have been postulated and are supported by different levels of evidence.[59] Shorter ICU and hospital stays and less need for sedation are the most widely recognized benefits, whereas improved patient comfort, decreased work of breathing, improved oral hygiene, better long-term laryngeal function, faster weaning from mechanical ventilation, lower risk of ventilator-associated pneumonia, and lower mortality rates have also been reported but are supported by a lower level of evidence.[59]

For the population of critically ill adult patients, PDT has been recommended as the procedure of choice for performing elective tracheostomy.[59,60] PDT is recommended on the basis of a lower risk of wound infection, being able to perform it at the bedside rather than transferring critically ill patients to the operating room, and better cost-effectiveness compared with surgical tracheostomy.[60]

Upper airway obstruction due to tumor, edema, infection, stenosis, or trauma represents the other major category of indications for tracheostomy. However, the overall safety of performing PDT in emergent situations and with unprotected airways is extremely controversial, and, in these conditions, the procedure should be reserved for selected patients and performed only by experienced providers.[13] Anatomic suitability for this procedure must be determined preoperatively with the patient's neck extended. Maximum neck extension increases the length of the cervical trachea and defines critical anatomic landmarks, such as the cricoid cartilage and sternal notch. A contraindication to the procedure is the inability to palpate the cricoid cartilage above the sternal notch. Similarly, the patient with a midline neck mass, high innominate artery, or large thyroid gland should undergo open surgical tracheostomy in the operating room. Coagulopathies should be corrected preoperatively. Ideally, the functional platelet count should be 50,000 or greater, and the international normalized ratio (INR) should be corrected to 1.5 or less. However, there have been reports of PDT safely performed in patients with severe thrombocytopenia.[61]

Patients requiring a positive end-expiratory pressure (PEEP) of 15 cm H_2O or higher are at high risk for complications such as subcutaneous emphysema and pneumothorax, and when possible, the procedure should be postponed for these patients. PDT is relatively contraindicated in nonintubated patients with acute airway compromise and in the pediatric population. For airway compromise in nonintubated patients, the risks are related to the length of the procedure and the inability to perform the procedure under direct endoscopic visualization without an ETT. Reasons to avoid PDT in children include the different airway anatomy and dimensions and the technical difficulties of maintaining adequate ventilation with a bronchoscope within a small ETT. Selected cases may present an exception to these contraindications, depending on the experience of the providers.[13]

V. PERCUTANEOUS DILATIONAL CRICOTHYROTOMY

A. Principles and Planning

This chapter focuses on percutaneous dilational techniques. Surgical cricothyrotomy and transtracheal catheter ventilation are discussed elsewhere in Chapter 31.

PDC is fast and usually easy to perform, even on patients with short necks or with spinal injury. Cricothyrotomy may be performed for elective airway management in trauma patients with technically challenging neck anatomy in lieu of tracheostomy, because it does not require a surgeon's skill to gain airway access and has fewer operative and postoperative complications.[62-65] Several commercially available devices use this technology. These devices have in common the insertion of an airway catheter over a dilator, which is usually introduced over a guidewire. The guidewire is inserted through a needle or over-the-needle catheter (i.e., Seldinger technique) after making an initial skin incision. This technique, often used for the insertion of catheter introducer sheaths and central lines, is familiar to anesthesiologists. An airway over a dilator and guidewire is preferable because of the inherent safety of this technique and the ability to insert an airway of far greater diameter than the initial catheter.

The Nu-Trake device (Smiths Medical, Dublin, OH) introduces a housing that is similar to a dilator but made in two parts, with the needle loaded coaxially within it. After the needle is withdrawn, metal airways with obturators are serially introduced inside the housing until the desired diameter of tube is reached.

Several devices allow insertion of the dilator directly over a needle or directly into the skin incision. Although they lack the step of introducing a guidewire, they are included in this discussion because they require a skin

incision and a dilator for insertion of the airway. PDC is gaining popularity in the emergency room, ICU, and operating room. It is similar to another popular ICU technique, PDT, which is an elective procedure.

Airways can be introduced rapidly by the Seldinger over-the-wire technique, which allows positive-pressure ventilation without modification of standard ventilation devices. Although the technique requires more time to perform than needle cricothyrotomy, it may be more effective in providing adequate ventilation and oxygenation.

Several cricothyrotomy sets (Melker Emergency Cricothyrotomy Catheter Set, Cook Critical Care, Bloomington, IN; Portex Mini-Trach II, Smiths Medical, Keene, NH; Pertrach, Pulmodyne, Inc., Indianapolis, IN) can be inserted by the PDC technique. The Melker device uses a skin incision, followed by insertion of a guidewire and insertion of a dilator and airway catheter (i.e., cricothyrotomy tube). The Melker set is available in 3.5-, 4.0-, and 6.0-mm-ID, uncuffed airway catheter sizes with lengths of 3.8, 4.2, and 7.5 cm, respectively. The Melker set also comes in a military version that is modified for direct insertion through an incision without the use of a guidewire (similarly, the Portex cricothyroidotomy kit [PCK] and Nu-Trake from Smiths Medical and the Quicktrach I and II from VBM are designed for single insertion without a guidewire). The 4.0-mm-ID airway catheter is 7.5 cm long. This allows use of a smaller-diameter tube of sufficient length for an adult neck. The military version is available with cuffed and uncuffed airway catheters. A cuffed, 5.0-mm-ID, 9-cm-long airway catheter also has been introduced into the market. These sets are available with adapters so that jet ventilators and conventional ventilators can be attached to the airway device. Pertrachs are available with 5.5- and 7.1-mm-ID cannulas.

The over-the-wire technique offers several advantages. Even if the over-the-needle or direct dilational technique, such as the Quicktrach, PCK, or the Melker military version, may be faster to perform, the reported difficulties and complications are greater. This is also true for the Nu-Trake device. Complications have included failure to gain airway access, multiple attempts at cannulation, mediastinal injury, pneumothorax, and severe bleeding. The wire-guided technique has the disadvantage of the wire kinking. Several clinical and cadaver-based studies have established the safety and efficacy of the percutaneous over-the-needle or -cannula, wire-guided technique.[42,66-71] For some of the devices, their use, diffusion, and success seem to have been influenced by local availability, original country of manufacturing, preliminary animal studies, and marketing, despite scarce clinical evidence of efficacy.

B. Insertion Techniques

1. Percutaneous Dilational Cricothyrotomy Device

The PDC device manufactured by Melker contains a scalpel blade; a syringe with an 18-G over-the-needle catheter or a thin-walled introducer needle, or both; a guidewire; a dilator of appropriate length and diameter; and a polyvinyl airway catheter with or without a cuff (Fig. 30-7). A universal kit combines open cricothyrotomy and percutaneous tools in a single tray. (Although it defeats the concept of a percutaneous approach, it may be useful in remote or austere locations.) Detailed insertion instructions for this type of device are available from the manufacturer's Website, brochure, and CD. A description of the Melker insertion technique (Fig. 30-8) follows:

1. Position the patient supine, and if there is no contraindication, slightly extend the neck by using a roll under the neck or shoulders. If cervical spine injury is suspected, properly immobilize the head and neck, and maintain a neutral position.
2. Open the prepackaged cricothyrotomy set, and assemble the components. Whenever possible and appropriate, use aseptic technique and local anesthetic.
3. Identify the CTM between the cricoid and thyroid cartilages.
4. Carefully palpate the CTM, and while stabilizing the cartilage, make a vertical or horizontal skin incision using the scalpel blade (can also be performed after the Seldinger technique). Make a stab incision (vertical or horizontal) through the lower third of the CTM. An adequate incision eases introduction of the dilator and airway, but the incision can follow the placement of the guidewire.
5. Attach the supplied syringe to the 18-G introducer needle–plastic catheter (over the needle technique) system (same that you would use to place an angio-catheter), or alternatively attach the syringe to the introducer needle only (having removed the plastic catheter) if you prefer or are concerned the plastic catheter may kink. Insert the syringe-needle-catheter or syringe-needle only, and advance it through the incision into the airway at a 45-degree angle to the frontal plane in the midline in a caudad direction. When advancing the needle forward, entrance into the airway can be confirmed by aspiration with the syringe resulting in free air return or air bubbles in a saline-filled syringe.
6. Remove the syringe and needle, leaving the plastic catheter or introducer needle in place. Do not attempt to advance the plastic catheter completely into the airway, which may result in kinking of the catheter and an inability to pass the guidewire. Advance the soft, flexible end of the guidewire through the catheter or needle and several centimeters into the airway.
7. Remove the plastic catheter or needle, leaving the guidewire in place.
8. Advance the handled dilator inside the airway catheter (single dilation if a preincision was made), tapered end first, into the connector end of the airway catheter until the handle stops against the connector. With other sets, insert the dilator to the recommended depth, or insert the dilator over the guidewire for a preinsertion dilation (recommended if a preincision was not made). Use of lubrication on the surface of the dilator may enhance the fit and placement of the emergency airway catheter.

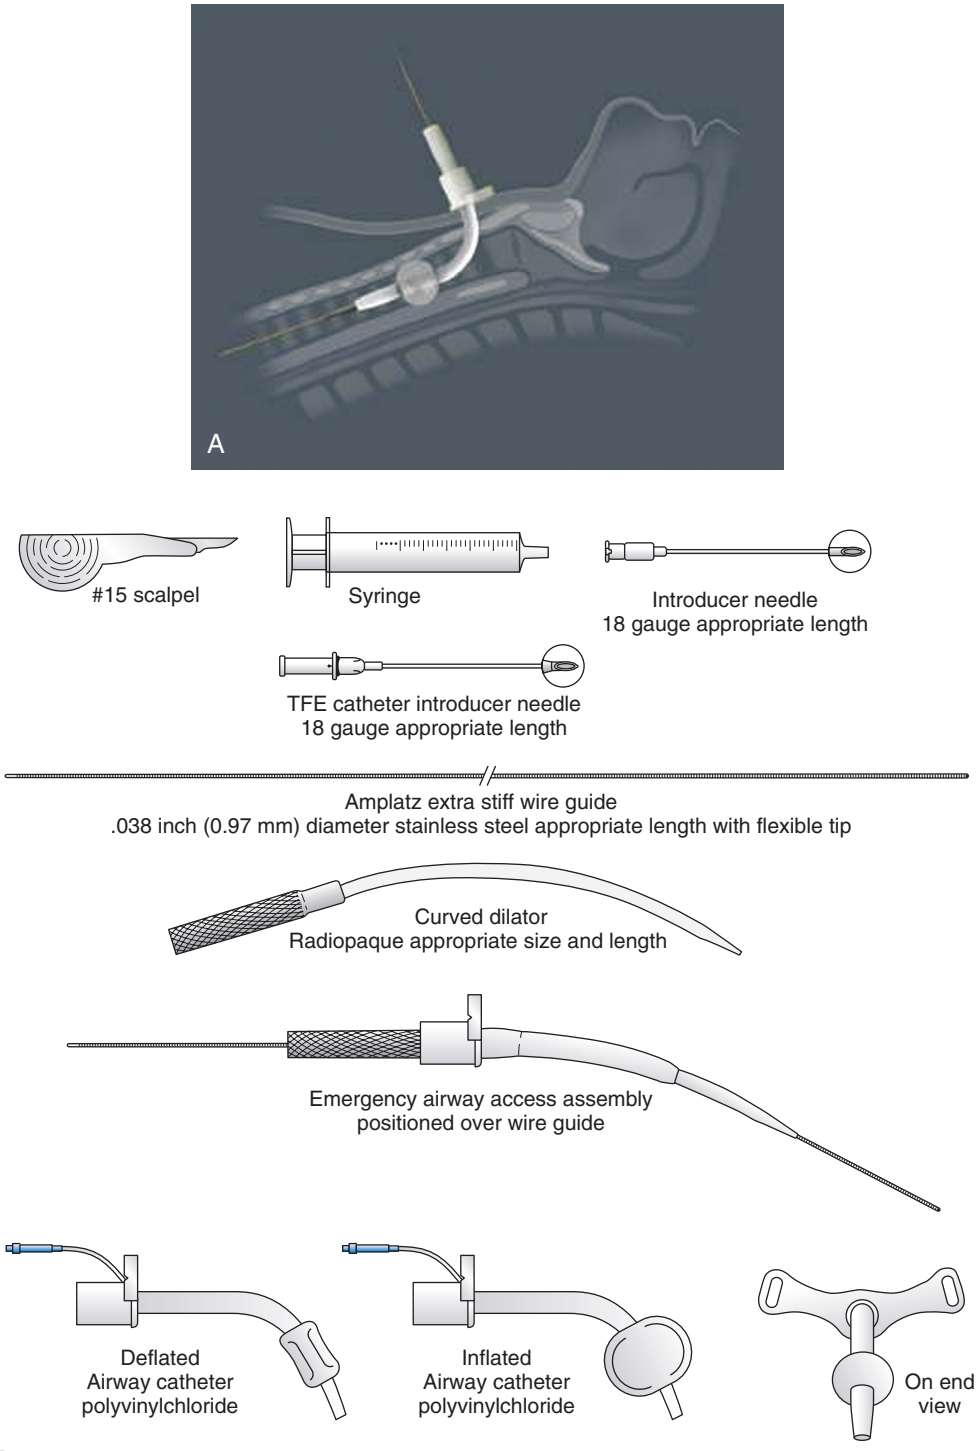

Figure 30-7 **A,** Melker cuffed cannula inserted in a model. **B,** Melker cricothyrotomy kit, which consists of the items shown and a tracheostomy cloth tape strip for fixation of an airway catheter. (Courtesy of Cook Medical, Bloomington, IN.)

9. Advance the emergency airway access assembly over the guidewire until the proximal stiff end of the guidewire is completely through and visible at the handle end of the dilator. Always visualize the proximal end of the guidewire during the airway insertion procedure to prevent its inadvertent loss into the trachea. Maintaining the guidewire position, advance the emergency airway access assembly over the guidewire with an in-and-out motion.
10. As the airway catheter is fully advanced into the trachea, remove the guidewire and dilator simultaneously.
11. If a cuffed tube is inserted, inflate it with 10 mL of air with the syringe provided.
12. Fix the emergency airway catheter in place with the cloth tracheostomy tape strip in a standard fashion.
13. Using its standard 15- to 22-mm adapter, connect the emergency airway catheter to an appropriate ventilatory device.

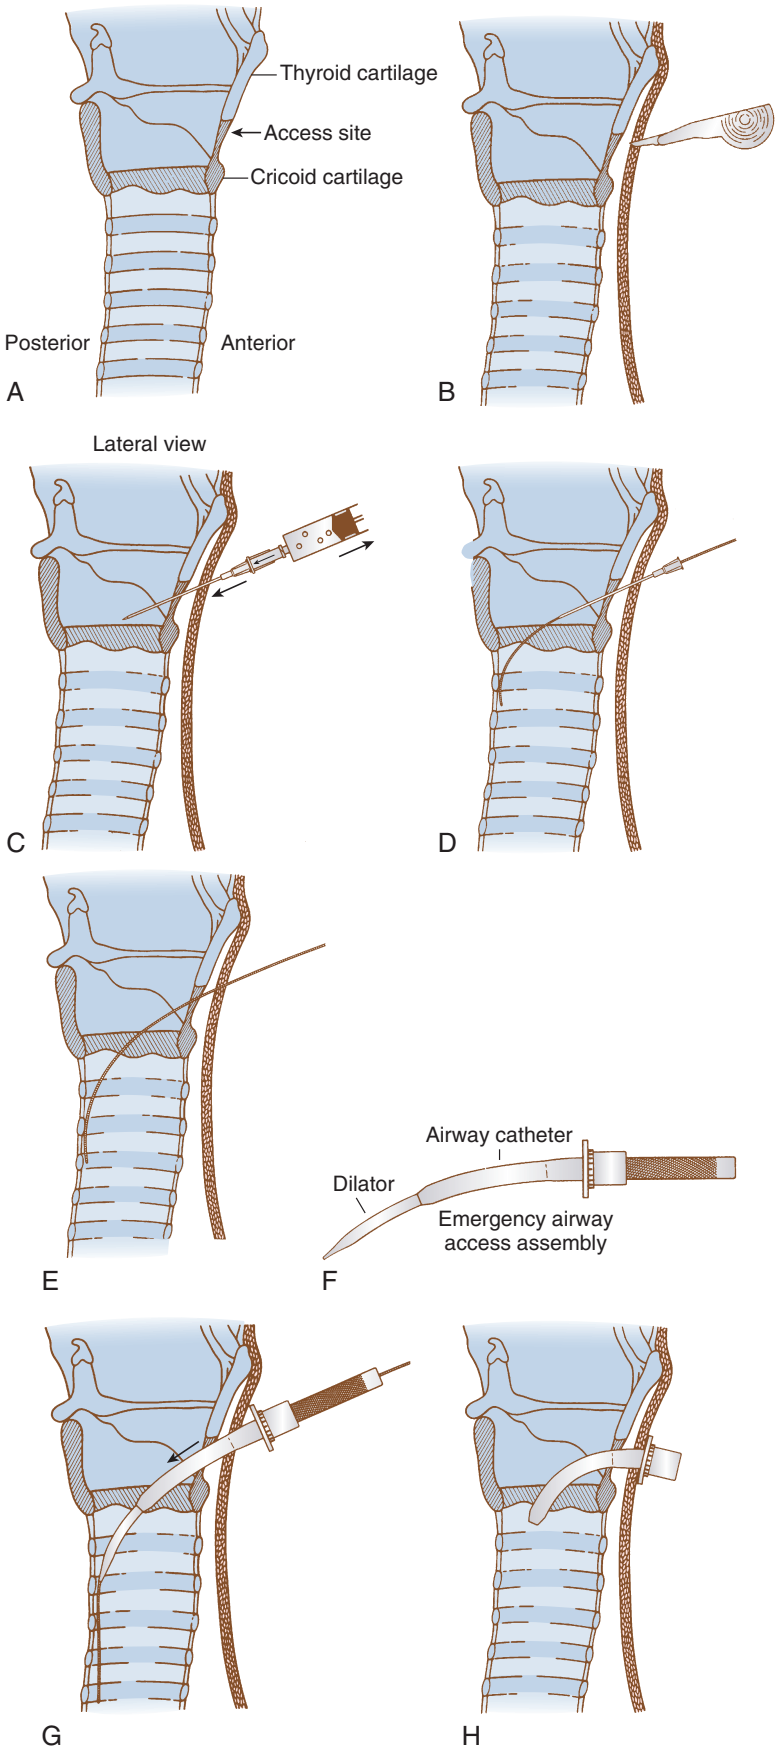

Figure 30-8 **A** to **H,** Melker insertion technique. (From Melker emergency cricothyrotomy sets: Suggested instructions for placement, instruction pamphlet. Cook Critical Care, Bloomington, IN, 1988.)

2. Skin Incision Before Needle Insertion

Few authors recommend an incision before introducing the catheter for two reasons. First, the catheter is more likely to kink when the needle is removed, making it difficult to pass the guidewire. Second, there have been reports of an inability to advance the dilator because the skin incision was not next to the guidewire. Extending the incision to the guidewire solved the problem. Anesthesiologists and critical care physicians usually make a skin incision after wire introduction. In that case, a firm incision next to the wire, which is carefully done to avoid cutting the wire, into the CTM is recommended. Predilation, which is done with the dilator only before inserting in the airway cannula, can help with placement, reducing the likelihood of the cannula grasping tissue (i.e., gap between the airway cannula and dilator).

3. Vertical Versus Horizontal Incision

It is unclear whether a horizontal or vertical skin incision is superior. The literature is evenly divided on this matter but usually refers to surgical cricothyrotomy. It can be argued that a vertical incision is better during emergency cricothyrotomy because it can be extended superiorly or inferiorly if the relationship of the skin and CTM changes (as frequently happens). A vertical stab through the CTM in the inferior third is recommended to ease placement of the dilator and avoid the cricothyroid arteries, which often anastomose in the midline superiorly.

4. Over-the-Needle Catheter Versus Introducer Needle

The guidewire through a needle tends to be superior when a skin incision is not used, but it has a similar success rate to that for an over-the-needle catheter if an incision is used initially. It appears that catheters kinked only when attempts were made to pass the total length of the catheter into the airway.

5. Percutaneous Dilational Cricothyrotomy

a. ARNDT

The Arndt cricothyrotomy cannula (Cook Medical) is technically a percutaneous dilational wire-guided cannula designed for transtracheal jet ventilation (Fig. 30-9; see Fig. 30-3).

b. PERTRACH

The Pertrach (Fig. 30-10) is similar to the previously described devices, except that the guidewire and dilator are a single unit. The introducer needle must be split after the distal end of the guidewire is advanced so that the dilator can be introduced (Fig. 30-11). This is cumbersome, especially in emergency situations, and requires the guidewire and dilator to be advanced far down the airway. A study in cadavers showed equal success for PDC with the Pertrach and surgical cricothyrotomy. Surgical cricothyrotomy was faster, but it was impossible to predict whether bleeding complications would have been higher with the surgical cricothyrotomies. The manufacturer and the users have reported problems with the needle, which is occasionally difficult or impossible to split.

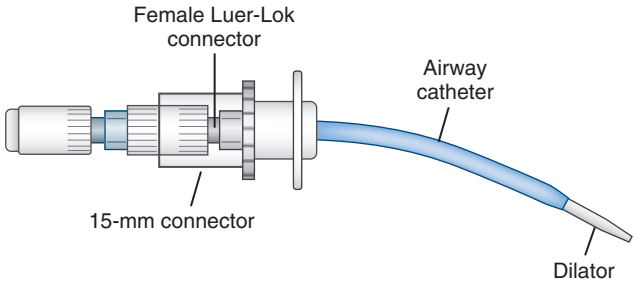

Figure 30-9 Arndt cricothyrotomy cannula components. (Courtesy of Cook Medical, Bloomington, IN.)

c. NU-TRAKE

The Nu-Trake device has a rigid airway and may be difficult to secure. The Nu-Trake requires far greater insertion forces than other devices, often resulting in the introducer-stylet embedding in the posterior wall of the trachea. The device has had frequent air leaks, and the lumen has a tendency to occlude on the posterior wall of the trachea. Subcutaneous emphysema, cricoid cartilage injury, cricotracheal ligament perforation, posterior wall perforation, and incidental submucosal airway hemorrhage have also been described.

d. QUICKTRACH AND PORTEX CRICOTHYROIDOTOMY KIT

The Quicktrach (Rüsch, VBM) (Fig. 30-12) and PCK (Portex) (Fig. 30-13) offer a single-step technique that is preceded by a skin incision, proceeds over a needle, and is not guided by a wire. The devices are technically faster to use but overall are less safe, carrying a higher complication rate (e.g., multiple attempts, inability to advance the cannula, false pas sage) than the Seldinger technique. The PCK (Fig. 30-14) has a Veress needle system, which is designed to detect pressure on the posterior wall of the

Figure 30-10 Pertrach cannula.

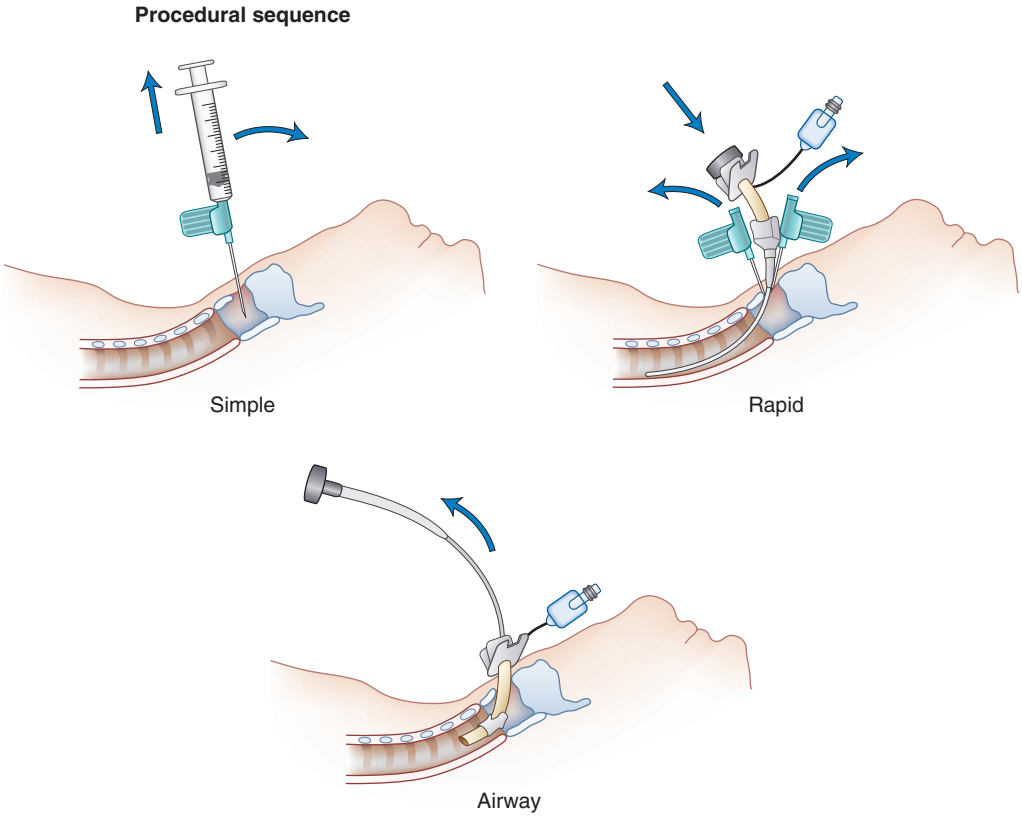

Figure 30-11 Pertrach technique steps.

trachea. The PCK is inserted directly through the CTM after a skin incision (Fig. 30-15).

The fast access that these systems provide can be life-saving in remote locations and in treating a severely damaged airway, outweighing the potential complications. However, their use in less emergent situations may be questionable, especially by first-time users.

VI. PERCUTANEOUS DILATIONAL TRACHEOSTOMY

A. Principles and Planning

PDT is an accepted alternative to surgical tracheostomy, and it is gaining in popularity, particularly for patients in the ICU who have been intubated or are expected to

Figure 30-12 Quicktrach I standard set. (Courtesy of Teleflex Medical, Research Triangle Park, NC.)

Figure 30-13 Quicktrach II cricothyrotomy set. (Courtesy of VBM Medical, Noblesville, IN.)

Figure 30-14 Portex cricothyroidotomy kit. (Courtesy of Smiths Medical, Dublin, OH.)

need endotracheal intubation for extended periods.[59,72-76] PDT is a mostly elective procedure, although there have been reports of PDT safely performed in selected emergent situations.[13] Cricothyrotomy is a preferred route for emergent airway access.

As with any procedure, proper planning begins with a history and physical examination, and palpation of critical landmarks, such as the cricoid cartilage and sternal notch, is mandatory. The neck must be inspected to exclude a high innominate artery or midline neck mass. Preoperative testing is minimal and includes a recent chest radiograph and serum determinations of hemoglobin, prothrombin time (PT), partial thromboplastin time, and platelets. The INR, which is calculated to reflect the PT, best reflects coagulation status. Although 1 is a normal value, an INR corrected to less than 1.5 is acceptable. Because bleeding is usually minimal, crossmatching of blood cell units is unnecessary, even in the presence of a low hemoglobin level.

A fully equipped difficult airway cart should be available nearby in the event of accidental extubation during the procedure. In patients with thick, large necks, consideration should be given to placement of an extra-long tracheostomy tube to prevent accidental decannulation or displacement into the pretracheal soft tissues. Ideally, four people are required for the procedure, including the operating physician, a resident or critical care colleague to perform the bronchoscopy, a respiratory technician or other qualified staff member to assist in adjusting ventilator settings and to hold the ETT firmly in position, and a nurse to administer medications, monitor vital signs, and assist in obtaining necessary materials and instruments. The surgeon and necessary instruments usually are positioned to the patient's right, the respiratory technician to the left, and the bronchoscopist at the head of the bed.

Many kits are commercially available for this procedure. The most widely used are those based on the original Ciaglia technique (Fig. 30-16A) and subsequent modifications that led to the single-dilator kits. Included in this category is the Ciaglia Blue Rhino G2 Advanced Percutaneous Tracheostomy Kit (Cook Medical), the Portex ULTRAperc Single-Stage Dilator (Smith Medical), and the Ciaglia Blue Dolphin balloon percutaneous tracheostomy kit (Cook Medical).

The Portex Griggs Percutaneous Dilation Tracheostomy Kit (Smiths Medical), based on the Griggs guidewire dilating forceps technique, is widely used. Detailed insertion instructions for these types of devices are available from the manufacturers' Web sites, brochures, and CDs. The following paragraphs offer a brief description of the general principles of appropriate planning for these procedures and detailed instructions on how to perform PDT with the single-dilator technique.

The instruments should be placed on a stand over the patient's bed in the order in which they will be used. An appropriately sized bronchoscope with a suction port must be chosen to fit within the ETT or nasotracheal tube while allowing adequate ventilation. A pediatric bronchoscope must be used when the ETT has an ID of less than 7.0 mm. A video monitor, if available, may be connected to the bronchoscope, allowing full visualization of the intratracheal portion of the procedure by the operating surgeon and staff. Any procedure involving manipulation of the trachea is highly stimulating to the patient and requires adequate local anesthesia supplemented by intravenous sedation. Local anesthesia, consisting of 1% or 2% lidocaine with a 1:100,000 solution of epinephrine, is used for generous infiltration of the incision site down to the level of the trachea. Topical anesthesia in the form of 2% to 4% lidocaine may be injected through the bronchoscope and is useful in decreasing the cough reflex during intratracheal instrumentation. Intravenous anesthesia is required, and the particular drug combination depends on the patient and the institution. Frequently used medications include midazolam, fentanyl, remifentanil, propofol, and dexmedetomidine. The presence of an anesthesiologist is recommended, but this depends on the hospital setting and availability. Care should be exercised in managing the ETT, performing the bronchoscopy, and administering drugs, particularly in elderly patients, because large fluctuations in blood pressure and heart rate may occur even with small doses. Muscle relaxation is recommended to facilitate procedures.

B. Insertion Techniques

1. Seldinger Guidewire and Single-Dilator Kit

1. The patient is positioned as for conventional tracheostomy with the head extended on the neck, and anatomic landmarks are marked (see Fig. 30-6, *B*). A standard preparation and drape are applied.
2. The skin and subcutaneous tissues are infiltrated with 2% lidocaine and a 1:100,000 solution of epinephrine one or two finger breadths below the previously palpated and marked cricoid cartilage (Fig. 30-17, *A*).
3. A 1.5-cm horizontal skin incision is made, and the subcutaneous tissues are bluntly separated with a curved hemostat. No attempt is made to manipulate the strap muscles or thyroid gland.
4. At this point, the fiberoptic bronchoscope (FOB) is advanced until its tip is aligned with the lower margin of the ETT (advance in a supraglottic device until the cricoid is visualized). External

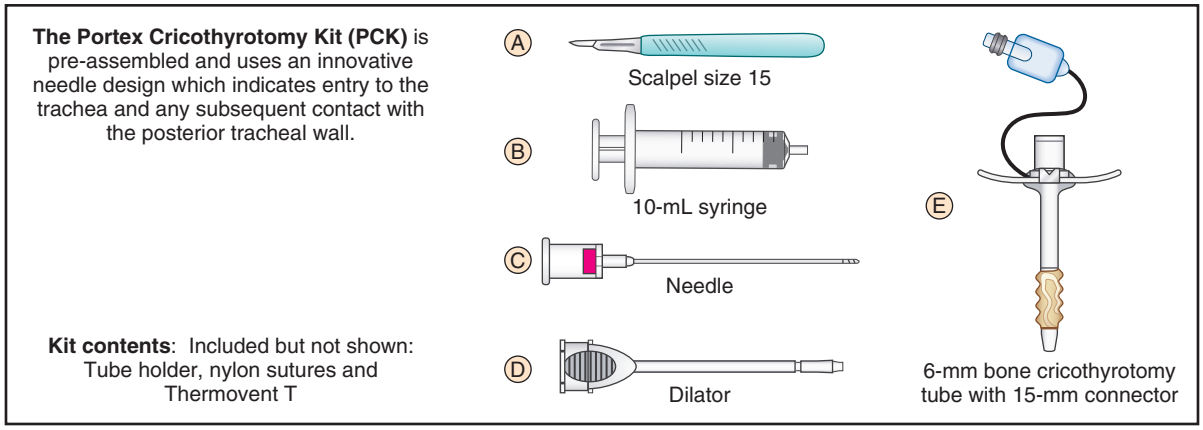

Figure 30-15 Portex cricothyroidotomy kit *(PCK)* insertion technique. (Modified from Smiths Medical, Dublin, OH.)

manipulation and transtracheal illumination can facilitate structure recognition.

5. Any ties securing the ETT are loosened, and the FOB and ETT are withdrawn slowly in unison until the incision is maximally transilluminated.
6. The FOB, which may be connected to a monitor, is maintained in this position throughout the procedure, allowing direct visualization of every step.
7. The 16- or 17-gauge introducer needle is inserted between the first and second or second and third tracheal rings (see Fig. 30-17, *B*).
8. A midline intercartilaginous placement is verified bronchoscopically.

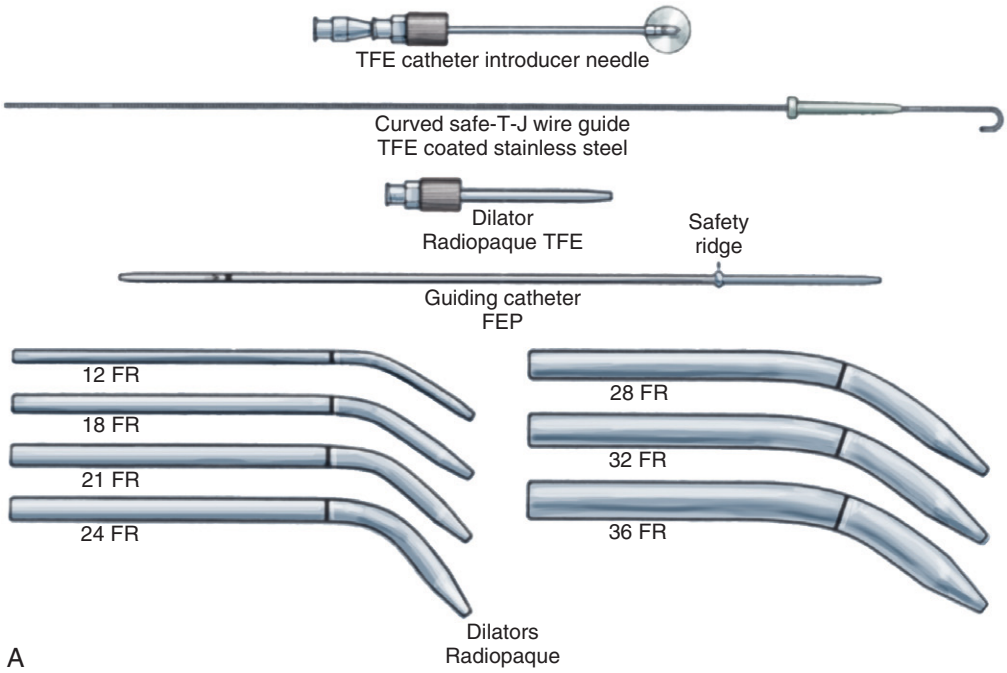

Figure 30-16 **A,** Ciaglia kit. (Courtesy of Cook Critical Care, Bloomington, IN.)

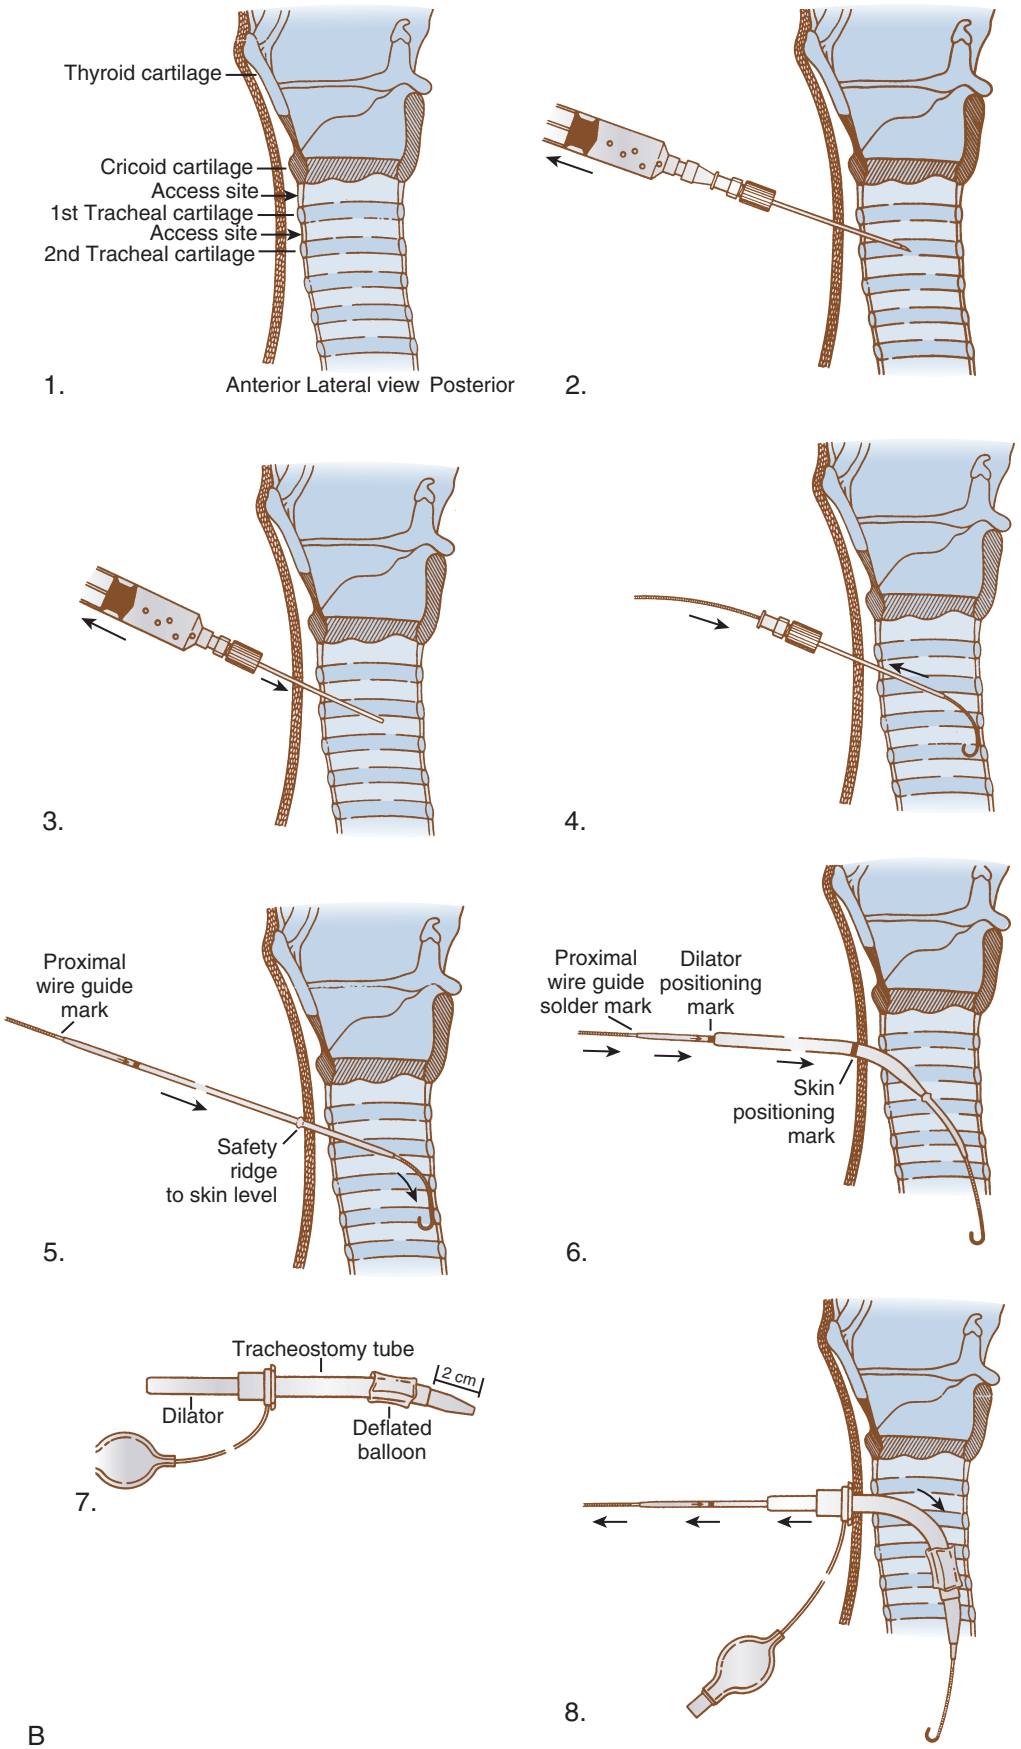
9. The needle is withdrawn, leaving the overlying catheter sheath through which the guidewire can be inserted (see Fig. 30-17, C and *D*).
10. The sheath is removed and replaced by a 14-F introducer dilator, which is advanced over the guidewire (several times); this maneuver enlarges the tracheal aperture sufficiently to allow easy placement of the 12-F guiding catheter.
11. The guiding catheter and guidewire are left in place and form the backbone over which the single dilator is used.
12. The single dilator with the hydrophilic coating moistened is advanced over this unit (see Fig. 30-16, *B*), several times if necessary, until resistance is minimal. The chosen depth of dilation also depends on the size of the cannula to be inserted.
13. The dilator is replaced by the preloaded tracheostomy tube, which is advanced into the trachea. Some resistance may be encountered at the interface between the dilator and tracheostomy tube.
14. The guidewire, guiding catheter, and dilator are removed and replaced by the inner cannula.
15. The ventilatory apparatus is connected to the tracheostomy, which is secured with four corner sutures.
16. When ventilation is adequate, the ETT is removed while examining the vocal folds. A postoperative chest radiograph is obtained to rule out a pneumothorax. In a patient with a large, thick neck, a longer tracheostomy tube should be used to prevent accidental displacement of the tube into the pretracheal soft tissue. In the event of accidental decannulation within 5 days of the procedure, the ICU staff is advised to reintubate the patient orally rather than attempt to reinsert the tracheostomy tube.

Precautions in the performance of this technique include the following:



- Always confirm access into trachea by air bubble aspiration.
- Maintain safety positioning marks of the guidewire, guiding catheters, and dilator during the dilating procedure to prevent trauma to the posterior wall of the trachea.
- Tracheostomy tubes should fit snugly to the dilator for insertion. Generous lubrication of the surface of the dilator enhances fit and placement of the tracheostomy tube.

2. Ciaglia Blue Rhino G2 Advanced Percutaneous Tracheostomy Kit

The Ciaglia Blue Rhino G2 Advanced Percutaneous Tracheostomy Kit (Cook Medical) (Fig. 30-18, *A*) has a curved dilator that is advanced over a guiding catheter and creates a tracheostomy opening in one pass, obviating the need for multiple dilators as with previous kits (see Fig. 30-18, *B*). The softness of the dilator, the hydrophilic coating, and the one-passage technique are the main advantages of this widely used percutaneous tracheostomy system, which has been at least as safe as the PDT techniques in multiple trials.[40,77-81]

3. Ciaglia Blue Dolphin Balloon Percutaneous Tracheostomy Kit

The Ciaglia Blue Dolphin Balloon percutaneous tracheostomy kit (Cook Medical) offers an improvement on the single-dilator PDT technique. This system combines balloon dilation and tracheal tube insertion in a single step (Fig. 30-19). The underlying principle is that balloon dilation should minimize pressure on the anterior tracheal wall and deliver an even and controlled radial

B

dilation. Given the novelty of this device, data from the literature are insufficient to determine any advantage of this system compared with established methods and devices.

4. Portex ULTRAperc Single-Stage Dilator

The Portex ULTRAperc Single-Stage Percutaneous Dilation Tracheostomy Kit (Smiths Medical) is based on the widely accepted Seldinger guidewire technique. The kits are available with the Blue Line Ultra Suctionaid Tracheostomy Tube that features an integrated suction lumen for removal of pooled secretions (Fig. 30-20).

In a study comparing the ULTRAperc device with the Blue Rhino in mannequin and porcine models, dilation with the ULTRAperc set was subjectively easier and required less force, and the time for tracheostomy tube

Figure 30-18 **A,** Ciaglia Blue Rhino G2 tray. **B,** Blue Rhino percutaneous tracheostomy dilator. (Courtesy of Cook Medical, Bloomington, IN.)

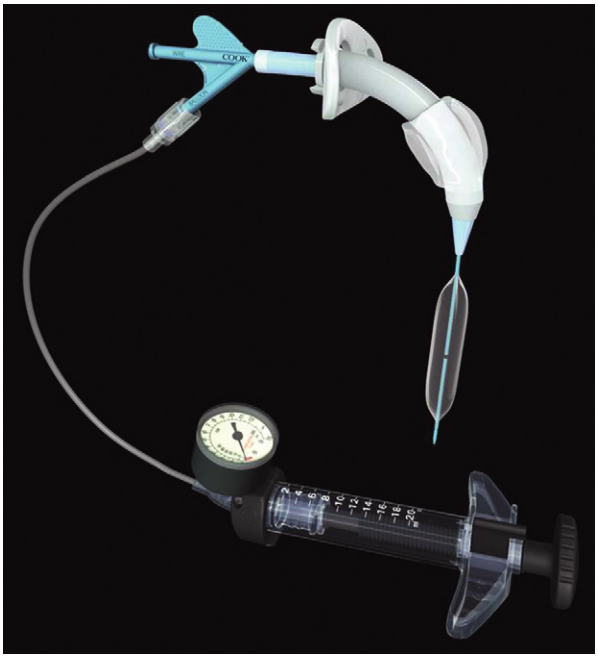

Figure 30-19 Ciaglia Blue Dolphin balloon percutaneous tracheostomy introducer. (Courtesy of Cook Medical, Bloomington, IN.)

insertion was shorter.[82] The investigators suggest that the ULTRAperc set is subjectively easier to use, quicker, and causes less anterior-posterior tracheal compression during tracheostomy tube insertion compared with the Blue Rhino set in mannequin and porcine airway models. This advantage may be from the tracheostomy tube introducer in the ULTRAperc set that allows smooth passage of the tracheostomy tube through the dilated stoma.

5. Portex Griggs Percutaneous Dilation Tracheostomy Kit

The Portex Griggs Percutaneous Dilation Tracheostomy Kit (Smiths Medical) features guidewire dilating forceps that are central to the Griggs PDT technique (Fig. 30-21). Dilating forceps specially designed to slide along a prepositioned guidewire are used to open pretracheal tissue and the anterior tracheal wall in preparation for tube insertion. Use of the forceps causes less compression compared with the cone-shaped, single-stage dilators. In a prospective, randomized comparison of progressive-dilational versus forceps-dilational percutaneous tracheostomy,[83] the progressive-dilational tracheostomy took longer, caused more hypercapnia, and caused more minor and major difficulties than forceps-dilational tracheostomy. We agree that the guidewire dilating forceps technique is safe and easy to learn, and it may be quicker than the progressive-dilational technique. Sometimes, the forceps cannot be inserted to the full length due to thick subcutaneous tissue of the anterior neck. Switching from forceps to a progressive dilator allows completion of the procedure without complications.[31,84] The Portex Griggs Percutaneous Dilation Tracheostomy Kit also may be used in combination with Suctionaid tracheostomy tubes with an integral suction lumen to aid suctioning of secretions from above the cuff.

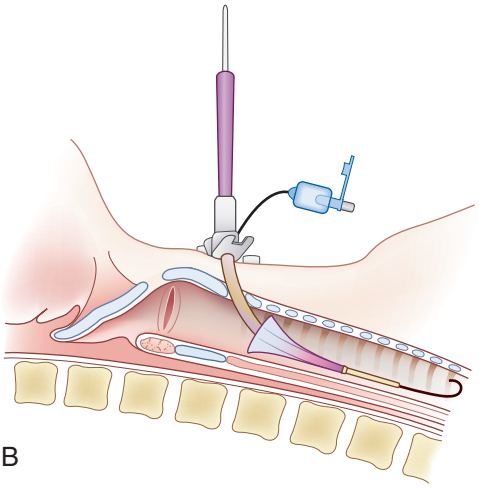

Figure 30-20 **A,** Portex ULTRAperc kit. **B,** Insertion of the ULTRAperc cannula with a handle introducer. (**A,** Courtesy of Smiths Medical, Dublin, OH.)

6. Percutwist

Increased control over the dilating maneuver from start to finish is one of the advantages of the Percutwist (Rüsch-Teleflex Medical) (see Fig. 46-19 in Chapter 46). Another is the possibility to lift the anterior tracheal wall, facilitating the endoscopic view of the dilation site during the procedure. Gradual application of the forces applied to produce dilation may increase the safety of this technique, although cases of posterior tracheal wall injury have been reported.[78,85]

7. Translaryngeal Tracheostomy Kit

The Translaryngeal Tracheostomy Kit (Mallinckrodt, Mirandola, Italy) is used mostly in European countries to perform translaryngeal tracheostomy according to the technique introduced by Fantoni in 1997. The critical steps of this procedure and use of this system are summarized in Figure 46-16 (see Chapter 46). Percutaneous tracheostomy has a learning curve and requires appropriate training. All studies comparing different methods

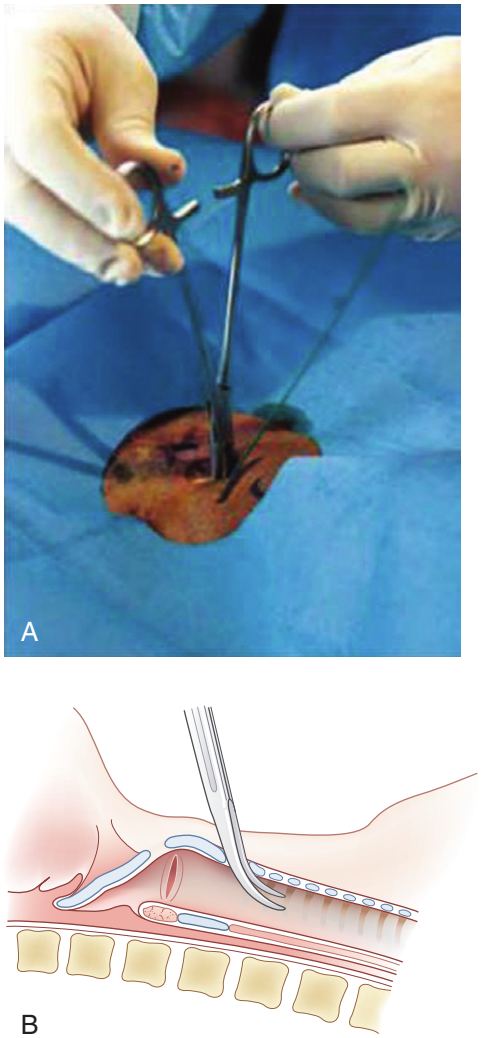

Figure 30-21 **A,** Portex Griggs forceps used for dilatation during surgery. **B,** Diagram of forceps dilatation. (**B,** Courtesy of Smiths Medical, Dublin, OH.)

should take into consideration potential differences in training of the personnel performing PDT with each proposed technique. Different environments and patient characteristics may dictate the choice of a specific technique or determine the preference for a specific system.

8. Controversies and Questions

a. USE OF BRONCHOSCOPY AND ULTRASOUND

The issue of bronchoscopy has been hotly debated in the literature over the past 2 decades. Those in favor argue that it is easy to perform and adds to the safety of the procedure by significantly decreasing or eliminating the risk of false passage, pneumomediastinum, pneumothorax, and subcutaneous emphysema. Bronchoscopy allows early detection and suctioning of intratracheal blood and secretions. The bronchoscope also allows proper midline needle placement between the second and third tracheal rings and prevents injury to the posterior tracheal wall.

Opponents argue that bronchoscopy increases the length and cost of the procedure and does not add to safety in experienced hands. Moreover, the presence of the bronchoscope within the ETT may result in CO_2 retention and difficulty ventilating the patient. The accumulated weight of evidence in the literature points to the advantages of bronchoscopy for safety reasons.[86,87] Nonetheless, a large meta-analysis was not able to demonstrate a clear advantage of bronchoscope-guided procedures in terms of decreasing overall mortality and major perioperative complications.[88]

Ultrasound has been proposed as a useful tool to identify the anatomy of airway, blood vessels, and other structures, such as the thyroid gland and isthmus. Ultrasound has in some cases replaced bronchoscopic guidance.[89] However, a combination of the two (depending on resource availability) may offer better results. Whether ultrasound can reduce the incidence of tracheal-innominate fistulas (a rare but deadly complication) needs further investigation.[90]

b. PATIENT'S HABITUS

Controversy exists regarding the suitability of percutaneous tracheostomy in obese patients. Obesity may preclude adequate palpation of critical landmarks and increase the risk of false passage or accidental decannulation into the soft tissues of the neck. Optimal positioning of the neck usually permits localization of the cricoid cartilage and sternal notch. Vigorous spreading of the subcutaneous tissues during the procedure facilitates palpation of the tracheal rings for precise needle placement. The risk of false passage may be addressed by always using a bronchoscope and ensuring step-by-step visualization.

Accidental decannulation in these patients is more likely to occur because of the displacement of the tube in the abundant soft tissues. Using proximally extended tracheostomy tubes dramatically reduces the risk of this complication. Ben Nun and colleagues presented a case series of 154 critically ill adult patients in whom percutaneous tracheostomy using the Griggs technique was performed at the bedside.[91] Eighteen of these patients had a short, fat neck as their only risk factor for PDT. Short, fat neck was defined as a neck circumference greater than 46 cm, with a distance between the cricoid cartilage and the sternal notch of less than 2.5 cm and distance between the cricoid cartilage and the pretracheal soft tissues of more than 2.5 cm. No complications were reported in this group. Heyrosa and coworkers reported their results for a series of 89 obese patients (body mass index [BMI] >35 kg/m^2) undergoing PDT and 53 obese patients (same BMI) undergoing open tracheostomy, and they found the same complication rate (6.5%) for the two groups.[92]

Aldawood and colleagues performed PDT in 50 obese patients, mostly without bronchoscopic guidance.[93] They reported an increased rate of major complications compared with nonobese patients (12% versus 2%, $P = 0.04$) but a similar rate of minor complications for the two groups.[93] They defined obesity as a BMI of 30 kg/m^2 or higher. The most frequent major complication was "procedure aborted, not otherwise specified," but no surgical conversion, pneumothorax, or death occurred in either group. The investigators concluded that PDT could be performed safely in most obese patients.

In a prospective evaluation of endoscopic PDT in 500 consecutive intubated adults in the ICU, patients with a BMI of 30 kg/m^2 or greater had a significantly greater ($P < 0.06$) number of complications (15%) than the patients (8%) with a BMI less than 30 kg/m^2.[94] This risk was even more significant for patients with a BMI of 30 or more who were also in ASA physical status class 4 (11 of 56 [20%]) ($P < 0.02$). Byhahn and colleagues reported an extremely high complication rate (43.8%) for 73 obese patients and found that obese patients (BMI >27.5 kg/m^2) had a 2.7-fold increased risk for perioperative complications and a 4.9-fold increased risk for serious complications compared with nonobese patients.[95] The researchers concluded that percutaneous tracheostomy in obese patients was associated with a considerably increased risk for perioperative complications, especially for serious adverse events. Comparison of the results and conclusions from these studies is problematic because of the different criteria used in defining obesity, the dissimilar primary and secondary end points, and the use of different percutaneous techniques for PDT.

VII. POSTOPERATIVE CONSIDERATIONS

A. Cricothyrotomy

Cricothyrotomy is usually performed emergently to secure a difficult airway, but it can be performed electively.[7] When cricothyrotomy is performed under less than ideal circumstances, it should be considered a temporary measure, and when the patient is stabilized, endotracheal intubation with or without an FOB or a tracheostomy should be performed. The FOB affords an opportunity to evaluate the airway, especially at the site of the cricothyrotomy. The cricothyrotomy site should be examined frequently for signs of infection, and all patients should have a careful neurologic and airway evaluation before discharge from the hospital to ensure that there has been no damage to the vocal cords or other proximate structures. There is no consensus of opinion on what work-up is necessary after emergency cricothyrotomy, but any complaints by the patient of difficulty swallowing or phonating should be carefully evaluated. Complication rates from properly performed emergent cricothyrotomy are acceptably low.

B. Percutaneous Tracheostomy

With the termination of the intense stimulation produced by the procedure, the effects of the sedation may become more pronounced, and particular care must be taken in monitoring for changes in vital signs such as hypotension, tachycardia, or oxygen desaturation. In some cases, pharmacologic intervention may be required. Excess secretions or blood may compromise ventilation and result in an oxygen saturation drop, requiring suctioning. A postoperative chest radiograph is required to ensure the absence of pneumothorax and pneumomediastinum.

Many of these patients have copious secretions from the tracheostomy site because of their associated pulmonary condition. A tracheostomy tube with an inner cannula facilitates care and hygiene and ensures added safety by easy removal if obstruction from secretions occurs. The percutaneous technique is primarily dilational with minimal tissue dissection, resulting in a tighter tract and a very snug fit of the tracheostomy tube. The technique does not allow placement of traction sutures at the level of the trachea. Because of these factors, the patient should be reintubated orally in the event of accidental decannulation within the first 5 days of the procedure, while the tract is still relatively immature. Attempts at replacing the tracheostomy tube in an emergent situation may cause bleeding, the creation of a false passage, pneumomediastinum, hypoxia, or death.

1. Complications and Outcome Data

a. CRICOTHYROTOMY

The reported complication rate is 6% to 8% for elective cricothyrotomy and 10% to 40% for emergent procedures.[96,97] The morbidity and mortality rates for elective cricothyrotomy are similar to those for elective tracheostomy. Boyd and colleagues found 10 complications (6.8%) in 147 cricothyrotomies, but no differentiation was made between elective and emergency procedures. In 1976, Brantigan and Grow reported a 6.1% complication rate for 655 cases, most of which were correctable and self-limited, and this compared favorably with the complication rate associated with tracheostomy. The same investigators implicated the presence of acute laryngeal pathology (especially from prolonged intubation before cricothyrotomy) as the predisposing factor in the subsequent development of subglottic obstruction.[98]

Adverse effects of cricothyrotomy can be categorized as those that occur early and those that occur late in the postoperative period. Early complications include asphyxia related to failure to establish the airway, hemorrhage, improper or unsuccessful tube placement, subcutaneous and mediastinal emphysema, prolonged procedure time, pneumothorax, and airway obstruction. Esophageal or mediastinal perforation, vocal cord injury, aspiration, and laryngeal disruption may also occur.[99] Long-term complications include tracheal and subglottic stenosis (especially in the presence of preexisting laryngeal trauma or infection), aspiration, swallowing dysfunction, tube obstruction, tracheal-esophageal fistula, and voice changes.[100] Voice change is the most common complication, occurring in up to 50% of cases.[20] Voice problems include hoarseness, weak voice, or decreased pitch. The voice dysfunction may be caused by injury to the external branch of the superior laryngeal nerve, decreased cricothyroid muscle contractility, or mechanical obstruction related to narrowing of the anterior parts of the thyroid and cricoid cartilages.[101] Infection, late bleeding, persistent stoma, and tracheomalacia have also been reported. Although subglottic stenosis is the most frequently reported major complication after cricothyrotomy,[102] it is rare after tracheostomy. Pneumothorax and major blood vessel erosion are also associated with tracheostomy. Other complications associated with tracheostomy include mediastinal emphysema, accidental extubation, cardiac arrest, and death.

The complication rate for cricothyrotomy is higher in the pediatric population. Pneumothorax is the most

common complication in children (5%to 7%) and is rarely seen in adults. Between 1% and 2% of adults develop subglottic stenosis after tracheostomy, compared with 2% to 8% of children. Children undergoing cricothyrotomy have a mortality rate up to 8.7%. Prehospital cricothyrotomy performed by emergency medical services (EMS) personnel carries a higher risk of morbidity than the in-hospital procedure. Spaite and Joseph reported an overall acute complication rate of 31% for 20 emergency patients. Failure to secure the airway accounted for the major complication rate (12%). Minor complications included right main stem intubation, infrahyoid placement, and thyroid cartilage fracture. Sixty surgical cricothyrotomies performed by trained aeromedical system personnel had a complication rate of 8.7%.[103] These complications included significant hemorrhage or soft tissue hematoma and incorrect placement. All the previous complications are from surgical or mixed surgical and percutaneous cricothyrotomy studies. Problems and complications associated specifically with percutaneous cricothyrotomy include difficulties with insertion, esophageal or mediastinal misplacement, and bleeding.[104] The overall reported complication rate is 5%. Complications included CTM calcification, blockage by secretions, dystrophic ossification, and heterotrophic bone formation. Displacement of the tube into the mediastinum may occur and can cause emphysema, respiratory distress, and pneumothorax.[105] Bleeding occurs in 2% of cases, but significant hemorrhage requiring surgical intervention is rare. The Seldinger technique appears to lessen the incidence of bleeding and promote a more precise technique of insertion.[106]

b. PERCUTANEOUS TRACHEOSTOMY

Most studies report excellent success and low complication rates with PDT.[90,107,108] Since PDT became common clinical practice, data on the utility of this procedure and its potential advantages over standard tracheostomy have been reported in many publications.[36,73,90,107,109,110]

Potential complications of tracheostomy, whether performed openly or percutaneously, can be described as intraoperative or postoperative and as early or late; they are listed in Box 30-2. The overall complication rate reported for PDT in large studies, systematic reviews, and meta-analyses ranges from about 6% to 15%.[85,111-114] It has been suggested that bronchoscopy-guided PDT might have a lower incidence of complications compared with PDT performed without bronchoscopy,[86,87,115] but the data on this issue are mixed, and other studies have not confirmed this hypothesis.[88] Among intraoperative complications, premature extubation and bleeding are most concerning and reported more frequently. Early postoperative complications include tube malpositioning, bleeding, subcutaneous emphysema, and pneumothorax. The most significant late complications are glottic and tracheal stenosis and stomal infection. A rare but deadly late complication is tracheal-innominate fistula.[90] Whether this complication is related to any specific technique or anatomic variants (e.g., tracheostomy performed too low, cannula not appropriately chosen, variant blood vessel anatomy) must be determined, as well as the possible contribution of ultrasound to reduce the incidence. However, because the incidence of this complication is low, a very large number of observations would be required to evaluate the value of an intervention to decrease it.

Box 30-2 Complications of Percutaneous Dilational Tracheostomy

Intraoperative Complications

Hemorrhage
Loss of airway or premature extubation
Pneumothorax
Tracheal-esophageal fistula or posterior tracheal wall injury
Hypoxia and ventilation problems
Hypotension
Cardiopulmonary arrest
Recurrent laryngeal nerve injury

Postoperative Complications

Early
Hemorrhage
Stomal infection
Pneumothorax and subcutaneous emphysema
Tube obstruction
Late
Displaced tracheostomy tube or unplanned decannulation
Granuloma
Subglottic stenosis
Stomal infection or infection of lower respiratory tract
Tracheocutaneous fistula

The differences between techniques used, operators' experience, patient selection criteria, and indications and timing of the procedures make it difficult to perform an accurate comparison of the data available from the literature on the overall safety of PDT with that for standard open tracheostomy. However, there seems to be a significant amount of evidence to support that PDT has a lower incidence of peristomal bleeding and wound infection compared with open tracheostomy.[73-76,88] For these reasons, it has been advocated that PDT should be considered the procedure of choice for performing elective tracheostomy in critically ill patients.[74,88] The decreased incidence of bleeding may be related to the lack of sharp dissection and the tamponade effect of the dilator. The much smaller wound created with the PDT technique reduces the surface area available for bacterial colonization and may explain the low rate of wound infection. Late outcome studies evaluating serious long-term complications associated with PDT indicate that the incidence of clinically significant tracheomalacia or stenosis requiring corrective intervention is low.[116]

After decannulation, 16 patients were evaluated by means of physical examination, standardized interviews, and fiberoptic laryngotracheoscopy. The subjective rating was good for all patients. Laryngotracheoscopy showed incidental tracheal changes in two patients consisting of soft tissue swelling and a membranous scar, respectively. Neither of these findings required treatment.[117] Histologic studies were conducted on 21 laryngotracheal specimens from patients who had undergone PDT or standard open tracheostomy. In the percutaneous group, cartilage

fractures associated with a strong inflammatory response were found in one third of cases, compared with a more limited inflammatory response in the standard group. There was no clinical evidence of laryngotracheal stenosis in either group.

Carrer and associates, in a prospective observational study of 181 ICU patients receiving PDT over a 6-year period, reported a 0.7% rate of tracheal stenosis requiring tracheal stent placement and a 1.4% rate of recurrent granuloma of the stoma that was treated with laser resection. Late decannulation seemed the major risk factor for these infrequent but clinically significant late complications.[107]

2. Practical Applications of Cricothyrotomy

The superiority of the percutaneous technique over the surgical technique has turned attention toward the different cricothyrotomy kits available and their applications, success rates, and complications. An over-the-needle, wire-guided dilation technique is safer and adaptable to various practitioners (with different training time and specialties) and is still relatively fast. Over-the-needle techniques that do not use a guidewire, even if often reported to be faster and easier, can result in higher complication rates.

Another important issue is establishing indications based on patients' injuries and habitus and on clinical scenarios.[118,119] Percutaneous techniques are increasingly used in the prehospital setting and for major facial injuries, neck abnormalities, or challenging anatomy. Many patients can be assisted or ventilated with a bag-valve-mask if definitive cricothyrotomy is performed, and they can be jet ventilated or ventilated mechanically if a needle cannula has been placed.

Cricothyrotomy is an important tool for managing the impossible airway or the threatened airway, and it often is the last and only way to avoid anoxia. In the previous edition of this textbook, a simplified protocol was proposed for prehospital emergency trauma airway control (Fig. 30-22). The protocol can be expanded by including an in-hospital approach (see Fig. 30-23 and the Difficult Airway Society's "cannot ventilate, cannot intubate" scenario (http://www.das.uk.com/guidelines/cvci.html) or the ASA algorithm.[49] Both scenarios converge on an emergency pathway, in which the option of awake airway control or awakening the patient is not possible. In this emergency pathway, as interpreted by a modified ASA difficult airway algorithm (Fig. 30-24), cricothyrotomy performed surgically or percutaneously plays a fundamental role.

When dealing with difficult airways, planning includes ventilation and intubation. Regardless of the techniques and devices that may offer assistance with bag-mask ventilation or intubation, if one or the other fails, a supraglottic device is the first alternative to further attempts to intubate and bag-mask ventilate, and the last is an invasive airway approach (i.e., cricothyrotomy).

In the past few years, many changes in airway management occurred as a result of better airway equipment availability and implementation of airway protocols. As observed by Timmerman and colleagues and Combes and associates, cricothyrotomy is rare, even in emergency airway conditions, if an airway protocol is used (assuming no major neck trauma).[120,121] However, a careful reading of the literature shows a significant number of complications that may question the underuse of more invasive techniques and argue for the earlier use of these techniques, depending on the level of training, the setting, and clinical conditions. Appropriate training is fundamental to maintain proficiency in the technical skills required to perform these invasive procedures safely, rapidly, and effectively.

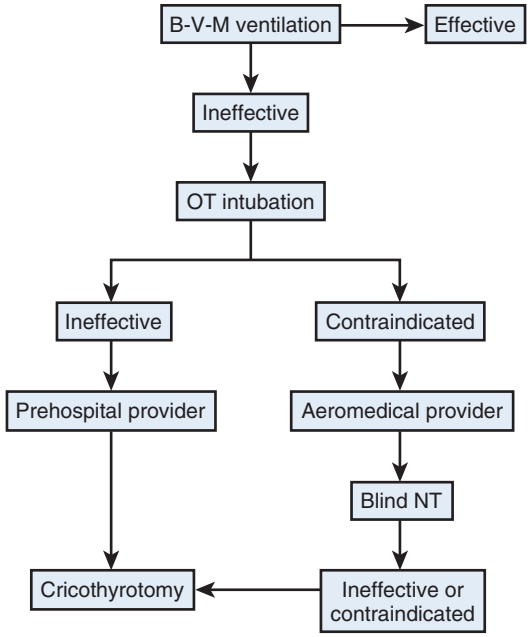

Figure 30-22 Emergency airway protocol for prehospital care. *B-V-M,* Bag-valve-mask; *NT,* nasotracheal; *OT,* orotracheal.

VIII. TRAINING MODELS

Because PDC is rarely performed, there is a need for quality teaching and training aids.[25,122] Although the technique closely mimics over-the-wire vascular insertion methods, it is sufficiently different that anesthesiologists ideally should practice on a regular basis.[27,57] Simple and inexpensive models can be made for training residents and inexperienced personnel, as well as maintaining the skills and proficiency of the trainees and experts.

Of the available animal models, dogs appear to be most similar to humans. The canine CTM, muscles, and cricothyroid area are similar to those in humans. The tracheal dimensions of the 25-kg dog are comparable to those of the adult human.[2] Cricothyrotomy has been performed on other animals, including pigs, sheep, and goats. The larynx is significantly smaller in these animal models, and 3.5- or 4.0-mm-ID sets must be used for teaching. In pigs, attempts to pass a needle or over-the-needle catheter into the cricothyroid space may result in hitting cartilage. The space can be entered only by directing the needle cephalad, not caudad. Dissection of the larynx revealed a projection on the inferior surface of the thyroid cartilage that articulated with the cricoid

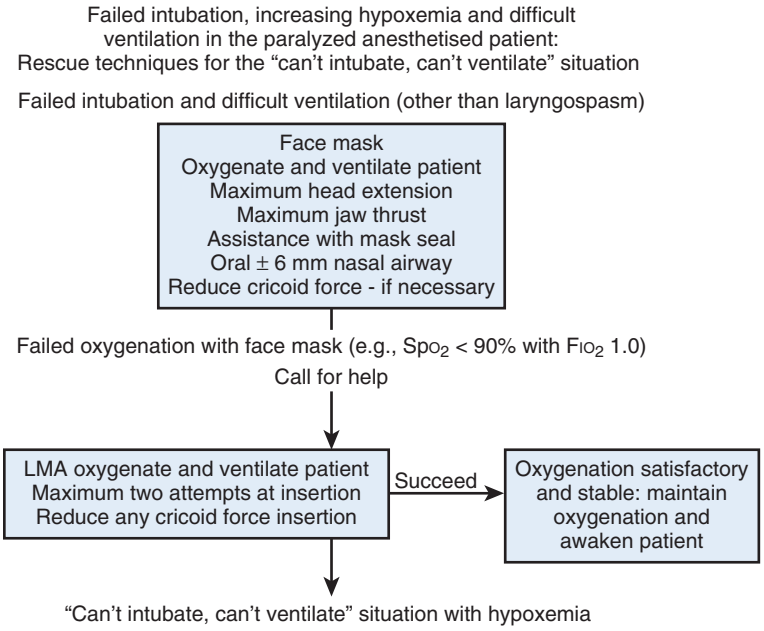

Figure 30-23 The Difficult Airway Society cannot intubate algorithm. (Courtesy of the Difficult Airway Society, London, United Kingdom.)

cartilage. This cornu had been previously described and had to be removed to perform cricothyrotomy studies.[101] The pig trachea model (professionally isolated and prepared) is used for airway training and is combined with manikin simulations for the education of residents and faculty in surgical and percutaneous cricothyrotomy in teaching institutions, workshops, and airway management courses (e.g., Society for Airway Management, Difficult Airway Workshop, American Society of Anesthesiologists Annual Meeting).

Fresh and embalmed cadaver specimens can be used.[67,123-125] The former are superior because the laryngeal structures of embalmed specimens are somewhat constricted because of muscle contraction, and it may be more difficult to discern the cricothyroid space. Mannequins can also be an acceptable model, and several products are available, but cheaper and simple models can also be used for skill maintenance and simulation.[126] Simulation and practice-workshops are used in teaching programs or as part of dedicated airway management courses or meetings.[56,127-129]

IX. MISCELLANEOUS CONSIDERATIONS

A. Cuff Pressure

Tracheostomy tube cuffs are used to create a seal against the tracheal mucosa, thereby minimizing aspiration, and to facilitate positive-pressure ventilation by preventing leakage of air. Tracheal stenosis from low-volume, high-pressure, low-compliance cuffs was a major complication of tracheostomy during the 1960s. These cuffs may exert pressures as high as 180 to 250 mm Hg on the tracheal mucosa, far in excess of the normal capillary perfusion

1. One attempt for each.
2. Supraglottic method, laryngoscopy, or cricothyrotomy, either surgical or percutaneous.

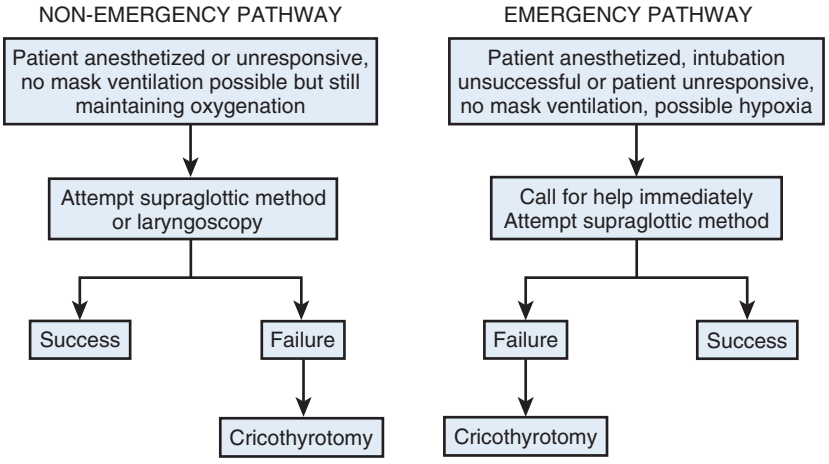

Figure 30-24 Modified American Society of Anesthesiologists cricothyrotomy airway algorithm. (Modified from the American Society of Anesthesiologists, Park Ridge, IL.)

pressures of 20 to 30 mm Hg. The result is a time-related, progressive ischemic injury ranging from inflammatory changes to chondronecrosis and tracheal stenosis or tracheomalacia. With the accumulated evidence attesting to the deleterious effects of low-volume, high-pressure cuffs, there has been a gradual shift in the past 3 decades toward the use of high-volume, low-pressure cuffs because they are safer.

The transition in the 1970s to high-volume, low-pressure cuffs decreased the incidence of cuff-related tracheal stenosis by 10-fold because of the ability of the cuff to seal the airway at pressures below the mucosal capillary perfusion pressure. These cuffs inflate symmetrically, adapt to the tracheal contour, and allow pressure distribution over a wide area. The risk of overinflation with resultant high intracuff pressures may be minimized by the following:

- Having a pressure-controlled cuff with a pressure pop-off valve, which prevents inflation beyond 20 mm Hg (although less than 20 mm Hg has been associated with increased risk of leakage of bacterial pathogens around the cuff into the lower respiratory tract)[130]
- Regular measurement of intracuff pressure with a manometer attached to a three- or four-way stopcock (the latter gives more accurate results)
- Cuff deflation for as long as safely possible in patients who do not require mechanical ventilation

B. Infections

1. Risk Factors

a. DISRUPTION OF HOST DEFENSES

Performing a tracheostomy requires a skin incision, thereby disrupting this highly effective natural barrier to infection. The resultant open surgical wound provides a wide surface area for colonization, which may occur from surrounding skin, preexisting infected pulmonary secretions, aspiration of oropharyngeal secretions, or instrumentation or handling of the tracheostomy tube.

The nose, paranasal sinuses, and pharynx, where filtration and humidification and local leukocyte antibacterial activity occur under normal circumstances, are all bypassed in the patient with a tracheostomy. Impaired vocal fold adduction in patients with tracheostomies and the presence of the tube prevent generation of an effective cough. Oropharyngeal secretions, often colonized with potentially pathogenic gram-negative organisms, are ineffectively cleared or swallowed, allowing some degree of aspiration and contamination of the tracheobronchial tree.

b. TRACHEOSTOMY TUBES

Most tracheostomy tubes, ETTs, and cuffs are made of polyvinyl chloride, a plastic to which bacteria readily adhere. Clumps of rod-shaped and coccoid bacteria have been identified on the surface of ETTs and, by extension, tracheostomy tubes. Cultures of this material have grown a variety of gram-negative and gram-positive bacteria, including *Pseudomonas aeruginosa*, *Proteus mirabilis*, *Staphylococcus aureus*, and *Staphylococcus epidermidis*. These bacterial clumps may reach the tracheobronchial tree and lungs through detachment and aspiration or be dislodged during suction or bronchoscopy. Tracheostomy tubes that are made of polyvinyl chloride may serve as reservoirs for persistent contamination of the tracheobronchial tree.

2. Infection Sites

a. STOMAL INFECTION

Colonization of the surgical wound after tracheostomy occurs within 24 to 48 hours with primarily gram-negative organisms, including *Klebsiella*, *P. aeruginosa*, *Escherichia coli*, and occasionally *S. aureus*.[7,131] Wound edges may demonstrate mild erythema, and yellow or green secretions from the area may be copious, particularly in the first 7 to 10 days. These findings are more marked after standard open tracheostomy than PDT, probably because of the very small incision and tight tract in the latter procedure. Frequent and meticulous wound care with mechanical débridement, if necessary, is the best way to deal with this situation. Progressive cellulitis, despite aggressive local care, indicates infection, usually polymicrobial, and warrants systemic antibiotics. Rarely, necrotizing stomal infections may occur, with substantial loss of soft tissue down to and including the tracheal wall. This may create difficulties in maintaining adequate mechanical ventilation. Progression of the process may result in carotid artery exposure, with its attendant risks. Management involves replacing the tracheostomy tube with an ETT and aggressive wound débridement and cleaning with antiseptic dressings. Rarely, local flaps may be necessary to provide soft tissue coverage for vital structures.

b. TRACHEOSTOMY TUBES

Colonization of the wound, along with mechanical irritation from the tube, cuff, and tube tip, means that there is always some degree of localized, reversible tracheitis, which often manifests by increased secretions. Progression of this situation may lead to loss of tracheal support, resulting in tracheal stenosis or tracheomalacia. Full-thickness loss may result in life-threatening complications such as tracheal-esophageal or tracheal-innominate fistula. Selecting appropriate tube sizes, materials, and cuffs can minimize mechanical irritation. The cuff should be inflated only when necessary.

The known bacterial colonization of polyvinyl chloride devices makes a strong argument in favor of more frequent tube changes, perhaps weekly, in ventilator-dependent, critically ill patients.

c. HOSPITAL-ACQUIRED AND VENTILATOR-ASSOCIATED PNEUMONIA

Hospital-acquired pneumonia (HAP) accounts for up to 25% of all ICU infections and for more than 50% of the antibiotics prescribed.[132] Ventilator-associated pneumonia (VAP) occurs in 9% to 27% of all intubated patients.[133,134] In ICU patients, almost 90% of HAP episodes occur during mechanical ventilation. In mechanically ventilated patients, the incidence increases with duration of ventilation.[130] Important risk factors for HAP include exposure to invasive respiratory devices and

aspiration of oropharyngeal pathogens or leakage of secretions containing bacteria around the ETT.[130]

Newly developed taper-shaped cuffs and suction above the cuff systems (Mallinckrodt TaperGuard Evac tube and Portex SACETT) seem to significantly reduce microaspiration compared with the Hi-Lo cuffs, reducing the incidence of VAP. The introduction of similar improvements for tracheostomy tubes may contribute to a reduction in the incidence of VAP in long-term mechanically ventilated patients.

d. CLEANING AND SUCTIONING

Under normal circumstances, the nose efficiently warms, humidifies, and filters inspired air; in the patient with a tracheostomy, these functions must be restored artificially. Dehydration of the respiratory tract results in impaired mucociliary function, causing inspissated secretions and atelectasis.[135] Providing adequate humidification is essential for all patients. Suctioning of secretions to maintain pulmonary toilet and patency of the tracheostomy tube constitutes an integral component of the care of the tracheostomy patient receiving mechanical ventilation and should be carried out according to the patient's needs.

Hypoxia, cardiac dysrhythmia, injury to the tracheobronchial tree, atelectasis, and infection have been associated with suctioning. These events can be minimized by close attention to technical details. Factors that may contribute to hypoxia include suctioning of oxygen-rich air for too long and the use of inappropriately large catheters. This can be prevented by applying suction for less than 2 seconds with a catheter less than one half of the size of the tracheostomy tube and ventilating the patient with 100% oxygen for at least 5 breaths before and after suctioning. A strictly aseptic technique using disposable catheters is mandatory to reduce the risk of cross-contamination.

Meticulous care of the tracheostomy tube and peristomal area is important for maintaining a patent airway and preventing infection and breakdown of the skin. Placement of a tracheostomy tube with an inner cannula is mandatory. This cannula should be removed and cleared several times daily in the early postoperative period. Complete occlusion of the lumen with blood, crusts, and secretions may occur, resulting in hypoxia or death; in this circumstance, rapid removal of the inner cannula is potentially life-saving.

Bacterial colonization of the peristomal area occurs and cannot be prevented with antibiotics. The wound should be cleaned of accumulated secretions and crusts with hydrogen peroxide to prevent breakdown of the skin and progression from wound colonization to infection. The skin under the tracheostomy neck plate should be kept dry with a thin, nonadherent dressing. Petroleum-based products should be avoided on open wounds because they may stimulate granulation tissue and result in myospherulosis.

e. SWALLOWING AND COMMUNICATION

In patients with tracheostomies in place who require mechanical ventilation, the incidence of swallowing dysfunction approaches 80%.[136,137] The cause in most cases is multifactorial and may include the following:

- Glottic injury from previous orotracheal or nasotracheal intubation, or both
- Limitation of normal laryngeal excursion by the tethering effect of the tracheostomy tube
- Compression of the esophagus, particularly in the presence of an inflated cuff
- Desensitization of the larynx and loss of protective reflexes related to chronic diversion of air through the tube
- Impaired vocal fold adduction
- The use of anxiolytics or neuromuscular blocking agents, or both
- Altered mental status or underlying neuromuscular illness

For patients on ventilators with minimal swallowing abnormalities and negligible aspiration, oral feedings may be possible, particularly with the help of the speech-language pathologist. Selection of appropriate food consistencies and emphasis on specific head positions may minimize or prevent aspiration. With mild or moderate aspiration, eligible patients on or off the ventilator may benefit from the use of a Passy-Muir valve. This device may reduce aspiration and improve deglutition by restoring subglottic air pressure.

Unfortunately, for most ventilator-dependent patients with a tracheostomy, the degree of swallowing dysfunction is such that oral intake is not an option. In these cases, enteral feeding is preferred when the gastrointestinal tract can be used safely. It is convenient, there are fewer metabolic and infectious complications, and the cost is lower than that of parenteral nutrition.

Placement of a cuffed, nonfenestrated tracheostomy tube necessarily results in aphonia. Every effort should be made to reestablish effective communication. Involving the speech-language pathologist and adequately assessing the patient's cognitive and linguistic skills are essential. Before establishing the best form of communication, the speech-language pathologist may seek the assistance of an otolaryngologist in confirming that the upper airway is patent and physiologically intact. When clinically possible, cuffed tracheostomy tubes may be exchanged for cuffless or fenestrated tubes, allowing speech by manual occlusion of the tube on expiration or by placement of a device, such as a Passy-Muir valve. This valve may also assist the patient in coughing and swallowing. Successful implementation of communication strategies or devices depends on detailed instruction, encouragement, and support by the speech-language pathologist of the nursing staff, patient, and family.

X. CONCLUSIONS

In the 1970s, after a 50-year hiatus, cricothyrotomy became recognized as an important procedure for emergency airway management. Despite considerable evidence that cricothyrotomy can be life-saving and has an acceptable low complication rate, controlled trials comparing various techniques have not been and are unlikely to be performed. This is largely the result of the

infrequency with which physicians and other health care providers encounter patients requiring emergency cricothyrotomy. The lack of opportunity to perform cricothyrotomy or other emergency airway procedures is a problem for anesthesiologists, who are the recognized airway experts. Although the opportunity to perform a cricothyrotomy is rare, it must be performed expeditiously and correctly when required. We think that PDC should be easy for anesthesiologists to learn because it is similar to the Seldinger technique for insertion of catheters and sheaths, a technique used on a daily basis. The anesthesiologist should be well trained in emergency airway techniques and have appropriate equipment available at all times.

Although anesthesiologists practice primarily in the operating room, they are likely to be called on to perform emergency airway procedures in other settings. They are often asked by colleagues to lecture on difficult airways and emergency airways.

PDT is a safe and technically simple alternative to open surgical tracheostomy. It may be performed independently of operating room schedules and eliminates the need to move critically ill patients from one location to another, with all the associated risks. The simplicity of the procedure, however, does not alter the need for proper preoperative planning, meticulous preparation and execution of the procedure, and appropriate postoperative care.

XI. CLINICAL PEARLS

- Clinicians should quickly recognize a severe airway obstruction and a hypoxic condition to allow fast intervention.
- Proper airway anatomy recognition, even with an ultrasound-assisted evaluation, is the first step in successful management and avoidance of complications.
- The anesthesiologist should always consider the danger of piercing the posterior wall of the trachea and midline neck blood vessels.
- Cricothyrotomy is the technique of choice to secure the airway in emergencies and pending airway obstruction.
- Percutaneous dilational tracheostomy (PDT) is better performed under direct visualization (e.g., flexible fiberoptic bronchoscopy) below first tracheal ring.
- Training should be maintained by performing at least one procedure twice each year on live models and specialized mannequins.
- Percutaneous dilational techniques do not prevent complications. Disasters can be prevented by proper knowledge, preparation, anatomic identification, procedural indications, and skill acquisition and maintenance.

V. Choosing the Right Technique

VI. Complications
- A. Hemorrhage
- B. Tube Misplacement
- C. Accidental Extubation
- D. Other Complications

VII. Conclusions

VIII. Clinical Pearls

I. INTRODUCTION

A. General Principles

Emergency surgical airway management comprises four distinct but related techniques that gain access to the infraglottic airway. These are needle cricothyrotomy, percutaneous cricothyrotomy, surgical cricothyrotomy, and surgical tracheostomy. In emergency situations, cricothyrotomy is greatly preferred over tracheostomy because of its relative simplicity, speed, and lower complication rate. The airway is very superficial at the level of the cricothyroid membrane (CTM), separated from the skin only by the subcutaneous fat and anterior cervical fascia. The trachea moves progressively deeper in the neck as it travels caudally, making anterior access more difficult and introducing additional anatomic barriers (e.g., thyroid isthmus.) Needle cricothyrotomy with percutaneous transtracheal ventilation may provide temporary oxygenation in some patients, but the technique does not provide a secure (protected) airway and cannot support ventilation. Needle cricothyrotomy is reviewed elsewhere in this textbook (see Chapter 30). The emphasis in this chapter is on surgical and percutaneous cricothyrotomy; because the former, and in some cases the latter, places a cuffed endotracheal tube (ETT) in the trachea.

Any discussion of surgical airway management techniques must account for three important concepts:

1. Those Responsible for Surgical Airway Management Have Limited or No Experience

Most clinicians who are responsible for airway management have either limited or no experience with these procedures. Whether in the prehospital setting, the emergency department, the operating room, the inpatient unit, or the intensive care unit, surgical airway management is simply not required very often, largely because of high proficiency with direct laryngoscopy, increasing capability of identifying difficult airways (DAs) in advance, and the multitude of sophisticated alternative intubation devices that can be used when direct laryngoscopy is not possible or unsuccessful. The progressive diminution in use of emergency surgical airway procedures over the past two decades has many causes but is primarily the result of two evolutionary changes: (1) the shift in emphasis in trauma airway management from avoidance of oral laryngoscopy to widespread acceptance of gentle, controlled, oral laryngoscopy with in-line cervical spine immobilization and (2) the growing proficiency of clinicians from multiple specialties with rapid-sequence intubation (RSI).

Contemporary emergency department studies using RSI demonstrate high success rates (97% to 99%) and an infrequent need for surgical airway rescue (0.5% to 2.0%) even though the unselected nature of the patients and the large percentage with trauma result in a high proportion of DAs compared with those seen in elective surgery.[1-5] Despite increasing familiarity with alternative airway rescue devices (e.g., flexible and semirigid fiberoptic bronchoscopy, video laryngoscopy, retroglottic airways, supraglottic airways, retrograde intubation, lighted stylet) that further reduce the need for cricothyrotomy, the surgical airway remains the final pathway on all failed airway algorithms.[6] Therein lies the dilemma. As clinicians embrace new technologies and devices that make the need for surgical airway management increasingly rare, acquisition and maintenance of the skills necessary to perform surgical airway management, which in some cases is the only method capable of sustaining a patient's life, become increasingly elusive.

2. Surgical Airway Management Is Often Performed in Unstable Patients

Surgical airway management is infrequently, if ever, performed in stable patients and is often needed in a "cannot-intubate, cannot-ventilate" (CICV) situation, when failure to perform the technique properly and in a timely fashion may prove disastrous. The patient in need of emergency cricothyrotomy is typically one who has a significantly distorted airway anatomy or who has been subjected to multiple failed intubation attempts, or both. The operator is required to establish an airway in the presence of potentially overwhelming difficulty and with very little time.

3. If a Surgical Approach Fails, Few, If Any, Options Remain

Most would consider surgical cricothyrotomy to be the ultimate consideration among a series of airway management options. In addition, a failed surgical cricothyrotomy may result in bleeding, loss of airway integrity, or further airway distortion, making the success of subsequent rescue attempts highly unlikely.

In sum, emergency cricothyrotomy is a rarely performed procedure, done under duress by clinicians who may have limited experience, in patients in whom it is difficult to perform and who are likely to die if it fails. These challenges speak powerfully to those involved in airway management, counseling them to invest the time required to master this crucial technique. Fortunately, although it has been unfairly cloaked in mystique and represented as dramatic and difficult, cricothyrotomy is a relatively straightforward procedure that can be accomplished with a high success rate and a low rate of complications by providers with adequate but not extensive training. This training can be achieved by using various animal models (not whole animals) and through medical simulation.

B. Historical Perspective

The surgical airway as a life-saving procedure has been appreciated for thousands of years. The first depictions of surgical tracheostomy were found on Egyptian tablets dating from 3600 BC.[7] In the second century AD, Galen suggested tracheostomy, utilizing a vertical incision, as an emergency treatment for airway obstruction.[8-10] Vesalius later published the first detailed descriptions of tracheostomy in the 16th century, using a reed to ventilate the lungs. Ironically, his alleged resuscitation of a Spanish nobleman through tracheostomy and ventilation led to condemnation by the Spanish Inquisition and his ultimate death.[11] The first record of a successful tracheostomy performed in the United States was in 1852; the patient later died of airway stenosis, a common complication at that time. A paper from 1886 described a mortality rate of 50% for tracheostomy and a high incidence of stenosis, which accounted for many of the deaths.[12]

Chevalier Jackson published a landmark paper on tracheostomy in 1909, which enumerated principles still relevant today.[13] He described a surgical mortality rate of only 3%, which he attributed to several factors: optimal airway control before surgery, use of local anesthesia rather than sedation, use of a well-designed tube, and meticulous surgical and postoperative care. Jackson achieved international recognition; however, so did his condemnation of "high tracheostomy" as the cause of subglottic stenosis. The high tracheostomy he referred to was a cricothyrotomy, which at that time involved division of the cricoid or thyroid cartilage. Modern cricothyrotomy involves incision of the CTM only. In 1921, Jackson published a study of 200 patients referred to him for postcricothyrotomy stenosis. Aside from the obvious referral bias, the indication for a surgical airway at that time was primarily inflammatory lesions of the upper airway, which probably accounted for the high incidence of subglottic stenosis.[14]

Although in retrospect it was the technique and the underlying condition that were largely responsible for the high rate of stenosis, fear of this complication condemned the technique of cricothyrotomy for over half a century. In the interest of developing a technique that was safer and quicker than Jackson's open dissection, Toye and Weinstein described the first percutaneous tracheostomy in 1969.[15] However, cricothyrotomy was not widely reconsidered as a surgical airway option until 1976, when Brantigan and Grow published the results of cricothyrotomy for long-term airway management in 655 patients.[16] In their series, the rate of stenosis was 0.01%, no major complications were described, and the procedure was found to be faster, simpler, and less likely to cause bleeding than tracheostomy. Subsequent studies have supported their conclusion that cricothyrotomy is a safe and effective surgical airway procedure and should be the preferred technique when emergent surgical airway control is needed.[7,17,18] Contemporary case series have demonstrated that cricothyrotomy can be performed with a high success rate and a reasonably low complication rate by hospital-based physicians and other clinicians (i.e., nurses, paramedics) providing prehospital care.[13,19-25]

C. Definitions of the Surgical Airway

The definition of surgical airway can be so broad as to comprise all forms of airway management that require

the creation of a new opening into the airway. C*ricothyrotomy* is the establishment of a surgical opening in the airway through the CTM and placement of a cuffed tracheostomy tube or ETT. Cricothyrotomy has also been referred to as cricothyroidotomy, cricothyroidostomy, cricothyrostomy, laryngostomy, or laryngotomy; however, *cricothyrotomy* is presently the preferred term. *Tracheostomy* differs from cricothyrotomy in the anatomic location of entry into the airway. Tracheostomy is the establishment of a surgical opening in the airway at any level including at or caudal to the first tracheal ring.

Surgical airways may be further subclassified according to the technique used: (1) surgical (sometimes referred to as "open" or "full open" or "full surgical"); (2) percutaneous (more precisely described by the actual technique, such as Seldinger); (3) dilational (a distinct percutaneous approach); and (4) transtracheal catheter.

The terms *surgical cricothyrotomy* and *surgical tracheostomy* refer to the use of a scalpel and other surgical instruments to create an opening in the airway.[26,27] This technique allows the creation of a definitive, protected airway by the insertion of a cuffed tracheostomy tube with an internal diameter sufficient for ventilation, oxygenation, and suctioning.

The percutaneous dilational technique utilizes a kit or device that is intended to establish a surgical airway without requiring a formal surgical cricothyrotomy (see Chapter 30 for a detailed discussion). Following a small skin incision, the airway is accessed by a small needle through which a flexible guidewire is passed using the Seldinger technique. The airway device is then introduced over a dilator and passed over the guidewire and into the airway in a manner analogous to that of central line placement. An alternative percutaneous technique has been used that relies on placement of an airway device using a direct puncture into the airway; an example is the Nu-Trake Adult Emergency Cricothyroidotomy Device (Smiths Medical, Keene, NH). A large-bore metal needle or a sharp trocar within the catheter is used to puncture the airway directly, without the use of a guidewire. Direct puncture devices are more hazardous and have fallen out of favor because of a higher incidence of complications and a lower success rate compared with other percutaneous techniques.[28-32]

Transtracheal catheter ventilation, considered the least invasive surgical technique, involves the direct placement of a moderate-bore catheter through the CTM.[33] The small caliber of these devices does not allow adequate oxygenation without attachment to a high-pressure oxygen source or jet ventilator, except in small children, and does not support adequate ventilatory gas exchange. A 6-F reinforced fluorinated ethylene propylene, kink-resistant emergency transtracheal airway catheter (Cook Critical Care, Bloomington, IN) has been designed as a kink-resistant catheter for this purpose.

D. Role of the Surgical Airway

The relative merit of percutaneous dilatational tracheostomy versus open surgical tracheostomy continues to be a subject of debate. Although formal open tracheostomies are primarily performed by surgeons, the percutaneous dilatational tracheostomy is frequently performed by anesthesiologists and other nonsurgical intensivists, particularly in the intensive care setting. This technique was originally described by Toye and Weinstein in 1969, but it did not gain popularity until the results with a modified device were reported by Ciaglia and colleagues in 1985.[12,15] There have been no clinical studies to date demonstrating the superiority of any one approach over another or of any of these devices over formal surgical cricothyrotomy.

II. ANATOMY

An understanding of the anatomy of the upper airway and the neck is required for the successful and rapid performance of a surgical airway. Most emergent surgical techniques involve surgical fields that become rapidly obscured by blood and for this reason they are, essentially, "blind" procedures. The identification of anatomic landmarks is critical.

A. Bones and Cartilages

The horseshoe-shaped hyoid bone is the most cephalad rigid structure in the anterior neck, palpable approximately one finger breadth cephalad to the laryngeal prominence. It suspends the larynx during phonation and respiration by the thyrohyoid membrane and muscle.

The thyroid cartilage is the largest structure of the larynx and consists of two laminae fused in the midline to form the laryngeal prominence. The angle of this fusion is more acute in males, creating the more distinct prominence known as the Adam's apple. The separation of the laminae superiorly forms the palpable superior thyroid notch. The laryngeal prominence of the thyroid cartilage represents the most readily and consistently identified landmark in the neck when one is performing a surgical airway. The superior and inferior cornua of the thyroid cartilage are the posterior extensions of the upper and lower edges of the lamina. The thyrohyoid ligament attaches to the superior cornu, and the posterior cricoid cartilage articulates with the inferior cornu.

The cricoid cartilage, the only complete cartilaginous ring in the upper airway, defines the inferior aspect of the larynx (Fig. 31-1). It is shaped like a signet ring, with the wider lamina posterior. Superiorly, the lamina has synovial articulations with the arytenoids and thyroid cartilage. Anteriorly, the cricoid ring is attached to the inferior thyroid cartilage by the CTM.

B. Cricothyroid Membrane

The CTM is a fibroelastic tissue that covers the cricothyroid space, between the thyroid cartilage and the cricoid ring. It is trapezoidal in shape and in the average adult is 1 cm high and 2 to 3 cm wide. It is located in the midline, approximately 2 to 3 cm below the laryngeal prominence. The vocal cords are located 1 cm above the CTM and therefore are rarely injured during a cricothyrotomy.

Several anatomic characteristics make this membrane an ideal choice for emergency airway access. It is a subcutaneous structure located just beneath the skin, a small

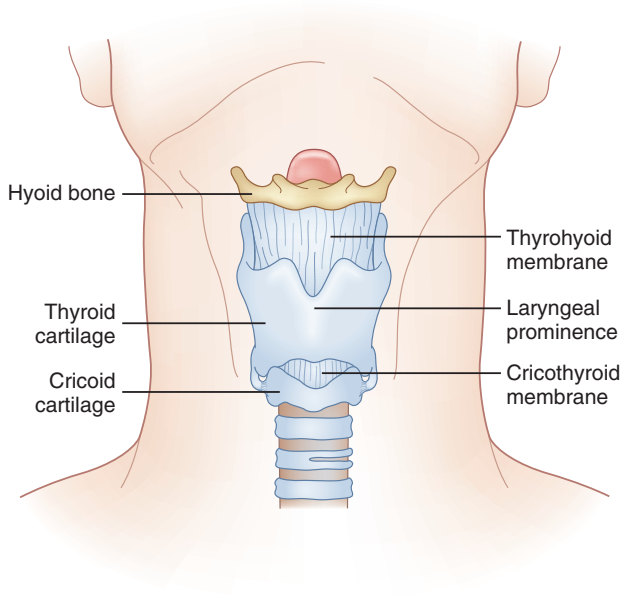

Figure 31-1 Surface anatomy of the larynx. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management*, ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

amount of subcutaneous fat, and the anterior cervical fascia in most patients. Accordingly, it is easily palpated as a depression inferior to the thyroid cartilage, bounded on its inferior aspect by a hard ridge, the cricoid cartilage. The ligament does not calcify with age. It has no overlying muscles, major vessels, or nerves. It is supported by the anterior cervical fascia, which is not robust at this level.

C. Vascular Structures

The major arteries of the neck always lie deep to the pretracheal fascia and should not present a concern when incising the skin over the CTM. The paired superior thyroid arteries arise from the external carotid arteries, superior and lateral to the cricoid cartilage. The anterior branches of these arteries run along the upper thyroid isthmus to anastomose in the midline. The unpaired inferior thyroid artery also anastomoses with the superior thyroid artery at the isthmus. In 10% of the population, the potentially large thyroid ima artery ascends anterior to the trachea to join the anastomoses. A large venous plexus is found over the thyroid isthmus.

The right and left cricothyroid arteries are branches of the right and left superior thyroid arteries, respectively, and in most patients they cross the superior aspect of the CTM to anastomose in the midline.[34] Although they are at risk for injury during a cricothyrotomy, they do not appear to be clinically significant. Bleeding is often self-limited and is easily controlled with gauze packing. There is no venous plexus over the CTM.

D. Thyroid Gland

The isthmus of the thyroid gland lies anterior to the trachea, generally between the second and third tracheal rings, although it may extend to the first and fourth rings. Its size and location can be variable; however, its average height and thickness are 1.25 cm. A pyramidal lobe of the thyroid gland is present in one third of the population and extends superiorly from the isthmus, over the cricoid membrane and larynx to the left of the midline.

E. Anatomic Variations

In infants, the hyoid bone and cricoid cartilage are the most prominent structures in the neck. The laryngeal prominence does not develop until adolescence. The larynx also starts higher in the neck of the child; it descends from the level of the second cervical vertebra at birth to the level of the fifth or sixth in the adult.[35] The laryngeal prominence is more acute and therefore more prominent in adult males compared with females. This also results in longer vocal cords and accounts for the deeper voices of males.

The CTM varies in size among adults and can be as small as 5 mm in height. This space may narrow further with contraction of the cricothyroid muscle.[36] The CTM in the child is disproportionately smaller in area than that in the adult (Fig. 31-2). In an infant, the width of the membrane constitutes only one fourth of the anterior tracheal diameter, as opposed to three fourths in the adult. Because of this smaller area and the difficulty in identifying landmarks in children, emergency surgical cricothyrotomy is difficult and hazardous in small children and is not recommended in those younger than 10 years of age. In this age group, placement of a needle catheter with percutaneous transtracheal ventilation is the preferred method.

Identification of landmarks in the obese, edematous, or traumatized neck can be difficult. The CTM usually lies 1.5 finger breadths (using the patient's fingers) below the laryngeal prominence. Alternatively, its location may be estimated to be three to four finger breadths above the suprasternal notch when the neck is in a neutral position.

There can be significant variation in the arterial and venous pattern in the anterior vessels of the neck, which can result in a major artery's crossing the midline. This is rarely a problem for cricothyrotomy, because most anomalous vessels are present lower in the neck.

III. SURGICAL CRICOTHYROTOMY

A. Indications and Contraindictions

The primary indication for an emergent surgical airway (Box 31-1) is the failure of endotracheal intubation or alternative noninvasive airway techniques in a patient who requires immediate airway control. The American Society of Anesthesiologists (ASA) DA algorithm advocates a surgical airway as the final end point for the unsuccessful arm of the emergency pathway.[37,38] There are a number of other DA algorithms in the literature, as well as numerous modifications of the ASA guidelines; however, all comprehensive pathways include the surgical airway as the technique of choice when others have failed.[38-40] Despite the introduction of numerous

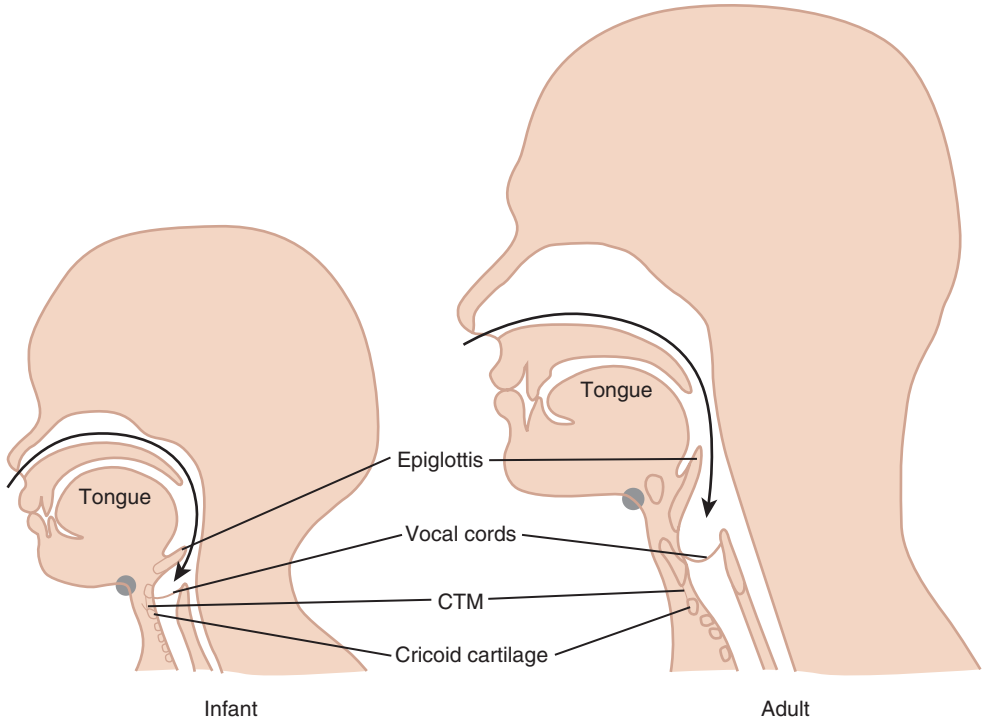

Figure 31-2 Anatomic differences in the pediatric compared with the adult airway: (1) higher, more anterior position for the glottic opening; (2) relatively larger tongue in the infant, which lies between the mouth and glottic opening; (3) relatively larger and more floppy epiglottis in the child; (4) the cricoid ring is the narrowest portion of the pediatric airway (in the adult, the narrowest portion is the vocal cords); (5) different position and size of the cricothyroid membrane *(CTM)* in the infant; (6) sharper, more difficult angle for nasotracheal intubation; (7) larger relative size of the occiput in the infant. See text for details. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management*, ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

alternative rescue devices, the most common error in the management of the DA is persistent attempts at laryngoscopy in a failed airway situation.[41-43] This behavior has been associated with increased morbidity and mortality.[41] Identification of the CICV scenario should result in immediate consideration of surgical airway access. If alternative methods are tried despite inability to oxygenate and ventilate the patient by bag and mask, precious time may be lost in what are ultimately futile attempts, and by the time cricothyrotomy is undertaken and accomplished, delays in achieving airway control and oxygenation will have led to hypoxic brain injury.

Box 31-1 Indications for Cricothyrotomy

Inability to Secure the Airway Using a Less Invasive Technique

1. Massive upper airway hemorrhage
2. Massive regurgitation
3. Maxillofacial trauma
4. Structural abnormalities of the airway (congenital or acquired)

Airway Obstruction

1. Traumatic
   a. Airway edema (includes thermal/inhalation injury)
   b. Foreign body
   c. Airway stenosis or disruption
2. Nontraumatic
   a. Airway edema
   b. Mass effect (e.g., tumor, hematoma, abscess)
   c. Upper airway infection (supraglottitis)

In most circumstances, cricothyrotomy is regarded as an emergency rescue technique when other noninvasive rescue techniques, such as the laryngeal mask airway, have failed, are predicted to fail, or are unavailable.[1] There are occasions, however, when a cricothyrotomy is the primary airway of choice. An example is the patient who has such severe facial trauma that nasal or oral approaches to the airway are deemed impossible. There also has been a renewed interest in the role of elective cricothyrotomy in the operative setting. Some cardiothoracic surgeons prefer cricothyrotomy to a tracheostomy in their patients with a median sternotomy, believing that the higher location of the airway wound reduces the potential for contamination of the sternal wound.[11] A study described the use of elective cricothyrotomy instead of tracheostomy in the intensive care unit for trauma patients with technically challenging neck anatomy. The procedure was described as simpler with no difference in short- or long-term complications.[44]

Cricothyrotomy is considered safe in trauma patients with unstable cervical spine injuries provided that cervical spine immobilization is maintained.[45,46] Although coagulopathy has been described as a relative contraindication, there are reports of successful cricothyrotomy after systemic fibrinolytic therapy for acute myocardial infarction.[47]

Often, the main hurdle to performing cricothyrotomy is simply making the initial decision to forego further

attempts at laryngoscopy or with other rescue devices and to proceed with a surgical airway. Noninvasive airway management methods are used so successfully that cricothyrotomy is often viewed as a procedure that will never be required. However, the single-minded pursuit of multiple noninvasive airways with resultant delay in the initiation of a surgical airway can result in hypoxic disaster, particularly if the patient is not able to be oxygenated and ventilated adequately with a bag and mask between attempts.

The decision to proceed to a surgical airway must also take into account some other important variables. The airway provider must appreciate whether the surgical airway will bypass the airway problem anatomically. For example, if the obstructing lesion is infraglottic, performing a cricothyrotomy may be a critical waste of time. The patient's anatomy and pathology must be considered when weighing the difficulty of performing a cricothyrotomy. Placement of the initial skin incision is based on palpation of the pertinent anatomy. Adiposity, burns, trauma, or infection may make palpation difficult; they do not represent absolute contraindications, but the strategy may need to be adjusted. The operator must also consider the type of invasive technique (i.e., open surgical or percutaneous). This consideration takes into account provider preference based on experience, the patient's presentation, and equipment availability.

Contraindications for surgical airway management are few and, with one exception, are relative. That one exception is young age. Children have a small, pliable, mobile larynx and cricoid cartilage, making cricothyrotomy extremely difficult. For children younger than 10 years, unless the larynx and cricoid cartilage are teenage or adult sized, percutaneous transtracheal ventilation should be used as the surgical airway management technique of choice. Two other situations have been proposed as absolute contraindications: tracheal transection and laryngeal fracture.[48] In either situation, tracheostomy has been recommended as the preferred method. Although anatomically and philosophically appealing, this assertion is clinically impractical. First, these injuries may not be readily apparent at the bedside. Second, there may be no other means of securing the airway in a dying patient. Third, expert surgical backup may not be readily available, and tracheostomy is a much more complicated procedure than cricothyrotomy. Therefore, these, too, should be considered relative contraindications; cricothyrotomy should be recognized as carrying significant risk in these situations and used when there is thought to be no other method to secure the airway. Relative contraindications also include preexisting laryngeal or tracheal pathology such as tumor, infections, or abscess in the area in which the procedure will be performed; hematoma or other anatomic destruction of the landmarks that would render the procedure difficult or impossible; coagulopathy; and lack of operator expertise.

The presence of an anatomic barrier in particular should prompt consideration of alternative techniques that might result in a successful airway. However, in cases in which no alternative method of airway management is likely to be successful or timely enough, cricothyrotomy should be performed without hesitation. The same principles apply for both the cricothyrotomy and percutaneous transtracheal ventilation. Percutaneous transtracheal ventilation is the surgical airway method of choice for children younger than 10 years of age. The cricothyrotomes have not been demonstrated to improve success rates or time or to decrease complication rates when compared with surgical cricothyrotomy. As with formal cricothyrotomy, experience, skill, knowledge of anatomy, and adherence to proper technique are essential for success when a cricothyrotome is used. The large size and cutting characteristics of the insertion part of the cricothyrotome are likely to cause more damage in the neck than either an open cricothyrotomy or a Seldinger-based technique.

B. Procedure

1. Equipment

Tracheostomy tubes are made in a variety of designs and materials.[15] They may have a single lumen, but many have an inner cannula that can easily be removed to allow routine cleaning and prevention of mucous obstruction. Most tubes also come with a blunt-tipped obturator that is used to facilitate insertion and reduce trauma. The tubes may be rigid or flexible and kink resistant, and they may have variable curves, angles, and sizes, depending on the anatomic needs of the patient. Tracheostomy tubes are secured with twill or with a padded fastener that goes around the neck and attaches to the neck plate of the tube. Tubes may be cuffed or uncuffed. Cuffs should be kept at inflation pressures of 20 to 25 mm Hg, but over the short term, inflation can be judged by palpation of the reservoir balloon.[49] Underinflation can increase aspiration, whereas high cuff pressures can cause mucosal ischemia and subsequent tracheal stenosis or tissue necrosis.

It is critical that whatever surgical technique is chosen, the instrument and its location are familiar to the airway providers. The kit needs to be easily accessible, compact, and ideally located in a DA cart that is positioned in the room or otherwise readily accessible (Fig. 31-3). The operating room tracheostomy surgical trays are not appropriate for this purpose because of their size and complexity. It is recommended that a custom

Figure 31-3 A simply organized cricothyrotomy tray with tracheal hook, Trousseau dilator, scalpel, and tracheostomy tube. (Photograph courtesy of R.M. Walls, Boston, MA)

Box 31-2 Recommended Contents of Cricothyrotomy Kit

A. Trousseau dilator
B. Tracheal hook
C. Scalpel with No. 11 blade
D. Cuffed, nonfenestrated No. 4 Shiley tracheostomy tube
E. Several 4 × 4 gauze sponges, 2 small hemostats, surgical drapes

From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.

cricothyrotomy kit be assembled with the components listed in Box 31-2 or that a commercial kit designed for this purpose be utilized. A commercial kit has become available that offers both the Seldinger technique and the necessary instruments for a surgical cricothyrotomy with a cuffed tracheostomy tube all in one system (Fig. 31-4).

2. Landmarks

The CTM is the anatomic site of access in the emergent surgical airway, regardless of the technique used. The CTM is identified by first locating the laryngeal prominence of the thyroid cartilage. This may be easier to appreciate in males because of their more prominent thyroid notch. Approximately 1 to 1.5 patient finger breadths below the laryngeal prominence, the membrane may be palpated in the midline of the anterior neck as a soft depression between the inferior aspect of the thyroid cartilage above and the rigid cricoid ring below. The thyrohyoid space, which lies superior to the laryngeal prominence and inferior to the hyoid bone, should also be identified. This space should be distinguished from the CTM to avoid misplacement of the tracheostomy tube above the vocal cords. In children, the CTM is disproportionately smaller because of a greater overlap of the thyroid cartilage over the cricoid cartilage. For this reason, cricothyrotomy is not recommended in children younger than 10 years of age.

The same anatomic or physiologic abnormalities (i.e., trauma, morbid obesity, congenital anomalies) that precipitated the surgical airway may also hinder easy palpation of landmarks. The location of the CTM can be estimated by placing four fingers on the neck, vertically, with the small finger in the sternal notch. The membrane is approximately located under the index finger, and this can serve as a point at which the initial incision is made. A vertical skin incision is preferred in the emergent situation because of the location of major blood vessels as well as ease in locating the membrane. Palpation through the vertical incision can then confirm the location. Identification may be assisted by using a locator needle attached to a syringe containing saline or lidocaine. Aspiration of air bubbles suggests entry into the airway, but this does not distinguish between the CTM and an intertracheal space.

Although palpation of the CTM is easily performed on most patients, the particular condition creating the airway difficulty may obscure traditional landmarks. The urgency and anxiety associated with a failed airway may further compound this difficulty. Therefore, it is the practice of some anesthesiologists to mark the skin overlying the approximate location of the CTM before the procedure begins if a possible DA is anticipated. Routinely palpating the CTM on patients is also recommended to become familiar with the landmarks.

Figure 31-4 A Melker Universal Cricothyrotomy Set combines capability for a percutaneous, Seldinger-based cricothyrotomy *(right side)* with a simple instrument set for a full surgical cricothyrotomy *(left side)*. The same cuffed tracheostomy tube is used for either technique, but a blunt introducing cannula is substituted when surgical insertion is desired. C. Surgical Cricothyrotomy Techniques

1. Traditional Surgical Cricothyrotomy: The "No-Drop" Technique

a. PREPARATION OF THE NECK

Appropriate antiseptic solution should be applied and sterile technique observed as much as possible. The procedure should not be delayed if time does not allow ideal preparation. Suction, a bag-valve-mask, and oxygen should be immediately available. The tracheostomy tube should be opened and prepared for insertion at this time. There may be circumstances (e.g., conscious patient) in which it is desirable to infiltrate the skin and subcutaneous tissues with 1% lidocaine. The operator may wish to localize the membrane at this time using a 20-G needle. On aspiration of air into syringe, lidocaine can be injected into the airway. The injection precipitates a cough in the patient with intact airway reflexes; however, this serves to disperse the lidocaine and diminish further stimulation in the conscious patient. Caution is advised in patients with potentially unstable cervical spine injuries.

b. LANDMARK IDENTIFICATION

An emergent cricothyrotomy is best thought of as a procedure that is done by touch rather than by visualization. The identification of the external landmarks before initiating the incision and the use of a method to maintain knowledge of the anatomic relationships (see later discussion) are keys to success. The operator should be positioned on the same side of the patient as the operator's dominant hand (i.e., the hand that will be used to make

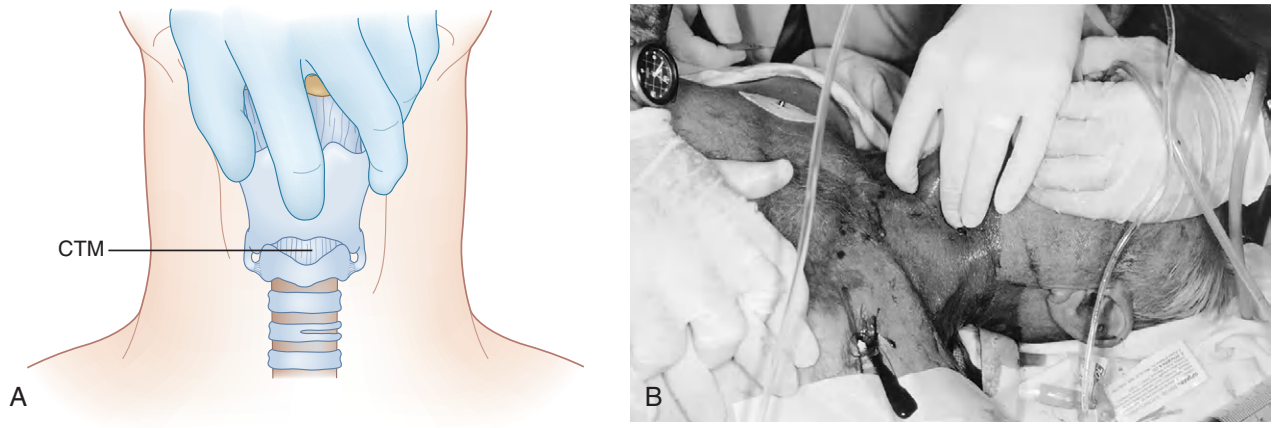

Figure 31-5 **A** and **B,** With the superior cornua of the larynx firmly immobilized by the thumb and long finger of the nondominant hand, the index finger is free to palpate and locate the cricothyroid membrane *(CTM).* (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

the incisions); for example, a right-handed operator stands to the patient's right. After identification of the laryngeal prominence, the superior horns of the thyroid cartilage are firmly grasped between the thumb and long finger of the nondominant hand. This leaves the index finger ideally positioned to localize the CTM and re-identify its location at any time during the procedure by capitalizing on the constancy of the relationship as long as the thyroid cartilage is not released. Therefore, it is critical that control of the larynx with this hand be maintained until the placement of the tracheal hook (Fig. 31-5).

c. VERTICAL SKIN INCISION

The operator uses the dominant hand to make a generous vertical incision in the midline, with its center over the CTM. The incision should be at least 2 cm in length and may need to be extended in patients with significant obesity or if identification is difficult. The incision should go through subcutaneous tissues down to, but not into, the thyroid and cricoid cartilages (Fig. 31-6).

d. CONFIRMATION OF MEMBRANE LOCATION

With the thumb and long finger maintaining control of the thyroid cartilage, the index finger may now be inserted into the incision. Without interposed skin and tissues, it is much easier to appreciate the structures of the anterior neck and to confirm the location of the CTM. The index finger can be left in the wound, resting on the inferior aspect of the anterior larynx, indicating the superior limit of the CTM (Fig. 31-7).

e. HORIZONTAL INCISION OF THE CRICOTHYROID MEMBRANE

The index finger may be withdrawn just prior to incision or left in the wound to serve as a guide. The CTM should be incised horizontally for a distance of 1 to 2 cm (Fig. 31-8). It is recommended that an attempt be made to incise the lower half of the membrane to avoid the superiorly placed cricothyroid artery and vein. This can be difficult to achieve, and inadvertent injury to these vessels is rarely clinically significant. Despite the exposure obtained with the skin incision, bleeding from the skin and various vascular structures eliminates a clear view of

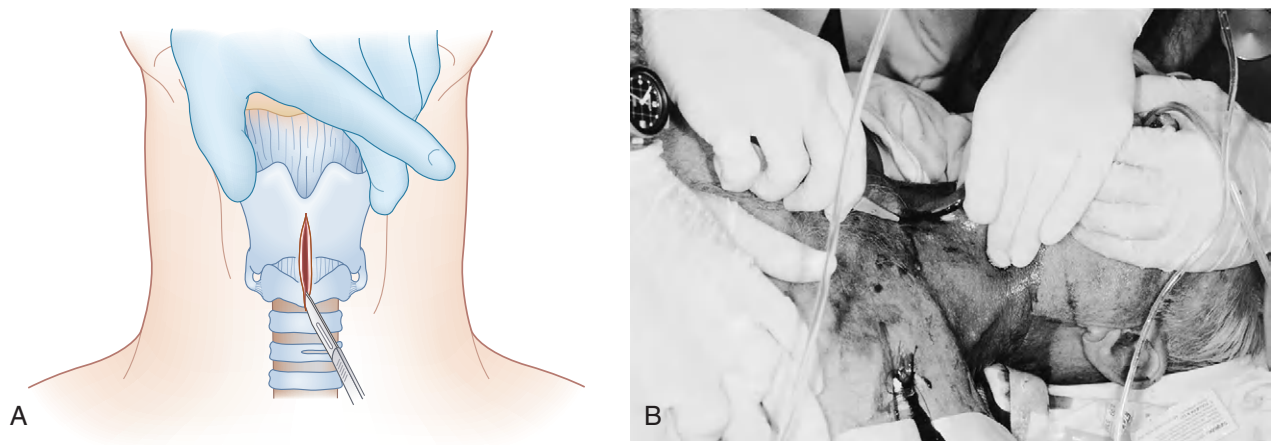

Figure 31-6 **A** and **B,** A vertical skin incision is made down to, but not through, the airway. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

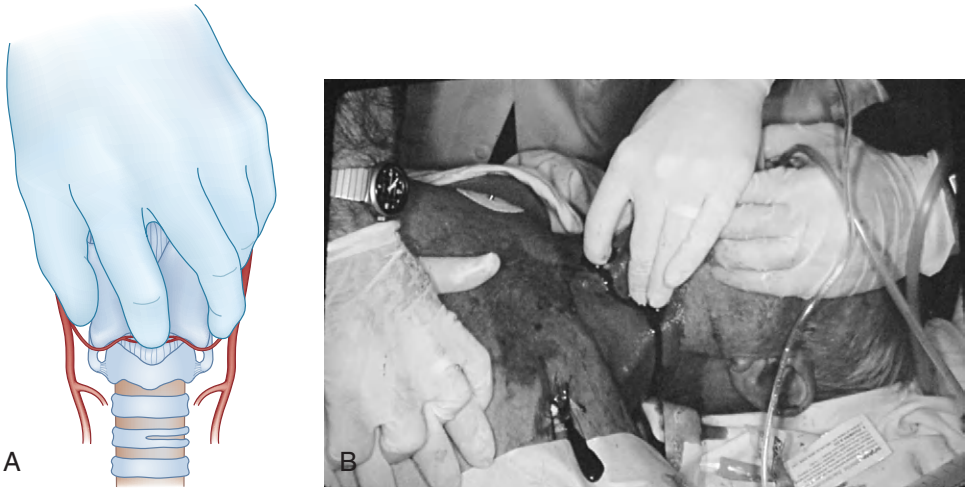

Figure 31-7 **A** and **B,** The index finger can now directly palpate and relocate the cricothyroid membrane. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

the field in most cases. Time does not permit the operator to attempt to deal with bleeding so as to achieve a bloodless field. Maintenance of the anatomic relationships outlined previously allows the procedure to be completed expeditiously without the need for direct visualization of the structures of interest. If significant bleeding occurs, it can be dealt with (usually by simple wound packing) after the airway has been secured.

Attempts at ventilation (which have to be discontinued at this point) may result in the presence of air bubbles appearing in the wound and tissues of the neck in synchrony with respirations. The index finger may also be reinserted into the opening to confirm the proper location of the incision in the membrane.

f. INSERTION OF THE TRACHEAL HOOK

Laryngeal control should be maintained with the thumb and long finger of the nondominant hand. The hook is held in the dominant hand, turned so that it is oriented transversely, and then inserted into the trachea through the surgical opening (Fig. 31-9). The index finger of the nondominant hand can serve as a guide to help place the hook into the incision. Once through the CTM, the device hook is rotated so that the hook is oriented in the cephalad direction. The hook is firmly applied to the inferior border of the thyroid cartilage, and gentle upward and anterior traction with the hook handle at a 45-degree angle to the anterior neck skin can be used to bring the airway up to the skin (Fig. 31-10). The hook is then passed to an assistant to maintain immobilization and control of the larynx. The assistant will not release the hook under any circumstance until a definitive airway has been successfully inserted and placement is confirmed; thus the term "no drop technique." The operator's nondominant hand may then be released for completion of the procedure, with the proviso that the tracheal hook is maintaining control and should not be removed until confirmation of tube placement has been obtained.

g. DILATION OF THE OPENING WITH DILATOR

The Trousseau dilator is then inserted using the dominant hand. It is our preference to insert the dilator so that the

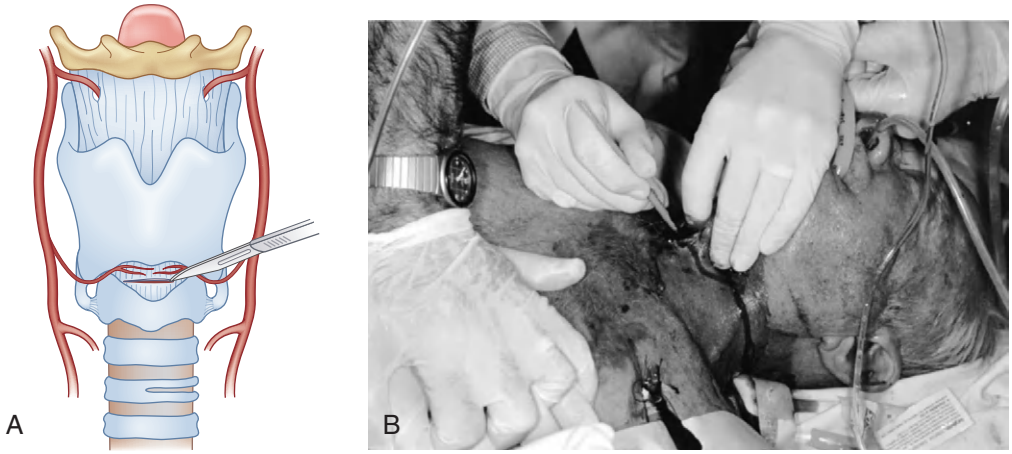

Figure 31-8 **A** and **B,** A transverse incision is made in the cricothyroid membrane staying low to attempt to avoid the cricothyroid artery and vein. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

Figure 31-9 The tracheal hook is inserted into the wound, oriented transversely, and then rotated to pick up the inferior edge of the thyroid cartilage. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

prongs are oriented to dilate the opening in the rostral-caudal direction rather than transversely (Fig. 31-11). Although the dilator appears to be designed to insert directly into the airway and dilate transversely, it is the rostral-caudal dimension of the CTM that provides the most resistance to cannulation, so it is desirable to dilate in this plane. The Trousseau dilator is inserted only a couple of millimeters into the airway and then opened to dilate the airway. With the airway thus opened, the dilator, in situ, is transferred from the operator's dominant hand to the nondominant hand, where it can be held from underneath (see Fig. 31-11). This frees the dominant hand to insert the tracheostomy tube.

h. INSERTION OF THE TRACHEOSTOMY TUBE

The tracheostomy tube is then inserted with the obturator in place (Fig. 31-12). To avoid unnecessary delays at this juncture, the tube should have been removed from its packaging before initiation of the procedure and the blunt-tipped obturator should already have been inserted. The tube is oriented along the handle of the dilator (i.e., at a 90-degree angle to the patient) and inserted between the dilator blades, following their natural curve. As the tracheostomy tube gains the airway and is passing between the prongs of the Trousseau dilator, it is helpful to rotate the dilator handle counterclockwise 90 degrees (see Fig. 31-12) so that the dilation occurs in the transverse rather than the rostral-caudal dimension. The reason is that when the tracheostomy tube has gained access into the airway, the prongs of the Trousseau dilator may themselves inhibit successful passage of the tip of the tracheostomy tube down the trachea. Through rotation of the Trousseau dilator, the prongs are moved out of the way to either side of the tube, but dilation is continued to assist in placing the tracheostomy tube until it is firmly seated against the anterior neck. The dilator is gently removed as the tube is being advanced, just before it is seated in its final position (Fig. 31-13).

i. CUFF INFLATION AND SECURING THE TRACHEOSTOMY TUBE

The cuff should be inflated. The obturator is then removed, and the inner cannula, if one is present, is inserted to allow the attachment of the ventilation bag. Care must be taken during the initial assembly of the tracheostomy tube not to lose track of the inner cannula, which is needed for the attachment of ventilation devices. The tracheostomy tube can be secured with twill or with a padded fastener that goes around the neck and attaches to the neck plate of the tube.

j. CONFIRMATION OF TUBE POSITION

The tracheostomy tube position can be confirmed using the same methods as those used to confirm ETT position. Carbon dioxide detection can be used to confirm correct placement in the airway. If there is concern that the tube is placed outside the trachea, a nasogastric tube may be gently inserted. In the airway the tube advances easily, but resistance is met if the tube is in a false passage. Auscultation of both lungs and the epigastric area is also recommended, although esophageal placement of the tube is highly unlikely. A chest radiograph can be helpful in the identification of barotrauma. Only after the position of the tube is certain should the tracheal hook be

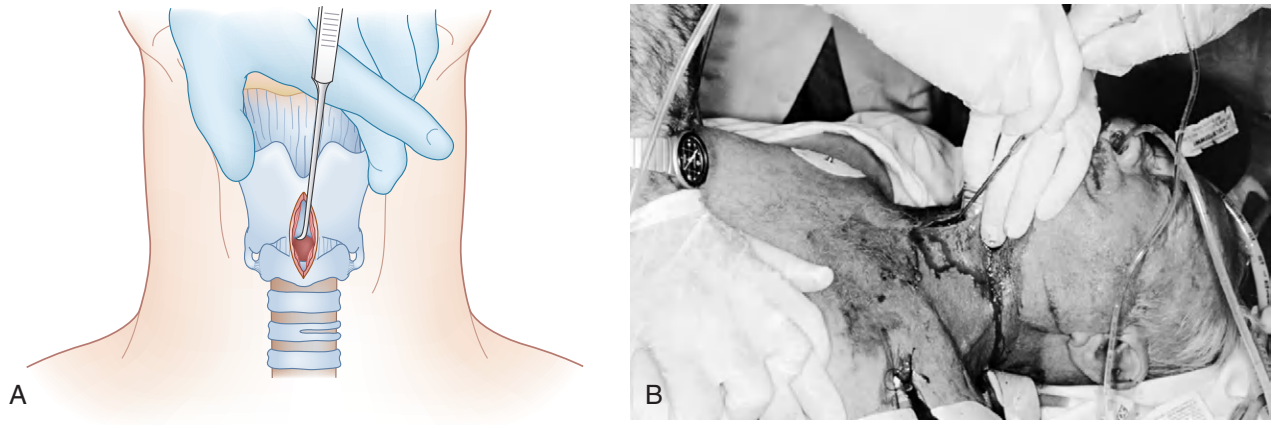

Figure 31-10 **A** and **B,** The tracheal hook exerts light traction on the inferior aspect of the thyroid cartilage. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

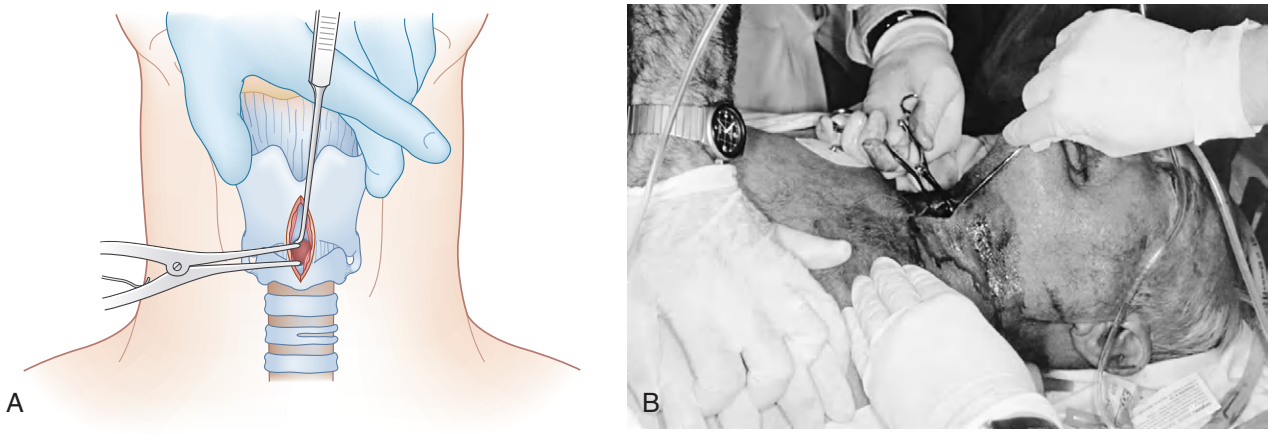

Figure 31-11 **A** and **B,** The Trousseau dilator is used to enlarge the vertical dimension of the membrane, the aspect providing the most resistance to insertion of the tube. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

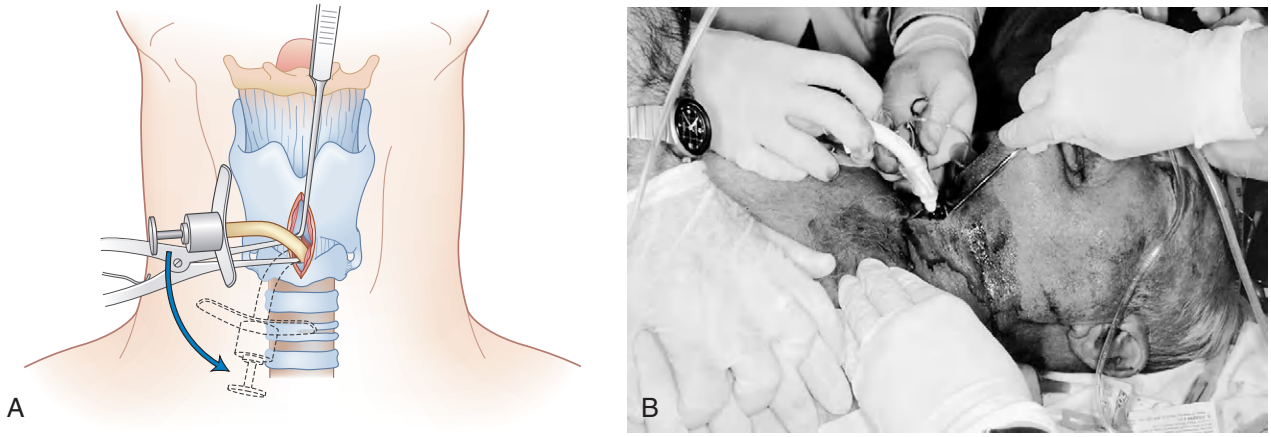

Figure 31-12 **A** and **B,** The tracheostomy tube is inserted, and the dilator can then be rotated counterclockwise 90 degrees to facilitate passage of the tube. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

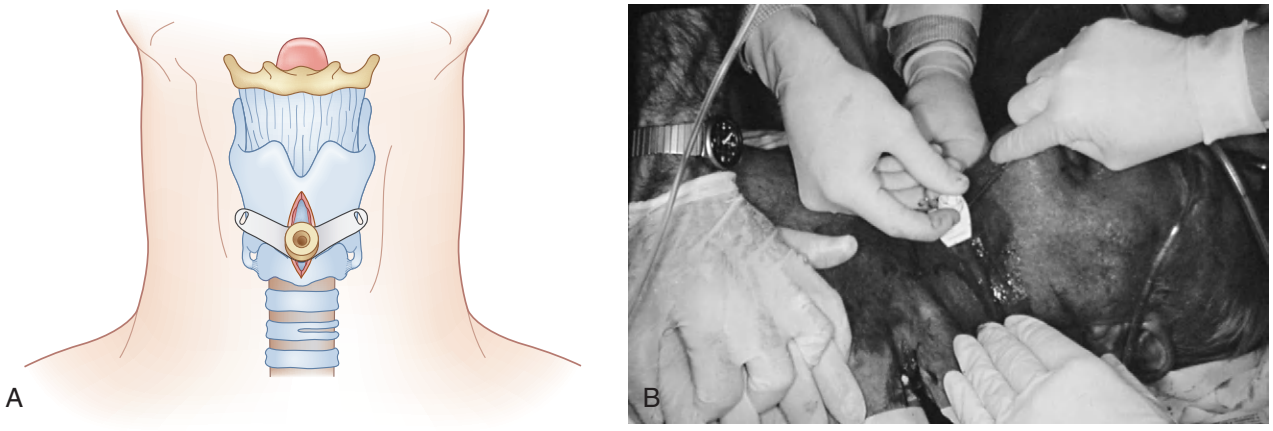

Figure 31-13 **A** and **B,** The tube is firmly seated, and the dilator can be removed. It is best to leave the hook in situ until placement is confirmed and the cuff has been inflated. (**A** adapted from and **B** from Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

removed. This should be done with great care to avoid hooking a part of the tracheostomy tube and inadvertently extubating the patient. If the tube was inadvertently placed in a false passage, correction is greatly facilitated with the hook still in place.

2. Rapid Four-Step Technique

The rapid four-step technique (RFST) is an attempt to simplify the cricothyrotomy procedure by using a horizontal stab incision through the skin and membrane simultaneously, followed by tracheal hook traction applied caudad at the cricoid ring.[16] Cadaveric studies have shown RFST to be simple to learn and faster in obtaining a surgical airway than the open technique just described.[50-52] Other advantages include the following: (1) less equipment is necessary (it is performed with a scalpel, hook, and tracheostomy tube); (2) it may be performed independently; and (3) the operator is positioned at the head of the bed, similar to the stance for performance of orotracheal intubation.

Acute complications from RFST may be more common than with the traditional "no-drop" method. The stab technique may increase the incidence of trauma to the posterior trachea and anterior aspect of the esophagus. In cadaveric models, an increase in damage to the cricoid ring due to direct traction on the ring with the tracheal hook was found.[1,50-52] This may be remedied through the use of a double-hook device that disperses the forces across the cricoid ring.[1,51]

RFST may not be as desirable in patients in whom landmark identification is difficult. In this circumstance, we recommend beginning with a vertical incision, similar to the traditional technique described previously.[16] There are no clinical studies that report the success rates and associated acute and delayed complications of RFST compared with traditional methods in live patients. The choice between the RFST and the traditional technique is an individual one, because there is no clear evidence that either method is superior or more likely to bring success than the other.

As with other techniques, attempts should be made to oxygenate and ventilate the patient maximally before and during the procedure. The anterior neck should be prepared as described earlier for the "no-drop" technique. From a position at the head of the bed, RFST is performed in the following manner.

a. LANDMARK IDENTIFICATION

As in traditional cricothyrotomy, the airway is accessed through the CTM. Therefore, the identification of landmarks is exactly the same as described previously (Fig. 31-14; see Fig. 31-5). Because of the horizontal stab incision, however, it is even more critical to be confident of the location of the membrane. If there is uncertainty, it is recommended to begin with a vertical incision first, as described earlier.

b. HORIZONTAL STAB INCISION

A single horizontal stab incision using a no. 20 scalpel is made directly through the skin, subcutaneous tissues, and CTM. The incision should be approximately 1.5 cm wide, and because of the size of the no. 20 blade, widening of the opening is rarely required (Fig. 31-15). If the anatomy is not readily palpable through the skin, an initial vertical incision should be created to allow subsequent palpation of the anatomy and identification of the CTM. Once the CTM has been incised, the no. 20 blade is maintained in the airway until the tracheal hook is secured.

Figure 31-14 The landmarks are palpated as for the "no-drop" technique, but the horizontal skin incision leaves little room for error, so extra care is needed. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management*, ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

c. STABILIZATION OF THE LARYNX WITH THE TRACHEAL HOOK

A tracheal hook is placed parallel to the scalpel on the caudal side of the blade (Fig. 31-16). The hook is rotated to secure and control the cricoid ring, and the scalpel is then removed from the airway. The tracheal hook is used to apply gentle traction on the cricoid ring to lift the airway up toward the surface of the skin and to provide modest stoma dilation (Fig. 31-17). The direction of force on the hook is reminiscent of the "up and away" direction

Figure 31-15 A single, horizontal, stab incision is made through skin and membrane. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management*, ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

Figure 31-16 The hook is oriented transversely and inserted alongside the scalpel before the scalpel is removed. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

Figure 31-18 The tracheostomy tube is inserted and then verified and secured in the usual fashion. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

employed with laryngoscopy. The amount of traction force required for easy intubation (18 newtons) is significantly lower than the force that is associated with breakage of the cricoid ring (54 newtons); however, the chance of trauma may be further reduced by using a double-tined hook.[1] Use of the hook in this direction usually provides sufficient widening of the incision to obviate the need for further dilation (i.e., Trousseau dilator). Placement of the hook on the cricoid ring may also reduce the possibility of intubating the pretracheal potential space, which is essentially eliminated due to the apposition of the airway and the subcutaneous fat by the traction on the hook.

d. INSERTION OF THE TRACHEOSTOMY TUBE

With adequate control of the airway using the hook placed on the cricoid ring, a tracheostomy tube is gently inserted through the cricothyroid space into the trachea (Fig. 31-18). The cuff is then inflated, the tube is secured, and its location is confirmed by the same methods described earlier.

Figure 31-17 The hook exerts traction on the superior aspect of the cricoid cartilage and skin, pulling the airway up into the field. (From Walls RM, Luten RC, Murphy MF, Schneider RE: *Manual of emergency airway management,* ed 2, Philadelphia, 2004, Lippincott Williams & Wilkins.)

3. Percutaneous Cricothyrotomy Techniques

Numerous commercial cricothyrotomy devices are available, many of which use a modified Seldinger technique to assist in the placement of a tracheal airway (see Fig. 31-4). There are aspects of this technique that may make it appealing to the anesthesiologist. This method is similar to the one commonly used for placement of central venous catheters and offers some familiarity to the operator who is uncomfortable or inexperienced with the surgical cricothyrotomy technique described earlier. This technique can be learned quickly. By the fifth practice attempt on a mannequin model, 96% of anesthesiologists achieved success within 40 seconds.[6] However, the technique still requires knowledge of the anatomy and the ability to localize the membrane and has several steps, so it approaches the open technique in complexity. When compared with the standard open technique in cadavers and dog models, there were no differences in performance times or complications.[53-55] It is estimated that the procedure may be accomplished in 40 to 100 seconds.[6,27,53-55] Also, the percutaneous cricothyrotomy kits are preassembled and commercially available, whereas at present the surgical tools used in the traditional approach are not (except in the combination kit shown in Fig. 31-4). It seems intuitive that the percutaneous technique should result in less bleeding, but no studies have been performed to assess the significance of any difference. One of the limitations is the relatively smaller lumen, which is of no real concern in an emergency, and in some models the absence of a cuff, which could be an issue if airway protection from emesis or hemorrhage is needed. It is suggested that a device with a cuff be selected, because many of these procedures are performed on patients who have not been fasted or are actively hemorrhaging and require further airway protection. The Melker

Figure 31-19 The finder needle is inserted through the cricothyroid membrane. A small, vertical skin incision may be made before insertion of the needle or later, just before insertion of the airway and dilator. (Photograph from STRATUS Center for Medical Simulation, Brigham and Women's Hospital, Boston, MA, used with permission.)

Figure 31-20 The wire is fed through in a caudad direction; then the needle is removed. (Photograph from STRATUS Center for Medical Simulation, Brigham and Women's Hospital, Boston, MA, used with permission.)

Cuffed Emergency Cricothyrotomy Catheter Set and the Melker Universal Cricothyrotomy Set are available with a cuffed airway catheter (Cook Critical Care).

As with other techniques, attempts should be made to preoxygenate and ventilate the patient maximally before and during the procedure. The anterior neck should be prepared as described earlier. Although the kits may vary, most of the percutaneous cricothyrotomy kits use the Seldinger technique and share the following steps.

a. LANDMARK IDENTIFICATION

The CTM is identified using the same methods described previously. The nondominant hand is then used to control the larynx and maintain identification of the landmarks.

b. INSERTION OF LOCATOR NEEDLE

The introducer needle is then inserted through the skin and the CTM in a slightly caudal direction. The needle is attached to a syringe and advanced with the dominant hand while negative pressure is maintained on the syringe. The sudden aspiration of air indicates placement of the needle into the tracheal lumen (Fig. 31-19).

c. INSERTION OF THE GUIDEWIRE

The syringe is then removed from the needle, and a soft-tipped guidewire is inserted through the needle into the trachea in a caudal direction. The needle is then removed, leaving the wire in place. As with most Seldinger techniques, control of the wire must be maintained at all times (Fig. 31-20).

d. SKIN INCISION

A small skin incision is then made adjacent to the wire. This facilitates passage of the airway device through the skin. Alternatively, the skin incision may be made vertically over the membrane before insertion of the needle and guidewire.

e. INSERTION OF THE AIRWAY

The airway catheter provided in the kit (3 to 6 mm internal diameter), with an introducing dilator in place, is then inserted over the wire into the trachea. If resistance is met, the skin incision should be deepened and a gentle twisting motion applied to the airway device (Fig. 31-21). After the airway device is firmly seated against the skin, the wire and obturator are removed together, leaving the tracheostomy tube in place. Tube location should then be confirmed, as described previously, and secured properly. The devices are radiopaque.

IV. TRAINING ISSUES

A survey published in 1995 found that although 80% of anesthesiology programs taught cricothyrotomy as part of their curriculum, most of them did so through lectures only, with no practical experience.[21] In a survey published in 2003, only 21% of anesthesiologists claimed skills to perform cricothyrotomy.[56] Most anesthesiology graduates have never performed a cricothyrotomy during their training.[6]

The merits of a procedure are irrelevant if hesitancy on the part of the provider leads to a significant delay in establishing a definitive airway. Discomfort with a procedure is usually overcome with technical proficiency obtained through stepwise practice; however, this procedure is performed so rarely that proficiency must be obtained through scheduled, simulated learning. Invasive airway methods, like any other invasive procedures, must be learned and practiced at regular intervals to maintain proficiency.

The advent of emergency medicine as a specialty with its own airway expertise has resulted in a significant decrease in exposure to emergency airways for anesthesiology trainees. The success of RSI in the emergency setting, as well as advances in airway management techniques in anesthesiology, have prompted editorials concerned with the problem of gaining and maintaining competence in invasive airway management.[57-59] Studies suggest a current cricothyrotomy rate of approximately 1% of all emergency airways and a dramatically lower rate in the operating suite. Regardless of the setting, this incidence is too low to ensure adequate training, but it

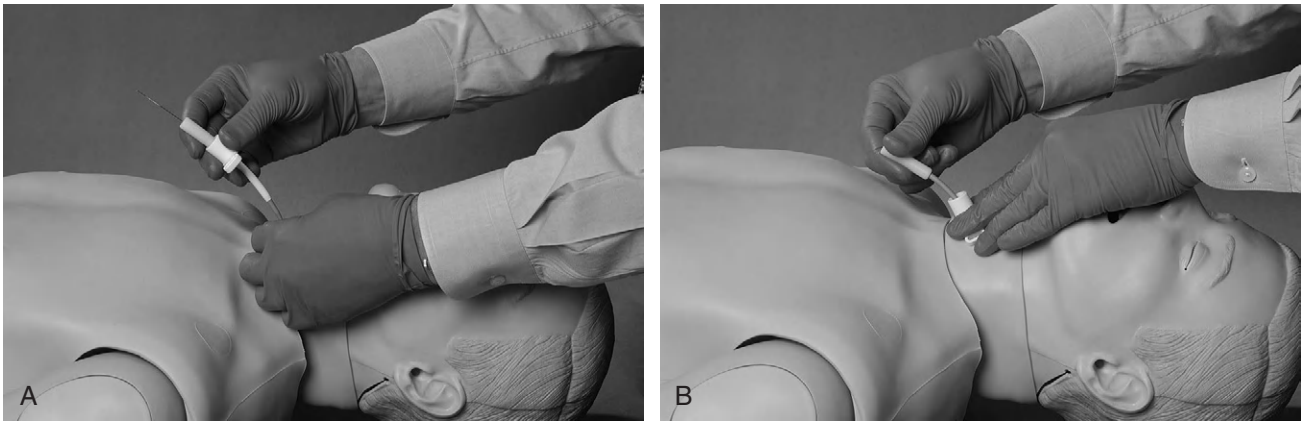

Figure 31-21 **A,** The airway is inserted over the guidewire with the dilator in place. **B,** The dilator and wire are then removed together. (Photograph from STRATUS Center for Medical Simulation, Brigham and Women's Hospital, Boston, MA, used with permission.)

highlights the probability that most airway managers will be called on to perform an invasive airway at some point in their career.

The practice required to obtain familiarity with the equipment and technique must take place outside the clinical setting. Of anesthesiology programs that instruct their residents on cricothyrotomy, 60% use lectures only, which is a poor teaching technique for developing proficiency in manual skills.[21] One study using a mannequin model determined that five cricothyrotomies were necessary to reach a steady performance state in which the procedure could be completed in 40 seconds.[25]

No studies have identified the optimal interval between training episodes for retention, although one small report suggested increased retention when training was repeated monthly versus every 3 months.[38] Studies in cadavers performed primarily to compare different surgical airway techniques incidentally identified a similar rapid learning curve.[60,61] There are no studies examining the clinical correlation of these training techniques, but the high success rate of emergency cricothyrotomy suggests that retention and competence have occurred.

On the basis of the limited available literature, some recommendations regarding the learning and retention of invasive airway techniques can be made: (1) identify a preferred method of invasive airway management that is immediately available; (2) become trained in the procedure by performing a sufficient number of repetitions under the supervision of a qualified instructor, using an animal or simulator model, or both; and (3) practice the technique in one to two refresher sessions per year on animal or simulator models, with five repetitions per session.

Animal tracheas may be obtained from a slaughterhouse at relatively low cost, and the technique may be attempted multiple times on each specimen (pigs and sheep are most commonly used). Simulators represent a significant capital investment, but newer simulators are much less expensive and much simpler to operate than older models. Models specifically for cricothyrotomy training are also available. Formal training under expert guidance is available through some difficult airway continuing medical education (CME) courses.

V. CHOOSING THE RIGHT TECHNIQUE

As described in the introduction, the typical clinical milieu in which an emergency surgical airway is performed will inevitably be impacted by four simultaneous challenges: (1) the patient will be compromised; (2) there will be very little time to establish the airway; (3) few, if any, other options will remain if the procedure is unsuccessful; and (4) the operator will have limited experience with the technique. It therefore becomes imperative to select a method with the highest likelihood of success and the lowest complication rate.

Guidance from the literature on choosing the best technique is limited and difficult to translate into clinical practice. There are no human studies comparing the various surgical airway techniques. The available comparative evidence is based almost entirely on studies using animal, cadaveric, or mannequin models.

Acknowledging this limitation, several generalizations can be made:

- Dilational techniques that rely on direct puncture into the airway are associated with an unacceptably high rate of complications, including injury to airway structures and catheter misplacement.[28-31] These techniques cannot be recommended unless other options are unavailable.
- The success rates of open surgical and percutaneous guidewire (Seldinger) cricothyrotomy are roughly comparable.[62]
- The complications associated with open surgical and Seldinger cricothyrotomy are distinctly different. When complications arise with open surgical cricothyrotomy, bleeding or injury to airway structures is the predominant problem. With Seldinger cricothyrotomy, the most common complication is misplacement of the airway into the pretracheal or paratracheal spaces.[62]

Equipment availability, experience, and backup resources play a significant role in technique selection. In weighing the priorities at hand when performing an emergent surgical airway, the prime directive must always be successful placement of the airway. Based on the third generalization, confidence with the identification of surgical airway landmarks becomes a critical question in the decision-making process.

If surgical airway landmarks are easily identifiable, the clinician can confidently employ whichever technique he or she feels most comfortable performing. Conversely, if airway landmarks are difficult or impossible to palpate (e.g., in a patient with morbid obesity), the Seldinger technique has a predictably high rate of airway misplacement. If a definitive airway is urgently needed in this situation, the open technique is preferred. Another option is to perform a hybrid technique during which a formal vertical skin incision is made to better palpate the CTM, and the technique is then continued using the Seldinger method.

VI. COMPLICATIONS

The rate of complications associated with emergency cricothyrotomy is difficult to quantify with precision. A critical review of the literature reveals that many of apparent complications are the result of the patient's underlying illness or occur as a consequence of the unsuccessful attempts at airway management preceding cricothyrotomy. In addition, the definition of complications, variations in technique, and the skill of the operators vary widely from study to study.

With these limitations in mind, the complication rate after surgical cricothyrotomy is highly variable, ranging from 14% to 50% depending on the technique, clinical setting, definition of complications, and experience of the operator.[2,9,18,52,63-67]

A. Hemorrhage

When surgical cricothyrotomy is performed, venous hemorrhage is the rule rather than the exception. This seldom interferes with successful completion of the procedure, and bleeding can usually be controlled with direct pressure or postprocedure suture closure of the incision. Major arterial hemorrhage can result from inadvertent laceration of the thyroid ima artery located near the isthmus of the thyroid, but this would require considerable misplacement of the skin incision from that described here. If the dissection strays far from the midline, the carotid artery or jugular vein can be injured. Arterial bleeding is distinctly unusual if the procedure is performed as described previously. Although it may seem intuitive that bleeding would be less likely after percutaneous cricothyrotomy, this has never been assessed in randomized human trials.

B. Tube Misplacement

Tracheostomy tube misplacement is the most important potential complication of both surgical and percutaneous cricothyrotomy. Whether it is considered a complication or a failure of the procedure, inadvertent placement of the tube in either the pretracheal or paratracheal soft tissues can be a lethal error. If ventilation is attempted before misplacement is recognized, massive subcutaneous emphysema and distortion of the neck can ensue, making subsequent efforts to gain the airway extremely difficult. This is perhaps the strongest argument for the use of surgical (rather than percutaneous) cricothyrotomy; in the former, the entry into the airway is confirmed by palpation and by direct insertion of the hook, dilator, and tracheostomy tube through an open incision.

C. Accidental Extubation

Replacing a decannulated tube into a recently performed tracheostomy can be extremely difficult, and great care must be taken to ensure that decannulation does not occur. Tracheostomy ties should be applied immediately after tracheal entry has been confirmed by capnography and under the direct supervision of the operator. Additional care should be taken to prevent excessive neck movement or entanglement by monitor lines or intravenous tubing if the patient is being transported. Violent coughing or exaggerated neck movement may also cause the tube to dislodge, and the patient should be appropriately sedated. Finally, self-extubation can occur if the patient is not unconscious or sedated.

D. Other Complications

Injury to the posterior laryngeal wall or esophagus can occur if an excessively deep incision is made when entering the airway. This is easily avoidable, provided careful technique is used. Insertion of a cricothyrotome adjacent to or through the airway can result in significant local tissue damage, including vascular injury and esophageal injury.

VII. CONCLUSIONS

Surgical cricothyrotomy is a rare procedure that is often performed by clinicians with little or no experience in situations in which a patient cannot be intubated via the orotracheal route and rescue ventilation has not been successful. Several different techniques are described in the literature, including open surgical or percutaneous (Seldinger or dilational percutaneous) technique. Each technique is a viable option. Which technique is chosen is based on provider comfort and the equipment available. Children younger than 10 years of age are a unique patient population in which the anatomy precludes traditional surgical or percutaneous cricothyrotomy and a transtracheal catheter-based procedure should be considered the method of choice. It is critical that any clinician who manages the airway in a patient have the knowledge and ability to perform a surgical cricothyrotomy or catheter-based procedure.

VIII. CLINICAL PEARLS

- New technology and improved skill in performing direct laryngoscopy have reduced the need for

emergent surgical cricothyrotomy, and this has implications for skill retention among physicians managing airways in the emergency setting.

- Surgical cricothyrotomy is indicated in the "cannot intubate, cannot ventilate" (CICV) situation, in which direct laryngoscopy and rescue techniques have failed.
- Surgical cricothyrotomy can be performed via a percutaneous Seldinger technique or an open technique, and there is few data on which method is optimal.
- The presence or absence of adequate anatomic landmarks can help guide the clinician with technique selection. If the cricothyroid membrane is easily identifiable, either method can be used. If landmarks are difficult to identify (e.g., in obese patients), the open technique is more likely to be successful.
- Needle cricothyrotomy is preferred in children younger than 10 years of age because of the unique anatomic differences (i.e., small cricothyroid membrane) in this patient population.

I. OVERVIEW

A. American Society of Anesthesiologists Closed Claims Studies

For the past several decades, the Committee on Professional Liability of the American Society of Anesthesiologists (ASA) has studied adverse anesthetic outcomes based on closed claims files of nationwide insurance carriers.[1] From the beginning, it was evident that adverse outcomes involving the respiratory system constitute the single largest class of injury, representing one third of the overall claims. Generally involving healthy adults undergoing nonemergency surgery with general anesthesia, three mechanisms of injury accounted for approximately three quarters of the adverse respiratory events in the 1970s and early 1980s: inadequate ventilation (38%), esophageal intubation (18%), and difficult endotracheal intubation (DI; 17%). The remaining adverse respiratory events were produced by a variety of low-frequency (≤2%) mechanisms, including airway obstruction, bronchospasm, aspiration, premature and unintentional extubation, inadequate inspired oxygen delivery, and endobronchial intubation.[1]

Care was judged to be substandard in more than 80% of the cases of inadequate ventilation and esophageal intubation. Almost all (>90%) of the claims for inadequate ventilation and esophageal intubation were considered preventable with better monitoring, compared with only 36% of claims for DI. Death and permanent brain damage were more frequent in claims for inadequate ventilation and esophageal intubation (>90%) than in claims for DI (56%). Median payments were $240,000 for inadequate ventilation, $217,000 for esophageal intubation, and $76,000 for DI.[1]

In 23% of the claims for esophageal intubation, there was documentation of DI; in 73%, there was sufficient information to reconstruct the time to detection of esophageal intubation. Within this latter subset, 3% of esophageal intubations were detected within 5 minutes, 61% in 5 to 10 minutes, and 36% after 10 minutes. Auscultation of breath sounds (presumed) was documented in 63% of the claims for esophageal intubation. In 48% of cases, auscultation led to the erroneous conclusion that the tube was in the trachea. This diagnostic error was eventually recognized in a variety of ways, including reexamination with direct laryngoscopy, absence of the

endotracheal tube (ETT) in the trachea at the time of an emergency tracheostomy, resolution of cyanosis after reintubation, and discovery of esophageal intubation at autopsy. Cyanosis was documented in 52% of the claims and preceded the recognition of esophageal intubation in only 34% of the cases.[1]

Because pulse oximetry and capnography have been used since the mid-1980s, data from the closed claims project were analyzed in 1999 to determine whether these monitoring modalities correlated with improvement in patients' safety. After monitoring was instituted, respiratory events decreased, primarily in claims for injuries caused by inadequate ventilation and, to a lesser extent, esophageal intubation (Fig. 32-1).[2]

1. Pediatric Versus Adult Anesthesia Closed Malpractice Claims

Outcome studies in pediatric patients revealed that adverse respiratory events constitute a leading cause of morbidity and mortality.[3-5] The ASA closed claims study provided a database to compare pediatric and adult cases in which an adverse outcome occurred.[5] The pediatric claims presented a different distribution of damaging events compared with claims of adults (Tables 32-1 and 32-2). Respiratory events and mortality rate were greater in pediatric claims.[5] Anesthetic care was more often judged "less than appropriate," and the complications more frequently were considered preventable with better monitoring. The median payment to the plaintiff was greater for pediatric claims than for adult claims. Cyanosis (49%), bradycardia (64%), or both often preceded cardiac arrest, resulting in death (50%) or brain damage (30%) in previously healthy children.[5]

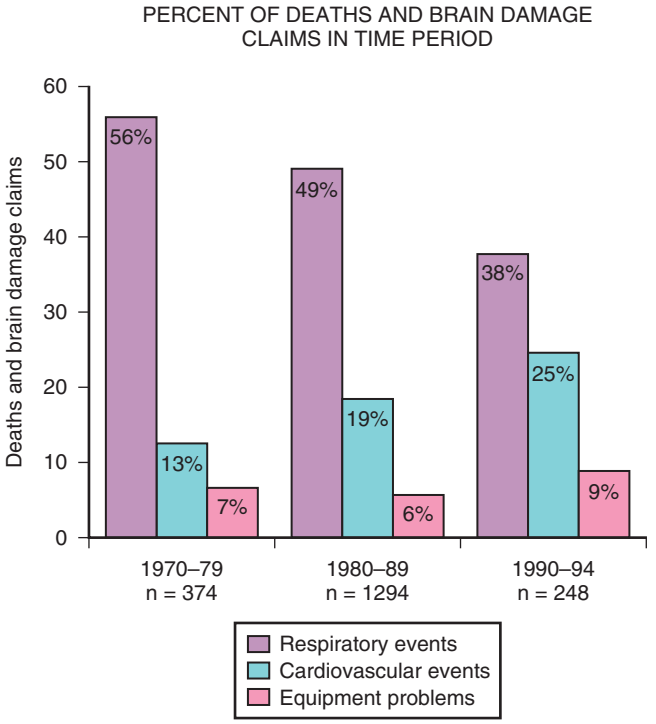

Figure 32-1 The incidence of respiratory, cardiovascular, and equipment-related damaging events as a percentage of total claims for death and brain damage in each time period ($P \leq 0.5$, Z test). (Modified from Cheney FW: The American Society of Anesthesiologists Closed Claims Project: What have we learned, how has it affected practice, and how will it affect practice in the future? *Anesthesiology* 91:552–556, 1999.)

B. The Magnitude of the Problem of Endotracheal Tube Misplacement

Outcome studies have repeatedly identified adverse respiratory events including unrecognized esophageal intubation as a leading and recurring cause of injury in anesthetic practice.[6-10] The report on confidential enquiries into maternal deaths in England and Wales in 1979-1981 revealed that 8 of 22 deaths attributable to anesthesia were related to difficulty in endotracheal intubation.[9] In 4 patients, the ETT proved to be misplaced in the esophagus.[9] An investigation of anesthesia deaths in Australia revealed that 69% were related to airway management, with esophageal intubation once again identified as an important contributing factor.[8]

All anesthesiologists experience esophageal intubations sometime in their career, especially during training and when difficulty in visualizing the larynx is encountered. Most esophageal intubations are immediately and easily recognized. What is intriguing is the rare situation in which misplacement of the ETT in the esophagus is

not recognized, resulting in grave consequences. Failure to recognize esophageal intubation is not limited to junior residents or inexperienced personnel; it has occurred with experienced anesthesiologists. A case was reported in which three "consultant anaesthetists" failed to recognize esophageal intubation.[6] There are also many case reports describing anesthetic catastrophes and near-disasters in patients whose esophagus had been unintentionally intubated and in whom some or many of the common signs indicative of proper ETT placement were misleading.[8,11-17]

Unintentional esophageal intubation occurs more frequently in emergency airway management, in critically ill patients, and in patients who suffer cardiac arrest during out-of-hospital paramedic intubation.[18-20] In one report, esophageal intubation occurred in 8% of emergency intubation attempts in critically ill patients.[20] In a study of paramedics trained in direct laryngoscopic endotracheal intubation, there were 14 esophageal intubations in 779 patients, an incidence of 1.8%.[18] Esophageal tube placement was recognized and corrected in 11 of the 14 patients; three esophageal intubations (0.4% of the total) were not recognized and remained uncorrected. In another study, 25% of tracheas intubated in the prehospital setting had improperly placed ETTs detected on arrival at the hospital.[21] Contributing factors to this high incidence of esophageal intubation include intubation under less than optimal conditions; unavailability of monitoring equipment, protocols, or algorithms; violation of the standard technique of auscultation of lung fields and the epigastrium; and intubation attempts by nonexpert personnel.[18-22]

It is obvious that grave consequences can occur if the ETT is misplaced in the esophagus or in a main stem bronchus or if inadvertent extubation occurs. Therefore, whenever endotracheal intubation is performed, clinicians should verify that the ETT is placed in the trachea and that the tube is positioned at an appropriate depth inside the trachea.

II. CONFIRMATION OF ENDOTRACHEAL TUBE PLACEMENT

A. Is There an Ideal Test for Confirmation of Endotracheal Tube Placement?

Over the years, the search has continued for an ideal test for confirmation of ETT placement. Such a test should be simple, quick, reliable, safe, inexpensive, and repeatable and should require minimal training. It should function in patients of different age groups, in various locations, and during DI. It should not yield false results, even in patients with cardiac arrest.

Unfortunately, such a perfect test does not yet exist. Many clinical signs and technical aids have been described to confirm endotracheal intubation. A number of these reports relied on the placement of two ETTs, one in the trachea and the other in the esophagus.[23-25] This scenario makes the observer's decision as to which tube is in the trachea or esophagus much easier and helps in the recognition of esophageal intubation. However, the clinician does not have the luxury of choice between two ETTs in a given clinical situation.[24,25]

In the assessment of these tests, the reader must understand what is meant by false-negative and false-positive results. Although not all reports are in agreement, most use the term *false-negative* when the ETT is in the trachea but the test fails and *false-positive* when the ETT is in the esophagus but the result mimics that of endotracheal intubation.[24,25] For capnography, a false-negative result occurs when the ETT is in the trachea but the waveform is absent, and a false-positive when the ETT is in the esophagus but the waveform is present.[24,25] To avoid confusion and to maintain conformity, these definitions are retained throughout the discussion that follows.

B. Methods of Verification of Endotracheal Tube Placement

Methods of verification of ETT placement (or detection of esophageal intubation) can be classified into nonfailsafe, almost failsafe, and failsafe types, depending on their reported reliability and specificity.

1. Non-Failsafe Methods

a. OBSERVATION AND PALPATION OF CHEST MOVEMENTS

Commonly used maneuvers to confirm endotracheal intubation are observation of symmetrical bilateral chest movements and palpation of upper chest excursions during compression of the reservoir bag. These signs can

easily distinguish tracheal from esophageal intubation in most patients. However, in obese patients, women with large breasts, and patients with a rigid chest wall, barrel chest, or less compliant lungs, these signs can be misinterpreted to indicate that the ETT is in the esophagus.[26] More important, upper chest wall movements simulating ventilation of the lungs can be seen and felt with an esophageally placed ETT. This phenomenon has been described in many instances of what ultimately proved to be esophageal intubation, and it has been reported in patients with intrathoracic hiatal hernia and after gastric pull-up operations.[11-17,26]

Pollard and Junius studied chest movements during esophageal ventilation in a male cadaver after a cuffed ETT was placed into the esophagus and attached to an inflating bag.[16] As they reported, "Chest and epigastric movements observed when the bag was compressed were indistinguishable from those normally seen in ventilation of the lungs even in the upper chest area." When the body was dissected starting with the epigastrium, it was noted that "the stomach was being inflated and was spontaneously deflating via the esophagus, the feel of the inflating bag being indistinguishable from normal pulmonary ventilation." Even when the lower end of the esophagus was occluded, "chest movements still appeared identical to those seen when the lungs are inflated." After the chest was entered, it was observed that "chest movements were caused by the flat esophagus distending into a firm tube that lifted the heart and upper mediastinal structures forward, elevating the sternum and ribs." The lifting of the chest wall by the distended esophagus is the most plausible explanation for the presumed chest movements seen during esophageal ventilation. Another possible mechanism is that gastric insufflation causes upward displacement of the diaphragm and outward movement of the lower chest. With release of bag compression, gas escapes from the stomach up the esophagus, allowing the diaphragm to move downward and the lower chest to move inward.[16]

b. AUSCULTATION OF BREATH SOUNDS

Auscultation of bilateral breath sounds is the most common method used to ensure proper ETT placement. It can be done repeatedly anywhere endotracheal intubation is performed and whenever change in the position of the tube is suspected. In almost all cases, breath sounds heard near the midaxillary lines leave very little doubt regarding the position of the ETT. However, in numerous anecdotal reports, deceptive breath sounds were heard in cases that proved to be esophageal intubation.

There are several reasons why sounds heard with esophageal intubation may mimic breath sounds from the lungs. The combination of esophageal wall oscillations with gas movement and acoustic filtering can produce inspiratory or expiratory wheezes indistinguishable from sounds arising from gas movement in the airway.[13,27,28] The high flow rate, distribution, and volume of gas delivered through the esophagus may lead to auscultation of predominantly bronchial breath sounds.[13] In infants and children, esophageal sounds can be easily transmitted to wide areas of the chest wall.[29] The quality of breath sounds may also differ depending on whether the chest is auscultated near the middle line or laterally near the axilla and may vary with the presence of pulmonary disease and from patient to patient.

Sounds retrieved by an esophageal stethoscope are different from those heard with a precordial stethoscope and should not be used to differentiate endotracheal from esophageal intuation.[16,25] In patients with a thoracic stomach or hiatal hernia, many of the clinical signs of esophageal intubation may be obscured. Because of the intrathoracic location of a large distensible viscus, bilateral breath sounds may be heard during manual ventilation.[12] For these reasons, whenever abnormal breath sounds are heard, they should not be relied on to confirm endotracheal intubations.[30]

Proper verification of ETT placement by auscultation is dependent on the clinician's experience.[31] In one study in the critical care setting, experienced clinicians identified ETT location correctly, whereas inexperienced examiners were correct in only 68% of cases.[31]

c. ENDOBRONCHIAL INTUBATION

Intentional endobronchial intubation has been used to discriminate between endotracheal and esophageal intubation when doubt exists.[32] The ETT is advanced until breath sounds are lost on one side and unilateral breath sounds are heard on the other side. That should not happen if the tube is in the esophagus. The ETT is then gradually withdrawn 1 to 2 cm beyond the point at which bilateral breath sounds are heard. This technique has been used in infants and children, particularly in infants with tracheoesophageal fistulas.[33] However, it is not recommended for routine use because it can precipitate carinal irritation and bronchospasm.[34]

d. EPIGASTRIC AUSCULTATION AND OBSERVATION FOR ABDOMINAL DISTENTION

Auscultation of the epigastric area to elicit air movement in the stomach has been suggested as a routine maneuver after endotracheal intubation, even before auscultation of the chest.[14,15,25,26] However, normal vesicular breath sounds from the lungs can be transmitted to the epigastric area in tracheally intubated patients who are thin or small.[26] On rare occasions, esophageal intubation may not be easily distinguishable from endotracheal intubation if epigastric auscultation alone is used. Furthermore, there are circumstances, such as obstetric emergencies, in which prepping of the abdomen before induction of anesthesia precludes epigastric auscultation after intubation.[25]

Abdominal distention caused by gastric insufflation after compression of the breathing bag in cases of esophageal intubation can be readily observed in most patients. Occasionally, this sign may not be a reliable indicator of esophageal intubation for the following reasons[16,26,35]:

1. Gastric insufflation and abdominal distention might have occurred during prior mask ventilation.
2. Gastric distention may not be apparent in obese patients.
3. A previously placed nasogastric tube (NGT) can cause intermittent decompression of the stomach.

4. Gradual gastric filling can be difficult to distinguish from normal abdominal movements because of the esophageal reflux of gases.

Conversely, gastric distention can occur in patients with congenital or acquired tracheoesophageal fistula despite placement of the tube in the trachea.[33]

e. COMBINED AUSCULTATION OF EPIGASTRIUM AND BOTH AXILLAE

In a study of 40 adult patients intubated in both the trachea and the esophagus, "blinded" observers auscultating both axillae failed to diagnose esophageal intubation in 15% of cases.[36] When movement of the abdominal wall alone was used to assess ETT position, false results were obtained in 90% of cases. In contrast, the combined auscultation of the epigastrium and both axillae was found to be totally reliable in diagnosing esophageal intubation.[36] These findings emphasize the importance of combining tests to achieve a high degree of reliability in assessing ETT placement.

Detection of misplaced ETTs by auscultation of the chest and epigastrium is probably more difficult in infants than in adults. Uejima reported on two children,[29] aged 7 months and 5 years, in whom esophageal intubation occurred. In both, bilateral chest movements and breath sounds were heard over four areas of the chest and over the epigastrium. However, these "breath sounds" were not vesicular in nature. The ease of transmission of sounds from the esophagus to the chest and epigastrium may mimic breath sounds, especially in infants, emphasizing again that whenever any but normal vesicular breath sounds are heard, they should not be relied on to confirm endotracheal intubation.[25]

Attempts have been made to quantify and assess breath sound characteristics using electronic stethoscopes placed over each hemithorax and the epigastrium. With the use of computerized analysis, researchers digitized and filtered breath sounds to remove selected frequencies. Preliminary results suggested that this technique, when incorporated into a three-component, electronic stethoscope-type device, provides an accurate, portable mechanism to reliably detect ETT position in adults.[37] However, before this method gains wide acceptance, further evaluation is necessary in a broader population of patients with a variety of pathologic states and with different conditions and environments.

f. RESERVOIR BAG COMPLIANCE AND REFILLING

Manual compression of the reservoir bag after endotracheal intubation and cuff inflation yields a characteristic feel of compliance of the lungs and chest wall, whereas passive exhalation on release of bag compression is accompanied by rapid bag refilling. In almost all esophageal intubations, compressing the reservoir bag does not inflate the chest and is not followed by appreciable refilling. However, exceptions to this rule do occur, as has been shown in reports of accidental esophageal intubations. In these cases, repeated filling and emptying of the stomach resulted in concomitant emptying and refilling of the reservoir bag, leading to the erroneous conclusion that the ETT was in the trachea.[13,14,16,17,35]

It is possible that high fresh gas flow might have contributed to reservoir bag refilling in these cases. To enhance the reliability of this test, it has been suggested that the fresh gas flow should be shut off temporarily.[38] If this is done, chest inflation and rapid bag refilling can be repeatedly done (three to five times) in tracheally intubated patients but not in esophageally intubated patients. Because changes in lung or chest wall compliance can be misinterpreted by the clinician compressing the reservoir bag and high airway resistance can lead to slow refilling, this test, used alone, should not be relied on to distinguish esophageal from endotracheal intubation.[26]

g. RESERVOIR BAG MOVEMENTS WITH SPONTANEOUS BREATHING

Movement of the reservoir bag during spontaneous breathing has been considered one of the signs indicative of endotracheal intubation. However, it has been demonstrated that this sign can be unreliable. In a group of anesthetized patients, the trachea and esophagus were intubated and the patients were allowed to breathe spontaneously.[39] With the ETT intentionally occluded, the high negative intrapleural pressures generated with spontaneous breathing efforts were transmitted to the esophagus, resulting in reservoir bag movements and measurable tidal volumes (V_T) up to 180 mL. Therefore, slight reservoir bag movements or measurements of small V_T during spontaneous breathing are not reliable indicators of endotracheal intubation.[39]

h. CUFF MANEUVERS AND NECK PALPATION

The higher-pitched sound produced by leakage around a tube placed in the trachea with the cuff deflated during compression of the reservoir bag, compared with the "flatus-like" sound of leakage around a tube placed in the esophagus, has been used as a distinguishing test.[26] As has been shown in case reports, when the cuff of an esophageally placed ETT is inflated close to the cricoid cartilage, the characteristic guttural sound may be absent or may become higher pitched, resembling leakage around a tracheally placed ETT.[16]

Palpation of the cuff on each side of the trachea between the cricoid cartilage and the suprasternal notch while moving the tube has been proposed to confirm endotracheal intubation.[26] After intubation and cuff inflation, 2 or 3 fingers are placed above the suprasternal notch. Several rapid inflations of the cuff are performed (up to 10 mL of air). An outward force is felt by the palpating fingers if the ETT is in correct position. Intermittent squeezing of the pilot balloon of a slightly overinflated cuff with the thumb and index finger while sensing the transmitted pulsations in the neck has also been suggested as a sign for confirming ETT placement.[40] Likewise, a maneuver using the pilot balloon as a sensor has been proposed.[34] A high-volume, low-pressure, prestretched cuff may not be palpable despite correct placement.[34] Conversely, an inflated cuff can be palpated in the neck in cases of esophageal intubations.[17] Therefore, these maneuvers should not be relied on in verifying endotracheal intubation.[25,26,30]

If an assistant gently palpates the trachea in the suprasternal notch or applies cricoid compression during endotracheal intubation, an "old washboard-like" vibration is appreciated as the ETT rubs against the tracheal rings.[41] It has been suggested that there should be no false-positive results of this sign if the ETT is misplaced in the esophagus, because the esophagus is soft and lies posterior to the trachea. Thus far, there have been no controlled studies to confirm the validity of this sign.

i. SOUND OF EXPELLED GASES DURING STERNAL COMPRESSION

Pressing sharply on the sternum while listening over the proximal end of the ETT to detect a characteristic feel and sound of expelled gases from the airway is occasionally used to distinguish esophageal from endotracheal intubation.[16] This test is mistrusted by many because of (1) inability to distinguish gases expelled passing through the ETT from gases passing through or around a tube misplaced in the esophagus, (2) inability to distinguish gases being expelled through the nose, and (3) inability to distinguish esophageal and stomach gases present from prior mask ventilation.[16]

j. TUBE CONDENSATION OF WATER VAPOR

The basic principle of tube condensation as a sign of ETT placement is that water vapor seen in clear plastic ETTs is more likely to be present with gases exhaled through a tracheally placed tube than with gases emanating from the stomach through a tube in the esophagus (Fig. 32-2). Two studies have demonstrated water condensation in all cases in which ETTs were placed in the trachea.[36,42] However, water condensation can and does occur when ETTs are placed in the esophagus. The fact that condensation was noticed in 85% of esophageal intubations in one study and in 28% in another study should strongly discourage its presence from being interpreted as a reliable indicator of a successful intubation.[36,42]

k. NASOGASTRIC TUBES, GASTRIC ASPIRATES, INTRODUCERS, AND OTHER DEVICES

A test devised to distinguish between tracheal and esophageal placement of an ETT involves threading a lubricated NGT through the tube in question, applying continuous suction, and attempting to withdraw the NGT.[43] This test exploits the distinguishing feature that the esophagus will collapse around the NGT when suction is applied, whereas free suction applied in the trachea will continue.

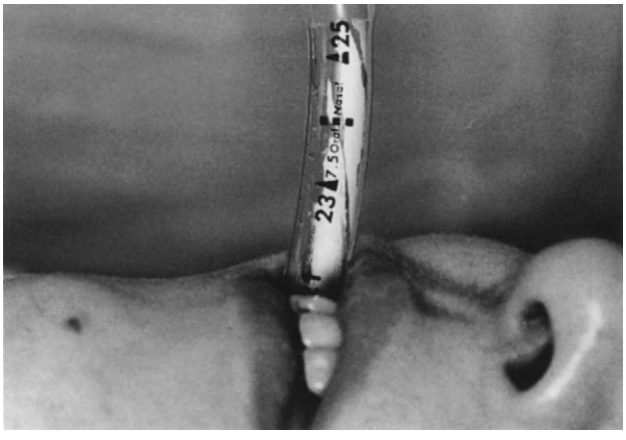

Figure 32-2 Condensation of water vapor seen in an endotracheal tube after endotracheal intubation during exhalation.

In a study of 20 patients in whom both trachea and esophagus were intubated, the ability to maintain suction and the ease of withdrawal during continuous suction clearly distinguished between the two positions.[43] When the NGT was in the trachea, suction applied to it could be maintained easily because the trachea remained patent and air was entrained through the open end of the tube. This allowed the NGT to be withdrawn easily despite suctioning. In contrast, when suction was applied to the NGT in the esophagus, the esophageal wall collapsed around it, thereby obstructing suction and interfering with easy withdrawal of the NGT. Although the length of the NGT that could be easily inserted before an impediment or resistance was felt (5 to 15 cm distal to the tip of the tube) identified correct tracheal placement, it was less useful in identifying esophageal intubation. Similarly, the nature of the aspirate (mucus versus bile or gastric juice) was found to be of limited value in most patients. Because the total time spent to make these observations was 20 to 30 seconds, the authors concluded that the test is reliable.[43] Despite their enthusiasm, this test is very rarely used because of the availability of better methods.

The Eschmann introducer is a 60-cm-long device (10 cm shorter than other similar devices) composed of two layers: a core of tube woven from Dacron polyester threads and an outer resin layer to provide stiffness, flexibility, and a slippery, water-impervious surface. Frequently, the device is referred to as a "gum elastic bougie"—despite the fact that it is not gum, not elastic, and not a bougie.[44] The introducer has a 35-degree kink located 2.5 cm from its distal end. Because its outer diameter (OD) is 5 mm, it can be used with ETTs with an inner diameter (ID) of 6 mm or greater. The device has been used for many years to facilitate intubation and has been introduced to differentiate tracheal from esophageal intubation in emergencies when there is doubt about the ETT location.[26] When inserted through the lumen of the ETT, the curved tip of the lubricated introducer may be felt rubbing over the tracheal rings, and resistance is encountered as the tip of the introducer meets the carina or a main stem bronchus at approximately 28 to 32 cm in the adult. If the ETT is in the esophagus, the introducer passes without resistance to the distal end of the esophagus or stomach.[26] Forceful insertion of an excessive length of the introducer could conceivably result in bronchial rupture or other injuries. This has led the manufacturer to discourage its use as an ETT changer, because other devices specifically designed for this purpose are now available.[45]

l. TRANSTRACHEAL ILLUMINATION

The success of transillumination of the soft tissues of the neck anterior to the trachea in accomplishing guided oral or nasal intubation has culminated in the development of improved lighted stylets and introducers (see

Figure 32-3 When the lighted stylet (or introducer) enters the larynx, an intense, circumscribed, midline glow seen in the region of the laryngeal prominence is suggestive of endotracheal intubation.

Chapter 21).[46-48] It has also prompted investigators to use transtracheal illumination to differentiate esophageal from tracheal ETT placement and to position the ETT accurately inside the trachea. Transmission of light through tissues depends on thickness, compactness, color, density, and light absorption characteristics of the tissue; wavelength, quality, and intensity of the light; proximity of the tissue to the light source; and the ambient lighting conditions in the room.[49] Typically, endotracheal intubation with the lighted stylet or introducer inside the ETT or placement of the stylet in the lumen of the ETT after intubation gives off an intense, circumscribed, midline glow in the region of the laryngeal prominence and sternal notch (Fig. 32-3). The illumination is mostly seen opposite the thyrohyoid, cricothyroid, and cricotracheal membranes. In the event of esophageal intubation, the light is either absent or perceived as dull and diffuse.

To enhance transillumination, darkening the room, dimming the overhead lights, and applying cricoid pressure (to approximate the tracheal wall to the light source and stretch the soft tissues anterior to the light source) have been recommended.[46-49] Newer lighted stylets or introducers, battery operated or incorporating a fiberoptic light source, have brighter lights than earlier prototypes. Consequently, dimming of the overhead lights or application of cricoid pressure may not be necessary. The reliability of transtracheal illumination in distinguishing esophageal from endotracheal intubation in adults has been demonstrated.[49,50] In one study conducted on five cadavers, only 1 of 56 intratracheal placements was misidentified as esophageal, whereas of 112 extratracheal placements (esophageal or pyriform fossa), 1 was misidentified as intratracheal.[50] In another study of 420 adult patients, tracheal transillumination was graded as excellent in 81% of patients and as good in the remaining 19%.[49] In contrast, transesophageal illumination could not be demonstrated in any patient. Despite these reports, false-negative results (ETT in trachea but no transillumination) with the use of the newer lighted stylets and introducers in patients with neck swelling or dark skin and in obese patients have been noticed.[31] Similarly, occasional false-positive results have been observed in thin patients. Nonetheless, the use of transillumination could reduce unrecognized esophageal intubations, especially outside the operating room where other technical aids are not available.[49,50]

Reports have delineated several complications with these transillumination devices.[51-53] Loss of the bulb into the lung necessitating bronchoscopic removal has been reported.[51] A change in design involving encasement of the bulb in a plastic retaining cover has virtually eliminated the possibility of this complication in future.[47] Other reports have described arytenoid subluxation.[52,53] However, this complication can occur after conventional intubation, and there is no evidence of an increased incidence with the use of lighted stylets.

m. PULSE OXIMETRY AND DETECTION OF CYANOSIS

Although unrecognized esophageal intubation ultimately leads to a severe fall in O_2 saturation (and detectable cyanosis), minutes may elapse before this happens. A disturbing finding that emerged from the ASA closed claims study is that detection of esophageal intubation required longer than 5 minutes in 97% of cases.[1] Furthermore, detectable cyanosis preceded the recognition of esophageal intubation in only one third of cases. Several factors contribute to the delay in diagnosing esophageal intubation by pulse oximetry or in detecting cyanosis, or both.

Reliance on the appearance of cyanosis as a clue to esophageal intubation can contribute to such a delay. Recognition of cyanosis usually necessitates the presence of more than 5 g/dL of reduced hemoglobin, which corresponds to 75% to 85% O_2 saturation.[54] The detection may also depend on the concentration and type of hemoglobin. With severe anemia, cyanosis may not be apparent until the arterial oxygen saturation (Sao_2) falls to 60%. An infant with a high proportion of fetal hemoglobin may still look "pink" at an arterial partial pressure of oxygen (Pao_2) near 40 mm Hg because of the increased blood affinity of O_2 and leftward shifting of the fetal oxyhemoglobin dissociation curve; for this reason, a serious reduction in Pao_2 may develop before cyanosis is apparent.[55] Recognition of cyanosis is influenced by the limited exposure of the patient's body and the insensitivity of the human eye to changes in skin color or even the color of the blood during arterial desaturation. It could also be affected by variations in room lighting and the color of the surgical drapes.

Noninvasive monitoring of oxygen saturation by pulse oximetry (SpO_2) has proved to be a reliable indicator of Sao_2.[56,57] It is undoubtedly quicker to detect changes in SpO_2 than to rely on clinical detection of cyanosis. The main limitation of pulse oximetry is that it does not measure Pao_2, which may fall long before SpO_2 is affected.

Preoxygenation of the patient's lungs before anesthetic induction extends the period of time before a decrease in Sao_2 occurs in case of esophageal intubation.[58,59] In general, O_2 deprivation or apnea after air breathing results in a substantial fall in Pao_2 within 90 seconds, whereas Pao_2, after O_2 breathing, remains higher than 100 mm Hg for at least 3 minutes of apnea, and Sao_2 does not change during this period.[54,58] Consequently, pulse oximetry after preoxygenation does not immediately indicate that the esophagus has been intubated.[59] Because of this prolonged

interval with normal SpO_2 being recorded initially after the intubation attempt, misplacement of the ETT may not be suspected later when SpO_2 begins to decrease.[1,59] Furthermore, the risk of misinterpretation of clinical findings suggestive of esophageal intubation may be greater when other clues such as decrease in SpO_2 or cyanosis are not yet manifest.[1] This "hazard" of preoxygenation has led a few clinicians to abandon such a practice so that esophageal intubation can be more readily appreciated.[60] One does not need to go to such extremes as to abandon a practice that has definite merits. However, the presence of normal pulse oximetry readings after intubation should not be taken as evidence of successful endotracheal intubation, and after preoxygenation, oxyhemoglobin desaturation, as indicated by pulse oximetry, is a relatively late manifestation of esophageal intubation.[1,13,59,61-63]

Both O_2 consumption and cardiac output can influence the Sao_2 through their effects on mixed venous oxygen tension ($P\bar{v}O_2$) and mixed venous oxygen content ($C\bar{v}O_2$).[54] A decrease in O_2 consumption associated with anesthetic induction or an increase in cardiac output or both can lead to an increase in $P\bar{v}O_2$ and $C\bar{v}O_2$. The high $P\bar{v}O_2$ retards the decrease in PaO_2 in the event of O_2 deprivation resulting from esophageal intubation and consequently may delay its recognition. Conversely, in patients with low SaO_2 and in those who have high O_2 consumption (e.g., children, women in labor, morbidly obese patients) or decreased functional residual capacity (FRC), oxyhemoglobin desaturation may occur faster.

With the vocal cords open, manual ventilation into the esophagus can result in alveolar gas exchange. In 18 of 20 patients studied after intentional intubation of both the esophagus and the trachea, ventilation into the esophagus caused cyclic compression of the lungs by the distending stomach and esophagus, leading to some gas exchange evidenced by recording of carbon dioxide at the proximal end of the ETT.[35] Although in this situation esophageal ventilation causes ventilation of the lungs with room air, it considerably delays the onset of cyanosis and oxyhemoglobin desaturation. Similarly, respiratory efforts by a spontaneously breathing patient through the unintubated trachea may delay the recognition of esophageal intubation. Esophageal ventilation may also be effective in yielding apneic oxygenation if the cords are open and there is a leak around the cuff of the misplaced esophageal tube.

n. THE BECK AIRWAY AIRFLOW MONITOR

The Beck Airway Airflow Monitor (BAAM; Great Plains Ballistics, Lubbock, TX) consists of a cylindrical plastic whistle with a 2-mm-diameter aperture (Fig. 32-4). When connected to the proximal end of an ETT in a spontaneously breathing patient, the airflow is forced through the small lumen, producing a loud whistle.[64] The pitch during inspiration and exhalation differs because of varying airflow velocities. The BAAM has been used to assist blind intubation and guide the ETT into the trachea. The loudness of the whistle indicates proximity to the tracheal air column, whereas cessation of the sound implies esophageal intubation, obstruction of the ETT, or excessive leak around the ETT. In patients who are not breathing spontaneously, a gentle squeeze of the chest produces whistling if the ETT is in the trachea. Because the whistle is produced by the airflow, an ETT in the pharynx can produce a whistle. Reports on this device have been limited to case reports and one study in neonates.[64] More research is needed to determine its validity.

o. CHEST RADIOGRAPHY

A chest radiograph can diagnose esophageal intubation if the ETT is located in the lower esophagus distal to the carina (Fig. 32-5).[65] Because a tube in the esophagus is

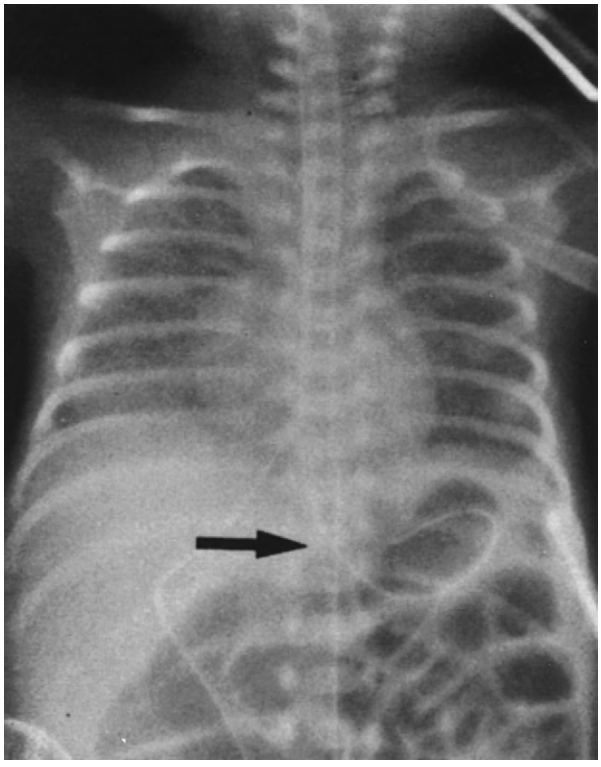

Figure 32-5 Endotracheal tube (ETT) malposition. The ETT is at the gastroesophageal junction *(arrow)*. Moderate intestinal dilation is seen. (From Mandel GA: Neonatal intensive care radiology. In Goodman LR, Putman CE, editors: *Intensive care radiology: Imaging of the critically ill,* Philadelphia, 1983, WB Saunders, p 290.)

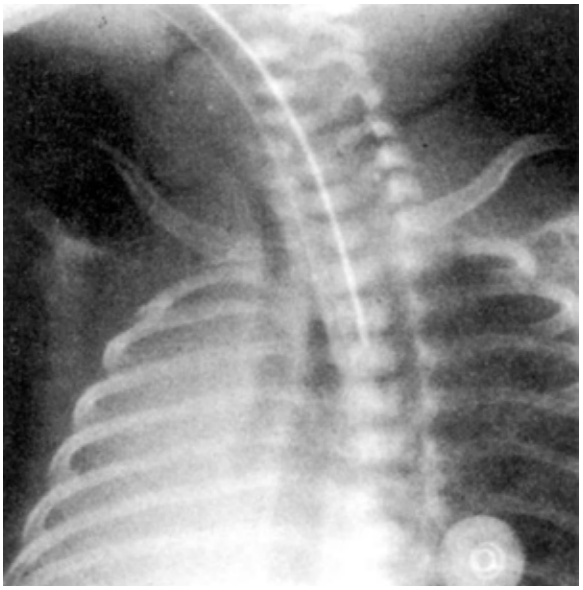

Figure 32-6 Right posterior oblique portable chest radiograph with patient's head turned to the right shows air-filled trachea projecting to right of endotracheal tube (ETT). The ETT aligns with the air-filled distal esophagus. This is the best position for diagnosis of esophageal intubation. (From Smith GM, Reed JC, Choplin RH: Radiographic detection of esophageal malpositioning of ETTs. *AJR Am J Roentgenol* 154:23, 1990.)

often projected over the tracheal air column on anteroposterior chest radiographs, the radiologic features of esophageal intubation are usually difficult to assess.[63] However, it should be suspected in the following situations[63,65]:

- If any part of the border of the ETT is seen outside or lateral to the air column of the tracheobronchial tree (in the absence of a pneumomediastinum)
- In the presence of esophageal air and gastric distention, particularly if an NGT is in place
- If there is a noticeable deviation of the trachea caused by an overinflated cuff.

Although a lateral view of the chest could precisely reveal esophageal intubation, such views are often difficult to obtain. However, in one study, ETT location was identified correctly in 92% of the films taken with the patient in a 25-degree right posterior oblique position with the head turned to the right side.[63] Because the esophagus is located slightly to the left as well as behind the trachea, this projection presents the relationship *en face* with respect to the radiologic beam, resulting in avoidance of superimposition of the trachea over the esophagus (Fig. 32-6). Because radiography is time-consuming and not failsafe, it should never be relied on for diagnosis of esophageal intubation, even in the critical care setting.

p. IMPEDANCE RESPIROMETRY

Impedance respirometry, which measures electrical conductivity of the thorax, has been used to monitor respiratory rate in the critical care setting and to monitor apnea in infants. The ability of impedance respirometry to distinguish esophageal from endotracheal intubation has been explored.[66,67] A high-frequency alternating current is passed between two electrodes placed on the anterior chest wall. With the increase in lung volume during inspiration, there is an associated decrease in lung electrical conductivity and therefore increased impedance.[66,67] These changes can be measured and displayed as a waveform. If the esophagus is intubated, such an effect on thoracic impedance should be absent. Although assessment by thoracic impedance plethysmography was found to have 100% sensitivity in the detection of esophageal ETT placement in a study in adult patients,[66] it correctly identified only 76 of 80 ETTs in children.[67] Of those incorrectly identified, one was in the trachea and three were in the esophagus. Obviously, more studies are needed before any conclusions can be made. Although it is not a perfect test, use of impedance respirometry could decrease the time taken to identify incorrect placement when combined with other methods of ETT verification.[67]

2. Almost Failsafe Methods

a. IDENTIFICATION OF CARBON DIOXIDE IN EXHALED GAS

The availability of capnometry (measurement of CO_2 in expired gas) and capnography (instantaneous display of the CO_2 waveform during the respiratory cycle) for intraoperative monitoring has prompted clinicians to extend their use to facilitate detection of esophageal intubation.[35,68-71] The principle of use stems from the fact that exhaled CO_2 can be reliably detected during controlled or spontaneous ventilation in patients with adequate pulmonary flow whose trachea is intubated, whereas no CO_2 can be detected in gases emanating from an ETT in the esophagus.

Studies have revealed that the combined use of capnography and pulse oximetry could avert more than 80% of mishaps considered preventable.[72] In an amendment to its original basic intraoperative monitoring standards, the ASA stated the following: "When an ETT is inserted, its correct positioning in the trachea must be verified by clinical assessment and by identification of CO_2 in the expired gas. End-tidal CO_2 ($Etco_2$) analysis, in use from the time of ETT placement, is strongly encouraged." (Standards for Basic Anesthetic Monitoring, 2003 Directory of Members, American Society of Anesthesiologists, Park Ridge, IL, p 493.) Identification of CO_2 in the exhaled gas has emerged as the standard for verification of proper ETT placement. Furthermore, interruption of CO_2 sampling in the exhaled gas due to disconnection, obstruction, accidental tracheal extubation, or total loss of ventilation is immediately detected. Two main methods are currently used: capnography and colorimetric detection of CO_2.

CAPNOGRAPHY. Currently available CO_2 analyzers use various principles to measure CO_2 in the inspired and exhaled gases on a breath-to-breath basis and display the CO_2 waveform by mass spectrometry, infrared absorption spectrometry, or Raman scattering. A normal capnographic waveform in relation to the respiratory cycle is shown in Figure 32-7.[73] A mass spectrometric tracing showing CO_2 waveforms after esophageal intubation and

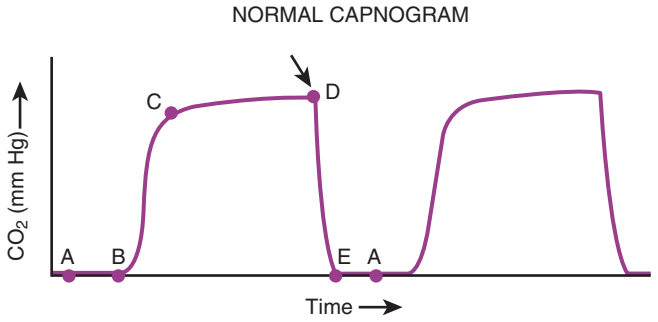

Figure 32-7 The CO_2 waveform. *A,* Expiratory pause begins. *A–B,* Clearance of anatomic dead space. *B–C,* Dead space air mixed with alveolar air. *C–D,* Alveolar plateau. *D,* End-tidal partial pressure of CO_2 registered by capnograph *(arrow)* and beginning of inspiratory phase. *D–E,* Clearance of dead space air. *E–A,* Inspiratory gas devoid of CO_2. after correct placement of the ETT in the trachea is shown in Figure 32-8. Although capnography typically distinguishes tracheal from esophageal intubation, false-negative results (i.e., ETT in trachea, absent waveform) and false-positive results (i.e., ETT in esophagus or pharynx, present waveform) have been reported.

Since the advent of capnography to confirm ETT placement, there have been reports of markedly different problems yielding unexpected false-negative results. For example, disconnection of the ETT from the breathing apparatus, apnea, and equipment failure may be misinterpreted as absent waveform caused by esophageal intubation.[74] A kinked or obstructed ETT interferes with sampling of exhaled gas and may lead to an absent or distorted waveform. Lack of a CO_2 waveform caused by severe bronchospasm has also been reported.[74] Unintentional application of positive end-expiratory pressure (PEEP) to a loosely fitted or uncuffed ETT can cause exhaled gases to escape around the distal lumen of the tube and may result in a sampling error and absent waveform.[75] In addition, dilution of exhaled gases by high fresh gas flow in a Mapleson D system when proximal sidestream sampling is used in infants weighing less than 10 kg leads to erroneous sampling.[76,77] This problem can be corrected by distal sampling from the ETT, up to the 12 cm mark; by use of a mainstream sampling device; or by use of special ventilators.[77] Lower sampling flow rates and gas sampling line leaks can result in artifactually low exhaled CO_2 values and an abnormal waveform.[78,79]

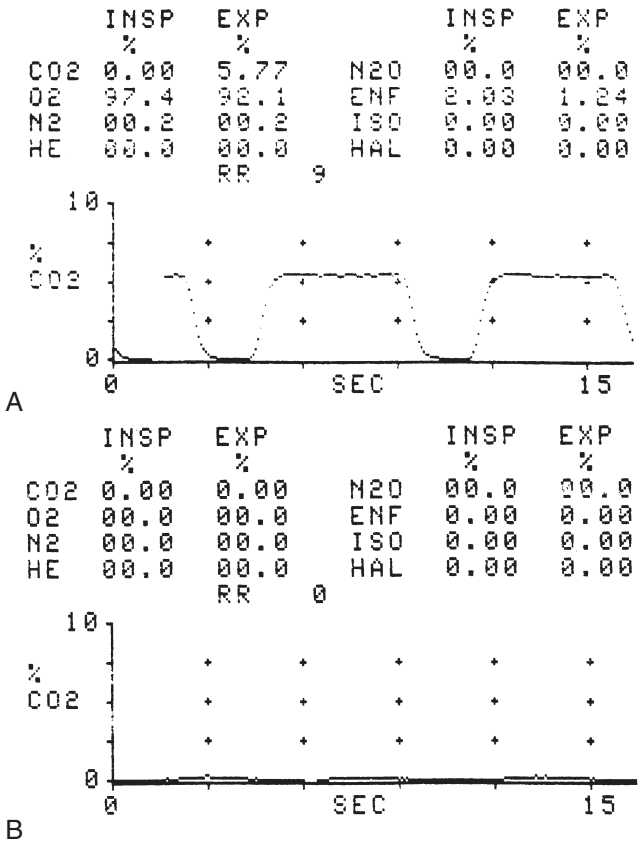

Figure 32-8 **A,** Normal capnograph, endotracheal tube (ETT) in trachea. **B,** Absent capnograph, ETT in esophagus.

Marked diminution of pulmonary blood flow increases the alveolar component of the dead space.[54,70] Low cardiac output, hypotension, pulmonary embolism, pulmonary stenosis, tetralogy of Fallot, and kinking or clamping of the pulmonary artery during pulmonary surgery all cause a decrease in end-tidal carbon dioxide partial pressure (P_{ETCO_2}), reflecting an increase in alveolar dead space.[54,80,81] Other factors contributing to the increased alveolar dead space during anesthesia include patient age, large V_T, use of negative phase during exhalation, short inspiratory phase, and presence of pulmonary disease.[54,81] As a result of the widespread destruction of alveolar capillaries in patients with chronic obstructive pulmonary disease, an increased alveolar dead space ensues. An increase in alveolar dead space is manifested as a decrease in P_{ETCO_2} and an increase in the Pa_{CO_2} to P_{ETCO_2} difference (normally 0 to 5 mm Hg).[54,81] If capnography alone is relied on to confirm ETT placement in patients who have a very large alveolar dead space, the low P_{ETCO_2} values might mislead the clinician into thinking that the ETT was not placed in the trachea.

An abrupt reduction in cardiac output reduces P_{ETCO_2} by two mechanisms: First, a reduction in venous return causes a decrease in CO_2 delivered to the lungs, and second, the increase in alveolar dead space dilutes the CO_2 from normally perfused alveoli, thus decreasing P_{ETCO_2}.[82-84] When cardiac arrest ensues, CO_2 is no longer delivered to or eliminated through the lungs even if ventilation is adequate, and consequentially P_{ETCO_2} values exponentially decrease to remarkably low values (<0.5%). Ninety seconds after experimentally induced ventricular fibrillation, P_{ETCO_2} is usually decreased by 90%.[85] Accordingly, a decision regarding the location of the ETT based on capnographic findings alone during cardiac arrest may lead to a misdiagnosis.

Experimental cardiac arrest demonstrated a remarkably high correlation between P_{ETCO_2}, cardiac output, and coronary perfusion pressure during closed-chest precordial compression, during open-chest cardiac massage, and after resuscitation.[86,87] Similar observations were reported during episodes of cardiac arrest in critically ill patients.[86,87] The restoration of spontaneous circulation is

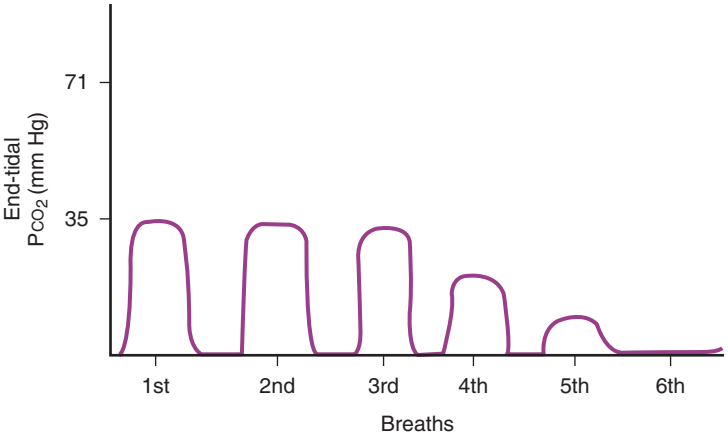

Figure 32-9 CO_2 waveforms obtained in a 10-year-old boy with an esophageal intubation. The waveform looks normal during the first three breaths but becomes flat very quickly. (From Sum Ping ST: Esophageal intubation. *Anesth Analg* 66:483, 1987.)

heralded by a rapid increase in P_{ETCO_2} within 30 seconds. This overshoot in P_{ETCO_2}, which is characteristic of successful resuscitation, may exceed the prearrest value and reflects washout of CO_2 that has accumulated in venous blood and in tissues during circulatory arrest.[86,88] In patients in whom resuscitative efforts fail to restore spontaneous circulation, P_{ETCO_2} remains low or even declines, whereas in those who eventually regain spontaneous circulation, P_{ETCO_2} reaches 19 mm Hg or higher. These observations suggest that capnography can be used for monitoring the adequacy of blood flow generated by precordial compression during cardiopulmonary resuscitation and can serve as a prognostic indicator of successful resuscitation.[86,88]

False-positive results can occur when the ETT is misplaced in the esophagus after exhaled gases are forced into the stomach during bag-mask ventilation preceding intubation attempts.[85,89] If enough alveolar gas reaches the stomach, a CO_2 concentration greater than 2% may be initially detected, and the CO_2 waveform may be indistinguishable from that observed with endotracheal intubation.[35,89,90] In fact, CO_2 waveforms have been observed in one third of esophageal intubations,[90] but repeated ventilation results in rapidly diminishing CO_2 levels while the waveform becomes rather flat and irregular (Fig. 32-9).[35,89] As a result of the dilution with successive ventilation, it is very unlikely that any CO_2 would be detected after the sixth breath or after 1 minute in cases of esophageal intubation, making it easy to distinguish esophageal from endotracheal intubation.[35] It has also been observed that compression of the chest caused clear, peaked CO_2 elevation in 18 of 20 tracheally intubated patients but no changes in esophageal intubation.[35] This simple, quick maneuver together with other signs can confirm proper ETT placement.

False-positive results can potentially occur in cases of esophageal intubation after ingestion of carbonated beverages or antacids.[91-93] High CO_2 levels (20%) are present in all carbonated beverages.[92] Sodium bicarbonate, an ingredient found in most antacids (except sodium citrate), reacts with hydrochloric acid in the stomach, releasing CO_2 levels comparable to those found in alveolar gas. With carbonated beverages, CO_2 levels as high as 5.3% can be measured initially with esophageal ventilation, rendering correct assessment of ETT placement rather difficult.[92] However, rapid decline in CO_2 levels occurs with successive ventilations (Fig. 32-10). The abnormal CO_2 waveform may give an important clue in the early detection of esophageal intubation.[92] Because a normal-looking CO_2 waveform during the first few ventilations is no guarantee of correct ETT placement, the waveform must be watched closely for at least 1 minute after placement of the tube.

It should be emphasized that a normal waveform is not synonymous with presence of the tube in the trachea.[89] A normal waveform may be observed without a tube present in the trachea during spontaneous or controlled ventilation in cases of face mask anesthesia, use of a laryngeal mask airway, and use of the esophageal-tracheal Combitube (ETC) (Tyco-Healthcare-Kendall-Sheridan Corporation, Mansfield, MA), with which ventilation is carried out through the pharyngeal perforations.[94,95] A normal waveform may also be present and sustained if the distal end of the ETT is in the pharynx but not necessarily in the trachea.[94] This situation should be suspected by the unusual volume of cuff air required to stop the leak and an increased peak inspiratory pressure.

Although capnography has been widely used in operating rooms, its use in emergency rooms, intensive care units, and hospital floors has been rather limited because of the need for warm-up and careful calibration time; the requirement for an external power source, which limits use in emergency situations; and the fact that the technology is not easily transferable to the patient's side. Portable apnea monitors that use infrared spectrometry for sensing CO_2 have been used for confirmation of ETT placement.[96] Although they do not accurately quantify CO_2 concentration, a moving-bar indicator with seven light-emitting diodes does provide an estimate of 1.5 percentage points per illuminated diode. Gas is aspirated through plastic tubing attached to the elbow connector proximal to the ETT, allowing the monitor to sense CO_2 in the first exhalation after intubation. The device is cheap and portable, operates for 90 minutes on batteries, and requires neither warm-up time nor calibration. This electronic instrument can also function as a breathing circuit disconnection alarm.[96]

COLORIMETRIC END-TIDAL CARBON DIOXIDE DETECTION. Early studies attempted to quantitate the amount

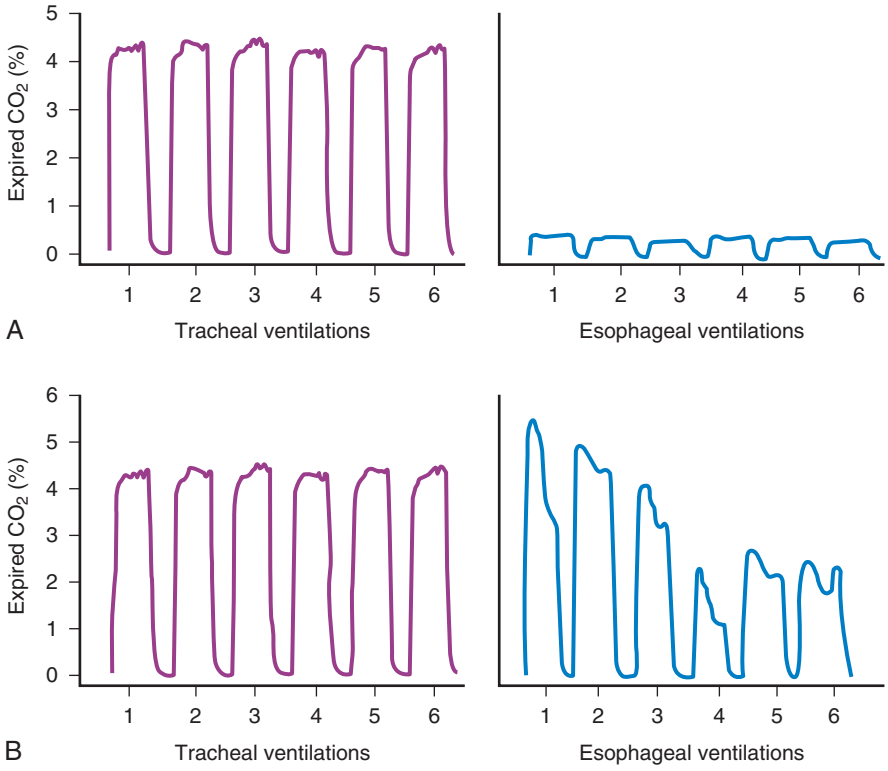

Figure 32-10 Expired CO_2 waveform during tracheal and esophageal ventilations before **(A)** and after **(B)** addition of a carbonated beverage in the stomach. (From Sum Ping ST, Mehta MP, Symreng T: Reliability of capnography in identifying esophageal intubation with carbonated beverage or antacid in the stomach. *Anesth Analg* 73:333–337, 1991.)

of CO_2 in exhaled gas and relied on the reaction of CO_2 with another substance such as barium hydroxide to produce a color change.[97] Thereafter, chemical indicators that change colors in the presence of increased hydrogen ion concentrations were used. The Einstein CO_2 detector was constructed by attaching a 15-mm adapter to one end of a DeLee mucus trap containing a mixture of 3 mL of phenolphthalein and 3 mL of cresol. When the exhaled gas is bubbled through the chamber, carbonic acid formation causes a dramatic color change from red to yellow within seconds. Failure of the solution to change from red to yellow should suggest esophageal intubation.[98]

Several disposable colorimetric CO_2 detectors are currently available. The Easy Cap II CO_2 Detector (Nellcor Puritan Bennett, New York, NY; Fig. 32-11) can be connected between an ETT and a breathing circuit or bag-mask assembly.[99-104] The detector contains filter paper impregnated with a colorless liquid base and a pH-sensitive indicator (metacresol purple) that reversibly changes from purple to yellow as a result of pH change when exposed to CO_2 and reverts to purple when CO_2 is no longer present. The color changes are made visible through a transparent dome in the plastic housing of the device. In general, a purple color (A range) indicates a CO_2 level of 0.5% or less. The B range is a dusty tan color, reflecting levels of 0.5% to 2%. When the detector is exposed to CO_2 levels greater than 2%, the color brightens to a yellow-tan color, the C range.

Studies have shown that colorimetric P_{ETCO_2} monitoring is reliable in verifying proper ETT placement in nonarrested patients.[99-104] In one study,[103] the mean minimum CO_2 concentration required for detection of the perceivable color change was 0.54% (4.1 mm Hg) and ranged from 0.25% to 0.60% (1.9 to 4.6 mm Hg). When an ETT is correctly placed in a patient with adequate pulmonary blood flow, the detector should register C. The color change occurs immediately with the first breath in almost all patients. In the nonarrested patient when the device registers low or absent CO_2 (A reading), esophageal

intubation should be strongly suspected. If a C reading is obtained in an arrested patient, proper ETT placement is confirmed. In contrast, an A reading (absence of color change) during manual ventilation in a patient with cardiac arrest is consistent with either an esophageal or an endotracheal intubation in patients with profound low-flow state resulting from prolonged arrest or inadequate resuscitation. In another study, for 28 of 106 endotracheal intubations in "pulseless" patients the detector did not show any color change, indicating a Pa_{CO_2} of less than 4 mm Hg.[104] A multicenter trial of a colorimetric CO_2 detection device found that all cardiac arrest patients who survived to admission had a value of C registered on the monitor.[105] No patient in whom the detector failed to register color change survived. Therefore, the device may be useful as a prognostic indicator of successful resuscitation.[104]

Although the availability of such a device is considered a great leap forward, it has its own pitfalls and is not a substitute for assessment skills. Because the device has a dead space of 38 mL, the manufacturer does not recommend its use in children weighing less than 15 kg, although its efficacy in verifying endotracheal intubation has been confirmed in infants as young as 6 months.[106] The color change may be difficult to discern under low-light conditions and may be misinterpreted by color-blind individuals. The detector is not sensitive to temperature, but it is eventually affected by humidity. Water vapor interferes with the chemical reaction and inactivates the device; it can be rendered ineffective within 15 minutes if the patient is receiving humidified gases. It has been suggested that trapping the humidity with a passive moisture exchanger may extend the useful life of the device.[106] The manufacturer cautions against use of the device in conjunction with a heated humidifier or nebulizer and emphasizes that it is not intended to be used for longer than 10 minutes after intubation. Because the indicator permanently changes color if exposed for a prolonged period to low CO_2 or other acids in the air, the device is packaged in a gas-impermeable metallic foil and is marketed as a single-use item. The packaged detector has a shelf life of 15 months if left unopened but may not function properly if the package is accidentally opened and the device is exposed to room air for several hours. For this reason, it is essential to verify that the indicator color is purple before use. Clinicians should familiarize themselves with the Et_{CO_2} detectors in their institutions and the appropriate color changes before use of these detectors.

Widespread use of colorimetric CO_2 detectors has been hampered by limitations in their performance characteristics. Newer colorimetric CO_2 indicators seem to have overcome some of these limitations.[107] With this improved technology, it is expected that detectors will be more durable during prolonged exposure to heat, humidity, and CO_2. Furthermore, they will be cheaper and will have a longer shelf life. However, there are potential sources of rare errors with the use of colorimetric CO_2 monitoring, even in the nonarrested patient. After manual bag-mask ventilation before intubation, CO_2 from the exhaled air may be blown into the stomach and may result in detectable CO_2 levels, yielding a false-positive yellow color if the ETT is misplaced in the esophagus. Ventilating the patient with six breaths results in a washout of CO_2 to near-zero if the ETT is misplaced in the esophagus. Close observation of the color of the detector is essential during and after the delivery of six quick breaths so that false-positive results are avoided.

Concerns about inadvertent detection of gastric CO_2 from ingested beverages after esophageal intubation, which can potentially vitiate colorimetric CO_2 detection, have been raised.[101] In a study of carbonated beverage ingestion and esophageal intubation in the cardiac arrest porcine model, the amount of CO_2 released did not result in spurious color change of the detector in the four animals studied and did not cause difficulty in interpretation of the readings.[108] Therefore, concern that false-positive results might be caused by esophageal placement in a patient who has recently ingested carbonated beverages appears to be unwarranted.[104,108]

Colorimetric CO_2 is a simple, safe, highly sensitive, reliable, and quick method for confirming ETT placement in the nonarrested patient. Unlike capnography, it is portable (pocket sized) and does not require calibration or a power source. It is useful in places where capnography is unavailable, such as hospital floors, emergency departments, and prehospital settings. As with capnography, false-negative results (i.e., ETT in trachea, no color change) may occur. Very rarely, false-positive results (i.e., ETT in esophagus, with color change) can occur with the first few breaths. In the arrested patient, interpretation of "no color change" requires caution because it may indicate circulatory arrest, inadequate resuscitation, or esophageal intubation.

b. ESOPHAGEAL DETECTOR DEVICE/SELF-INFLATING BULB

Use of the esophageal detector device (EDD) is based on anatomic differences between the trachea and the esophagus.[109] The trachea in the adult is 10 to 12 cm long, and its diameter can vary from 13 to 22 mm. The trachea remains constantly patent because of C-shaped rigid, cartilaginous rings that are joined vertically by fibroelastic tissue and closed posteriorly by unstriped trachealis muscle. The esophagus is a fibromuscular tube, 25 cm long in adults, which extends from the cricopharyngeal sphincter to the gastroesophageal junction; there is no intrinsic structure to maintain its patency.

Wee and O'Leary and their colleagues introduced a new method using a simple device to distinguish esophageal from endotracheal intubation.[109,110] The principle underlying use of the EDD is that the esophagus collapses when a negative pressure is applied to its lumen, whereas the trachea does not. The device consists of a 60-mL syringe fitted by an adapter that can be attached to an ETT connector. When the syringe is attached to an ETT placed in the trachea, withdrawal of the plunger of the syringe aspirates gas freely from the patient's lungs without any resistance apart from that inherent in the device (Fig. 32-12). If the ETT is in the esophagus, withdrawal of the plunger causes apposition of the walls of the esophagus, occluding its lumen around the ETT, and a negative pressure or resistance is felt when the plunger is pulled back. Wee conducted a study in 100 patients in whom placement of ETTs and esophageal tubes was

Figure 32-12 The esophageal detector device consists of a 60-mL syringe fitted by an adapter to an endotracheal tube connector.

Figure 32-13 The self-inflating bulb is fitted with a standard 15-mm adapter. (From Salem MR, Wafai Y, Joseph NJ, et al: Efficacy of the self-inflating bulb in detecting esophageal intubation: Does the presence of a nasogastric tube or cuff deflation make a difference? *Anesthesiology* 80:42–48, 1994.)

assessed using the EDD.[109] There were 99 first-time correct identifications of ETT placement, and the mean time required to diagnose tube placement was 6.9 seconds. Application of constant but slow aspiration has been recommended to avoid the suction effect and prevent mucosal damage. Endotracheal intubation is confirmed if 30 to 40 mL of gas is aspirated without resistance in adults or 5 to 10 mL in children older than 2 years of age.[109-111]

Nunn simplified the EDD by replacing the syringe with an Ellik evacuator, which is a self-inflating bulb (SIB) with a capacity of 75 to 90 mL.[112] After intubation, the device is connected to the ETT, and the bulb is compressed. Compression is silent, and refill is instantaneous if the ETT is in the trachea. In contrast, if the ETT is in the esophagus, compression of the SIB is accompanied by a characteristic flatus-like noise, and the SIB remains collapsed on release. The test can be accomplished easily within 3 seconds, and the outcome is unmistakable.[113] This technique has been further modified by compressing the SIB before, rather than after, connection to the ETT connector.[114] Investigations that used the latter technique confirmed earlier studies and demonstrated that the sensitivity, specificity, and predictive value of the SIB are 100% (Figs. 32-13 and 32-14).[115-118]

Despite the efficacy of both the EDD and the SIB in differentiating esophageal from endotracheal intubation in essentially healthy patients, there have been reports of false-negative results (i.e., the ETT is in the trachea, but

Figure 32-14 In a demonstration, collapsed self-inflating bulbs were connected simultaneously to tracheally and esophageally placed endotracheal tubes (ETTs) in the presence of a nasogastric tube. The bulb connected to the ETT in the trachea instantaneously reinflated, whereas that connected to the ETT in the esophagus remained collapsed. (From Salem MR, Wafai Y, Joseph NJ, et al: Efficacy of the self-inflating bulb in detecting esophageal intubation: Does the presence of a nasogastric tube or cuff deflation make a difference? *Anesthesiology* 80:42–48, 1994.)

gas cannot be aspirated by the EDD or the SIB does not reinflate). The EDD or the SIB may fail to confirm ETT placement in infants, in whom the tracheal wall is not held open by rigid cartilaginous rings; if the ETT is obstructed by kinking or by the presence of material in the ETT; and in patients with severe bronchospasm.[119-122] Slow or no reinflation of the SIB may be encountered if the tube bevel is at the carina or in the right main stem bronchus.[24] In such cases, slight retraction or rotation of the ETT usually corrects the position of the tube and orientation of the bevel, resulting in instantaneous reinflation of the SIB.[121,123] The SIB may also fail to reinflate or may reinflate slowly when connected to a properly placed ETT in patients with morbid obesity (MO)[123,124] and in patients who have a marked reduction in expiratory reserve volume, such as in those with pulmonary edema or adult respiratory distress syndrome, parturients undergoing cesarean section, and patients undergoing chest compression during resuscitation. The presence of secretions causing airway obstruction may also lead to a false-negative result.[123,125]

In a study involving 2140 consecutive anesthetized adult patients,[123] the overall incidence of false-negative results with the SIB (i.e., no reinflation or reinflation delayed for longer than 4 seconds) was 3.6%. It was apparent that the choice of technique used can contribute to false-negative results. When the SIB was fully compressed before connection to the ETT in 1117 patients, the incidence was 4.6%, whereas false-negatives were reduced to 2.4% in 1023 patients when the SIB was compressed after connection to the ETT. Most of the patients (85.5%) in whom false-negative results were obtained had MO (body mass index >35 kg/m^2) (Table 32-3). We surmise that this phenomenon seen in patients with MO and in pregnant women is related to marked reduction in FRC after anesthetic induction and muscular paralysis in the supine position leading to reduced caliber of intrathoracic airways and collapsibility of the trachea on application of subatmospheric pressure by the SIB.[123-125] It is also possible that the negative pressure generated (greater than –50 cm H_2O) may cause collapse and invagination of the posterior tracheal wall. Further compression can occur as a result of mediastinal compression.[124,125] The chain of events that may lead to failure of the SIB to confirm endotracheal intubation is presented in Figure 32-15. If the SIB is compressed after connection to the ETT rather than before, a volume of gas is first introduced into the airway before subatmospheric pressure is generated by the SIB; this would limit the collapse of the SIB that is observed when it is compressed before connection to the ETT.[123-125]

TABLE 32-3

Demographics of False-Negative Results in Determining Correct ETT Placement with the Self-Inflating Bulb

Patient Condition	T1	T2
Morbid obesity	45	20
Severe bronchospasm	2	2
Elderly with chronic obstructive pulmonary disease	2	2
Main stem intubation	1	0
Pulmonary secretions	1	0
Pulmonary edema	0	1
Total	51	25

In T1, the self-inflating bulb (SIB) is compressed before it is connected to the endotracheal tube (ETT). In T2, the SIB is first connected to the ETT and is then compressed. See text for details.
From Wafai Y, Salem MR, Joseph NJ, Baraka A: The self-inflating bulb for confirmation of endotracheal intubation: Incidence and demography of false negatives. *Anesthesiology* 81:A1303, 1994.

(From Lang DJ, Wafai Y, Salem MR, et al: Efficacy of the self-inflating bulb in confirming endotracheal intubation in the morbidly obese. *Anesthesiology* 85:246–253, 1996.)

Advantages of the SIB include low cost, unlimited shelf life, no power source, usability with one hand, and usability in areas of low light. It is quick to use (<10 seconds) and is unaffected by ingested carbonated beverages, antacids, or exhaled CO_2 in the event of esophageal intubation. Unlike capnography, it can confirm endotracheal intubation before manual ventilation is initiated, thus avoiding the undesirable effects of esophageal ventilation.[116,118] The performance of the SIB should not be affected by a cardiac arrest, the presence of an NGT, or cuff deflation.[118] Studies found the EDD/SIB to be more accurate in verifying proper ETT placement in patients with out-of-hospital cardiac arrest and during emergency intubations than CO_2 detection methods.[126,128] Indeed, it has been the method preferred by emergency medical personnel.[126-128] Verification of ETT placement with the SIB enables physicians and emergency personnel to proceed with other resuscitation duties. Other studies found the SIB to be complementary to CO_2 detection.[31,129,130]

Some studies have found a high incidence of false-negative results with the use of the SIB in patients with out-of-hospital cardiac arrest.[130,131] Although the SIB correctly identified all esophageal intubations, it identified only 72% of ETTs placed in the trachea, whereas 60% of the latter were identified by CO_2 detection. Combining the SIB with CO_2 detection enhanced the sensitivity to 90.8%.[130] Possible reasons for incomplete or no reinflation of the SIB were similar to those presented in Table 32-3.

Based on the findings in a porcine cardiac arrest model, it has been suggested that the decreased muscle tone of the posterior tracheal wall that occurs during cardiac arrest could result in mucosal aspiration, airway blockage, and increased false-negative results associated with the use of EDDs.[132] These findings, however, could be explained by the excessive negative pressure generated with the use of certain SIBs.[133] Because no single test for verifying ETT position is reliable, all available modalities should be tested and used in conjunction with proper clinical judgment in cases of out-of-hospital cardiac arrest.[130,131]

Concern has been raised that false-positive results (i.e., ETT in esophagus, but SIB reinflates) may occur as a result of gastric insufflation after bag-mask ventilation before intubation. In one study, it was demonstrated that even after the intentional delivery of three small breaths (300 to 350 mL each), the SIB was effective in detecting esophageal intubation in all 72 patients.[116] In another study, despite the use of mask ventilation before intubation, the authors did not observe a single instance of instantaneous reinflation of the SIB from the esophagus.[113] In a study of one pig, Foutch and associates[134] used a syringe similar to that of Wee[109] and found that the device was effective in detecting esophageal intubation even after 1 minute of bag-mask ventilation.[132] Although these studies imply that the SIB is effective in detecting esophageal intubation after mask ventilation (and modest gastric insufflation), it may fail occasionally in cases of massive gastric insufflation or if the lower esophageal tone is decreased.[125,135] It is recommended that, when the SIB is used to confirm endotracheal intubation, the test should be undertaken before ventilation is initiated through the ETT.

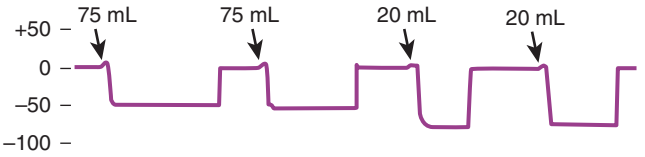

Figure 32-16 Representative tracing of negative pressure (mm Hg) generated by large (75 mL) and small (20 mL) self-inflating bulbs (SIBs) when the SIB is compressed before it is connected to the endotracheal tube placed in the esophagus. The small SIB generates greater negative pressure than the large SIB. See text for details.

It is essential that the SIB be of an appropriate size.[118,119] Although a smaller SIB (capacity 20 mL) has a smaller radius and therefore generates a higher negative pressure (Fig. 32-16), it is unreliable in detecting esophageal intubation if the SIB is compressed after connection to the ETT.[136] The larger SIB (capacity 75 mL) is recommended because it does not yield false-positive results when either technique is used.[137] Although SIBs can be constructed by fitting a bulb with a standard 15-mm adapter, they are commercially available for single use. The devices are checked before use by connecting the compressed SIB to a clamped ETT; absence of reinflation is an indication of airtightness (Fig. 32-17). We have found that proper function of the device is not affected when a bacterial or viral filter is placed between the device and the ETT connector.

An SIB that incorporates a colorimetric CO_2 detector is now available (Fig. 32-18). This new device (Salem SIB; Mercury Medical, Clearwater, FL) should enable clinicians to assess reinflation of the SIB after connection to the ETT and simultaneously to observe the color change indicative of the presence or absence of CO_2 in the expired gas during reinflation of the SIB. The use of this device should eliminate most of the false results and lead to accurate verification of the location of the ETT before manual ventilation is initiated.

Use of the SIB has been extended to identify the location of the ETC and facilitate its proper positioning using

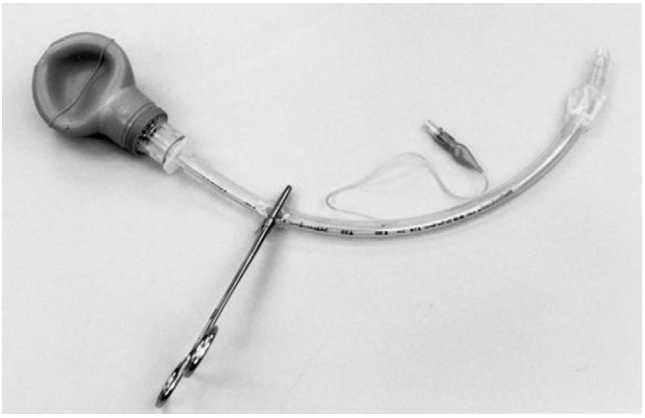

Figure 32-17 Testing the self-inflating bulb for leakage. The compressed bulb is connected to a clamped endotracheal tube. Absence of reinflation is indicative of airtightness. This test reveals any leakage from the bulb or the connector (such as a cracked connector or loose fitting).

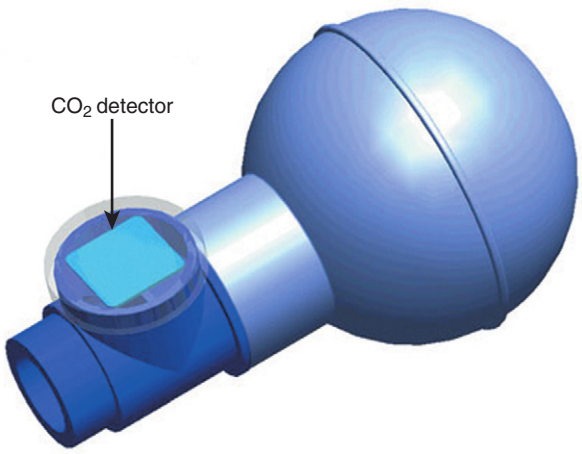

Figure 32-18 Salem self-inflating bulb. See text for details. (Courtesy of Mercury Medical, Clearwater, FL.)

a simple algorithm (Figs. 32-19 and 32-20).[95] This may be of importance if the ETC is used in patients whose lungs cannot be ventilated by mask and whose trachea cannot be intubated. After blind placement, the compressed SIB is connected to the distal lumen. Instantaneous reinflation implies that the ETC is in the trachea and ventilation is carried out through the distal lumen; absence of reinflation is indicative of esophageal placement, which is very common. In this position, the pharyngeal balloon and the distal cuff are inflated and the compressed SIB is connected to the proximal lumen; instantaneous reinflation is expected to occur because the compressed SIB aspirates gas from the lungs through the

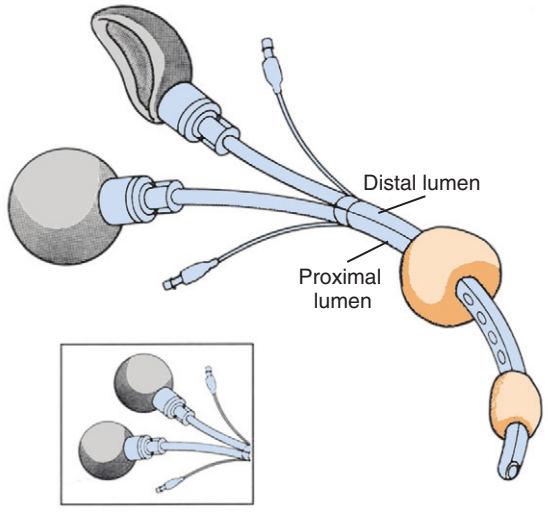

Figure 32-19 Schematic diagram depicting outcome when the compressed self-inflating bulb is connected to the distal and proximal lumens of an esophageal-tracheal Combitube in the esophageal position. Notice that the bulb connected to the distal lumen remains collapsed, whereas that connected to the proximal lumen instantaneously reinflates. The insert depicts the outcome when the Combitube is in the trachea: Both bulbs instantaneously reinflate. (From Wafai Y, Salem MR, Baraka A, et al: Effectiveness of the self-inflating bulb for verification of proper placement of the esophageal-tracheal Combitube. *Anesth Analg* 80:122–126, 1995.)

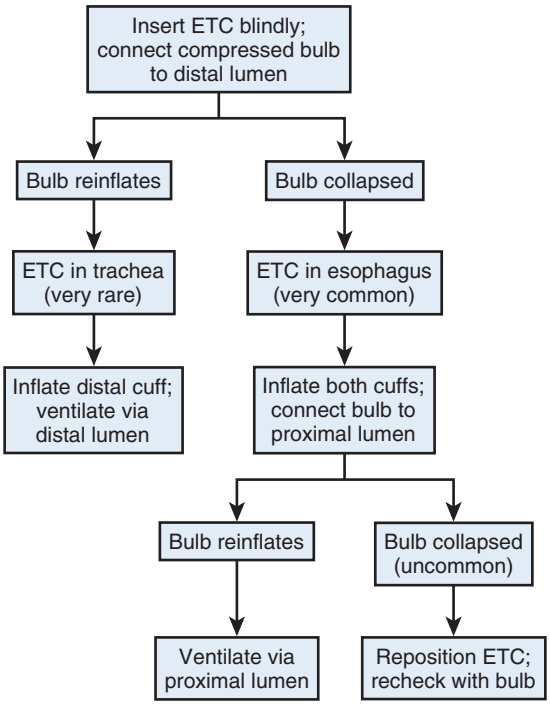

Figure 32-20 Algorithm for identifying the position and facilitating proper placement of the esophageal-tracheal Combitube *(ETC)* after blind placement. (From Wafai Y, Salem MR, Baraka A, et al: Effectiveness of the self-inflating bulb for verification of proper placement of the esophageal-tracheal Combitube. *Anesth Analg* 80:122–126, 1995.)

pharyngeal perforations. If slow or no reinflation of the SIB occurs, repositioning the ETC (pulling it back 1 to 2 cm) may be indicated, and rechecking with the SIB confirms proper placement. Controlled ventilation is then carried out through the proximal lumen. Proper positioning and adequacy of ventilation can be further confirmed by the presence of breath sounds, absence of gastric insufflation, capnography or colorimetric CO_2 detection, and pulse oximetry.[95]

c. ACOUSTIC DEVICES AND REFLECTOMETRY

Devices that use sonic techniques as the basis for distinguishing tracheal from esophageal intubation have been developed. The mechanism of action of the Sonomatic Confirmation of Tracheal Intubation (SCOTI) device (Penlon; Abingdon, Oxfordshire, UK) is recognition of the resonating frequencies, which vary according to whether the tube is in an open structure (trachea) or a closed structure (esophagus).[138] Although the concept is intriguing, the inability to configure the device correctly with all types and lengths of ETTs has limited its usefulness as an indicator of endotracheal intubation.[139-142] Disappointing sales led to withdrawal of the device from the market in 1996.[143]

Another approach employs the principle of acoustic reflectometry by projecting a series of sonic impulses into the airway and placing a miniature microphone in the ETT wall to monitor sound pressure.[144] The presence of deflection at the ETT tip allows discrimination between esophageal and endotracheal intubation. With acoustic

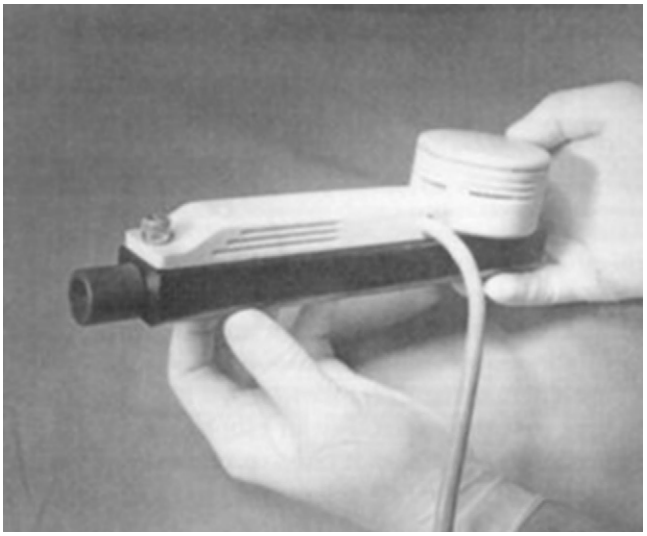

Figure 32-21 A Hood Labs (Pembroke, MA) two-microphone acoustic reflectometer. (From Raphael DT, Benbassat M, Arnaudov D, et al: Validation study of two-microphone acoustic reflectometry for determination of breathing tube placement in 200 adult patients. *Anesthesiology* 97:1371–1377, 2002.)

reflectometry, one-dimensional image of a cavity, such as the airway or the esophagus, is constructed. The reflectometric area-distance profile consists of a constant cross-sectional area segment (length of the ETT), followed either by a rapid increase in the area beyond the tube in case of endotracheal intubation or by an immediate decrease in the area in case of esophageal intubation.[145] In a study of 200 endotracheal intubations confirmed by capnography, acoustic reflectometry correctly identified 198 (Figs. 32-21 through 32-23). In 2 patients, endotracheal intubations were interpreted as an esophageal intubation. However, all 14 esophageal intubations were correctly identified.[146] Because it is noninvasive and rapid (<3 seconds), acoustic imaging may become popular in future in the determination of the location of ETT placement in patients with cardiac arrest, particularly when visualization of the glottis is not possible. With technical improvement in the computer-based system, acoustic reflectometry may have value as an imaging adjunct device that can be used in the diagnosis and treatment of airway emergencies.[146]

3. Failsafe Methods

a. DIRECT VISUALIZATION OF THE ENDOTRACHEAL TUBE BETWEEN THE CORDS

Sighting of the ETT passing through the larynx during intubation or confirmation of the presence of the ETT between the cords after intubation is one of the most reliable methods to ensure correct ETT placement. Two maneuvers can be helpful to assist direct visual confirmation of endotracheal intubation, one during and the other after intubation.

If the ETT is introduced directly posterior to the laryngoscope blade, as shown in Figure 32-24A, the laryngoscopist's view of the cords may be obscured and the ETT may inadvertently enter the esophagus. This can be avoided by directing the ETT from the right corner of the mouth toward the larynx. As seen in Figure 32-24B, this maneuver can allow visualization of the ETT entering the larynx, thus confirming endotracheal intubation. The other maneuver that can be performed after intubation but before removing the laryngoscope from the mouth involves gentle posterior displacement of the ETT toward the palate (Fig. 32-25).[147] The backward push on the tube against the forward traction of the laryngoscope blade exposes the cords by altering the direction of the ETT as it enters the larynx.[147] This maneuver can be helpful in cases in which the cords are obscured by the ETT as it enters the larynx.

Viewing the ETT entering the larynx cannot be accomplished in all cases of direct laryngoscopy, especially if intubation is difficult and during blind nasal intubation. Even after visualization of the ETT entering the larynx, the tube may slip out of the larynx while the laryngoscope is being removed, during taping of the tube, while the patient is being positioned, or during transportation. This tends to occur more frequently if

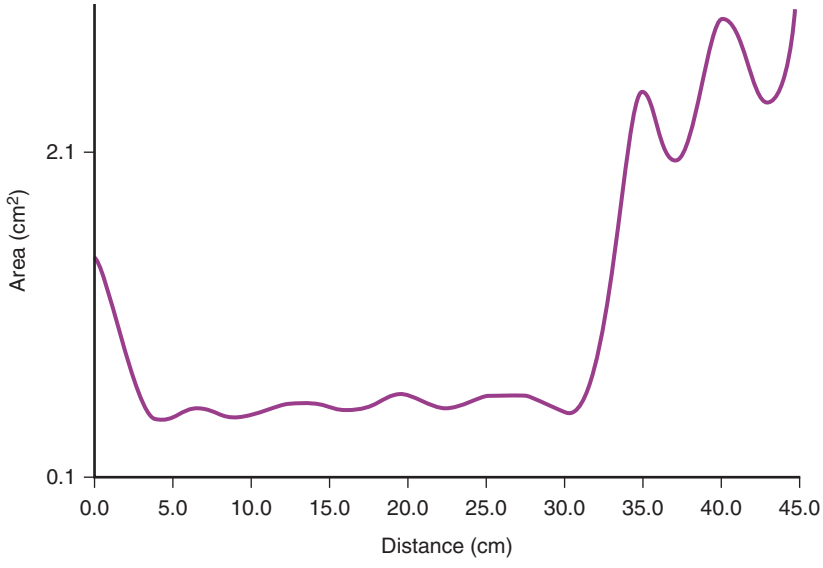

Figure 32-22 An acoustic reflectometry area-distance profile consists of a plot of the total cross-sectional area of the cavity versus axial length down into the cavity. If the endotracheal tube (ETT) is placed in the trachea, the reflectometric profile consists of a constant cross-sectional area segment (length of ETT), followed by a rapid increase in the area beyond the carina. (From Raphael DT, Benbassat M, Arnaudov D, et al: Validation study of two-microphone acoustic reflectometry for determination of breathing tube placement in 200 adult patients. *Anesthesiology* 97:1371–1377, 2002.)

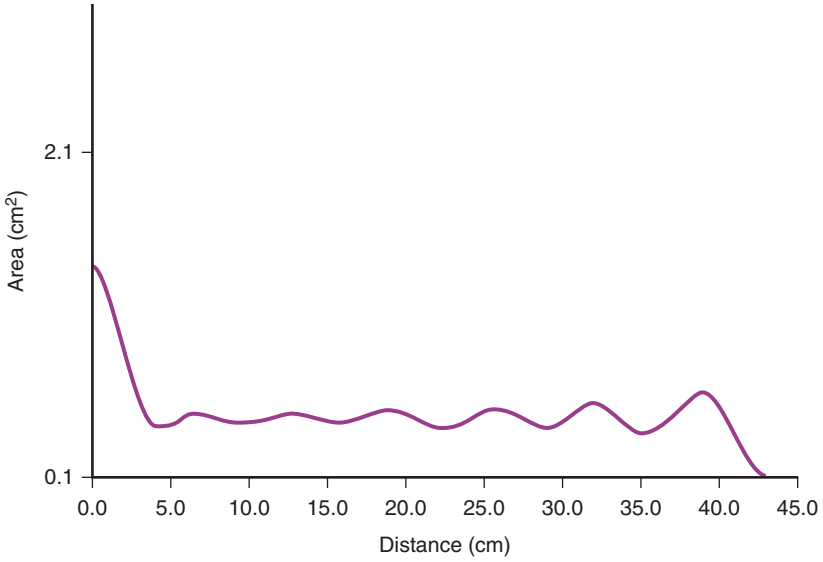

Figure 32-23 If the endotracheal tube (ETT) is placed in the esophagus, the reflectometric profile consists of a constant cross-sectional area segment (length of ETT), followed by an immediate decrease in the area distal to the tube. (From Raphael DT, Benbassat M, Arnaudov D, et al: Validation study of two-microphone acoustic reflectometry for determination of breathing tube placement in 200 adult patients. *Anesthesiology* 97:1371–1377, 2002.)

the distal end of the ETT lies just below the cords or high in the trachea.

b. FLEXIBLE FIBEROPTIC BRONCHOSCOPY

A sure method for confirmation of endotracheal intubation is visualization of the tracheal rings and carina with a flexible fiberoptic bronchoscope (FFB) after intubation.[147-149] This is convenient only when an FFB is readily available or when the instrument is used to aid intubation (see Chapter 19). It should be emphasized that visualization of the vocal cords and tracheal rings through the FFB before the ETT is threaded over it does not guarantee endotracheal intubation. There are three reasons why the ETT may not follow the path of the FFB into the trachea.[148,150-152] First, a stiff, large ETT may carry a relatively thin FFB into the esophagus even if the tip of the scope was originally placed in the larynx and trachea.[148,150] Second, the tip of the tube and its Murphy eye are at 90 degrees to the right when the concavity of the ETT is facing anteriorly.[148,152] Consequently, the tip of the tube may be blocked from entering the larynx by the right arytenoid cartilage, the vocal cord, or both. If excessive force is used, the tube may slip into the esophagus. This problem can be corrected by a 90-degree counterclockwise rotation.[148,152] Third, if the scope is inserted through a tube placed nasally, the FFB may exit the tube through the Murphy eye and may actually enter the trachea, but in this case it will be impossible to thread the tube over the scope.[148,151] To ensure that endotracheal intubation has been accomplished, the FFB should be withdrawn after placement of the tube and then reintroduced to visualize the tracheal rings and carina and to determine the distance from the distal end of the tube to the carina.[148]

III. VERIFICATION OF ENDOTRACHEAL TUBE INSERTION DEPTH

According to the ASA closed claims analysis, the combination of inadvertent extubation and main stem

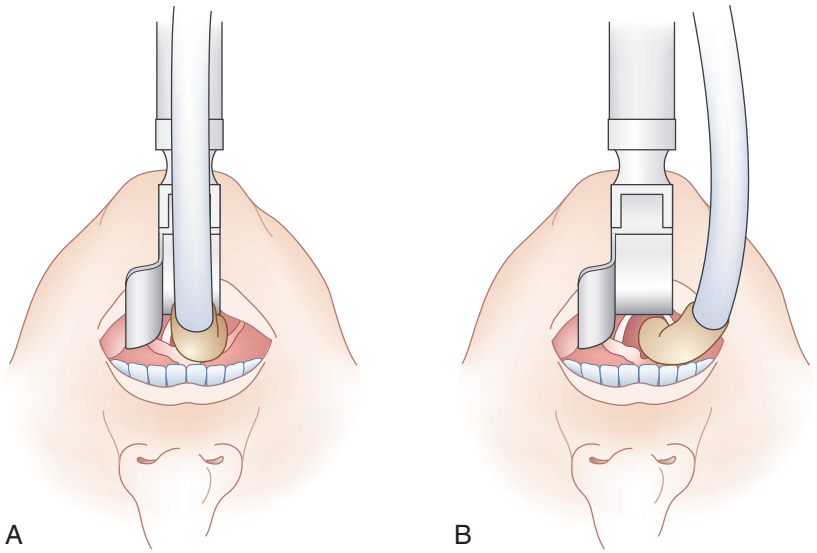

Figure 32-24 **A,** When the endotracheal tube (ETT) is introduced directly posterior to the blade, the view of the cords may be obscured and the tube may enter the esophagus instead of the trachea. **B,** Directing the ETT from the right corner of the mouth toward the larynx can allow better visualization of the tube entering the larynx.

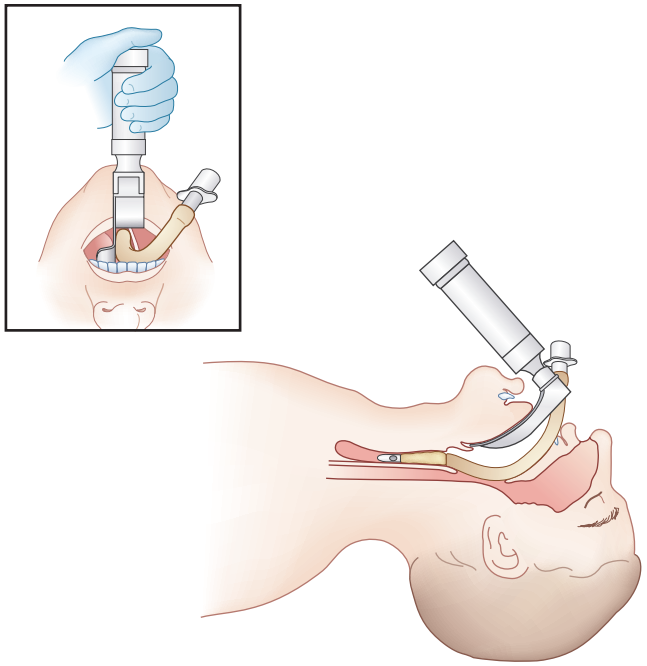

Figure 32-25 Posterior displacement of endotracheal tube restores the view of the larynx. (From Ford RW: Confirming endotracheal intubation: A simple manoeuvre. *Can Anaesth Soc J* 30:191–193, 1983.)

intubation accounts for 2% of all adverse respiratory events in adults and 4% in pediatric patients.[1,5] Analysis of the Australian Incident Monitoring Study (AIMS) found that "accidental" bronchial intubation accounted for 3.7% of the total incidents reported. Most of the bronchial intubations were detected in the operating room (93.5%), during maintenance of anesthesia (77.9%), and by unexplained O_2 desaturation alone (63.6%). Capnography remained normal or unremarkable during 88.5% of episodes.[153] The incidence of main stem intubation in the critical care setting, not detected by clinical examination but discovered on chest radiography after intubation, is 4%.[20] Applying a strict definition of "acceptable ETT placement" as more than 2 cm but no more than 6 cm above the carina (with the head in a neutral position) in adult patients after emergent intubation, Schwartz and colleagues found an incidence of 15.5% of inappropriately placed ETTs according to radiologic assessment, with a higher incidence in women than in men.[154]

Fortunately, endobronchial intubation is not a common cause of death, but if it remains unrecognized, it can lead to hypoxemia secondary to collapse of the contralateral lung and hyperinflation of the intubated lung with resultant tension pneumothorax. The ensuing hypoxemia depends on the degree of venous admixture ($\dot{V}/\dot{Q} > 0$), the magnitude of intrapulmonary shunting where $\dot{V}/\dot{Q} = 0$, the fraction of inspired oxygen (F_{IO_2}), the degree of inhibition of hypoxic pulmonary vasoconstriction, and the level of $S\bar{v}O_2$. Unintentional main stem intubation can result in one of several scenarios depending on the location of the distal end of the tube (Fig. 32-26).[155] Placement of the ETT high in the right main bronchus (or even at the carina) may result in preferential ventilation of the right lung. Retrograde gas flow may lead to partial ventilation of the left lung if the ETT cuff does not provide a tight seal (see Fig. 32-26A).[153] A biphasic CO_2 waveform may be noticed (when the two lungs have different time constants).[156] Ventilation with high flow rates through an ETT whose tip is placed just proximal to the orifice of the right upper lobe bronchus promotes negative pressure (Bernoulli effect) and atelectasis of the right upper lobe (see Fig. 32-26B). Placement of the ETT further down the right main bronchus prevents ventilation of the left lung and occludes the right upper lobe bronchus (see Fig. 32-26C). An ETT placed in the lower portion of the trachea may obstruct a congenital tracheal bronchus, causing upper right lobe atelectasis (Fig. 32-27; see Fig. 32-26D).[157,158] In this rare anomaly, the bronchus to the right apical lung segment or the bronchus to the right upper lobe arises directly from the trachea, usually less than 2 cm from the carina.

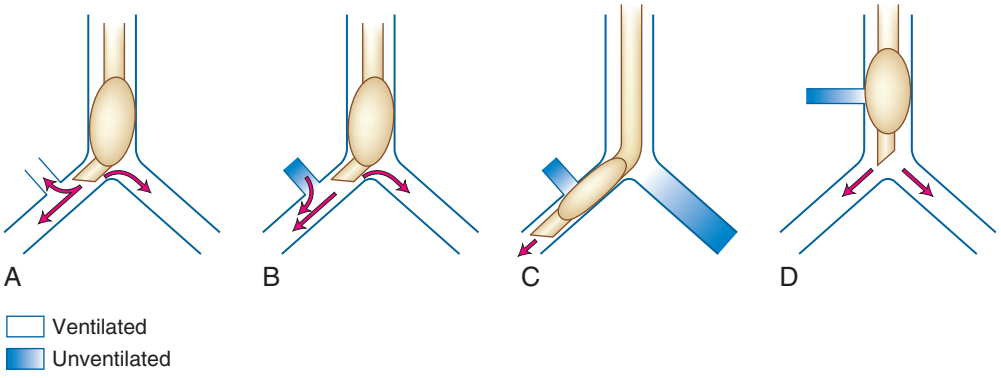

Figure 32-26 Unintentional intubation of the main stem bronchus can result in one of several scenarios, depending on the location of the distal end of the endotracheal tube (ETT). **A,** Placement of the ETT high in the right main bronchus may result in preferential ventilation of the right lung. Retrograde gas flow may lead to partial ventilation of the left lung if the ETT cuff does not provide a tight seal. **B,** Ventilation with a high flow rate through an ETT whose tip is placed just proximal to the orifice of the right upper lobe bronchus promotes negative pressure and atelectasis of the right upper lobe. **C,** Placement of the ETT further down the right main bronchus prevents ventilation of the left lung and occludes the right upper lobe bronchus. **D,** A tube placed in the lower portion of the trachea may obstruct a congenital tracheal bronchus, causing upper right lobe atelectasis. (Modified from Mecca RS: Management of the difficult airway. In Kirby RR, Gravenstein N, editors: *Clinical anesthesia practice*, ed 2, Philadelphia, 2007, Saunders, pp 921–954.)

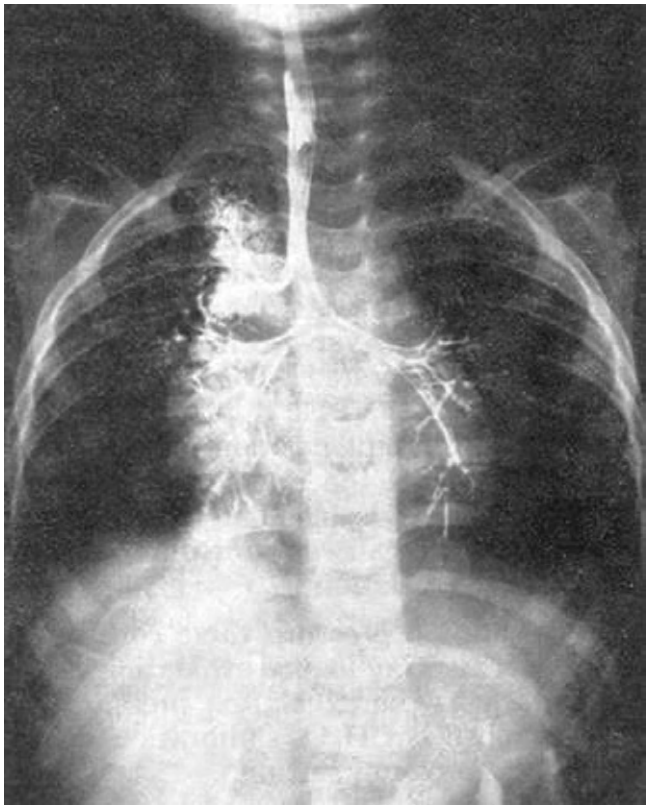

Figure 32-27 Bronchographic study revealing the presence of an apically displaced right tracheal bronchus. The left tracheal shadow at the level of the first rib is suggestive of a vascular ring, although this was not verified by cardiac catheterization or esophagograms. The potential for inadvertent intubation or occlusion of this lower airway anomaly is apparent. (From Venkateswarlu T, Turner CJ, Carter JD, Morrow DH: The tracheal bronchus: An unusual airway problem. *Anesth Analg* 55:746, 1976.)

A. Methods of Verification of Endotracheal Tube Insertion Depth

To decrease the likelihood of main stem intubation and unintentional extubation, clinicians should aim at positioning the distal end of the ETT in the middle third of the trachea. Various methods can be used before, during, or after intubation to locate the ETT at an appropriate depth in the trachea.

1. Referencing the Marks on the Tube Before and After Intubation

In one method, the ETT is placed alongside the patient's face and neck with the tip of the tube lying at the suprasternal notch and the tube aligned to conform externally to the position of the nasal or oral ETT. The centimeter marking at which the tube intersects with the teeth or gums for oral intubation, or the naris for nasal intubation, is noted so that the ETT can be secured in that position after intubation. In another method, the orally placed ETT is secured at the upper incisor teeth (or gums) at the 23-cm mark in men and the 21-cm mark in women of average adult size.[159] This method was found to be reliable in anesthetized patients but not in critically ill patients.[20,159] We have observed that in tall men and in patients in whom excessive head extension is needed, the ETT may need to be secured at the 24- or 25-cm mark; in some shorter women, it may need to be secured at the 19-cm mark for optimal placement of the distal end of the ETT in the middle of the trachea. Formulas regarding the appropriate length of the ETT are available for infants and children. The reader is referred to pediatric anesthesia texts for this information.

BOX 32-1 Precautions to Prevent Endotracheal Tube Displacement

- The laryngoscope blade should be gently removed after intubation while the endotracheal tube (ETT) is secured in position.
- The ETT should be taped or anchored carefully in place.
- An oropharyngeal airway (or a bite block) placed adjacent to the ETT can minimize movement of the ETT inside the mouth and prevent its dislodgement, especially during coughing.
- The head should be kept in neutral position unless head extension or flexion is needed for the surgical procedure.

2. Direct Visualization of the Tube and Its Cuff

Positioning of the distal end of the ETT in the middle of the trachea is a relatively easy maneuver when the ETT can be seen entering the larynx during direct laryngoscopy. Because the length of the trachea is 10 to 13 cm in an average adult, placing the upper end of the cuff of an ETT (7 or 8 mm ID in size) 2 cm below the vocal cords positions the distal end of the tube approximately 4 cm from the carina. In a simple study based on measurements, it was found that, except in cases of short tracheas, placing the upper end of the cuff 2 cm below the cords predictably positioned the distal end of the ETT in the middle of the trachea.[160] This maneuver should be used whenever orotracheal intubation is performed under direct laryngoscopy.

3. Prevention of Endotracheal Tube Displacement After Intubation

Despite initial proper positioning, the ETT can still slip out of the larynx (or move closer to the carina) while the laryngoscope blade is being removed, during taping of the tube, after the position of the head is changed, during positioning of the patient, or during transportation. Several precautions should be undertaken to prevent ETT displacement (Box 32-1).

4. Influence of Positioning on Endotracheal Tube Insertion Depth

Excessive movement of the ETT can occur during extension and flexion of the head.[161,162] In a radiologic study in adults, Conrardy and coworkers demonstrated an average 3.8-cm movement of the ETT toward the carina when the head was moved from full extension to full flexion (Fig. 32-28).[161] In some patients, this movement reached as much as 6.4 cm. With lateral head rotation, the ETT moved an average of 0.7 cm away from the carina. Because the average movement of the ETT when the head is moved from the neutral position to full extension or full flexion is 1.9 cm in the adult, it is unlikely that

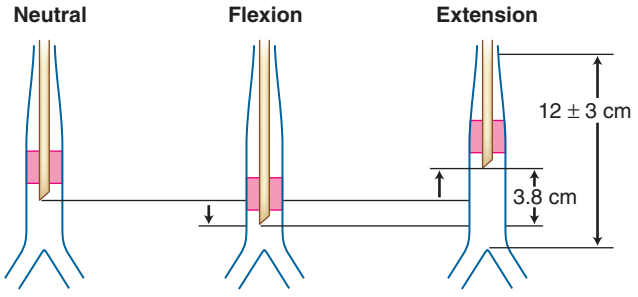

Figure 32-28 Mean movement of an endotracheal tube (ETT) with flexion and extension of the neck from the neutral position. The mean ETT movement between flexion and extension is about one third to one fourth of the length of an adult trachea (12 ± 3 cm). (From Conrardy PA, Goodman LR, Lainge F, et al: Alteration of ETT position: Flexion and extension of the neck. *Crit Care Med* 4:8–12, 1976.)

extubation or main stem intubation would occur during this movement if the distal end of the tube is in the middle of the trachea, but it could occur if it is too high or too low in the trachea.

Malpositioning of the ETT can occur with changes in patient positioning,[163] with displacement of the diaphragm, and during surgical manipulation of the trachea or esophagus, especially if the ETT is not initially placed in the middle of the trachea. A high incidence of main stem intubation has been reported after institution of the Trendelenburg position. The weight of the abdominal organs results in cephalad shift of the diaphragm and the carina, which may cause a taped ETT to relocate into a main stem bronchus. The opposite can happen when the reverse Trendelenburg position is used.

Many reports have confirmed tracheal tube migration on creation of a pneumoperitoneum during laparoscopic procedures, increasing the risk for endobronchial intubation.[164-169] Although the Trendelenburg tilt can lead to further migration, movement can also occur during upper abdominal laparoscopic procedures performed in the reverse Trendelenburg position.[165] The mechanism is similar to that for the Trendelenburg position, but the diaphragm is displaced cephalad by the insufflated gas rather than the weight of the abdominal contents. After positioning of the tip of the ETT at 30 to 40 mm from the carina, it was found that the distance significantly decreased to 26 mm (range, 17 to 35 mm) in patients undergoing laparoscopic cholecystectomy. The maximum distance of tube migration was 8 mm (range, 0 to 15 mm). One fifth of the patients would have been at risk of bronchial intubation if the ETT had not been carefully positioned.[167] ETT migration occurs more often in obese patients undergoing laparoscopic procedures compared with open abdominal surgery. In 17% of obese patients, the tube advances into the right bronchus.[168] ETT displacement also occurs in children undergoing laparoscopic procedures. In one study,[169] maximal displacement was 0.5 + (0.05 × age in years) for 20-degree head-down tilt, 0.6 + (0.09 × age) after insufflations, and 1.2 + (0.11 × age) for 20-degree head-down tilt and insufflations. However, in no patient did endobronchial intubation occur when the ETT was placed according to the intubation depth marking as recommended by the manufacturer.

Obviously, the tip of the ETT should be placed in the middle of the trachea, or 3 to 4 cm above the carina in adults. If the ETT moves toward the carina, then carinal stimulation may cause tachycardia, hypertension, or bronchospasm and increase the risk of bronchial intubation.[163] If the ETT moves outward, the cuff may cause injury to the vocal cords and increase the risk of accidental extubation. If the ETT is placed appropriately in the middle of the trachea, it is very unlikely (except in infants) that endobronchial intubation or extubation will ensue.

Because the trachea and the esophagus are invested in the same cervical fascia, pulling on either structure during surgery can misplace an ETT. This can occur during repair of esophageal atresia in infants and during esophagoscopy. Excessive movement of the head and neck of intubated patients must be avoided; however, if such movements are necessary, they should be done carefully. The position of the ETT should be rechecked when the patient's position is altered; when the head is moved; after surgical manipulation of the trachea or esophagus; whenever displacement of the diaphragm is suspected (e.g., changes in FRC, changes in position, abdominal insufflation); and when an unexplained decrease in Sa_{O_2}, increased airway pressure, cuff leak, or biphasic CO_2 waveform is noticed.

The ease with which main stem intubation can occur with head flexion and unintentional extubation with head extension is of particular concern in the infant, especially in the neonate, whose trachea is only 4.7 to 5.7 cm long (Fig. 32-29).[170,171] When endotracheal intubation is performed in infants, precautions should be taken to ensure that the ETT is placed far enough in the trachea but not in a main stem bronchus. One precaution is to use an ETT that has circumferential marks at 2.2 cm from the distal end and to introduce the marker on the ETT as far as the cords in term infants, slightly above the cords in preterm infants, and slightly below the cords in older infants. Another alternative that has been recommended is to use ETTs with diameters of 2.5, 3.0, and 3.5 mm and marks at 2.2, 2.4, and 2.6 cm, respectively, from the distal end. The reader is referred to pediatric anesthesia texts for more details.

5. Observation and Palpation of Chest Movements and Auscultation of Breath Sounds

Observation or palpation of an asymmetrical chest movement and detection of unequal bilateral breath sounds should alert the clinician to the possibility of a main stem intubation (usually on the right side). In addition, absence of right apical movement or breath sounds, or both, implies that the ETT and its cuff are obstructing the right upper lobe bronchus. Gradual withdrawal of the tube should correct the problem. Although auscultation of bilateral breath sounds is the most common method used in detecting main stem intubation, investigations revealed that this may not be a reliable diagnostic modality.[153,172,173] Brune and colleagues observed that

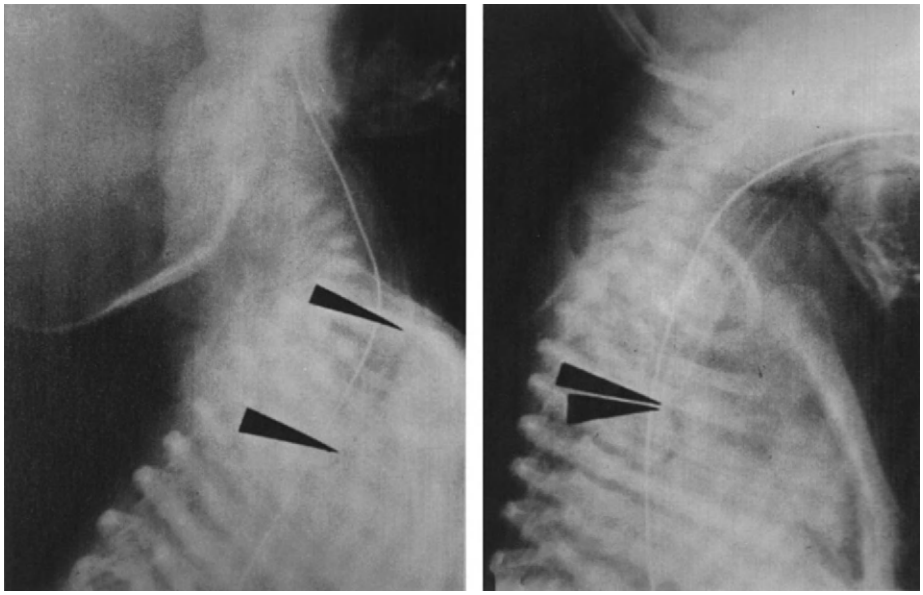

Figure 32-29 Radiographs illustrate the effect of head position on placement of the endotracheal tube (ETT) in newborn infants. The upper arrow indicates the tip of the ETT; the lower arrow indicates the tip of the carina. Notice the marked excursion of the tip of the tube with head flexion *(right)*. (From Todres ID, deBros F, Kramer SS: Endotracheal tube displacement in the newborn infant. *J Pediatr* 89:126–127, 1976.)

60% of endobronchial intubations occurred despite the presence of equal breath sounds on auscultation.[172]

The inaccuracy of the auscultation method may be related to the structure of the tip of the ETT when it is placed near the carina.[174] The Murphy eye, which is present in most ETTs, is a 1.0-cm elliptical port located 0.8 cm from the tip on the right side of the tube, opposite the bevel. The eye was originally designed to allow ventilation of the lungs if the bevel becomes occluded and also to allow ventilation of the right upper lobe if the ETT is accidentally advanced into the right main stem bronchus.[144] Studies confirmed that the Murphy eye can maintain gas flow through the space between the ETT cuff and the right main stem bronchus and that it permits ventilation (albeit inadequate) of the left lung, thus allowing breath sounds to be heard bilaterally, until the tip is inserted 2 cm beyond the carina. Unilateral breath sounds may not be heard until the tube tip is further advanced to 3.2 cm beyond the carina.[174] Accordingly, the Murphy eye reduces the reliability of chest auscultation in detecting endobronchial intubation.[174]

Despite the limitations of auscultation of bilateral breath sounds, continuous or repeated auscultation to detect intraoperative complications such as bronchial intubation and obstructed airway has been emphasized.[175] The limitations and difficulties encountered in continuously and simultaneously auscultating right and left breath sounds have led investigators to explore other methods to amplify breath sounds.[37,176] In one method, already discussed, breath sounds are quantified using electronic stethoscopes placed over each hemithorax and epigastrium.[37] In another, a system that makes it possible to "visualize" breath sounds is used. The visual stethoscope allows real-time fast transformation of the sound signal and three-dimensional color rendering of the results on a computer with simultaneous processing of two individual sound signals.[176] With continuous bilateral breath sounds displayed, the clinician can monitor left and right breath sounds simultaneously and can rapidly detect any changes.[176] This system has potential advantages in assessing breath sounds throughout the surgical procedure, not just to verify ETT placement. Furthermore, more than one individual can monitor breath sounds.

Preliminary studies of both the electronic and the visual stethoscope showed precise accuracy for detecting endobronchial intubation.[37,176] During advancement of the ETT, alterations of the shape of the visualized breath sounds appeared before changes in breath sounds were detected by auscultation. However, these studies were conducted in nonobese patients without lung pathology in a quiet operating room. Further evaluation is needed in patients with a variety of pathologic conditions and under different ambient conditions.[37,176]

6. Cuff Maneuvers and Neck Palpation

Various maneuvers involving palpation of the ETT cuff on each side of the trachea above the suprasternal notch (e.g., rapid cuff inflations, intermittent squeezing of the pilot balloon of a slightly overinflated cuff, use of the pilot balloon as a sensor while palpating the cuff in the neck) have been proposed to ensure that the ETT is not in a main bronchus.[177,178] Suprasternal palpation of the cuff provides a high degree of confidence that the distal tip of the tube is more than 2 cm from the carina, whereas if the cuff is not palpable, the tip is probably close to the carina.[178]

7. Use of Fiberoptic Bronchoscopes

During fiberoptic intubation, the distance from the distal end of the ETT to the carina should be determined and the position of the ETT can be easily corrected, if necessary.[148,149] The distal end of the tube is usually positioned approximately 4 cm from the carina in adult patients.

The use of FFB to evaluate the position of the ETT has been extended to the critical care setting to obviate the necessity of frequent chest radiographs.

8. Transtracheal Illumination

Transillumination techniques can help position the ETT tip at a reliable distance above the carina. Two methods have been suggested. In one, the flexible lighted stylet is placed inside the ETT so that the stylet bulb is positioned at the tube's distal opening before intubation.[49,50] By observing maximal illumination at the sternal notch (a consistent anatomic landmark) during intubation, the tip of the tube can be placed consistently 5.0 ± 1.0 cm from the carina.[50] In the other method, the tip of the lighted stylet is placed inside the ETT, just proximal to the cuff, before intubation. Visualization of transillumination distal to the cricoid cartilage is indicative of proper cuff positioning. In this position, the distance between the tip of the ETT and the carina varies from 3.7 to 4 cm in adults. Use of either method can reduce the need for radiographic confirmation of ETT positioning.

9. Capnography

In cases of main stem intubation, the capnographic waveform usually shows a normal pattern. If a biphasic waveform is noticed, main stem intubation or impingement of the tube on the carina should be suspected.[156] Other causes of biphasic waveforms should be excluded, such as lateral decubitus position, kyphoscoliosis causing compression of the lung, pulmonary disease, spontaneous breathing efforts, hiccups, and sampling line leak.[30,79,156]

10. Use of the Esophageal Detector Device/Self-Inflating Bulb

The EDD with SIB is of no value in diagnosing main stem intubation. However, main stem intubation should be suspected if there is slow reinflation of the SIB.[137] Rotation or gradual pullback of the ETT, or both, may lead to instantaneous reinflation of the SIB.

11. Chest Radiography

In critically ill patients, a portable chest radiograph can easily detect main stem intubation and can determine the location of the distal end of the tube in relation to the carina (Fig. 32-30).[20,65,154] Because malpositioned ETTs may not be detected by routine clinical assessment, some investigators are recommending that chest radiographs should remain the standard practice in the critical care setting.[65,154]

IV. CONCLUSIONS

The goals of endotracheal intubation are to place the ETT in the trachea and to position the tube at an appropriate depth inside the trachea. Unrecognized esophageal intubation and ETT malposition are a leading cause of injury involving the respiratory system in anesthetic practice and in the prehospital setting. Although they are rare events, the outcome is so devastating that awareness of their occurrence is essential whenever endotracheal intubation is performed.

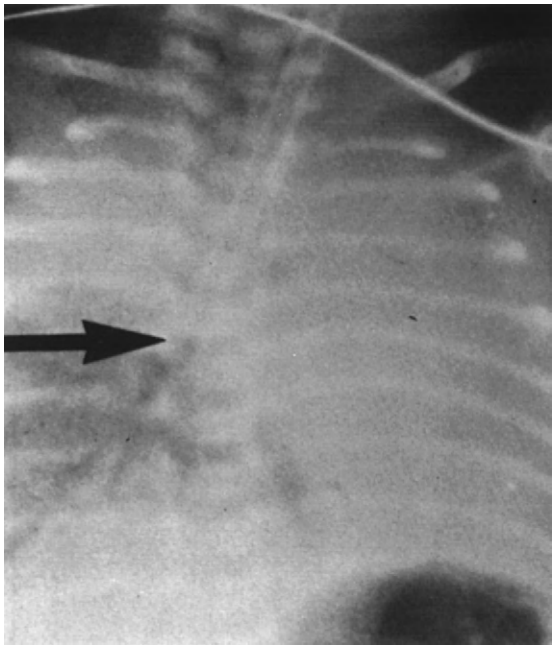

Figure 32-30 Malposition of the endotracheal tube (ETT). The ETT is in the bronchus intermedius *(arrow)*. Notice the airless left lung and right upper lobe. (From Mandel GA: Neonatal intensive care radiology. In Goodman LR, Putman CE, editors: *Intensive care radiology: Imaging of the critically ill,* Philadelphia, 1983, WB Saunders, p 290.)

A vast array of methods has been described to verify ETT placement. In most patients, these methods (alone or in combination) can successfully and quickly differentiate esophageal from endotracheal intubation. Nevertheless, almost all of these methods have been documented to fail under certain circumstances. It is crucial that clinicians involved in endotracheal intubation have the necessary airway management skills, perform these tests accurately, and interpret their results correctly. Obviously, not all of these tests can be applied in every situation, but the clinician should be familiar with and use as many tests as possible. Prioritization of these tests depends on many factors, including experience, availability of devices, condition of the patient, and the setting in which endotracheal intubation is performed.

Viewing the ETT passing between the cords during direct laryngoscopy and visualization of the tracheal rings and carina with an FFB after intubation are the only foolproof methods of confirming endotracheal intubation. In the nonarrested patient, CO_2 monitoring can quickly differentiate tracheal from esophageal intubation. In the arrested patient, CO_2 monitoring can be unreliable, although it can be useful as a prognostic indicator of the efficacy of resuscitation. Devices such as the EDD/SIB may be more useful in patients with cardiac arrest, but they can also yield false results.

Placing the distal tip of the ETT in the middle of the trachea can be accomplished by positioning the upper end of the cuffed ETT 2 cm below the vocal cords during direct laryngoscopy or by placing the distal tip of the tube 4 cm above the carina with the aid of an FFB in adults. The position of the ETT should always be verified by clinical assessment (auscultation of both axillae and the epigastrium). If direct visualization cannot be done,

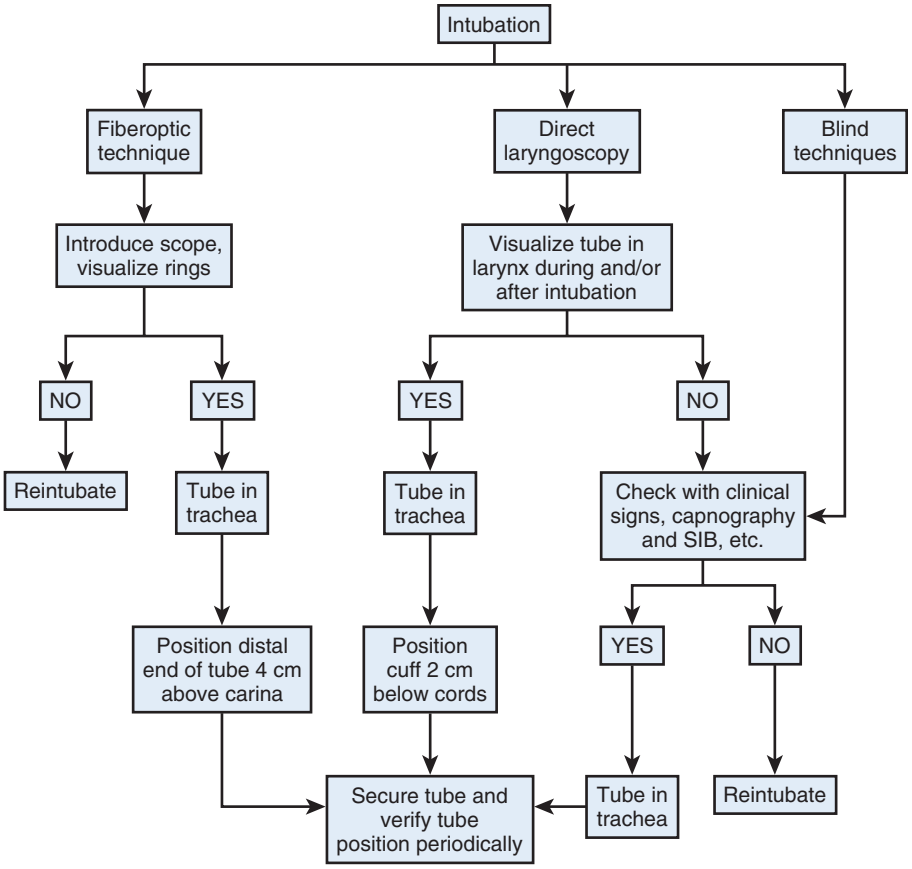

Figure 32-31 Proposed algorithm for verification of endotracheal tube (ETT) position and insertion depth during elective endotracheal intubation. Intubation is performed using an ETT of appropriate size and length. Blind techniques include blind nasal or oral intubation and intubation with introducers or intubating stylets. Verify tube position periodically, especially in the following situations: changes in ETT position, changes in head or body position, suspected decrease in functional residual capacity or displacement of the diaphragm, traction on trachea or esophagus, unexpected fall in arterial oxygen saturation (Sao_2), biphasic CO_2 waveform, and unexpected cuff leak. Cuff leak after adequate cuff inflation can be a result of leakage around the cuff or loss of air from the cuff; causes include cuff protruding above cords, ETT too small, extremely compliant airway, tracheomalacia, tracheoesophageal fistula (very rare), defective cuff or damage to cuff during intubation, defective pilot-balloon system, and kinking of connecting tubing. *SIB*, Self-inflating bulb. (From Salem MR: Verification of ETT position. *Anesthesiol Clin North Am* 19:813–839, 2001.)

referencing the marks on the ETT, use of transillumination techniques, or cuff maneuvers can be helpful. In emergency and critical care settings, a chest radiograph can easily detect malpositioned ETTs that may not be detected by routine clinical assessment. Other techniques (use of an FFB, cuff maneuvers, transillumination) can obviate the necessity for frequent chest radiographs.

On the basis of available information, two algorithms are proposed: one for verification of ETT position in elective intubation (Fig. 32-31) and the other for emergency intubation (Fig. 32-32). These algorithms are designed to assist the clinician and should not be a substitute for clinical judgment. Under no circumstances should clinical signs be ignored in the presence of conflicting information from monitors and technical aids.

V. CLINICAL PEARLS

- The ideal test for confirmation of endotracheal tube (ETT) placement should be simple, quick, and repeatable; it should function in patients of different age groups, in various locations, and during difficult intubation (DI); and it should not yield false results even in patients with cardiac arrest.
- Contributing factors to the high incidence of esophageal intubation in patients who experience cardiac arrest during out-of-hospital paramedic intubation include intubation under less than optimal conditions; unavailability of monitoring equipment, protocols, or algorithms; violation of the standard technique of auscultation; and intubation attempts by nonexpert personnel.
- Whenever "abnormal" breath sounds are heard by auscultation, they should not be relied on to confirm endotracheal intubation.
- Tube condensation of water can and does occur when an ETT is placed in the esophagus, and its presence should not be interpreted as a reliable indicator of a successful intubation.
- Oxyhemoglobin desaturation is a relatively late manifestation of esophageal intubation.
- CO_2 levels as high as 5% can be detected initially in cases of esophageal intubation after the ingestion of carbonated beverages or antacids. However, rapid decline in CO_2 levels occurs with successive ventilation.
- Capnography and use of colorimetric end-tidal CO_2 detectors can provide a prognostic indicator of successful resuscitation.
- Visualization of the tracheal rings through a flexible fiberoptic bronchoscope (FFB) before the ETT is threaded over it does not guarantee successful endotracheal intubation.
- Common causes of false-negative results with the use of the self-inflating bulb (SIB) include decreased FRC (e.g., obesity, pregnancy, infants), ETT at the carina or main stem bronchus intubation, bronchospasm, and secretions.

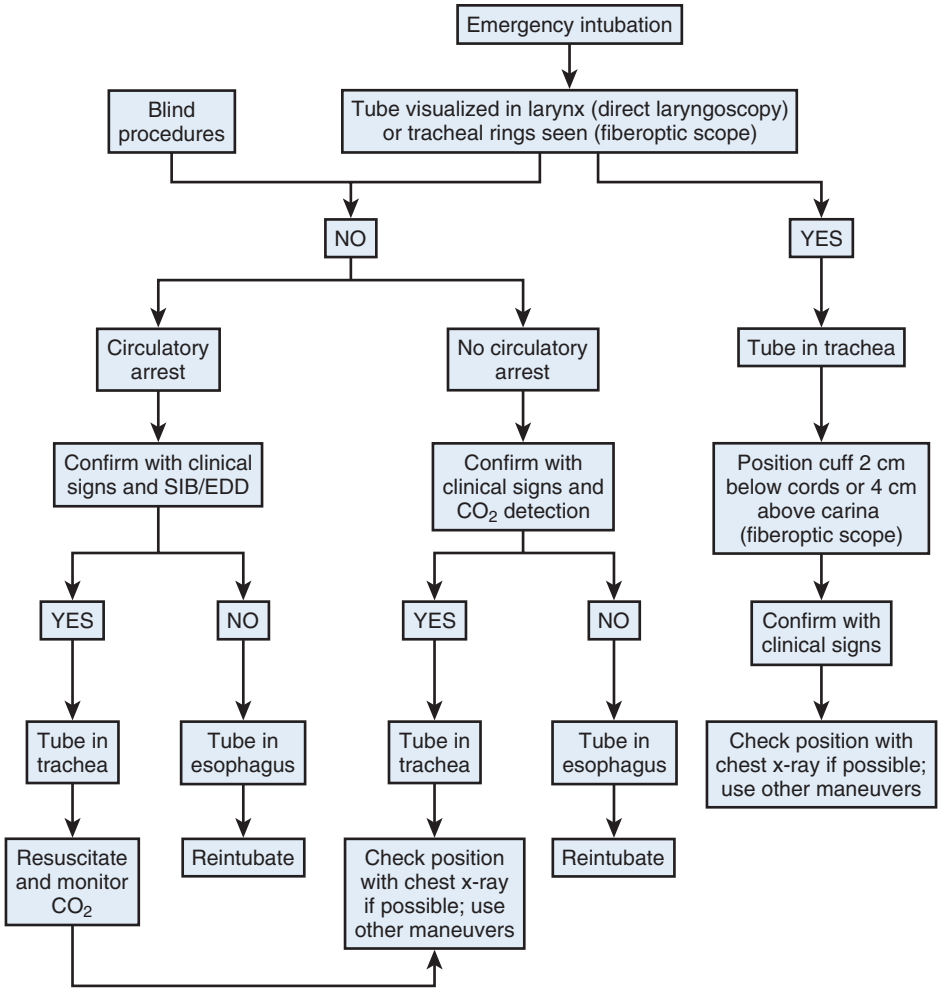

Figure 32-32 Proposed algorithm for verification of endotracheal tube (ETT) position and insertion depth during emergency intubation. In the emergency and critical care settings, chest radiographs (frequently obtained) can easily detect malpositioning of a tracheally placed ETT. Other techniques (e.g., flexible fiberoptic bronchoscopy, cuff maneuvers, transillumination) can decrease the need for frequent chest radiographs. In patients with circulatory arrest, CO_2 monitoring can be unreliable. In these patients, devices such as the self-inflating bulb/esophageal detector device *(SIB/EDD)* are more helpful. During cardiopulmonary resuscitation, monitoring of CO_2 can serve as a prognostic indicator of the efficacy of resuscitation. (From Salem MR: Verification of ETT position. *Anesthesiol Clin North Am* 19:813–839, 2001.)

- The Murphy eye reduces the reliability of chest auscultation in detecting endobronchial intubation.

I. INTRODUCTION

Prehospital airway management ranges from the use of basic airway maneuvers in the management of the unresponsive patient to the need for a surgical airway (i.e., cricothyrotomy) in the "cannot intubate, cannot ventilate" (CICV) situation. Because transport time from the scene of an emergency is often delayed by distance, traffic conditions, and victim extrication, skilled providers can be assets to the most seriously ill or injured patients. However, the scope of practice for emergency medical services (EMS) providers throughout North America varies broadly. In some systems, airway management is provided exclusively by basic emergency medical technicians (EMTs) who are not trained in endotracheal intubation, cricothyrotomy, or extraglottic airway devices, leaving the airway uncontrolled and susceptible to gastric inflation and aspiration induced by bag-mask ventilation, which produces a difficult airway or complete airway obstruction that may be impossible to resolve. Other systems use highly trained paramedics and allow the use of medication-assisted intubation and a variety of airway devices, which opens the door to potential clinical errors and complications such as airway trauma, misplaced tubes, and unrecognized esophageal intubation.

The variability in EMS systems throughout North America is dictated by several factors, including historical system design, state laws, system size, volunteer versus paid provider status, physicians' preferences, and economic issues. For example, in large urban systems, a lack of high-quality medical direction and monitoring may make medication-assisted intubation difficult to successfully implement and sustain. In rural systems, the frequency of intubation may be low, making it difficult to acquire and maintain the necessary skill levels. Prehospital intubation can be challenging compared with the in-hospital environment. EMS providers work in a variety of conditions that complicate the task of airway management, ventilation, and oxygenation. Extreme weather, enclosed working spaces (e.g., cars, small rooms, hallways), bystander distractions, and a variety of other challenging situations face the EMT and paramedic.[1]

Some aspects of an EMS system design are essential for maximizing provider competency. The frequency with which any provider performs advanced airway management is critical for maintaining skill competency.[2,3] Some systems have reported very low rates of intubation, especially for pediatric patients.[4-6] How can competency be maintained when providers intubate three or four times per year?[2,7-9] Should they intubate when the frequency is so low? System medical directors must answer these questions when designing, evaluating, or refining an EMS system. Physicians must be artful in selecting airway strategies, training providers, monitoring interventions, and maintaining quality.[7]

II. HISTORY OF AIRWAY MANAGEMENT BY EMERGENCY MEDICAL SERVICES

Before the 1950s, prehospital airway management was provided by relatively unskilled providers in most EMS systems throughout the United States. Progressive systems of the time provided bag-mask ventilation with an oropharyngeal or nasopharyngeal airway. In some cases, training was limited to basic first aid without training in airway adjuncts.[10-12]

In the 1960s, the quality of prehospital care came into focus with publication of *Accidental Death and Disability: The Neglected Disease of Modern Society* by the National Research Council and development of a national

standards curriculum for EMTs that defined minimal training and equipment.[13] Standards included training in the use of basic equipment such as bag-mask ventilation, oropharyngeal and nasopharyngeal airways, and suction.

In the late 1960s, the concept of advanced-level care was introduced first in Northern Ireland under the leadership of Dr. Frank Pantridge and subsequently implemented in several cities in the United States, including New York, Miami, Seattle, and Pittsburgh. In these systems, paramedics were trained to provide endotracheal intubation in the field along with other advanced life support interventions. Most programs included training in the operating room under the supervision of an anesthesiologist. This innovation was helpful for victims of respiratory and cardiac arrest who were unresponsive. However, there were still challenges for patients with respiratory failure, shock, or other premorbid conditions who were responsive but in need of definitive airway management. In the absence of sedation and rapid-sequence intubation (RSI) protocols, intubation for these conditions was often performed by employing *brutane*—the use of force to assist in performing a medical procedure, such as intubating the trachea.

In the 1970s, some paramedic systems began to use neuromuscular blocking drugs to manage patients' airways with great success. These programs provided significant medical oversight that included monitoring successful outcomes and complications associated with endotracheal intubations.[14] System medical directors had concerns about the use of medication-assisted intubation, including the issue of increased time at the scene by paramedics and complications such as unrecognized esophageal intubation.[15-17]

Drug-assisted intubation is a relatively new idea that is used on a limited basis in EMS systems in North America. Because success rates for drug-assisted endotracheal intubation vary greatly among EMS groups, it is not routinely recommended.[8,9] However, the National Association of EMS Physicians has developed guidelines for implementing drug-assisted intubation programs that include provider training, patient selection, use of standardized protocols and resources for storage and delivery of medications, training in verification and monitoring of end-tidal carbon dioxide, a continuous quality improvement program, and research on a system level to verify effectiveness of the program.[18]

Alternative airway devices have been used in prehospital care since the advent of prehospital advanced life support. Devices include the esophageal obturator, gastric tube airway, esophageal-tracheal Combitube, and King laryngeal tube (LT) airway. Many studies have demonstrated their relative effectiveness compared with bag-mask ventilation and endotracheal intubation (ETI) ventilation.[19-21]

III. PREHOSPITAL CARE OF AIRWAY PATIENTS

Prehospital care of airway patients addresses the spectrum of clinical conditions faced in emergency departments, critical care units, and operating rooms. In the ideal world, providers would be prepared to deal with airway management and ventilation for all possible conditions, but the scope of practice and provider skill levels vary in North America. In other parts of the world, where physicians staff EMS vehicles, skill levels may be more uniform. At the entry level of emergency medical response (EMT-Basic), forced positive pressure with bag-mask ventilation and rapid transport may be the only options available. ETI has been considered the gold standard for definitive airway management, but the diverse skill levels found in prehospital care and the use of extraglottic airway devices in EMS have challenged this idea. High rates of unrecognized esophageal or hypopharyngeal placement or dislodgement have raised concerns about ETI as a default strategy for EMS providers.[16,17]

A. Basic Airway Management

Most EMS providers are equipped to manage the patient who is unresponsive or in respiratory or cardiac arrest. Since the late 1960s, EMT-Basic training has included the use of oropharyngeal and nasopharyngeal airways, bag-mask ventilation, and suctioning. Training has emphasized appropriate mask seal, controlled volumes and inspiratory times, and the avoidance of hyperventilation in cardiac arrest and shock states.[11,22-24]

Complete airway obstruction by acute epiglottitis, foreign bodies, laryngeal-tracheal trauma, airway hematomas, and numerous other conditions is a challenge in hospitals staffed by highly skilled airway managers and particularly in the prehospital environment, where the necessary tools and skills may not be available. In these unfavorable settings, rapid transport to surgical intervention may be the only practical option. In rural environments where transport times are prolonged, upper airway obstruction is more likely to be a fatal condition.

B. Extraglottic Airway Devices

Use of the King LT as a primary and alternative airway device has been an effective prehospital airway strategy.[17,25,26] Because alternative airway devices do not provide definitive protection against aspiration, they typically are used temporarily until ETI can be achieved in the field or in the emergency department. In one case report, the King LT resulted in tongue engorgement when left in place for approximately 3 hours.[27]

The double-lumen esophageal-tracheal Combitube is an alternative airway device commonly used in EMS. It has been used by Basic and Advanced EMTs as a primary airway device and by paramedics as a rescue device. Effectiveness of the Combitube has varied among studies in prehospital care. Cady and colleagues found it had no effect on patient outcomes compared with ETI.[28] In a study of prehospital physicians, the Combitube was superior to ETI in the management of cardiopulmonary arrest.[29] When the King LT and Combitube were compared in a study of EMS providers, nurses, and physicians, the King LT was inserted faster and preferred by 96% of the participants.[30]

For patients with acute respiratory distress and acute pulmonary edema, continuous positive airway pressure

(CPAP) has significantly improved outcomes and reduced the need for intubation in prehospital care.[31] CPAP has also proved to be cost-effective in the prehospital environment.[32]

Some studies have shown increased morbidity rates with prehospital intubation. Others have demonstrated no increase in mortality rates despite significant errors such as esophageal intubation, dislodgement, or failed ETI.[33] A study of patients with acute respiratory distress showed a decrease in mortality rates when advanced interventions such as ETI were used in the prehospital environment.[33]

Some investigators think that ETI should not be standard operating procedure for EMS systems. Variables cited as key factors in determining whether a given EMS system should use ETI include low case exposure and inadequate operating room training for paramedics and paramedic students. However, it has been shown that if a minimum number of intubations is used as the criterion to permit ETI in the field, the overall numbers of ETI performed in the field decrease because fewer providers meet the minimum number needed to permit continued performance of the skill.[2] Additionally, supraglottic devices have demonstrated equivalency to ETI in many studies, and many advocate using alternative strategies for ensuring the success rates for intubations, such as simulation and cadaver training.[21,34,35] When time in the operating room is made available to paramedics, it can be a significant training adjunct for clinical practice.

The U.S. National Highway Traffic Safety Administration (NHTSA) requires only five intubations to be eligible for paramedic certification.[22-24] This level is well below the recommended level of 35 ETIs for emergency medicine residents. Anesthesiology residents must perform between 45 and 60 ETIs to achieve at least a 90% success rate in the controlled setting of the operating room.[36] Wang and colleagues calculated the learning curves for paramedic students performing ETI and found that at 20 to 25 ETIs in live subjects must be performed to achieve success rates of at least 90%.[2] This finding argues that paramedics with only five ETIs during training may have little skill in performing intubations.

Medical oversight is a critical part of any EMS airway program. Direction by physicians has enhanced the cognitive (though not the technical) skills of paramedics and improved patient selection.[7]

IV. SYSTEM STRUCTURE AND TYPES OF PROVIDERS

The foundation for any EMS program is provided by system-wide protocols. Almost every system in North America has protocols that delineate the specific steps of care, types and dosages of medications, and other special considerations needed to rescue patients. Protocols usually are designed by a group of physicians, an EMS medical advisory committee, or an EMS medical director. In the case of advanced airway management in the United States, protocols relating respiratory failure, cardiac arrest, and airway obstruction are derived from the National EMS Education Standards and from guidelines for CPR and emergency cardiac care by the American Heart Association (AHA), International Liaison Committee on Resuscitation (ILCOR), and other reputable bodies.[37-39]

The guidelines for airway management have significantly changed over the past decade. The most striking modification is incorporation of waveform capnography as the gold standard for endotracheal tube confirmation and continuous verification of intratracheal positioning. In some EMS jurisdictions, waveform capnography has become a requirement for all intubations. The value of this strategy was established by Silvestri and colleagues, who demonstrated no unrecognized esophageal intubations when capnography was used in their EMS system.[16]

A. Emergency Medical Technicians

Typically, EMTs are trained in the use of basic airway methods that include, use of oral and nasal airways, and administration of oxygen and suction. Some EMT programs permit the use of extraglottic devices.

B. Advanced Emergency Medical Technicians

Advanced training includes skills such as electrocardiogram interpretation, advanced or alternative airway management (e.g., ETI, use of dual-lumen airway devices), intravenous fluid therapy, and intravenous administration of certain medications. Advanced EMT training is shorter and more focused than paramedic training. Advanced EMT programs are more commonly used in rural, volunteer EMS systems because the ability to attend longer training programs may not be feasible and the call volume is less than in larger markets.

C. Paramedics

Paramedics have the highest level of EMT training in the United States and Canada. A paramedic completes a course that follows the standardized national curriculum (e.g., as prescribed by NHTSA) or meets the standards of some other educational paradigm. A paramedic performs advanced tasks, such as electrocardiogram interpretation, drug therapy administration, invasive airway techniques, and manual defibrillation. Paramedics also may be involved in critical care transport operations. For these services, EMS providers are involved primarily in the transfer of acutely ill and injured patients from one care center to another. EMS providers who function in this role often have additional training in specialized devices, such as intravenous infusion pumps, ventilators, and counterpulsation aortic balloon pumps. Paramedics and critical care nurses are commonly employed in medical evacuation (Medevac) programs that use helicopters for transport (also referred to as Helicopter EMS or HEMS). These programs are designed to transport a critically ill patient from the scene of an emergency or a local community hospital to a specialized care facility.

V. PHYSICIAN OVERSIGHT AND CONTINUOUS QUALITY ASSURANCE

Physician oversight of prehospital care has been an essential component since the earliest EMS advance life support programs.[10] It has included training and evaluation, protocol development, radio communications with providers in the field, review and observation of patient care delivery, and continuous quality assurance programs. Airway management has been a central issue in advanced EMT and paramedic training since the early 1970s.

A. Training

High-quality training is the most important part of any EMS system. EMS airway management and ventilation training has ranged from basic skill instruction on a manikin to supervised clinical application in the operating room, emergency department, and prehospital environments. Innovative strategies have included cadaver practice and manikin practice in a simulation environment.

B. Continuous Quality Improvement

The most important role for a physician in prehospital care is continuous quality improvement. Poor airway management in prehospital care can result in brain injury and death. Every case of airway management and ventilation should be reviewed by the medical director's staff. At a minimum, this includes tracking success rates for intubation and alternative airway devices and documenting end-tidal carbon dioxide values at the scene, during transport, and on arrival at the hospital. The receiving emergency department should be routinely contacted by the medical director's staff for confirmation of airway device placement on arrival. Figure 33-1 is a review form that might be used for this purpose. Figure 33-2 is a more comprehensive form used by a hospital-based program using RSI.

VI. CONCLUSIONS

Depending on the level of training, EMTs can offer emergency care that includes many airway management techniques. ETI performed by personnel other than physicians is under intense scrutiny to ascertain its benefit. In the meantime, medical oversight as part of a comprehensive quality program is essential for successful airway management. For a physician planning an EMS system, the training strategy should be appropriately matched to the level of provider, protocols, system issues (e.g., response times, hospital transport times, environmental factors), and scope of practice. Factors that can limit the introduction of advanced skills such as use of supraglottic devices, ETI, and medication-assisted intubation include volunteer EMTs with limited training time, an inability to closely monitor providers, and failure to employ a comprehensive airway management quality program.

VII. CLINICAL PEARLS

- Emergency medical services (EMS) provide a variety of prehospital care, including airway management.
- Emergency medical technicians (EMTs) work in many environments that complicate the task of airway management, including extreme weather, small, enclosed working spaces, and bystander distractions.
- EMS programs and EMT training are based on established protocols that delineate the specific steps of care, types and dosages of medications, and other special considerations needed to rescue patients. Protocols usually are designed by a group of physicians, an EMS medical advisory committee, or an EMS medical director and are based on national standards and curricula.
- EMTs are trained to assess a patient's condition and to perform the procedures needed to maintain a patent airway with adequate breathing and cardiovascular circulation until the patient can be transported to a hospital for definitive medical care.
- EMTs can mange the patient who is unresponsive or in cardiorespiratory arrest. Depending on the level of training and local protocols, they can use bag-mask ventilation, suctioning, drug-assisted intubation, oropharyngeal and nasopharyngeal airways, and alternative devices such as the Combitube and King laryngeal tube (LT) airway.
- The most important role for a physician in prehospital care is continuous quality improvement, because poor airway management can result in brain injury and death.

Medical Control
Follow-up Runsheet

Chapter 34

Disaster Preparedness, Cardiopulmonary Resuscitation, and Airway Management

JOSEPH H. MCISAAC III | LAUREN C. BERKOW

I. Introduction

I. INTRODUCTION

Disasters happen. They happen frequently, but they are not uniformly distributed in time and geography. Any particular place tends to experience them infrequently. Although there are many definitions of disaster, the most common medical definition of a disaster is an "event that results in casualties that overwhelm the health care system in which the event occurs."[1] Typically, disasters degrade the fundamental infrastructure necessary for a viable economy and civil society. This disruption magnifies the impact of the event by widening the gap between needed and available resources (Fig. 34-1).

In most parts of the world, natural disasters, such as floods, major storms, earthquakes, wildfires, tsunamis, and epidemics, occur at higher frequencies than man-made disasters, such as wars or technologic events. Catastrophic events can be viewed by scale (local versus regional), proximity (happens locally versus somewhere else), time scale (discrete versus continuous), degree and type of infrastructure degradation (minimal versus total, physical

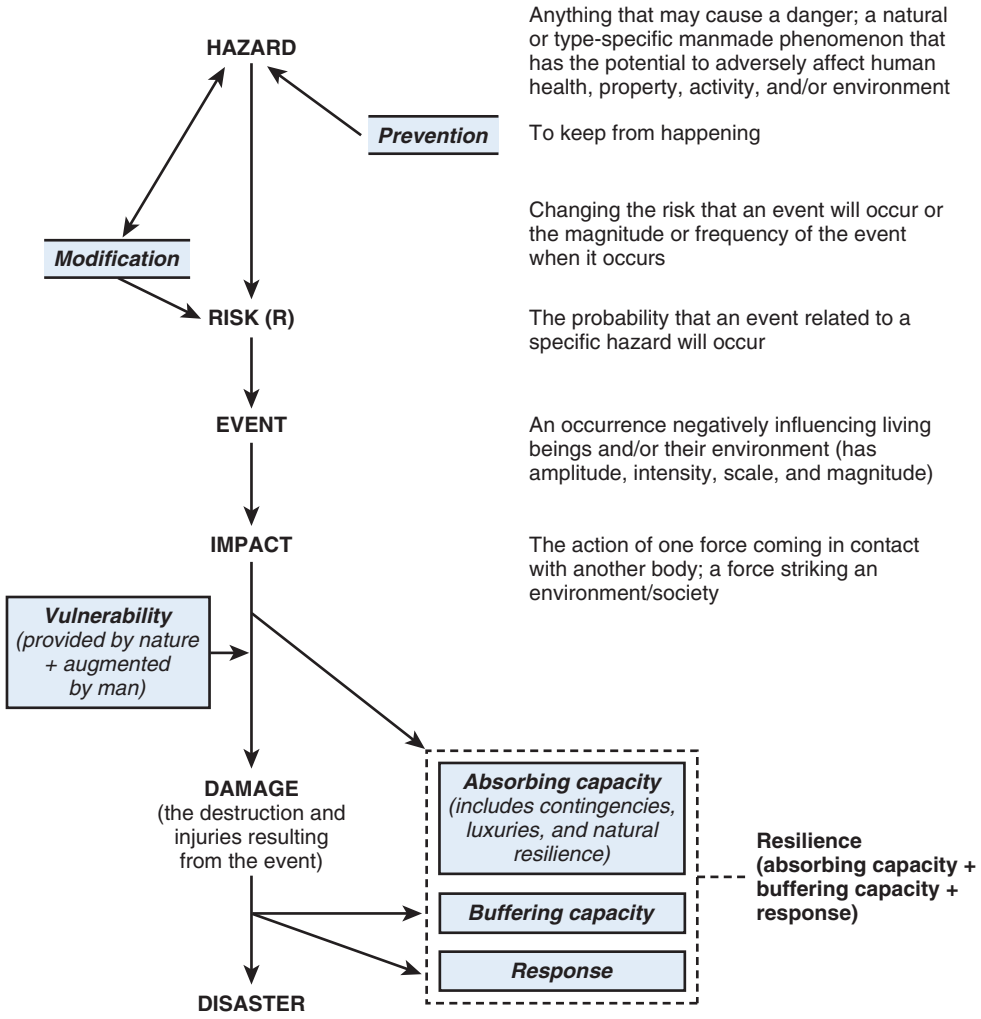

Figure 34-1 Standardized definitions of terms used to communicate by the various disciplines involved in disasters. (Modified from Task Force for Quality Control of Disaster Medicine (TFQCDM)/World Association for Disaster and Emergency Medicine (WADEM): *Health disaster management: guidelines for evaluation and research in the Utstein style*, vol 1. Available at http://www.wadem.org/guidelines/chapter_3.pdf [accessed March 2012].)

destruction versus loss of personnel), and casualty spectrum.

II. DISASTER TRIAGE

Triage is the act of sorting casualties. It implies that numbers of casualties exceed available medical resources. During routine circumstances in modern hospitals, the sickest patients receive the highest priority. During mass casualty events, patients are sorted into several levels based on the ability to help the greatest number while conserving scarce resources. Several systems are in use, and all are based loosely on military systems but have not been scientifically validated.[2] Patients who require intense resources with little likelihood of salvage are called *expectant*. They are expected to die and are given comfort measures only. Those with severe but treatable conditions are marked as *immediate*. Wounded who can wait are referred to as *delayed* or *minimal* (Fig. 34-2). Because triage depends on resources, repeat triage should occur when there is a change in patient status, available care, and transfer to another facility.

III. SURGE CAPACITY

The concept of *surge capacity* is important beyond the emergency department. As the number of arriving patients peaks, the ability to expand services and number of beds is critical. Although temporarily increased capacity can result from cancellation or delay of routine patient load, there ultimately must be an expansion of overall facility capacity or introduction of new facilities into the system.[3] This can be done by adding portable facilities, recruiting administrative space within the institution, or using municipal buildings (e.g., schools) for treatment space. Unless providers and supplies can be augmented from outside the disaster zone, creative allocation of resources is the only option. The Agency for Healthcare Research and Quality (AHRQ) has developed an online, disaster-specific hospital surge model that can be used for planning.[4]

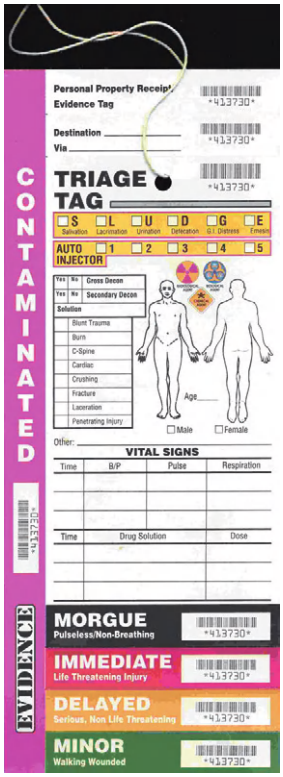

Figure 34-2 Example of a triage tag. (Courtesy of Disaster Management Systems, Inc., Pomona, CA.)

IV. ALTERED STANDARDS OF CARE

In large-scale disasters, an altered standard of care must be implemented. Chronic diseases such as diabetes, hypertension, and hypothyroidism become uncontrolled as the medication supply is depleted. Life-threatening conditions such as coronary ischemia and dialysis-dependent renal failure can no longer be treated adequately. Scarce resources are more appropriately directed to others. Loss of sanitation and hygiene increase the frequency of wound infection, respiratory diseases and gastrointestinal diseases. Acute shortages of antibiotics can become a major limitation, and determination of the standard of care can be set regionally (e.g., in pandemic influenza) or done on an ad hoc basis.[5]

V. HOSPITAL INCIDENT COMMAND SYSTEM

All U.S. hospitals are required by The Joint Commission (TJC), formerly the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), and by governmental policies to have disaster plans prepared and tested twice per year. The most accepted standard for hospital disaster response is the Hospital Incident Response System (HICS) (http://www.hicscenter.org/index.php [accessed March 2012]). HICS consists of a command and control framework headed by the incident commander and prioritized task lists for each designated subordinate. Modeled on military combat systems and perfected by the California Fire Service, HICS is a time-tested system.

VI. OPERATING ROOM PREPARATION

On notification of a disaster situation, the local institution's operating room disaster standard operating procedure should be used.[6] HICS does not delineate how a surgical service should organize the operating room. The HICS model should be used with a single chief of the operating room, preferably a senior anesthesiologist who is in communication with the emergency department, intensive care units, postanesthesia care unit, the chief of perioperative nursing, and the hospital's surgical chief.

VII. ANESTHETIC AND RESUSCITATION TECHNIQUES

A. Emergency Airway Management and Ventilation

Emergency airway management strategies during disasters are closely coupled with triage plans and available resources. Resources are not expended on casualties that are designated as expectant. In a mass casualty situation, patients requiring ventilator support may be beyond the capabilities of the system. The goal is to have all patients breathe spontaneously. Placing patients in a lateral (rescue) position may be the most reasonable approach in some situations. Oral airways, nasal airways, supraglottic devices, and surgical airways are relatively low-technology options. Anecdotal reports from World War I describe using a midline tongue retraction suture or piercing the tongue with a piece of wood, but these methods are of questionable value.

Tracheal intubation, except when performed blindly, requires a light source and a laryngoscope. Typically, the intubated patient requires controlled ventilation. Use of a surgical airway is rarely indicated, but it remains an option in selected cases. The expenditure of effort and resources for such a patient may not be consistent with the most good for the greatest number, but care should not be denied to a salvageable casualty when time and resources are available. Advanced techniques are only as good as their availability and the skill of the practitioner. Several types of portable ventilators can be used during a respiratory disease pandemic if normal infrastructure (i.e., electrical power and compressed gas) is available. Figure 34-3 shows a portable ventilator.

B. Anesthetic Techniques

Trauma often is regarded as the predominant source of surgical disease among mass casualties in a disaster. Although that is usually the case at the outset, routine surgical disease evolves to become a major concern over time because of delays in caring for victims. Some maladies (e.g., strangulation of an incarcerated hernia) progress to the acute stage, whereas others (e.g., lacerations, fractures) progress to infection and gangrene because of deferred care and difficulty with hygiene and sanitation. Babies continue to be born, and the complications of childbirth must be addressed.

Choice of anesthetic technique depends on the resources available and the skill of the practitioner. Total

Figure 34-3 Example of portable ventilator used for treating mass casualties. (Courtesy of Allied Healthcare Products, Inc., St. Louis, MO.)

intravenous anesthesia (TIVA) with local anesthetic infiltration has been the default option when resources are constrained. Needed quantities of parenteral agents such as ketamine, narcotics, benzodiazepines, propofol, and barbiturates are compact, easy to transport, and easy to store. Judicious infiltration of local anesthetics can provide acceptable conditions for short procedures when used alone. Baker and colleagues[7] described three levels of military anesthesia care on the battlefield: sevoflurane inhalation using standard anesthesia machines at the highest level, drawover vaporizers at the intermediate level, and TIVA at the lowest level. Regional anesthesia, particularly nerve blocks placed with a nerve stimulator or ultrasound if available, has enjoyed popularity in war zones and during the 2010 Haiti earthquake.[8]

The Omeda Universal Portable Anesthesia Complete (U-PAC) drawover anesthesia system (GE Healthcare, Fairfield, CT) has been deployed with the U.S. military. Drawover features include durability, compactness,

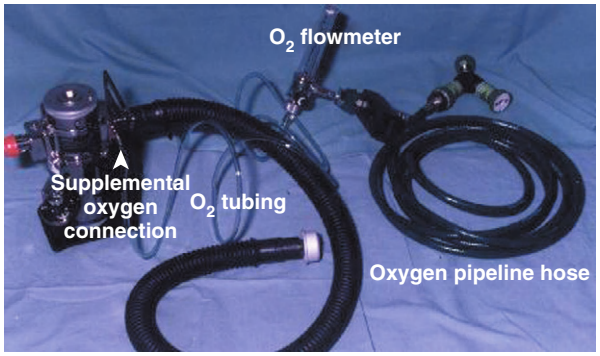

Figure 34-4 Omeda Universal Portable Anesthesia Complete (U-PAC) drawover anesthesia system. (Courtesy of GE Healthcare, Fairfield, CT.)

portability, low capital investment, low operating expense, and no requirement for compressed gas or electricity.[9] Components of a drawover system include a vaporizer powered by patient respiration or a self-inflating bag with a one-way valve (Fig. 34-4).

VIII. PLANNING AND PREPARATION

The key to successful management during a disaster is good preparation and planning, which starts with a realistic understanding of the situation. When preparing to meet the needs of a distant event, the response should be tailored to the acute and endemic disease spectrum, climate, degree of infrastructure impairment, and cultural particulars of the affected area. An area with inadequate transportation; total loss of power, water, and sanitation; and tenuous security after a major earthquake has significantly different needs from an area experiencing pandemic influenza (Fig. 34-5). Logistics are always the major limiting factor. Resupply may be uncertain or nonexistent. Local manufacture of substitutes (e.g., boiled linen for sterile dressings) may be the only option. Compressed gas and intravenous fluids are heavy, bulky, and in short supply. Lack of refrigeration limits use of certain pharmaceuticals. Modern sterilization methods may not be available, requiring improvisation. Boiling metal

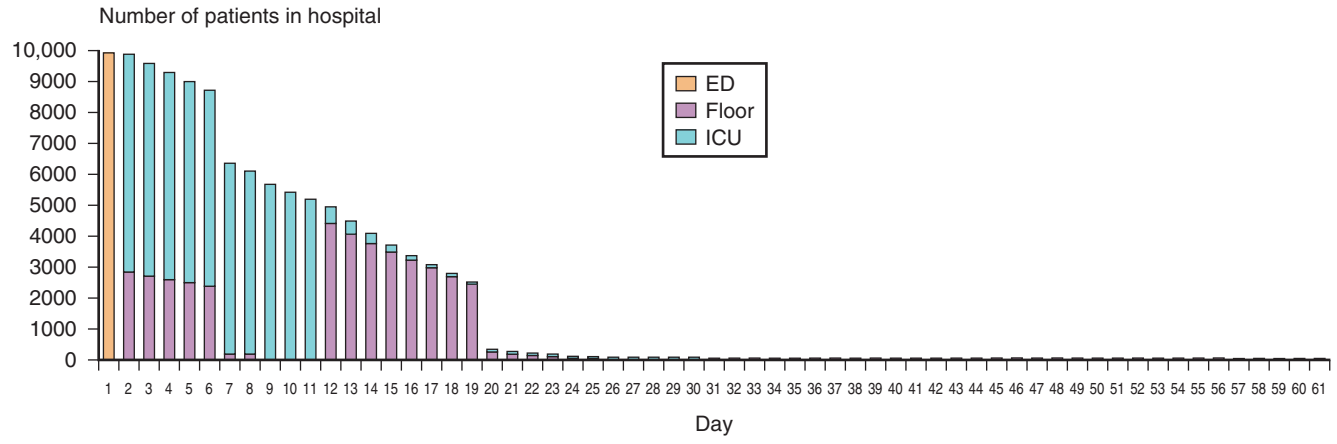

Figure 34-5 Time course of hospitalized patients after a 10-kT nuclear detonation. *ED,* Emergency department; *ICU,* intensive care unit. (From U.S. Department of Health and Human Services: Hospital surge model. Available at http://www.hospitalsurgemodel.org (accessed March 2012).)

instruments for 15 to 30 minutes renders a high degree of asepsis. After thorough cleaning with soap or detergent, soaking heat-intolerant equipment in common household bleach (i.e., sodium hypochlorite solution) is an excellent means of sterilization, but it tends to degrade many materials after repeated application.

A. The U.S. National Disaster System

The National Incident Management System (NIMS) provides a systematic,[10] proactive approach to guide all levels of governmental departments and agencies, nongovernmental organizations, and the private sector to work seamlessly to prevent, protect against, respond to, recover from, and mitigate the effects of incidents, regardless of cause, size, location, or complexity, to reduce the loss of life and property and harm to the environment. NIMS works hand in hand with the National Response Framework (NRF).[11] NIMS provides the template for the management of incidents, and the NRF provides the structure and mechanisms for national-level policy for incident management.

The National Disaster Medical System (NDMS) is a nationwide partnership designed to deliver quality medical care to the victims of and the responders to a domestic disaster.[12] NDMS provides state-of-the-art medical care under any conditions at the disaster site, in transit from the impacted area, and in participating definitive care facilities.

B. National Disaster Medical System Teams

The NDMS consists of several teams: Disaster Medical Assistance Team (DMAT), Disaster Mortuary Operational Response Team (DMORT), Veterinary Medical Assistance Team (VMAT), and National Medical Response Team (NMRT).

DMATs provide primary and acute care, triage of mass casualties, initial resuscitation and stabilization, advanced life support, and preparation of sick or injured for evacuation. The basic deployment configuration of a DMAT consists of 35 persons, including physicians, nurses, medical technicians, and ancillary support personnel. They can be mobile within 6 hours of notification and are capable of arriving at a disaster site within 48 hours. They can sustain operations for 72 hours without external support. DMATs are responsible for establishing an initial (electronic) medical record for each patient, including assigning patient-unique identifiers to facilitate tracking throughout the NDMS.

NMRTs provide medical care after a nuclear, biologic, or chemical incident. This team can provide mass casualty decontamination, medical triage, and primary and secondary medical care to stabilize victims for transportation to tertiary care facilities in a hazardous material environment. The basic deployment configuration of an NMRT consists of 50 persons.

C. Strategic National Stockpile

The Strategic National Stockpile is a national repository of antibiotics, chemical antidotes, antitoxins, life-support medications, intravenous administration and airway maintenance supplies, and medical and surgical items. The Strategic National Stockpile is designed to supplement and resupply state and local public health agencies in the event of a national emergency anywhere and at anytime within the United States or its territories.

D. Surgical Specialty Teams

Besides military medical assets controlled by the federal government, the NDMS has several International Medical Surgical Response Teams (IMSuRT) for rapid deployment of surgical expertise to disaster zones. The NDMS is organizing a prototype Multispecialty Surgical Enhancement Team (MSET) consisting of anesthesiologists, trauma surgeons, neurosurgeons, and orthopedic surgeons. No specific doctrine has been announced. It can be anticipated that multiple teams will be formed.

E. Infrastructure Resiliency

Disaster preparedness must consider infrastructure resilience. This can be accomplished through hardening of existing infrastructure such as utilities and communications or through the acquisition of alternatives. Examples are alternative power sources such as solar-, mechanical-, and steam-powered engines; amateur radio as a substitute for standard communications; and food prepared for long-term storage.

F. Anticipating Surprise

Expect the unexpected. Failure to predict surprise can result in panic, paralysis, and a sense of defeat. Developing a psychology to anticipate unexpected occurrences and then training for such contingencies creates an atmosphere of resilience. Attitude is probably the most important characteristic that determines outcome. In retrospect, most surprises can be seen as having indicators that were overlooked or recognized but rejected as unbelievable. Typically, they are high-impact, low-probability events.[13]

G. Decontamination, Personal Protective Equipment, and Isolation for Chemical, Biologic, and Radiologic Events

Personal protective equipment (PPE) is used by medical personnel to prevent occupational exposure to infectious, radiologic, or chemical agents. Gloves, gowns, and masks are a normal part of responders' daily lives under universal precautions. High-risk infections such as tuberculosis require the use of high-efficiency particulate air (HEPA) filtration masks, most commonly the N95 mask, a filter found to remove at least 95% of airborne particles during worse-case testing. Negative-pressure isolation rooms and wards are used to keep airborne infection risks contained.

It is important to distinguish between decontamination and isolation. Infectious patients cannot be decontaminated because the infection is internal. Patients with external chemical and radiologic contamination should be decontaminated to minimize the patient's exposure

to the agent and the exposure of the treating staff. Removal of clothing and washing with copious amounts of water (with or without soap) constitute the best universal decontamination strategy. This can be accomplished for mass casualties through a formal decontamination system or by any improvised method that accomplishes the goal. Employing a method for assessing the effectiveness of decontamination (e.g., testing patients after decontamination with a Geiger counter, chemical meter, or using a surrogate tracer) can increase confidence in the system, but studies have consistently shown several orders of magnitude of contamination reduction using only clothing removal and shower. The main exception to this rule is a gross level of contamination by persistent chemicals used by the military, such as thickened nerve agents and some vesicants. These scenarios are more likely to occur in large-scale chemical warfare, which is unlikely to occur because most armies have eliminated their inventories. First responders at the hospital level typically wear level C PPE, whereas first responders at a site of high agent concentration often wear level A or B PPE.[14]

Use of PPE imposes a burden on the caregiver. Besides the psychological impact and heat stress, there are measurable impediments to vision, hearing, communications, and manual dexterity. Suyama and colleagues found that for a non–PPE-wearing operator,[15] needle-to-skin time favored intravenous placement over intraosseous but that an intraosseous approach provided faster vascular access when wearing PPE. The affect of PPE on airway management seems less clear. Although Greenland and coworkers found that PPE affected bronchoscopy but not intubation,[16] Castle and colleagues found that chemical-biologic-radiologic-nuclear (CBRN) PPE significantly impaired intubation but not laryngeal mask airway placement while kneeling,[17] sitting, or lying on the floor.

IX. BASIC LIFE SUPPORT AND CARDIOPULMONARY RESUSCITATION GUIDELINES

The 2005 American Heart Association (AHA) guidelines for basic life support (BLS) and cardiopulmonary resuscitation (CPR) recommended the sequence of airway, breathing, and circulation (A-B-C).[18] The first steps in the 2005 BLS were opening the airway, checking for breathing, and providing two rescue breaths if adequate breathing is not detected. The third step was to initiate chest compressions (Fig. 34-6). To check for breathing, lay rescuers and health care providers were advised to "look, listen, and feel." Health care providers were then advised to check for a pulse after delivery of the initial rescue breaths to a nonresponsive, nonbreathing individual.

The 2005 CPR guidelines recommended two rescue breaths, each given over 1 second, with sufficient tidal volume to produce visual chest rise. If an advanced airway was in place, the guidelines recommended 8 to 10 breaths per minute without synchronizing breaths between chest compressions.

Updated BLS and CPR guidelines were released by the AHA in 2010.[19-21] Table 34-1 summarizes these guidelines. The recommended sequence was changed to circulation, airway, and breathing (C-A-B). In conditions of low blood flow (e.g., cardiac arrest), oxygen delivery to the brain and heart is limited primarily by blood flow instead of arterial oxygen content.[22] Using cardiac-only resuscitation and minimizing delays or interruptions in chest compressions can improve survival.[23] Evidence does not show any difference in survival rates between chest compressions delivered alone and chest compressions combined with positive-pressure ventilation.[23-25] The AHA currently recommends that chest compressions be initiated before rescue breaths or advanced airway placement. Rescue breaths are provided after the first cycle of chest compressions (Fig. 34-7). "Look, listen, and feel" has been removed from the 2010 algorithm.

Although the optimal oxygen concentration to be delivered during CPR has not been defined, current AHA guidelines recommend initial delivery of 100% oxygen during resuscitation. After return of spontaneous circulation, the 2010 guidelines recommend titration of oxygen administration to maintain an oxygen saturation level of 94% or greater to avoid hyperoxia when appropriate monitoring is available. Box 34-1 summarizes the changes pertaining to airway management during CPR that were introduced in the 2010 AHA guidelines.

X. INITIAL AIRWAY MANAGEMENT DURING CARDIOPULMONARY RESUSCITATION

A. Rescue Breathing

Initial rescue breathing during CPR should be provided through a mouth-to-mouth method, mouth-to-barrier device, or bag-mask ventilation (if available). Each rescue breath should be given over 1 second with a sufficient tidal volume to produce a visible chest rise. Two ventilations should be provided after every 30 compressions (30:2 compression-to-ventilation ratio). Trained lay rescuers or health care providers should initiate rescue breathing. An *untrained* lay rescuer should provide chest compressions only and not initiate rescue breathing. If a pulse is present, one rescue breath should be given every 6 seconds and the pulse rechecked every 2 minutes.

The airway should be opened by a head tilt–chin lift maneuver, unless a cervical spine injury is suspected. If a cervical spine injury is suspected, a jaw thrust should be performed with the head maintained in a midline position.

B. Airway Adjuncts

Oropharyngeal airways can be used to assist bag-mask ventilation by displacement of the tongue, which can occlude the airway. Oropharyngeal airways are recommended for unconscious patients and should be placed by rescuers trained in their use.

Nasopharyngeal airways are better tolerated in conscious patients than are oral airway adjuncts, and they can assist ventilation by relieving nasopharyngeal obstruction.

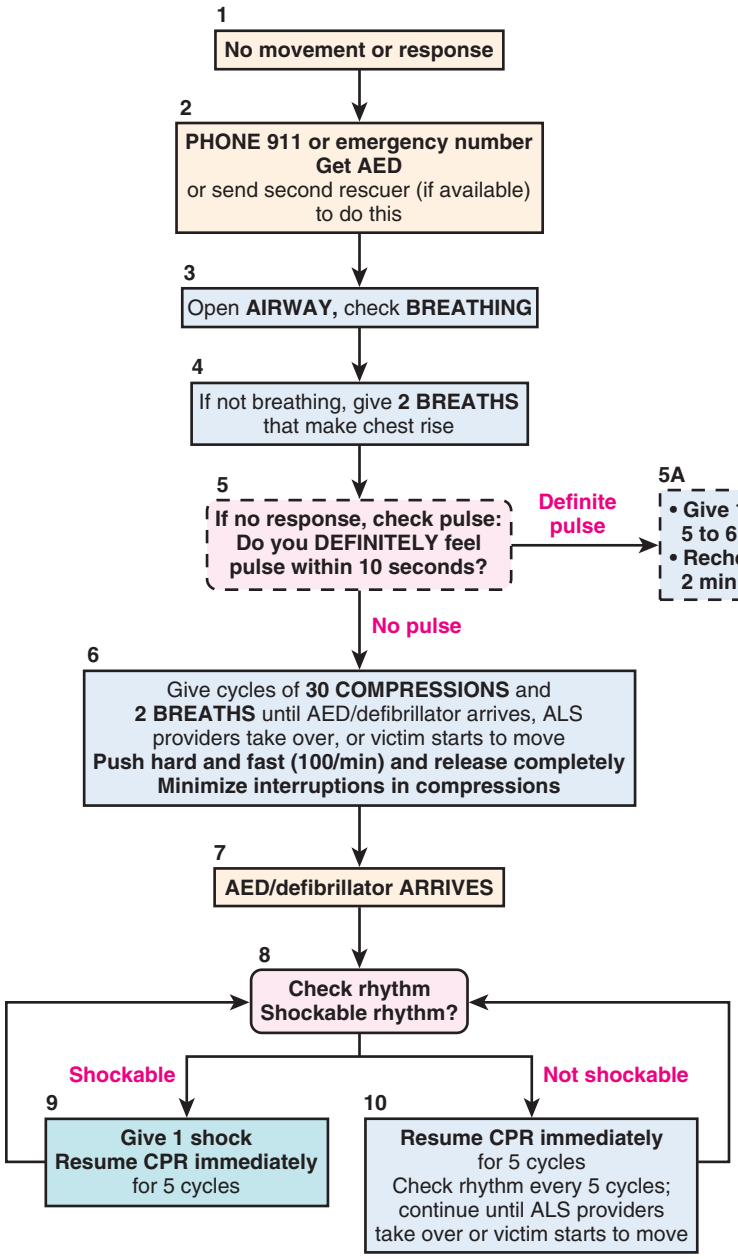

Figure 34-6 The 2005 adult basic life support health care provider algorithm. *AED,* Automatic external defibrillator; *ALS,* advanced life support; *CPR,* cardiopulmonary resuscitation. (From Emergency Cardiovascular Care (ECC) Committee, Subcommittees, and Task Forces of the American Heart Association: 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 112(Suppl):IV1–IV203, 2005.)

Nasal airway adjuncts should be placed by a rescuer trained in their use, and they should be used with caution if a basilar skull fracture or coagulopathy is suspected.

XI. ADVANCED AIRWAY MANAGEMENT DURING CARDIOPULMONARY RESUSCITATION

Endotracheal intubation during CPR should be performed by trained health care providers, and interruptions of chest compressions should be minimized. Endotracheal intubation through direct laryngoscopy may be more difficult if performed during chest compressions. Prolonged attempts at tracheal intubation should be avoided, especially if chest compressions are halted during attempts. Placement of an endotracheal tube or other advanced airway device has not been associated with any improvement in return of spontaneous circulation. Endotracheal intubation attempts by inexperienced providers may result in complications such as failed intubation or esophageal intubation.[26]

After endotracheal tube placement, ventilations are delivered without interruption of chest compressions at a rate of one breath every 6 to 8 seconds. Certain resuscitation medications (Box 34-2) can be delivered through the endotracheal tube. Secretions can be removed from the airway through the endotracheal tube, and the endotracheal tube cuff may provide a barrier against aspiration.

A. Confirmation of Endotracheal Tube Placement During Cardiopulmonary Resuscitation

The 2005 CPR guidelines recommended the use of exhaled carbon dioxide (CO_2) detectors or esophageal

Naloxone

detectors for confirmation of endotracheal tube placement in addition to clinical assessment by auscultation and direct visualization. Exhaled CO_2 detectors may produce a false-negative result due to decreased blood flow and CO_2 delivery to the lungs, pulmonary embolus, pulmonary edema, or severe airway obstruction.[27] False-positive readings have been detected when the stomach contains large amounts of carbonated liquids.[28]

The 2010 CPR guidelines recommend the use of continuous waveform capnography for confirmation of endotracheal tube placement during CPR, although the use of exhaled CO_2 detectors or esophageal detectors is considered acceptable if waveform capnography is not available. Continuous waveform capnography may have decreased specificity and sensitivity during prolonged resuscitation and decreased perfusion.

Thoracic impedance measurement may aid in detection of esophageal intubation, but evidence is insufficient to recommend its use for confirmation of endotracheal tube placement. Thoracic impedance is significantly higher during inspiration than during expiration, and changes in impedance, which can be measured by

defibrillation pads, occur only if the endotracheal tube is correctly placed.[29]

B. Use of Cricoid Pressure During Cardiopulmonary Resuscitation

The 2005 CPR guidelines recommended the use of cricoid pressure by a third rescuer if the victim is deeply unconscious. Evidence suggests that applying cricoid pressure may impede ventilation and interfere with the placement of advanced airway devices or intubation.[30,31] The 2010 guidelines recommend *against* the routine use of cricoid pressure as part of airway management during CPR.

C. Supraglottic Airway Devices

The 2005 and 2010 AHA CPR guidelines support the use of a supraglottic airway device as an alternative to endotracheal intubation. Box 34-3 lists the supraglottic devices that have been studied for use in cardiac arrest and acknowledged by the AHA. Because intubation through a supraglottic airway does not require glottic visualization, placement may be faster than endotracheal intubation, and it may result in shorter no-flow times (i.e., period when chest compressions are halted for other interventions).[32,33] Supraglottic airway placement should be considered as an option if endotracheal intubation fails. Ventilations are delivered through a supraglottic airway device in the same ratio as through an endotracheal tube (i.e., one breath every 6 to 8 seconds without interruption of chest compressions).

If available, newer supraglottic airway devices that provide a conduit for intubation can be considered. Preliminary evidence supports their use in the prehospital environment, especially if difficulty with intubation is encountered.[34,35]

D. Role of Advanced Airway Devices

Advanced airway management techniques such as fiberoptic intubation and video laryngoscopy have not been widely studied as intubation techniques for airway management during CPR. Preliminary evidence suggests that video laryngoscopy may be an acceptable alternative to conventional laryngoscopy, especially for difficult intubations.[36,37] Advanced airway devices may not be easily accessible in the prehospital environment. Inadequate light conditions and the lack of electricity may limit the usefulness of video laryngoscopy outside the hospital setting.

Box 34-3 Supraglottic Airways Approved by American Heart Association for Use in Cardiopulmonary Resuscitation

Laryngeal tube (LT)

XII. ALTERNATIVE METHODS OF OXYGEN DELIVERY DURING CARDIOPULMONARY RESUSCITATION

A. Oxylator

The Oxylator (CPR Medical Devices, Ontario, Canada) is a fixed-flow automatic resuscitation management system with an adjustable pressure limit. Several models exist, including the Oxylator EMX, which is recommended for prehospital use (Fig. 34-8). The Oxylator delivers oxygen flow at 30 L/min until an adjustable maximum pressure (up to 45 cm H_2O) is reached, at which point passive exhalation occurs to an airway pressure of 2 to 4 cm H_2O. The device allows manual (rescuer initiated) and automatic inhalation modes. The Oxylator works with medical oxygen or hospital air supply, tank, or compressor; it does not require electricity; and it can be connected to a face mask, supraglottic airway, or endotracheal tube.

Potential advantages of the Oxylator over bag-mask ventilation include consistent ventilation and oxygenation to a set pressure; possible avoidance of hyperventilation, excessive ventilation, or gastric insufflation; and early detection of airway obstruction.[38] Use of the Oxylator in the automatic mode can free the CPR provider to focus on other resuscitation tasks. The Oxylator may be useful in austere environments in which access to the patient's head and airway may be limited.

B. ResQPOD

The ResQPOD (Advanced Circulatory Systems, Roseville, MN), designated an AHA class 2A recommendation for patients in cardiac arrest, is an impedance threshold device. By regulating thoracic pressure during ventilation, the device increases blood flow to the heart and brain, increases systolic blood pressure, and increases the success rate of defibrillation. By preventing excess air from entering the thorax during ventilation, the device increases thoracic negative pressure and increases blood flow to the heart. It is placed proximal to a face mask, supraglottic

Figure 34-8 The Oxylator EMX is a positive-pressure resuscitation and inhalation system. (Courtesy of Lifesaving Systems, Inc., Roswell, GA.)

Figure 34-9 The ResQPOD is an impedance threshold device that provides perfusion on demand (POD) by regulating pressures in the thorax during states of hypotension. (Courtesy of Vygon, Ecouen, France.)

airway, or endotracheal tube and connects to the source of ventilation (Fig. 34-9). The ResQPOD also contains timing-assist lights to guide proper ventilation rates and prevent hyperventilation. Use of this device during CPR has improved survival rates.[39]

C. Passive Oxygen Insufflation

Oxygen can be delivered passively through an oropharyngeal airway, face mask, supraglottic airway, or modified endotracheal tube (Boussignac endotracheal tube, Vygon Corporation, Montgomeryville, PA). The Boussignac tube contains capillaries through which oxygen is delivered by continuous insufflation, generating a constant positive alveolar pressure. The proximal end of the tube remains open to allow exhalation (Fig. 34-10). The changes in intrathoracic pressure that occur during chest compressions trigger passive inhalation and active exhalation, allowing adequate gas exchange.

Passive oxygen delivery does not require the use of a rescuer to deliver ventilations, minimizes interruptions in chest compressions, and may reduce the risk of barotrauma caused by excessive ventilation. Evidence shows passive oxygen delivery to be as effective as bag-mask ventilation or mechanical ventilation through an endotracheal tube.[40,41] Passive oxygen delivery is described as an alternative but not a replacement for ventilation during CPR in the 2010 AHA guidelines.

XIII. CHALLENGES OF AIRWAY MANAGEMENT DURING CARDIOPULMONARY RESUSCITATION

When a patient requires CPR in an emergency situation, immediate airway management is required. In the prehospital setting, no general medical history or intubation history is available to guide airway management decisions. Within the hospital setting, patient information may or may not be accessible. Even if it is available, adequate time may not exist to review the information. Knowledge of previous difficulty with ventilation or intubation is often unknown.

A. Access to the Airway

Access to the airway during CPR may be limited in the prehospital and hospital settings. Outside of the hospital, CPR may be required in whatever location or situation the victim presents, and access may be limited by the outside environment or accident scene. Airway access may also be challenging inside an ambulance or helicopter. Other equipment required to resuscitate the patient and treat life-threatening injuries may also limit access to the patient. Within the hospital setting, access to the patient's airway may be limited by equipment, invasive lines or monitors, or the small size of many hospital rooms and intensive care suites. During mass casualty disasters, PPE or chemical protection gear may make airway management more difficult.

B. Cervical Spine Injury

Cervical spine injury has been diagnosed in 2% to 5% of patients after traumatic injury.[42] If the anterior and posterior columns of the cervical spine are injured, the injury is considered unstable.[43] Most trauma patients are placed in a cervical collar until cervical injury is ruled out; some of these patients may require CPR and emergent airway management before a radiologic examination can be obtained. Significant head injury is associated with traumatic cervical spine injury; patients with a Glasgow

Box 34-4 Airway Management Recommendations for Patients with Suspected Cervical Spine Injury

Rapid-sequence intubation is most often recommended.
Manual in-line stabilization of the cervical spine minimizes movement during intubation.
No safe amount of cervical spine movement has been defined.
A selection of laryngoscope blades and sizes should be available.
Supraglottic airway devices can be used as airway adjuncts.
No specific intubation method is recommended.

Modified from Ollerton JE, Parr MJA, Harrison K, et al: Potential cervical spine injury and difficult airway management for emergency intubation of trauma adults in the emergency department—a systematic review. *Emerg Med J* 23:3–11, 2006.

Coma Scale score of 8 or less often require emergent airway management.[44]

Manual in-line stabilization of the cervical spine is recommended for airway management in patients with a suspected or known cervical spine injury to reduce the potential for neck movement. Neck traction is not recommended. The presence of a cervical collar increases the difficulty of intubation. If necessary, the collar may be removed for airway management, provided that manual in-line stabilization is maintained.

No one method of intubation has been proved to be safest, and rapid-sequence intubation by direct laryngoscopy is the most commonly reported technique. Evidence shows that some degree of cervical spine motion occurs with all methods of intubation,[45,46] but data are lacking about whether the small amount of movement that occurs during airway management is clinically significant. A higher incidence of cervical spine limitation and difficult intubation may exist among elderly patients.[47] Box 34-4 describes recommendations for airway management in the patient with a suspected or known cervical spine injury.

C. Equipment Challenges

In the prehospital environment, airway management must be provided with the equipment that is available. Depending on the resources, a full complement of airway equipment, including oxygen supplies, may or may not be available. Equipment also may be unavailable within the hospital if airway management is required in a location remote from the operating room or intensive care setting. The type of airway management provided may be dictated by the available supplies and equipment, and adjunct airway devices for difficult airway management may not be quickly accessible. In the emergent setting, bag-mask ventilation should be initiated and maintained until additional airway equipment becomes available.

XIV. CONTROVERSIES

A. Role of Hyperventilation

Evidence suggests that hyperventilation may decrease overall survival and should be avoided.[48] Excessive ventilation should also be avoided because of the risk of gastric insufflation, regurgitation, or aspiration. Hyperventilation increases intrathoracic pressure and results in reduced coronary perfusion pressures.[49]

B. When to Secure the Airway

Existing information is inadequate to guide the ideal timing of advanced airway device placement. Evidence supports the practice of initiating chest compressions early, before the start of airway management. Airway management strategies should minimize interruptions in resuscitation. Newer, advanced airway devices that can be placed quickly and that do not require direct visualization of the vocal cords may achieve this goal.

XV. CONCLUSIONS

Disasters occur frequently but rarely in any one place. Triage, surge capacity, and altered standards of care are ways to ration scarce resources when demand outstrips supply. Planning and preparing for disasters can help to mitigate their impact. The HICS is used in U.S. hospitals for management during major incidents. The NDMS, operating under the National Incident Command System, is responsible for addressing major disasters within the United States.

The updated CPR guidelines stress initiation of chest compressions before airway management. Advanced airway devices such as supraglottic airways can be considered if access to the patient is limited or endotracheal intubation fails. Airway management during CPR or disaster situations is often guided by the resources available to the provider, which may be limited.

XVI. CLINICAL PEARLS

- Disaster management should start with a bottom-to-top approach, followed by a multiple-scale approach.
- Communication, preservation of infrastructure, and mitigation techniques are essential during a disaster response.
- The 2010 AHA CPR guidelines recommend beginning chest compressions before initial airway management (i.e., circulation, airway, and breathing).
- Hyperventilation during CPR should be avoided, and it may reduce overall survival.
- Limited access to the patient may make airway management and resuscitation during disasters more challenging.

I. INTRODUCTION

Anesthetic administration in a patient with a full stomach poses three challenges to the anesthesia provider: prevention of gastric regurgitation, prevention of pulmonary aspiration, and institution of appropriate airway management. The accepted safe anesthesia management plan for reducing pulmonary aspiration of gastric contents in these patients involves identifying those at risk for gastric regurgitation and pulmonary aspiration by using practice guidelines for preoperative fasting, implementing prophylactic pharmacologic therapies, and applying appropriate airway management techniques that may reduce the risk of pulmonary aspiration. A review of the relevant literature suggests that the incidence of perioperative pulmonary aspiration is declining.[1] Mortality rates for this dreaded complication have dramatically decreased over the past few decades.[1]

II. DEFINITION OF PULMONARY ASPIRATION

Perioperative *pulmonary aspiration* of regurgitant gastric contents is defined as the presence of bilious secretions or particulate matter in the tracheobronchial tree. The term *bronchoaspiration* has been used to describe the same phenomenon, but the previous nomenclature for pulmonary aspiration is used in this chapter.[2] Pulmonary aspiration can occur at any time preoperatively until 2 hours after terminating anesthesia. Diagnosis is made by direct examination of the airway, bronchoscopic assessment of the tracheobronchial tree, or postoperative

imaging that demonstrates lung infiltrates not previously identified on the preoperative radiograph.[3] The incidence, morbidity, and mortality from pulmonary aspiration are considered in Chapter 12.

III. TIMING OF PULMONARY ASPIRATION

Patients with a full stomach are considered to be at high risk for pulmonary aspiration, which may occur before or during induction of anesthesia or at emergence from anesthesia. Most adult cases of pulmonary aspiration occur during induction of anesthesia (i.e., before laryngoscopy and tracheal intubation) (50%), during laryngoscopy (29%), or during and after emergence from anesthesia.[1,4] In the pediatric population, most cases of pulmonary aspiration occur during induction with an inhalation anesthetic or tracheal intubation without a muscle relaxant, and more than 30% take place during emergence and extubation.[3]

Although most instances of pulmonary aspiration coincide with anesthetic induction, laryngoscopy, or surgery, they can also occur postoperatively.[5] Patients who are at risk before surgery are also at risk during the postoperative period because the residual effects of anesthetic agents, muscle relaxants, and narcotic analgesics decrease protective airway reflexes.

IV. PHYSIOLOGIC RISK FACTORS IN THE PERIOPERATIVE PATIENT

Several physiologic risk factors predispose to aspiration pneumonitis (Table 35-1):

1. Increased gastric fluid volume (GFV) with acidic pH, increased bacterial count, or solid material
2. Delayed gastric emptying
3. Impaired protective physiologic mechanisms, which include reduction in lower esophageal sphincter (LES) and upper esophageal sphincter (UES) pressure
4. Loss of protective airway (laryngeal-pharyngeal) reflexes

A. Gastric Volume and pH

The widely cited criteria for aspiration pneumonitis (GFV = 0.4 mL/kg and pH < 2.5), which were generated from the study of a single Rhesus monkey and extrapolated to humans, have been refuted.[6] Current evidence supports a dose-response relationship for gastric volume instilled directly into the lung and gastric acidity. The lethal dose for acid pulmonary aspiration has been studied in numerous animal models.[5,7,8] James and colleagues demonstrated that hydrochloric (HCl) acid instilled directly into rat tracheas resulted in a high mortality rate.[9] Late mortality rates were 90% with a volume of 0.3 mL/kg at a pH of 1.0 and 14% with a volume of 1 to 2 mL/kg at a pH less than 1.8. An investigation involving primates demonstrated that aspiration of large volumes (0.8 to 1.0 mL/kg) of acid at a pH of 1 was associated with severe pneumonitis. Instillation of smaller volumes (0.4 to 0.6 mL/kg) produced mild radiologic and clinical changes but no deaths. The median lethal dose for acid aspiration into the lungs was 1.0 mL/kg. Extrapolation of these data to humans provides a critical volume of approximately 50 mL for severe pulmonary aspiration in adults.[10]

The effect of aspiration of milky products into the lungs has also been studied in animals.[11] Acidification of human milk to a pH of 1.8 with HCl acid increased the severity of aspiration pneumonitis compared with 5%

TABLE 35-1

Physiologic Risk Factors for Regurgitation and Aspiration of Gastric Contents

Physiologic Effect	Risk Factors
Increased gastric volume, pressure, and acidity	Less than 6 hours of NPO (e.g., recent meal, drink, alcohol)
	Gastric insufflation (e.g., mask ventilation)
	Acid hypersecretion (e.g., hypoglycemia, alcohol, increased gastrin secretion)
Delayed gastric emptying	Intestinal obstruction (e.g., opioids, anticholinergics)
	Drugs
	Pregnancy
	Obesity
	Diabetes, peptic ulcer disease, trauma
	Sympathetic stimulation (e.g., acute pain, anxiety, stress)
Impaired protective physiologic mechanism	Autonomic neuropathy (e.g., diabetic gastroparesis)
Decreased LES tone	Pregnancy
	Gastroesophageal reflux
	Hiatal hernia
	Laryngoscopy
	Cricoid pressure application
Decreased UES tone	General anesthesia and sedation
Loss of protective airway (laryngeal-pharyngeal) reflexes	Altered mental state or head injury
	CNS-depressant drugs
	Cerebral hemorrhage or infarct
	Neurologic diseases (e.g., multiple sclerosis, Guillain-Barré, cerebral palsy, Parkinson's disease)
	Neuromuscular diseases (e.g., muscular dystrophies, myasthenia gravis)

CNS, Central nervous system; *LES,* lower esophageal sphincter; *NPO,* nil per os (no oral intake); *UES,* upper esophageal sphincter.

dextrose acidified to a pH of 1.8 with HCl acid. Acidification of human breast milk with gastric juice instead of HCl acid did not increase the severity of lung injury. Instillation of soy-based formula or other dairy milk formula into the lungs caused a less severe form of acute injury.[12] Human milk is particularly noxious when aspirated compared with other types of milk.

In normal, healthy children, the range of residual gastric volume at the time of anesthetic induction is broad. Cote and coauthors reported values of 0.11 to 4.72 mL/kg, which were higher than the values (0.01 to 4.08 mL/kg) reported by Splinter and associates.[13,14] Children in clinical studies typically have average gastric volumes greater than 0.4 mL/kg and acidic pH levels,[14-22] but they rarely have (1 in 10,000 anesthetics) aspiration pneumonia associated with anesthesia.[23] Instead of focusing on GFV at induction, the emphasis to prevent pulmonary aspiration should be on patients' comorbidities, their risk factors, type of anesthesia, and characteristics of the aspirate.

B. Delayed Gastric Emptying

Patients who have delayed gastric emptying are considered to have a full stomach and to be at risk for pulmonary aspiration. Patients' conditions that delay gastric emptying include obesity, pregnancy, diabetes, peptic ulcer disease, trauma, stress, and acute pain.

C. Impaired Protective Physiologic Mechanisms

1. Lower Esophageal Sphincter Tone

The LES forms a border between the stomach and the esophagus, with the lower esophagus creating a sling around the abdominal esophagus.[24] Barrier pressure is the difference between LES pressure and gastric pressure. Intragastric pressure is normally less than 7 mm Hg. Normal resting LES pressure in conscious individuals is 15 to 25 mm Hg higher than intragastric pressure. An incompetent LES reduces barrier pressure and increases the risk of regurgitation of gastric contents.

LES tone reduction is the major problem in patients with gastroesophageal reflux (GER) during anesthesia and in disease states. In patients presenting with hiatal hernia, the maximum pressure at the gastroesophageal junction was lower (17.1 mm Hg) than the pressure in healthy volunteers (28 mm Hg).[25] Intragastric pressure increases to 35 mm Hg when the stomach is distended.[26] Gastric distention with increased intragastric pressure and reflex relaxation of the LES causes spontaneous GER. When esophageal pressure equals gastric pressure, the development of a common cavity leads to spontaneous GER.[27]

Patients with coexisting gastroesophageal pathology presenting for anesthesia are susceptible to GER. The mechanism for reflux is a transient relaxation of the LES.[27,28] Anesthetic agents and techniques relax the LES, reduce barrier pressure, and predispose the patient to GER.[29] Cricoid pressure application and laryngoscopy during anesthesia also lower LES tone.[30] Drugs that lower LES tone include anticholinergics, benzodiazepines, dopamine, sodium nitroprusside, ganglion blockers, thiopental, tricyclic antidepressants, β-adrenergic stimulants, halothane, enflurane, opioids, and propofol.[29] Inhalation agents can reduce the LES pressure below the intragastric pressure, depending on the degree of relaxation.[29,31] Propofol has no effect on barrier pressure except for a transient decrease in LES tone and gastric pressure at 1 minute, which return to baseline values later.[32] Drugs that increase LES pressure include antiemetics, cholinergic drugs, succinylcholine, pancuronium, metoclopramide, domperidone, edrophonium, neostigmine, metoprolol, metoprolol, α-adrenergic stimulants, and antacids.[29,32]

2. Upper Esophageal Sphincter Tone

The cricopharyngeus muscle acts as the functional UES. It is one of the two inferior constrictor muscles of the pharynx. It extends around the pharynx from one end of the cricoid arch to the other and is continuous with the circular, muscular coat of the esophagus.[24] In the conscious, healthy patient, the UES helps to prevent pulmonary aspiration by sealing off the upper esophagus from the hypopharynx.[33]

Various anesthetic techniques and agents (except ketamine) reduce the UES tone and predispose the patient to regurgitation of material from the esophagus into the hypopharynx. Residual neuromuscular blockade (even with train-of-four ratio of 0.7) puts the patient at risk for pulmonary aspiration because of a reduction in UES tone and impaired swallowing.[34-38]

D. Loss of Protective Laryngeal-Pharyngeal Airway Reflexes

Four well-defined reflexes in the upper airway protect the lungs from aspiration. They are apnea with laryngospasm, coughing, expiration, and spasmodic panting that involves the glottic area and the true or false vocal cords.[39] Impaired laryngeal-pharyngeal function usually results from an altered consciousness level. Patients with central nervous system disorders, cerebrovascular injuries, head trauma, alcohol intoxication, and neuromuscular disorders (particularly myotonia dystrophica and scleroderma) have an increased pulmonary aspiration risk due to diminished pharyngeal sensation and diminished protective airway reflexes.[40]

Anesthetic agents that result in the loss of UES tone impair protective reflexes.[41] Prevention of protective laryngeal closure permits entry of this foreign matter into the tracheobronchial passages, causing regurgitation of gastroesophageal contents into the pharynx.

V. PATIENTS AT RISK FOR PULMONARY ASPIRATION

Recognition of patients who have any of the aforementioned risk factors for pulmonary aspiration is the first step toward minimizing the incidence of perioperative pulmonary aspiration. These patients can be categorized in two groups: those with a full stomach (i.e., history of ingestion of a meal with less than 6 hours fasting time)[42] and those designated as having a full stomach despite a prolonged preoperative fast.

Patients who are at high risk for pulmonary aspiration are at the extremes of age, have altered consciousness, have ingested solids or liquids despite orders to take nothing by mouth (*nil per os* [NPO]), are pregnant (particularly those in labor), or have sustained trauma. Trauma, even if not abdominal, delays gastric emptying.[43,44] Trauma patients, especially those in acute pain who are scheduled for emergency surgery, have decreased gastrointestinal motility and increased gastrointestinal secretion despite fasting preoperatively.[45] The incidence of pulmonary aspiration increases markedly after trauma because of recent ingestion of food, depressed consciousness, diminished or absent airway reflexes, or gastric stasis induced by raised sympathoadrenal influx of catecholamines. In 53 adults with Glasgow Coma Scale scores less than 8 who were intubated by the London Helicopter Emergency Medical Service, the incidence the of gross pulmonary aspiration was 38%.[46,47]

Other factors increase the risk of pulmonary aspiration. Medications that delay gastric emptying affect the protective physiologic mechanisms. Patients receiving narcotics are expected to have delayed gastric emptying,[48,49] but it has also been demonstrated that administration of opioids in a single dose to healthy patients did not delay gastric emptying or affect acidity.[50-52]

Long-standing diabetes and gastroparesis are risk factors. Diabetic gastroparesis impairs gastric emptying and may compromise LES function.[1,53-55] Patients who are morbidly obese can have delayed gastric emptying, increased abdominal pressure, and a difficult airway, all of which are potential risks for pulmonary aspiration. The gastric volumes in 71% of these patients are in the at-risk range compared with the levels found in normal subjects.[56] The risk of aspiration also is increased for patients with stress and acute pain, raised intracranial pressure, and neuromuscular disorders.

Certain types of surgery are associated with pulmonary aspiration. The incidence of silent gastric regurgitation is higher in esophageal,[1,4] upper abdominal,[57] and emergency laparoscopic operations.[58,59] Comorbidities are more likely in patients with American Society of Anesthesiologists (ASA) IV or V physical status. Emergency surgery, especially when performed at night, is a risk factor for aspiration.

Failed tracheal intubation of a patient with a difficult airway can lead to hypoxia associated with gastric regurgitation and pulmonary aspiration. General anesthesia administration in patients with a full stomach necessitates tracheal intubation to protect the airway from pulmonary aspiration. If tracheal intubation that is undertaken to isolate the airway and avoid pulmonary aspiration proves to be difficult, the procedure itself can lead to pulmonary aspiration. A difficult intubation can be predicted in only two thirds of cases. Problematic anesthetic inductions compounded by difficult tracheal intubation, difficult mask ventilation, inadequate anesthesia with coughing or straining, difficult emergence, or difficult extubation constitute prime conditions for gastric regurgitation and pulmonary aspiration, and they have been reported in up to 77% of these cases.[60-63]

Regional anesthesia may be followed by complications. Regional anesthesia is usually considered safe in patients at risk for pulmonary aspiration because they are awake and have intact protective airway reflexes.[64] However, after administration of spinal anesthesia, some patients develop extensive sympathetic block followed by hypotension, vomiting, difficulty swallowing, or impaired cough reflex.[1] The risk of pulmonary aspiration is exacerbated by difficulty in swallowing because of a high level of sympathetic block. Concomitant administration of narcotics or sedatives can obtund the protective airway reflexes, leading to gastric regurgitation and pulmonary aspiration.[39,65,66] Vomiting associated with sympathetic blockade–induced hypotension requires turning the patient's head to the lateral position and placing the patient in the Trendelenburg position to avoid pulmonary aspiration of gastric contents.

VI. PERIOPERATIVE ANESTHESIA CONSIDERATIONS IN FULL-STOMACH PATIENTS

Anesthetic management in patients with a full stomach involves preemptive methods to minimize pulmonary aspiration and its morbidity. Goals are to minimize the volume of gastric contents, reduce GER, and prevent perioperative pulmonary aspiration. Preemptive measures to accomplish these goals include preoperative fasting, pharmacologic therapies to decrease gastric acidity, facilitation of gastric emptying or drainage, and competent LES tone maintenance. Full-stomach precautions dictate the anesthetic induction technique. Appropriate airway management techniques include effective cricoid pressure (CP) application, tracheal intubation, or the use of other airway devices.

A. Preoperative Fasting

Historically, adult patients have fasted 8 to 12 hours before surgery to reduce the volume of gastric contents and the aspiration pneumonitis risk. The National Confidential Enquiry into Perioperative Deaths highlighted the issue of preoperative starvation.[67] NPO after midnight is an accepted preoperative order. Long fasting before an elective operation is uncomfortable and creates detrimental effects by causing thirst, hunger, irritability, noncompliance, and resentment in adult patients.[57] Prolonged fasting is especially deleterious in children because it produces dehydration or hypoglycemia.[21,68] During the past 20 years, several scientific papers have challenged the traditional practice of preoperative fasting for more than 8 hours. The current understanding of gastric emptying physiology has generated revised preoperative fasting policies.[3,21,50,69-77]

Despite the knowledge that the stomach handles emptying solids and liquids differently, physicians traditionally lumped consideration of them together in the standard preoperative order: NPO after midnight the day before surgery. After an extensive review, the ASA task force revised policies and published specific practice guidelines for preoperative fasting.[42,78]

The Fourth National Audit Project (NAP4) was conducted by the Royal College of Anaesthetists and the Difficult Airway Society. The large-scale review of

airway-related complications was published in 2011 after analyzing the events included in NAP4 from September 1, 2008, to August 31, 2009.[63] The NAP4 examined records for major complications among the 2.9 million general anesthetics in the operating rooms, airway management procedures in intensive care units (ICUs), and airway management techniques in the emergency departments across the United Kingdom.[63] The data revealed 184 serious airway-related complications that led to death, brain damage, emergency invasive airway access through the neck, unanticipated admission to the ICU, or prolonged ICU stay.[63] The most frequent fatal complication from general anesthesia was pulmonary aspiration of regurgitated gastric contents, which was implicated in 50% of the deaths.[63] Cook and colleagues thought that pulmonary aspiration was a well-recognized problem for patients under general anesthesia and that it should be preventable in most cases. However, in some cases reported in the study, proper precautions were not taken.[63] The incidence in NAP4 was three to five times higher than that found in the analysis of the ASA Closed Claims Project database reported from the United States.[79]

1. Liquids

Residual gastric volume is directly related to regurgitation and pulmonary aspiration. However, the ASA Task Force on Preoperative Fasting, despite extensive scrutiny of the existing data, has been unable to establish a link between residual gastric volume and pulmonary aspiration.[78,80]

a. CLEAR LIQUIDS

Clear liquids in healthy patients empty exponentially. The gastric emptying half-life ($t_{1/2}$) of clear liquids is 12 minutes, which is considerably faster than for solids. Theoretically, for a patient who consumes 500 mL of clear liquid, almost 97% of the liquid is eliminated from the stomach after five half-lives (i.e., 60 minutes).[81-83] The rate of gastric emptying after a liquid meal has been well studied in adults.[74,76,80] The studies demonstrated that after drinking 750 mL of pulp-free orange drink, the mean $t_{1/2}$ ranged from 10 ± 7 to 20 ± 11 minutes. The fastest $t_{1/2}$ for an individual subject was 2.9 minutes, and the slowest $t_{1/2}$ was 41.6 minutes, indicating that almost complete gastric emptying could be accomplished in 2 hours (approximately five half-lives) after a clear liquid drink was consumed. Even in individuals with the slowest emptying rates, only 10% or less of the original liquid was retained in the stomach after 2 hours.[72,75,84-86]

The ASA Committee on Standards and Practice Parameters supports a fasting period of 2 hours after the ingestion of clear liquids for all patients.[78] Clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. The clear liquid category does not include alcohol. The volume of liquid ingested is less important than the type of liquid.

b. MILK

In term and preterm infants, breast milk leaves the stomach more rapidly than formula milk. The gastric emptying $t_{1/2}$ for breast milk is approximately 25 minutes; for formula milk, it is twice as long.[87,88] Consultants and the ASA Committee on Standards and Practice Parameters recommend fasting 4 hours after breast milk and 6 hours after infant formula.[78]

2. Solids and Nonhuman Milk

Gastric emptying for solids occurs in a linear pattern with time, and 10% to 30% of ingested solids may remain in a patient's stomach after 6 hours.[89] Gastric emptying is inhibited when the duodenum is distended; when the chyme contains a high concentration of acid, proteins, or fats; or when the osmolarity is not iso-osmolar. Gastric emptying after solid ingestion also depends on body posture after intake, exercise, meal weight, size of food particles, amount of food, and the type of food.[90,91] Lack of readily available, appropriate methodology makes the assessment of stomach contents in the perioperative period difficult.

Miller and coworkers investigated patients who ate a light breakfast of a slice of buttered toast and a cup of tea or coffee with milk 2 to 4 hours before surgery.[92] Gastric contents were measured by inserting a gastric tube after anesthetic induction. There was no significant difference in gastric volume or pH between the control group (fasting) and the study group. Soreide and associates investigated a group of healthy, female volunteers who ingested a standard hospital breakfast of one slice of white bread with butter or jam, one cup (150 mL) of coffee without milk or sugar, and one glass (150 mL) of pulp-free orange juice.[93] Gastric contents were measured by repeated ultrasonography and paracetamol absorption techniques. No solid food was detected in any volunteer 240 minutes after breakfast. The latter test determined that at least 4 hours between eating and surgery are needed for solid foods to empty from the stomach.

It is appropriate to fast at least 6 hours after intake of a light meal or nonhuman milk before elective procedures. The ASA Committee on Standards and Practice Parameters revised the guidelines because the members found that intake of fried or fatty foods or meat could prolong gastric emptying time. In these situations, 8 hours or more may be needed for preoperative fasting.[78]

3. Patients with Diabetes

Radioisotopic techniques and electrical impedance tomography have been used to show that type 1 diabetic patients have delayed gastric emptying.[55] After ingestion of a semisolid meal, the mean $t_{1/2}$ of gastric emptying was 54.8 ± 26.6 minutes in diabetic patients compared with 40.4 ± 8.6 minutes in nondiabetic control subjects. Diabetic patients require a longer fasting period (8 hours) than nondiabetic patients.

4. Ambulatory Patients and Anxiety

Anxiety delays gastric emptying and increases acid secretion.[94,95] Ambulatory surgery increases anxiety. A background study showed that the mean gastric volume was 69 mL in outpatients and 33 mL in inpatients, with an average pH of less than 2.5 in both groups.[96]

To test the hypothesis that preoperative stress affects residual GFV and pH in pediatric patients, children between the ages of 3 and 17 years were randomly

assigned to three groups: outpatients, inpatients, and patients who had multiple operations.[13] There were no differences in the residual GFV between the three groups and no differences in gastric contents between inpatients and outpatients. The relationships among oral premedication, preoperative anxiety, and gastric contents showed that premedication reduces anxiety. However, there were no correlations among the type of premedication, level of anxiety, gastric volume, and gastric pH.[97]

B. Fasting Guidelines Summary

Almost 80% of elective operations are scheduled for ambulatory patients or those with same-day admittance. The ASA Task Force on Preoperative Fasting recommends avoiding anesthetizing a patient with a full stomach to reduce the risk of pulmonary aspiration.[80] The ASA practice guidelines about minimum fasting period for ingested material include the following recommendations: clear liquids, 2 hours; breast milk, 4 hours; infant formula, nonhuman milk, and a light meal, 6 hours. A fast should precede elective procedures requiring general anesthesia, regional anesthesia, or sedation or analgesia (i.e., monitored anesthesia care). The guidelines also recommend a fasting period for a meal that includes fried foods, fatty foods, or meat of 8 hours or more before elective procedures. Diabetic patients need 8 hours or more for gastric emptying after ingesting semisolid material.

Most anesthesiologists practicing outpatient anesthesia in the United States have conformed to the recommendation of the ASA practice guidelines for preoperative fasting time.[77] Similar opinions from associations linked to the World Federation of Societies of Anesthesiologists and from the current literature have led to changes in preoperative fasting guidelines worldwide.[69-71,98,99]

C. Role of Preoperative Ultrasonography

Ultrasonography has been proposed as a useful, noninvasive, bedside tool to determine gastric content and volume in the perioperative period based on studies in parturients,[100] a pilot phase study enrolling 18 healthy adult volunteers,[101] and a follow-up phase II study enrolling 36 adult volunteers that suggested the gastric antral cross-sectional area was a reliable indicator of the quantitative assessment of gastric volume in the right lateral decubitus position.[101] Another prospective trial performed an ultrasonographic qualitative and quantitative analysis of the gastric antrum in 200 fasted patients undergoing elective surgery by assigning a grade to each patient on a 3-point grading scale. Eighty-six patients were categorized as grade 0, suggesting an empty antrum (0 mL); 107 patients as grade 1, suggesting minimal fluid volume (16 ± 36 mL) detected only in the right lateral decubitus position; and 7 patients as grade 2, suggesting a distended gastric antrum with fluid 180 ± 83 mL visible in supine and right lateral decubitus positions.[102] Results of this study of elective surgical patients indicates that preoperative ultrasonography may be able to help identify patients who are at higher risk of pulmonary aspiration. Because certain patient populations, such as trauma patients undergoing surgery, are known to be at high risk for pulmonary aspiration with associated morbidity and mortality,[46] it seems prudent to use ultrasonography as a screening tool preoperatively for these patients.

D. Pharmacotherapy

The ASA practice guidelines do not recommend the routine preoperative use of gastrointestinal stimulants, medications that block gastric acid secretion, antacids, prokinetics, antiemetics, or anticholinergics to reduce the risk of pulmonary aspiration in patients who have no apparent increased risk.[78,80]

Proton pump inhibitors (PPIs) reduce intragastric acidity and gastric juice volume, and they have been advocated for preanesthetic use to prevent pulmonary aspiration.[103] Peptic ulcer bleeding is common, and recurrent bleeding is an independent risk factor for mortality. A PPI infusion prevents recurrent upper gastrointestinal bleeding after endoscopic therapy.[104] A study from Japan showed that rabeprazole may be a suitable alternative to standard H_2-blocker prophylaxis against acid aspiration pneumonia.[105]

Surveys on pulmonary aspiration prophylaxis in the full-stomach, nonobstetric population are rare. The accepted pharmacologic regimens include an attempt to manipulate the gastric pH, volume, and barrier pressure.[106-114] Other surveys of antacid prophylaxis are limited to obstetric anesthesia.[115-120] Most studies suggest improved safety from reduced gastric volume or an increase in gastric pH, or both.[1,121-131] However, no data show evidence of improved outcome after the use of antacids, H_2-receptor blockers, PPIs, or prokinetics. Because of the paucity of data and a lack of evidence to prove the value of pharmacologic therapies for preventing pulmonary aspiration, it is not possible to provide a cost-benefit ratio.[78,80]

E. Preoperative Gastric Emptying

Preoperative stomach emptying through a gastric tube is beneficial for patients at risk for pulmonary aspiration (e.g., small bowel obstruction). Any contents emptied from the stomach make anesthesia induction safer for the patient.

Preoperative gastric emptying concerns include the effect of routine gastric tube insertion before emergency surgery for at-risk patients, the effect of an in situ gastric tube on the efficacy of CP application during induction of anesthesia, and the effect of the gastric tube on GER and pulmonary aspiration in mechanically ventilated patients.

1. Preoperative Gastric Tube Insertion Before Emergency Surgery

Preoperative gastric emptying is not without hazards. Preoperative insertion of a gastric tube and subsequent gastric emptying in an awake, unsedated patient elicits a profound sympathetic response and oxygen desaturation.[132] This response, which is similar to the cardiovascular response after tracheal intubation without analgesia,[133,134] puts the patient with cardiac problems at

risk for cardiac ischemia and dysrhythmias. Routine preoperative nasogastric tube placement is not recommended except in selected patients with small bowel or gastric outlet obstruction. Although the gastric tube helps to reduce intragastric volume and pressure, it does not guarantee that the stomach is completely empty. Preoperative nasogastric tube insertion and stomach decompression are recommended only in patients with a distended stomach (e.g., bowel obstruction).

2. In Situ Gastric Tube During Induction

The disposition of an existing gastric tube during induction of general anesthesia is a debatable issue. After the stomach is decompressed, the gastric tube can be removed or left in situ during a rapid-sequence induction (RSI). Although the presence of the gastric tube may impair the function of the UES and LES,[135] studies with cadavers have shown that the efficacy of CP application during induction of anesthesia is not impaired.[136,137] If the patient has a nasogastric tube, it need not be withdrawn before induction of anesthesia because it acts as an overflow valve and prevents pressure buildup in the stomach; it also allows drainage during anesthesia induction.[138]

3. Effects of Gastric Tube Placement in Mechanically Ventilated Patients

The third concern was tested in mechanically ventilated ICU patients to determine the effect of the nasogastric tube size on the incidence of GER.[139] The concern about GER is that it can result in pulmonary aspiration and bacterial pneumonitis. Investigators found no significant difference in GER and pulmonary aspiration with the use of small-gauge and large-gauge nasogastric tubes.

4. Sealing the Esophagus by Inflatable Cuffs

Inflating a cuff at the gastroesophageal junction to prevent gastric reflux is considered to be unsafe. A newly designed, but similar nasogastric device with an inflatable balloon to occlude the gastric cardia (Aspisafe, Braun, Melsungen, Germany) was first studied in pigs (Fig. 35-1).[140] After gastric filling with large volumes, despite maneuvers and drugs used to promote regurgitation, the new nasogastric device did not produce GER.[140] The same experiment was duplicated in healthy volunteers and surgical patients considered to be at risk for pulmonary aspiration, and findings were similar.[140] Use of this device is considered safe because there was no test evidence of GER after RSI.[39]

The device was subsequently studied in conjunction with the use of a laryngeal mask airway (LMA). A dye indicator injected into the stomach revealed that the balloon tube prevented GER.[141] Future clinical studies should decidedly prove balloon tube safety and usefulness in preventing regurgitation during induction and emergence.

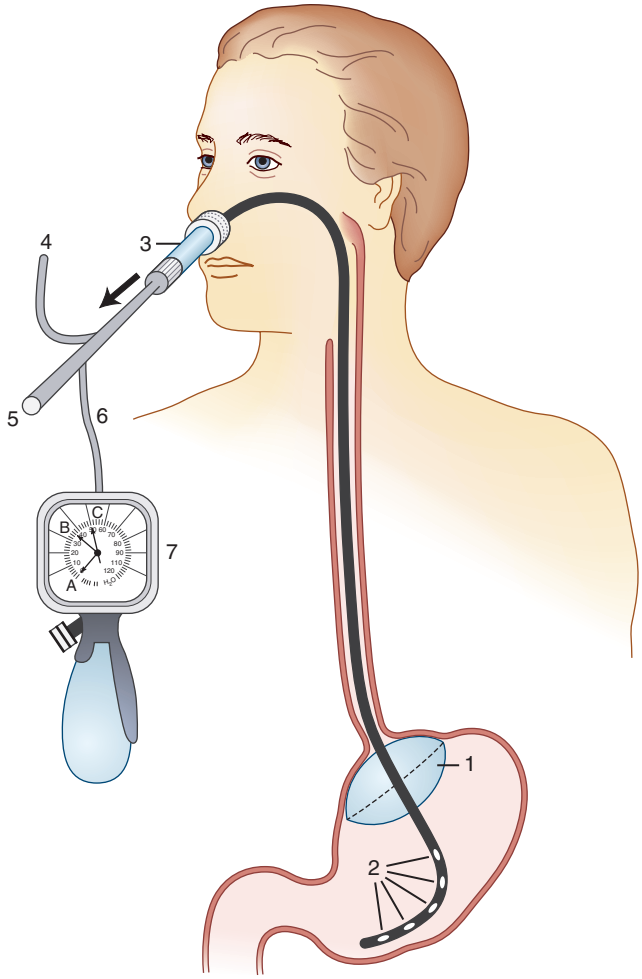

Figure 35-1 The nasogastric balloon tube that is used to occlude the cardia in a patient has several components: *1,* inflatable balloon; *2,* lateral openings to aspirate stomach contents and equilibrate pressure between the stomach and the outside air; *3,* pliable nose stopper with a foam ring and locking device (enlarged drawing to illustrate); *4,* separate lumen ("slurp lumen"); *5,* main lumen with an aspiration connection; *6,* branch tube with the subsidiary lumen leading into the inside of the balloon; *7,* pressure monitoring device (*A,* pressure level in the deflated state of the balloon; *B,* pressure level in the inflated state of the balloon; *C,* pressure level when the aspiration tube is pulled tight, resulting in close appositional contact of the balloon with the cardia). (From Roewer N: Can pulmonary aspiration of gastric contents be prevented by balloon occlusion of the cardia? A study with a new nasogastric tube. *Anesth Analg* 80:378–383, 1995.)

VII. GENERAL ANESTHESIA MANAGEMENT

The goals of general anesthesia in full-stomach patients include skillful airway management and prevention of pulmonary aspiration of gastric contents. Airway management techniques used to isolate the trachea from the gastrointestinal tract with a cuffed tracheal tube include intubation of the trachea in an awake patient using a flexible fiberoptic bronchoscope (FOB), optical stylet, or a video laryngoscope and use of RSI and tracheal intubation technique after preoxygenation and effective CP application.

A. Awake Tracheal Intubation in Patients at High Risk for Pulmonary Aspiration

The advantages of securing the airway with the patient awake compared with RSI and intubation in patients with a full stomach and a difficult airway are the

avoidance of loss of protective reflexes, failure of CP to prevent pulmonary aspiration, failed tracheal intubation leading to hypoxia and brain death, and cardiovascular collapse.

A full-stomach patient with a difficult airway warrants an awake tracheal intubation. The potential for managing a difficult airway (i.e., difficult intubation or difficult mask ventilation) may be self-evident because of a preexisting or acquired condition. However, normal individual anatomic variation may contribute to the difficulty with tracheal intubation or mask ventilation. Various physical characteristics are associated with a difficult airway, including a small mouth, limited mouth opening, short interincisor distance, prominent upper incisors with overriding maxilla, short neck, limited neck mobility, receding mandible or mandibular hypoplasia, high-arched and narrow palate, temporomandibular joint dysfunction, rigid cervical spine, obesity, and congenital anomalies found in infancy. Morbidly obese patients and infants particularly are at risk for a difficult airway and pulmonary aspiration. No single feature on physical examination accurately predicts a difficult intubation, but a variety of simple diagnostic tests have been suggested to identify patients with difficult airways.[142-154]

A priority in managing patients with a difficult airway and a full stomach is securing the airway with a tracheal tube while the patient is awake. This has several advantages, including maintenance of protective airway reflexes, uncompromised airway exchange and oxygenation, and maintenance of normal muscle tone, which helps in the identification of anatomic landmarks.

Intubation of the trachea while the patient is awake is a useful technique with a high degree of acceptance by patients, and it is considered a fail-safe method of choice when gastric regurgitation and pulmonary aspiration are likely.[155] Awake intubation is useful in situations of anticipated difficulties in tracheal intubation and in patients with intestinal obstruction, gastrointestinal hemorrhage, or upper airway obstruction; in seriously ill or moribund patients; and in those with respiratory failure.[156]

In patients with intestinal obstruction, paralytic ileus with abdominal distention, or upper gastrointestinal hemorrhage, the timing of regurgitation of gastric contents into the pharynx, particularly between the loss of consciousness and tracheal intubation, is greatly increased. Intubation of the trachea while the patient is awake is therefore a sound practice that affords protection against inhalation of gastric contents, loss of the airway, hypoxia, and cardiovascular collapse. Successful accomplishment of awake intubation in patients at risk for pulmonary aspiration depends on several factors, including adequate psychological preparation, use of an intravenous antisialagogue to dry up the oropharyngeal secretions, judicious intravenous sedation, topicalization of the airway, skills and experience of the endoscopist, and the nature and urgency of the surgery.

Before topicalization of the airway, the administration of anticholinergic drugs minimizes secretions, allowing adequate penetration of local anesthetic through the mucosa, enhancing the local anesthetic effects, and enabling better visualization through the bronchoscope. The drawback of using anticholinergic drugs in patients with a full stomach is that it can reduce LES tone and barrier pressure, creating a potential risk for pulmonary aspiration.

Efficacy and safety of awake intubation in full-stomach patients can be accomplished with the use of minimal sedation, administration of oxygen by nasal cannula during intubation, and application of local anesthetic to the pharynx, larynx, and trachea. The premise of conscious sedation is to balance the comfort of the patient and tolerance of the procedure and still have a patient responsive to commands. Judicious sedation with small amounts of short-acting benzodiazepines and narcotics helps allay anxiety and helps the patient who is awake tolerate any discomfort that occurs during tracheal intubation. Ovassapian and colleagues presented the concept of awake fiberoptic intubation using judicious sedation and topicalization of upper and lower airways in patients at high risk for pulmonary aspiration.[157] An accompanying editorial stated that this study of 121 patients was too small to accept the safety of the technique of awake intubation, sedation, and topicalization of the airway.

Topicalization of the lower airway (i.e., below the vocal cords) in an awake patient at risk for pulmonary aspiration is controversial. However, topicalization of the airway adds to the patient's comfort and enhances the chances of successful awake tracheal intubation. There are several ways to anesthetize the upper and lower airway, including administering local anesthetic spray to the mucosa, administering lidocaine jelly to the base of the tongue, bilateral blockade of the internal branch of the superior laryngeal nerve (i.e., sensory to the base of the tongue, vallecula, epiglottis, and larynx up to the level of the cords), bilateral glossopharyngeal nerve blocks (i.e., eliminates gag reflex), and transtracheal injection of local anesthetic through the cricothyroid membrane (i.e., anesthetizes the airway below the vocal cords).

After judicious sedation and topicalization of the airway, several techniques can be used to accomplish awake intubation, including blind nasal intubation, FOB intubation, use of optical stylets, use of video laryngoscopy, intubating laryngeal mask airways (ILMAs), lightwand-guided intubation, and retrograde intubation. There are advantages and drawbacks with each of these techniques.

B. Rapid-Sequence Induction

RSI of anesthesia to protect the airway from pulmonary aspiration of gastric contents has evolved since the introduction of succinylcholine in 1951 and the first description of CP by Sellick in 1961.[135] The primary objective of RSI is to minimize the time interval between loss of consciousness and tracheal intubation. The essential features of RSI include preoxygenation with 100% oxygen, administration of a predetermined induction dose, application of effective CP, and avoidance of positive-pressure ventilation until the airway is secured with a cuffed tracheal tube.[158,159] Many emergency physicians use RSI of anesthesia as their technique of choice to facilitate orotracheal intubation in patients presenting to the emergency room.[160-165] Having specialized equipment for

management of failed tracheal intubation is an integral part of RSI.[42,166-168]

RSI plays a major role in emergency anesthesia and is used almost universally for obstetric general anesthesia in the United Kingdom and United States[158]; however, it is practiced less widely in mainland Europe.[169] A survey of French anesthetists showed that only 23% used a full complement of measures to prevent pulmonary aspiration, and CP was rarely used,[1,170] but the incidence of fatal aspiration in France is lower than in other countries (1.4 per 10,000 versus 4.7 per 10,000 episodes of anesthesia).[1,170]

No prospective studies identify the efficacy of RSI in preventing morbidity or its safety. In the past decade, changes in available induction agents, muscle relaxants, airway adjuncts, and increased research in airway management have led to opportunities for RSI in general anesthesia practice to evolve further.

Preoxygenation is a standard component of RSI.[159] Preoxygenation with fresh gas flows of 100% oxygen through a mask with a good fit for 3 to 5 minutes is recommended. Alternatively, a series of four vital capacity breaths of 100% may be used in an emergency.[159] Thiopental remains the most popular induction agent for RSI,[159] although propofol also is used extensively. Other intravenous induction agents include ketamine and etomidate.[171,172]

Succinylcholine remains the muscle relaxant of choice for use in RSI.[159] Certain conditions may preclude the use of succinylcholine, as in burns and spinal cord injuries, because administration of succinylcholine can result in adverse effects such as hyperkalemia and dysrhythmias. Several studies have demonstrated that rocuronium in adequate doses (0.8 to 1.2 mg/kg) produces intubation conditions rapidly comparable to those with succinylcholine 1 mg/kg.[173,174] However, this large dose leads to prolonged duration of action of up to 1 hour.[175] In a patient with a difficult airway, this drug may allow less margin for error than succinylcholine.[176] Fifty percent of cases of difficult intubation occur without preoperative predictive signs and can increase the risks of gastric regurgitation and pulmonary aspiration in full-stomach patients.[177]

1. Modified Rapid-Sequence Induction

RSI is a well-established technique in anesthesia practice. During standard RSI, patients are made apneic and unconscious without establishing the ability to ventilate the lungs. Positive pressure usually is avoided to prevent gaseous distention of the stomach and subsequent pulmonary aspiration in RSI. However, avoidance of ventilation of the lungs during RSI precludes the ability to test the airway and verify that a patient's lungs can be ventilated by mask before the administration of a muscle relaxant. The technique of RSI therefore involves inherent risks to the patient, including the possible inability to secure an airway or to ventilate the lungs and oxygenate the patient who is unconscious and apneic. During RSI, failure to secure the airway can lead to many attempts at tracheal intubation with subsequent trauma to the airway, and failure to ventilate the lungs can lead to hypoxia, hypercarbia, and alterations in heart rate and blood pressure, resulting in significant morbidity. These risks may not be warranted or appropriate, particularly in patients who are at risk for gastric regurgitation and pulmonary aspiration. For them, appropriate management can include modification of the standard RSI technique consisting of preoxygenation, laryngoscopy using an elevated-head position,[178] induction of anesthesia, application of CP, apneic diffusion oxygenation,[179] and the added step of gentle positive-pressure ventilation of the lungs before tracheal intubation.[135,180]

A modified RSI technique allows the anesthesia provider to confirm that the patient's lungs can be ventilated and the patient can be oxygenated by mask before insertion of a cuffed tracheal tube. Positive pressure is provided by a face mask before and after the administration of the muscle relaxant. However, the risks and benefits of modified RSI have to be considered in a patient with a full stomach and a potentially difficult airway. The risks of being unable to intubate the trachea and ventilate the lungs have to be weighed against the risk of pulmonary aspiration; the results of both complications can be disastrous if they are not managed appropriately. However, the risk of cerebral hypoxia due to inadequate oxygenation must outweigh the risk of pulmonary aspiration. Cerebral hypoxia is not treatable and can result in devastating morbidity and mortality, whereas pulmonary aspiration is treatable and has a good outcome in current clinical practice.

2. Cricoid Pressure

CP is an integral component of RSI and is an accepted standard of care during anesthesia and to a lesser extent during resuscitation in patients with a full stomach.[159,181-183] As early as the 1770s, CP was recognized as an important method to occlude the esophagus and prevent gastric distention during lung ventilation of drowning victims.[184] However, it was almost 200 years later that Sellick introduced CP into clinical anesthesia practice.[135] Although studies cite increasing concerns regarding the safety and efficacy of CP, it is still widely practiced.[185-187]

The cricoid cartilage is a complete circle shaped like a signet ring. It is attached superiorly to the thyroid cartilage by the cricothyroid ligament and inferiorly to the first tracheal ring by the cricotracheal membrane. The esophagus begins at the lower border of the cricoid cartilage, and the cricopharyngeus muscle guards the esophageal opening. The cricoid cartilage is different sizes and has different locations in adults and children.

The CP, a force measured in newtons (N), must be of sufficient amount applied during induction of general anesthesia to prevent regurgitation from the esophagus and stomach. Regurgitation of stomach contents depends on esophageal pressure, gastrointestinal pathology, intragastric pressure, UES and LES pressures, and the effectiveness of occluding the esophageal lumen. On the basis of several studies,[136,188-192] a force (CP) of 44 N (9.8 N = 1 kg = 2.2 lb) was accepted as the gold standard for prevention of gastric regurgitation in adults when applied in the standard or tonsillectomy position.[192] CP greater than 44 N prevents gastric regurgitation. When appropriate force is applied, the upper end of the esophagus is occluded and compressed against the C6

vertebra. In paralyzed intubated patients, lowering the CP to 40 N increased esophageal pressure to more than 38 mm Hg.[193] In a study using the double-lumen Salem sump tube in 20 women undergoing emergency cesarean delivery under general anesthesia,[194] the mean gastric pressure was 11 mm Hg (range, 4 to 19 mm Hg). It was predicted that 99% of women undergoing emergency cesarean delivery having a gastric pressure of 25 mm Hg were unlikely to have regurgitation of fluid. Evidence from a cadaver study showed that a CP of 30 N prevents regurgitation of esophageal fluid even with gastric pressure at 42 mm Hg. Anatomic studies suggest that a CP of 30 N is adequate and should reduce the risk of esophageal rupture.[137,193]

The CP necessary to provide an adequate occlusive effect in children of different age groups is debatable. No data are available to clarify this issue. An observational study using the bench model indicated that the mean cricoid force applied clinically to a 5-year-old child should be 22.4 to 25.1 N.[195]

a. HEAD AND NECK POSITION

Sellick made the original recommendation to use the tonsillectomy position, without a pillow, with CP applied at the C5 vertebra.[135] The rationale for the tonsillar position is that it increases the concavity of the cervical spine, stretches the esophagus, and prevents lateral displacement of the esophagus. Unfortunately, this mode of CP application often worsens the view at laryngoscopy.[196] The head position must be ideal for intubating with head extension on the neck, neck flexion, and a pillow beneath the occiput.[197]

b. TIMING OF CRICOID PRESSURE APPLICATION

The timing and amount of CP applied during induction of general anesthesia are important. The original recommendation was synchronous CP application; moderate pressure in an awake, conscious individual; and a gradual increase to a full force of 44 N immediately on loss of consciousness. Applying a full force of 44 N before induction in a conscious individual is detrimental; it produces significant discomfort, complete airway obstruction,[198] retching, and vomiting.[181] Vomiting with continued CP application can cause death from pulmonary aspiration or a ruptured esophagus.[199,200]

A cricoid yoke has been used to apply pressure in awake volunteers without considerable pain or coughing.[189] The accepted practice is to apply a lower CP (20 N) before induction of anesthesia and increase it to 30 N as the patient loses consciousness.[201]

Reluctance to use CP stems from faulty technique of its application and its effect on airway management, reported cases of pulmonary aspiration, and esophageal rupture. CP application causes anatomic distortion of the upper airway, making airway management more difficult. Most data were collected with a CP of 40 N. Studies show that a CP of 30 N applied in an upward and backward manner improves the laryngoscopic view during intubation.[201] Similarly, Randell and colleagues showed that CP,[202] modified to backward, upward, rightward pressure (BURP) on the thyroid cartilage, improved the view in 57 of 68 cases. The thyroid cartilage is the surface marking for the glottic opening, and application of BURP on the thyroid cartilage therefore improves the glottic view at laryngoscopy.[203]

c. SINGLE-HANDED CRICOID PRESSURE

For single-handed CP, the thumb and middle finger are placed on either side of the cricoid cartilage, and the index finger is placed above to prevent lateral movement of the cricoid.[135] The laryngoscopic view is better with the head in the Magill position and better with single-handed CP than with double-handed CP.[204]

Another single-handed method is to place the palm of the hand on the sternum, applying pressure with only the index and middle fingers.[205] This technique improved the laryngoscopic view of the glottis. In infants and children, the single-handed technique compressing the cricoid cartilage is performed with the little or middle finger while the same hand holds the face mask.[206]

CP should be applied with the left hand from the left side of the patient. This prevents interference with laryngoscopy, specifically when the laryngoscope blade is inserted from the right corner of the mouth.

d. DOUBLE-HANDED CRICOID PRESSURE

The bimanual or two-handed CP technique uses the single-handed technique in addition to using the assistant's right hand to provide counterpressure beneath the cervical vertebra for neck support. This maneuver provides support to the hyperextended arch of the vertebral column to maintain the efficacy of CP and to optimize the laryngoscopic view. Variations of this technique include placing the left hand behind the head and holding the extended head to maintain the Magill intubating position.[207]

e. CRICOID PRESSURE IN CLINICAL PRACTICE

In clinical practice, application of a predetermined CP can be sustained by the assistant for only a short period. Application of CP with a flexed arm can be sustained only for a mean time of 3.7 minutes at 40 N, with considerable onset of pain at 2.3 minutes. This limitation has important clinical implications in cases of failed tracheal intubation in full-stomach patients. Application of CP in clinical practice may interfere with airway management (i.e., tracheal intubation, face mask ventilation, and LMA placement), and failure to manage the airway appropriately is a more frequent cause of morbidity and mortality than pulmonary aspiration.[208]

VIII. MANAGEMENT OF THE DIFFICULT AIRWAY IN THE FULL-STOMACH PATIENT

Management of difficult RSIs in full-stomach patients is little studied. Airway catastrophes occur predominantly when airway difficulty is not recognized before anesthesia is administered.[209,210] Although airway difficulty should be anticipated in 90% of cases, a prospective study showed that only approximately 51% of difficult intubations were recognized and expected.[211] Difficult and

failed tracheal intubations occur more frequently during an emergency than during elective surgery, during nights than during days, and during weekends than during weekdays.[97,212,213] Unanticipated difficult intubations in full-stomach patients undergoing emergency surgery poses additional problems. There is no option for anesthesiologists to postpone surgery, and the risk of pulmonary aspiration of gastric contents is much greater.

In full-stomach patients, repeated attempts to intubate the trachea increase the risk of airway trauma, bleeding, and laryngeal edema, and failure to secure the airway can increase the incidence of pulmonary aspiration.[214] Hypoxia and death can result from failure to oxygenate the patient and ventilate the patient's lungs or from unrecognized intubation of the esophagus, neither of which is caused solely by failed tracheal intubation.[142]

Significant advances in airway management have been made in the past 2 decades. New airway devices and adjuncts to assist in the tracheal intubation of difficult airways are available. In most cases of difficult intubation, a partial view of the glottis is possible (i.e., grade III laryngoscopic view).[97,167,212] Of the many airway devices available to physicians in the United Kingdom and Canada, the Eschmann stylet (gum elastic bougie) is used to facilitate tracheal intubation in more than 95% of grade III laryngoscopic views.[215] Another commonly used device is the McCoy laryngoscope (CLM, Mercury Medical, Clearwater, FL), which can improve visualization of the larynx in up to 50% of cases with difficult laryngoscopic views.[216,217]

Additional levering laryngoscopes include the Flipper (Rusch, Research Triangle Park, NC) and the Heine Flex Tip (Heine USA, Dover, NH). These laryngoscopes were designed to provide greater flexibility and improved visualization of the larynx in patients with a difficult airway, smaller mouth opening, or restricted head and neck movement.[218]

A practical classification proposes subdividing the grade 3 Cormack-Lehane laryngoscopic view into two grades: grade 3A, in which the epiglottis is visible and can be elevated with the laryngoscope blade, and grade 3B, in which the epiglottis is visible but cannot be elevated.[219] This new classification is as sensitive and more specific than the Cormack-Lehane classification in predicting difficult tracheal intubation, but it is more sensitive and more specific in predicting easy tracheal intubation.[219]

A manikin-simulated difficult airway study showed that the Eschmann stylet and a fiberoptic stylet were effective in facilitating tracheal intubation in a simulated grade 3A Cormack-Lehane view, with success rates of 100% and 98%, respectively.[220] The mean times to successful intubation were similar between groups: 31 seconds for the Eschmann stylet and 29.2 seconds for the fiberoptic stylet.[220] However, in the simulated grade 3B Cormack-Lehane view, use of the fiberoptic stylet significantly improved the success rate (98% for the fiberoptic stylet and 9% for the Eschmann stylet) and reduced the mean time to successful tracheal intubation (31 seconds for the fiberoptic stylet and 45.6 seconds for the Eschmann stylet).[220]

A. Difficult Airway Management Using the Laryngeal Mask Airway

Before 1990, the choice of airway devices was limited to the face mask or the tracheal tube. The LMA (LMA North America, San Diego, CA) is one of the most significant and important airway devices introduced for airway management. Several supraglottic airway devices have been developed since then, including the Air-Q (Mercury Medical, Clearwater, FL); i-gel (Intersurgical Ltd., Berkshire, United Kingdom); Streamlined Liner of the Pharynx Airway (SLIPA, Curve Air Ltd., London, United Kingdom); and Ambu Aura Laryngeal Mask (Ballerup, Denmark). Second-generation supraglottic devices include the esophageal-tracheal Combitube (Tyco Healthcare, Mansfield, MA) and the King Laryngeal Tube Suction (LTS) and the King LTS disposable (LTS-D) (King Systems, Noblesville, IN).

Archie Brain, the inventor of the LMA, has continued to develop variations of the original device. These modifications include eight sizes of the original Classic Laryngeal Mask Airway (LMA Classic, LMA North America, Inc., San Diego, CA), the LMA Classic with a disposable connector to facilitate tracheal intubation (LMA Classic Excel), a single-use LMA (LMA Unique), a reinforced but flexible LMA (LMA Flexible), an LMA specifically designed for blind tracheal intubation (ILMA-Fastrach), an LMA fitted with an integral gastric access or venting port (LMA ProSeal), and its disposable version (LMA Supreme). The LMA is a recognized part of the ASA difficult airway algorithm. As a ventilatory device or intubating conduit, or both, the LMA fits into the difficult airway algorithm in several places.

1. Classic Laryngeal Mask Airway

The use of the LMA Classic is contraindicated in full-stomach patients and patients at high risk for pulmonary aspiration because of gastrointestinal pathology, obesity, GER, or emergency surgery. The main disadvantage of using the LMA Classic in patients with a full stomach or obstetric patients is an increased risk of gastric regurgitation and pulmonary aspiration. The LMA Classic design is such that even when correctly placed, its tip lies against the UES, and the device does not isolate the respiratory tract from the gastrointestinal tract. Because the esophagus is included in the rim of the LMA Classic, it does not protect the lungs from regurgitated gastric contents. Full-stomach and pregnant patients may be vulnerable to gastric regurgitation and pulmonary aspiration with the use of this device.[221]

Studies of gastric regurgitation and pulmonary aspiration rates associated with using these supraglottic devices have mainly focused on the LMA Classic. A meta-analysis of 547 publications suggested that the overall incidence of pulmonary aspiration associated with the LMA Classic is about 2 cases per 10,000 patients,[222] a figure corroborated by a large number of studies. This rate is comparable to that of outpatient anesthesia administered with a face mask and tracheal tube (Table 35-2).[53] Studies also have demonstrated that the use of the LMA Classic is associated with a reduction in barrier pressure at the LES.[223] In comparing the cuffed tracheal tube with the

LMA Classic during general anesthesia with positive-pressure ventilation, Valentine and colleagues (using a pH electrode placed in the midesophageal zone) determined that there were significantly more episodes of reflux among the LMA Classic patients.[224] In contrast, Agro and associates found no episodes of reflux with the use of LMA Classic in patients undergoing elective orthopedic surgery.[225] The association between GER and the LMA Classic is not clear. However, there is insufficient evidence to support the hypothesis that the reduction in lower esophageal pH is influenced directly by the pressure or the volume in the cuff of the LMA Classic.[226] Application of CP reduces LES pressure[30]; a similar reflux may occur because of the increased pharyngeal pressure exerted by the LMA Classic. There is controversy about the effect of the LMA Classic on LES tone, with some studies reporting a reduction in tone and others reporting no change.[223,227] However, it is accepted that UES function is relatively unimpaired by the LMA Classic. Some anesthesiologists believe that the LMA Classic is contraindicated in patients with a full stomach and in obstetric patients.

Despite the pulmonary aspiration risks with an LMA Classic (with or without CP) being the same as those encountered with a face mask,[222,228] particularly in patients with a full stomach, there are several case reports documenting the use of the LMA Classic after failed tracheal intubation attempts during emergency cesarean section. In these cases, the LMA Classic device provided a clear airway and was useful in rapidly providing oxygenation and relieving hypoxia. There were no reports of pulmonary aspiration.[222,229-233] In 1346 elective cesarean sections, the LMA Classic was used as an alternative to tracheal intubation to ventilate lungs. The tracheal tube was blindly inserted with minimal cardiovascular responses, and there was no incidence of pulmonary aspiration in 98% of cases.[234] In another study, the LMA Classic was used in 1067 patients undergoing elective cesarean sections.[98] After RSI with CP, the LMA Classic was inserted, and an effective airway was obtained in 1060 patients (99%). There were no episodes of pulmonary aspiration, hypoxia, laryngospasm, or gastric insufflation.[235]

The major benefit of using the LMA Classic after failed tracheal intubation attempts in a patient with a full stomach is that it serves as a rescue device and provides oxygenation.[236] However, because of the potential for gastric regurgitation and the risk of pulmonary aspiration, a choice must be made about whether to use the LMA Classic as a definitive airway or as a conduit for tracheal intubation. Technical problems associated with the LMA Classic include the less than ideal position of the device in relation to the glottic opening and downfolding of epiglottis in the LMA Classic aperture bars. The blind passage of a tracheal tube through the LMA Classic has an unacceptably low degree of success. Difficulties include catching the tracheal tube tip on the aperture bars or the anterior commissure because of the natural bend in a standard polyvinyl chloride tracheal tube and the natural bend where the tube exits the LMA. When CP was not applied, Heath and Allagain could intubate the trachea blindly through the LMA Classic in 72% of patients at first attempt and in most patients when time was not limited.[237] However, the blind technique of tracheal intubation through the LMA Classic often requires significant manipulation of the head and neck to accomplish the intubation. An Eschmann stylet can be used to aid tracheal intubation. A high success rate was obtained for patients in whom difficult intubation was not anticipated by inserting the Eschmann stylet with its angulated end pointing anteriorly until it passed through the grille of the LMA Classic and then rotating the Eschmann stylet by 180 degrees.[238] Failures, however, have been reported with this visually unassisted guided technique of endotracheal intubation through the LMA Classic.[239] Because of the potential problems, in an urgent situation, blind tracheal intubation through the LMA Classic may not be advisable. Fiberoptic-guided tracheal intubation through the LMA Classic has been shown to be the most reliable technique, which has a much higher success rate than other approaches (Fig. 35-2).[213-237]

If the LMA Classic is used as a definitive airway without the passage of a tracheal tube, timing of the removal of the device in a patient with a full stomach

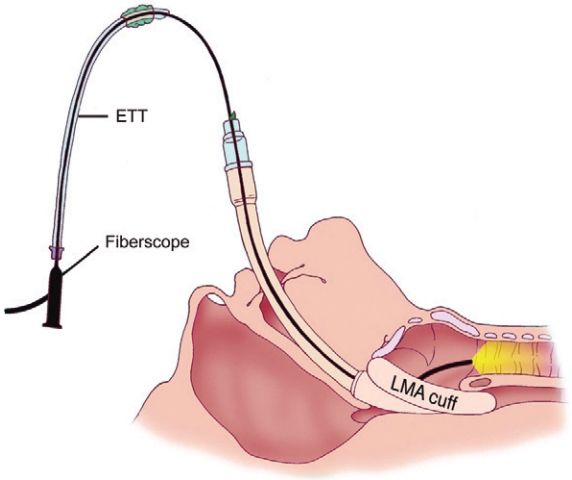

Figure 35-2 Fiberoptic-guided intubation. The laryngeal mask airway *(LMA)* is inserted and the cuff is inflated. The fiberscope is inserted through the LMA, through the vocal cords, and into the trachea. The endotracheal tube *(ETT)* is mounted on the fiberscope. The ETT is threaded over the flexible fiberoptic bronchoscope into the LMA shaft with the bevel pointed 90 degrees to the left; as it enters through the maximum aperture bars, it is rotated anteriorly. After it is located in the trachea, placement is confirmed by detection of end-tidal carbon dioxide. (Courtesy of Publications and Creative Services, Baylor College of Medicine, Houston, TX.)

becomes crucial. A randomized, controlled trial demonstrated that the pH in the lower esophagus was significantly higher in patients in whom the LMA Classic remained in situ until the end of the case, at which point the patient was able to follow commands. It is suggested that the LMA Classic should be removed only when the patient has fully regained consciousness at the end of the anesthetic.[240]

2. Fastrach Intubating Laryngeal Mask Airway

After attempts to intubate the trachea of patients with a full stomach have failed, an alternative to using the LMA is to use the Fastrach intubating laryngeal mask airway (ILMA-Fastrach). The ILMA-Fastrach is designed specifically to overcome the problems associated with blind tracheal intubation using the LMA Classic. The ILMA-Fastrach consists of a rigid, anatomically curved airway tube made of stainless steel with a standard 15-mm connector. The tube is wide enough to accommodate an 8.0-mm tracheal tube and short enough to ensure passage of the tracheal tube beyond the vocal cords.

The highest degree of success in intubating the trachea blindly through the ILMA-Fastrach can be achieved by using the special tracheal tube (Euromedical ILM Tracheal Tube, Euromedical, Sungai Petani, Kedah, Malaysia) supplied with the device. This silicon tube is soft tipped, straight, wire reinforced, and cuffed. Ferson and colleagues reported their clinical experience with the ILMA in 254 patients with difficult airways,[241] including patients with Cormack-Lehane grade 4 views; patients with immobilized cervical spines; those with airways distorted by tumors, surgery, or radiation therapy; and those wearing stereotactic frames. The device was particularly useful in patients undergoing emergency or elective surgery for whom tracheal intubation with a rigid laryngoscope had failed.[242-244] Similar multicenter trials and reports have described the use of an ILMA-Fastrach in patients with difficult airways and failed tracheal intubation (including emergency cases at risk for aspiration).[245-251] The ILMA-Fastrach has been used as a rescue device by emergency room physicians after failed RSI.[252] Our institution has reported cases in which the device proved to be a life-saving rescue device after failed tracheal intubation during emergency cesarean section.[253,254]

3. ProSeal Laryngeal Mask Airway

The ProSeal laryngeal mask airway (PLMA) is a complex and potentially useful device for patients particularly at risk for gastric regurgitation and pulmonary aspiration. Some anesthesiologists refuse to use the LMA Classic because of concerns regarding gastric distention with positive-pressure ventilation and the potential for pulmonary aspiration. To address these issues, the primary goal of designing the PLMA was to construct a device with improved ventilatory characteristics that also offered protection against gastric insufflation and regurgitation. The principal feature of the PLMA is a double mask forming two end-to-end junctions: one with the respiratory tract and the other with the gastrointestinal tract. In contrast, the original LMA Classic forms a single end-to-end junction with the respiratory tract. The PLMA has a modified posterior cuff that provides high seal pressure—up to 30 cm H_2O—providing a tighter seal against the glottic opening with no increase in mucosal pressure. The PLMA also offers a better airway seal at a given pressure than the LMA Classic.[255] When properly positioned, the distal orifice of the PLMA lies against the UES and separates the esophagus and stomach from the glottic area. It has an integral gastric access and venting port that allows passage of a 14-F gastric tube, allowing suctioning of gastric contents.

In awake volunteers, neither the PLMA nor the LMA Classic appeared to interfere with UES or LES tone.[256] No manometric studies have been performed to assess LES function in anesthetized patients, but FOB inspection of the PLMA drainage tube showed that the UES was completely open in 3% to 7% of paralyzed patients and in 9% of nonparalyzed patients.[257,258] This effect, which may have implications for the frequency of regurgitation into the drainage tube, may be mechanical, a local reflex, or result from direct exposure to atmosphere through the drainage tube.

The PLMA is easy to insert and is a more effective ventilatory device when using positive-pressure ventilation. A meta-analysis using Fisher's method has shown that the PLMA forms a more effective seal with the respiratory tract than the LMA Classic.[259] The efficacy of the seal with the gastrointestinal tract has been determined by measuring the airway pressure at which air leaks into the drainage tube in anesthetized adults. Depending on cuff volume,[260] the efficacy of the seal for air is at least 27 to 29 cm H_2O,[255,261] and for fluid, the efficacy is 19 to 73 cm H_2O, with a similar seal mechanism for the respiratory tract.

The drainage tube provides a conduit to the gastrointestinal tract. It is also possible to insert a gastric balloon tube to further reduce the risk of pulmonary aspiration.[141] The success rate for gastric tube insertion is 88% to 100%.[258,261] Inserting a gastric tube has several advantages. The tube allows removal of gas or fluid from the stomach, the process of insertion provides information about the position or patency of the drainage tube, and the tube can function as a guide for PLMA reinsertion if accidental displacement occurs.[262]

The incidence of gastric insufflation seems to be low, even at high airway pressures.[255,263] Gastric insufflation has been detected in only 1 of 572 patients (data from seven studies).[255,257,258,261,263-265] Gastric insufflation is less common with the PLMA than with the LMA Classic when high positive-pressure ventilation is used.[255]

There are at least two reports of the PLMA being used in the difficult airway scenario. Keller and colleagues,[263] in a prospective study of morbidly obese patients (i.e., patients at risk for gastric regurgitation and pulmonary aspiration), found that the PLMA was successful in 11 of 11 patients who were difficult or impossible to intubate with a laryngoscope. However, there are two case reports of pulmonary aspiration of gastric contents using the PLMA. In the first patient, brownish fluid was seen ejecting from the drainage tube of PLMA after administration of reversal agents at the end of surgery. There were clinical signs of pulmonary aspiration without any radiologic changes.[266] In the second patient, foldover malposition of the distal cuff against the posterior oropharyngeal wall

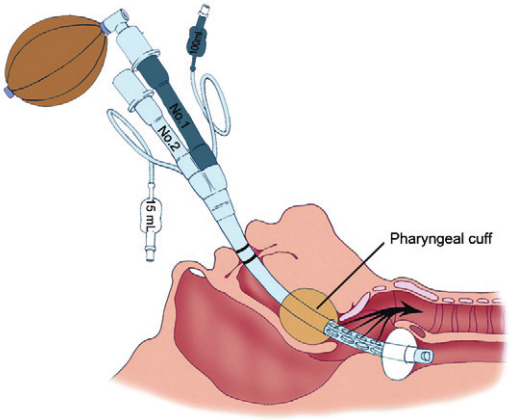

Figure 35-3 Esophageal-tracheal Combitube (ETC) in the esophagus. The ETC tube is advanced until the black rings are at the level of the teeth or alveolar ridges. The distal cuff is inflated with 15 mL of air to seal the esophagus, and the proximal cuff is inflated with 85 mL (37-F ETC) to 100 mL (41-F ETC) of air; this secures the tube in the correct position and occludes the nasal and oral passages. Ventilation is attempted through lumen no. 1. (Courtesy of Publications and Creative Services, Baylor College of Medicine, Houston, TX.)

(confirmed later by FOB) during insertion was cited as the reason for pulmonary aspiration.[267]

In two reports, the PLMA was used successfully in obstetric patients after failed tracheal intubation.[268] Keller and colleagues showed that the PLMA was a rescue device after failed tracheal intubation in an obstetric patient with hemolysis, elevated liver enzymes, and low platelet count (HELLP syndrome) and proved to be useful for postoperative respiratory support for 8 hours until the platelet count had increased and the patient was hemodynamically stable.[268]

Emergence characteristics for the PLMA seem to be similar to those for the LMA Classic.[257] Practical considerations include suctioning the gastric tube and reversing any residual neuromuscular blockade before beginning of emergence. As with the LMA Classic, the patient should not be disturbed, and the PLMA should be removed only when the patient is conscious and obeys commands. When the patient is fully awake and responsive to verbal commands, the device is removed with the cuff inflated along with the gastric tube on continuous suction to prevent any oropharyngeal secretions from entering the laryngopharynx.

B. Esophageal-Tracheal Combitube in the Full-Stomach Patient

The Combitube, developed by Frass and colleagues, is a disposable, polyvinyl chloride, double-lumen airway device that combines the features of an esophageal obturator airway and a tracheal tube.[269] It functions well in both the esophageal and tracheal positions.[270] Using the Lipp maneuver,[271] the Combitube is inserted blindly. Insertion usually results in esophageal placement (Fig. 35-3), and ventilation is initiated through the gastric lumen.[272] With both cuffs inflated, ventilation through the proximal lumen allows airflow through eight oval fenestrations from the hypopharynx into the trachea. An effective seal of the latex oropharyngeal cuff prevents the escape of air from the mouth and nose. Instead, air is forced into the trachea and lungs. If the Combitube is placed in the esophagus, gastric fluids can be aspirated through the gastric lumen. If breath sounds are not heard, the Combitube has more than likely been placed in the trachea (Fig. 35-4). Without removing the Combitube, ventilation is switched to the tracheoesophageal lumen and confirmed with auscultation and capnography.

Unsatisfactory ventilation through either lumen indicates that the Combitube is too far advanced into the esophagus to produce airway obstruction by the oropharyngeal cuff (Fig. 35-5A). In this situation, the distal esophageal cuff and the oropharyngeal cuff are deflated, and the Combitube is withdrawn approximately 2 to 3 cm (see Fig. 35-5B). The esophageal cuff and the oropharyngeal cuff are then reinflated, and pulmonary ventilation is resumed.[119]

The Combitube serves as a rescue device for establishing an airway in the "cannot intubate, can ventilate" and "cannot intubate, cannot ventilate" situations, and it is particularly useful in the full-stomach patient. It is inserted blindly or under direct laryngoscopy,[273] can secure the airway easily and rapidly, and requires minimal preparation (i.e., can be properly used with relatively little formal training).[60] Combitube placement by inexperienced personnel (e.g., ICU nurses) under medical supervision was found to be as safe and successful in providing effective oxygenation and ventilation of the lungs as tracheal intubation performed by ICU physicians during cardiopulmonary resuscitation.[274] As a rescue device, it is helpful in securing the airway if vocal cord visualization is compromised or if oropharyngeal bleeding has occurred.

The Combitube prevents pulmonary aspiration during cardiopulmonary resuscitation,[270] especially when protective airway reflexes are absent, protecting the airway from pulmonary aspiration of gastric contents.[275] Frass and coworkers found that the tracheoesophageal lumen served as a conduit for decompression of gastric contents

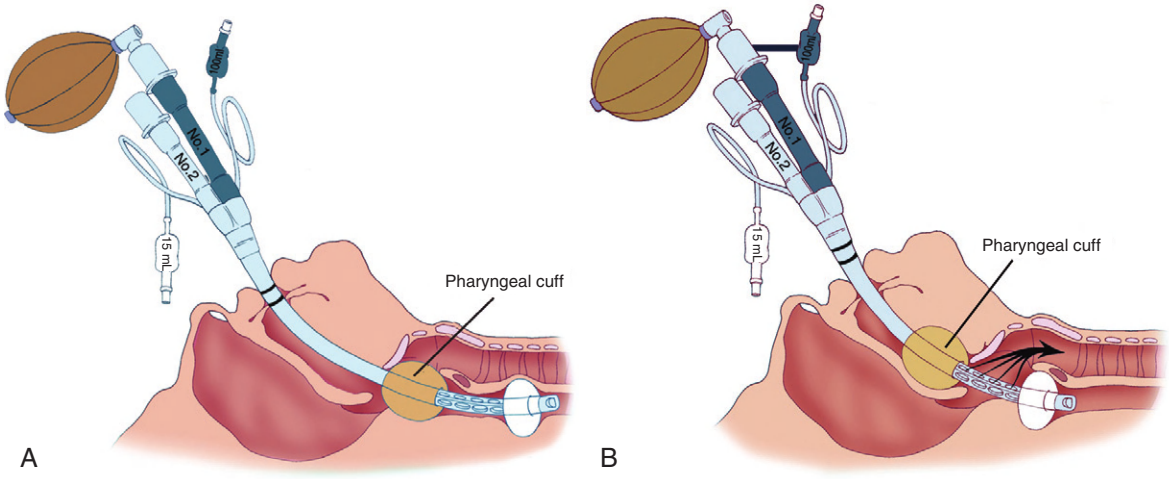

Figure 35-5 Placement of the esophageal-tracheal Combitube (ETC). **A,** Excessive insertion depth of the ETC causes obstruction of the glottic opening, and ventilation is impossible. **B,** Correct positioning is achieved by readjustment of the ETC, which is pulled back 2 to 3 cm (indicated by the two black rings), and ventilation through lumen no. 1 allows the passage of gas from the side orifices into the trachea *(arrow).* (Courtesy of Publications and Creative Services, Baylor College of Medicine, Houston, TX.)

and allowed gastric suctioning.[270] Urtubia and associates administered methylene blue orally to 25 patients before induction of anesthesia and found no evidence of methylene blue in the hypopharynx during laryngoscopy before Combitube placement or after its removal.[275] Hagberg and colleagues determined that the incidence of pulmonary aspiration is comparable for the Combitube and the LMA.[276]

C. Esophageal-Tracheal Combitube for Prevention of Pulmonary Aspiration

Many case reports attest to the safety of the Combitube and the use of the tracheoesophageal lumen as an effective decompression channel for regurgitated gastric contents, which prevents pulmonary aspiration during cardiopulmonary resuscitation or during anesthesia.[276-278] The 10-F orogastric tube, available in the prepackaged Combitube kit, can be readily used for esophageal and gastric suctioning. The Combitube has been used successfully as a primary airway device in seven obstetric patients (R.M. Urtubia, personal communication, 2001), two of whom were reported.[279] They did not have a history of difficult tracheal intubation, and they underwent general anesthesia for emergency cesarean section. The Combitube was used as the initial airway device, and it allowed adequate oxygenation, ventilation, and protection from pulmonary aspiration of gastric contents.[279] Wissler reported the use of the Combitube under direct laryngoscopy during obstetric anesthesia.[280] The Combitube has become his primary choice for managing an anesthetized parturient whose trachea cannot be intubated or whose lungs cannot be mask ventilated while applying CP.[280]

If tracheal intubation becomes necessary, it can be achieved using the FOB with the Combitube in place. The fiberscope is passed alongside the Combitube, the oropharyngeal balloon is partially deflated, and tracheal intubation is achieved visually and is followed by removal of the Combitube without interruption of airway control, oxygenation, or ventilation (Fig. 35-6). This technique has been used for spontaneously breathing and mechanically ventilated patients.[44,281] One of the authors (AW) managed a morbidly obese, 550-pound woman with obstructive sleep apnea, who had been in the medical intensive care unit (MICU) with a Combitube in situ. Tracheal intubation was requested by the MICU team to help with weaning the patient from the ventilator. Using the hybrid technique of direct laryngoscopy and fiberoptic bronchoscopy, tracheal intubation was successfully accomplished, and was followed by Combitube removal.

Video film recordings of 25 patients undergoing laparoscopic cholecystectomy under general anesthesia and mechanical ventilation using the Combitube revealed no gastric insufflation at the beginning or end of surgery.[282]

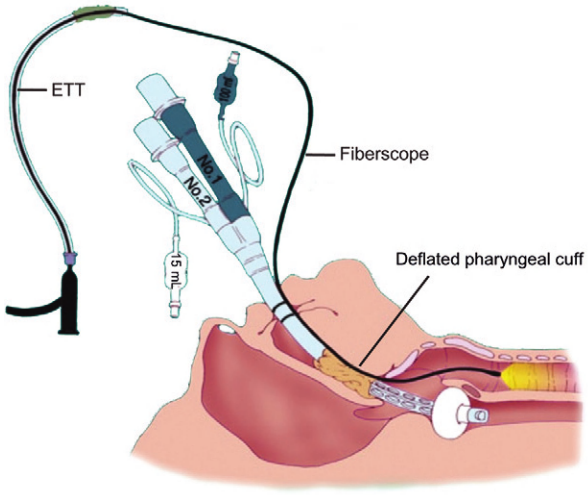

Figure 35-6 Tracheal intubation using a fiberscope can be achieved with the esophageal-tracheal Combitube (ETC) in place. The fiberscope is passed alongside the ETC with the pharyngeal cuff partially deflated. After tracheal intubation is established, the ETC is removed without interruption of airway control, oxygenation, or ventilation. *ETT,* Endotracheal tube. (Courtesy of Publications and Creative Services, Baylor College of Medicine, Houston, TX.)

A large, retrospective survey of 12,020 cases of nontraumatic cardiac arrest in Japan revealed 1594 instances of Combitube use without any evidence of pulmonary aspiration of gastric contents.[277]

The Combitube has several advantages compared with the LMA:

1. Preparation time is minimal.
2. The device is ideal for full-stomach patients and pregnant patients (especially after failed tracheal intubation), for whom oxygenation, avoidance of arterial desaturation, and pulmonary aspiration are important factors.
3. Lubrication is not required.
4. No special method is required for cuff inflation or deflation.

The few case reports of complications related to the use of the Combitube primarily involve the original version (41 F) of the device and are attributed to its stiffer, rather large, and potentially traumatic design.[283] These complications have included esophageal rupture, subcutaneous emphysema, piriform sinus rupture, pneumomediastinum, and pneumoperitoneum.[284,285] Common factors in these cases included difficult ambient conditions in the field or prehospital environment, multiple attempts to insert the device, resistance with insertion, and the use of excessive force.[286]

Several recommendations help to minimize the complications and to enhance the rate of successful placement of the Combitube:

1. Use the smaller Combitube SA universally for patients between 4 and 6 ft tall.
2. Briefly dip the device in warm saline before use.
3. Use the Lipp maneuver (i.e., holding the two ends of the Combitube together to bend it into a semicircle for a few seconds before insertion) during placement of the device.
4. Place the device under direct laryngoscopy.[273]
5. Use a gentle technique to reduce the hemodynamic response from stimulation of the proprioceptors at the base of the tongue.[283]
6. Inflate the oropharyngeal balloon slowly to the minimum volume necessary for an airtight seal to reduce soft tissue injury.[283]
7. Employ a reliable technique, using direct laryngoscopy as an aid to Combitube placement if necessary.[273]

Although there are no large, randomized studies that indicate the relative safety of the Combitube in preventing pulmonary aspiration of gastric contents, these recommendations are useful and appealing to health care personnel managing patients who have a full stomach, with or without a difficult airway.

D. King Laryngeal Tube Suction Airways in the Full-Stomach Patient

The King LTS and its disposable version, the King LTS-D, are second-generation supraglottic airways that are modifications of the Combitube. They are slightly shorter, softer, and smaller than the Combitube and may have a lower complication profile.[287] These devices are placed using gentle, blind insertion along the surface of the tongue from the mouth into the upper esophagus (see Fig. 37-7A in Chapter 37) . They have twin lumens, one for ventilation and the other for gastric suctioning with an 18-F orogastric tube and passive venting, thereby isolating the trachea from the esophagus (see Fig. 37-7B in Chapter 37). In contrast to the Combitube, they have a single pilot balloon for the proximal oropharyngeal nonlatex cuff and the distal esophageal cuff, preventing confusion regarding the choice of pilot balloon required for a particular cuff. They are easily placed,[288] use low-pressure cuffs,[289] allow exchange for a tracheal tube by passing an FOB preloaded with an Aintree airway exchange catheter[290] (see Fig. 37-7C in Chapter 37), and have been used during controlled ventilation and during spontaneous respiration.[288,291] Based on the literature, The device has potential for successful use in the full-stomach patient. A study comparing the LMA Classic and the King LT in 22 patients showed that the mean leak pressure was significantly higher for the King LT and that gastric insufflation was not observed with King LT.[289] A second study enrolling 30 patients showed that a ventilatory seal of 40 cm H_2O was easily obtained without gastric insufflation.[287] A case report of an obstetric patient demonstrated the successful use of King LTS in providing access for oxygenation and ventilation after failed tracheal intubation during an emergency cesarean section.[292]

IX. EXTUBATION

When an awake intubation or RSI is indicated to prevent pulmonary aspiration, an awake tracheal extubation should be considered to prevent airway complications and to enhance patient safety during emergence from general anesthesia, at extubation, and in the postanesthesia care unit.[293] The patient should be awake, conscious, and appropriately responding to commands before extubation. Daley and colleagues performed a survey of tracheal extubation of adult surgical patients who were still deeply anesthetized.[294] Most respondents in the survey, who otherwise used the technique for extubation, considered the risk of pulmonary aspiration a contraindication to deep tracheal extubation.

X. MANAGEMENT OF PULMONARY ASPIRATION

When a fully conscious person aspirates foreign substances into the tracheobronchial tree, a brief but effective bout of coughing can clear the aspirate. Patients with observed pulmonary aspiration under sedation should have the mouth and pharynx suctioned immediately so that the patency of the upper airway is restored. Suctioning solid or liquid material allows recovery of the aspirated material so that it is not absorbed by the lungs, and it stimulates coughing to further expel the aspirate. After asphyxiation has been averted, bronchoscopy can be performed to clear the obstructing material from the

lower airways. Bronchoscopy should not be routinely performed; it should be reserved for patients who have aspirated sufficient solid material to cause significant airway obstruction.[293] Damage to the mucosa of the tracheobronchial tree occurs within seconds, but the bronchial secretions neutralize the aspirated acid within minutes.[295] Attempts to neutralize the acid aspirate with saline or bicarbonate lavage have proved to be futile and may increase the damage.[296]

The treatment of pulmonary aspiration of gastric contents is aimed at restoring pulmonary function to normal as soon as possible. If the patient is awake and able to maintain a reasonable arterial oxygen tension (Pa_{O_2}), a conservative approach is to provide supplemental oxygen through a nasal cannula or a face mask. The inspired oxygen concentration (F_{IO_2}) can be increased to maintain Pa_{O_2} at approximately 60 to 70 mm Hg. This may suffice in a patient with a mild condition, but more aggressive therapy is indicated if aspiration is more severe. Severe bronchospasm may be treated by aminophylline infusion or the inhalation of a β-adrenergic bronchodilator.[296,297]

When severe pulmonary aspiration is suspected, early ventilatory support is the mainstay of treatment. Early continuous positive airway pressure (CPAP) is indicated in awake and alert patients who do not respond to a face mask. CPAP up to 12 to 14 mm Hg can be administered through a tight-fitting mask. If higher levels are required, mechanical ventilation should be considered. The level of CPAP can be reduced as the patient improves, but it should not be completely withdrawn before the alveoli can maintain stability. A high F_{IO_2} level can be used initially but should be decreased as soon as possible.[298]

If the patient is obtunded, a tracheal tube should be placed and mechanical ventilation initiated. Positive end-expiratory pressure (PEEP) should be applied, and F_{IO_2} should be decreased as soon as possible while adequate oxygenation is maintained. PEEP is commonly used to elevate functional residual capacity and prevent atelectasis resulting from poor ventilatory efforts.[297] It also improves the ventilation-perfusion ($\dot{V}/\dot{Q}$) ratio and allows the use of less toxic levels of oxygen to be administered, giving the lungs a chance to recover.[295] Caution should be exercised when using PEEP because high levels can worsen pulmonary damage by causing increased transudation of fluid through injured capillary beds.[299] Cereda and coworkers investigated the effect of PEEP in patients with acute lung injury and found that a PEEP of at least 15 cm H_2O was needed to prevent a decay in the respiratory system compliance.[300]

Despite these measures, if hypoxemia persists along with bilateral lung infiltrates and poor lung compliance, management should be similar to that for the acute respiratory distress syndrome (ARDS). A large, multicenter, randomized trial sponsored by the National Institutes of Health compared ventilation with lower versus traditional tidal volumes in patients with ARDS.[301] Smaller tidal volumes (6 mL/kg predicted body weight) and hypoventilation with permissive hypercapnia were associated with a 10% reduction in mortality, along with a shorter period using mechanical ventilation. The lower tidal volume ventilation approach protected the lungs from excessive stretch, improving several important clinical indicators of outcome in patients with ARDS.[301] An alveolar recruitment maneuver using a CPAP of 40 cm H_2O for 40 seconds improved oxygenation in patients with early ARDS who did not have impairment of the chest wall.[302] A recruitment maneuver with a smaller tidal volume was associated with a survival rate of 62%, compared with a rate of 29% when using conventional ventilation without the recruitment maneuver.[303]

Use of prophylactic antibiotics is not recommended.[304] Antibiotics alter the normal flora of the respiratory tract, which predisposes the susceptible patient to secondary infection with resistant organisms. Mitsushima and colleagues demonstrated that acid aspiration–induced epithelial injury led to subsequent bacterial infection in mice.[305] Approximately 20% to 30% of patients who manifest initial gastric content aspiration eventually develop a secondary infection.[202] Antibiotics should be reserved for patients who show signs of clinical infection and for patients who have aspirated grossly contaminated material into their lungs.

Wolfe and coworkers found that pneumonia resulting from gram-negative bacteria was more common after pulmonary aspiration among patients treated with corticosteroids than those who were not treated.[306] Corticosteroids interfered with the healing of granulomatous lesions in rabbit models.[307] The consensus appears to be that corticosteroids play no role in the treatment of aspiration pneumonitis.[308]

XI. CONCLUSIONS

Anesthetic intervention in patients with a full stomach presents the anesthesiologist with three challenges: prevention of gastric regurgitation, prevention of pulmonary aspiration, and appropriate airway management. Large surveys of pulmonary aspiration in general surgical patients found a low incidence of pulmonary aspiration of gastric contents and only a slightly greater risk among obstetric and pediatric patients. The resulting morbidity is also low, and death is rare. Changes in anesthetic practice and training probably have contributed to the decline in this dreaded complication. Preoperative fasting was introduced to reduce the risk and severity of aspiration pneumonitis. Adequate time (6 hours) must be allowed before surgery for solid foods to be emptied, but the evidence supports a reduction in the preoperative fluid fast for pediatric patients and allowance of unlimited clear fluids until 2 hours before any scheduled surgery. The routine preoperative use of multiple pharmacologic agents in patients who have no apparent risk for pulmonary aspiration is not recommended. Meticulous attention to airway management of patients at risk for pulmonary aspiration is crucial. RSI and CP, although accepted in routine practice, have never had scientific validation. Many patients at risk for pulmonary aspiration because of pregnancy, obesity, extremes of age, or comorbidities are likely to desaturate more rapidly during prolonged periods of apnea associated with difficult tracheal intubation during RSI. Awake tracheal intubation and being prepared to deal with difficult or

failed tracheal intubation in patients with a full stomach are essential to the successful management of these patients.

XII. CLINICAL PEARLS

- The incidence of pulmonary aspiration in the general surgical population is low, but it is slightly increased among obstetric, pediatric, and trauma patients.
- Recommendations for preoperative fasting times are 2 hours for clear liquids and 6 hours for solids.
- Preoperative ultrasonography of the gastric antrum may be used to screen patients at risk for perioperative pulmonary aspiration of regurgitant gastric contents.
- Routine preoperative use of gastrointestinal stimulants, H_2-receptor antagonists, and proton pump inhibitors (PPIs) is not recommended in patients with no increased risk of pulmonary aspiration.
- Meticulous attention to airway management during induction, through emergence, and after extubation is crucial for patients at risk for pulmonary aspiration.
- Awake tracheal intubation and dealing with a difficult or failed airway in a patient with a full stomach requires expertise in advanced airway management.
- Airway management skills should be advanced by participating in workshops and by frequently using them in routine clinical practice.

Chapter 36

The Difficult Pediatric Airway

RANU R. JAIN | MARY F. RABB

I. Introduction

II. Anatomy of the Pediatric Airway
- A. Larynx
- B. Epiglottis
- C. Subglottis

III. Evaluation of the Pediatric Airway
- A. Diagnostic Evaluation

IV. Classification of the Difficult Pediatric Airway

V. Pediatric Airway Equipment
- A. Face Mask
- B. Oropharyngeal Airway
- C. Nasopharyngeal Airway
- D. Endotracheal Tube
- E. Endotracheal Tube Exchangers
- F. Laryngoscopes
  1. Straight vs. Curved Blades
  2. Oxyscope
  3. Anterior Commissure Laryngoscope
  4. Bullard Laryngoscope
  5. Angulated Video-Intubation Laryngoscope
  6. Truview Laryngoscope
  7. GlideScope Video Laryngoscope
  8. Airtraq Optical Laryngoscope

  1. Lighted Stylets
  2. Optical Stylets
  3. Video-Optical Intubation Stylet
- H. Laryngeal Mask Airways
  1. LMA Family
  2. Air-Q Intubating Laryngeal Airway
- I. Rigid Ventilating Bronchoscope

VI. Induction Technique

VII. Airway Management Techniques
- A. Techniques for Ventilation
- B. Techniques for Intubation
  1. Direct Laryngoscopy
  2. Blind Intubation Technique
  3. Fiberoptic Laryngoscopy
  4. Bullard Laryngoscope
  5. Dental Mirror–Assisted Laryngoscopy
  6. Retrograde Intubation
  7. Emergency Access

VIII. Complications of Airway Management

IX. Airway Diseases and Implications
- A. Head Anomalies
  1. Airway Implications
  2. Specific Anomalies
- B. Facial Anomalies: Maxillary and Mandibular Disease
  1. Tumors
  2. Congenital Hypoplasia
  3. Inflammatory Disease
- C. Mouth and Tongue Anomalies
  1. Microstomia
  2. Diseases of the Tongue
- D. Nasal and Palatal Anomalies
  1. Choanal Atresia
  2. Nasal Masses
  3. Palatal Anomalies
  4. Adenotonsillar Disease
  5. Obstructive Sleep Apnea
  6. Retropharyngeal and Parapharyngeal Abscesses
  7. Pharyngeal Bullae or Scarring
- E. Laryngeal Anomalies
  1. Laryngomalacia
  2. Epiglottitis
  3. Congenital Glottic Lesions
  4. Recurrent Respiratory Papillomatosis
  5. Laryngeal Granulomas
  6. Congenital and Acquired Subglottic Disease
- F. Tracheobronchial Anomalies
  1. Tracheomalacia
  2. Croup
  3. Bacterial Tracheitis
  4. Mediastinal Masses
  5. Vascular Malformations
  6. Foreign Body Aspiration
  7. Other Tracheal Disease
- G. Cervical Spine Anomalies
  1. Limited Cervical Spine Mobility
  2. Congenital Cervical Spine Instability
  3. Acquired Cervical Spine Instability

X. Pediatric Trauma

XI. Extubation of the Difficult Airway

XII. Conclusions

XIII. Clinical Pearls

I. INTRODUCTION

One of the most challenging aspects facing anesthesiologists is maintaining the technical skills that are necessary for the management of the difficult airway (DA). The American Society of Anesthesiologists (ASA) guidelines define a *difficult airway* as the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with face mask ventilation of the upper airway, difficulty with endotracheal intubation, or both.[1] Recent reports demonstrate how important skilled airway management is to the practice of pediatric anesthesia. Data from the ASA Pediatric Closed Claims Data Base demonstrate a greater frequency of adverse respiratory events in the pediatric population.[2] In the pediatric closed claims analysis, respiratory events accounted for 43% of all adverse events, most frequently related to inadequate ventilation (20%). Esophageal intubation, airway obstruction, and *difficult intubation* (DI) combined accounted for 14% of the remaining adverse respiratory events. In the Pediatric Perioperative Cardiac Arrest (POCA) registry, 20% of all cardiac arrests were attributed to the respiratory system.[3] Airway obstruction and DI were responsible for 27% and 13% of these events, respectively. Incidence of difficult mask ventilation in nonobese children is 2.1%. Most of the patients who experience arrests from airway obstruction or DI have an underlying disease or syndrome.

In addition, infants and small children display anatomic differences compared with adults. Knowledge of these differences, as well as congenital syndromes and different disease states, is required for management of the DA. Airway management in the pediatric patient may require general anesthesia before intubation attempts, which might not be a primary approach in a cooperative adult patient.

II. ANATOMY OF THE PEDIATRIC AIRWAY

The pediatric airway, particularly in infants, is different from the adult airway. Understanding these differences is important when managing the pediatric airway. Following is a brief review of the anatomy of the normal pediatric airway.[4-7]

A. Larynx

The larynx is situated more cephalad at the third and fourth cervical vertebrae (C3-C4) level in the infant and migrates to the adult C5 level by 6 years.[6] Because the infant's larynx is more rostral (higher), the tongue is located closer to the palate and more easily apposes the palate. As a result, airway obstruction may occur during induction or emergence from anesthesia. A common misnomer is that the infant's larynx is more "anterior" when it is really more "rostral" or "superior" in the neck, compared with the adult larynx. In syndromes associated with mandibular hypoplasia, such as Pierre Robin, the larynx is actually positioned more posteriorly than normal. This results in a greater acute angulation between the laryngeal inlet and the base of the tongue. In this circumstance, direct visualization of the glottis may be difficult or impossible. Because of the cephalad position of the larynx and the large occiput, the "sniffing" position does not assist in visualization of the pediatric larynx.[4,7] Elevating the head only moves the larynx into a more anterior position. Infants should be positioned with the head and shoulders on a flat surface with the head in a neutral position and the neck neither flexed nor extended.[5]

B. Epiglottis

The infant epiglottis is long, stiff, and often described as Ω or U shaped.[6] It projects posteriorly above the glottis at a 45-degree angle. Because the epiglottis is more obliquely angled, visualization of the vocal cords may be difficult during direct laryngoscopy. It may be necessary to lift the tip of the epiglottis with a laryngoscope blade to visualize the vocal cords. Straight laryngoscope blades are often preferred for this reason. If the patient is not paralyzed, use of a Macintosh blade is less stimulating because it is not necessary to lift the epiglottis.

C. Subglottis

The cricoid cartilage is the narrowest portion of the infant's airway, about 5 mm in diameter, compared with the vocal cords of the adult airway.[6] The infant's larynx is funnel shaped with a narrow cricoid cartilage, whereas the adult airway is cylindrical. Tight-fitting endotracheal tubes that compress the mucosa at this level may cause edema and increase resistance to flow. Resistance to flow is inversely proportional to the radius of the lumen to the fourth power (r^4). One millimeter (1 mm) of edema can reduce the cross-sectional area of the infant trachea by 75%, versus 44% in the adult trachea.

III. EVALUATION OF THE PEDIATRIC AIRWAY

No completed studies have evaluated the predictors of DI in children. Physical examination to predict the potentially difficult airway should be guided from the knowledge of normal anatomy and the syndromes associated with the DA.

The evaluation of the pediatric airway should begin with a history and physical examination of the head and neck. The examinations mostly involve subjective experience, and consistent evaluation criteria should improve the ability to predict the DA. Clues to a potentially difficult airway include snoring, noisy breathing, difficulty breathing with feeding or an upper respiratory tract infection, and recurrent croup. Review of previous anesthesia records should be performed if available. If a DA is encountered, documentation of events and the ability to mask-ventilate is helpful for future caregivers. A prior uneventful anesthesia does not guarantee success the next time.[4,7]

Knowledge of syndromes that may adversely affect the airway is crucial to the management of the difficult pediatric airway. The presence of one anomaly mandates a search for others. A common feature in patients with many of these syndromes is *micrognathia*. Micrognathia

creates more difficulty with displacement of the tongue during direct laryngoscopy, thus increasing the chance that the glottis will be difficult to visualize.[4,7] The ability to intubate often changes as the child grows. Intubation often becomes easier with syndromes associated with micrognathia (e.g., Pierre Robin) as the patient ages. In mucopolysaccharide disorders or abnormalities involving the cervical spine (e.g., Klippel-Feil syndrome), intubation may become more difficult as the child ages.[5]

Abnormalities of the ear or the presence of ear tags has been suggested as an indicator of DI.[5] In one study, *bilateral microtia* was associated with an increased incidence of DI (42%, vs. 2% in unilateral microtia). Mandibular hypoplasia was associated with bilateral microtia 10 times more than with unilateral microtia (50% vs. 5%), thus allowing bilateral microtia to be used as an indirect predictor of DI.[8]

Physical examination must focus on the head, neck, and cervical spine. Many evaluations used to predict DA in adults have not been extrapolated to the pediatric population. Cooperation of the patient is necessary for precise evaluation. In the young or uncooperative child, appropriate evaluation is limited. Preliminary data indicate that the Mallampati classification may be an insensitive predictor of DI in the pediatric population.[9] Pediatric anesthesiologists are at a disadvantage because they are anesthetizing patients with less objective airway information available. This underscores the need for a skilled approach to the difficult pediatric airway.

Evaluations should focus on the size and shape of the mandible, size of the mouth and tongue, absence or prominence of teeth, presence of loose teeth, and the neck length and range of motion. Berry[10] suggests that the appropriate thyromental distance in infants is one finger breadth (1.5 cm). Lateral examinations of the head and neck may provide clues to the presence of micrognathia. Mandibular enlargement has also been identified as a risk factor for DI.

Cherubism is a childhood disease consisting of painless mandibular enlargement with or without maxillary involvement that progresses rapidly in early childhood and then regresses during puberty. In cherubism, the potential displacement space is encroached on by mandibular enlargement.[11] Palpation of the soft tissue of the potential displacement area may reveal the problem.

A. Diagnostic Evaluation

Magnetic resonance imaging (MRI) and computed tomography (CT) may be extremely helpful in the evaluation of airway pathology. Flexible fiberoptic endoscopy may be of benefit before intubation when visualization of vocal cords is thought to be difficult or when airway pathology is suspected. In patients with unilateral hemifacial microsomia, radiographic classification of the mandibular anatomy can help predict ease of intubation.[12]

Radiographic evaluation of patients with airway obstruction may be obtained in patients who present to the emergency room only if they are not in respiratory distress. Radiographs should be obtained in the upright position because obstruction may worsen in the supine position.[13] In this situation, it is mandatory that a clinician skilled in airway management and capable of managing a difficult pediatric airway accompany the patient along with the appropriate equipment.

Radiographs have high sensitivity (>86%) for the diagnosis of airway foreign body, exudative tracheitis, and innominate artery compression. For laryngomalacia and tracheomalacia, radiography has much lower sensitivity (5% and 62%, respectively).[13] Radiologic evaluation should not take precedence over airway control in patients with a compromised airway. Other physicians, especially the otolaryngologist, may be consulted and may support a DI.

IV. CLASSIFICATION OF THE DIFFICULT PEDIATRIC AIRWAY

Difficulty with ventilation, intubation, or both is the definition of a difficult airway according to the ASA DA management guidelines.[1] Recognition of the DA along with the circumstances that predispose to airway problems is crucial to the safe management of the pediatric airway. Classification of the difficult pediatric airway may be made according to the anatomic location affected. Major anomalies of the head, face, mouth and tongue, nasopharynx, larynx, trachea, and neck are listed.

V. PEDIATRIC AIRWAY EQUIPMENT

To manage a DA successfully, the appropriate equipment should be immediately available. We recommend the creation of a difficult pediatric airway cart stocked with equipment for patients ranging from premature infants to small adults. In addition, the American Academy of Pediatrics Section on Anesthesiology recommends the creation of a DA cart for all locations anesthetizing children.[14] This cart should be dedicated only for use in a DA or a "cannot intubate, cannot ventilate" scenario (Box 36-1).

Box 36-1 Pediatric Difficult Airway Cart

Assortment of laryngoscope handles or blades
Oxyscope
Endotracheal tubes (ETTs): 2.0-7.0 mm
Oral/nasopharyngeal airways
Bite blocks
Masks
Stylets
Endotracheal tube exchangers
Laryngeal mask airways (LMAs): all sizes
Fiberoptic intubation (FOI) equipment
Bronchoscopic swivel connector
Retrograde intubation kit
Percutaneous cricothyrotomy kit
Laryngoscope
McGill forceps
Albuterol adapters (for metered doses)
Intravenous (IV) catheters
Defogger
Yankauer: pediatric and adult sizes
Suction catheters
Lidocaine solution/jelly

A. Face Mask

When managing the DA, the ability to ventilate with a mask is more important than endotracheal intubation. When dealing with the pediatric airway, and especially the difficult pediatric airway, it is important to have a selection of masks readily available. Disposable clear-plastic masks with an inflatable rim are typically used. These masks should extend from the chin to the bridge of the nose. A leak-free seal should be obtained with minimal pressure applied to the face or mandible. Transparent masks allow visualization of secretions or vomitus during induction. These masks can be purchased in different flavors or scented before induction to make them less intimidating.

Face masks have been modified for fiberoptic intubation (FOI) in a variety of ways.[15-18] Frei and colleagues[16,17] described modifying a commercially available mask (Vital Signs) by drilling a hole into the lateral aspect of the mask and attaching a corrugated silicon tube. The center of the mask is fitted with a plastic ring covered by a silicon membrane. A hole 1 to 2 mm smaller than the outer diameter (OD) of the bronchoscope is punched into the membrane. This airway endoscopy mask has been used to facilitate fiberoptic bronchoscopy (FOB) in patients ranging in age from 3 days to 12 months with spontaneous ventilation and propofol sedation.[15] A commercially available face mask with a ventilation side port (MERA, Senko Ika Kogyo, Tokyo) was modified and used successfully to intubate fiberoptically nine patients age 3 months to 11 years under inhalational anesthesia with continuous manual ventilation.[18]

B. Oropharyngeal Airway

Upper airway obstruction may occur during induction of anesthesia because the infant's tongue is large in relation to the oropharynx. Appropriately sized oropharyngeal airways are necessary for air exchange. Guedel and Berman airways are the most common airways available. By holding the airway next to the child's face, the correct size can be estimated. If the airway is too short, obstruction may be worsened. If the airway is too long, the epiglottis or uvula may be damaged. Use of a tongue depressor to insert the oropharyngeal airway is recommended to avoid impaired lymphatic drainage of the tongue.[4]

C. Nasopharyngeal Airway

Nasopharyngeal airways are available in sizes 12 to 36 French (F) and are used with caution in pediatric patients with hypertrophied adenoids. The *modified nasal trumpet* was first described by Beattie, followed by its use in pediatric airway management as described by Holm-Knudsen in 2005 (Fig. 36-1).

D. Endotracheal Tube

Endotracheal tubes (ETTs) in a variety of sizes (2.5-7.0 mm) should be available for the pediatric patient. Laser-resistant, nasal/oral Ring-Adair-Elywn (RAE), and

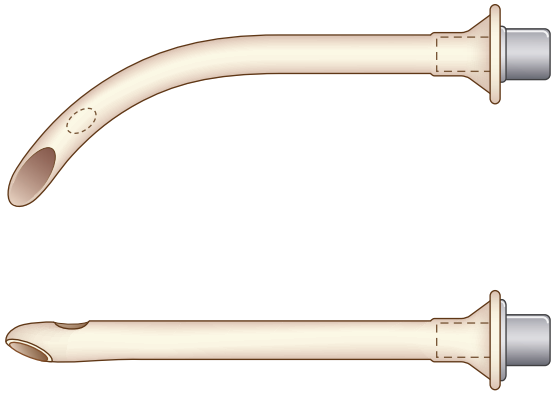

Figure 36-1 Modified nasal trumpet airway by Beattie is a nasal airway with an endotracheal tube connector wedged into the flared end. The patient can be ventilated through this modified nasal trumpet. The mouth, lips, and the other naris should be closed.

wire-reinforced ETTs are available for use depending on the surgical requirement. Determination of correct ETT size is based on the patient's age and weight. ETTs one-half size larger and smaller than the calculated size should be available (Fig. 36-2). Traditional teaching advocates the use of *uncuffed* ETTs in patients younger than 8 years. Pediatric ETTs with low-pressure high-volume cuffs are available for use in patients with low lung compliance or those at risk for aspiration. For *cuffed* ETTs, a half-size smaller tube should be used because the OD of the tube is larger with the cuff.[19]

Maintenance of air leak pressure at less than 25 cm H_2O with or without a cuff is recommended to minimize the occurrence of *postintubation croup*. Use of a manometer is recommended to avoid overinflation of the cuff. Koka and associates[20] cite the incidence of postintubation croup as 1%. In a prospective study of more than 5000 children, however, Litman and Keon[21] found that seven patients developed croup, defined as inspiratory stridor at least 30 minutes in duration, for an incidence of 0.1%. In that study, ETTs with air leak pressures greater than 40 cm H_2O were replaced with the next smaller size.[21] The presence or absence of a leak depends on the level of anesthesia and the use of muscle relaxants. Many clinicians use the degree of difficulty in passing the ETT below the vocal cords as the indicator of proper fit.

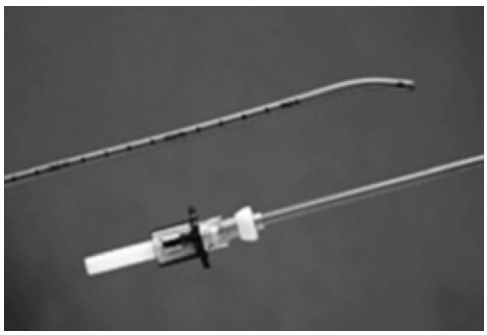

Figure 36-2 Frova Intubating Introducer (Cook Critical Care, Bloomington, IN) catheter is available in a pediatric size (8 F) that allows placement of a 3.0-mm endotracheal tube. It is hollow with two side ports, is blunt tipped, and has a Rapi-Fit adapter.

TABLE 36-1
Suggested Endotracheal Tube Size for Infants

Age	Size (mm ID)
Preterm (>1000 g)	2.5
Preterm (1000-2500 g)	3.0
Newborn to 6 months	3.0-3.5
1-2 years	4.0-4.5
>2 years	(Age +16)/4 = ID

ID, Internal diameter.

In general, there are many formulas to calculate the appropriate size of ETT. Formulas for selecting an uncuffed ETT in children older than 2 years include (age + 16)/4 or (age/4) + 4. The use of cuffed ETTs in newborns and children under 8 years has been studied. In a group of 488 patients, patients were randomly allocated to receive a cuffed or an uncuffed ETT.[22] The formula for the cuffed tube was (age/4) + 3. This formula was appropriate for 99% of patients. In that study, three patients in each group were treated for croup symptoms. Formulas for length of insertion of an oral ETT include length (cm) + 3 times internal diameter (mm) or length (cm) = age (years)/2 + 12.[19] In the premature or newborn infant, the rule is tip-to-lip distance in cm = 6 + weight (kg).[23] Whatever method is chosen, correct ETT position should be confirmed by auscultation of bilateral breath sounds (Tables 36-1 and 36-2). Also, leak should be checked to a permissible pressure.

Double-lumen tubes are not available for use in pediatric patients younger than 6 to 8 years. The Arndt Endobronchial Blocker (Cook Critical Care, Bloomington, Ind) has been used to provide one-lung ventilation in infants.[24] The 5.0-F blocker is available; the recommended ETT size is 4.5 mm. The Univent tube (Fuji Systems, Tokyo) is a single-lumen tube with an incorporated movable bronchial blocker inside.[25] Pediatric sizes of the Univent tube are available: 3.5-mm internal diameter (ID) and 4.5-mm ID. The 3.5-mm Univent tube does not have a lumen for suctioning or administration of oxygen to the blocked lung. FOB is needed for placement. Further detail regarding one-lung ventilation is provided in Chapter 26.

E. Endotracheal Tube Exchangers

Endotracheal tube (ETT) exchangers have multiple uses; they can be used to exchange damaged ETs and provide a conduit for reintubation, if necessary. Many different types of exchangers are available for use in adult patients. These tube exchangers are long, semirigid catheters that fit inside ETTs. The Frova Intubating Introducer (Cook Critical Care) is available in a pediatric size (8 F) that allows placement of a 3.0-mm ETT. It is 33 cm in length with a hollow lumen and a blunt curved tip that is shaped like the gum elastic bougie. The blunt curved tip can be passed "blindly" into the trachea when visualization of the glottis is inadequate. The Frova catheter has a hollow lumen and two side ports and is packaged with removable Rapi-Fit adapters that allow ventilation and a stiffening cannula[26] (Fig. 36-2).

Cook also manufactures airway exchange catheters (AECs) in four sizes. These catheters are blunt tipped and hollow, with distal side ports and a Rapi-Fit adapter. The 8-F size is 45 cm in length and can be used in 3.0-mm ETTs.[26]

TABLE 36-2
Formula for Endotracheal Tube (ETT) Size and Depth of Insertion

Type/Insertion	Formula
Uncuffed ETT	(Age + 16)/4 *or* ETT >2 years, Age/4 + 4
Cuffed ETT	Age/4 + 3
Length of insertion (oral)	Age (years)/2 + 12 *or* 3 × ID (mm)
Length of insertion (nasal)	3 × ID (mm) + 2

ID, Internal diameter.

F. Laryngoscopes

1. Straight vs. Curved Blades

Laryngoscope blades in different sizes and shapes should be available before induction of anesthesia. Laryngoscope blades fall into two categories: straight and curved. Because the epiglottis is angled posteriorly, visualization of the glottis may be difficult. *Straight* laryngoscope blades are often recommended for use in neonates and infants to lift the epiglottis. The most common straight blades include the Miller, Wisconsin, Wis-Hipple, and Wis-Foregger blades. *Curved* blades are more suitable for older children.

2. Oxyscope

The Oxyscope is a fiberoptic Miller no. 1 blade with a port for insufflation of oxygen during intubation. Oxygen insufflation during laryngoscopy in spontaneously breathing, anesthetized infants has been shown to minimize the decrease in transcutaneous oxygen tension, thus making airway instrumentation safer.[27]

3. Anterior Commissure Laryngoscope

The anterior commissure laryngoscope is frequently used by otolaryngologists for visualization of the glottis. It is a rigid, tubular, straight-blade laryngoscope with a distally located, recessed light source. This design permits enhanced visualization by preventing the tongue from obscuring the field of view.[28]

4. Bullard Laryngoscope

The Bullard laryngoscope (Circon ACMI, Stanford, Conn), developed by Dr. Roger Bullard at the Medical College of Georgia, is an indirect laryngoscope that utilizes fiberoptic and mirror technology to visualize the larynx.[29] Use of fiberoptics and a curved blade enable visualization of the larynx "around the corner" of the blade, thus eliminating the need to align the oral, pharyngeal, and tracheal axes. A standard laryngoscope handle or a flexible fiberoptic cable connected to a light source powers the fiberoptic light source. This laryngoscope is manufactured in three sizes: adult, pediatric, and pediatric long.[30] The adult size, with a blade that is

2.5 cm wide, is suitable for children older than 10 years. The *pediatric* version (newborn to age 2 years) has a blade 1.3 cm wide that extends 0.6 cm beyond the fiberoptics. This blade is recommended for use in neonates, infants, and smaller children. The *pediatric long* version is available for use in infants and small children up to age 10; it has a longer blade (1.4 cm) and a wider flange (1.6 cm). In the pediatric long version, a multifunctional stylet is attached to the fiberoptic bundle between the eyepiece and handle and aligns the tip of the ETT beneath the flange of the blade. The smallest ETT that passes over the stylet in the pediatric long version is 4.5 mm.[30]

The Bullard laryngoscope requires minimal mouth opening for its insertion (0.64 cm in cephalad-caudad axis). It has been used to intubate patients with unstable cervical spine or with Pierre Robin, Treacher Collins, Noonan's, or Klippel-Feil syndrome, among others.[29] The adult Bullard laryngoscope has been used successfully to intubate patients older than 12 months with normal airways.[31] Contact with the right aryepiglottic fold and, in children, contact with the anterior vocal cord occurred.[31,32] Compared with the Wis-Hipple 11/2, the adult Bullard laryngoscope provided a similar view and required a slightly longer time for intubation in children 1 to 5 years of age.[32]

5. Angulated Video-Intubation Laryngoscope

The angulated video-intubation laryngoscope (AVIL), invented by Dr. Marcus Weiss of Zurich, is an endoscopic intubation device. The AVIL consists of a cast-plastic Macintosh 4 laryngoscope, with the blade angulated distally, and an integrated fiberoptic endoscope (1.8 m long, OD 2.8 mm, VOLPI, Schlieren, Switzerland). The distal blade tip is angulated about 25 degrees to provide increased viewing for the fiberoptic lens. With the angulated tip, the AVIL resembles an activated McCoy blade. Flattening of the blade's vertical flange enables the device to be used in children. The fiberoptic endoscope runs from the handle to the tip of the blade. The AVIL uses conventional laryngoscopy techniques coupled with video monitoring from the blade tip. Styletted ETTs, in a "hockey stick" configuration, are passed along the vertical flange of the blade under video control.[33]

The AVIL has been used in patients ranging in age from 3 months to 17 years with manual in-line neck stabilization. In infants and small children, care should be taken with insertion of the blade; initial insertion of the blade was too deep in these patients.[34] Several reports document the use of this device in pediatric patients with a DA. The video laryngoscope has been used successfully to intubate children with Morquio's syndrome as well as a 3-day-old neonate with Pierre Robin syndrome.[33,35]

6. Truview Laryngoscope

The Truview (Truphatek International, Netanya, Israel) is a recently introduced rigid laryngoscope that has an angulated tip and an optical assembly that provides an illuminated and magnified view of the larynx. The optical system consists of a lens and a prism, which extends the view beyond the tip of the blade. The tip of the device is narrow to accommodate small mouth openings and angulated 46 degrees anteriorly to provide a wider view of the larynx using light refraction. This laryngoscope also has a side port that allows for oxygen insufflation and can be attached to video monitoring to assist with training. The height of the laryngoscope blade is 8 mm. Compared with traditional laryngoscopes, the Truview EVO2 laryngoscope offers various advantages and improves laryngoscopic view. A study by Singh and colleagues[35a] of 60 neonates and infants comparing the Truview EVO2 with the Miller blade demonstrated an improved laryngoscopic view with the Truview blade, with an increased time to intubation that was statistically but not clinically significant.
