7. GlideScope Video Laryngoscope

The GlideScope Video Laryngoscope (Cobalt, Verahon) has a reusable video baton and single-use laryngoscopy blades in two sizes. The laryngoscope comes with a monitor screen, and a video recording unit is also available. The GlideScope Cobalt model features a 10-mm laryngoscope blade. The blade is inserted in the midline without displacing the tongue.[36] Two studies have been reported using the GlideScope in children with normal airways. Both studies found it suitable for intubation in pediatric patients.[37,38] In one of the studies, the time required for intubation was longer.

8. Airtraq Optical Laryngoscope

The Airtraq Optical Laryngoscope (AOL; Prodol, Vizcaya, Spain) is a single-use indirect laryngoscope for tracheal intubation. The Airtraq comes in two pediatric sizes: infant (size 0) for ETT 2.5 to 3.5 and pediatric (size 1) for ETT sizes 3.5 to 5.5. Both sizes require a mouth opening of 12 to 13 mm. The rubber eyepiece may be used or a camera may be attached and used with a wireless monitor. Images from the distal tip of the blade are projected to the proximal eyepiece. The Airtraq is inserted midline, and the tip may be placed in the vallecula or used to lift the epiglottis. Once the glottis is visualized, the ETT is slowly advanced. For intubation, it is important to lubricate the ETT so that the tube advances easily. Problems with advancement of the ETT may be caused by too large diameter of the ETT, the guide channel, or incorrect angle of the ETT.[36] Two case reports documented the use of the Airtraq in pediatric patients with difficult airways: a 9-year-old child with Treacher Collins syndrome who weighed 23 kg[37] and a 4.8-kg infant with Pierre Robin syndrome.[38] Other case reports have documented difficulty with advancement of the ETT into the trachea despite a good view of the larynx.[39]

G. Stylets

There are various types of stylets available as adjuncts to endotracheal intubation, including the traditional malleable stylet, lighted stylets, and optical stylets. Stylets should be available for the DA. The stylet is inserted into the ETT until the distal end of the stylet is just short of the ETT tip. The ETT and stylet are bent into the desired shape, usually a hockey stick configuration. Complications associated with use of stylets include tracheal trauma, ETT obstruction, and shearing of the stylet.

When removal of a stylet becomes difficult, the tip should be examined.[40]

1. Lighted Stylets

Several different types of lighted stylets, or *lightwands*, are currently commercially available, including the Vital Signs Light Wand Illuminating Stylet (Vital Signs, Totawa, NJ) and the Tube Stat Lighted Stylet (Xomed, Jacksonville, Fla). Pediatric versions are available for use with ETTs as small as 2.0 to 4.0 mm. The use of the lighted stylet to guide blind endotracheal intubation relies on the principle of *transillumination*. The presence of a well-defined glow in the neck indicates tracheal placement. Esophageal placement is indicated by the absence of a glow in the neck. Several different reports describe successful intubation of pediatric patients with the lightwand.[41,42] Successful technique includes the following principles:

1. A small shoulder roll should be used to keep the head in a neutral to slightly extended position. This is extremely important in a small infant, whose neck naturally flexes when lying on a flat surface because of the large occiput.
2. The lightwand should be advanced in the midline; if the light deviates to one side, the lightwand should be withdrawn and repositioned.
3. The epiglottis is elevated by lifting the jaw with the nondominant hand.
4. Transillumination should be assessed before advancing the lightwand too far.
5. Blind nasal intubation in children is often easier with the rigid stylet left in place.
6. The wand is bent less sharply than for an oral intubation.

Benefits of light-guided tracheal intubation include use in obstructed conditions, low acquisition costs, and disposable components that eliminate the need for disinfection of equipment. As with any new technique, experience in patients with normal anatomy should be obtained before attempts in patients with a DA.

2. Optical Stylets

The first optical stylet, described in 1979, was a Hopkins telescope with a fiberoptic external light source (Karl Storz, Tuttlingen, Germany).[43] The Seeing Optical Stylet (SOS) system (Clarus Medical, Minneapolis) is a new, reusable, high-resolution fiberoptic endoscope with a malleable stainless steel stylet.[36] It combines the features of an FOB and a lightwand. The Shikani Seeing Stylet is portable, lightweight, and available in pediatric and adult versions. The pediatric version is compatible with ETTs 3.0 to 5.0 mm in size. The SOS can be inserted directly into an ETT, allowing intubation to be performed under direct vision. Illumination is provided by a standard green line fiberoptic laryngoscope handle or the included SITElite halogen handle. An adjustable tube stop with an oxygen port, which goes over the shaft of the stylet, allows supplemental oxygen to be delivered. Many factors do not affect the SOS, including cervical spine injury, small mouth, large tongue, and reduced jaw mobility.[36]

Pfitzner and colleagues[44] described the use of the Shikani SOS on eight occasions in seven patients with DA. There were seven successful intubations; one patient, who had previous surgery and radiotherapy for a retropharyngeal rhabdomyosarcoma, could not be intubated by any method. Two patients with limited mouth opening and one patient with a C1-C2 subluxation were intubated on the first attempt. A patient with Hunter's syndrome was intubated on the second attempt. A potential difficulty mentioned with the SOS is loss of the visual field, which occurs when the lens is next to a mucosal surface. Maneuvers to increase the operating space available are use of a laryngoscope to retract the base of the tongue, lifting the mandible, and pulling the tongue forward.[45]

The Shikani Stylet is inserted into the ETT after lubrication with silicon spray. The fiberoptic cable can be connected to a video monitor. The mandible is lifted with the left hand and displaced anteriorly until the lower teeth are anterior to the upper teeth.[45] The stylet with the loaded ETT is advanced into the trachea under direct vision. Laryngoscopy may be useful in cases of DI (Fig. 36-3). The Shikani Optical Stylet (Clarus Medical) is a portable video stylet.

3. Video-Optical Intubation Stylet

Another video-optical intubating stylet (Acutronic Medical Systems, Hirzel, Switzerland) consists of a flexible fiberoptic endoscope (developed by Dr. Weiss of Zurich). A sliding connector locks the video stylet onto the ETT adapter; it does not require neck extension but does require mouth opening. One report documents successful use of the video-optical intubating stylet in patients age 6 to 16 years, with a simulated grade III laryngoscopic view; 46 of 50 patients were intubated on the first attempt; four attempts were considered failures because of prolonged intubation time (>60 seconds).[46]

Figure 36-3 Shikani Seeing Optical Stylet (Clarus Medical, Minneapolis) is a reusable, high-resolution fiberoptic endoscope. The pediatric version is compatible with endotracheal tubes in the range of 3.0 to 5.0 mm. Supplemental oxygen can be delivered through the oxygen port. It can be used with the SITElite halogen handle (as shown) or a standard green line fiberoptic laryngoscope handle.

TABLE 36-3
LMA Classic Mask Size with Corresponding Cuff Volumes, ETT, and FOB

Mask Size	Weight (kg)	Maximum Cuff Volume (mL)	Maximum ETT Size	Maximum FOB (mm)
1	Infants up to 5	Up to 4	3.5 uncuffed	2.7
1.5	5-10	Up to 7	4.0 uncuffed	3.0
2	10-20	Up to 10	4.5 uncuffed	3.5
2.5	20-30	Up to 14	5.0 uncuffed	4.0
3	30-50	Up to 20	6.0 cuffed	5.0
4	50-70	Up to 30	6.0 cuffed	5.0
5	70-100	Up to 40	7.0 cuffed	5.0
6	>100	Up to 50	7.0 cuffed	5.0

LMA, Laryngeal mask airway; *ETT,* endotracheal tube; *FOB,* fiberoptic bronchoscope.

H. Laryngeal Mask Airways

1. LMA Family

The laryngeal mask airway (LMA North America, San Diego), introduced in 1983 and approved for use in 1991 by the U.S. Food and Drug Administration (FDA), is a standard part of the ASA DA algorithm.[1,47] Pediatric versions of the LMA Classic, as well as the disposable LMA, are available for use and are part of the pediatric DA algorithm, as described by Steward and Lerman.[48] Application of the LMA requires minimum training and can be useful in neonatal resuscitation.[49] The LMA Flexible is available in sizes 2 and 2.5, and the LMA ProSeal is available in a size 2. The size of the LMA in children is determined by the patient's weight, although a new method has been suggested. With the hand extended and palm side facing up, the thumb and little finger are extended. The second, third, and fourth fingers are placed together. The fully inflated LMA is placed against the palmar side of the patient's fingers, keeping the widest part of the LMA in line with the widest part of the three fingers. In a study of 163 children at birth to 14 years old, this method was correct in 78%. In the remaining patients, a difference of only one size was observed.[50]

The LMA has been described as a conduit for blind intubation as well as a conduit for fiberoptic intubation.[51-55] Awake placement of the LMA has been described in an infant with Pierre Robin syndrome.[56] Anterograde intubation through the LMA with a guidewire was also described in an infant with micrognathia who could not be intubated with conventional methods. A soft-tipped guidewire was advanced through the LMA and the position confirmed by fluoroscopy. An ETT was inserted over the guidewire, followed by removal of the LMA.[57] A review of the literature demonstrates different insertion techniques.

The standard technique described with the cuff *deflated* for adults has also been advocated for children. In addition, a rotational or reverse technique has been described. The LMA is inserted with the cuff facing the hard palate and then rotated and advanced simultaneously. An alternative technique involves inserting the LMA with the cuff partially inflated. Reports on placement of the LMA with the different techniques are conflicting. In children, one study compared two insertion techniques. The partially inflated cuff insertion technique does not increase the incidence of downfolding of the epiglottis and is an acceptable alternative to the standard technique.[58] In another study, insertion of the partially inflated LMA required less time and was associated with a higher success rate on first attempts compared with the standard (deflated) technique.[59] Results from a study detailing the fiberoptic positioning of the LMA in children with a DA show that 29.5% of patients had a grade I (full) view of the glottis, 29.5% had a grade II (partial) view, and 41% a grade III (epiglottis only) view. Children with a mucopolysaccharide disorder had a grade III view 54% and a grade I view 14% of the time.[60]

The ProSeal LMA is now available in pediatric sizes. This LMA has a second mask to isolate the upper esophagus with a second dorsal cuff to increase the seal against the glottis. Lopez-Gill and coworkers[61] found that it was easily inserted, and oropharyngeal leak pressure was greater than 40 cm H_2O (Table 36-3).

2. Air-Q Intubating Laryngeal Airway

The Air-Q Intubating Laryngeal Airway (ILA) (Cookgas, Mercury Medical, Clearwater, Fla) is a supraglottic device used both for airway maintenance during routine anesthesia and as a conduit for tracheal intubation for patients with a DA. Unlike the LMA, the ILA was designed primarily to allow for the passage of conventional cuffed tracheal tubes when used for blind tracheal intubation, and it has the option for subsequent removal. The ILA also shares some structural features with the intubating laryngeal mask airway (ILMA). Compared with the LMA, the ILA allows for straightforward passage of a cuffed tracheal tube when used as a conduit for tracheal intubation because of three design differences. First, the airway tube of the ILA is wider, more rigid, and curved. Second, removal of the detachable 15-mm proximal connector increases the ID of the airway tube. Third, the ILA's shorter length allows for easier removal after successful tracheal intubation. The Air-Q ILA is available in six sizes (1, 1.5, 2, 2.5, 3.5, and 4.5) for single use and in four sizes (2.0, 2.5, 3.5, and 4.5) for reuse. Sizing of the pediatric Air-Q ILA is similar to the LMA, in that it is weight based (size 1 for patients <5 kg; size 1.5 for 5-10 kg; size 2 for 10-20 kg).

The self-pressurized Air-Q ILA (ILA-SP) is a new first-generation supraglottic airway for children with a self-adjusting cuff and lack of a pilot balloon. A newer version

of the ILA-SP was recently introduced into our practice for routine airway maintenance in children. The ILA is currently the only supraglottic device available in pediatric patients designed to act as a conduit for tracheal intubation with cuffed tracheal tubes.

I. Rigid Ventilating Bronchoscope

The rigid ventilating bronchoscope is extremely useful for ventilating patients with a DA and is included in the most recent version of the ASA DA algorithm as an alternative device in the "cannot ventilate, cannot intubate" situation. In any situation of potential airway collapse, the otolaryngologist and the rigid ventilating bronchoscope should be immediately available (see Chapter 29).

VI. INDUCTION TECHNIQUE

The principles outlined in the ASA guidelines for DA management apply to the pediatric patient. Evaluation, recognition, and preparation are key elements.[1] Preoxygenation of pediatric patients, although difficult, should be attempted before any DA intervention, if possible. Studies have demonstrated that the optimal time for preoxygenation in pediatric patients is different from that in adults. Values ranging from 80 to 100 seconds have been reported for adequate preoxygenation in healthy children.[62,63] Summoning help early, using *awake intubation*, and preserving spontaneous ventilation during intubation attempts are also important when managing the DA. The awake or awake sedated approach is preferred in most circumstances when managing the DA. However, in pediatric patients, the patient's cooperation may limit the usefulness of awake intubation. One well-tolerated technique is placement of a lubricated LMA in awake infants, which provides an airway for inhalational induction.[56]

The traditional approach to the difficult pediatric airway has been maintenance of spontaneous ventilation under inhalational anesthesia. Premedication with oral or intravenous atropine (0.01-0.02 mg/kg) is indicated for vagolytic and antimuscarinic effects. Inhalation induction may be performed with sevoflurane in 100% oxygen. Sevoflurane has been used in the management of the DA with success.[64,65] The low blood gas solubility of sevoflurane and consequent rapid induction and emergence are advantageous when managing the DA. When the ability to ventilate the patient by mask is demonstrated, a small dose of muscle relaxant or propofol may be given to facilitate intubation.

For patients who can tolerate an *awake sedated* intubation technique, a variety of drugs can be used. One must always keep in mind the risk/benefit ratio when sedating a patient with a DA. Sedatives may further compromise an airway. Sedatives should not be given to any patient in acute distress or with the potential for acute obstruction. Use of sedatives should be based on careful physical examination, anesthesiologist experience with agents involved, and overall patient condition. If no other options are available, slow titration of pharmacologic agents to effect, without loss of spontaneous ventilation, should be performed. Use of pharmacologic agents that are easily antagonized is recommended. For older children and adolescents, a combination of midazolam and fentanyl may be used. Remifentanil can also be used. Dexmedetomidine has been used successfully to perform an awake fiberoptic intubation in a morbidly obese patient with facial, cervical, and upper thoracic edema.[66] In extreme circumstances, parental presence at induction may be allowed. Careful preparation of the parent must be performed prior to induction. As soon as the patient separates or begins to lose consciousness, a designated member of the operating room (OR) staff should immediately escort the parent out of the OR.

Another important aspect for successful airway management is *topicalization* of the airway with local anesthesia. In pediatric patients, this may be obtained by nebulizing, spraying, or swabbing local anesthetic solution or by applying viscous gel to a gloved finger. FOB with suction ports can be used to spray local anesthesia on the vocal cords under direct vision. The maximum dose of local anesthetic allowed should be calculated before topicalization. The drug of choice is *lidocaine* because it has the best safety profile. Maximum doses of lidocaine are 5 mg/kg. Agents containing benzocaine (e.g., Cetacaine spray; Americaine ointment; Hurricaine ointment, gel, or spray) should be avoided in infants and young children because of the risk of methemoglobinemia.[7]

VII. AIRWAY MANAGEMENT TECHNIQUES

A. Techniques for Ventilation

Obstruction of the upper airway is a common occurrence in pediatric patients undergoing an inhalation induction. Techniques for overcoming this type of obstruction include insertion of an appropriate-size oropharyngeal airway or a nasopharyngeal airway, or both. Another common mistake is occlusion of the submandibular space with incorrect placement of the anesthesiologist's hand. Care should be taken to position the hand on the tip of the mandible and not on the submandibular space. Chin lift or jaw thrust combined with continuous positive airway pressure (CPAP) at 10 cm H_2O has been shown to improve upper airway patency.[67]

Additional techniques are available for mask ventilation. The two-person technique involves either one person holding the mask with both hands while an assistant compresses the reservoir bag or a second person assisting in jaw lift while the first person continues to compress the reservoir bag. Another option is using the anesthesia ventilator to provide ventilation so that one person can hold the face mask with both hands.[68]

B. Techniques for Intubation

1. Direct Laryngoscopy

Tips for successful visualization of the larynx include proper use of external laryngeal pressure and positioning. Direct laryngoscopy involves alignment of the oral, pharyngeal, and laryngeal axes in order to visualize the glottis. Because the larynx is situated in a more cephalad position

and the occiput is large, the sniffing position in infants does not assist in visualization of the larynx.[4,7] The infant should be positioned with the head in a neutral position with the neck neither flexed nor extended.[69] A small shoulder or neck roll may be beneficial. Optimum external laryngeal manipulation (OELM) should also be used with a poor laryngoscopic view to improve visualization. OELM may improve the laryngoscopic view by at least one whole grade in adults. This is not cricoid pressure but rather pressing posteriorly and cephalad over the thyroid, hyoid, and cricoid cartilages. Benumof and Cooper[70] suggest that OELM should be an instinctive and reflex response to a poor laryngoscopic view. This maneuver has also proved effective in pediatric patients.[71] The main mechanism seems to be shortening of the incisor-to-glottis distance.

The two-anesthesiologist technique involves manipulating the larynx under direct vision by the laryngoscopist and intubation by a second anesthesiologist. This technique has been used successfully to intubate a 6-month-old infant with Pierre Robin syndrome and concomitant tongue-tie (ankyloglossia).[72]

The *retromolar* or *paraglossal* technique has been advocated as useful in cases of DI related to a small mandible.[73] A straight laryngoscope blade is introduced into the extreme right corner of the mouth overlying the molars, thus reducing the distance to the vocal cords. It is advanced in the space between the tongue and lateral pharyngeal wall until the epiglottis or glottis is visualized. The head is rotated to the left to improve visualization while applying external laryngeal pressure displacing the larynx to the right. Advancement of the ETT is facilitated by retracting the corner of the mouth to allow placement of the ETT. The styletted ETT should be shaped into the classic hockey stick configuration. An alternative approach involves placement of the ETT from the left side of the mouth.[74] Lateral placement of the laryngoscope blade reduces the soft tissue compression because the tongue is essentially bypassed. The maxillary structures are also bypassed by the lateral blade placement, thus improving the view.[4] Because there is a reduced space for displacement of the tongue in syndromes with micrognathia, this approach may be useful. The retromolar technique has been described as an alternative method for intubation of patients with Pierre Robin syndrome.[75] A pediatric version of the Bonfils Retromolar Intubation Fiberscope is the Brambrink Intubation Scope (Karl Storz). It is an optical stylet that allows a retromolar approach to the DA.[26]

In adults the *left molar* approach with a Macintosh blade and OELM has been reported to improve the glottic view in cases of difficult laryngoscopy.[76] Suspension laryngoscopy is often employed by otolaryngologists as an alternative technique for visualization of the difficult larynx. Intubation of an infant with Goldenhar's syndrome was accomplished by *suspension laryngoscopy*.[77] This method is similar to standard laryngoscopy by the retromolar technique.

With any direct laryngoscopy technique, limiting the number of attempts is recommended. Edema can rapidly occur and create a "cannot ventilate, cannot intubate" scenario.

2. Blind Intubation Technique

a. BLIND NASOTRACHEAL INTUBATION

Blind nasotracheal intubation requires preservation of spontaneous ventilation either under general anesthesia or with adequate vasoconstriction and topicalization of the nasal mucosa. The tip of the ETT is directed toward the larynx by listening to the intensity of the breath sounds or by the capnograph tracing. This technique requires extensive practice before use. Tips for this technique include external pressure on the neck, which may direct the glottis toward the ETT; placement of a stylet through the ETT after passage through the nasopharynx to direct the tip to the glottis; inflating the ETT cuff with air to center it at the glottis and then deflating it for actual passage; and repositioning of the head (flexion/extension) if the initial intubation attempt fails.[48] Pediatric patients with enlarged adenoids may be at risk for bleeding and trauma with this technique. Blind nasotracheal intubation of a neonate with Pierre Robin syndrome has been described.[78]

b. DIGITAL ENDOTRACHEAL INTUBATION

Digital intubation is a blind technique that is relatively easy to learn. Intubation of an 8-day-old, 3.3-kg neonate with Pierre Robin syndrome has been reported.[79] The left index finger is passed midline along the surface of the tongue until it passes the epiglottis. The left thumb may apply cricoid pressure to steady the larynx. The ETT, using the left index finger as a guide, is advanced into the trachea. This technique has been used as the primary method of intubating neonates in some neonatal centers.[80] As with any new technique, practice is required.

c. LIGHTWAND INTUBATION

Intubation with a lightwand is a blind technique that has found success in management of the difficult pediatric airway.[41,42] The success rate increases with experience; practice is thus required. As with any new technique, experience with patients who have normal anatomy should be gained first. Contraindications to the use of the lightwand include tumors, infections, trauma, and foreign bodies of the upper airway.[37] Causes of failed intubation include entrapment in the vallecula or the aryepiglottic folds. A shoulder roll helps to extend the head and neck and increase the exposure of the anterior neck. After preparation of the lightwand, the jaw is lifted with the nondominant hand or a laryngoscope blade. The lightwand is inserted in the midline into the patient's mouth, rotated around the patient's tongue, then gently rocked back and forth. If the ETT wand is in the trachea, a well-defined bright light (size of a quarter) is visible at the level of the subglottis on the anterior surface of the neck.

3. Fiberoptic Laryngoscopy

Aids for fiberoptic intubation (FOI) include face masks, oropharyngeal airways, guidewires, and the LMA.[81] The Frei mask previously described or variations of commercially available masks have been used with success.[15,16,82] The Patil-Syracuse mask is available in a size 2, but it is difficult to achieve a good seal with this mask. An endoscopy mask can be made by attaching a swivel fiberoptic

bronchoscope (FOB) adapter to a pediatric face mask in one of two ways[81]: a commercially available swivel adapter (Instrumentation Industries, Bethel Park, Pa) can be attached directly to the mask, or an adapter designed for attachment to the ETT (e.g., Portex bronchoscope adapter) can be connected to the face mask with a 15-mm to 22-mm adapter.

Oropharyngeal airways may also be modified for use in pediatric FOI. A strip may be cut from the convex surface of a Guedel-style airway to produce an aid for oral fiberoptic laryngoscopy, creating a channel. The fiberscope is placed in the channel, which helps maintain a midline position. The use of a smaller airway than predicted is suggested so that one may visualize the base of the tongue and epiglottis. Modified oropharyngeal airways are not effective as bite blocks, and one must be careful.[81] Also, a nipple from a baby bottle has been modified to act as a conduit for FOI in an infant with an unstable cervical spine. In this case, a hole was cut obliquely into the end of the nipple. After topicalization of the airway with 2% lidocaine, FOI was performed with a 4.0-mm uncuffed ETT.[83]

Flexible fiberoptic laryngoscopy is one of the cornerstones of DA management. Preparation for fiberoptic laryngoscopy should include preparation of the patient (antisialogue) and checking of the FOB, light source, and suction as well as standard airway equipment. An assistant is necessary for monitoring of the patient and providing a jaw lift, which is useful because it elevates the tongue from the posterior pharynx.[7] For older children and adolescents who will be sedated for the procedure, explanation and reassurance in a calm manner are helpful. A method of delivering oxygen is necessary as well. This can be accomplished in a variety of ways, either blowby from the anesthesia circuit or by nasal cannula. For patients who are anesthetized, an LMA or an endoscopy mask may be used to ventilate the patient while the intubation is being performed. Tips for successful oral intubation include midline placement of the FOB, advancement of the FOB only when recognizable structures are visualized, and retraction of the tongue with gauze or clamps if needed.[7] If the view from the fiberscope is pink mucosa, the FOB is slowly pulled back until a recognizable structure is seen. If the nasal route is chosen, a topical vasoconstrictor may be used to reduce the chance of bleeding. In a series of 46 patients with DA, fiberoptic nasal intubation was successful on the first attempt in 37 patients (80.4%) and on the second or third attempt in 7 patients (15.2%). Two failures occurred: one related to bleeding and the other to inability to introduce the scope nasally.[84]

Flexible fiberoptic laryngoscopy may be performed in a variety of ways. The standard technique involves passage of the ETT over the FOB. The ultrathin fiberoptic laryngoscope with a directable tip allows FOI to be performed with ETTs as small as 2.5 mm. Intubation of a 3-month-old infant with the Pierre Robin syndrome has been successfully performed with an ultrathin fiberscope.[85] A new 2.5-mm ultrathin flexible FOB with a 1.2-mm suction channel has been used to intubate a newborn with a DA.[86] This FOB has a 2.5-mm OD, 1.2-mm working suction channel, angle of deflection of 160 degrees up and 130 degrees down, and a working length of 450 mm.

In scenarios where the available bronchoscope is too large for the required ETT, a staged technique may be employed.[87] A FOB with a working channel, a cardiac catheter, and a guidewire are required. The guidewire is passed into the working channel of the fiberscope before intubation. The FOB guidewire assembly is then introduced into the mouth and positioned above the larynx. The guidewire is advanced into the trachea under direct visualization, followed by removal of the FOB. A cardiac catheter (used to stiffen the wire) is threaded over the guidewire. Finally, an ETT is advanced into the trachea over the guidewire-catheter assembly, which is then removed. A modification of this technique involves passage of the ETT over the guidewire without the reinforcing cardiac catheter. This has been used to intubate nasotracheally a 3-day-old infant with Pierre Robin syndrome.[88]

The fiberoptic bronchoscope may also be used as an aid for nasal intubation either under direct vision or with a guide. In these cases, FOB is introduced into one of the nares while the ETT is advanced into the trachea through the other naris.[38] Alternatively, if the ETT cannot be manipulated into the glottis, a guide may be placed in the opposite naris and directed into the trachea. The ETT is then removed and threaded over the guide. A urethral catheter has been used in this manner to assist in the intubation of a 2-week-old neonate with Klippel-Feil syndrome, occipital meningocele, and microretrognathia.[89] Another variation of the staged technique involves placement of a larger ETT into the larynx under fiberoptic visualization, followed by removal of the FOB, leaving the larger ETT in the larynx. A bougie is placed through the larger ETT into the trachea, and the ETT is removed. An appropriate-size ETT is then advanced over the bougie into the trachea.[90]

Flexible FOB intubation through the LMA has been successful.[52,53,91] Staged intubation techniques involving the LMA, FOB, guidewires, and catheters (dilators) have been reported, including the use of LMA-assisted wire-guided fiberoptic endotracheal intubation. In a series of 15 cases, Heard and colleagues[92] demonstrated that this technique was safe, successful, and easy to learn. After the FOB is placed through the LMA and the vocal cords are visualized, the guidewire is passed through the suction port of the bronchoscope and into the trachea. The LMA and FOB are carefully removed, and the ETT is advanced over the wire. A variation of this theme involves fiberoptic visualization of the glottis through the LMA followed by passage of a guidewire through the suction port of a FOB into the trachea as before. The fiberscope is then removed and an airway catheter or a ureteral dilator passed over the wire into the trachea through the LMA. The LMA is then removed and an ETT advanced over the catheter into the trachea.[93] This technique has been used successfully to manage the airway in children with mucopolysaccharidoses. The use of an LMA, an airway exchange catheter (AEC), and a 2.2-mm–OD FOB has also been described.[94] After placement of the LMA and visualization of the vocal cords, the fiberscope is removed. The fiberscope is placed into the lumen of a size 11 AEC,

which had been cut to 25 cm. This combination was advanced through the LMA into the trachea by a connector. The LMA and FOB are removed, and an ETT is advanced over the Cook AEC.

Przybylo and coauthors[95] reported the performance of a retrograde FOI through a tracheocutaneous fistula in a child with Nager's syndrome. The ultrathin FOB was passed through the fistula in a cephalad direction past the vocal cords and exiting the nares. The ETT was then advanced over the FOB into the trachea.

4. Bullard Laryngoscope

The pediatric Bullard laryngoscope is placed into the oropharynx in the horizontal plane. After passing the tongue, the handle is rotated to a vertical position. One must be careful to stay in the midline as the blade slides around the tongue. The handle then is lifted to visualize the glottis.[29] Once the glottis is visualized, a styletted ETT is advanced under direct vision into the trachea.

5. Dental Mirror–Assisted Laryngoscopy

The dental mirror can be used as an adjunct to direct laryngoscopy in order to view an anterior larynx. After direct laryngoscopy is performed, the dental mirror is inserted on the right side of the mouth and angled so that the vocal cords are seen. The handle of the mirror is moved to the left and held by the left hand. An appropriately shaped, styletted ETT then is advanced into the trachea while looking at the dental mirror. Practice is required to develop the necessary coordination. A Stortz no. 3 dental mirror and a Macintosh no. 1 laryngoscope have been used to intubate a 3.9-kg, 2.5-month-old infant.[96]

6. Retrograde Intubation

The classic retrograde technique involves percutaneous placement of an intravenous catheter through the cricothyroid membrane into the trachea followed by placement of a guidewire. The guidewire exits the mouth or nose and the ETT is then exchanged over the guidewire. If resistance to ETT passage occurs, counterclockwise rotation of the ETT may facilitate placement. This technique has been used for intubation of an infant with Goldenhar's syndrome.[97] A 14-F retrograde intubation set is commercially available from Cook for use with ETTs of ID 5.0 mm or greater.

A combined technique using the FOB and retrograde intubation has been used successfully in management of the difficult pediatric airway as well, as previously mentioned.[98]

A fiberoptic bronchoscope with a working channel is necessary for the combined technique. The guidewire is threaded into the suction port of an intubating FOB that has a preloaded softened ETT on it. The FOB is passed along the guidewire until it is past the vocal cords. When the scope is past the vocal cords, the wire is withdrawn and the ETT correctly positioned. This technique allows passage without obstruction from the arytenoid cartilage or epiglottis. Oxygen insufflation can be performed through the suction port as well, even with the wire in place. Care must be taken to limit flow to avoid tracheobronchial injury from excessive gas velocity. Audenaert and colleagues[99] used this technique in 20 patients with DA age 1 day to 17 years and reported no major complications. Retrograde wire-guided direct laryngoscopy has also been reported for airway management in a 1-month-old infant.[100] In that patient, attempts to pass a 2.5-mm ETT over the wire itself were unsuccessful, but endotracheal intubation was achieved over the wire with direct laryngoscopy.

7. Emergency Access

Emergency access is divided into the emergency surgical and the emergency nonsurgical airway.[1] Emergency *surgical airway* access is often difficult and requires the presence of a skilled anesthesiologist. It is the last resort in the "cannot ventilate, cannot intubate" arm of the ASA DA algorithm.[101] Three procedures are referred to in this category: emergency tracheostomy, emergency cricothyroidotomy, and percutaneous needle cricothyroidotomy. In children younger than 6 years, emergency tracheostomy is usually the procedure of choice because the cricothyroid membrane is too small for cannulation.[99] In older children, percutaneous needle cricothyroidotomy is often preferred over a surgical approach because most anesthesiologists can perform this technique rapidly. Also, there is less risk of injury to surrounding structures.[4] Emergency cricothyroidotomy kits are available from Cook with 3.5-, 4-, and 6-mm–ID airway catheters.

The emergency *nonsurgical airway* access includes use of the LMA, esophageal-tracheal Combitube, and transtracheal jet ventilation (TTJV).[1] The Combitube is available in a small-adult size and is contraindicated in patients less than 4 feet tall.[7] The LMA is useful in the management of the difficult pediatric airway, as stated previously, as an supraglottic airway device or as a conduit for intubation. However, in the presence of glottic or subglottic obstruction, the LMA is ineffective; TTJV is considered the technique of choice in this situation, as reported in two cases for laser endoscopic surgery.[102] Caution with TTJV is urged because serious complications may result from its use.[103] TTJV below a glottic or subglottic obstruction may result in barotrauma because the pathway for egress of air and oxygen is limited. Tension pneumothorax has been reported with jet ventilation through an AEC in an adult.[104]

VIII. COMPLICATIONS OF AIRWAY MANAGEMENT

Complications that result from intubation in adults can occur in the pediatric population as well. Airway injury accounted for 6% of claims in the ASA closed-claims database.[105] Four percent of the airway injury claims involved pediatric patients younger than 16 years. The most frequent sites of injury reported were the larynx (33%), pharynx (19%), and esophagus (18%). Injuries to the esophagus and trachea were more frequently associated with DI. Laryngeal injuries included vocal cord paralysis, granuloma, arytenoid dislocation, and hematoma. Pharyngeal injuries included lacerations, perforation, infection, sore throat, and miscellaneous injuries (foreign body, burn, hematoma, and diminished taste).

An oropharyngeal burn related to the laryngoscope lamp occurred in a term baby weighing 3.6 kg who was easily intubated at birth.[106] The laryngoscope was switched on before intubation. Lightbulb laryngoscopes, in contrast to fiberoptic laryngoscopes, can reach temperatures that would result in burns to the oropharynx. Filaments may overlap with use, and it is common for two or more coils to touch.[106] The resistance of the lamp decreases and the current increases, thus increasing the temperature. Koh and Coleman[106] recommend that all lightbulb laryngoscopes be switched on for less than 1 minute; if left on, the temperature of the bulb should be manually checked before intubation.

Difficult intubation accounted for 62% of all esophageal injuries, with most involving esophageal perforation (90%). Esophageal perforation following DI has been reported in a neonate.[107]

Laryngotracheal stenosis may be classified as glottic, subglottic, or tracheal. Prolonged intubation seems to be the major etiology. The mechanism responsible seems to be ischemic necrosis caused by pressure from the ETT against the glottic and subglottic mucosa. This results in an inflammatory reaction with a secondary bacterial infection and scar formation. Risk factors include too large an ETT, prolonged intubation, repeated intubation, laryngeal trauma, sepsis, and chronic inflammatory disease.[108]

The incidence of postintubation croup varies from 0.1% to 1%.[20,21] Risk factors include age under 4 years, tight-fitting ETT, repeated intubation attempts, duration of surgery exceeding 1 hour, patient's position other than supine, and previous history of croup. Reports are conflicting concerning the risk from a concurrent upper respiratory tract infection. Classic treatment consists of humidified air, nebulized racemic epinephrine, and dexamethasone. In pediatric trauma patients, absence of an air leak at extubation was the strongest predictor of postextubation stridor requiring treatment.[109]

IX. AIRWAY DISEASES AND IMPLICATIONS

A. Head Anomalies

Airway management can be adversely affected by conditions that involve enlargement of the head. Mass lesions and macrocephaly can interfere with mask ventilation or direct laryngoscopy, or both.

1. Airway Implications

Airway management in children with macrocephaly requires proper head and neck positioning and care of the associated airway anomalies that are a frequent finding in patients with mucopolysaccharidosis. If preoperative evaluation suggests presence of a DA, awake methods of endotracheal intubation should be initially attempted.

In children, awake intubation may require careful use of sedatives in addition to topical anesthesia to the oropharynx, larynx, and nasopharynx (for nasotracheal intubation). A limited number of attempts at direct laryngoscopy may be made. If these are not successful, one of the various techniques of nonvisual or indirect laryngoscopy as detailed earlier may be used to secure the airway. If the patient does not comply with awake endotracheal intubation without the use of an amount of sedative that risks respiratory compromise, general anesthesia may be induced as long as mask ventilation is possible. The patient may breathe a potent vapor anesthetic until a level of anesthesia is achieved that allows endotracheal intubation. Other options include fiberoptic laryngoscopy in a patient breathing spontaneously through a mask or an LMA, use of a lighted stylet, use of a Bullard laryngoscope, and the retrograde technique. When mask ventilation is known to be easy in children, muscle relaxants may be used if their use notably improves the chance of endotracheal intubation.

The pathologic conditions that involve enlargement of the head and affect the airway are encephalocele, hydrocephalus, and mucopolysaccharidosis, along with other, less common conditions, such as phakomatoses, craniosynostosis, or conjoint twins with face-to-face encroachment of the heads or proximity of the chests (thoracopagus).

2. Specific Anomalies

a. ENCEPHALOCELE

Patients with encephalocele may have other diseases that complicate airway management. The only two syndromes associated with encephalocele in which survival past infancy is likely are Roberts-SC phocomelia syndrome (includes pseudothalidomide syndrome, hypomelia-hypertrichosis–facial hemangioma syndrome) and facioauriculovertebral spectrum (includes first and second brachial arch syndrome, oculoauricular vertebral dysplasia, hemifacial microsomia, Goldenhar's syndrome). Encephaloceles, or neural tube defects of the head, usually occur in the occipital area, although they may involve the frontal and nasal regions. When large, they affect airway management by interfering with mask fit or laryngoscopy.[110]

b. HYDROCEPHALUS

Hydrocephalus is associated with more than 30 malformation syndromes. Some craniosynostosis syndromes are associated with hydrocephalus and result from bone compression that prevents free flow of cerebrospinal fluid; examples include achondroplasia, Apert's syndrome, and Pfeiffer's syndrome. Some of these diseases may affect the airway by more than one mechanism (e.g., children with hydrocephalus who also have Arnold-Chiari malformation). Difficulties with airway management are usually associated with the underlying pathology and interference with face mask ventilation.

c. MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses are a group of seven inherited lysosomal storage disorders caused by the deficiency of specific lysosomal enzymes required for the degradation of glycosaminoglycans (GAGs), which are complex macromolecules. The inability to degrade GAGs leads to their lysosomal accumulation and the subsequent clinical features of the disorders, which can include facial

coarsening, corneal clouding, valvular heart disease, hepatosplenomegaly, and dysostosis multiplex accompanied by short stature.

Mucopolysaccharidosis (MPS) type I, which results from the deficiency of L-iduronidase activity, can manifest as one of three different clinical phenotypes: Hurler's syndrome (i.e., MPS type IH), Scheie's syndrome (i.e., MPS type IS), or Hurler-Scheie syndrome (i.e., MPS type I H/S). Of these, Scheie's syndrome is the mildest form of the metabolic defect. The other mucopolysaccharidoses are Hunter's syndrome (type II), Sanfilippo's syndrome (type III), Morquio's syndrome (type IV), Maroteaux-Lamy syndrome (type VI), and Sly's syndrome (type VII).

The anesthetic morbidity of the mucopolysaccharidoses is 20% to 30%.[111] Morbidity is almost always related to respiratory difficulties. Intubation and maintenance of the airway might be difficult because of a variety of upper airway abnormalities, including micrognathia, macroglossia, patulous lips, restricted motion of the temporomandibular joints, friable tissues, and the presence of copious viscous secretions. Semenza and Pyeritz,[112] in a retrospective study on 21 patients with the diagnosis of MPS, found that the anatomic factors affecting respiratory status included (1) upper airway narrowing by hypertrophied tongue, tonsils, adenoids, and mucous membranes; (2) lower airway narrowing by GAG deposition within the tracheobronchial mucosa; (3) decreased thoracic dimensions related to scoliosis and thoracic hyperkyphosis; and (4) decreased abdominal dimensions because of lumbar hyperlordosis, gibbus formation, and hepatosplenomegaly. In addition, a short neck and an anterior and narrowed larynx may lead to an increased incidence of difficult or failed intubations.[113] In particular, patients with Hunter's, Hurler's, or Maroteaux-Lamy syndrome have significantly more airway difficulties as they grow older than MPS patients with other syndromes.[114]

The incidence of difficult intubation is high. In one review of 34 patients who underwent 89 anesthesias, the overall incidence of DI was 25% and failed intubation, 8%.[113] In children with Hurler's syndrome, incidence of DI was 54% and failed intubation, 23%. Herrick and Rhine[115] administered 38 anesthetics to nine patients with MPS (Hunter's, Hurler's, Sanfilippo's, and Morquio's syndromes) and found an overall incidence of airway-related problems of 26%, with a 53% incidence in patients with the Hurler's or Hunter's syndrome.

Belani and associates[116] reported their experience with 141 anesthetics in 30 patients with MPS. Visualization of the vocal cords during laryngoscopy was easier in children with Hurler's syndrome when they were younger (23 vs. 41 months; $P \leq 2.01$) and smaller (12 vs. 15 kg; $P \leq 2.05$). Also, children with preoperative obstructive breathing had a significantly higher incidence of postextubation obstruction. A total of 28 children underwent bone marrow transplantation; this reversed upper airway obstruction and also reversed intracranial hypertension.

Failure to insert an LMA or nasopharyngeal airway and fatal outcomes have been reported.[93,117,118] Consequently, nasotracheal intubation is not recommended, because of difficulties with the anatomy of nasal passages and potential hemorrhage from soft tissue trauma. Accumulation of mucopolysaccharides in the trachea may require a much smaller ETT than usual.[117] Tracheostomy can also be difficult technically in these patients and in one case was impossible even postmortem.[119]

Cervical instability, potential spinal cord damage, and severe thoracic and lumbar skeletal abnormalities make positioning and intubation difficult. In their series, in children with Hurler's syndrome, Belani and associates[116] found a 94% incidence of odontoid dysplasia, whereas 38% demonstrated anterior C1-C2 subluxation. To avoid cervical cord damage in patients with cervical instability, Walker and colleagues[113] described manual in-line stabilization during intubation and concluded that a pediatric FOB should be available for all known difficult intubations.[113] Tzanova and coworkers[120] reported successful anesthesia in a 23-month-old girl with Morquio's syndrome and unstable neck. The Truview laryngoscope has been used successfully in patients with unstable neck and those with cervical collars. Fiberoptic nasal intubation with spontaneous ventilation has been suggested as the method of choice.

A number of other skeletal deformities should also be considered in MPS patients. Chest cage dysfunction related to kyphoscoliosis leads to reduced vital capacity and restrictive pulmonary disorder.[69] Cardiac diseases are common in these patients. Both clinical and histologic studies of the cardiovascular system show progressive involvement of the coronary arteries, heart valves, and myocardium. The lumen of the coronary arteries is narrowed as a result of deposition of collagen and mucopolysaccharides in the intima. Coronary artery involvement and valvular involvement in patients with Hurler's syndrome have been reported.[114,121,122] Complications with 141 anesthetics in 30 patients with MPS included one child with intraoperative stroke and another with pulmonary edema; severe and extensive coronary obstruction was responsible for two intraoperative deaths, and coronary angiography underestimated coronary artery disease.[116]

Considering the high rate of DI in MPS patients, regional anesthesia seems a good alternative in older children. Failed epidural anesthesia was reported in one patient.[117] The deposition of mucopolysaccharides in either the general epidural space or the sheath of the nerve fibers, preventing direct access of the local anesthetic to the nerve, was suspected.

B. Facial Anomalies: Maxillary and Mandibular Disease

The pediatric airway may be complicated by a large number of syndromes involving the head, neck, and cervical spine. The airway and associated structures are deviated from the branchial arches. The first arch develops into the maxilla, mandible, incus, malleus, zygoma, and a portion of the temporal bone. The second arch develops into stapes, the styloid process of the temporal bone, and a portion of the hyoid. The third arch develops into the reminder of the hyoid. The fourth and six arches fuse to form the laryngeal structures, including the thyroid, cricoid, and arytenoid cartilages. The pharyngeal muscle develops from the fourth arch, whereas the sixth arch

gives rise to the laryngeal musculature. Failure of any of these to develop properly may lead to characteristic anomalies.

1. Tumors

a. CYSTIC HYGROMA

Cystic hygromas are multiloculated cystic structures that are benign in nature. They form as the result of budding lymphatics and thus may occur anywhere in the body, although most frequently in the neck (75%) and axilla (20%). As the tumor grows, it may cause symptoms from pressure on the trachea, pharynx, blood vessels, tongue, and nerves and eventually may severely compromise the airway. The tongue often protrudes outside the mouth and prevents its closure, making maintenance of the airway difficult if not impossible. Airway obstruction is the most critical complication of the cystic hygroma in the neck. The safest approach in these children seems to be nasal intubation,[123] either blind or with fiberoptic assistance with the patient awake. In extreme cases, tracheostomy may be necessary.

b. NECK TERATOMA

Teratomas of the head and neck are interesting because of their obscure origin, bizarre microscopic appearance, unpredictable behavior, and often dramatic clinical presentation. The reported incidence of cervical teratomas ranges from 2.3% to 9.3% of all teratomas. A teratoma is a true neoplasm, which includes four groups: dermoid cysts, teratoid cysts, true teratomas, and epignathi (pharyngeal teratomas).

Teratomas of the head and neck frequently arise with respiratory distress or even asphyxia at delivery, and a well-established plan for early airway management should be prepared. If they are untreated, the mortality of patients with these masses is 80% to 100%.[124] Fetal ultrasonography has been used since the 1970s to aid in the prenatal diagnosis. Antenatal diagnosis is important for two reasons. First, elective cesarean section should be planned to avoid dystocia and fetal trauma. Second, because immediate establishment of a patent airway is essential for survival, a team of pediatric airway experts must be available.

The ex utero intrapartum technique (EXIT) allows the continuance of fetoplacental circulation during cesarean section. Initially, only the infant's head and shoulders (but not the placenta) are delivered, thus maintaining uteroplacental blood flow. Intramuscular fentanyl and vecuronium are given, the infant's airway is secured, and then the umbilical cord is clamped and delivery of the infant completed. The EXIT has proved useful in cases of anticipated DA instrumentation of the neonate (e.g., large fetal neck masses causing airway obstruction).[125] Once the head of the neonate is delivered, a multitude of choices are available for airway management: direct laryngoscopy, FOI, pediatric Bullard laryngoscopy,[124] or tracheostomy. The EXIT procedure has proved to be safe and efficacious, allowing establishment of an airway in a controlled manner because the placenta allows continued gas exchange during airway manipulation.[126,127] Early identification of these masses allows controlled delivery of the neonate in a setting where pediatric anesthesiologists, surgeons, and neonatologists can develop strategies to minimize the risk of a postnatal respiratory death.

c. CHERUBISM

Cherubism is a familial disease of childhood in which patients acquire mandibular and sometimes maxillary enlargement. The mandibular rami hypertrophy, limiting the submandibular space for displacement of the tongue and making visualization of the glottis during direct laryngoscopy difficult.[11]

2. Congenital Hypoplasia

a. ACROCEPHALOSYNDACTYLY

Maxillary hypoplasia results from premature synostosis of facial and cranial sutures and usually manifests as one of multiple abnormal features in a group of rare but complex syndromes called *acrocephalosyndactylies*. Acrocephalosyndactyly encompasses a number of dysostoses, not all of which can be distinguished clearly. The midface retrusion gives the appearance of prognathia, although in reality the mandible is smaller than normal. In addition, there may be associated anomalies of the central nervous system (CNS; increased intracranial pressure, absent corpus callosum), the extremities, and in a small percentage of patients the heart.[128] Both the upper and the lower airway may be compromised in these patients.[129]

Multiple pathologic conditions may be seen; maxillary regression may be associated with choanal stenosis or atresia, reduction in nasopharyngeal space,[130] and palate deformity (narrow, high arched, or cleft). These features may cause respiratory compromise or obstructive apnea early in life, although as the child grows, obstruction can worsen because of continued restriction in growth of the maxillary region.[131-134] In one series, upper airway obstruction arose more frequently in Crouzon's disease and Pfeiffer's syndrome than in Apert's syndrome.

The incidence of airway obstruction has been addressed.[135] Of a total 40 patients with severe "syndromic" craniosynostosis (13 had Apert's syndrome and 27 had Crouzon's disease), 40% presented with airway obstruction (12.5% severe and 27.5% mild obstruction). There was no significant difference in the distribution of airway status between patients with Apert's syndrome and Crouzon's disease. The severe obstruction in the five patients resulted from midface hypoplasia, lower airway obstruction, tonsillar and adenoid hypertrophy, and choanal atresia.

Lower airway disease in the acrocephalosyndactylies occurs in the form of tracheomalacia, bronchomalacia, solid cartilaginous trachea lacking tracheal rings, and tracheal stenosis. Patients with tubular cartilaginous trachea have displayed a propensity for easy tracheal injury, edema, and stenosis and a potential for lower airway infection (tracheitis and bronchitis) and mucous plugging, because tracheal ciliary activity may be deficient. Sleep apnea was described in association with tracheal cartilaginous sleeve in a patient with Pfeiffer's syndrome.[136]

Airway problems can be divided into those arising from the nasal passages, nasopharynx, palate, or trachea.

Nasal septal deviation is a common feature of craniosynostosis patients and is considered a principal finding in Saethre-Chotzen syndrome. Narrowing of the nasal passages arises from maxillary hypoplasia. Although choanal atresia can occur, the usual picture is generalized narrowing. The nasopharynx is shallow because of hypoplasia of the maxilla and the altered angulation of the skull base. Palatal abnormalities further impinge on the nasopharynx. These deformities may consist of arched or ridged palates or increased thickness of the soft tissue. The degree of airway obstruction varies among these patients, being among the worst in those with Apert's syndrome. Complications have included cor pulmonale and even death from airway obstruction. Lower airway obstruction may result from a number of abnormalities, including subglottic stenosis and vertically fused tracheal cartilage. Subglottic stenosis is especially common in Crouzon's patients. Vertically fused tracheal cartilage has been reported in patients with Apert's, Crouzon's, and Pfeiffer's syndromes; the entire trachea is encased in a tube of nonsegmented cartilage. These children can be difficult to manage and usually present with episodes of recurrent lower respiratory tract infections, reactive airways disease, and chronically retained secretions.

Acrocephalosyndactyly disorders include Apert's syndrome (type I) and Apert-Crouzon (Crouzon's) disease. Acrocephalosyndactyly also occurs with other diseases, including Chotzen's (Saethre-Chotzen) syndrome and Pfeiffer-type acrocephalosyndactyly.

i. APERT'S SYNDROME. Apert's syndrome is characterized by agenesis or premature closure of the cranial sutures, midface hypoplasia, and syndactyly of the hands and feet that is symmetrical and involves at least the second, third, and fourth digits. Prevalence is estimated at 1 in 65,000 live births (~15.5 per 1 million population). Apert's syndrome accounts for 4.5% of all cases of craniostenosis. Concerning CNS abnormalities, intelligence varies from normal to mental deficiency, although a significant number of patients are mentally retarded. Malformations of the CNS may be responsible for most cases. Papilledema and optic atrophy with loss of vision may be present in cases of subtle increased intracranial pressure. Other abnormalities include cervical spine fusion, which is common and almost always involves C5-C6; osseous fusions may also be evident in other joints of the extremities and in the spine, tracheal cartilage anomalies, and diaphragmatic hernia.[137]

Airway Anomalies. These result from facial abnormalities, which include small nasopharynx and hypoplastic and retropositioned maxilla. DI in Apert's syndrome has been reported. One of the suggested mechanisms is trismus related to temporalis muscle fibrosis.[138] Both upper and lower airway can be compromised by complete or partial cartilage sleeve abnormalities of the trachea and obstructive sleep apnea.[129]

ii. CROUZON'S SYNDROME. Crouzon's syndrome (Crouzon's disease, craniofacial dysostosis) is closely related to Apert's syndrome. In 1912, Crouzon described the triad of skull deformities, facial anomalies, and exophthalmos.[139] Crouzon's syndrome is an autosomal dominant disorder with complete penetrance and variable expressivity.[140,141] About 50% of cases represent sporadic mutations, and 40% are familial. In the United States, prevalence is 1 per 60,000 live births (~16.5 per 1 million population). Crouzon's syndrome makes up approximately 4.8% of all cases of craniosynostosis at birth.[142] Crouzon's disease is associated with acanthosis nigricans (5%) and CNS defects such as chronic tonsillar herniation (73%), progressive hydrocephalus (30%), and syringomyelia.[143] Multiple sutural synostoses frequently involve premature fusion of the skull base sutures, causing midfacial hypoplasia, shallow orbits, a foreshortened nasal dorsum, maxillary hypoplasia, and occasional upper airway obstruction.[144]

Airway Anomalies. Crouzon's syndrome is characterized by premature closure of calvarial and cranial base sutures as well as those of the orbit and maxillary complex (craniosynostosis). Other features include beaked nose; short upper lip; mandibular prognathism; overcrowding of upper teeth; malocclusions; V-shaped maxillary dental arch; narrow, high, or cleft palate and bifid uvula; hypoplastic maxilla; and relative mandibular prognathism. Cervical fusion of C2-C3 and C5-C6 is present in 18% of cases.

iii. SAETHRE-CHOTZEN SYNDROME. Chotzen's syndrome is an autosomal dominant acrocephalosyndactyly that affects between 1 and 2 of every 50,000 people. Craniosynostosis, facial asymmetry, low frontal hairline, ptosis, brachydactyly, and cutaneous syndactyly of the fingers and of the second and third toes are characteristic features.[145]

b. ACROCEPHALOPOLYSYNDACTYLY

Acrocephalopolysyndactyly includes the following four types of syndromes:

- Noack's syndrome: similar to acrocephalosyndactyly type V (Pfeiffer type)
- Carpenter's syndrome: mental retardation, bradydactyly
- Sakati-Nyhan syndrome: hypoplastic tibias; deformed, displaced fibulas
- Goodman's syndrome: congenital heart defect, clinodactyly, camptodactyly, ulnar deviation, intact intelligence

i. PFEIFFER'S SYNDROME (TYPE I). Pfeiffer's (Noack's) syndrome (type I) is also a close relative of Apert's syndrome, although it is less severe. Pfeiffer's syndrome has three clinical subtypes and is manifested by craniosynostosis, broad thumbs and toes, variable maxillary retrusion, and partial soft tissue syndactyly. *Type I* is classic Pfeiffer's syndrome; affected patients have normal intelligence and a good prognosis. *Type II* is associated with cloverleaf skull, severe proptosis, and ankylosis of the elbows (Fig. 36-4). *Type III* is manifested by the absence of cloverleaf skull but the presence of elbow ankylosis and high morbidity in infancy. Other abnormalities are severe exorbitism that puts patients at risk for corneal exposure and damage, high-arched palate, crowded teeth, hydrocephalus, and seizures.[146]

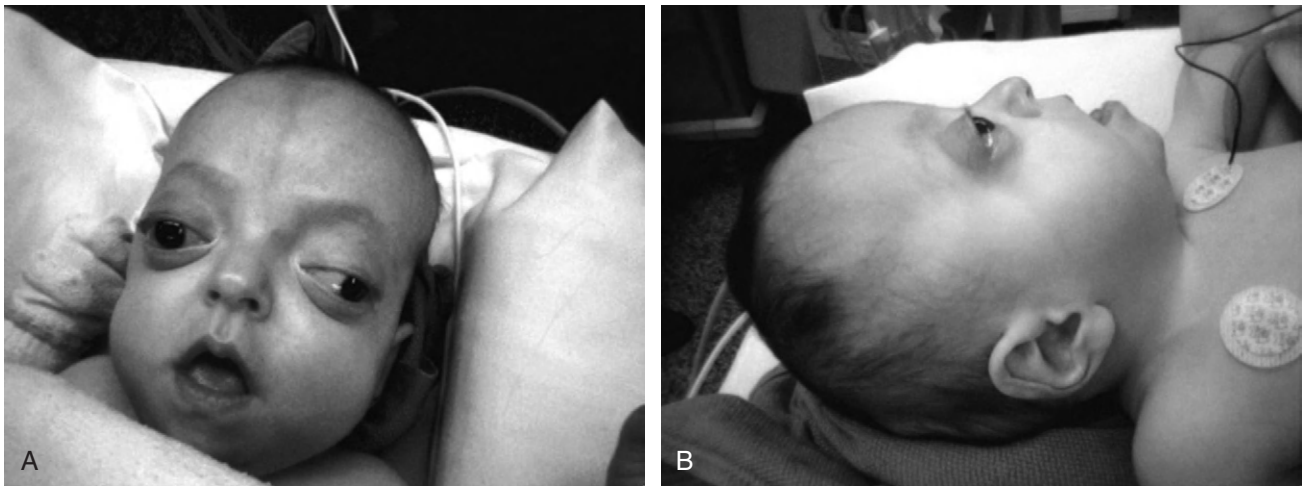

Figure 36-4 Pfeiffer's syndrome. Craniosynostosis, marked proptosis, and maxillary retrusion are present. Upper and lower airway obstruction may be present as well.

Airway Implications. As with Apert's syndrome, Pfeiffer's syndrome can arise with upper and lower airway obstruction. Congenital tracheal stenosis,[147] tracheal obstruction related to congenital tracheomalacia,[148] and obstructive sleep apnea have been reported.[149] In addition to a high incidence of vertebral fusion (73%), other radiologic abnormalities include hypoplasia of the neural arches, hemivertebrae, and a "butterfly" vertebra.[150] The C2-C3 level was most often involved, although fusion was noted at all levels of the cervical spine.

ii. CARPENTER'S SYNDROME (TYPE II). Carpenter's syndrome (type II) is typically evident at or shortly after birth. Because of craniosynostosis, the top of the head may appear unusually conical (acrocephaly) or the head may seem short and broad (brachycephaly). In addition, the cranial sutures often fuse unevenly, causing the head and face to appear dissimilar from one side to the other (craniofacial asymmetry). Other malformations of the skull and facial (craniofacial) region may include downslanting eyelid folds (palpebral fissures), a flat nasal bridge, malformed (dysplastic), low-set ears, small dental malformations,[151] and underdeveloped (hypoplastic) upper or lower jaw (maxilla or mandible), or both.

Additional abnormalities may include short stature, structural heart malformations (congenital heart defects), mild to moderate obesity, protrusion of portions of the intestine through an abnormal opening in the abdominal wall near the navel (umbilical hernia), or failure of the testes to descend into the scrotum (cryptorchidism) in affected males. Both normal intellect and mild mental retardation have been reported in patients with Carpenter's syndrome.[152,153]

Airway Implications. Difficult intubation might be expected in Carpenter's patients with hypoplastic upper or lower jaw, oral malformations, and obesity.

c. MANDIBULAR HYPOPLASIA

Mandibular hypoplasia is one of the main anomalies of the mandible, with a profound effect on airway management. Micrognathia results in posterior regression of the tongue and a small hyomental space. The mandible develops from the first branchial arch and is a feature in many rare syndromes (e.g., Pierre Robin, Treacher Collins, Goldenhar's, Nager's).[154] Although micrognathia is a feature typically shared by these syndromes, they often present additional specific features with adverse effects on the airway.

The finding of periauricular skin tags or abnormally developed external ears, which also develop from the first branchial arch, may be used as a marker for a potentially difficult airway.

Micrognathia may affect the airway in three ways: (1) the tongue may not be easily moved during laryngoscopy; (2) if the tongue is not pulled forward in the normal developmental manner, the laryngeal inlet appears more anterior and difficult to visualize; and (3) the oral aperture is not opened as easily or as widely.[155] Glossoptosis may further complicate the airway in micrognathic children. Glossoptosis makes displacement of the tongue to the left difficult, so the airway is difficult to visualize.

i. PIERRE ROBIN SYNDROME. Pierre Robin sequence, which affects 1 in 8500 newborns,[156] was described in 1923 by Pierre Robin as airway obstruction associated with glossoptosis and hypoplasia of the mandible. At present, this syndrome is characterized by retrognathia or micrognathia, glossoptosis, and airway obstruction. An incomplete cleft of the palate is associated with the syndrome in approximately 50% of these patients (Fig. 36-5). Pierre Robin sequence results from failure of mandibular growth during the first several weeks of embryogenesis. This causes posterior displacement of the tongue, which prevents normal growth and closure of the palate.

The Pierre Robin sequence represents a spectrum of anatomic anomalies whose common features include mandibular hypoplasia, glossoptosis, and cleft palate. Four types of airway obstruction have been described in patients with Pierre Robin sequence; in only 50% is the obstruction totally related to posterior positioning of the tongue.[157] Therefore, glossopexy fails to relieve airway

Figure 36-5 Pierre Robin syndrome. Marked micrognathia, glossoptosis, and cleft palate are evident. The micrognathia causes posterior displacement of the tongue, preventing normal development of the palate. Because of the upper airway obstruction present, an elective tracheostomy was performed.

obstruction in approximately half of all symptomatic patients with the Pierre Robin sequence. This may explain why the use of an oral or nasopharyngeal airway alone may not improve an already-difficult mask airway. Patients who fail to improve after glossopexy or nasopharyngeal airway placement, or both, usually require tracheostomy.[56]

Airway Implications. A large body of literature details airway management of patients with Pierre Robin sequence. Preoperative or postoperative airway obstruction and mask ventilation difficulties have been a frequent problem in these patients. In a 10-year retrospective study of 26 infants with Pierre Robin syndrome, Benjamin and Walker[158] found that awake intubation without general anesthesia proved to be safer and less difficult when a special-purpose slotted laryngoscope was used. Li and colleagues[159] reviewed the airway management in 110 children with Robin sequence. Prone posturing was effective in the treatment of mild airway obstruction in 82 patients (90.2%) who had noisy breathing sounds. Only 30% of the patients required endotracheal intubation and 6.6% required tracheostomy (all were eventually decannulated).

Alternative intubation techniques used successfully in patients with Pierre Robin syndrome include LMA,[56,160-162] FOB intubation,[88,163,164] FOI through an LMA,[52] rigid nasoendoscope with video camera or video intubation laryngoscope,[35] Trachlight with a homemade lighted stylet,[165-167] and retrograde intubation.[168] Digitally assisted endotracheal intubation and elective endotracheal intubation in prone position have also been reported.[78,79]

ii. TREACHER COLLINS SYNDROME. Treacher Collins syndrome (mandibulofacial dysostosis, Franceschetti's syndrome) results from a deficient vascular supply to the first visceral arch during the initial 3 to 4 weeks of gestation and is believed to be caused by a change in the gene on chromosome 5 that affects facial development and leads to hypoplasia of the facial bones, especially the zygoma and the mandible. There is a 50% chance that the child will pass the trait on to future generations. It is often associated with DI and airway obstruction, mainly related to micrognathia.

Facial clefting causes a hypoplastic facial appearance, with deformities of the ear, orbital, midface, and lower jaw regions. The clinical appearance is a result of the zygoma (malar bone) failing to fuse with the maxilla, frontal, and temporal bones. Highly variant degrees of involvement (complete, incomplete, abortive) can be seen, but common facial features include hypoplastic cheeks, zygomatic arches, and mandible; microtia with possible hearing loss; high-arched or cleft palate; antimongoloid slant to the eyes; colobomas; increased anterior facial height; malocclusion (anterior open bite); small oral cavity and airway with a normal-sized tongue; and pointed nasal prominence.

Most children with Treacher Collins syndrome have normal development and intelligence. However, additional physical findings have included a 40% hearing loss, dry eyes, cleft palate, and breathing problems. Both acute and obstructive sleep apneas have been described.[169,170]

An extensive array of complications can affect management. Because of the small jaw and airway, combined with the normal size of the tongue, breathing problems can occur at birth and during sleep when the base of the tongue obstructs the small hypopharynx. This can also cause serious problems during the induction of general anesthesia. Consequently, a tracheostomy may be required to control the airway adequately.

Airway Implications. The airway of children with Treacher Collins syndrome had been successfully managed with an LMA,[171-173] the Bullard intubating laryngoscope,[30] Augustine stylet,[174] and FOB. Rasch and coauthors[175] recommend that children with obstructive symptoms have laryngoscopy before anesthetic induction. If the glottic opening is visualized, inhalational induction can proceed. If the glottic structures cannot be visualized, the anesthetist must choose between awake oral or nasal intubation, elective tracheostomy, or FOI.

iii. GOLDENHAR'S SYNDROME/HEMIFACIAL MICROSOMIA. Synonyms of Goldenhar's syndrome (hemifacial microsomia) are first and second branchial arch syndrome, facioauricular vertebral spectrum, oculoauricular vertebral dysplasia, and oculoauriculovertebral spectrum disorder. The main feature of this condition is unilateral underdevelopment of one ear (which may not even be present) associated with underdevelopment of the jaw and cheek on the same side of the face. When this is the only problem, it is normally referred to as *hemifacial microsomia*, but when associated with other abnormalities, particularly of the vertebrae (hemivertebrae or underdeveloped vertebrae, usually in neck), it is referred to as *Goldenhar's syndrome*. However, these are likely two ends of the spectrum of the same condition.

The muscles of the affected side of the face are underdeveloped. There are often skin tags or pits in front of the ear or in a line between the ear and the corner of the mouth.

Children with the Goldenhar end of the spectrum may have congenital heart diseases in 5% to 58% of cases (ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot, coarctation of aorta). A variety of kidney abnormalities may also be present (e.g., ectopic kidneys, renal agenesis, hydronephrosis).

Airway Implications. Difficulties in airway management result from mandibular hypoplasia, cleft or high-arched palate, cervical vertebral anomalies, and scoliosis.[176] Suggested airway management approaches include using a lighted stylet,[177] suspension laryngoscopy,[77] or LMA under anesthesia or using awake FOI through a laryngeal mask.[178,179]

iv. NAGER'S SYNDROME. Nager's syndrome (mandibulofacial dysostosis) is a rare craniofacial disorder with fewer than 100 cases reported in the medical literature. The morphologic features of Nager's syndrome include downslanted palpebral fissures, malar hypoplasia, a high nasal bridge, atretic external auditory canals, and micrognathia (severe underdevelopment of the lower jaw). Proximal limb malformations include absent or hypoplastic thumbs, hypoplasia of the radius, and shortened humeral bones.[180] Many of the characteristic facial features may be similar to those of Treacher Collins syndrome. However, patients with Treacher Collins syndrome have more severe maxillary and zygomatic hypoplasia, downslanting palpebral fissures, and lower lid coloboma.

Among the additional problems of children with Nager's syndrome are stomach and kidney reflux and hearing loss. Cardiac and spine defects have been also reported.[181] Danziger and coworkers[181] reported four patients with a cardiac defect (type unspecified), and tetralogy of Fallot was reported in another patient.[154]

Airway Implications. Difficulties with airway management and postoperative airway obstruction may occur secondary to mandibular hypoplasia with micrognathia, restricted jaw mobility, and microstomia. Associated cleft lip or cleft palate, or both, and maxillary hypoplasia with midface deformities may further complicate airway management and appropriate mask fit during mask ventilation. The airway has been successfully managed with LMA,[182] retrograde intubation,[95] and FOI.[183]

d. SMITH-LEMLI-OPITZ SYNDROME

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive syndrome characterized by congenital anomalies affecting the airway; cardiorespiratory, gastrointestinal, and genitourinary systems; and CNS. SLOS has an incidence between 1 in 26,500 pregnancies in Canada and 1 in 50,000 pregnancies in the United States.[184,185] The syndrome results from an inborn error of cholesterol biosynthesis involving a deficiency of 3β-hydroxysterol δ7-reductase, the enzyme that catalyzes the reduction of 7-dehydrocholesterol to cholesterol.[186] Patients with SLOS can have severe growth failure, congenital anomalies affecting most organ systems, early death, developmental delay, and self-injurious and ritualistic behavior.[187-189]

Airway Implications. Patients with SLOS can be a challenge for airway management because of the typical dysmorphic facial features, including micrognathia, prominent incisors, cleft palate, and a small and abnormally hard tongue. There are several reports of DI and abnormal laryngoscopic views in patients with SLOS.[190-192] An LMA was used successfully in managing the airway in a newborn infant with SLOS.[193]

Quezado and associates[194] presented experience from a series of 20 anesthesias in 14 SLOS patients, prospectively deciding to use fiberoptic laryngoscopy as the initial technique of intubation in spite of the possible gastroesophageal reflux,[184] muscle rigidity,[192] and behavioral abnormalities in these patients.[189] In all patients, adequate spontaneous ventilation was maintained throughout the airway management. One patient had laryngospasm during induction, and one was intubated by an otolaryngologist.

e. CORNELIA DE LANGE (CRYPTOPHTHALMOS) SYNDROME

Cornelia de Lange syndrome (CDLS) is a syndrome of multiple congenital anomalies transmitted in an autosomal dominant pattern, characterized by a distinctive facial appearance, prenatal and postnatal growth deficiency, feeding difficulties, psychomotor delay, behavioral problems, and associated malformations mainly involving the upper extremities. The incidence is 1 per 30,000 to 50,000 live births.[195] A most important feature is a striking delay in the maturation of structure and function of most organ systems, including the CNS.[196] CDLS patients are short in stature (the syndrome is also called Amsterdam dwarfism),[197] have microcephaly (98%), and the facial features are perhaps the most diagnostic of all the physical signs. Cardiac defects occur in 15% of patients.[198]

Airway Implications. Intubation may be difficult because of a short (86%), often webbed neck; a high-arched (66%), sometimes cleft palate; and a small mouth with micrognathia (84%). There is also a high incidence of gastroesophageal reflux (58%) and hiatal hernia. There are a number of case reports of DI in CDLS; the airway was successfully managed by blind nasal intubation in one case.[199] Lumb and Carli[200] reported respiratory arrest in a 3-year-old child after caudal injection of bupivacaine and hypothesized that changes in intracranial pressure secondary to caudal injection might be the cause of the cardiac arrest.

f. HALLERMANN-STREIFF SYNDROME

Hallermann-Streiff syndrome (oculomandibulodyscephaly with hypotrichosis or oculomandibulofacial syndrome) is rare, with approximately 150 cases reported.[201] Cardinal features are dyscephaly with bird facies; frontal or parietal bossing; dehiscence of sutures with open fontanelles; hypotrichosis of scalp, eyebrows, and eyelashes; cutaneous atrophy of scalp and nose; mandibular hypoplasia; forward displacement of temporomandibular joints; high-arched palate; small mouth; multiple dental anomalies; and proportionate small stature.[202,203] Children with Hallermann-Streiff syndrome can have a multitude of cardiorespiratory problems. The incidence of cardiac anomalies is 4.8% and includes septal defects,

patent ductus arteriosus, and tetralogy of Fallot. Upper airway obstruction may result from small nares and glossoptosis secondary to micrognathia, which may lead to cor pulmonale.[201]

Airway Implications. The patients have natal teeth, which are brittle and may be easily broken or avulsed during laryngoscopy. The temporomandibular joint (TMJ) may be easily dislocated. At times, the TMJ is absent, making placement of the ETT by the oral route impossible. Small nostrils, deviated nasal septum, high-arched palate, and anterior larynx preclude blind nasotracheal intubation. The ascending ramus of the mandible is either underdeveloped or absent, resulting in a small mouth cavity. Intubation was achieved with difficulty in two cases with the patient under inhaled anesthesia. In both cases, mask ventilation was impossible.[203,204] Most patients with Hallermann-Streiff syndrome may require elective tracheostomy because of respiratory difficulty.[202]

g. TURNER'S SYNDROME

Turner's syndrome (gonadal dysgenesis) is caused by the absence of a second X chromosome. Manifestations of the syndrome include primary amenorrhea, genital immaturity, and short stature; intelligence is usually normal. Additional associated features that may influence the management of anesthesia include hypertension, short neck, high palate, micrognathia, the occasional presence of aortic stenosis or coarctation of aorta, and an absent kidney.

Airway Implications. Despite the micrognathia and the short neck, only one case of DI has been published.[205] Because of the small stature, unexpected unilateral endobronchial intubation was reported.[206]

3. Inflammatory Disease

a. JUVENILE RHEUMATOID ARTHRITIS (STILL'S DISEASE)

Juvenile rheumatoid arthritis (JRA) is a systemic disease of mesenchymal tissues, which may affect collagen and connective tissue of any organ and in which arthritis is one manifestation. Although it is beyond the scope of this review to describe this complex disease, the possible involvement of the heart (36% pericarditis confirmed by echocardiography) should be mentioned.

Abnormalities predisposing to DA management include temporomandibular ankylosis, mandibular hypoplasia, and cricoarytenoid arthritis. Atlantoaxial or low cervical subluxation may occur. The vertebrae may fail to grow, and ankylosis of the apophyseal joints may result.

Difficulty in maintaining the airway patency and inability to intubate the trachea are the most serious anesthetic problems in these children. Severe respiratory distress requiring endotracheal intubation has been reported in children with JRA.[207-210] Vetter[210] reported an acute exacerbation of JRA, manifesting as acute arytenoiditis and resulting in marked upper airway obstruction. Symmetrical swelling of the arytenoids and moderate swelling of the epiglottis were noted at laryngoscopy. In another case, direct laryngoscopy demonstrated immobile vocal cords, which were approximated to each other in the midline secondary to arthritis of the cricoarytenoid joints.[209] In both patients, intubation was achieved with some difficulty during direct laryngoscopy, and both recovered after large doses of steroids. Nevertheless, a fiberoptic bronchocope should always be available in case of failure.

C. Mouth and Tongue Anomalies

1. Microstomia

Microstomia (a small mouth opening) is uncommon and may be congenital or acquired. Pediatric microstomia may be congenital (in Freeman-Sheldon [whistling face], Hallermann-Streiff, and otopalatodigital syndromes) but is more often acquired after accidental thermal injuries, such as biting an electrical extension cord or ingesting household lye.[98]

a. CONGENITAL MICROSTOMIA

i. FREEMAN-SHELDON SYNDROME. Freeman-Sheldon syndrome (whistling face syndrome, windmill-vane-hand syndrome, craniocarpotarsal dysplasia, distal arthrogryposis type 2) is a rare congenital disorder defined by facial and skeletal abnormalities. The three basic abnormalities are microstomia with pouting lips, camptodactyly with ulnar deviation of the fingers, and talipes equinovarus.

Airway Implications. Anesthetic challenges include DA management, intravenous cannulation, and regional technique. Patients may be at increased risk for malignant hyperthermia and postoperative pulmonary complications. Oral FOI is considered the preferred airway management technique; the nasal route cannot be used because of small nostrils.[211] An LMA was used successfully in one patient after direct laryngoscopy proved to be impossible.[212,213]

ii. HALLERMANN-STREIFF SYNDROME. As discussed earlier, Hallermann-Streiff syndrome is a rare congenital disorder in which the presence of mandibular hypoplasia and microstomia makes intubation difficult.

Airway Implications. Again, these patients have brittle natal teeth that may be easily broken or avulsed during laryngoscopy. The TMJ may be easily dislocated[214] and at times is absent, making oral intubation impossible. The small nostrils, deviated nasal septum, high-arched palate, and anterior larynx preclude blind nasotracheal intubation. The ascending ramus of the mandible may either be underdeveloped or absent, resulting in a small mouth cavity. The options available to circumvent these problems are awake intubation, intubation over a fiberoptic bronchoscope, retrograde intubation,[214] and intubation under inhalational anesthesia. Even tracheostomy proved to be difficult in these cases; thus an experienced pediatric otolaryngologist should be available.[215]

b. ACQUIRED MICROSTOMIA

i. EPIDERMOLYSIS BULLOSA HEREDITARIA DYSTROPHICA. See "Pharyngeal Bullae or Scarring" under "Nasal and Palatal Anomalies."

Postburn contractures of the neck following a burn injury may hamper cervical hyperextension and lifting of the mandible. Direct laryngoscopy may also be difficult because of rigid scar tissue, which obscures the mandibular and laryngeal anatomy, or microstomia after retraction of scar tissue in facial burns.[216] Fiberoptic intubation is the method of choice for securing the airway,[217] but LMA can also be used successfully. Kreulen and colleagues[216] described a quick surgical neck release of contractures to facilitate endotracheal intubation in postburn patients. Bilateral commissurotomy to allow insertion of the laryngoscope into the mouth is also reported.[98]

ii. BURNS FROM LYE INGESTION. Microstomia from lye ingestion may be associated not only with limited mouth opening but also with such severe intraoral scarring that common landmarks guiding either rigid or flexible fiberoptic laryngoscopy are obscured, rendering oral and nasal intubation difficult or impossible.[98,218]

2. Diseases of the Tongue

Increase in tongue size is known as *macroglossia*, defined as a resting tongue that extends beyond the teeth or alveolar ridge.[219]

a. CONGENITAL DISEASE

i. HEMANGIOMA Hemangiomas are the most common tumor seen during infancy and affect 10% to 12% of white children.[220] Most hemangiomas (70%) are seen during the first weeks of life as an erythematous macula or a telangiectasia. All hemangiomas proliferate during the first year of life. Complications include ulceration, high-output cardiac failure, airway obstruction, and the *Kasabach-Merritt syndrome*, which results from platelet sequestration and destruction within the hemangioma as well as consumptive coagulopathy. It is fatal in 60% of children.

ii. LYMPHANGIOMA. Lymphangioma is a rare congenital disease of unknown etiology.[221] Cystic hygroma of the head and neck, with large lymphatic endothelium-lined cysts, is amenable to surgical excision. Cavernous or microcystic lymphangioma, however, is composed of small lymphatic spaces and poses a therapeutic dilemma by its propensity to cause airway and feeding difficulties and by its tendency to recur despite extensive surgery. All lymphangiomas are present at birth, even though they may not become apparent until the first or second year of life. Although the lymphatic malformation affects preferentially the submandibular space and the neck, it may extend cephalad and invade the tongue and surrounding structures.[221]

Airway Implications. Lymphangiomatous involvement of the tongue is generally diffuse and may result in dramatic macroglossia, extending the tongue outside the mouth beyond the lip margins. It is associated with airway obstruction as well as dysphagia and speech, orthodontic, and aesthetic problems. Acute enlargement of the tongue has been reported following trauma or upper respiratory tract infections. Of the multiple therapeutic methods advocated, surgical laser resection is the mainstay. Repeat laser resection may be necessary because of the tendency for recurrence. Spontaneous resolution is uncommon. In many patients, if lymphangioma is left untreated for extended periods, pulmonary hypertension and cor pulmonale may develop.

In one series, 9 of 18 patients (50%) reviewed required tracheostomy because of the size of the lymphoma and the tendency for recurrence.[222] Nasal fiberoptic intubation was used successfully in these patients.[223]

b. TRAUMATIC INJURY

Burns of the face and mouth can affect the tongue and pharynx. Aspiration of hot liquid can occur in conjunction with upper-body scald burns, leading to acute compromise of the airway, "thermal epiglottitis." Clinical features and radiologic findings are similar to those seen in patients with acute infectious epiglottitis.[224] Thermal epiglottitis can be an extremely difficult problem if subtle signs of impending airway compromise are not appreciated. The treatment should be approached with the same caution and preparedness for emergency airway management as in acute infectious epiglottitis. Immediate endotracheal intubation should be performed in those with acute respiratory distress, and prompt investigation by direct laryngoscopy in the OR is appropriate in those who have not yet developed overt respiratory distress.[225] Surprisingly, only 9.2% of 1092 burn patients admitted to the Shriners Burns Institute in Galveston, Texas, over a 5-year period needed endotracheal intubation or tracheostomy for more than 24 hours.[226] A similar incidence of endotracheal intubation (10%) was found after accidental inhalation of caustic substances.[227]

i. LYMPHATIC OR VENOUS OBSTRUCTION. Tongue swelling may result from prolonged surgical traction and local mechanical pressure. This may be caused by transesophageal echocardiography probe or by dentures in adults.[228,229] Angioneurotic edema or other reactions to drugs can cause marked swelling of the tongue, leading to life-threatening airway emergencies.[230-232]

c. METABOLIC DISORDERS

The *Beckwith-Wiedemann syndrome* (BWS) comprises a constellation of clinical features including the presence of omphalocele, macroglossia, hypoglycemia (related to hyperinsulinism), inguinal hernia with gigantism, organomegaly, renal medullary dysplasia, cardiac defects, and embryonic tumors occurring less frequently.[233]

Airway Implications. The anesthetic management of children with BWS may be complicated by a potentially difficult airway related to macroglossia.[234-236] Because of the high rate of omphalocele in this syndrome, anesthetic care is frequently required during the neonatal period. The LMA was used successfully in children with BWS.[233] Even though endotracheal intubation was possible in most case reports,[234,236,237] airway obstruction presented a major concern, especially after extubation. Swelling, secretions, and blood may precipitate complete airway obstruction. Because of the size of the tongue, additional pathology (tongue hematoma and bleeding) can increase

the difficulty of airway management and cause postoperative obstruction.[235]

i. GLYCOGEN STORAGE DISEASES. Glycogen storage diseases (GSDs) are a heterogeneous group of inherited disorders involving one of the several steps of glycogen synthesis or degradation. They occur in approximately 1 in 20,000 live births. Isolated deficiencies of virtually all the enzymes involved in glycogen processing have been described. The glycogen present in patients with GSD is abnormal in structure, amount, or both. Of the 10 Cori-type GSDs, only Cori's type II (*Pompe's disease*, also known as generalized glycogenosis or [lysosomal] acid maltase deficiency) is associated with glycogen infiltration of the skeletal muscle of the tongue, which can lead to macroglossia and potential airway issues.[238]

Airway Implications. Severe macroglossia may lead to airway obstruction during anesthetic induction, emergence from anesthesia, or the postoperative period. Associated cardiomyopathy, myopathy, nervous system involvement (especially the motor neurons in the brainstem and spinal cord), and alterations in the regulation of serum glucose concentrations are part of the clinical presentation. Only a few reports address airway problems related to macroglossia in patients with GSD.[239,240]

ii. LIPID STORAGE DISEASES. Lipid storage diseases are characterized by abnormal sphingolecithin metabolism, which results in an abnormal amount of lipid products being stored in the cells of the reticuloendothelial system. The lipids include cholesterol (xanthomatosis), cerebroside (Gaucher's disease), and sphingomyelin (Niemann-Pick disease). In *Gaucher's disease*, accumulation of the substrate leads to multiorgan dysfunction involving the brain, spleen, liver, lymph node, and bone marrow. Airway difficulties may arise because of trismus, limited neck extension, and upper airway infiltration with glucocerebroside. Kita and colleagues[241] found it was impossible to insert an LMA in a 9-year-old child with Gaucher's disease because of trismus and a narrowed oral cavity. Subsequently, FOI was performed successfully.

iii. NEUROFIBROMATOSIS. Neurofibromatoses are a group of hereditary diseases transmitted in an autosomal dominant manner and characterized by a tendency to form tumors of ectodermal and mesodermal tissues. Two distinct forms recognized on clinical and genetic grounds are designated neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF2).[242] *Von Recklinghausen's neurofibromatosis* (NF1) is one of the most common genetic disorders related to an autosomal dominant mutation and occurs at a frequency of 1 in 3000 to 4000 live births.[243] The clinical features of NF1 include café au lait spots; neurofibromas involving the skin, deeper peripheral nerves, nerve roots, and blood vessels; intracranial and spinal cord tumors; kyphoscoliosis; short stature; and learning disability. One feature common to all patients is disease progression over time. NF1 also is associated with a higher incidence of malignant disease than NF2.

Airway Implications. Possible problems in airway management of the patient with NF1 include the presence of intraoral lesions, tumors compromising the airway, and the presence of thoracic deformities or neurologic lesions. Although their presence in the upper airway is rare, neurofibromas may pose a serious problem in airway management. An estimated 5% of NF1 patients have intraoral manifestations of the disease.[244] Discrete neurofibromas may involve the tongue or the larynx.[245,246] This may cause obstruction, as well as symptoms of dyspnea, stridor, loss or change of voice, or dysphagia, and should warn the anesthetist of potential airway problems.[247] Airway obstruction after induction of anesthesia has been reported in patients with a tongue neurofibroma and a neurofibroma involving the laryngeal inlet.[244,247] Both patients required emergency tracheostomy. Even if intraoral pathology is recognized preoperatively, elective awake fiberoptic endotracheal intubation may fail because of a grossly distorted anatomy. In addition, the presence of macroglossia, macrocephaly, mandibular abnormalities, and cervical spine involvement may contribute to difficulties of airway management.[242]

d. TONGUE TUMORS

i. LINGUAL TONSIL HYPERTROPHY. The lingual tonsil, a normal component of Waldeyer's ring, consists of lymphoid tissue located at the base of the tongue. Acute inflammation and hypertrophy of lingual tonsils can occur and has been reported as one of the unusual causes of unexpected difficulty with both mask ventilation and endotracheal intubation.[248,249] Lingual tonsil hypertrophy (LTH), or lingual tonsillar hyperplasia, has occasionally been reported in children but more often occurs in adults, particularly in atopic individuals.[250,251] The etiology is unclear. However, LTH is thought to be a compensatory mechanism following removal of the palatine tonsils or secondary to a chronic, low-grade infection of the tonsils.[251,252]

Airway Implications. Clinically, LTH is not detectable on routine preoperative physical examination.[253] Although many patients are asymptomatic, others may complain of a globus sensation, alteration of voice, chronic cough, choking, or dyspnea.[254] Jones and Cohle[253] were the first to report a death secondary to failed airway management in a patient with unrecognized LTH. Asai and colleagues[248] reported a case of suboptimal ventilation and failed endotracheal intubation using various intubation strategies, including the intubating LMA and FOB.

Enlarged lingual tonsils can impinge against the epiglottis, displacing it posteriorly. This can make mobilization of the epiglottis difficult during direct laryngoscopy. Similarly, FOI is often equally difficult because the posterior displacement of the epiglottis causes interference with the insertion of the tip of the endoscope under it. These difficulties may be compounded by the presence of redundant pharyngeal tissue interfering with fiberoptic exposure and the use of muscle relaxants.[253] With the onset of neuromuscular blockade, the pharyngeal musculature relaxes, causing further posterior movement of the tongue and epiglottis.[255]

In a retrospective study of unexpected DI in 33 patients, Ovassapian and coworkers[256] reported that the only finding common to all patients was LTH observed on fiberoptic pharyngoscopy. Most of the patients had normal airway measurements (Mallampati class of I or II), and 36% of patients were difficult to ventilate.

The LMA has been used in "cannot intubate, cannot ventilate" situations caused by LTH with both success and partial success.[257-260] Asai and colleagues[248] highlighted that the LMA cannot always solve a truly glottic or subglottic problem; rather, the ventilatory mechanism must get below the lesion. If an airway cannot be established with an LMA, TTJV and cricothyrotomy are other options. Crosby and Skene[258] recommended the Bullard laryngoscope (which can be fitted with a camera) as the airway device of choice for LTH patients because its robust construction permits gentle manipulation of airway tissues, allowing it to create the necessary endoscopic airspace.

Other masses situated at the base of the tongue may displace the epiglottis and may distort the airway anatomy. Such masses include thyroglossal duct cysts and thyroid tumors.

D. Nasal and Palatal Anomalies

Nasal obstruction in pediatric patients may result from choanal atresia or stenosis, nasal masses, foreign body, trauma, or adenoidal hypertrophy, as well as choanal stenosis combined with nasal mucosal edema.[261,262] These lesions may become evident at birth or later in childhood. Nasopalatal anomalies can result in airway obstruction and feeding difficulty and can complicate airway management.

1. Choanal Atresia

Choanal atresia is a congenital anomaly of the nasal choana that results in lack of continuity between the nasal cavity and the pharynx. This entity is rare and results from failure of resorption of the nasobuccal membrane at the sixth to seventh week of gestation. Congenital choanal atresia is usually bony and unilateral, versus membranous and bilateral. Complete nasal obstruction in a newborn may cause death from asphyxia. During attempted inspiration, the tongue is pulled to the palate, obstructing the oral airway. Vigorous respiratory efforts produce marked chest retraction. Death may occur if appropriate treatments are not available; however, if the infant cries and takes a breath through the mouth, the airway obstruction is momentarily relieved. The crying then stops, the mouth closes, and the cycle of obstruction is repeated.

Many patients have associated narrowed nasopharynx, widened vomer, medialized lateral nasal wall, or arched hard palate. Associated malformations occur in 47% of infants without chromosomal anomalies. Such malformations include cleft palate, cleft lip, and Treacher Collins syndrome. The upper airway abnormalities are present in 56% of patients with choanal atresia.[263] Nonrandom association of malformations can be demonstrated using the CHARGE association, which appears to be overused in clinical practice. The components of the CHARGE association are coloboma, 80%; heart disease, 58%; atresia choanae, 100%; retarded growth, 87%; development, or CNS anomalies, 97%; genital hypoplasia, 75%; and ear anomalies or deafness, 88%. Other airway abnormalities, as part of the CHARGE association, may be present.[264]

A high level of suspicion is required to diagnose bilateral choanal atresia. Symptoms of severe airway obstruction and cyclic cyanosis are the classic signs of neonatal bilateral atresia. If bilateral, choanal atresia is a medical emergency that becomes evident after birth with severe respiratory distress and cyanosis. These signs resolve with crying and recur when crying stops or the infant attempts to feed. In unilateral disease, the signs and symptoms are less evident and thus may result in delayed diagnosis. These patients come to medical attention with unilateral nasal discharge and mouth breathing. Respiratory distress occurs when the second nostril becomes obstructed, as during an upper respiratory tract infection. Older children display nasal discharge, inability to blow the nose on the affected side, nasal speech, and mouth breathing.

The diagnosis is based on history and physical examination, inability to pass a nasal catheter into the nasopharynx, flexible fiberoptic examination, and radiologic studies. CT scan is useful in demonstrating the atretic area.

Airway Implications. Treatment of the choanal atresia is directed at providing the patient with a patent airway. Infants may benefit from the placement of an oral airway. Feeding may take place in the form of gavage. Endotracheal intubation is usually not needed unless there are associated congenital anomalies, and tracheostomy is not necessary. Surgical correction is not an emergency and uses an endonasal or a transpalatal approach, to remove the bony or membranous obstruction and part of the vomer and stent the newly created path. In infants, the transpalatal approach is used less often because of the risk of injury to the palatal growth center.

Roger and associates[265] evaluated the need for a tracheostomy and its timing in 45 patients during the evolution of CHARGE association. They found a high percentage of associated airway abnormalities: pharyngolaryngeal anomalies leading to dyspnea (58%; discoordinate pharyngolaryngomalacia, glossoptosis, retrognathia, laryngeal paralysis, DI) and tracheobronchial anomalies (40%; tracheoesophageal fistula, esophageal atresia, tracheomalacia). Tracheostomy was necessary in 13 patients (29%) despite that the posterior nasal choanae were patent in 10 patients. The authors concluded that often a tracheostomy could not be avoided in these patients, regardless of choanal patency, and that tracheostomy needs to be performed early to avoid hypoxic events.

Asher and coworkers[266] studied the association between catastrophic airway events and developmental delay in patients with CHARGE association. They found that children with CHARGE association have a propensity for airway instability, and that cerebral hypoxia contributed to the developmental delay in some of the patients. They recommended early tracheostomy rather than early choanal atresia repair in these patients to protect the CNS.

If micrognathia or subglottic stenosis is present, a difficult endotracheal intubation should be anticipated. Awake endotracheal intubation, direct laryngoscopy, indirect visual techniques, or nonvisual intubation techniques may be tried. If the patient with choanal atresia has tracheal stenosis, a smaller-than-usual ETT must be available.

2. Nasal Masses

Nasal mass lesions are rare disorders in the pediatric population, with an incidence of 1 in 20,000 to 40,000 live births.[267,268] Nasal mass lesions are a diverse group of lesions that include anomalies of embryogenesis, such as encephaloceles, dermal and nasolacrimal duct cysts, tumors, and inflammatory processes.[267] *Encephaloceles* represent herniation of CNS tissue at the level of the cranium. Although most encephaloceles are located in the occipital area, some occur anteriorly and may contain various quantities of brain tissue. Encephaloceles may be associated with midline defects. *Dermal cysts* become evident as hard intranasal masses that result from herniation of dura and subsequent contact with the skin. These midline defects may manifest as a nasal obstruction without a facial mass. There is a risk of local abscess formation and intracranial infection.

Tumors located in the nasal area in children are rare and include hemangiomas, neurofibromas, angiofibromas, hamartomas, lipomas, and rhabdomyosarcomas. Radiologic studies (CT, MRI, angiography) can elucidate the size and position of the mass and display coexistence of any cranial bone defect. The mainstay of treatment is surgery.

A foreign body in the nostril is a finding in small children, usually a toy part or food substance. This typically manifests as nasal discharge, which may be purulent, foul smelling, or bloody, and obstruction of the affected side. Diagnosis is made by history, examination of the nares, and occasionally, radiologic evaluation.

Airway Implications. Nasal masses can affect the management of the airway by interfering with mask ventilation or with direct laryngoscopy and endotracheal intubation. Nasotracheal intubation in these patients should be avoided. Extension of a cephalocele through a palatal defect interfered with endotracheal intubation in one patient.[269] All the airway implications previously discussed under choanal atresia with unilateral (or even bilateral) obstruction are valid in patients with nasal airway obstruction.

3. Palatal Anomalies

Cleft lip and cleft palate are the most common of the craniofacial anomalies, with an incidence of approximately 1 in 800 live births; 25% of cleft lip cases are bilateral, 85% of which are associated with cleft palate. There has been a move toward earlier surgical repair of both cleft lip and palate, with cleft lip repair being performed in the neonatal period in some centers.

Anomalies of the palate include cleft and high-arched deformities and hypertrophy of the alveolar ridge area. In two studies of children undergoing palate repair, the incidence of difficult laryngoscopy (Cormack and Lehane grades III and IV) was 6.5% and 7.4%.[263,270] Of the 59 patients with difficult laryngoscopy in Gunawardana's study,[263] 2.95% had unilateral cleft lip, 45.76% had bilateral cleft lip, and 34.61% had retrognathia. Interestingly, endotracheal intubation was successful in 99% of patients in whom laryngoscopy was difficult (failed intubation was 1%). There was a significant association between age and laryngoscopic view: 66.1% of patients with difficult laryngoscopies were younger than 6 months, 20.3% were 6 to 12 months, and 13.6% were 1 to 5 years old.

The presence of other associated congenital anomalies, including cardiac and renal anomalies, should always be remembered, particularly in children with isolated cleft palate. More than 150 syndromes have been described in association with cleft lip or palate, but fortunately all are rare. Some, however, have considerable anesthetic implications, and many involve potential airway problems, including the well-known Pierre Robin, Treacher Collins, and Goldenhar syndromes. Other, such as Klippel-Feil syndrome, may include abnormalities of the cervical spine.[271]

Henriksson and Skoog[272] reviewed the records of 154 patients who underwent closure of the palate and found that 84% had isolated cleft palate, 12% had Pierre Robin syndrome, and the rest had other identified syndromes. The risk of anesthetic complications was four times greater with surgery in children less than 1 year of age, with a sixfold increase when a more elaborate velopharyngoplasty technique was used.

The postoperative airway complications ranged between 5.6% and 8% in two surveys.[273,274] As a rule, patients with cleft palate with the Pierre Robin sequence or other additional congenital anomalies had an increased risk for airway problems after palatoplasty.

Palatal edema or hematoma may also develop. Swelling limited to the soft palate or uvula can cause posture-dependent airway obstruction in children.[275] Edema may result from instrumentation of the airway, burn injury, allergy, or infectious agents.

Many methods of management of DA in patients with cleft palate have been described. The use of firm pressure over the larynx (cricoid pressure) to aid laryngoscopy, with a bougie as a guide to endotracheal intubation, is relatively simple to perform by any competent anesthetist and is usually successful.[263] Other techniques (e.g., LMA, FOB) have been described,[271] especially when cleft palate is associated with different syndromes.

4. Adenotonsillar Disease

Together, the lingual tonsils anteriorly, the palatine tonsils laterally, and the pharyngeal tonsils (adenoids) posterosuperiorly form a ring of lymphoid or adenoid tissue at the upper end of the pharynx known as Waldeyer's tonsillar ring. All the structures of Waldeyer's ring have similar histology and function, and regarding airway management, they produce similar symptoms and require treatment. In response to recurrent infections, adenoids and tonsils can hypertrophy and lead to airway obstruction.[276]

Adenoidal hypertrophy peaks at 4 to 6 years of age and disappears by adolescence. Although a disease of the older child, hypertrophy can occur in the infant. One of

the major complications of adenoidal hyperplasia is *obstructive sleep apnea* (OSA). Signs and symptoms of airway obstruction include snoring and restless sleep, somnolence during the day, noisy breathing, mouth breathing, hyponasal speech, persistent nasal secretions, apnea, choking during feeding, respiratory distress, and behavioral disturbances.[163] If the condition is left untreated, failure to thrive; a characteristic, long adenoid facies with open mouth, palate, and dental malformations; and cardiovascular changes (cor pulmonale) reflective of chronic hypoxemia and hypercapnia may develop.[277]

Airway obstruction resulting from adenoid tissue is determined not by the absolute size of the adenoids but rather by their size relative to the volume of the pharynx.[249] Patients with preexisting diseases that reduce nasopharyngeal size or alter its integrity may have airway obstruction with only mild degrees of adenoidal hyperplasia. Examples are children with craniofacial anomalies (in whom the nasopharynx may be reduced in size) and those with nasal polyps, septal or turbinate malformations, MPS, or deficient pharyngeal support (Down syndrome).

Tonsillar hyperplasia is a physiologic phenomenon of childhood that peaks at about 7 years of age. It can cause OSA with restless sleep and an irregular breathing pattern, snoring, and intermittent periods of apnea as well as daytime somnolence, irritability, and poor school performance.[278] Long-standing partial obstruction of the airway can be associated with repeated hypoxic episodes and may result in pulmonary hypertension, cor pulmonale, and right-sided heart failure. Acute exacerbation of adenotonsillar hypertrophy may necessitate an emergency securing of the airway.[279,280]

The treatment of adenoidal and tonsillar hyperplasia is adenoidectomy and tonsillectomy. These are among the most common surgical procedures in children. There are multiple indications for excision of tonsils and adenoids.[276] Upper airway obstruction is of most concern for the anesthesiologist because these patients may have airway obstruction both during induction of anesthesia and in the postoperative period.

Airway Implications. Upper airway obstruction may occur after premedication, during induction of anesthesia, or following tracheal extubation. Visualization of the glottis during direct laryngoscopy may be difficult with tonsillar hypertrophy. Resection of tonsils and adenoids may not result in immediate relief of airway obstruction. Bleeding and edema can make the child susceptible to postoperative airway obstruction. Although it usually causes chronic upper airway obstruction, adenotonsillar hypertrophy can result in acute airway obstruction.[279-281] Airway assessment and management of patients with OSA caused by adenotonsillar hypertrophy are detailed in the next section.

Peritonsillar abscess in children manifests as a purulent mass surrounded by the tonsillar capsule. It occurs more frequently in untreated children with chronic tonsillitis or those who have been inadequately treated.[276] Signs and symptoms include fever, sore throat, tonsillar mass, dysphagia, drooling (caused by odynophagia and dysphagia), muffled voice, trismus (caused by irritation of pterygoid muscle by pus and inflammation), and variable degrees of toxic state. Peritonsillar abscess requires intravenous antibiotic therapy. If symptoms of airway obstruction develop or the patient fails to respond to medical therapy, needle aspiration, incision, and drainage with tonsillectomy are recommended.[276] In a prospective study of 50 adult patients with peritonsillar abscess, the Mallampati score did not correlate with the Cormack and Lehane glottic view during laryngoscopy because of palatopharyngeal arch distortion. There were no DIs in this study group.[282]

Peritonsillar abscess affects the airway in a manner similar to tonsillar hypertrophy, except that the patients may have trismus. There may be associated edema of the supraglottic area, uvula, and soft palate that exacerbates airway obstruction. Patients are susceptible to airway obstruction during either spontaneous breathing or manual mask ventilation. During direct laryngoscopy, care should be taken not to rupture the abscess. When large, the abscess may interfere with visualization of the vocal cords.

5. Obstructive Sleep Apnea

a. DEFINITION

Obstructive sleep apnea syndrome (OSAS) in children is a disorder of breathing during sleep characterized by prolonged partial upper airway obstruction or intermittent complete obstruction (obstructive apnea) that disrupts normal ventilation during sleep and normal sleep patterns.[283]

b. PREVALENCE OF SNORING

The prevalence of primary snoring ranges from 3.2% to 12.1%,[39] whereas the prevalence of OSAS ranges from 0.7% to 10.3%.[39,284,285] The ability to maintain upper airway patency during the normal respiratory circle is the result of a delicate equilibrium between various forces that promote airway closure and dilatation. This "balance of pressure" concept was first proposed independently by Remmers and colleagues[286] in 1978 and Brouillette and Thach[287] in 1979 and represents the current thought regarding the pathophysiologic mechanisms of OSAS.

The four major predisposing factors for upper airway obstruction are as follows:

- *Anatomic narrowing.* The upper airway behaves as predicted by the Sterling resistor model; the maximal inspiratory flow is determined by the pressure changes upstream (nasal) to a collapsible site of the upper airway, and flow is independent of downstream (tracheal) pressure generated by the diaphragm.
- Children with OSAS close their airways at the level of enlarged adenoids and tonsils at low positive pressures, whereas healthy children require subatmospheric pressures to induce upper airway closure.[288]
- *Abnormal mechanical linkage between airway dilating muscles and airway walls.* Control of the upper airway size and stiffness depends on the relative and rhythmic contraction of a host of paired muscles, which include palatal, pterygoid, tensor palatini, genioglossus,

TABLE 36-4
Adult vs. Childhood Obstructive Sleep Apnea Syndrome (OSAS)

geniohyoid, and sternohyoid. With contraction, these muscles promote motion of the soft palate, mandible, tongue, and hyoid bone. The activity of these muscles is dependent in particular on the brainstem respiratory network. Wakefulness conveys a supervisory function that ensures airway patency, and sedative agents that compromise genioglossal muscle activity may result in significant upper airway compromise. Roberts and others[289] demonstrated that mechanoreceptor- and chemoreceptor-mediated genioglossal activity is critical for maintenance of upper airway patency in both normal and micrognathic infants.

- *Muscle weakness.* There is little evidence to suggest that intrinsic muscle weakness is a major contributor to upper airway dysfunction. Nevertheless, in patients with neuromuscular disorders, airway obstruction is frequently observed during sleep.[290]
- *Abnormal neural regulation.* Subtle alterations in central chemoreceptor activity were found by different researchers. Gozal and others[291] reported that arousal to hypercapnia was blunted, whereas Onal and coworkers[292] found that upper airway musculature is more stimulated than the diaphragm.

c. PATHOPHYSIOLOGY AND CLINICAL PICTURE

The etiology and pathophysiology of obstructive sleep apnea in children are multifactorial, with anatomic and neuromuscular abnormalities playing a major role in the disorder.[293-297] Others, however, downplay the role of neuromuscular factors because the vast majority of children with OSAS can be cured by correcting anatomic obstructions. The narrowing of the airway lumen by hypertrophied lymphoid tissue, compliance, elasticity of the pharyngeal soft tissue, facial morphology, and the physiologic changes that occur in the pharyngeal dilators during sleep determine the severity of airway collapse.

Patients with dysmorphic constricted craniofacial development, such as those with Pierre Robin sequence; Treacher Collins, Apert's, or Crouzon's syndrome; or neuromuscular abnormalities, as in cerebral palsy and anoxic encephalopathy, have a much higher incidence of severe OSAS.

Adenotonsillar hypertrophy plays a major role in the pathogenesis of OSAS in children. The volume of lymphoid tissue in the upper airway increases from about 6 months of age up to puberty, with the maximum proliferation occurring in the preschool years, which coincides with the peak incidence of OSAS in children. Despite this narrowing of the upper airway by lymphoid tissue, most children do not develop OSAS. A normal child's airway is less likely to collapse in sleep than the adult airway.

One of the hallmarks of sleep-disordered breathing is fragmentation and disruption of normal sleep architecture. By definition, deeper levels of sleep, especially rapid eye movement (REM) sleep, are less susceptible to arousal from various stimuli, including adverse ventilatory events.[298] Oxyhemoglobin desaturation therefore tends to be more frequent and more severe during REM sleep. The hypercapnia and hypoxemia and resulting arousals associated with OSAS, at least in part, often result in a reduction in REM sleep.[298,299]

Although OSAS and hypertension are often associated in adults, children with OSAS also tend to have higher diastolic blood pressure. The cardiovascular changes appear to be the result of an increase in sympathetic tone that results from the sleep arousals, which in turn are related to the obstructive respiratory events.[300] The clinical presentation of OSAS in children has many similarities and important differences compared with the disorder in adults[245,299,301] (Table 36-4).

Unlike findings in adults, obesity is not a common factor in pediatric OSAS, although its role increases with the age of the child.[302] Abnormal sleep positions with preference for an upright position and hyperextension of the neck have been noted in children with sleep-related breathing disorders.[303]

Prolonged exposure to hypoxia and hypercarbia results in compensatory changes in the pulmonary vasculature. Pulmonary vascular resistance increases, causing increased right ventricular strain.[304] Severe cases may progress to pulmonary hypertension, dysrhythmias, and cor pulmonale.[305]

d. LABORATORY EVALUATION

Polysomnography (PSG) remains the gold standard for the diagnosis of OSAS in adults and children. In 1995 the American Thoracic Society adopted guidelines for performing PSG in children.[306] Use of PSG was recommended to differentiate primary snoring, which does not require any form of treatment, from OSAS, which can lead to cardiopulmonary dysfunction and functional

TABLE 36-5
Normal Sleep Study Measurements in Children

impairment if left untreated.[307] In general, studies show that history alone does not have sufficiently high diagnostic sensitivity or specificity to be the basis for recommending therapy.[308]

In a study of 50 healthy children, Marcus and colleagues[309] reported normal PSG values for the various respiratory events. The apnea indices (number of apneas per hours of total sleep time, TST) were 0.1 ± 0.5, with the minimum oxygen saturation being 96%, maximal drop in saturation 4%, and CO_2 over 55 mm Hg no more than 0.5% of TST. An abnormal study includes an apnea index greater than 1, oxygen desaturation greater than 4% more than three times an hour or associated with a greater than 25% change in heart rate, oxygen desaturation less than 92%, and elevation of end-tidal CO_2 to more than 52 mm Hg for more than 8% of TST, or 45 mm Hg for more than 60% of TST (Table 36-5).

e. AIRWAY IMPLICATIONS

Medical therapy of pediatric OSA is not considered to be consistently effective. Systemic or topical *steroids* may shrink lymphoid tissue, but the long-term effectiveness is not known, and a short course of systemic corticosteroids appears to be ineffective. Topical intranasal steroids appear to reduce the severity of OSAS.[310]

Adenotonsillectomy remains the mainstay of treatment for pediatric OSA.[311] The optimal age for adenotonsillectomy is 4 to 7 years, although a young age, even under 1 year, is not a contraindication for surgery for airway obstruction or OSA. Children with Down syndrome deserve further comment because they frequently have severe OSA.[312] Although data are conflicting on the usefulness of adenotonsillectomy in this group, it appears worthwhile if the tonsils or adenoids are obstructing the airway. If an adenotonsillectomy fails or is not considered appropriate therapy, uvulopalatopharyngoplasty may be effective.[39]

Several studies demonstrated the relative safety of adenotonsillectomy performed on an outpatient basis with a suitable period of postoperative observation and hydration. It appears that if children meet standard discharge criteria (normal respiratory parameters, no bleeding, adequate oral intake and pain control, normal mental status) at 4 to 6 hours after surgery, they can be safely discharged home regardless of age or preoperative diagnoses.

Minimal specific evidence exists for or against the use of *opiates and sedatives* in the perioperative period in children with OSAS. To date, there are only anecdotal reports of respiratory depression in children in response to sedatives such as chloral hydrate and in the postoperative period,[313,314] including hypoxia.[315-317] Children with OSAS appear to have increased sensitivity to opioids.

Waters and associates[318] found that children with OSAS develop more pronounced *respiratory depression* than with aged-matched control subjects when breathing spontaneously under anesthetic with the upper airway secured.[318] Addition of a small dose of opioids increased the respiratory depression in children with OSAS. The low dose of fentanyl used (0.5 µg/kg) precipitated central apnea in 46% of the OSAS group. In this study, the best predictor of opioid-induced central apnea was an increase in end-tidal CO_2 to levels greater than 50 mm Hg during spontaneous breathing after anesthetic induction. In contrast to the previous studies,[316,318-320] Wilson and coauthors[321] found no correlation between the preoperative cardiorespiratory sleep study (PSG and home sleep studies) parameters and opioid administration and postoperative outcome.

Few studies provide data pertaining to complications of surgery in children undergoing adenotonsillectomy for upper airway obstruction. All specifically address the risk of postoperative *respiratory obstruction*[315-317,319-324] (Table 36-6). The authors define "respiratory compromise" in various ways but generally consider the need for supplemental oxygen as a minimum criterion. The papers report a wide range for the incidence of postoperative respiratory complications (0-27%), primarily because their populations include different proportions of children with neuromuscular, chromosomal, and craniofacial disorders.

Young age (<3 years) and associated medical problems were found in most studies to define the highest-risk groups. A high preoperative respiratory disturbance index (apnea/hypopnea index) also seems to be a risk factor for postoperative complications.[316,317] Time to onset of respiratory compromise after adenotonsillectomy appears to be brief, although McColley and others[316] reported that one patient required 14 hours to manifest respiratory symptoms. Postobstructive *pulmonary edema* may develop in some children undergoing adenotonsillectomy for relief of upper airway obstruction. The incidence of this complication is unknown, and pulmonary edema often manifests immediately after endotracheal intubation.

The patient's position, especially after extubation, seems to be important for the development of airway obstruction. Ishikawa and colleagues[325] found that prone position increases upper airway collapsibility in anesthetized infants. Isono and associates,[326] in a study of adult patients, reported that lateral position structurally improves maintenance of the passive pharyngeal airway in OSA patients. These findings are in concordance with

TABLE 36-6
Respiratory Compromise After Adenotonsillectomy in Children with Obstructive Sleep Apnea Syndrome (OSAS)

Author	Year	Methodology and Rating	Inclusion Criteria	No.	Rate of Respiratory Compromise	Comments
McGowan et al.[324]	1992	Case series, level IV	Clinical upper airway obstruction	53	25%	Risk factors for complications were prematurity, adenoidal facies, preoperative respiratory distress.
McColley et al.[317]	1992	Case series, level IV	Abnormal PSG	69	23%	Onset up to 14 hours postop. Main risk factors were age and preop RDI.
Price et al.[318]	1993	Case series, level IV	Clinical upper airway obstruction, nap PSG	160	19%	Associations with risk factors (age, preop PSG) asserted but not quantitated.
Rosen et al.[319]	1994	Case series, level IV	Abnormal PSG	37	27%	Postop obstruction occurred within hours of surgery. All patients with complications were complex and had a higher mean RDI preop.
Helfaer et al.[320]	1996	Case series, level IV	Mild OSAS by PSG (no severe cases)	15	0%	No postop desaturation or obstruction in children with mild OSAS.
Geber et al.[321]	1996	Case series, level IV	Questionnaire	292	15% (38% if age <3 yr)	Included complex patients. Respiratory compromise developed only in patients who snored preop.
Rottschild et al.[325]	1994	Case series, level IV	Clinical diagnosis	69	7%	Specific diagnostic criteria for OSAS not specified.
Bivati et al.[320]	1997	Case series, level IV	Clinical diagnosis	3552 3 with PSG	25% (36% with abnormal PSG)	Included complex patients. No patient with normal PSA has postop respiratory complications.
Wilson et al.[322]	2002	Case series, retrospective	Abnormal PSG	163	21%	96% were managed in recovery room or ward setting.

the current practice of extubating and transporting children in the lateral position.

In a retrospective study of 163 OSAS children, Wilson and coworkers[321] found a 21% incidence of respiratory compromise requiring medical interventions after adenotonsillectomy. Ninety-six percent of the children with OSAS were managed in a recovery room or ward setting. Six children required postoperative admission to the intensive care unit (ICU).

Most of the polysomnographic studies done weeks after adenotonsillectomy in children with OSAS reported a cure rate between 85% and 100%.[327,328] A major concern in the immediate postoperative period is the effect of residual anesthesia, pain, sedative and analgesic medication, and edema of the pharyngeal tissues on the complication rate in this category of patients. Helfaer and coauthors[315] tried to respond to this question by comparing preoperative and first-night postoperative polysomnograms in children with mild OSAS.[315] Surprisingly, most of the children had improvements in their sleep studies on the night of surgery. These findings were not affected by the choice of intraoperative anesthetic. Specifically, intraoperative administration of narcotics was not associated with postoperative respiratory impairment. Even though this study was performed on a relatively small number of patients with mild disease, it was concluded that children with mild OSAS can be safely discharged home on the day of surgery (see Table 36-6).

In our institution, the criteria for postoperative admission are severe OSAS; age less than 3 years; associated craniofacial anomalies (including Down syndrome); associated neuromotor, cardiac, or pulmonary diseases; upper airway burn; hypotonia; morbid obesity; or children with recent upper respiratory tract infection.

In conclusion, the anesthetic management of OSAS should be directed toward assessing and managing the coexisting cardiac or pulmonary diseases; managing the airway, especially in syndromic children; minimizing the amount of opiates used intraoperatively; using capnography in postoperative period; and preventing and managing the possible postoperative complications. Preoperative sleep studies are necessary for a positive diagnosis and for decisions regarding postoperative monitoring. Therefore, anesthesiologists need to be familiar with reading a sleep study and interpreting PSG results.

6. Retropharyngeal and Parapharyngeal Abscesses

The various cavities and virtual spaces in the pharynx and neck are in anatomic continuity with one another. The retropharyngeal, parapharyngeal, peritonsillar, and submandibular spaces intercommunicate, and infection in one can extend to the others. The superior limit of the retropharyngeal space is the base of the skull; inferiorly, it extends into the mediastinum to the level of the tracheal bifurcation.

Retropharyngeal abscess is a rare but potentially fatal infection of the pharyngeal wall. It occurs primarily in pediatric patients; in one study more than half of the patients were younger than 12 months.[329] In children, it usually results from suppurative involvement of lymph nodes located in the retropharyngeal space. These nodes drain lymph from the pharynx, nasopharynx, paranasal sinuses, and middle ear. The most common pathogens are *Staphylococcus aureus* (25%), *Klebsiella* species (13%), group A streptococci (8%), and a mixture of gram-negative and anaerobic organisms (38%).[329,330] Other causes of retropharyngeal abscess include spread of infection from pharyngitis or peritonsillar abscess, penetrating trauma, and foreign body ingestion.

Clinical presentation of retropharyngeal abscess varies with the patient's age. Most children have fever, some degree of toxic appearance, a hyperextended or stiff neck, dysphagia, drooling, trismus, muffled voice, and respiratory distress. Infants and young children may have stridor. Older children with mediastinal involvement may, in addition, complain of chest pain. Physical examination may reveal cervical lymphadenopathy and pharyngeal swelling. A lateral radiograph of the neck typically shows widening of the retropharyngeal prevertebral soft tissue. CT is helpful in the diagnosis of retropharyngeal abscess but has difficulty differentiating cellulites and abscess. Lateral neck radiography was found to be very specific when the air sign was present.[331] Ultrasound imaging can also distinguish between suppurative and presuppurative stage.[332] Chest radiographs may show mediastinal involvement and tracheal deviation.[333]

Complications of retropharyngeal abscess include airway obstruction, abscess rupture, pneumonia, sepsis, and extension of the disease into the mediastinum and the carotid sheath, causing mediastinitis, jugular vein thrombosis, or penetration into the carotid artery. Treatment consists of airway support, antibiotic therapy, and early incision and drainage.

Airway Implications. The danger of retropharyngeal abscess is related to the potential for rapid progression to airway obstruction. In one report, 5 of 65 patients required tracheostomy.[334] There is also an ever-present risk of abscess rupture and aspiration of pus into the airway. The clinical presentation of children with retropharyngeal abscess can mimic that of children with epiglottitis and croup. The mortality rate is high; exact incidence is not known. In a retrospective study, Ameh[335] reported two deaths among 10 children surveyed; one child died before the abscess was drained, and the other died in the postoperative period because of laryngospasm. Coulthard and Isaacs[329] reported two deaths in 31 children with retropharyngeal abscess.

All patients with the diagnosis of retropharyngeal abscess must be considered to have a DA. The management depends on the severity of airway distress and degree of patient's cooperation. In most children, general anesthesia is required for airway management because few patients, if any, accept an awake technique. General anesthesia may be induced by inhalation of sevoflurane and oxygen with emergency plans for securing the airway should airway obstruction develops. If not in place, an intravenous line should be secured and atropine administered. It is advantageous to maintain spontaneous ventilation because neuromuscular blockade may relax the pharyngeal musculature and potentiate airway obstruction with an already-reduced pharyngeal space.

After adequate anesthetic depth is achieved, gentle direct laryngoscopy should be attempted, taking care not to rupture the abscess. If endotracheal intubation is not possible after limited attempts at direct laryngoscopy, a surgical airway should be considered for those with large lesions. In children with minimal respiratory distress and adequate mask air exchange, other intubation techniques (indirect visual or nonvisual) may be tried first. It is important to take special precautions not to traumatize the abscess during endotracheal intubation. Blind attempts at intubation, insertion of an LMA or oral airway, or overzealous direct laryngoscopy may result in rupture of the abscess.

7. Pharyngeal Bullae or Scarring

Epidermolysis bullosa (EB) describes a group of genetically determined mechanobullous disorders that vary in course and severity, ranging from relatively minor disability to death in early infancy.[336,337] They are characterized by an excessive susceptibility of the skin and mucosa to separate from the underlying tissues and form bullae following minimal mechanical trauma. The affected areas can be considerable in size as the bullae enlarge by expanding and tracking along the natural tissue planes. As with all blisters, they can be extremely painful. More than 20 types of EB are described,[338] with three major subtypes: *dystrophic*, *simplex*, and *junctional*, with each broad category of EB containing several subtypes.

a. DYSTROPHIC EPIDERMOLYSIS BULLOSA

Dystophic epidermolysis bullosa (DEB), which was first described by Fox in 1879, is probably the most frequent type of EB to have surgical treatment.[339,340] The prevalence of DEB is approximately 2 in 100,000 children.[341] The majority of DEB patients have wounds that are present at birth or shortly after, with a variety of blister sizes, some even exceeding 10 cm in diameter. The blisters of DEB are usually flaccid and filled with either a clear or a blood-stained fluid. New blisters tend to develop less frequently as the child ages. Scarring is unusual after a single episode of blistering, but blistering is much more easily provoked in previously blistered areas; it is this recurrence that causes atrophic scars to form. As a result of repeated skin infection, injury, and healing, patients with the dystrophic form develop *contractures*, which may involve the skin of the neck and mouth.

Oral, pharyngeal, and esophageal blistering is common in DEB. The recurrent blistering leads to progressive contraction of the mouth (causing limited opening) and fixation of the tongue. The associated pain and resulting dysphagia lead to a reduction of nutritional intake because eating is a painful, slow, and exhausting experience. Gastroesophageal reflux (GER) is common in patients with DEB. Esophageal scarring leads to dysmotility and the formation of strictures or webs, which contributes to the dysphagia by exacerbating oral, pharyngeal, and esophageal ulceration and also by increasing dental decay.

b. EPIDERMOLYSIS BULLOSA SIMPLEX

Almost all cases of epidermolysis bullosa simplex (EBS) are inherited in an autosomal dominant manner.[339] Although the exact prevalence of EBS is not known, it is thought to be approximately 1 or 2 in 100,000 children.[336] There are three major subtypes: Dowling-Meara, Weber-Cockayne, and Koebner.

Only the *Dowling-Meara* type (EBS herpetiformis) has airway implications. The onset of this type of EBS is usually in early infancy. There is a great range in the severity of Dowling-Meara, from relatively mild to exceptionally severe with death during the neonatal period. Oral involvement is usually not prominent, but a number of severely affected neonates exhibit extreme oropharyngeal involvement, which interferes with feeding. Patients may also have a tendency for GER and aspiration. Laryngeal involvement, causing a hoarse cry, is also regularly seen in Dowling-Meara EBS.

c. JUNCTIONAL EPIDERMOLYSIS BULLOSA

There are three major subtypes of junctional epidermolysis bullosa (JEB): Herlitz, non-Herlitz, and JEB with pyloric atresia. *Herlitz* JEB is the most common form. Formerly known as "lethal" JEB, it affects the larynx, producing a characteristic hoarse cry in infancy. This hoarseness is usually followed by recurrent bouts of stridor (caused by granulation tissue and not usually fresh blisters), each with the potential risk of fatal asphyxiation. The mouth and pharynx are often severely affected, causing substantial pain and feeding difficulties, which in turn lead to a profound failure to thrive. Death in the first 2 years of life is usual in Herlitz JEB, either from acute respiratory obstruction or from overwhelming sepsis related to a poor nutritional state.

d. AIRWAY IMPLICATIONS

Children with EB, especially DEB, are more likely to have airway management problems, with the risk of DI secondary to contracture formation. In addition to oral, pharyngeal, and laryngeal problems, head and neck skin involvement and contractures may make positioning for laryngoscopy difficult.[342] A DI should always be suspected and contingency plans made before embarking on anesthesia. To avoid prolonged facial manipulation during the procedure, airway maintenance by intubation is often preferred.[343] To reduce the risk of new laryngeal bullae formation, an ETT a half to one size smaller than predicted may be necessary. If a cuffed tube is required, the cuff should be slightly inflated. The risk of bullae formation after intubation is low because the larynx and trachea are lined with ciliated columnar epithelium rather than the squamous epithelium that lines the oropharynx and esophagus.[344]

Although securing the ETT by wiring it to a tooth has been advocated,[345] a more conservative approach is to tie the tube in place with either ribbon gauze or Vaseline gauze and a collar of adhesive tape around the ETT to prevent the ties from slipping. Nasal intubation can be performed, preferably with a fiberoptic scope, but blind nasal intubation should be avoided. Blind techniques (e.g., blind oral intubation or lighted stylet) have been used successfully but may result in trauma to the laryngeal structures if multiple unsuccessful attempts are required and probably should be avoided.[346]

The lips are lined with lubricated gauze at the place they touch the ET and also underneath the tie to prevent chafing. An intravenous cannula should be secured with a nonadhesive dressing. Central venous and arterial cannulas, if required, should be sutured in place.

In caring for patients with EB, it is important to take general precautions to protect the integrity of the skin from trauma, friction injury, and adhesive products. Areas susceptible to pressure (e.g., below face mask) should be generously lubricated. Patients receiving systemic corticosteroid therapy may need perioperative supplementation.

E. Laryngeal Anomalies

1. Laryngomalacia

Laryngomalacia is the most common congenital abnormality of the larynx and is characterized by a long, narrow epiglottis and floppy aryepiglottic folds.[341] It is the most common cause of noninfective *stridor* in children.[341] Stridor, usually present at birth, may appear after weeks or months. It may appear only with crying or in the presence of an acute upper respiratory infection. The stridor is inspiratory, high pitched, and more obvious in the supine position.[197] In the mild form, stridor peaks at 9 months and then levels off, declines, and disappears by 2 years of age.[347] Severe laryngomalacia may cause upper airway obstruction, cyanosis, failure to thrive, and cor pulmonale. GER has been reported as well, and antireflux therapy is recommended.[348]

Diagnosis of laryngomalacia is by endoscopy, particularly laryngoscopy. Indirect laryngoscopy is not practical for infants and children. Flexible endoscopy or rigid endoscopy may be necessary. General anesthesia is required.

Airway Implications. Patients with laryngomalacia are at risk for airway obstruction, and preparations for management of the difficult pediatric airway must be made. A gradual inhalation induction with 100% oxygen is performed, maintaining spontaneous ventilation. CPAP with 10 cm H_2O may be necessary to overcome obstruction, along with an oral airway and jaw lift. The time required for an adequate depth of anesthesia may be delayed in cases of airway obstruction. When deep levels of anesthesia are achieved, direct laryngoscopy may be performed. Topicalization of the vocal cords prior to laryngoscopy decreases the incidence of coughing. As stated previously, one should calculate the maximum dose before topicalization so that toxic doses are avoided.

Surgical treatment consists of either aryepiglottoplasty or laser excision of redundant supraglottic tissue.[349] Endoscopic division of the aryepiglottic folds has been suggested as the first-line therapy for severe laryngomalacia.[350]

2. Epiglottitis

Epiglottitis, more appropriately called *supraglottitis*, is a life-threatening infection of the epiglottis, aryepiglottic

folds, and arytenoids. It is a true airway emergency because supraglottitis may progress rapidly to complete airway obstruction. Supraglottitis is classically described as occurring between 2 and 8 years of age, although it can occur in infants, older children, and adults.[351] *Haemophilus influenzae* type B (Hib) is the most common causative agent, although other organisms have been reported. *Pseudomonas*, group A β-hemolytic *Streptococcus*, and *Candida* have been reported in the literature as etiologies of epiglottitis as well.[351-353] The introduction of the *H. influenzae* conjugate vaccine has dramatically reduced the incidence of supraglottitis, but vaccine failure does occur.[353] A high index of suspicion for the diagnosis of supraglottitis should be maintained because the disease has not been completely eliminated.

Children with epiglottitis often present with the four Ds of supraglottitis: drooling, dyspnea, dysphagia, and dysphonia. These children are described as "toxic appearing" and anxious, preferring to rest in the tripod position (upright sitting position, leaning forward with the mouth open).[352] High fevers and signs of respiratory distress evolve over a few hours. Stridor, if present, is usually inspiratory.[354]

Diagnosis is usually based on clinical findings. Radiographs are indicated only if the child has no respiratory distress and a physician capable of controlling the DA is in attendance. A lateral neck radiograph obtained with hyperextension during inspiration is the single best exposure. Classic findings include round, thick epiglottis (thumb sign), loss of the vallecular airspace, and thickening of the aryepiglottic folds.[351] Definitive diagnosis is made at laryngoscopy in the OR. No one should attempt to visualize the posterior pharynx in the emergency room. Dynamic airway collapse may occur, and complete obstruction ensues.

Airway Implications. The mainstay of therapy for supraglottitis is to obtain an airway, usually with a multidisciplinary approach in an organized and controlled manner. An otolaryngologist capable of performing an emergency tracheostomy is present at the induction. The difficult pediatric airway cart, a rigid bronchoscope, and tracheostomy set must be in the OR. When dealing with the child with epiglottitis, it is vital that the child remain calm. If separation from the parents is too stressful, parental presence at induction, after proper preparation, should be considered. Sedation is not advised in this situation. After placement of a precordial stethoscope and pulse oximeter, a gradual inhalation induction with 100% oxygen is performed with the child in the sitting position. Maintenance of spontaneous ventilation is crucial; CPAP at 10 cm H_2O may be beneficial in maintaining a patent airway. Once anesthesia is induced, an intravenous line is placed and a volume bolus of 10 to 30 mL/kg of lactated Ringer's solution is given. The rest of the monitors are applied, and atropine or glycopyrrolate is given intravenously before laryngoscopy for its antimuscarinic effect. After an adequate depth of anesthesia is obtained, direct laryngoscopy is performed and an oral ETT is placed. Identification of a cherry-red edematous epiglottis is diagnostic. A tip for successful intubation is that gentle pressure applied to the chest may reveal expiratory gas bubbles. A styletted ETT, one or two sizes smaller than predicted, is placed into the trachea.[354] If the patient cannot be intubated, the DA algorithm is followed. Rigid FOB may be attempted if the condition permits, or a surgical airway is obtained.

After the appropriate cultures are obtained, antibiotic therapy is initiated. Some advocate changing the oral ETT to a nasotracheal tube because of the greater stability of the nasotracheal tube. The mean duration of intubation ranges from 30 to 72 hours. Extubation is performed when the patient demonstrates clinical improvement and there is evidence of an air leak around the ETT. Some clinicians advocate the use of dexamethasone before extubation to reduce the incidence of postextubation stridor.[351]

3. Congenital Glottic Lesions

Congenital laryngeal anomalies include laryngomalacia, vocal cord paralysis, laryngeal web, and atresia. *Vocal cord paralysis* is the second most common cause of congenital laryngeal malformations.[355] Bilateral vocal cord paralysis is often associated with CNS abnormalities such as Arnold-Chiari malformation. Birth trauma may also induce vocal cord paralysis. The presentation of bilateral vocal cord paralysis is high-pitched inspiratory stridor and a normal or mildly hoarse cry. Severe airway obstruction may develop that requires emergency intubation or tracheostomy.[355] Occasionally, vocal cord paralysis resolves spontaneously or after a ventriculoperitoneal shunt is placed.[356] In unilateral paralysis, the left side is more frequently affected. Cardiovascular and mediastinal problems are often associated with unilateral paralysis.[355] Unilateral paralysis arises with a weak cry.[276] It seldom requires surgery.[356]

Laryngeal webs occur when there is failure of recanalization of the larynx during embryologic development. In general, webs occur at the level of the glottis, causing respiratory distress at birth. They may be thin and limited to the glottis, with minimal airway obstruction. Significant airway obstruction is usually the result of more extensive webs. These webs are thick, extending into the subglottis. Surgical treatment is endoscopic division of the web for smaller webs. Laryngotracheal reconstruction may be needed for extensive webs.

Laryngeal atresia is a rare and often fatal anomaly. Survival depends on the presence of an associated tracheoesophageal fistula or immediate tracheostomy at birth.[355]

Airway Implications. The degree of obstruction determines the method used for airway management. Severe forms require a surgical airway; milder cases may be managed with intubation. Intubation may be performed either awake or after inhalation induction, depending on the patient and the situation. Preparations for a failed intubation should be made.

4. Recurrent Respiratory Papillomatosis

Laryngeal papillomatosis, or recurrent respiratory papillomatosis (RRP), is the most frequent benign tumor of the larynx, with an incidence in the United States of 4.3 per 100,000 children. It is caused by the human

papillomavirus (HPV) types 6 and 11. It is also the second most common cause of hoarseness in children.[357] Laryngeal papillomas are located primarily in the larynx on the vocal cord margins and epiglottis; however, any part of the respiratory tract may be affected.[358] RRP may affect children and adults. The juvenile form is often more aggressive than the adult form of the disease. Pediatric patients with RRP often wheeze and the diagnosis may be delayed. The primary symptom of RRP is hoarseness or a weak cry. Stridor is often the second symptom to develop, usually starting as inspiratory and progressing to biphasic with advancing disease.[357] Other symptoms may include chronic cough, paroxysms of choking, failure to thrive, and respiratory fatigue.[358] Diagnosis is made with a flexible fiberoptic nasopharyngoscope. If patient's cooperation limits the examination, general anesthesia may be needed. Treatment consists of CO_2 laser microlaryngoscopy, which vaporizes the lesions and causes minimal bleeding. Frequent surgical procedures may be required to control the disease. Medical management includes the use of acyclovir, interferon-α, cidofovir, and indole 3-carbinol.[358]

Airway Implications. Airway obstruction has been reported with induction of anesthesia in patients with RRP.[359] Anesthetic evaluation should include careful preoperative assessment of the airway and the emotional status of the child.[360] Sedation is necessary because these patients require frequent surgeries, but it should be avoided in patients with respiratory compromise. In appropriate cases, parental presence in the OR may be beneficial. Anesthesia should be induced with an inhalational induction in 100% oxygen while maintaining spontaneous respirations. Patients may be apprehensive about the mask, and an alternative technique, such as cupping the hands around the circuit to increase the concentration of the inhalational agent, may be useful.[360] This is a recognized DA, and appropriate equipment and personnel should be in the OR before induction.

5. Laryngeal Granulomas

Laryngeal granulomas are frequently the result of prolonged endotracheal intubation.[108] However, granuloma formation has been reported after short-term intubation as well. Other factors contributing to granuloma formation include female gender, size of the ETT, position of the ETT, traumatic intubation, and excessive cuff pressure.[82] The incidence in adults has been described as 1 in 800 to 1 in 20,000.[361] Typically, granulomas form in the posterior glottis on the medial aspect of the arytenoids.[106] Hoarseness is a common feature. Treatment consists of inhaled steroids, antireflux measures, antibiotics, and surgical removal under direct visualization.[82]

Airway Implications. If the granulomas are large or pedunculated, airway obstruction may be seen. Awake intubation may be indicated in the adult population, or rarely, inhalation induction with intubation in the pediatric population. ETTs smaller than predicted should be immediately available.

6. Congenital and Acquired Subglottic Disease

a. SUBGLOTTIC STENOSIS

Subglottic stenosis may be classified as congenital or acquired. It is defined as the presence of an abnormally small subglottic lumen (<3.5 mm in diameter in newborn).[355] *Congenital subglottic stenosis* is the third most common congenital anomaly.[356] Patients may present with mild or severe airway obstruction. Another common presentation is recurrent croup.[355] Patients who develop recurrent croup with upper respiratory tract infections during the first years of life should be evaluated for congenital subglottic stenosis. Acquired subglottic stenosis is usually the result of endotracheal intubation. Definitive diagnosis is made with rigid endoscopy. Treatment consists of anterior or multiple cricoid splitting with cartilage graft interpositioning (mitomycin). The success rate for these procedures is approximately 90%.[356]

b. CROUP

Croup, or *laryngotracheobronchitis*, is the most common cause of infectious airway obstruction in children. The incidence of croup in the United States is 18 per 1000 children annually. The peak incidence is 60 per 1000 among children 1 to 2 years of age.[351] Croup affects children between the ages of 6 months and 4 years, with peak incidence in early fall and winter. Parainfluenza type I is the most common etiologic agent responsible for croup. This is a viral infection that affects the subglottic region of the larynx, causing edema. The disease has a gradual onset, usually arising after an upper respiratory tract infection. Symptoms include inspiratory stridor; suprasternal, intercostal, and subcostal retractions; and a croupy or barking cough. Anteroposterior films of the neck show the classic church steeple sign (symmetrical narrowing of the subglottic air).[351]

For mild cases, treatment consists of breathing humidified air or oxygen.[351] In severe cases, treatment with nebulized racemic epinephrine (0.25-0.5 mL in 2 mL of saline) is indicated. Repeated treatments, every 1 to 2 hours, may be necessary. Because the duration of action is brief (<2 hours), rebound respiratory distress may develop after treatment, and observation is necessary. Studies suggest that patients may be discharged from the emergency room after a 3-hour observation period provided that the parents are reliable and easy access to the ER is available. Racemic epinephrine should be used with caution in patients with tachycardia or underlying cardiac abnormalities, such as tetralogy of Fallot or idiopathic hypertrophic subaortic stenosis.[362]

After years of debate, the use of *steroids* in the treatment of mild to moderate viral croup has gained acceptance.[363-365] Treatment with steroids has been associated with a reduction in admissions and length of stay.[365] Dexamethasone, 0.6 mg/kg (maximum dose, 10 mg) intravenously, is the standard dose. Dexamethasone (0.6 mg/kg) given orally was associated with more rapid resolution of symptoms than nebulized dexamethasone.[363] *Heliox*, a mixture of helium and oxygen, has also been used in the treatment of viral croup. Helium is an inert, nontoxic gas that has low specific gravity, low viscosity, and low density. Because of these properties,

helium reduces airway resistance by decreasing turbulent flow in the airway.[366] If the preceding measures fail, intubation is necessary.

Airway Implications. As with all cases of upper airway obstruction, preparations for management of a difficult pediatric airway must be made. The appropriate equipment and personnel must be in the OR at induction. A gradual inhalation induction is performed with 100% oxygen maintaining spontaneous respirations. Intubation is performed with an ETT one or two sizes smaller than predicted, to decrease the risk of subglottic stenosis. Extubation is performed after an adequate air leak around the ETT is demonstrated.

F. Tracheobronchial Anomalies

1. Tracheomalacia

Tracheomalacia is characterized by weakness of the tracheal wall related to softness of the cartilaginous support. This allows the affected portion to collapse under conditions where the extraluminal pressure exceeds the intraluminal pressure.[367] Tracheomalacia may be classified into either congenital (primary) or acquired (secondary). *Congenital tracheomalacia* may be further subdivided into idiopathic or syndromic conditions. Tracheoesophageal fistula, CHARGE syndrome, and DiGeorge's syndrome are associated with congenital tracheomalacia. *Acquired tracheomalacia* is typically caused by extrinsic compression of great vessels or is secondary to bronchopulmonary dysplasia. Symptoms include episodic respiratory distress, persistent dry cough, wheezing, dysphagia, and recurrent respiratory infections. Failure to wean from the ventilator or failure of extubation may also be indicative of tracheomalacia.[367]

Airway Implications. Airway obstruction has been reported in patients with tracheomalacia during general anesthesia, even in asymptomatic patients.[368,369] Collapse of the affected segment occurs during expiration and with particularly forceful expiration or coughing. CPAP with or without intermittent positive-pressure ventilation (PPV) can alleviate the obstruction.[370] Noninvasive PPV through a face mask has been used successfully to prevent reintubation in an infant with tracheomalacia postoperatively.[371]

2. Croup

See previous discussion.

3. Bacterial Tracheitis

Bacterial tracheitis, formerly called *pseudomembranous tracheitis* or *membranous laryngotracheobronchitis*, is a potentially life-threatening disease. It is an infection of the subglottic region, and progression to full airway obstruction is possible. Bacterial tracheitis is believed to result from a bacterial superinfection preceded by a viral upper respiratory tract infection.[372] The peak incidence is in the fall and winter, affecting children from age 6 months to 8 years. *S. aureus*, *H. influenzae*, α-hemolytic *Streptococcus*, and group A *Streptococcus* are the usual causative agents. Patients usually present with a several day history of viral upper respiratory symptoms followed by rapid deterioration. The patient develops high fever, respiratory distress, and a toxic appearance. In contrast to those with supraglottitis, these patients have a substantial cough, appear comfortable when supine, and tend not to drool.[351]

In contrast to those with laryngotracheobronchitis, patients with bacterial tracheitis do not respond to racemic epinephrine or corticosteroids. Radiographs of the airway often show irregular tracheal densities and subglottic narrowing.[372] Patients with severe respiratory distress should be taken to the OR for rigid endoscopy and intubation.

Airway Implications. Patients with bacterial tracheitis have the potential for airway obstruction. Preparations for management of the difficult pediatric airway must be made, including a rigid bronchoscope. Inhalation induction with maintenance of spontaneous respirations is preferred. Endoscopy is performed with removal of the sloughed mucosa. Intubation is performed, and specimens for culture and Gram stain are taken. Broad-spectrum antibiotics are started and continued for 10 to 14 days. Intubation is usually required for 3 to 7 days.[351]

4. Mediastinal Masses

Anesthesia for patients with mediastinal masses, usually *anterior* mediastinal masses, is associated with a high risk of airway obstruction, hemodynamic instability, or even death from extrinsic compression of three structures: the heart, great vessels (primarily superior vena cava), and the trachea and bronchi.[373] Induction of anesthesia and PPV may exacerbate the airway compression in a variety of ways. Loss of intrinsic muscle tone, reduced lung volumes, and a reduced transpleural pressure gradient combine to increase the effects of extrinsic compression. Cardiac arrest, superior vena cava syndrome, and airway occlusion are problems that can occur during induction of anesthesia.[374-376] Airway compression during induction of anesthesia can occur even in asymptomatic patients.[375] These complications may be unresponsive to position changes or open cardiac massage.

Mediastinal masses may be divided into anterosuperior, visceral, and posterior. The anatomic location of the mediastinal mass varies with age. In children, mediastinal masses are predominantly found in the *posterior* mediastinum. *Neurogenic tumors*, especially neuroblastomas, are the most common mediastinal tumor in young children. *Germ cell tumors* are the second most common anterior mediastinal mass in children. In adolescents, *lymphomas* are the most common anterior mediastinal mass.[373]

Symptoms such as orthopnea, stridor, and wheezing are ominous signs of airway obstruction.[377] Positional dyspnea, tachyarrhythmia, and syncope suggest right-sided heart and pulmonary vascular compression. Syncope during a Valsalva maneuver suggests significant vascular encroachment.[373] Children usually display symptoms earlier than adults. Small decreases in airway diameter result in increased resistance. Preoperative evaluation should focus on symptoms of respiratory compromise in the supine and standing positions. Intolerance of the supine position indicates compression by the mass on the

trachea, heart, pulmonary artery, or superior vena cava. Preoperative CT scan should be obtained. Minimum criteria for safe administration of general anesthesia should be a tracheal cross-sectional area at least 50% of predicted and a peak expiratory flow rate at least 50% of predicted value.[378]

Airway Implications. Patients with a mediastinal mass are considered difficult to ventilate. Avoidance of general anesthesia, muscle relaxants, and PPV are the mainstay of anesthetic management for patients presenting for biopsy before irradiation or chemotherapy. Biopsies should be performed, if at all possible, under local anesthesia.[379] Ketamine, local anesthesia, and a 50:50 mixture of O_2 and nitrous oxide (N_2O) while maintaining spontaneous ventilation have been used successfully for a diagnostic biopsy in a 13-year-old patient.[380] Placing the patient in reverse Trendelenburg position may help.

With pediatric patients, general anesthesia may be needed for biopsy. Recommendations have been made for a rigid pediatric bronchoscopy and femoral-to-femoral bypass standby.[375,381] If possible, irradiation of the mass before general anesthesia may reduce the risk associated with anesthesia. Peripheral shielding of the mediastinum may allow subsequent tissue biopsy.[382] For older children, an awake fiberoptic intubation or FOB should be performed to assess the degree of obstruction after topicalization of the airway. In small infants and children, an awake intubation is not practical. In these patients, an inhalation induction with maintenance of spontaneous ventilation is recommended. Intravenous access must be obtained in a lower extremity before induction.[381] Induction of anesthesia in the lateral semi-Fowler position has been recommended.[376] Maintenance of spontaneous ventilation is vital; however, this is not foolproof.[383] Heliox (80% helium, 20% O_2) has been used for induction with sevoflurane and an LMA for successful airway management in a 3-year-old patient with severe respiratory distress related to a massive mediastinal mass.[384]

If airway obstruction or hemodynamic collapse occurs with induction, the following steps are suggested. First, one attempts to pass the ETT down the least obstructed bronchus. If passage of the ETT is not possible, rigid bronchoscopy to bypass the obstruction is attempted. Position changes to the lateral or prone position may alleviate the obstruction by changing the weight distribution of the tumor. Finally, cardiopulmonary bypass has been recommended.[375] Airway obstruction may occur during emergence as well. Extubation should be performed with the patient awake. These patients should be monitored postoperatively in the ICU.

5. Vascular Malformations

Vascular malformations result from abnormal development of the arterial component of the branchial arch system, resulting in complete or incomplete encirclement of the trachea or esophagus, or both.[385] In 1945, Gross[386] introduced the term *vascular ring* to describe this anomaly. Patients with vascular rings may present with symptoms of respiratory distress or dysphagia because of tracheoesophageal compression. Patients may present with respiratory distress after birth or may be asymptomatic for life. Most children with vascular rings present with nonspecific symptoms such as stridor, dyspnea, cough, or recurrent respiratory tract infection.[387] Dysphagia is often the primary symptom in adults with vascular ring.[385] In a retrospective review of vascular rings, 74% of the malformations were symptomatic, with inspiratory stridor and wheezing as the main complaints.[387]

Various types of vascular rings have been described, including double aortic arch and right aortic arch with aberrant left subclavian artery. The *double aortic arch* usually arises earlier than other varieties requiring surgical correction.[385] Associated cardiac anomalies are often present with the vascular ring. Diagnosis is confirmed by radiologic studies. A chest radiograph may indicate the site of the ascending and descending aorta. A barium esophagogram may disclose extrinsic compression of the esophagus. Angiography has been considered the gold standard for identifying vascular rings. CT and MRI scans are able to assist in the diagnosis of vascular ring and determine the anatomy. The diagnosis of vascular ring may be delayed because of the nonspecific symptoms.[387] Patients who are symptomatic should undergo surgery. Surgical correction is by a left thoracotomy, right thoracotomy, or median sternotomy.[385]

Airway Implications. Patients with a vascular ring are at risk of airway obstruction from compression of the trachea. Tracheomalacia may be present as well. Maintenance of spontaneous ventilation until the trachea is intubated with a reinforced ETT may be beneficial. A rigid bronchoscope should be available to serve as an airway stent in the event of airway collapse.

6. Foreign Body Aspiration

Foreign body aspiration is a cause of significant morbidity and mortality in the pediatric population. Young children are at increased risk for foreign body aspiration, with children less than 2 years old most often affected.[388] A second peak of aspiration occurs between ages 10 and 11 years.[389] Most of the deaths occur in children younger than 1 year. The objects most frequently aspirated are food products. There is only a slight propensity for the object to lodge on the right side because of symmetrical bronchial angles in children under 15 years old. The left main stem bronchus is displaced by the aortic knob by age 15, creating a more obtuse angle at the carina.[390]

Witnessed events are easier to diagnose. A history of choking, gagging, or coughing is usually given. Patients may be asymptomatic at the time or may develop symptoms of acute distress. A persistent cough, wheezing, or recurrent pneumonia may be the initial sign if the aspiration occurred in the past. The American Academy of Pediatrics has developed guidelines for the management of choking episodes. For children under 1 year, back blows and abdominal thrusts with the child in a head-down position are recommended. The Heimlich maneuver is reserved for older children and adults.[391]

Classically, peanuts should be removed promptly because of the inflammatory reaction to the peanut oil.

Emergency removal is indicated if the patient is in distress or if the foreign body is in a precarious location. If the patient is stable, radiographs may be taken to assist in localizing and identifying the foreign body. If the foreign body is radiopaque, it is easily identified. Radiolucent foreign bodies may demonstrate soft tissue density in or narrowing of the airway.[13] Indirect signs of air trapping, mediastinal shift, or atelectasis may be present. Lateral decubitus films are helpful in infants and younger children because they cannot cooperate with expiratory films.[390] The downside lung should be deflated unless it is obstructed with a foreign body.[389]

Airway Implications. In general, inhalation induction *without* cricoid pressure is the favored technique for removal of foreign bodies in the airway, regardless of the type of object, according to a postal survey of members of the Society for Pediatric Anesthesia.[388] (For foreign bodies in the upper esophagus, a rapid-sequence induction without cricoid pressure was the preferred technique, whereas for objects in the lower esophagus and stomach, a rapid-sequence induction *with* cricoid pressure was chosen.) Cricoid pressure may cause harm if the foreign body is sharp or positioned in the larynx. If the case is not an emergency, one can wait until the appropriate nothing-by-mouth time has passed. In a retrospective review of anesthetic management for tracheobronchial foreign body removal, neither spontaneous nor controlled ventilation was associated with an increased incidence of adverse events.[392]

With an inhalation induction, a prolonged induction may occur because of airway obstruction. CPAP at 5 to 10 cm H_2O and assisted ventilation may be needed at times to maintain a patent airway. After an adequate level of anesthesia is obtained, topicalization of the airway may decrease the incidence of coughing or laryngospasm. Use of a ventilating rigid bronchoscope allows ventilation during the procedure. High oxygen flow rates may be needed to overcome the presence of an air leak around the FOB. Communication between the anesthesiologist and the endoscopist is crucial because this is a shared airway. The patient may require intermittent ventilation if desaturation occurs during the FOB. When the foreign body is grasped, the glottis should be relaxed for removal. Short-acting muscle relaxants, propofol, or deeper inhalational anesthesia may be used. The forceps and the bronchoscope are removed from the trachea as a single unit.[354] Dislodgement of foreign bodies at the glottic or subglottic area has been reported.[393] If a foreign body is dislodged and obstructs the trachea, the bronchoscope must be used to push the foreign body into a main stem bronchus to enable ventilation of one lung. FOB with tracheotomy removal of a bronchial foreign body has been used successfully to remove an object that was too large to pass through the subglottis.[394]

When the foreign body is removed, the patient is usually intubated with an appropriate-size ETT. Depending on the amount of edema from the procedure, the patient should be able to be extubated. Postoperatively, racemic epinephrine (0.5 mL of 2.25% solution in 3 mL of saline) may be used for stridor. Dexamethasone is often given for edema.

7. Other Tracheal Disease

Tracheal stenosis is congenital or acquired. *Congenital* stenosis may be associated with congenital airway malformations such as tracheoesophageal fistula, hypoplastic lungs, and tracheomalacia. Congenital complete *tracheal rings* are also a cause of tracheal stenosis. In this condition, the rings are fused posteriorly and there is no posterior membranous wall. *Acquired* stenosis is usually attributed to prolonged intubation, inhalational injuries, trauma, or tumors. Symptoms include stridor, wheezing, croup, tachypnea, and cough. For mild lesions, conservative therapy is warranted. Surgical treatment involves tracheal resection with primary reanastomosis for short-segment lesions. Anterotracheal split procedures may be used for longer segmental lesions. Laser excision of granulation tissue at the repair site may be needed.[276]

Airway Implications. Tracheal stenosis may cause difficulty with ventilation or ETT advancement. Minimal trauma to the airway can lead to acute airway obstruction.[276] Use of an LMA has been described in two patients with subglottic stenosis in whom the stenotic areas were 2 mm or less.[395,396] Passage of the rigid bronchoscope should be performed only at definitive repair.

G. Cervical Spine Anomalies

1. Limited Cervical Spine Mobility

Limited cervical spine mobility may be caused by congenital or acquired disorders. The two congenital disorders that limit the mobility of the cervical spine are Klippel-Feil syndrome and Goldenhar's syndrome.

a. KLIPPEL-FEIL SYNDROME

Klippel-Feil syndrome is characterized by fusion of two or more cervical vertebrae. Other features include short neck, a low posterior hairline, scoliosis, and congenital heart disease.[397] Difficulty with airway management usually arises in the latter half of the first decade of life. The degree of difficulty with airway management depends on the severity of neck fixation.

b. GOLDENHAR'S SYNDROME

See under "Mandibular Hypoplasia."

c. JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis is a chronic arthritis with variable manifestations. Several different subgroups of disease have been identified: systemic onset (Still's disease), polyarticular, and oligoarticular (see under "Facial Anomalies: Maxillary and Mandibular Disease").

d. AIRWAY IMPLICATIONS

Careful preoperative evaluation of patients with limited cervical mobility must be done before anesthetic induction. Previous anesthetic records, if available, should be reviewed for any relevant information. Because a DA is presumed to exist, preparation for management of the difficult pediatric airway must be made. In cases of limited cervical mobility, the ability to align the oral, pharyngeal, and laryngeal axes for visualization of the

glottis is impaired. The presence of TMJ involvement may limit mouth opening as well. Awake endotracheal intubation is recommended in this scenario. Many techniques are available for use, including FOB, Bullard laryngoscope, retrograde wire technique, and lightwand. This may not be suitable in younger patients. For patients who will not cooperate with an awake technique, a mask induction with 100% O_2 and spontaneous ventilation is indicated. Retrograde intubation, suspension laryngoscopy, and fiberoptic intubation through the LMA have all been reported in pediatric patients with Goldenhar's syndrome.[77, 97, 398] The lightwand was used to intubate an 18-day-old infant with right hemifacial microsomia.[42]

2. Congenital Cervical Spine Instability

Cervical spine instability, if unrecognized, is a potential cause of serious morbidity and even mortality during airway management. Cervical spine instability or subluxation most often involves the atlanto-occipital joint. Congenital syndromes such as trisomy 21, Hurler's syndrome, Hunter's syndrome, and Morquio's syndrome are associated with cervical spine instability.[399] Of these, trisomy 21 is the syndrome most often encountered by anesthesiologists.

a. DOWN SYNDROME

Trisomy 21 (Down syndrome) occurs in approximately 1 of every 660 live births. Mental retardation, congenital heart disease, OSA, and congenital subglottic stenosis may be present. Approximately 20% of patients have ligamentous laxity of the atlantoaxial joint, which may allow atlantoaxial instability. This may predispose them to cervical spinal cord compression. Children are at risk for injury during hyperextension, hyperflexion, or increased rotation of the neck.[275,400] Signs of cervical spinal cord compression include loss of ambulatory function, spasticity, hyperreflexia of the lower extremities, extensor plantar reflexes, and loss of bowel and bladder control. Other signs may include increased fatigue with walking and torticollis.[400] Preoperative evaluation of the patient with Down syndrome must attempt to discover any preexisting signs or symptoms of spinal cord compression. The issue of screening for atlantoaxial instability in patients with Down syndrome is controversial. The American Academy of Pediatrics Committee on Sports Medicine and Fitness decided that the value of cervical spine radiographs is uncertain in screening for possible catastrophic neck injury in athletes with Down syndrome.[400] However, Pueschel[401] argued that patients should be screened for atlantoaxial instability. A survey of the Society of Pediatric Anesthesia found that members obtain preoperative radiographs (18%) or subspecialty consultation (8%), or both, for asymptomatic patients. For symptomatic patients, radiographs and preoperative consultations are obtained 64% and 74% of the time, respectively. The majority of respondents attempt to maintain the head in a neutral position for both symptomatic and asymptomatic patients.[402]

Airway Implications. Airway management for patients with Down syndrome should consider the possibility of cervical spine instability with cord compression. In addition, the large tongue and potential for OSA can lead to upper airway obstruction. Patients who have symptoms of cord compression should have radiographic evaluation before any elective surgical procedure. Lateral extension and flexion radiographs of the upper cervical spine can reveal atlantoaxial subluxation. An odontoid process (axis) to anterior arch (atlas) distance greater than 4.5 mm indicates abnormal instability.[400]

For emergency surgery, cervical spine precautions should be used in patients who are symptomatic. In-line stabilization of the cervical spine for direct laryngoscopy should be used. Techniques for airway management that require minimal neck movement may be useful (e.g., Truview or Bullard laryngoscope, lightwand, angulated video laryngoscope, SOS).

3. Acquired Cervical Spine Instability

Acquired cervical spine instability in pediatric patients can result from multiple trauma or head and neck trauma. Any pediatric patient with a severe head injury should be treated as though a cervical spine injury is present.[403] An estimated 1% to 2% of pediatric patients with multiple trauma have a cervical injury.[391] Pediatric patients with underlying medical conditions such as Down syndrome may be more susceptible to cervical cord injury.[391] Pediatric patients less than 8 years old are at increased risk for injury to the upper cervical spine and craniovertebral junction. Only 30% of cervical injuries occur below C3 in children younger than 8. They also have a higher incidence of *spinal cord injury without radiographic abnormality* (SCIWORA).[404] Immobilization of a patient with suspected cervical injury is crucial so that further damage to the cord is prevented. A hard collar, spine board, and soft spacing devices between the head and securing straps are needed. The occiput is large, and a blanket under the torso allows the neck to rest in a neutral position.

Airway Implications. The choice of airway management depends on the degree of urgency associated with the intubation. Techniques that minimize head extension and cervical flexion are mandatory. Trauma patients are considered at risk for aspiration, and appropriate measures need to be taken.

For an urgent airway in a patient with a DA or facial fractures, a surgical airway may be the best option. If time allows, a limited number of attempts at direct laryngoscopy may be performed. The Truview or Bullard laryngoscope may be useful in this situation. In an emergency, the LMA may be used to ventilate or oxygenate the patient until a formal airway is established. This does not provide protection against aspiration.

For a nonurgent intubation, further evaluation of the cervical spine is warranted. When the cervical spine has been "cleared" by the neurosurgeon or trauma surgeon, a rapid-sequence induction with cricoid pressure may be performed after adequate preoxygenation if the airway appears reasonable. If the cervical spine is unstable, a rapid-sequence induction with cricoid pressure may be performed with in-line stabilization. Fluoroscopy was used to assist the intubation of an 11-year-old patient

with an unstable subluxation of C1-C2 after a motor vehicle crash.[405] Awake techniques such as flexible fiberoptic laryngoscopy, Bullard laryngoscope, lightwand, SOS, or retrograde intubation may be indicated if the patient has an unstable cervical spine and a DA.

X. PEDIATRIC TRAUMA

All pediatric trauma patients are considered to have a cervical spine injury until proved otherwise. In addition, these patients are at risk for aspiration. Oxygen should be administered and ventilation assisted if needed as soon as possible. Trauma patients should be immobilized on a spine board with a rigid collar as previously described. After an evaluation of the airway, one should decide on the method of intubation. If the airway is judged to be adequate, a rapid-sequence induction with cricoid pressure and manual in-line stabilization should be employed. If the airway cannot be secured, the ASA DA algorithm should be followed. In a DA scenario, one of the previously described awake techniques may be used. In certain cases, awake tracheostomy or surgical cricothyrotomy may be indicated. A multidisciplinary approach to the management of the difficult pediatric trauma airway is necessary.

XI. EXTUBATION OF THE DIFFICULT AIRWAY

The management of the difficult pediatric airway does not end until the plan for extubation has been established. Choices include extubation over an airway catheter or guidewire or extubation when an air leak develops, as with epiglottitis. Preparations for the difficult pediatric airway must be made because an extubation may lead to a reintubation. If airway edema is suspected at the end of the surgery, because of either the intubation process or the surgery, dexamethasone may be of benefit. Postoperative ventilation may be indicated as well until the edema resolves. Extubation has been successfully performed over an airway exchange catheter in an adolescent with a DA.[406] Alternatively, a 0.018-inch guidewire has been used to maintain airway access in a 2-year-old child with severe micrognathia and tetralogy of Fallot.[407]

XII. CONCLUSIONS

Unexpected difficulties with airway management in otherwise healthy children are rare after exclusion of predictors of difficult intubation, such as mandibular hypoplasia, limited mouth opening, and facial asymmetry, including abnormalities of the ear, syndromes, obstructive sleep apnea syndrome, and stridor. Difficulties that occur are probably a result of inexperience or inadequate supervision and lack of pediatric airway training. Thorough preoperative assessment and anticipation of airway difficulties, as well as education, continuous training, and regular practice in basic airway management, are necessary to reduce the incidence of pediatric airway difficulties. Besides inexperience with the pediatric airway, most morbidity and mortality in pediatric airway management is attributed to a failure to recognize and overcome functional airway problems because of insufficient depth of anesthesia or muscle paralysis, and not to a failure to intubate.

XIII. CLINICAL PEARLS

- The pediatric airway anatomy is different in children. Their larynx is located higher in the neck with a relatively larger tongue; they have a differently shaped epiglottis; and the vocal cords are angled.
- The newborn rib cage is oriented parallel, and the intercostal muscles are not as effective at increasing intrathoracic volume with inspiration.
- The work of breathing for each kilogram of body weight is similar in infants and adults.
- The oxygen consumption of a full-term newborn (6 mL/kg/min) is twice that of an adult (3 mL/kg/min), which results in increased respiratory rate.
- The infant's tidal volume is relatively fixed.
- Minute alveolar ventilation is more dependent on increased respiratory rate than on tidal volume.
- Functional residual capacity of an infant is similar to FRC of an adult when normalized to body weight, because the ratio of alveolar minute ventilation to FRC is doubled (with hypoxia or apnea or under anesthesia), the infant's FRC is diminished, and desaturation occurs more precipitously.
- In infants, most airflow resistance occurs in the bronchial and small airways.
- Resistance to airflow is inversely proportional to the radius of the lumen to the fourth power for laminar flow, and to the radius of the fifth power (r^5) for turbulent flow.
- Radiographic evaluation may be extremely helpful to diagnose a difficult airway.
- Radiographs of the upper airway (AP and lateral films, fluoroscopy) may show site and cause of airway obstruction.
- When necessary, MRI and CT provide more detailed information if time permits.

I. INTRODUCTION

Difficult laryngoscopy, failed intubation, and inability to ventilate or oxygenate after induction of general anesthesia (GA) for cesarean delivery (C/D) are major contributory factors leading to maternal morbidity and mortality. In Western countries, the recognition of adverse maternal and neonatal outcomes associated with difficult airway (DA) management has led to a dramatic decline in the use of GA for both elective and emergency C/D.[1-3]

The overall general anesthesiology practice in industrialized countries in the last 2 decades has undergone a dramatic change. Management of the DA has emerged as one of the most important patient safety issues. Guidelines and strategies for management of the DA have been published by the American Society of Anesthesiologists (ASA),[4] the Difficult Airway Society (DAS) in the United Kingdom,[5] and the Canadian,[6] French[7] and Italian[8] national societies' work groups on difficult airway management. These guidelines are applicable to the general surgical population. However, none of the guidelines address management of the DA in an obstetric situation, especially in the context of urgency in delivering the baby.

There are differences among these standards, guidelines, algorithms, recommendations, and protocols, but in practice and in medicolegal cases, the distinction between terminologies can be blurred (Table 37-1).[9] Published literature shows that the guidelines from the ASA Task Force on Management of the Difficult Airway have been discussed in 18% of nonobstetric medicolegal cases and were useful both in defending care (defense, 8%) and in criticizing care (plaintiff, 3%).[10] Expert witnesses also have used these guidelines in litigated obstetric DA management cases.

II. DEFINITIONS

There is no consensus on a standard definition of the DA in the literature. The ASA Task Force defined DA as a clinical situation in which a conventionally trained anesthesiologist experiences difficulty with face mask ventilation, difficulty with intubation, or both. The original ASA description of difficult intubation (DI) included a limit of 10 minutes or multiple attempts. The wisdom of this definition must be questioned in obstetrics especially, given the fact that GA is generally reserved for emergency C/D in which delivery of the baby is of the utmost urgency. The common practice in obstetric anesthesia is to use a single dose of succinylcholine when anesthetizing for C/D under GA. In the obstetric situation, *difficult intubation* is the inability of an experienced anesthesiologist to intubate within one dose of succinylcholine.[11] A more apt definition of *failed intubation* in obstetric patients is inability to secure the airway with two attempts using a conventional laryngoscope or an alternative airway device to assist with tracheal intubation.

III. ANESTHESIA-RELATED MATERNAL MORTALITY

Although the total number of maternal deaths has been decreasing steadily in the last few decades both in the United States and United Kingdom (Table 37-2),[12,13] anesthesia-related complications rank seventh among the leading causes of maternal death, in both countries (Fig. 37-1).[14,15] Even in the developing countries, anesthesia is emerging as an additional risk for maternal mortality and remains largely under-reported.[16,17] Failures in airway management are a primary cause of anesthesia-related maternal deaths in the underdeveloped countries.[18]

The first national study of anesthesia-related maternal mortality in the United States between 1979 and 1990 was published in 1997.[19] Most of these deaths (82%) took place during C/D. Death rates for GA during C/D increased from 20 per million in 1979-1984 to 32.3 per million in 1985-1990. Conversely, the death rate for regional anesthesia (RA) during the same periods declined from 8.6 to 1.9 per million, respectively. The relative risk for GA increased to 16.7 from 1985 to 1990. The case fatality risk ratio for GA was. 2.3 times that of RA from 1979 to 1984 and increased to 16.7 times from 1985 to 1990.[19] The majority of maternal deaths were related to difficult or failed intubation, pulmonary aspiration, or respiratory complications.

A follow-up study examined 12 years of anesthesia-related maternal deaths between 1991 and 2002 and

TABLE 37-1

Definition of Terms and Degree of Obligation

Terms	Definitions	Degree of Obligation
Standards	Generally accepted principles for patient management; exceptions are rare, and failure to follow is often difficult to justify	Mandatory
Strategy	A well-planned series of steps for achieving a goal	Voluntary
Guidelines	Systematically developed statements to assist practitioners for specific clinical circumstances; incorporates the best scientific evidence with expert opinion	Voluntary
Practice policies	Describe present recommendations issued to influence practitioners in reaching decisions about interventions	Voluntary
Recommendations	Suitable and useful strategy; not as strict as standards or guidelines	Voluntary
Options	Different possibilities are available; neutral assessment	Voluntary
Protocols and algorithms	Stepwise procedures or decision trees to guide practitioners through diagnosis and treatment of various clinical problems	Voluntary

compared them with data from 1979 to 1990 to estimate trends over time and to compare the risks of GA and RA during cesarean delivery.[13] Results showed that 86 pregnancy-related deaths were associated with complications of anesthesia, accounting for 1.6% of the total. Case-fatality rates for GA declined from 16.8 per million in 1991-1996 to 6.5 per million in 1997-2002 (Table 37-3).

Complications related to anesthesia still occur, despite the decrease of almost 60% in anesthesia-related maternal mortality between 1979-1990 and 1991-2002. Although deaths from GA during C/D declined, about two thirds of the anesthesia-related deaths were caused by intubation failure or induction problems.[13] The decline in GA-related case fatalities was explained by improvements in management of the DA and failed intubation and by increased expertise of anesthesiologists with the laryngeal mask airway (LMA) and other airway devices.[13]

A review of maternal mortality in Michigan from1985 to 2003 identified eight anesthesia-related deaths.[20] Seven of these deaths were due to anesthesia-related factors. Interestingly, there were no deaths during induction of GA. The deaths were caused by airway obstruction or hypoventilation during emergence, lapses in monitoring, or lack of supervision in the postoperative period. Other risk factors included African-American race and obesity. This study highlighted the importance of airway-related problems during emergence, particularly in obese patients and in the African-American population, as well as the importance of vigilance in monitoring and management in the postoperative period for prevention of airway-related complications.

In the United Kingdom, despite the decline in the total number of maternal deaths, anesthesia-related causes consistently accounted for approximately 10% of the total direct deaths. During the period 1982-1984, anesthesia was the third leading cause of maternal death, resulting in 19 of 243 deaths, of which 15 were due to airway-related difficulties.[21] The confidential enquiry spanning 1994-1996 showed that anesthesia was responsible for only 1 of 268 maternal deaths. In the Confidential Enquiry into Maternal and Child Health (CEMACH) 2000-2002 study, there were six direct deaths, all related to GA.[15] Maternal deaths from complications of GA included a risk of 1 maternal death in 20,000. These

cardiopulmonary arrests and deaths were related to difficult or failed intubation, difficult pulmonary ventilation resulting in failure to oxygenate, pulmonary aspiration, or acute respiratory distress syndrome (ARDS). In all of these cases, the anesthesia care was considered substandard.[15]

IV. OBSTETRIC ANESTHESIA CLOSED CLAIMS STUDIES

The 2009 closed claims study published in the United States revealed that obstetric anesthesia claims for injuries from 1990 to 2003 had declined compared with claims for injuries before 1990.[1] In the period 1990-2003, the proportion of maternal death or brain damage and that of newborn death or brain damage decreased. Respiratory causes of injuries also decreased, from 24% to 4% in claims from 1990 or later. Claims related to inadequate oxygenation or ventilation and those related to aspiration also decreased.

Despite the decrease in claims, one of the most common anesthesia-related causes of maternal death or damage associated with GA was difficult tracheal intubation. Airway-related claims involved multiple attempts at tracheal intubation leading to progressive difficulty with ventilation. In two of the claims, tracheal intubation was assessed to be difficult preoperatively with a backup plan to awaken the patient and perform fiberoptic intubation. However, progressive airway difficulties occurred while attempts were made to awaken the patients, resulting in adverse outcomes.

The number of claims related to difficult tracheal intubation after 1990, compared with pre-1990 claims, was unchanged.[1] However, the overall improvement in closed claims statistics and the decline in anesthesia-related maternal mortality in more recent years were probably attributable to implementation of a minimum standard of care requiring the use of respiratory system monitors (pulse oximetry and capnography) during anesthesia in modern practice, enhanced awareness of the risk of pulmonary aspiration of gastric contents in the obstetric patient, decreased use of GA in obstetric practice, and use of advanced airway management techniques.

V. WHY IS ADVANCED AIRWAY MANAGEMENT IMPORTANT?

There have been tremendous advances in airway management in recent years, including an explosion in the use of airway devices as adjuncts to airway management. There has been a vast increase in the body of knowledge and in publications worldwide in this field. Improvements in advanced airway management have led to a documented decline in the incidence of airway-related perioperative morbidity in the surgical population.[22] Similarly, in the last 2 decades, anesthesiologists' focus on improving management of the DA and of failed intubation, experience with the LMA, application of the ASA difficult airway algorithm (DAA), and advanced airway management strategies have helped decrease GA-related case fatalities in obstetric cases.[13]

Because GA for cesarean delivery is frequently reserved for true emergencies, these high-level stress situations may lead to inadequate airway assessment or preparation, which can contribute to the risk of difficult or failed tracheal intubation, leading to the possibility of morbidity and mortality in both mother and baby.

Because the medical-legal liability associated with airway-related adverse maternal outcomes is high,[1] it is essential that all those practicing obstetric anesthesia as part of airway management should do the following:

1. Assess risk factors that predispose to airway-related complications
2. Be cognizant of predictors of the DA
3. Have appropriate algorithms and airway devices and equipment immediately available in the labor and delivery suite and in the operating room to manage the DA
4. Have an airway rescue plan, within the framework of the ASA DAA, for managing the DA
5. Be cognizant of the twin goals of urgently delivering the baby and preventing pulmonary aspiration, which can be hard to balance
6. Acquire and maintain advanced airway management skills.

A heightened awareness of the difficult obstetric airway among all anesthesia practitioners and use of video laryngoscopes, alternative devices to assist with tracheal intubation, and supraglottic devices as a bridge to ventilation, oxygenation, and airway management may further minimize or even help eliminate airway-related maternal morbidity and mortality. Unfortunately, there is a learning curve associated with acquiring these advanced airway skills.

VI. RISK ASSESSMENT

Anatomic and physiologic factors alter the airway during pregnancy, placing the parturient at risk for difficult laryngoscopy, difficult tracheal intubation, and difficult mask ventilation (DMV). There is no single factor that explains the high incidence of failed tracheal intubation and respiratory-related injury in obstetrics. Difficult laryngoscopy or DMV may be related to excessive weight gain and upper airway edema during pregnancy,

compounded by breast enlargement and by additional changes in preeclampsia. Rapid onset of hypoxemia associated with DA may be caused by respiratory changes, cardiovascular impairment from aortocaval compression, gastrointestinal changes placing the parturient at risk for pulmonary aspiration, and acute respiratory distress syndrome secondary to respiratory-related complications.

A. Airway

Airway changes occur during pregnancy, labor, and delivery.[23] Further, the incidence of Mallampati (MP) class III and class IV scores increases during labor compared with the prelabor period, and these changes are not reversed by 48 hours after delivery. Therefore, it is absolutely necessary to examine the airway of a parturient in labor before administering anesthesia for a cesarean delivery.[24]

An increase in the ground substance of the airway connective tissue, caused by elevated levels of estrogen during pregnancy, an increase in total body water, and an increase in interstitial fluid and blood volume, results in hypervascularity and edema of oropharynx, nasopharynx, and respiratory tract. Excessive weight gain during pregnancy, preeclampsia, iatrogenic fluid overload, excessive bearing-down efforts during labor, and increase in venous pressure all lead to increased upper airway mucosal edema. Additional upper airway changes include tongue engorgement during pregnancy, which leads to decreased mobility of the floor of the mouth and changes in the MP score.[25] Several published reports have described development of airway edema during labor and delivery, in preeclampsia, and after massive fluid and blood transfusion resuscitation following postpartum hemorrhage.[26-30] In some of these reports, the associated difficulties in tracheal intubation were secondary to changes in the MP score.

Because of the increased vascularity and engorgement of the mucosa, the parturient is at increased risk for epistaxis after manipulation of the nasopharynx with nasotracheal intubation and for swelling of the airway and is vulnerable to increased trauma with repeated attempts at intubation.[31] Avoidance of manipulation of the nasopharynx, use of smaller-sized tracheal tubes, and strict adherence to no more than two attempts at tracheal intubation[32] are vital measures to avoid airway-related trauma, complications, and catastrophes.

B. Respiratory Changes

The enlargement of the uterus during the course of pregnancy causes a 25% decrease in expiratory reserve volume and a 15% decrease in residual volume, resulting in an overall 20% decrease in functional residual capacity (FRC). In the supine position, the FRC is 70% of its normal capacity measured in the upright position. The supine position, particularly in an obese parturient, can result in airway closure and an increase in the alveolar-arterial gradient during normal tidal respiration, predisposing the parturient to lower partial pressure of oxygen. At the same time, oxygen consumption is increased by 20% secondary to the metabolic needs of the growing fetus, uterus, and placenta. The increase in oxygen consumption, along with decreased FRC, places the parturient at increased risk for hypoxemia and its consequent adverse neurologic effects (brain death), especially during DI, failed intubation, and DMV.

C. Cardiovascular Changes

The gravid uterus compresses the inferior vena cava in the supine position, resulting in a decrease in venous return and cardiac output. The reduction in cardiac output, together with elevated oxygen consumption, can further decrease oxygen saturation. The decrease in cardiac output and the ensuing hypoxemia during a "cannot intubate, cannot ventilate" (CICV) situation predisposes the mother to myocardial hypoxemia, cardiovascular arrest, and compromised uteroplacental perfusion, which can also place the fetus' well-being at risk. Maintaining left uterine tilt, establishing an airway with adequate ventilation and oxygenation in a timely manner, maintaining adequate perfusion in mother and baby, and ensuring cardiovascular stability become extremely important to ensure a safe outcome for both mother and bady.

D. Gastrointestinal Changes

Other risk factors include pregnancy-related hormonal, anatomic, and physiologic gastrointestinal changes that place the parturient at risk for gastric regurgitation and pulmonary aspiration during GA. The gravid uterus shifts the stomach cephalad and changes the angle of the gastroesophageal junction, resulting in incompetence of the gastroesophageal pinchcock mechanism. The lower esophageal tone is decreased, leading to increased gastric reflux. There is a progesterone-mediated smooth muscle relaxant effect on the gastrointestinal mucosa. Furthermore, gastric emptying is prolonged during labor. Therefore, the parturient is at risk for gastric regurgitation, active vomiting, and pulmonary aspiration during GA, in case of a DA, or during failed intubation. Aspiration-related deaths during pregnancy occur from complications associated with induction problems such as DI, esophageal intubation, and inadequate attempts at ventilation.[12]

E. Obesity

Weight gain during pregnancy results from the increasing size of the uterus and fetus, increased blood and interstitial fluid volumes, and deposition of new fat. There is a correlation between weight gain and an increase in the MP score.[30] Pregnancy also results in a significant increase in breast size and engorgement. In the supine position, the enlarged breasts can encroach into the neck area, impeding effective application of cricoid pressure and leading to difficulty with laryngoscope blade insertion.

Obesity has reached epidemic proportions in the United States, and the incidence of obesity in pregnancy has doubled in the last 10 years. A body mass index (BMI) greater than 25 kg/m^2 is considered overweight, and a BMI greater than 30 kg/m^2 is considered obese.[33] In the nonobstetric population, a BMI greater than

26 kg/m^2 results in a threefold increased incidence of DMV and a 10-fold increased incidence of difficult tracheal intubation.[34,35] Both prepregnancy obesity and excessive weight gain during pregnancy are associated with comorbidities such as hypertension or preeclampsia with intrauterine growth retardation, diabetes and macrosomia, and dysfunctional labor, thus increasing the incidence of operative cesarean delivery. The incidence of postpartum hemorrhage is higher in these patients, leading to increased likelihood of a GA intervention.

Because weight gain and obesity are associated with an increase in the MP score, the incidence of a partially obliterated oropharyngeal space in an obese parturient is doubled compared with that in nonpregnant patients. The aforementioned changes, the breast engorgement, and anthropometric differences between patients create a risk for difficult laryngoscopy, DI, and DMV.[30,36,37] DI is encountered more frequently in morbidly obese parturients weighing more than 130 kg.[38] Mask ventilation tends to be difficult because of low chest wall compliance and increased intra-abdominal pressure. In obesity, the respiratory-related changes of pregnancy are even more significant, with a marked decrease in FRC such that the closing capacity exceeds the FRC during tidal breathing, leading to a decrease in arterial oxygen tension and predisposing the parturient to a much higher risk of hypoxemia during a DI or DMV encounter. Obesity compounds all the risk factors associated with normal pregnancy, including DA, difficult laryngoscopy, DI, DMV, and aspiration-related complications.

In the obese parturient, a thorough preoperative assessment, a review of comorbidities, and a previous anesthetic history for difficulty with tracheal intubation are essential to allow for proper preparation and appropriate interventions. Placing the obese parturient in the so-called ramped position before induction of GA is critical to facilitate ventilation and improve laryngoscopic visualization of the glottis for intubation. The aim is to achieve the best alignment of the three axes (oral, pharyngeal, and laryngeal) in obese patients, thereby enhancing the success rate of intubation at the first attempt.

VII. INCIDENCE OF DIFFICULT OR FAILED INTUBATION IN OBSTETRICS

In 1998, the incidence of difficult laryngoscopy or tracheal intubation in the nonobstetric population was 0.1% to 13%.[39] In the obstetric population, the incidence of difficult tracheal intubation was found to be 1/250[40] to 1/280,[41] 1/300,[42] and 1/750.[36]

A review of GA for cesarean deliveries from 1990 to 1995 showed the incidence of difficult tracheal intubation to range from a high of 16.3% to a low of 1.3%.[2] There was a sentinel CICV incidence of 1 in 536 cases; in this patient, multiple attempts at intubation, unsuccessful mask ventilation, failed Combitube placement, and unsuccessful cricothyroidotomy resulted in cardiopulmonary arrest followed by surgical tracheostomy. Resuscitation was accomplished, but the mother remained in a coma until death, and the baby suffered significant neurologic injury.

In a review of GA for cesarean deliveries from 2000 to 2005, the incidence of CICV was 1 in 98. The single case of CICV occurred after failed tracheal intubation, unsuccessful LMA placement, and hypoxemia; successful cricothyroidotomy resulted in a good outcome for both mother and baby.[43]

VIII. PREDICTION OF DIFFICULT AIRWAY MANAGEMENT

The ASA DAA recommended an airway-related history to detect medical, surgical, and anesthetic factors that might indicate the presence of a DA. The guidelines also recommended an airway physical examination using assessment of multiple airway features before initiation of anesthetic care and airway management in all patients.[4] The ASA closed claims analysis (2005) showed that 8% of patients did not have a preoperative history or airway physical examination.[10]

A retrospective audit was performed of all obstetric GAs, a total of 3430 cases over an 8-year period.[44] None of the patients had a failed or esophageal intubation. There were 23 DIs, an incidence of 1:156. Anticipated difficult tracheal intubation occurred in 9 patients, 3 of whom underwent awake fiberoptic intubation; in the remaining 6 patients, who were morbidly obese, the DI was managed by senior trainees or consultants. Unanticipated difficulties occurred in 14 patients (61%). The preoperative assessment was found to be inadequate in these cases, being either not recorded (6 cases) or poorly documented (8 cases).

The first step in management of the high-risk airway is recognition of its presence. Research involving the best practices in promoting patient safety in airway management with rapid-sequence induction (RSI) suggests performing an adequate preoperative evaluation and examining the airway so as to be able to better predict difficult laryngoscopy, DI, and DMV. Similarly, because of the airway-related changes that occur during pregnancy, the obstetric airway should be considered a high-risk airway and therefore a thorough preoperative airway assessment and documentation should be required.

A. Preoperative Assessment

1. History and Evaluation

According to the ASA Task Force, an airway history and a focused review of medical records must be conducted when feasible.[4] Obviously, airway evaluation and prediction of DA in an obstetric patient starts with a thorough, focused airway-related history and evaluation of specific airway-related examination findings.[45] A thorough history addresses any difficulty with previous GAs, obstructive sleep apnea (OSA) or snoring, head and neck abnormalities, and diseases that might impair the airway and result in difficult tracheal intubation. A history of DA management should be considered a strong predictor of problems unless the history was related to a specific reversible disease process such as a dental abscess. The history may be available from verbal recollections by the patient, previous anesthetic records, hospital notes, a letter describing DA management, or a

Medic-Alert bracelet. The introduction of anesthesia information management systems and mandatory electronic medical records should be extremely useful in the future as "airway alerts" are built in to notify future practitioners of the specific details encountered with DA management in a particular patient.

Preexisting conditions that can lead to difficulties in managing the airway include bull neck (neck circumference >16 cm in women), large breasts, large tongue, limited cervical movement, limited mouth opening, prominent upper incisors, and receding jaw.

The physical examination should include assessment of facial and neck masses, quality of dentition, buck teeth, small or large chin, maxillary and mandibular position, pharyngeal structures and high arched palate, and any deformity resulting from trauma, tumor, or inflammation.

2. Predictors of Difficult Airway

Numerous investigators have attempted to predict DA by using a simple bedside physical examination. There are numerous publications describing univariate or multivariate predictors of DI in nonobstetric patients and a handful relating the use of multivariate predictors of the DA, such as MP classification.

Yentis described the problems with many studies examining the prediction of DA.[46] It is appropriate here to delineate the terms used to describe the accuracy and predictive power of these tests. A test to predict DI should have high *sensitivity*, so that it will identify most of the patients in whom intubation will be truly difficult. It should also have a high *positive predictive value* (PPV), so that only a few patients with airways actually easy to intubate will be subjected to the protocol for DA management. The test should also have a high specificity, so that it will identify most patients in whom tracheal intubation will be truly easy (Table 37-4).[46] Excellent interobserver reliability is essential for any test to have high specificity, sensitivity, and PPV in predicting a DA.

B. Quantitative Evaluation of Difficult Intubation

Multiple external features are associated with difficult laryngoscopy and intubation. In an urgent or emergent obstetric situation, a practical, systematic, and rapid evaluation of the airway is necessary and important to predict a potentially difficult laryngoscopic view and DMV before initiation of RSI for GA in a cesarean delivery. The evaluation should dictate the management plan and the availability of airway rescue devices.

The LEMON mnemonic represents one such assessment that is simple and quick, can be performed on any emergency patient, and has proved to have high PPV.[47] The LEMON mnemonic represents the following five elements for preanesthetic assessment (Box 37-1):

L: Look externally—The initial impression of potential airway difficulty is based on assessment for any obvious anatomic distortions or external features that may make intubation difficult, such as facial and periorbital edema in a preeclamptic patient.

E: Evaluate the 3-3-2 Rule—Measuring the geometry of the airway can predict the anesthesia practitioner's ability to align the oral, pharyngeal, and tracheal axes.

- Mouth opening—The interincisor distance between the patient's incisor teeth or the mandibular opening in an adult should be at least 4 cm or 3 fingerbreadths

BOX 37-1 LEMON Airway Assessment Method

L—Look externally for anatomic features that may make intubation difficult
E—Evaluate the 3-3-2 Rule
  Mouth opening (3 finger breadths)
  Hyoid-chin distance (3 finger breadths)
  Thyroid cartilage-floor of mouth distance (2 finger breadths)
M—Mallampati score
  Class I: soft palate, uvula, pillars visible
  Class II: soft palate, uvula visible
  Class III: soft palate, base of uvular visible
  Class IV: hard palate visible
O—Obstruction: Examine for partial or complete upper airway obstruction
N—Neck mobility

From Reed MJ, Dunn MJ, McKeown DW: Can an airway assessment score predict difficulty at intubation in the emergency department? *Emerg Med J* 22:99–102, 2005.

TABLE 37-4
Statistical Terminology and Calculation*

Term	Calculation
True positive (TP)	Difficult intubation that had been predicted to be difficult
False positive (FP)	Easy intubation that had been predicted to be difficult
True negative (TN)	Easy intubation that had been predicted to be easy
False negative (FN)	Difficult intubation that had been predicted to be easy
Sensitivity	Percentage of correctly predicted difficult intubations as a proportion of all intubations that were truly difficult—that is, TP/(TP+FN)
Specificity	Percentage of correctly predicted easy intubations as a proportion of all intubations that were truly easy—that is, TN/(TN+FP)
Positive predictive value	Percentage of correctly predicted difficult intubations as a proportion of all predicted difficult intubations—that is, TP/(TP+FP)
Negative predicted value	Percentage of correctly predicted easy intubations as a proportion of all predicted easy intubations—that is, TN/(TN+FN)

*The sensitivity, specificity, and positive predictive value of each test are calculated using the Cormack-Lehane score as the constant variable.
Adapted from Yentis SM: Predicting difficult intubation: Worthwhile exercise or pointless ritual? *Anaesthesia* 57:105-109, 2002.

- The distance from the hyoid cartilage to the chin should be at least 3 cm or 2 finger breadths (under the chin). The ability of the mandible to accommodate the tongue can be estimated between the mentum and the hyoid bone. A smaller mandible is less likely to accommodate the tongue, which can impair visualization during laryngoscopy. An unusually large mandible can elongate the oral axis.
- The distance between the thyroid notch and the floor of the mandible (top of the neck) should be at least 2 finger breadths.

M: Mallampati score—The degree to which the tongue obstructs the visualization of the posterior pharynx has some correlation with the ability to visualize the glottis. The MP score can be estimated by having the patient, in a sitting position, open the mouth fully and protrude the tongue as far as possible without phonation. The relationship of the base of the tongue to the oropharyngeal structures—uvula and tonsillar pillars and fauces—is assessed as follows:
- Class I : Soft palate, uvula, faucial, and tonsillar pillars visible (easy intubation)
- Class II: Soft palate, uvula visible
- Class III: Soft palate, base of uvula visible
- Class IV: Hard palate only visible (DI)

O: Obstruction—Pathologic conditions such as edema, glottic tumor, lingular tonsil, hyperplasia, and trauma can cause obstruction and can make laryngoscopy and ventilation difficult.

N: Neck mobility—This is a vital requirement for successful intubation. The sniffing position is the optimal, classic position of the head and neck for facilitating intubation. The extension of the atlanto-occipital (A-O) joint on the cervical spine so as to be able to align the three axes (oral, pharyngeal, and laryngeal) during laryngoscopy enhances the ease of laryngoscopy and tracheal intubation. Normal A-O joint extension of the head over the neck is 35 degrees. It can be assessed easily by getting the patient to place the chin down on the chest and tilt the head backward as far as possible. A reduction in A-O joint extension of 12 degrees (33%) or more correlates with intubation difficulty; complete joint immobility significantly compromises the laryngeal view. Limited A-O joint extension is present in certain pathologic states such as spondylosis, rheumatoid arthritis, and cervical spine stenosis, resulting in symptoms of nerve compression with cervical extension. Complete A-O joint immobility (e.g., hard-collar neck immobilization) can compromise the view of the glottis during laryngoscopy.

C. Additional Tests

Difficult laryngoscopy was defined by the ASA Task Force as the inability to visualize any part of the vocal cords despite multiple attempts at conventional laryngoscopy.[4] The original Cormack and Lehane classification of laryngoscopic views was used to describe the visibility of the glottis during laryngoscopy with a conventional laryngoscope and to predict the ease of intubation.[48] The view at laryngoscopy was divided into four grades on the basis of a study in obstetric patients.[49] The entire glottis is visible in a grade 1 view, whereas in a grade 2 view only the posterior portion of the glottis is visible; in a grade 3 view, only the epiglottis is seen, and in grade 4 view not even the epiglottis is seen. Grades 3 and 4 are considered to indicate DI.

1. Thyromental Distance

The thyromental distance (TMD) is defined as the distance from the chin (mentum) to the top of the notch of the thyroid cartilage with the head fully extended; it must be measured with a ruler for accuracy. The TMD gives an estimate of the mandibular space and helps in determining how readily the laryngeal axis will fall in line with the pharyngeal axis when the A-O joint is extended[50]:

- A TMD measurement of 6.5 cm or greater with no other abnormalities indicates the likelihood of easy intubation.
- A TMD measurement of 6.0 to 6.5 cm indicates that alignment of the pharyngeal and laryngeal axes will be challenging and that difficulty with laryngoscopy may result. However, intubation is possible with the use of adjuncts such as an Eschmann introducer or an optical stylet.
- A TMD measurement of less than 6 cm indicates difficult laryngoscopy; specifically, intubation may be impossible.

TMD, in conjunction with other parameters such as the MP classification, has been used to predict DI.

2. Sternomental Distance

The sternomental distance (SMD) is measured from the sternum to the tip of the mandible with the head fully extended and the mouth closed. The normal measurement is 13.5 cm. The SMD and the corresponding laryngoscopic view were documented in 523 parturients undergoing elective or emergency C/D under GA.[51] An SMD of 13.5 cm or less had a sensitivity of 66.7%, a specificity of 71%, and a PPV of only 7.6%. Eighteen patients (3.5%) had a Cormack-Lehane grade 3 or 4 laryngoscopic view and were classified as having potentially difficult tracheal intubations. The SMD on its own as a sole indicator of DI was not useful, and the suggestion was to incorporate it with other tests in the preoperative airway examination.

3. Jaw Protrusion

Jaw protrusion (also termed *prognathism* or *subluxation*) is assessed by the mandibular protrusion test, which demonstrates the extent to which the lower incisors can be slid in front of the upper ones[52]:

- Class A: The lower incisors can be protruded anterior to the upper incisors.
- Class B: The lower incisors can be brought edge-to-edge with the upper incisors.
- Class C: The lower incisors cannot reach the top incisors.

Class C protrusion was associated with difficult laryngoscopy and DMV, whereas class A protrusion rarely produced any difficulty.

4. Studies Assessing Predictors of Difficult Airway in Obstetrics

a. MALLAMPATI CLASSIFICATION

A number of studies in both general surgical and obstetric patients have indicated that the MP classification is a simple, reproducible, reliable, and important parameter in evaluating and assessing the airway. It has been used as a single predictor and as a part of multivariate analysis to predict difficult tracheal intubation. However, studies have shown that the MP classification by itself has limited discriminative power in accurately predicting difficult tracheal intubation.

In obstetric patients, the MP score has been used as a single parameter to illustrate the dramatic airway changes that occur in pregnancy and to highlight the importance of preoperative assessment of the airway. Pilkington and coworkers (1995) evaluated the MP class at 12 weeks' and 38 weeks' gestation[30]; photographs taken at the two time periods demonstrated the increase in MP class in the same patient as gestation advanced. The MP score correlated with the increase in body weight, implying that oropharyngeal edema was responsible for the increase in the MP score.

b. MULTIVARIATE PREDICTORS

Rocke and colleagues (1992) were the first to use multivariate predictors to predict difficult tracheal intubation.[36] They evaluated the MP classification as modified by Samsoon and Young, referring to it as the Modified Mallampati Test (MMT), along with other predictors in 3440 patients undergoing elective or emergency C/D under GA. Data were collected on 1606 patients, representing 46.7% of the obstetric surgical patients. Of the patients studied 1500 underwent general anesthesia. Other risk parameters for DA that they assessed included short neck, which equates with decreased A-O joint extension; receding mandible or decreased TMD (<3 finger breadths); and protruding maxillary incisors indicating significant overbite, which would equate to the current class C jaw protrusion or class III upper lip bite test.[53]

Rocke's group made subjective assessments of the ease or difficulty of tracheal intubation according to the following scale (Table 37-5)[36]:

- Grade 1: Easy—intubation at first attempt with no difficulty
- Grade 2: Some difficulty—insertion of tracheal tube not achieved at first attempt; no difficulty but successful intubation after adjustment of laryngoscope blade and/or adjustment of head position, not requiring additional equipment, removal and reinsertion of the laryngoscope, or senior assistance
- Grade 3: Very difficult—requiring removal of the laryngoscope, further oxygenation by mask ventilation, and subsequent intubation with or without the use of airway adjuncts (e.g., Eschmann introducer, alternative laryngoscope blade) or intubation by a senior colleague
- Grade 4: Failed intubation—several attempts at intubation or unrecognized esophageal intubation by resident, followed by subsequent tracheal intubation by senior anesthesiologist

Based on these various parameters, the relative risk of experiencing difficult tracheal intubation (compared with an uncomplicated MMT class I airway) was determined as follows: 3.23 for MMT class II, 7.58 for MMT class III, 11.3 for MMT class IV, 5.01 for short neck, 9.71 for receding mandible, and 8.0 for protruding incisors. The investigators analyzed the univariate individual risk factor (i.e., MMT class) and combinations of the various risk factors and showed that a patient with an MMT III or IV classification plus protruding incisors, a short neck, and a receding mandible would have a probability of difficult laryngoscopy greater than 90% (Fig. 37-2). This study highlighted the importance of preoperative airway assessment to determine the best anesthetic intervention and the importance of prospectively preparing for airway interventions in the true obstetric emergency C/D under GA.

Gupta and colleagues evaluated the obstetric airway,[54] using the MMT and the Wilson risk sum, to assess the potential for DA in 372 patients undergoing elective or emergency C/D under GA. The Wilson risk sum score was ascertained by adding scores for five factors (weight, head and neck movement, jaw movement/jaw protrusion, receding mandible, and buck teeth). The investigators also compared the sensitivity, specificity, and PPV of the MMT score (60%, 97.6%, and 65%, respectively) with the data published by Rocke and coworkers[36] for laryngoscopy (59.2%, 74.1%, and 4.0%, respectively). The MMT was reproducible and was more sensitive than the Wilson risk sum score. As a screening test for prediction of DI, the Wilson risk sum score was less sensitive

(36%) but had almost the same specificity (98.5%) and PPV (64%) as the MMT. When both tests were combined as predictors, the sensitivity was improved to 100%, the specificity was marginally decreased to 96.2%, and the PPV (64.8%) remained almost the same, compared with the MMT score alone. Gupta and colleagues concluded that, in obstetric patients, use of the Wilson risk sum score along with the MMT score resulted in high sensitivity, high specificity, and a high PPV.[54] This study highlighted the importance of incorporating multiple predictors rather than using single (univariate) predictors of difficult laryngoscopy and intubation. There was a significant relationship between increased weight and external laryngeal manipulation.

Merah and associates studied the potential of five airway measurements to predict a difficult direct laryngoscopy in 80 West African obstetric patients during C/D under GA.[37] The five bedside tests that were evaluated were MMT, TMD, SMD, horizontal length of mandible, and interincisor gap. Eight patients (10%) had difficult laryngoscopy. The MMT as a sole predictor had a sensitivity, specificity, and PPV of 87.1%, 99.6%, and 70%, respectively. In light of the current state of knowledge with respect to airway evaluation, the investigators concluded that this prediction tool would behave similarly in Caucasians as in West Africans. Weight contributed to the prediction of difficult laryngoscopy. The difference between the mean weights of difficult-to-intubate patients (109 ± 12.4 kg) and easy-to-intubate patients (81 ± 12.0 kg) was statistically significant. The combination of MMT and TMD yielded values of 100%, 93.1%, and 61.5% for sensitivity, specificity, and PPV, respectively. The researchers concluded that MMT can be used as the sole predictor of difficult tracheal intubation.

Kodali and colleagues performed a two-part study to evaluate airway changes during labor and delivery.[23] In part I, they used the conventional Samsoon modification of the MP airway classification. The airway was photographed at the onset of labor ("prelabor") and at the end of labor ("postlabor"). Pregnant women with MP class IV airways were excluded from this initial part of the study. In part II, prelabor and postlabor upper airway volumes were measured by acoustic reflectometry. In part I (n = 61), there was a significant increase in MP class between prelabor and postlabor measurements (P < 0.0001). The airway increased by one class in 20 parturients (33%) and by two classes in 3 parturients (5%). At the end of labor, there were 8 parturients with MP class IV (P < 0.01) and 30 with MP class III or IV (P < 0.0001). In Part II (n = 21), there were significant decreases in oral volume (P < 0.05) and in pharyngeal area (P < 0.05) and volume (P < 0.001) after labor and delivery.

Boutonnet and associates methodically evaluated the changes in MP class at four time intervals in 87 pregnant patients: during the eighth month of pregnancy (T_1), at placement of the epidural catheter (T_2), at 20 minutes after delivery (T_3), and at 48 hours after delivery (T_4).[24] MP class did not change for 37% of the patients. The proportion of patients falling into MP class III or IV at the various times of assessment were as follows: T_1, 10.3%; T_2, 36.8%; T_3, 51%; and T_4, 20.7%. The differences in the percentages were all significant (P < 0.01). The incidence of MP classes III or IV increased during labor compared with prelabor period, and these changes were not reversed by 48 hours after delivery.

The studies by Kodali and Boutonnet and their colleagues confirmed the frequent increase in MP score during pregnancy and particularly during the course of labor.[23,24] These findings suggest that it is imperative to evaluate the airway in early labor and to reevaluate it before anesthetic management for operative delivery.

c. META-ANALYSIS OF BEDSIDE SCREENING TEST PERFORMANCE

Shiga and colleagues systematically determined the diagnostic accuracy of bedside tests for predicting difficult tracheal intubation in patients with no airway pathology.[55] Thirty-five studies comprising 50,760 patients, including both surgical and obstetric patients, were selected from electronic databases (Table 37-6).

The overall incidence of difficult tracheal intubation was 5.8% (95% confidence interval [CI], 4.5% to 7.5%). Screening tests included the MP oropharyngeal classification, TMD, SMD, mouth opening, and Wilson risk score. Each test yielded poor to moderate sensitivity (20% to 62%) and moderate to fair specificity (2% to 97%). The meta-analysis found that the most useful bedside test for prediction was a combination of the MP classification and TMD (positive likelihood ratio, 9.9; 95% CI, 3.1 to 31.9). The study concluded that in surgical patients, this combination of tests added some incremental diagnostic value compared with the value of each test alone.[55]

The meta-analysis showed that in the obstetric population (2155 patients), the prevalence of difficult tracheal intubation was 3.1% (95 % CI, 1.7 to 5.5). The diagnostic performance of the MP classification in obstetric and obese populations was similar to that in the overall surgical population. The diagnostic odds ratios in these populations were similar, and the trend toward poor sensitivity and fair specificity remained. In the obstetric patients, the MP classification yielded a sensitivity of 56%, a specificity of 81%, and a likelihood ratio of 0.6%. The meta-analysis data in the obstetric patients remained inconclusive because of the small number of studies and heterogeneity.

TABLE 37-6

Pooled Estimates of Bayesian Statistics from Six Bedside Tests for Difficult Intubation (DI)*

*Post-test probability = ((pretest odds) • likelihood ratio)/(1 + (pretest odds) • likelihood ratio); where pretest odds = pretest probability/(1 – pretest probability). The DerSimonian-Laird random-effects model was used throughout. Significant heterogeneity ($P < 0.1$) was found except where indicated.

†Difference not significant.

From Shiga T, Wajima Z, Inoue T, Sakamoto A: Predicting difficult intubation in apparently normal patients. *Anesthesiology* 103:429–437, 2005.

Whereas in the obese patients (BMI > 30 kg/m^2), the incidence of difficult tracheal intubation was 15.8 % or three times higher than in the overall population. Obese patients with a 15% pretest probability of DI had a 34% risk of difficult tracheal intubation after a positive MP class result, which is twice the risk of the overall population with a 5% pretest probability. Similarly, obese pregnant patients also had a higher incidence of difficult tracheal intubation. Because of the higher incidence of difficult tracheal intubation, the MP classification may yield higher post-test probability of difficult tracheal intubation in obese patients than in the overall population.[55]

5. Trends in Anesthesia in Obstetrics

Cesarean delivery is the commonest major surgical procedure carried out in the United States (U.S. Centers for Disease Control and Prevention National Center for Health Statistics Report 2010) and the incidence is increasing worldwide.[56] The increased incidence of maternal morbidity and mortality associated with GA in obstetric patients and the heightened awareness among anesthesia practitioners of the risk for DA and failed intubation in obstetrics has led to an increased use of RA techniques. A 2009 closed claims analysis found that use of RA was 65% before 1990 and increased to more than 80% since then, whereas the use of GA declined from 33% before 1990 to 17% after 1990.[1] National Health Service maternity statistics show that the number of obstetric GAs for C/D administered in the United Kingdom fell from over 50% in 1989-90, to as low as 5% in 2004-2005.[57] Johnson and colleagues similarly found a marked decline in GA for C/D, from 79% to less than 10% over the same period.[58]

The current trend in the United States and the United Kingdom is to use GA mainly for the true emergency C/D, if there is insufficient time for a regional technique, or in cases in which there is a contraindication to RA. Despite the decline in the use of GA for C/D, the incidence of difficult tracheal intubation was not found to be significantly different (5% before 1990 versus 3% after 1990).[1] Encountering a DA in the obstetric population is not uncommon; therefore, the emerging problem of declining airway skills is important, as evidenced by a rise in the rate of failed tracheal intubation, from 1:300 between 1978 and 1983 to 1:250 in 1994.[40,59,60] It is uncertain whether these concurrent trends are interrelated. The risk of failed tracheal intubation is considerably higher for emergency than for elective C/D, with 80% of airway-related fatalities occurring during emergency C/D (nights and weekends) and usually involving trainees.[40] A review of GA for C/D at a tertiary hospital during the period 1990-1995 showed a decline in the use of GA, from 7.2% to 3.6%.[2] A further review of GA for C/D from 2000 to 2005 in the same institution showed that GA use had further declined to a low incidence of about 1%.[43]

Because of the decreased use of GA for C/D, anesthesia trainees' experience of GA in obstetric patients is also on the decline. The lack of opportunities for training and maintenance of airway skills is an emerging concern.[58,61,62]

IX. RECOMMENDATIONS FOR MANAGEMENT OF THE DIFFICULT AIRWAY

Guidelines for the management of anticipated and unanticipated DA have been published by various national societies. The guidelines of the ASA Task Force were originally developed as a consequence of the high number of perioperative respiratory adverse events during airway management.[63,64] The updated version of the DAA was published in 2003 (Fig. 37-3).[4] The ASA DAA guidelines include evaluation of the airway, physical examination (as described earlier), basic preparation for the DA, and follow-up care. Although these points are applicable to the obstetric patients as well, some elements of the ASA DAA and their adaptability to the obstetric DA cannot be assessed due to the lack of strong evidence. The available evidence on management of the DA in the obstetric patient is mainly in the form of case reports. The ASA DAA provides a framework for management of the DA and should be modified and adapted to the obstetric patient where applicable.

A key point of the ASA DAA and its strength is the recommendation of a clear strategy for management of both the anticipated and the unanticipated DA. This strategy, however, depends on the skills and preferences of the anesthesia practitioner. The ASA Task Force strongly recommended the use of strategies to maintain oxygenation throughout the process of airway management. It is the cornerstone of airway management in situations including the nonemergency pathway, the emergency pathway, and increasing hypoxemia during the CICV critical airway situation. Crucial elements of the ASA DAA include an early attempt at insertion of the LMA if face mask ventilation is not adequate (strengthened in the updated version), the possibility of awakening the patient, and simple "call for help" at an early stage. These are all applicable in the obstetric DA scenario and add to the strength of the algorithm. As mentioned earlier, the ASA DAA offers many options; however, it is not specific for an urgent obstetric situation.

X. EQUIPMENT (DIFFICULT AIRWAY CART)

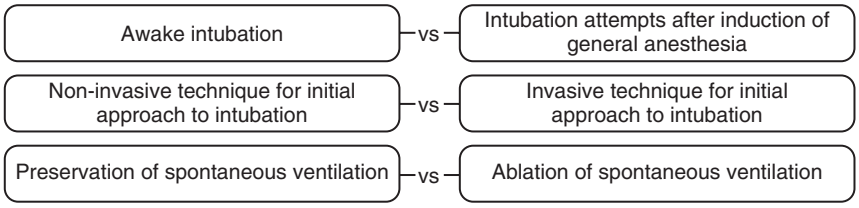
The ASA DAA recommended that anesthesia personnel familiarize themselves with the patients and the airway equipment in advance. Likewise, the ASA Practice Guidelines for Obstetric Anesthesia recommended that airway equipment should be readily available in the labor and delivery area.[45] Based on our own experience, we believe that equipment and anesthesia personnel should actually be *immediately* available in the labor and delivery area, throughout the 24-hour shift, on a daily basis. Our current practice is to have a designated DA cart immediately available inside our obstetric operating rooms for use in airway emergencies, and this policy has proved to be invaluable on many occasions.[65-67]

The fiberscope is located in a predesignated slot on the side of our DA cart. The top shelf has all the equipment and local anesthetics required for an awake tracheal intubation as well as an optical stylet for optimizing the glottic view during a DI under GA. The next three drawers are organized to follow the sequence of clinical scenarios that one might encounter during an unanticipated DA:

- Drawer A: Supraglottic airways of sizes 3 and 4 (LMA Excel, Fastrach LMA, ProSeal LMA) for use in the nonemergency pathway
- Drawer B: Specialized supraglottic airways (Combitube 37 F, King LTS-D sizes 3 and 4) for use in the emergency pathway
- Drawer C: Equipment available for invasive airway access (cricothyroidotomy kit, transtracheal jet cannula with adapter) for use in the emergency pathway, critical airway situation

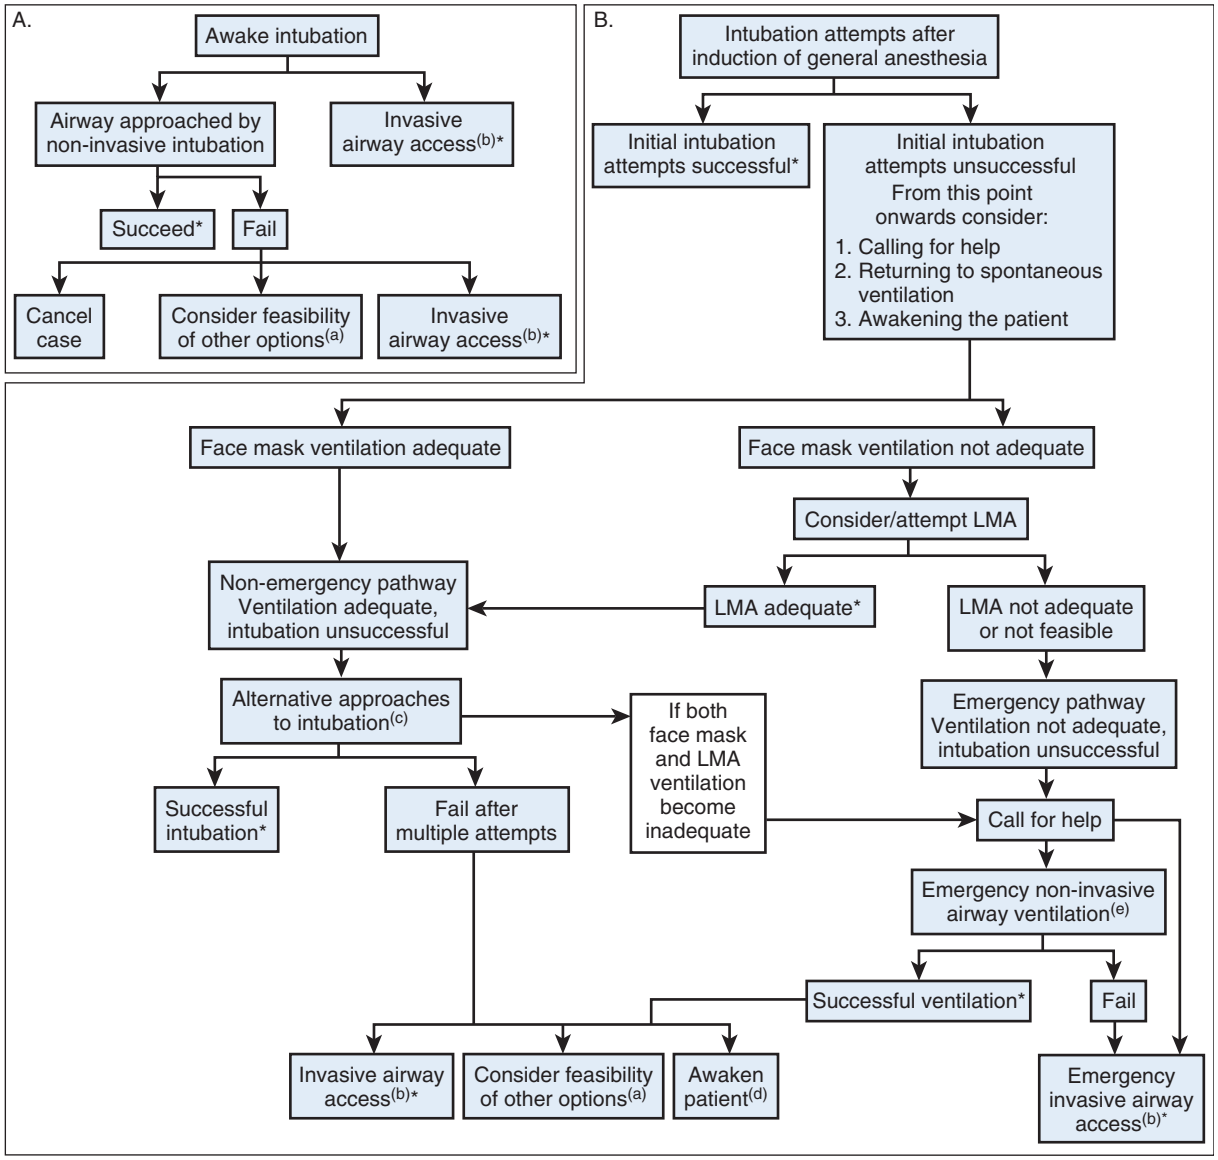
XI. ANTICIPATED DIFFICULT INTUBATION

Because the incidence of difficult tracheal intubation is significantly higher in the obstetric population, especially during emergency C/D and on nights and weekends,[40] it is only prudent to avoid GA for C/D if other safe anesthetic choices are available. In modern obstetric anesthesia practice, neuraxial anesthesia is administered to some patients who would have received GA in the past, such as patients with severe preeclampsia with lower platelet count, placenta previa without active bleeding, or umbilical cord prolapse in a parturient with a functioning epidural catheter.



The use of neuraxial anesthesia is based on current evidence in the literature, which includes the following:

1. An increased use of epidural anesthesia during labor in high-risk parturients
2. A heightened awareness that an in situ functioning epidural catheter may decrease the necessity for GA in an urgent situation
3. Understanding that the presence of a functioning epidural catheter allows analgesia to be converted to epidural anesthesia, if necessary for a C/D
4. Appreciation of the risks of airway complications associated with GA for C/D
5. Improvement in the quality of intraoperative and postoperative pain management, with the addition of opioids to the local anesthetic, during spinal and epidural blocks
6. Keeping parturients awake and allowing for bonding with the baby during C/D



The current practice of placing epidural catheters prophylactically, early in labor, in high-risk parturients who have clinical conditions such as morbid obesity, DA, or obstetric comorbidities or complications has reduced the risk of an unanticipated GA. This is considered best practice and is in keeping with the most recent ASA guidelines for obstetric anesthesia.[45] The practice guidelines advocate this concept of using a prophylactic epidural in high-risk parturients, which basically involves the placement of a catheter and the confirmation of functionality with small amounts of local anesthetic, early in labor, and possibly before a request for analgesia. This provides a readily available neuraxial route of anesthesia, should an

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficulty with patient cooperation or consent
   - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies:

*Confirm ventilation, tracheal intubation, or LMA placement with CO_2.

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid branchoscope, esophageal-tracheal Combitube ventilation or transtracheal jet ventilation.

Figure 37-3 Difficult airway algorithm (DAA). *LMA,* Laryngeal mask airway. (From American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology* 98:1269–1277, 2003.)

emergent operative delivery be necessary. If the epidural catheter is not functioning well, it should be replaced with either a functioning continuous epidural catheter or a continuous spinal catheter.

Current evidence confirms the efficacy of dosing in situ epidural catheters in achieving decision-to-delivery intervals (DDI) for C/D and is comparable to that achieved with GA.[68,69] Evidence suggests that it is necessary to allow the shortest DDI for the true fetal distress situation; additionally, the recommended 30-minute DDI for emergency cesarean deliveries is appropriate[18] and allows the administration of a spinal anesthetic. Holcroft and colleagues showed the outcomes classified by type of anesthesia.[70] DDI for GA was almost 15 minutes shorter than for spinal anesthesia and 13 minutes shorter than for epidural anesthesia (P = 0.0002). The epidural group had functioning labor epidurals that were converted to surgical anesthesia for C/D, whereas the spinal anesthesias were performed after the decision for C/D was made. There were no differences in the incidence of 1-minute Apgar scores lower than 7 based on anesthesia type, but there was a significant increase in 5-minute APGAR scores lower than 7 in the GA group. There was no difference in the umbilical arterial pH between the groups, but the base excess was significantly worse in the GA group. The investigators concluded that although GA is considerably faster than either spinal or epidural anesthesia, it is well established that GA poses greater maternal risk.[13,71] Therefore, the benefits of obtaining anesthesia sooner versus the risk of a maternal complication must be weighed and determined by the obstetrician and anesthesiologist working in consultation together in each individual case. The American Congress of Obstetricians and Gynecologists (ACOG) Committee Opinion entitled, "Anesthesia for Emergency Deliveries" endorsed the following stance: "Cesarean deliveries that are performed for a nonreassuring fetal heart rate pattern do not necessarily preclude the use of regional anesthesia."[72] These guidelines require both familiarity and knowledge for application in an urgent C/D situation.

Another option for neuraxial techniques for C/D is deliberate continuous spinal analgesia using the Tuohy needle and an epidural catheter. A recent study by Palanisamy and colleagues confirmed that (1) the rate of use of GA for cesarean delivery between 2000 and 2005 was low, approximately 1%; (2) 85% of GAs were administered for emergent deliveries; (3) most were performed because of a perceived lack of time, particularly for the emergency deliveries; (4) very few GA cases resulted from failure of neuraxial anesthesia techniques; and (5) there was a very low incidence of GA-related morbidity with no cases of mortality.[43] This study confirmed first, that the policy of placing epidural catheters prophylactically in high-risk parturients, particularly obese parturients with potential DA, has reduced the risk of unanticipated GA. Second, the adoption of a more aggressive approach toward management of inadequate neuraxial block (by replacing epidural catheters for suboptimal analgesia during labor) may have reduced the incidence of intraoperative conversion to GA. Third, the willingness to perform emergent spinal anesthesia, including intentional continuous spinal techniques, especially in patients with certain comorbid conditions (e.g., severe preeclampsia)[73,74] or morbid obesity,[75] may have been partly responsible for the reduction in GAs.

The use of a combined spinal/epidural technique for labor analgesia in a high-risk parturient may not be the most prudent choice. Even though several studies have found a lower incidence of failed epidural analgesia after initiation of analgesia with a combined spinal/epidural technique,[76,77] there is a disadvantage in that the correct placement of the epidural catheter in the epidural space cannot be verified until the spinal anesthesia wanes. Therefore, if a functioning epidural is important, so as to be able to convert to surgical anesthesia for emergency C/D, especially in a parturient who has a high probability of a DA or a nonreassuring fetal status, then a combined spinal/epidural technique is not the preferred technique for labor analgesia.

If neuraxial anesthesia is contraindicated due to maternal hemorrhage, coagulopathy, or umbilical cord prolapse, one may have to resort to GA. The DA cart should be immediately available in the operating room and should include other advanced airway devices such as a cricothyroidotomy kit and transtracheal jet ventilation (TTJV) equipment. It is prudent to inform the ear, nose, and throat surgeon or the general surgeon to remain readily available in these situations.

XII. AIRWAY MANAGEMENT STRATEGIES

A. Cesarean Delivery

The anesthesia practitioner must have a clear and effective plan for managing a patient with DA, a difficult or failed intubation, or a CICV in a parturient undergoing C/D under GA. The ASA DAA is a beginning for an organized approach to DA problems.[4] All anesthesia practitioners must be familiar with the ASA DAA. Although this algorithm is commendable in providing a logical, well-organized overview of the DA, it is not easily memorized and is not easy to implement in emergency situations, especially when two lives (mother and baby) are at risk. The United Kingdom DAS basic guidelines[5] are more linear and emphasize a four-point approach with each plan consequent on failure of the previous plan (Fig. 37-4):

- Plan A: Initial intubation attempt
- Plan B: Secondary intubation attempt
- Plan C: Maintain oxygenation and ventilation using rescue techniques with supraglottic devices and bail out
- Plan D: Invasive techniques for the CICV situation

Two principles are emphasized in these guidelines: (1) maintenance of oxygenation during the execution of each plan and (2) seeking the best assistance available as soon as difficulty with laryngoscopy is experienced.

For purposes of this discussion, we have adapted our recommendations for airway management strategies in the obstetric patient with due consideration to both the ASA DAA guidelines and the U.K. DAS guidelines.

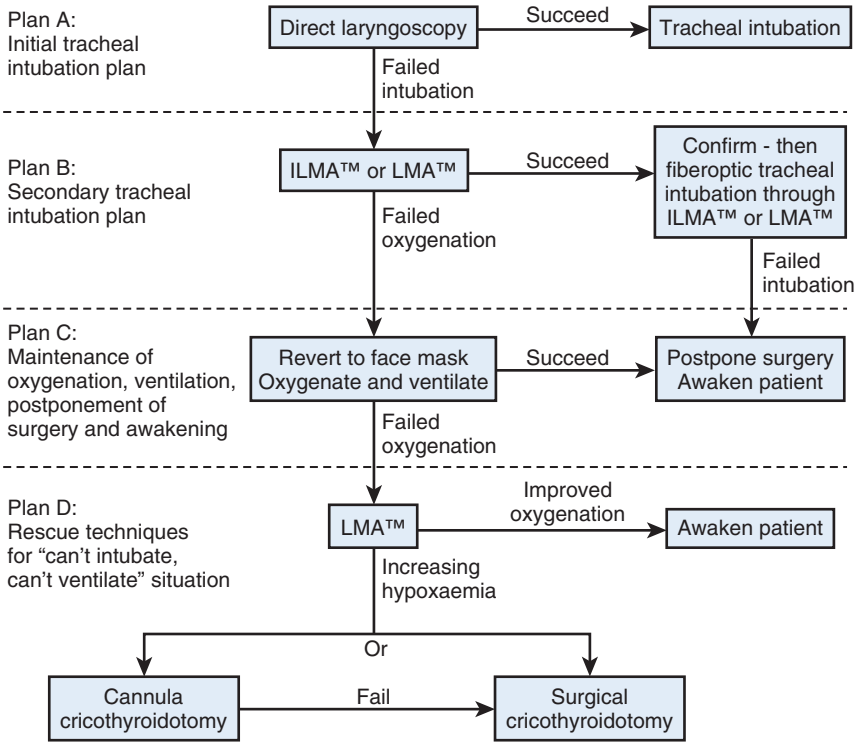


Figure 37-4 Airway management strategies for patients undergoing cesarean delivery. *ILMA,* Intubating laryngeal mask airway; *LMA,* laryngeal mask airway. (Adapted from Henderson JJ, Popat MT, Latto IP, Pearce AC: Difficult Airway Society guidelines for management of the unanticipated difficult intubation. *Anaesthesia* 59:675–694, 2004.)

B. Awake Fiberoptic Intubation

In a parturient who has a known history of DA, an anticipated DA, morbid obesity, certain anatomic features indicating that tracheal intubation by conventional means is likely to be difficult or impossible, or contraindications to RA and is undergoing C/D, a safe option is to secure the airway with the tracheal tube while the patient remains awake. If RA is not an option and time is not an issue, an awake tracheal intubation can be performed safely with the use of either a flexible fiberscope or a video laryngoscope.[78,79] The following paragraphs describe the logical approach to awake tracheal intubation.

Adequate preparation is crucial to the success of an awake tracheal intubation and has several aspects:

- Psychological preparation of the patient.
- Administration of an antisialagogue such as glycopyrrolate, 0.2 to 0.3 mg intravenously, 10 to 15 minutes before the application of topical anesthesia to dry the oropharyngeal secretions. Excessive secretions interfere with the effects of local anesthetics. Glycopyrrolate, being a quaternary ammonium compound, does not cross the placenta.
- Judicious sedation with midazolam (1 mg) and fentanyl (50 to 100 μg) intravenously, so that the patient is calm and cooperative, without risking respiratory depression in the mother or neonate. Opioids produce analgesia and depress the airway reflexes to facilitate smooth oropharyngeal and laryngeal instrumentation.
- Adequate topicalization of the airway with local anesthetic to make it nonreactive to physical stimulation. Topical anesthesia of the oropharynx is achieved with 4 or 5 short sprays of 4% lidocaine to the palate, base of the tongue, and lateral and posterior pharyngeal walls. Two minutes after the spray of local anesthetic, 2% lidocaine gel is spread on the base of the tongue with a tongue blade, to supplement the topical anesthesia and to prevent gagging. Use of a good topical anesthetic before endoscopy prevents coughing, gagging, and laryngeal spasm and contributes to the success of the technique. Depressed gag and airway reflexes can make the parturient more susceptible to pulmonary aspiration of gastric contents. Ovassapian and colleagues[80] presented the concept of topicalization of the lower airway and awake fiberoptic tracheal intubation in patients at high risk for pulmonary aspiration and have helped diffuse that controversy.
- The "Spray as you go" technique with local anesthetic spray of 2% lidocaine. This is used for application of the topical anesthetic and for anesthetizing the upper airway from the tip of the tongue to the trachea.
- The advanced airway management skills of the operator. The skill of the anesthetist is equally important for success of the technique.

Research has documented the successful use of awake fiberoptic tracheal intubation in 60 parturients with DAs undergoing C/D.[81] These parturients received judicious sedation and underwent full topicalization, including transtracheal injection of lidocaine (except that those parturients with coagulopathy received nebulized lidocaine), and there were no cases of pulmonary aspiration.

Lower esophageal tone is maintained in patients who are not oversedated and prevents pulmonary aspiration regardless of the extent of topicalization. In our own institution, we are occasionally faced with similar clinical situations and have successfully used awake, oral fiberoptic intubation to secure the airway before administration of GA for cesarean delivery.[82]

The nasal route for awake, fiberoptic tracheal intubation has been used occasionally in pregnant women. However, it should be used with caution because of the hyperemic nasal mucosa and the potential for inducing epistaxis.

XIII. UNANTICIPATED DIFFICULT TRACHEAL INTUBATION

A. Step 1: Initial Tracheal Intubation Attempt

We propose a five-step flow chart for unanticipated difficult tracheal intubation after induction of GA in the obstetric patient (Fig. 37-5). It is based on the ASA DAA and the U.K. DAS algorithm and is modified for the obstetric patient. Each step should not take longer than 30 to 45 seconds, so no more than 5 minutes should elapse before the decision is made to use invasive airway access in the emergency pathway—critical airway scenario.

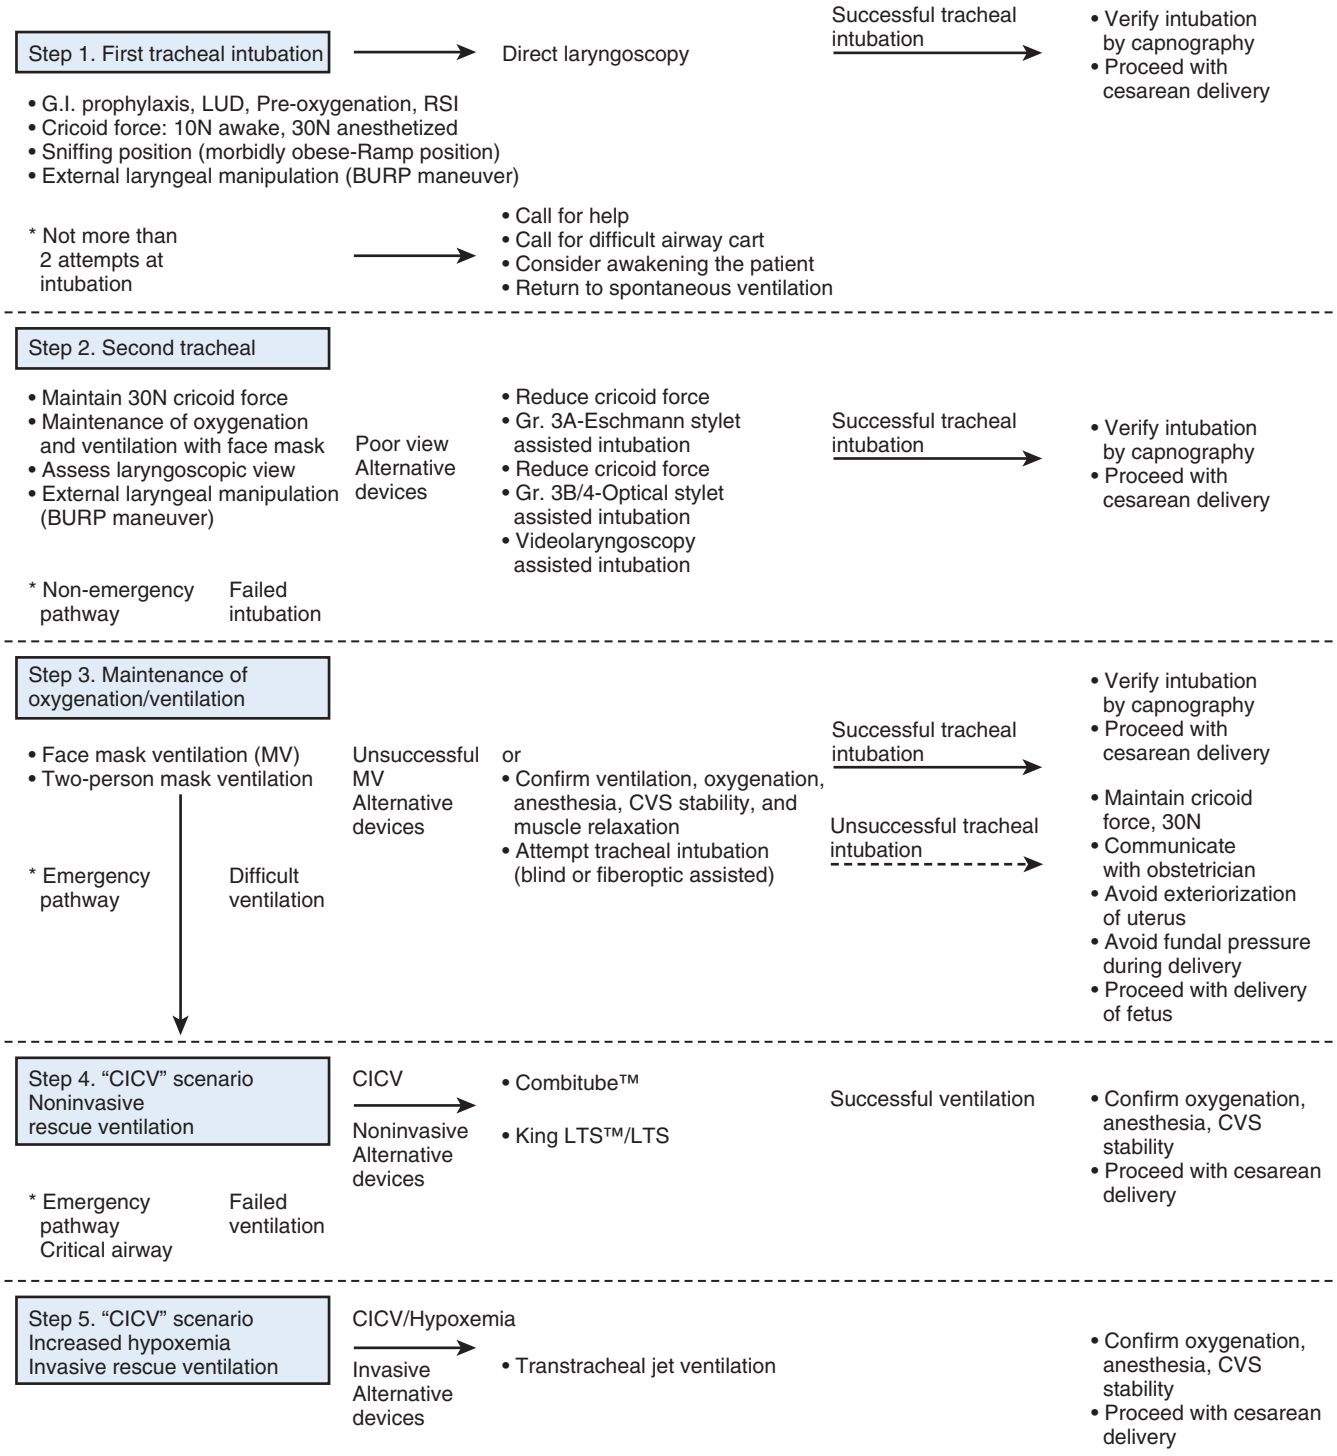
If the decision is made to proceed with GA, and before induction of anesthesia and intubation, one must strictly adhere to certain basic principles: use of gastrointestinal prophylaxis to prevent aspiration; optimal positioning, including the placement of a wedge under the right hip to offset any aortocaval compression; and use of the ramped-up position in obese parturients to facilitate laryngoscopy, tracheal intubation, and ventilation.

Induction of anesthesia is preceded by preoxygenation to effectively denitrogenate the lungs; effective use of a preoxygenation technique that maximizes oxygen stores (preoxygenation for 3 to 5 minutes or 4 deep breaths over 30 seconds)[83]; and the first attempt at direct laryngoscopy should always be performed in optimal conditions. After succinylcholine administration and confirmation of adequate muscle relaxation, appropriate head and neck position, and use of effective cricoid pressure, proceed with RSI and tracheal intubation. The application of optimal external laryngeal manipulation to optimize the laryngoscopic view may be critical. All these elements are important in managing the DI scenario (see Fig. 37-5, Step 1) and are discussed in detail in the following sections.

1. Aspiration Prophylaxis

Because of the risk for gastric regurgitation and pulmonary aspiration, all pregnant patents are considered to have a "full stomach" regardless of their preoperative fasting status. Aspiration risk can be mitigated by oral administration of triple pharmacologic prophylaxis that includes sodium citrate to neutralize the acidic contents of the stomach; intravenous (IV) administration of a histamine (H_2) receptor antagonist to reduce gastric acid secretion; and IV administration of a gastrokinetic drug, such as metoclopramide, to speed up gastric emptying and increase the tone of the lower esophageal sphincter.

2. Positioning



Proper positioning of the patient is an often missed critical step in facilitating laryngoscopy, tracheal intubation, and mask ventilation, if needed. The optimal sniff position (slight flexion of the neck and extension of the head on the neck), which aligns the oral, pharyngeal, and laryngeal axes into a straight line, is mandatory to facilitate tracheal intubation.[52] The neck should be flexed on a pillow and the A-O joint extended to achieve the optimal sniffing position. However, in morbidly obese patients including parturients, one should utilize the head-elevated laryngoscopy (HELP) position and create a ramp, using folded towels or blankets under the shoulders and head to ensure that the head and shoulders are higher than the chest.[84] The HELP position is determined by drawing an imaginary horizontal line that connects the patient's sternal notch with the external auditory meatus, so that the head and neck are at a slightly higher elevation than the chest. The Troop Elevation Pillow (Mercury Medical, Clearwater, FL) is shaped like a ramp and is designed to optimize the HELP and sniffing positions.

3. Cricoid Pressure

Cricoid pressure has played an important role in prevention of pulmonary aspiration since its introduction by Sellick.[85] It is an integral part of the flow chart for the patient having RSI for cesarean delivery. Sellick first described a neck maneuver to compress the esophagus between the cricoid cartilages anteriorly and the body of the sixth cervical vertebra posteriorly in order to prevent regurgitated gastric contents from entering the hypopharynx during induction of GA.[85] Typically, a cephalad and posteriorly pointing force of 10 newtons (N), applied by the thumb and index finger of the assistant, is required in the awake patient; this force increases up to 30 N in the unconscious patient.[86,87] On the other hand, as important as cricoid pressure is to prevent regurgitation of gastric contents into the oropharynx,[88] excessive cricoid pressure may obscure the glottic view by displacing the vocal cords anteriorly or laterally.[89] The assistant may be asked to transiently reduce or release cricoid pressure, with suction at hand, so that the glottic area and vocal cords can be visualized, despite the possible risk of pulmonary aspiration in the event of gastric regurgitation.[90,91] Aspiration is treatable, whereas irreversible hypoxia is not.

4. External Laryngeal Manipulation

Various steps taken to optimize the laryngoscopic view with external laryngeal manipulation, referred to as the BURP maneuver (i.e., backward, upward, rightward pressure on the thyroid cartilage) and the use of an Eschmann introducer can maximize the success of tracheal intubation. The use of optimal external manipulation (i.e., the BURP maneuver) involves pressure on the thyroid cartilage and displacement of the larynx in three specific directions—posteriorly against the cervical vertebrae, as far superiorly as possible, and slightly laterally to the right.[92] Because the thyroid cartilage is the surface

* Note: Steps 1 through 5 should be time limited. No more than 30-45 seconds each.

Figure 37-5 Five-step approach to unanticipated difficult tracheal intubation during rapid-sequence induction *(RSI)* of anesthesia in the obstetric patient. The BURP maneuver consists of backward, upward, and rightward pressure on the thyroid cartilage. *CICV,* "Cannot intubate, cannot ventilate"; *CVS,* cardiovascular system; *G.I.,* gastrointestinal; *Gr.,* Cormack-Lehane grade (laryngoscopic view); *LUD,* left uterine displacement; *N,* newtons (unit of force).

marking for the laryngeal aperture, proper application of the BURP maneuver improves the laryngoscopic view. In a study comparing glottic views with and without use of the BURP maneuver, it was shown that the BURP maneuver improved the glottic view by at least one whole grade and reduced the incidence of failure to view any portion of the glottis from approximately 9.2% to 1.6%.[92]

B. Step 2: Second Tracheal Intubation Attempt

1. Consider Calling for Help, Returning to Spontaneous Ventilation, and Awakening the Patient

In all but the most urgent situations, one can consider awakening the mother and reassessing the fetus before proceeding with an alternative plan. However, in urgent and emergent C/D situations under GA, the goal should be to balance maternal oxygenation, prevention of pulmonary aspiration, and expeditious delivery of the fetus. Such a situation dictates addressing management of the DA after a failed tracheal intubation attempt. Appropriate initial management and procedures after failed attempts at tracheal intubation can influence and even ensure the final optimal and best outcome for both mother and baby. Calling for help is critical; it should be done sooner rather than later. Immediate access to the DA cart is critical as well.

Despite use of optimal positioning and the BURP maneuver, if the first attempt at intubation fails because of a poor view, particularly a grade 3 laryngoscope view, other alternative intubation devices (i.e., Eschmann introducer, optical stylet, video laryngoscope) should be considered to assist in the second attempt at intubation (see Fig. 37-5, Step 2). There should be no more than two attempts at tracheal intubation in an obstetric patient. The second attempt at laryngoscopy should be considered the "best attempt at tracheal intubation." To increase the success rate, it should be performed by a reasonably experienced anesthesiologist, the optimal sniff or ramped position should be used, and external laryngeal manipulation should be applied. Additionally, the laryngoscope blade type and handle may need to be changed. If necessary, cricoid pressure may be transiently released to optimize the glottic view.

Persistent attempts during emergency tracheal intubation have shown that there was a significant increase in the rate of airway-related complications as the number of laryngoscopic attempts increased (comparing ≤2 with >2 attempts), resulting in hypoxemia (11.8% versus 70%), regurgitation of gastric contents (1.9% versus 22%), aspiration of gastric contents (0.8% versus 13%), bradycardia (1.6% versus 21%), and cardiac arrest (0.7% versus 11%) ($P < 0.001$).[32] We also recommend limiting the intubation attempts to two in an emergent obstetric case.[93-95]

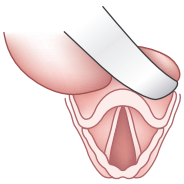
2. Role of Eschmann Introducer (Gum Elastic Bougie)—Grade 3A Laryngoscopic View

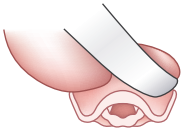
The Eschmann introducer, commonly referred to as the gum elastic bougie, is used universally to facilitate difficult tracheal intubation.[96] The original Cormack and Lehane classification of laryngoscopic view[50] was recently modified by Cook,[97] who proposed subdividing grade 3 into grades 3A and 3B (Fig. 37-6). In grade 3A, the glottic aperture cannot be seen but the epiglottis can be visualized and elevated; hence, a role for indirect methods, such as the Eschmann introducer, is indicated. Success rates have been shown to be similar between the Eschmann introducer and optical stylets in the grade 3A airway (31 versus 29.2 seconds).[98]

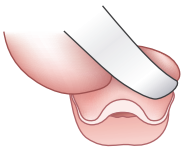
3. Role of Optical Stylets—Grade 3B/4 Laryngoscopic View

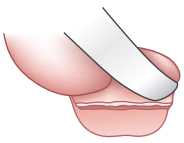
In grade 3B, when the glottic aperture cannot be seen and the epiglottis is visualized but cannot be elevated, other alternative methods may be used (see Fig. 37-6).[99] Optical stylets have been used successfully to facilitate rapid tracheal intubation in the grade 3B laryngoscopic view and to help confirm tracheal tube placement.[98] The success rate has been shown to be higher with optical stylets than with the Eschmann introducer, and the time required is shorter with optical stylets in the grade 3B view (31 versus 45.6 seconds).[98]

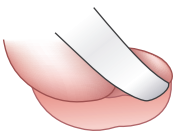
4. Role of Video Laryngoscopy











Video technology has become widespread across medical/surgical disciplines and allows improved visualization of anatomic detail. Besides allowing management of the DA, video laryngoscopy can be a useful teaching tool during both direct and indirect laryngoscopy.[100] The portability of video laryngoscopes should facilitate their use in the operating room and also in managing airway calls in emergency departments, intensive care units, endoscopy suites, and radiology suites. It seems only natural that video laryngoscopy will become the norm in managing and teaching the DA in the near future.

Perhaps, in situations in which traditional laryngoscopy fails during the first attempt, the next attempt (best attempt at tracheal intubation) should be the use of a video laryngoscope with which the operator is familiar. Some of the devices available include the Berci Kaplan DCI, Glidescope, McGrath Scope, and CMAC Storz. The Glidescope has been successfully used in large studies and case series.[78,101] Potential difficulty can be overcome by using a rigid stylet and shaping the tracheal tube before attempting insertion.

Channeled video laryngoscopes include the AirTraq, Pentax, and KingVision. These scopes are designed to provide an easy glottic view without aligning the oral, pharyngeal, and tracheal axes and have a channel for holding the tracheal tube. There has been one report of two cases of rapid tracheal intubation using Airtraq in morbidly obese parturients undergoing emergency cesarean delivery after failed tracheal intubation.[102]

Some centers have already implemented the practice of video laryngoscopy as the "first-look" airway device for immediate C/D under GA, and for the anticipated difficult tracheal intubation. The use of alternative devices such as the Eschmann introducer, optical stylets, and video laryngoscopes can enhance the intubation success rate during the second tracheal intubation attempt.

Cook's modification of Cormack and Lehane's Laryngeal Grades of the Airway

	Visualized oral opening	Potential intubation implications
 Grade 1	Entire glottic opening from the anterior to posterior commissure	Should facilitate an easy intubation
 Grade 2	Just the posterior portion of glottis	Normally not difficult to pass a styletted otracheal tube through the laryngeal aperture
 Grade 3a*	Epiglottis only (epiglottis can be lifted using a laryngoscope blade)	Intubation is difficult but possible using a bougie introducer or flexible fiberoptic scope
 Grade 3b*	Epiglottis only (but epiglottis cannot be lifted from the posterior pharynx using a laryngoscope blade)	Intubation can be difficult because insertion of a bougie introducer (e.g., gum elastic bougie) may be impeded, which can directly affect the successful use of a bougie introducer or a flexible fiberoptic scope
 Grade 4*	Only soft tissue, with no identifiable airway anatomy	Difficult intubation, requiring advanced techniques to intubate the trachea

*Tracheal intubation normally requires an advanced airway technique beyond direct laryngoscopy

Figure 37-6 Cormack and Lehane's laryngeal grades of the airway, as modified by Cook. (Adapted from Cook TM: A new practical classification of laryngeal view. *Anaesthesia* 55:274–279, 2000.)

C. Step 3: Maintenance of Oxygenation and Ventilation

The goals and priorities in airway management strategies after a failed second tracheal intubation should include (1) maintenance of maternal oxygenation, (2) prevention of gastric regurgitation, (3) airway protection, and (4) expeditious delivery of the fetus (see Fig. 37-5, Step 3).

Maintaining oxygenation in the parturient is of paramount importance. Pregnancy-related changes can result in rapid development of hypoxemia and acidosis.[103] Because adequate oxygenation is critical, mask ventilation in the presence of cricoid pressure is attempted. If mask ventilation is difficult, an optimal or best attempt at ventilation (i.e., two-person mask ventilation via a conventional face mask) is initiated while cricoid pressure (30 N) is maintained.[95]

The algorithm then divides into two pathways, determined by the presence or absence of adequate face mask ventilation.

After a failed second attempt at tracheal intubation, if oxygen saturation is maintained, the patient is considered to be on the *nonemergency pathway* (cannot intubate, but can ventilate), and use of the classic LMA, the intubating laryngeal mask airway (ILMA), or the ProSeal laryngeal mask airway (PLMA) as a rescue device must be considered. The revised ASA DAA, based on evidence in the literature, supports the role of the LMA in airway management.[104,105] The LMA not only is useful to provide maternal oxygenation, ventilation, and anesthesia but also serves as a conduit for intubation. Cricoid pressure may have to be reduced or released transiently to allow proper placement of the LMA.[91] The LMA or ILMA may

be used as a conduit for tracheal intubation, either blind or fiberoptically assisted (see Fig. 37-5, Step 3).

1. The Classic Laryngeal Mask Airway

The classic LMA has been widely used for the difficult obstetric airway without any episodes of gastric regurgitation or pulmonary aspiration.[40,106-109] Han and colleagues successfully used the classic LMA as a ventilatory device in 1060 of 1067 parturients undergoing elective cesarean delivery.[110] No episodes of hypoxia, regurgitation, or aspiration were reported. Multiple case reports in the literature have described successful use of the classic LMA after failed tracheal intubation in obstetric patients.[107,111-114] In patients requiring tracheal intubation, fiberoptic-guided tracheal intubation through the classic LMA is reliable.[115] However, a longer tracheal tube (e.g., Endotrol, Microlaryngeal, or Nasal Ring-Adair-Elwyn) is needed. The Aintree exchange catheter (Cook Medical, Bloomington, IL) may also be used to facilitate intubation through the classic LMA.

The fiberscope/Aintree catheter exchange technique is extremely useful in switching from an LMA to a tracheal tube.[116] The Aintree catheter is 56 cm long and, once preloaded on the fiberscope, allows the distal 3 to 4 cm of the fiberscope to be available for manipulation and passage via the LMA into the trachea. The inner diameter of the Aintree catheter is 4.8 mm, allowing it to be preloaded on no larger than a 4.0-mm pediatric fiberscope. Its removable Rapi-fit connector allows for oxygen insufflation, if necessary, during the airway exchange. Its external diameter is 6.5 mm, allowing it to be used as an airway exchange catheter (AEC) for tracheal tubes that have an internal diameter of 7 mm or more. This airway exchange technique involves the following steps (see Fig. 35-2 in Chapter 35):

1. Insertion of LMA and cuff inflation
2. Confirmation for easy ventilation and oxygenation
3. Passage of fiberscope, preloaded with Aintree catheter, via the LMA into the trachea under vision
4. Removal of fiberscope, leaving the Aintree catheter in the trachea, with the LMA in situ
5. Deflation of LMA cuff, followed by removal of LMA
6. Passage of tracheal tube of at least 7 mm internal diameter over the Aintree catheter into the trachea

2. The Intubating Laryngeal Mask Airway

The LMA Fastrach or ILMA is designed to specifically overcome the problems associated with blind tracheal intubation through the classic LMA.[117] The ILMA is particularly useful during failed intubation in an emergency C/D because it provides oxygenation and a conduit for blind tracheal intubation and prevents pulmonary aspiration. Several studies have shown successful use of the ILMA to help visually unassisted tracheal intubation in patients with a DA.[115,117,118] The ILMA was used successfully after failed tracheal intubation during an emergency C/D in a patient who was morbidly obese and eclamptic and in a second case in which RA had failed and was followed by GA resulting in failed tracheal intubation.[66,67] The ILMA proved to be a life-saving device in both parturients.

3. The ProSeal Laryngeal Mask Airway

The PLMA is a unique device that represents a substantial change in LMA design. The PLMA offers several advantages over the classic LMA for failed tracheal intubation in obstetrics: (1) the seal is 10 cm H_20 higher, giving it greater ventilatory capability[119]; (2) it enables correct positioning in which the glottis is isolated from the esophagus and therefore may provide airway protection and protection against pulmonary aspiration[120,121]; (3) it facilitates gastric tube insertion to empty the stomach of fluid and air insufflated during difficult face mask ventilation. The PLMA has been used successfully after failed intubation during emergency C/D.[120,122-124]

After failed tracheal intubation, and once the anesthesia practitioner is able to successfully achieve pulmonary ventilation and oxygenation through the LMA, caution must be used in selecting a nonirritating inhalation anesthetic and in providing an adequate depth of anesthesia. Sevoflurane provides rapid, smooth induction and adequate depth of anesthesia; it is the least irritating volatile agent,[125] and it helps facilitate tracheal intubation through the LMA in patients with a DA.[126]

If tracheal intubation is difficult via the LMA and the fetal or maternal condition warrants immediate surgery, the obstetrician should be asked to proceed with cesarean delivery while the anesthesia care team maintains cricoid pressure and provides oxygenation and anesthesia via the LMA. Communication with the obstetrician should include the need to avoid both exteriorization of the uterus and fundal pressure during cesarean delivery, because of the unprotected airway and the risk of regurgitation and aspiration (see Fig. 37-5, Step 3).

D. Step 4: CICV—Noninvasive Rescue Ventilation

1. Emergency Pathway

If face mask ventilation was not adequate and the LMA was ineffective in providing oxygenation and ventilation, the patient is considered to be on the *emergency pathway* (CICV) and will require rescue ventilation with other noninvasive devices[4] such as the Combitube. King LTS/LTS-D may be a suitable alternative to the Combitube (see Fig. 37-5, Step 4).

2. Combitube

The Combitube should be considered in emergency airway situations, especially when patients are at risk for pulmonary aspiration, tracheal intubation has failed, and LMA is not effective.[127,128] The ASA DAA suggests use of the Combitube after failed pulmonary ventilation with conventional face mask and LMA.[4] The successful use of the Combitube has been described after failed tracheal intubation in an emergency C/D.[127]

Even though the Combitube is losing its popularity in Canada and the United Kingdom, it is still a part of the ASA DAA, the American Heart Association guidelines, and the European Resuscitation Council guidelines. The ASA DAA incorporated use of the Combitube in the emergency pathway (i.e., the life-threatening CICV

situation) in which establishing ventilation and oxygenation is critical. It may also be particularly useful for difficult or failed tracheal intubations in obstetric patients, who are at increased risk for gastric regurgitation and pulmonary aspiration.

When properly positioned, the Combitube allows ventilation with a higher seal pressure than the classic LMA, protects against regurgitation, and allows a subsequent attempt at fiberoptic intubation while the inflated esophageal cuff maintains airway protection.[127,129] Although there have been failures,[130] the Combitube has been used successfully in cases of difficult tracheal intubation[127,131] and CICV,[132,133] including failure with the LMA.[134] The Combitube may offer significant advantages over the LMA in parturients. These advantages include isolation of the stomach from the glottic area and minimal need for preparation. Oxygenation and pulmonary ventilation can be achieved rapidly, especially because the parturient is prone to rapid arterial oxygen desaturation. The Combitube has been shown to prevent pulmonary aspiration during cardiopulmonary resuscitation and to protect the airway from pulmonary aspiration of gastric contents during obstetric anesthesia.[129,135]

The Combitube is a disposable double-lumen tube with two cuffs and two pilot balloons that is designed for blind insertion. If blind insertion is difficult or unsuccessful, the Combitube may be placed in the upper esophagus under direct vision with the use of a laryngoscope. Ventilation is initially attempted through lumen 1, which forces air into the trachea (see Fig. 35-3 in Chapter 35). Causes of failed ventilation with the Combitube include inadvertent tracheal placement (5%), deep insertion laryngospasm, and bronchospasm. The steps in troubleshooting Combitube use are important to understand, especially when one is confronted with a critical airway. The Combitube is designed to enter the esophagus after blind insertion. If ventilation is difficult through the blue lumen 1, the Combitube could be in the trachea, and ventilation must be switched to the clear lumen 2, allowing air to enter the trachea directly through the open end. If the Combitube is inserted too deep (see Fig. 35-5A in Chapter 35), ventilation is impossible and the pharyngeal balloon must be deflated, the Combitube pulled back 1 to 2 cm, and ventilation switched back to the blue lumen 2 (see Fig. 35-5B in Chapter 35). The original Combitube is a large, bulky device and can cause esophageal damage; therefore, the small adult (SA) size is recommended.[136]

3. Other Alternative Airway Devices

The King LT (known as the laryngeal tube in Europe) differs from the Combitube by being smaller, shorter, and softer and having a non-latex oropharyngeal cuff. The design of the King LT allows easy insertion, provides vertical positioning latitude, uses low-pressure cuffs,[119,137] and allows passage of an AEC while simultaneously providing an esophageal barrier (Fig. 37-7A).[138] It is a versatile airway device that can be used in elective or emergent conditions or DA, and ventilation can be spontaneous or controlled.[139]

The King LTS/LTS-D is the double-lumen version. It has dedicated ventilation and gastric access lumens and allows passage of an 18-F orogastric tube via the gastric drainage lumen (see Fig. 37-7B). Ventilatory seal with the King LT and airway pressure of 40 cm H_2O was found to be possible without gastric inflation in 30 patients.[140] The LMA was compared with King LT in 22 patients, and the mean leak pressure was significantly greater for the King LT[141]; gastric insufflation did not occur with the King LT. The King LTS/LTS-D may be useful in situations in which the patient is at risk for aspiration. In a case report, the King LTS was used successfully to establish ventilation and oxygenation after failed intubation in an emergency C/D.[142]

Exchange of the King LT for a tracheal tube can be accomplished with a fiberscope and an AEC (see Fig. 37-7C).[138] The incidence of complications and adverse airway events is minimal with the use of this device.[119]

If oxygenation and ventilation are not established with either the LMA, the Combitube, or the King LT and the patient develops increasing hypoxemia (associated with bradycardia), the patient is considered to be in the *emergency pathway—critical airway* situation, which is a life-threatening emergency requiring immediate invasive intervention and rescue ventilation with either percutaneous cricothyroidotomy, TTJV, or surgical tracheostomy (see Fig. 37-5, Step 5).[4,5]

E. Step 5: CICV with Increasing Hypoxemia—Invasive Rescue Ventilation

1. Emergency Pathway—Critical Airway

All current airway guidelines[4-6] recommend management of the CICV situation using either cannula cricothyroidotomy with percutaneous TTJV or surgical cricothyroidotomy.

The scenario of failed intubation, increasing hypoxemia, and difficult ventilation often occurs secondary to repeated unsuccessful attempts when a "can ventilate" situation rapidly develops into a CICV situation, resulting in significant maternal morbidity, including hypoxic brain damage, and maternal mortality. The fetus is also at risk for severe neurologic injury. Rapid development of severe hypoxemia, particularly if associated with bradycardia, is an indication for imminent intervention with an invasive airway rescue technique.

Once the decision is made to perform an invasive procedure, it is essential to use an effective technique. Rapid reoxygenation is critical and is best achieved with a combination of an invasive airway device and a ventilation technique that is capable of delivering effective ventilation and high minute ventilation with a fraction of inspired oxygen (F_{IO_2}) of 1.0.

2. Cricothyroidotomy and Transtracheal Jet Ventilation

The risks of invasive rescue techniques must be constantly weighed against the risks of hypoxic brain damage or maternal death.[143] In Palanisamy's study,[3] among the 98 parturients who received GA for C/D, there was a sentinel case of DI, resulting in a critical airway incident (CICV) that necessitated a surgical cricothyroidotomy.

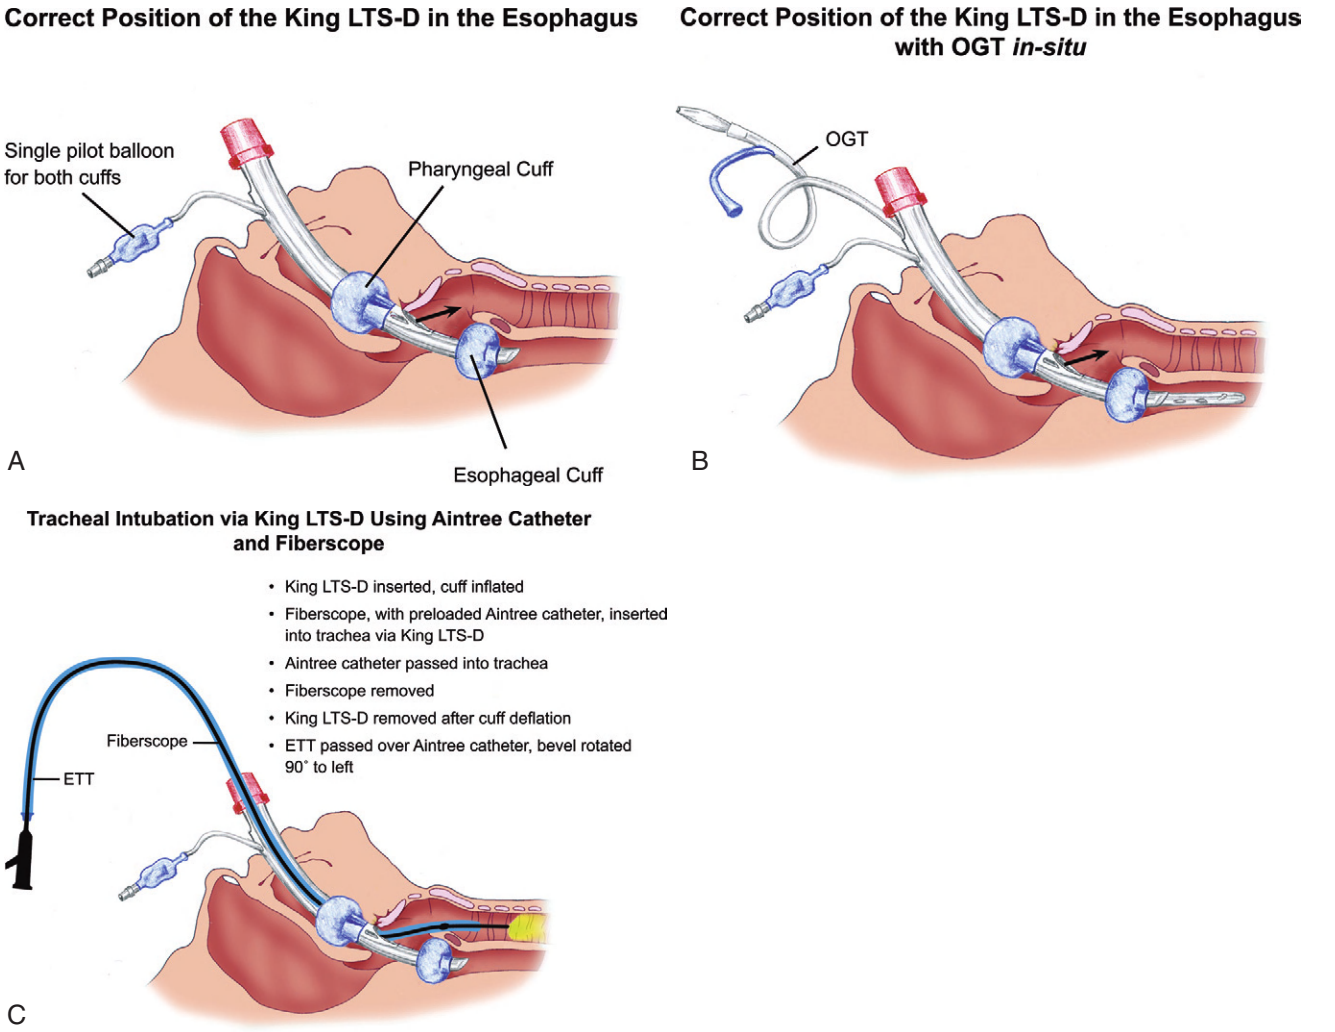


Figure 37-7 King LTS-D supraglottic airway. **A,** Correct position in the esophagus. **B,** Correct position with orogastric tube *(OGT)* in situ. **C,** Tracheal intubation using Aintree catheter and fiberscope. *ETT,* Endotracheal tube. (Courtesy of Baylor College of Medicine, Houston, TX.)

The investigators reported that the total time taken from RSI of anesthesia to surgical cricothyroidotomy was less than 5 minutes.[3]

The anesthesia practitioner must be prepared to use invasive techniques to secure the airway via the cricothyroid membrane. Success depends on understanding the anatomy of the cricothyroid membrane and factors that determine efficacy of ventilation airway devices.[144,145]

a. CANNULA CRICOTHYROIDOTOMY WITH PERCUTANEOUS TTJV

This technique involves the combination of insertion of a cannula or catheter through the cricothyroid membrane and use of a high-pressure source for ventilation. TTJV can provide effective ventilation[146,147]; however, it is fraught with barotrauma hazards and is associated with a low success rate.[148-150] It is important to keep the upper airway patent and open to allow for deflation of the lungs and exhalation through the upper airway. If an LMA has been used, it can be left in place to allow for exhalation.

The needle cricothyroidotomy entails insertion of a catheter (usually an intravenous catheter) through the cricothyroid membrane; the needle through the catheter is then removed, and the anesthetist advances the guidewire through the catheter using the Seldinger technique. Next, a dilator is advanced over the guidewire, then removed, and a tracheostomy tube is inserted.

b. SURGICAL CRICOTHYROIDOTOMY

A simplified cricothyroidotomy technique can be performed in 30 seconds.[151] This technique consists of the following four steps:

Step 1—Identification of the cricothyroid membrane
Step 2—Horizontal stab incision (no. 20 scalpel) through skin and membrane
Step 3—Caudal traction on the cricoid membrane with a tracheal hook
Step 4—Intubation of the trachea

Cricothyroidotomy can be particularly difficult in the obese patient. Insertion of the tube can be facilitated by passage of an introducer (bougie) through the incision or by the use of a tracheal retractor.[152]

Guidewire techniques of cricothyroidotomy can be successful. The Melker guidewire intubation set is now available with a cuffed tube. It has been shown that the

technique can be performed in 40 seconds after practice in a mannequin.[153]

3. Extubation

The ASA Task Force regarded the concept of an extubation strategy as a logical extension of the extubation process.[4] The closed claims analysis for DA management in surgical patients concluded that development of management strategies covering emergence and the recovery phase after extubation may improve patient safety.[10]

An emerging problem in obstetric patients is respiratory-related complications after emergence and maternal mortality after extubation.[20] The data from the Confidential Enquiries into Maternal Death from the United Kingdom and a study from the United States on anesthesia-related deaths in Michigan indicated that airway management of the obstetric patient during induction of GA,[20,154] including intubation, was without complications; however, critical airway and ventilation incidents including hypoventilation or airway obstruction occurred during emergence, extubation, or recovery.

Current literature does not provide a sufficient basis for evaluating the merits of an extubation strategy.[4] The focus has been mainly on addressing strategies, safety concerns, and techniques for intubating the trachea after induction of anesthesia, with relatively little attention paid to extubation strategies. The U.K. data specifically mentioned lack of training as partly responsible for the undesirable outcomes after extubation. The review from Michigan identified eight anesthesia-related deaths between 1985 and 2003. All of these deaths occurred as a result of airway obstruction or hypoventilation during emergence and recovery. Lapses in standard postoperative monitoring and inadequate supervision by an anesthesiologist were identified. Obesity and African-American race also seemed to be important risk factors for anesthesia-related maternal mortality.

Proposals to improve patient safety in obstetrics must require identification of preexisting comorbidities that can lead to postoperative respiratory complications. Standard monitoring in the postoperative period that includes pulse oximetry must be mandatory. As perioperative physicians, anesthesiologists are uniquely qualified to supervise the anesthesia care team; to manage and minimize anesthesia-related maternal risk; to provide peripartum medical diagnosis and treatment; to facilitate life-saving airway management interventions; and to lead prompt, coordinated, and effective resuscitation efforts to prevent airway catastrophes in obstetric patients.

Further attention is required for high-risk extubation patients, such as obese parturients and patients with an edematous airway, obstructive sleep apnea, or known or suspected airway management difficulties. Development of a strategy to maintain continuous access to the airway, so as to facilitate potential rescue of the airway, must be considered. Postextubation hypoventilation, airway compromise, ventilation-perfusion inequalities, and airway obstruction due to respiratory fatigue or apneic episodes may affect the patient in the operating room during emergence or in the immediate postoperative recovery period. Maintenance of continuous access to the airway after extubation with an AEC can be an important component of an extubation strategy in these selected patients.[155] The AEC is well tolerated by most patients (90%) and therefore is a valuable option.[155] Currently, there are no evidence-based guidelines regarding the optimal period of time for which to maintain airway access after extubation via an indwelling AEC. Experts have suggested at least 30 to 60 minutes or until the likelihood of reintubation is minimized.[156-159] Patients with the potential for periglottic edema may benefit from extending the duration of the in-dwelling AEC to 60 to 120 minutes.[155]

The presence of an AEC to assist in reintubating and resecuring the airway is another major step toward improving patient safety and must be considered for obstetric patients who are potentially at high risk for airway-related catastrophes during emergence and after extubation.

XIV. COMMUNICATION AND DOCUMENTATION

After a failed tracheal intubation and successful airway management in a patient undergoing C/D, the following measures need to be adopted at the conclusion of the procedure:

1. Comprehensive documentation in the patient's chart outlining the problem and measures taken to manage the airway
2. Communication with the patient and the family
3. A detailed letter for the patient to carry describing the events that took place and their subsequent management
4. An airway alert in the electronic medical record
5. Application for a Medic-Alert band for the patient
6. Notification to the DA registry

XV. CONCLUSIONS

Difficult laryngoscopy, failed tracheal intubation, and inability to ventilate or oxygenate after induction of GA for C/D are major contributory factors leading to maternal morbidity and mortality. Management of the DA has emerged as one of the most important safety issues. The necessity of a focused history, physical examination, and airway evaluation for predictors of DI and difficult ventilation allows the anesthesia practitioner to develop appropriate strategies of management for the obstetric patient. Heightened awareness of GA-related maternal mortality has led to a dramatic increase in the use of neuraxial anesthesia techniques in obstetric patients, with a consequent decrease in anesthesia-related maternal mortality. Despite the decrease in maternal mortality, however, DI continues to be a high-liability issue.

Emergency airway management after failed intubation in obstetrics presents a challenge for the anesthesia practitioner. The dictum of having preformulated strategies for airway management in place before induction is important. Working within the framework of the ASA DAA; seeking help sooner rather than later; deciding to restrict the number of attempts to no more than two

after failed tracheal intubation; using alternative devices to assist tracheal intubation; using supraglottic airways; maintaining oxygenation throughout the execution of the plan; and using invasive techniques such as cricothyroidotomy in a CICV situation are keys to successful outcome for both mother and baby.

The declining use of GA in obstetrics is concerning because of the diminished airway management skills of anesthesia trainees in obstetrics. Solutions to the problem include a dedicated and structured advanced airway management (AAM) rotation for anesthesia trainees, formal curriculum and teaching of the DAA, and systematic practice and repetition of AAM clinical skills in the operating room in surgical patients. High-fidelity simulation training with formal instruction in management of failed tracheal intubation, difficult ventilation, and cricothyroidotomy skills in obstetric emergency situations should be taught and practiced. Simulator training and protocols to deal with airway management issues may enhance the skills of the anesthesia trainee for future management of airway issues in obstetric patients.

XVI. CLINICAL PEARLS

- Cesarean delivery is the most common major surgical operation carried out in the United States (U.S. Centers for Disease Control and Prevention's National Center for Health Statistics report) and is increasing in incidence throughout the world.
- Anesthesia-related maternal complications rank seventh in the United States and the United Kingdom as a cause of maternal mortality; airway-related causes feature as a predominant category and are preventable.
- Pregnancy-related anatomic and physiologic changes predispose parturients to difficulty with intubation, ventilation, and extubation.
- Early preoperative assessment for patients undergoing labor and delivery must include a thorough airway history and examination and a rescue plan for potential failed tracheal intubation. Appropriate airway equipment and personnel must be immediately available in labor and delivery sites to manage the difficult airway (DA).
- Regional anesthesia (RA) is safe in most parturients undergoing cesarean delivery; in certain exceptional situations, an awake tracheal intubation is considered the safest choice in cases of anticipated or known DA in a parturient undergoing cesarean delivery.
- Adequate preoxygenation, left uterine displacement, head-elevated positioning, and use of supplementary high-flow oxygen via nasal cannula enhances oxygenation.
- Alternative airway devices such as optical stylets or video laryngoscopy should be used after a failed second attempt at tracheal intubation in the unanticipated DA (cannot intubate, can ventilate) scenario.
- First generation supraglottic airways such as the laryngeal mask airway (LMA) and second-generation supraglottic airways such as the King LTS-D should be considered as ventilatory devices in the unanticipated DA ("cannot intubate, cannot ventilate" [CICV]) scenario.
- Invasive airway access with a percutaneous/surgical cricothyrotomy or transtracheal jet ventilation (TTJV) may be necessary in the situation of critical airway with hypoxemia.
- Problems related to emergence and extubation have emerged as the most common cause of airway-related maternal mortality in recent reports from United States and the United Kingdom.
- Documentation should be provided in the patient's record if difficulty is encountered with laryngoscopy, tracheal intubation, ventilation, or tracheal extubation.

  1. Special Considerations and Anesthesia Objectives
  2. Intraoperative Ventilation Techniques and Strategies
  3. General Anesthesia Management for Pediatric Airway Endoscopy and Microlaryngeal Surgery
  4. Complications of Pediatric Airway Endoscopy
  5. Recurrent Respiratory Papillomatosis
- D. Foreign Bodies in the Airway and Esophagus
  1. Foreign Body Aspiration
  2. Complications of Endoscopy for Foreign Body Removal

VI. Conclusions

VII. Clinical Pearls

I. GENERAL CONSIDERATIONS

The range and precision of laryngologic surgical procedures have dramatically expanded over the past decade. Patient outcomes have improved due to technologic advances such as the introduction of high-magnification operating microscopes and video endoscopes, instrument miniaturization, new injection materials, and the use of powered instrumentation and optical fiber–based lasers.[1-5]

Advances and demands of the new surgical techniques and an expanding patient population that was previously considered unsuitable for surgery have created novel challenges for the anesthesiologist. State-of-the-art anesthesia and airway management for laryngeal surgery require the anesthesiologist to be adept with various methods of managing the difficult airway and performing airway exchange, to competently execute intraoperative ventilation strategies, to be proficient with inhalational and total intravenous anesthesia, and to quickly tailor

anesthetic techniques to the various durations of the surgical cases. New challenges have developed with the widespread introduction of minimally invasive laryngeal robotic surgery, which demands a fully open surgical field for three-dimensional visualization and superior motor control.[4,6,7]

Successful anesthetic management of microlaryngeal cases requires a high degree of cooperation with the surgeon, a reciprocal understanding of the potential problems, and adequate preparation on both sides to meet the anticipated challenges that may arise.[1,3,8,9] Thorough appreciation by the anesthesiologist of the complexity of the upper airway anatomy, the pathologic process involved, and all steps of the surgical procedure is necessary for devising a rational anesthetic plan and maintaining a good working relationship with the surgeon.[1,8,10] The expert ability to safely share the patient's airway with the surgeon, in conjunction with an intimate knowledge of possible immediate intraoperative and early postoperative complications of laryngeal surgery, greatly contributes to safe patient management in the perioperative period.[8]

Microlaryngeal surgery encompasses a wide range of laryngeal procedures that can be organized in two broad categories: phonomicrosurgery (i.e., benign and malignant vocal cord lesions, laser laryngeal surgery, and vocal cord augmentation) and laryngeal framework surgery (i.e., vocal cord paralysis and motion disorders, scarring, stenosis of the glottic, subglottic, and tracheal areas, and laryngeal trauma).[1] For practical purposes, these may be further categorized as involving endoscopy alone, surgical excision, injection, dilation, or a combination of these approaches.

This chapter focuses on airway management and anesthesia for microlaryngeal surgery, diagnostic direct laryngoscopy, and endoscopy (i.e., bronchoscopy and esophagoscopy). A combination of these three interventions, called *panendoscopy*, is typically performed as part of the diagnostic work-up for patients with head and neck cancer, and is accompanied by surgical biopsies of the base of the tongue, piriform sinuses, nasopharynx, and other diseased or suspicious areas.[11-13] Additional surgical indications for bronchoscopy and esophagoscopy are discussed in the corresponding sections of this chapter, and management of pediatric patients is discussed separately from approaches to adults.

II. PATIENT PREOPERATIVE EVALUATION AND PREPARATION

Patients presenting for phonomicrosurgery may have a variety of comorbidities contributing to their voice symptoms and affecting anesthetic management. Changes in voice quality can be exaggerated by inadequate airflow production (e.g., chronic obstructive pulmonary disease [COPD]) or vocal fatigue caused by neuromuscular disorders (e.g., myasthenia gravis, muscular dystrophy, Parkinson's disease).[1] Various rheumatologic and musculoskeletal ailments can alter posture, impairing voice quality, and endocrine disorders, such as hypothyroidism, can cause dysphonia as a result of swelling in the Reinke's space (i.e., superficial lamina propria) of the vocal cords.[1]

Almost one half of the patients presenting with laryngeal and voice disorders have silent laryngopharyngeal reflux as the primary cause or as a significant etiologic factor.[1,14] Coexistent significant glottic insufficiency (e.g., vocal cord paralysis) may place these patients at increased risk for aspiration of gastric contents,[13,15] and it can usually be diagnosed during a routine preoperative flexible fiberoptic laryngoscopy or laryngostroboscopy performed by the surgeon. Those presenting for esophagoscopy for evaluation and treatment of esophageal obstructing lesions, achalasia, Zenker's diverticulum, active gastrointestinal bleeding, or esophageal foreign body removal constitute another category of patients at high risk for aspiration. Even when gastroesophageal reflux is not clinically significant, adequate preoperative pharmacologic control of the symptoms is warranted: the combination of acid exposure and direct trauma from the operating procedure and the endotracheal intubation can lead to laryngeal mucosal injury.[16]

Many patients presenting for laryngeal surgery and panendoscopy have a long history of heavy smoking and drinking,[17] which are directly linked to the development of squamous cell carcinoma of the larynx, the second most common malignancy of the head and neck.[18] It is not uncommon for these patients to present with anemia.[18] Appropriate laboratory studies should be obtained, and the electrolyte and fluid status of these patients should be optimized preoperatively.

Chronic cigarette smoking and alcohol use can cause induction of the cytochrome P450 multi-enzyme system, leading to increased perioperative requirements for opioids and neuromuscular blockers and generation of higher levels of potentially toxic metabolites of volatile halogenated anesthetic agents.[19-22] Patients with chronic alcohol consumption require preoperative evaluation of liver function and coagulation status. For those with advanced liver disease, controlled hypotensive techniques should be avoided, and intraoperative hypotension should be treated aggressively to prevent adverse outcomes associated with prolonged decrease in hepatic circulation and further deterioration of liver function.[23]

Many patients who present for laryngeal surgery are elderly and have cardiovascular disease. Appropriate diagnostic tests are indicated for them as part of the preoperative work-up. The pulmonary status of COPD patients should be optimized to decrease airway reactivity and the possibility of postoperative pulmonary complications. Patients with significant lung disease and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch may not be suitable candidates for intraoperative ventilation techniques, such as spontaneous ventilation, apneic intermittent ventilation (AIV), or jet ventilation (JV),[22-24] which may be required for microlaryngeal surgery (see "Intraoperative Ventilation Techniques and Strategies for Microlaryngeal Surgery").

The rate of difficult endotracheal intubation may reach almost 16% among patients presenting for ear, nose, or throat cancer surgery,[25] which is on average six times higher than among the general surgical patient population.[25-29] Comprehensive preoperative airway

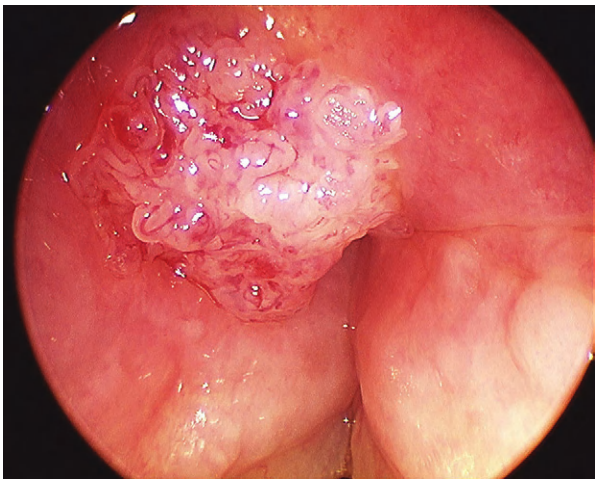

Figure 38-1 Epiglottic carcinoma. (Courtesy of Edward Damrose, MD, Stanford University Medical Center, Stanford, CA.)

assessment is paramount (see Chapter 8); however, standard anesthesia airway assessment tests fail to account for aspiration risk, lower airway problems, and base of the tongue pathology (e.g., epiglottic cancer, epiglottic and vallecula cysts, lingual tonsillar hypertrophy). Pathology of the base of the tongue may be encountered with increased frequency in patients presenting for panendoscopy and microlaryngeal surgery (Fig. 38-1).

Postradiation changes in the neck and decreased mandibular protrusion are important factors predicting the risk of impossible mask ventilation, difficult mask ventilation, and difficult intubation in patients at risk for these conditions (see Chapter 8),[30,31] and these risk factors may occur with increased frequency among patients presenting for microlaryngeal surgery or panendoscopy.[12] The pharyngeal space may also be reduced by limited submandibular compliance of the soft tissues (e.g., cancerous involvement, masses, inflammation, previous radiation therapy) (Fig. 38-2), which may result in difficult intubation or failed intubation due to the restriction of the space that accommodates the tongue during direct laryngoscopy.[32]

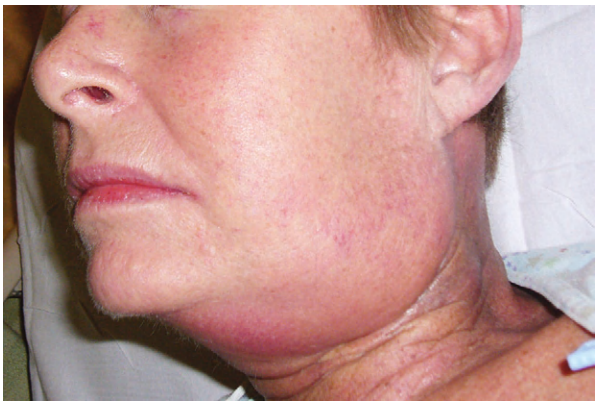

Figure 38-2 Postradiation neck changes and decreased submandibular compliance in a patient presenting for panendoscopy. Notice the postincisional neck scar, and Postradiation changes that have resulted in fibrotic changes in the skin and subcutaneous tissues of the neck and induration of the submandibular space.

Figure 38-3 Patient with a laryngeal carcinoma, fixed hemilarynx, and severe inspiratory stridor presented for panendoscopy and subsequent tracheostomy. The *black check mark* indicates a thyroid notch, a *horizontal black line* corresponds to the top of the cricoid cartilage, and a *black dot* represents the location of the cricothyroid membrane. Notice the inflammatory skin changes. The vocal cords were visible during preoperative nasal endoscopy. Endotracheal intubation was successfully accomplished by video laryngoscopy after inhalational induction.

Pharyngeal restriction can be further accentuated by a large tongue or intraoral masses that can be exophytic and mobile.[32] Drooling, dysphagia, and expiratory snoring are the signs of marked pharyngeal restriction,[17,32] but inspiratory stridor at rest represents the most worrisome sign, suggesting a reduction in airway diameter at the supraglottic, periglottic, or glottic level of at least 50%.[15,31-33]

Airway compromise in these patients may also involve the lower airways. Airway narrowing at the tracheal or tracheobronchial level is typically characterized by expiratory stridor, whereas biphasic inspiratory-expiratory stridor usually points to obstructive subglottic lesions.[8] In some cases, preoperative examination of the flow-volume loops may be helpful.[34]

It is prudent to assess the laryngeal mobility, the degree of tracheal deviation, and the location of the cricothyroid membrane (CTM).[18] Significant tracheal deviation, especially in combination with the fixed hemilarynx (Fig. 38-3) and poor or absent visualization of the vocal cords during preoperative nasal endoscopy, can be an ominous sign,[33,35] warranting performance of an awake tracheostomy, if technically feasible. Usually, the extent of disease in elective cases has been comprehensively evaluated preoperatively by routine chest radiography, computed tomography (CT), magnetic resonance imaging (MRI), and flexible fiberoptic laryngoscopy, providing the anesthesiologist with valuable information regarding the location, size, spread, and vascularity of the obstructive lesions; the degree of obstruction; the mobility of the vocal cords; and the extent of laryngeal and tracheal deviation or compression.[8,18,36] Preoperative discussion of these findings with the surgeon helps to devise safe and rational airway management and anesthetic plans for the patient.[18]

Other airway considerations for patients presenting for microlaryngeal surgery or panendoscopy include

Figure 38-4 Commonly used operating laryngoscopes. The posterior apertures of the Kleinsasser *(left),* Dedo *(center),* and Holinger *(right)* operating laryngoscopes are shown. The bigger size and wider channel of the Kleinsasser and Dedo laryngoscopes allows passage of the surgical instruments and binocular microlaryngeal surgery. Notice the metal cannula inserted into the left side port of the Kleinsasser laryngoscope for supraglottic jet ventilation (JV). In the Dedo scope, the JV port is integrated with the lumen, and it can be used for smog evacuation during laser surgery. The Holinger laryngoscope is monocular but has greater maneuverability. It is widely used for diagnostic laryngoscopy and visualization of the anterior commissure. The left side channel of the Holinger laryngoscope is occupied by a light guide. Supraglottic JV through the Holinger laryngoscope requires insertion of a metal cannula inside its lumen (see Fig. 38-15).

anticipation of the presence of supraglottic and glottic edema due to inflammation, infection, tumors, previous radiation therapy or repeated endoscopies,[37] and careful dental assessment. Gentle airway manipulation during direct laryngoscopy is essential. The use of a smaller-diameter endotracheal tube (ETT) is frequently warranted, and the absence of dental trauma should be documented before surgical instrumentation of the patient's airway commences.

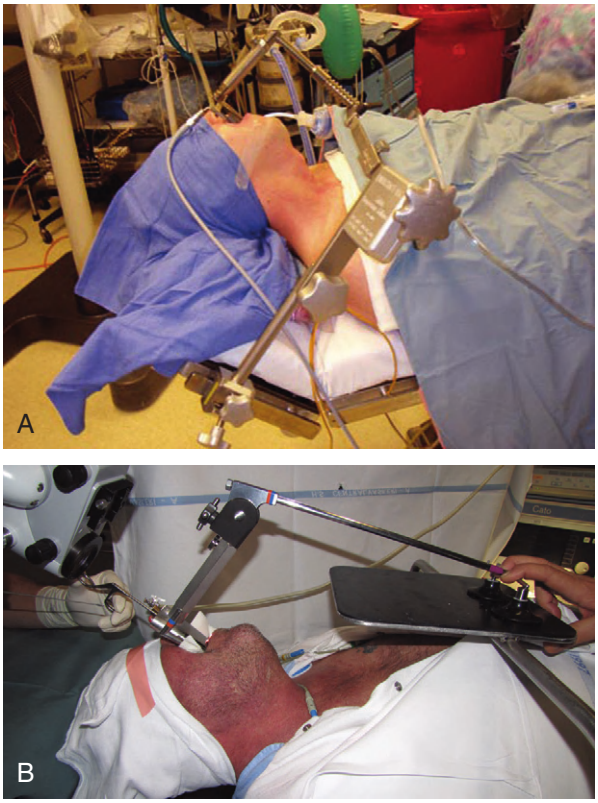

Figure 38-5 Types of suspension laryngoscopy. **A,** Gallows-type suspension device. **B,** Fulcrum-type suspension device (Storz apparatus). Notice the patients' neck flexion and head extension, which are required for suspension laryngoscopy. III. OPERATIVE LARYNGOSCOPY AND MICROLARYNGEAL SURGERY

A. Special Considerations and Anesthesia Objectives

In contrast to direct laryngoscopes used by the anesthesiologists, which are designed only to identify the glottic opening, operating laryngoscopes can provide excellent and wide laryngeal exposure and allow diagnostic examination, biopsy, and operation on structures in the larynx and pharynx, with minimal distortion of the areas of surgical interest.[16,38] The handles of these laryngoscopes are integrated with the blades and have a wide proximal aperture that facilitates the passage of instruments during suspension laryngoscopy.[38,39] Many types of laryngoscopes exist (Fig. 38-4), each offering certain advantages for its intended application, such as the ability to better expose supraglottic, glottic, or subglottic areas.[38] Many laryngoscopes are multipurpose, and selection is frequently dictated by individual or institutional preference.[38]

With the use of these laryngoscopes, systematic endoscopy of the larynx and pharynx frequently proceeds in three stages, progressing from handheld examination to suspension laryngoscopy (for more detailed evaluation with the straight and angled telescopes) and then to microlaryngoscopy using the operating microscope for image magnification, biopsy, microsurgery, or laser surgery.[38] Suspension laryngoscopy (Fig. 38-5) frees the surgeon's hands for precision bimanual surgery and facilitates maintenance of a stable plane of anesthesia.[38,40] The use of a video monitor by the surgeon permits the anesthesiologist to observe the surgical procedure and monitor the patient's airway.

The essential requirements for precision microlaryngeal surgery and optimal preservation of function include a clear and still surgical field, absence of patient movement, and allocation of sufficient time to carefully complete the procedure in an unhurried manner.[9,38,39,41] The patient's airway must be protected from blood, debris, and irrigation fluid, and ventilation must be adequately controlled.[3,8,41] The anesthesiologist must safely share the patient's airway with the surgeon, and must be prepared to skillfully and confidently switch from one ventilation technique to another during the case if needed or dictated by surgery.

In most surgical procedures, the patient's airway is shared with the surgeon, and immediate access to the airway is difficult or impossible because the operating room (OR) table is turned 90 or 180 degrees away from the anesthesiologist. The ETT must be secured diligently to prevent accidental extubation under the surgical drapes or withdrawal of the ETT into the larynx, resulting in a sudden air leak or possible compression of the anterior branch of the recurrent laryngeal nerve by the ETT cuff.[42,43]

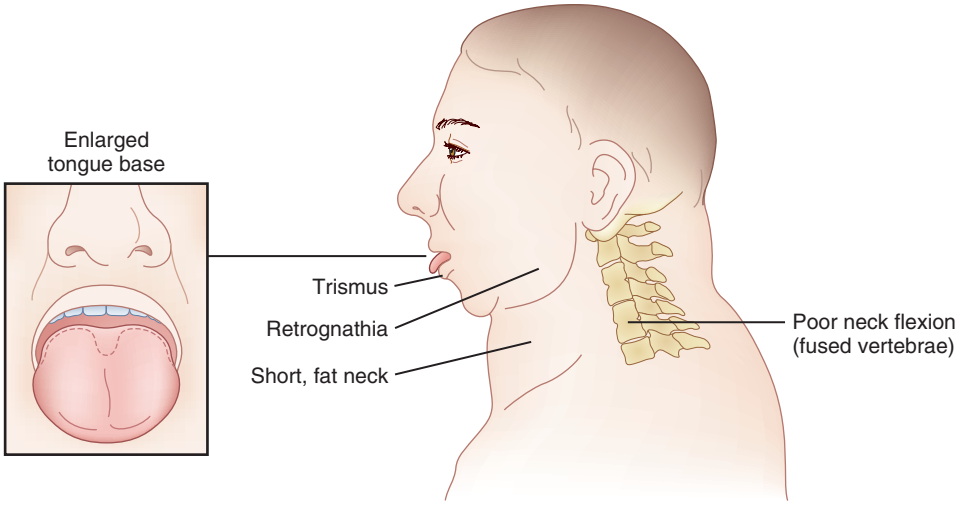

Figure 38-6 Anatomic features associated with a difficult airway exposure. Difficult laryngeal exposure during direct or suspension laryngoscopy may be encountered in patients with retrognathia; lingual hypertrophy or poor palatal visualization; trismus or reduced interincisor opening; short, thick neck; and limited neck extension. (From In Rosen CA, Simpson CB, editors: *Operative techniques in laryngology*, Berlin, 2008, Springer-Verlag, p 56.)

Performance of conventional and operative direct laryngoscopy, supraglottic tissue distention, and laryngeal stimulation elicit intense cardiovascular responses, resulting in tachycardia, arterial and pulmonary hypertension, and arrhythmias.[44-46] Although these responses are usually short lived, myocardial ischemia and compromise of cerebral circulation may occur in high-risk patients, resulting in adverse outcomes.[47-49] Anesthetic technique should ensure a stable plane of anesthesia, nonstimulating emergence from anesthesia, a rapid return of consciousness, and protective airway reflexes, and it should facilitate quick discharge of patients, because most of these surgical procedures are done on an outpatient basis.[3,8]

Special attention should be directed to adequately protecting the patient's eyes and arms to prevent accidental injury or compression by heavy surgical instrumentation.[9] When rigid endoscopy is planned, a tooth guard should be used routinely.[34] It may be prudent to warn the patients in advance of the potential for dental trauma, and any previous dental damage should be carefully documented.[34,43]

Patients who are vocal performers or use the voice in some professional capacity present unique challenges.[16] The anesthesiologist must frequently think outside the box and exercise different advanced airway management options to avert trauma to the patient's vocal cords and cricoarytenoid joints.

B. Airway Management for Microlaryngeal Surgery

1. Conventional and Advanced Airway Management

Patients presenting for diagnostic direct laryngoscopy and microlaryngeal surgery frequently have a difficult airway. The chosen approach to this airway depends on the pathology and the patient's symptoms. In situations with critical airway compromise, an awake tracheostomy may be warranted from the outset, but it may prove to be technically challenging or impossible and may require general anesthesia. Even if an awake tracheostomy is chosen as a primary approach, full backup preparation for alternative airway management is necessary.

Video laryngoscopy reliably improves laryngeal exposure by at least one grade,[50-54] allows continuous observation of the entire intubation procedure by the entire team, and may therefore be a near-ideal technique for managing difficult airways in patients presenting for microlaryngeal surgery. Choosing the video laryngoscopic device depends on the operator's preference and must consider the nature and location of the lesions. For example, it may be safer to navigate around tumors at the base of the tongue with the Pentax Airway Scope, whose blade engages under the epiglottis, unlike other devices that typically require the tip of the blade to be placed in the vallecula. Video laryngoscopes that use the steering technique (i.e., styleted ETT), such as the Glidescope video laryngoscope, offer better control of intubation and may facilitate ETT maneuvering around the intraoral masses.[55] Although the use of the Glidescope may be less traumatic compared with the Airtraq in patients presenting for microlaryngeal surgery,[56] in the largest published series of Glidescope-assisted intubations in more than 2000 patients with difficult airways,[57] the strongest predictor of the steering technique failure was altered neck anatomy with presence of a surgical scar, radiation changes, or a mass. These conditions are frequently encountered in patients presenting for diagnostic direct laryngoscopy and microlaryngeal surgery.

Although advanced airway management techniques can be highly successful when direct laryngoscopy fails, the patient's unfavorable anatomy (Fig. 38-6) may not be modifiable for the surgical exposure, which requires the use of the largest operating laryngoscope and placement of the patient's head in the Boyce-Jackson position using a combination of cervical flexion and atlantooccipital extension (see Fig. 38-5).[1,38,58,59] If suspension laryngoscopy fails or if the location of the lesion is not easily accessible, it can be performed, to the extent microlaryngeal surgery permits, with the help of the flexible

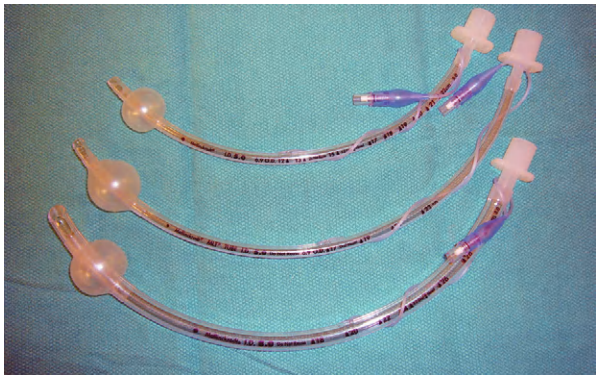

Figure 38-7 Microlaryngeal tracheal (MLT) tube. A standard endotracheal tube (ETT) with an inner diameter (ID) of 5.0 mm *(top)* is compared with a 5.0-mm ID MLT tube *(center)* and 8.0-mm ID ETT *(bottom)*. A greater length and bigger cuff diameter of the MLT tube (equivalent to a standard 8.0-mm ID ETT) allows a sufficient depth of tracheal placement, a connection to the anesthesia circuit, and an adequate seal of the trachea.

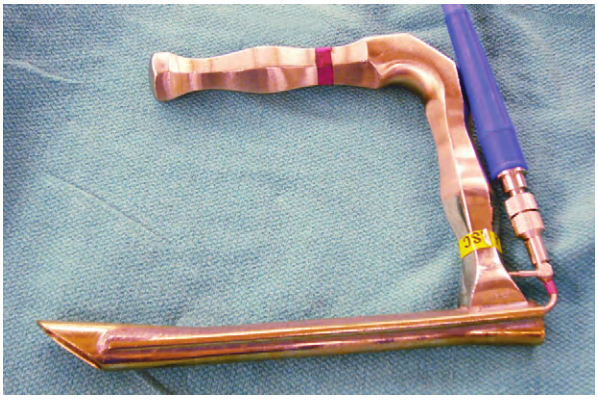

Figure 38-8 Holinger anterior commissure laryngoscope. The pointed tip and the leverage capability of the laryngoscope facilitate visualization of at least part of the glottis. An anterior flare at the tip of the laryngoscope allows it to serve as a guide to endotracheal intubation.

fiberoptic bronchoscope (FFB) inserted through the laryngeal mask airway (LMA).[60-62] The intubating laryngeal mask airway (iLMA) offers certain advantages, such as a rigid, wide metal tube that can accommodate a large-diameter FFB,[61] optimal alignment of the iLMA aperture with the glottic opening,[63] diminished hemodynamic responses compared with suspension laryngoscopy,[61] and superior ventilation capabilities.[63-66]

The iLMA is associated with an outstanding success rate for blind endotracheal intubation in patients with difficult airways.[63,65] Unfortunately, the manufacturer-supplied iLMA ETTs are too big for most microlaryngoscopic surgery. An ETT with a smaller inner diameter (ID) (e.g., 5.0-mm ID microlaryngeal tracheal [MLT] tube) is typically required to maximize the surgical view (Fig. 38-7). Placement of MLT tubes through the iLMA can be achieved with the help of a small-diameter FFB; however, passage of the ETT through the laryngeal inlet into the trachea is blind. Blind advancement of the ETT may cause inadvertent laryngeal trauma and core out pedunculated supraglottic or glottic tumors, nodules, or cysts.[56,67] When the FFB route (with or without the use of a supralaryngeal airway device) is chosen for endotracheal intubation, it is advantageous to closely match the outer diameter (OD) of the scope with the ID of the ETT to minimize the risk of complications associated with blind ETT advancement. Use of optical stylets (e.g., Bonfils, Shikani, Clarus Video System) may also be beneficial in that regard, because the ETT will follow the trajectory of the stylet navigated under direct vision through the vocal cords. However, most of the available adult-size stylets require the use of an ETT with a minimum ID of 5.5 to 6.0 mm.

The decision to proceed with an awake or asleep approach to an anticipated difficult airway should follow the American Society of Anesthesiologists (ASA) difficult airway algorithm,[68] with special attention directed to predictors of difficult mask ventilation, impossible mask ventilation, and their association with difficult intubation (see Chapter 8). The anesthesiologist also should review the pertinent preoperative findings identified on flexible fiberoptic laryngoscopy, chest radiography, CT, and MRI and should discuss these findings with the surgeon.

If an asleep approach to the difficult airway is chosen, several preformulated alternative airway management plans must be in place before induction of anesthesia. If the airway is marginal, the patient's neck should be prepped, and the surgical team should be present on induction, ready to perform an emergent cricothyrotomy or tracheostomy, or to employ rescue techniques such as the use of the surgical anterior commissure scope or a rigid bronchoscope.[11,18,69,70] The anterior commissure scopes (e.g., Holinger, Ossoff-Pilling, Benjamin Slimline/Super-Slimline, Jackson) (Fig. 38-8; see Fig. 38-4) have great leverage capabilities, incorporate the recessed lighting and concurrent rigid microsuction, and can be very effective in handling poor laryngeal exposure or glottic obstruction.[1,13,38,69] The anterior flare at the distal oval end allows these scopes to be used as a conduit for orotracheal intubation when the bougie introducer or the ETT is passed directly down the lumen (Fig. 38-9).[69]

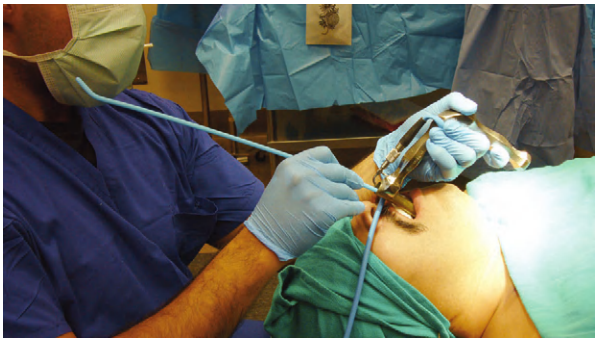

Figure 38-9 Airway rescue is achieved with a bougie introducer and a Holinger laryngoscope in a patient with difficult laryngeal exposure. The endotracheal tube (ETT) cannot be directly advanced down the narrow barrel of the Holinger laryngoscope due to impaired visualization during tube advancement. The bougie introducer is used first, followed by removal of the laryngoscope and railroading the ETT over the bougie into the patient's trachea. The ETT can be directly advanced through the wider lumen of other laryngoscopes, such as the Lindholm or Dedo (see Fig. 38-14).

In experienced hands, rigid bronchoscopy may be used to rescue failed direct laryngoscopy and failed intubation and to manage a "cannot intubate, cannot ventilate" (CICV) situation.[68] It also serves as an indispensable tool for managing acute airway obstruction resulting from foreign bodies, hemoptysis, or tumors.[71] After the bronchoscope is placed into the patient's trachea by the surgeon, manual (Fig. 38-10) or JV can commence in a safe manner through the lumen of the bronchoscope. Subsequent airway exchange to the ETT can be performed using a bougie introducer (Fig. 38-11).[72,73] This exchange technique can also be conducted when the rigid bronchoscope is employed first as part of a panendoscopy procedure in patients with abnormal airway.

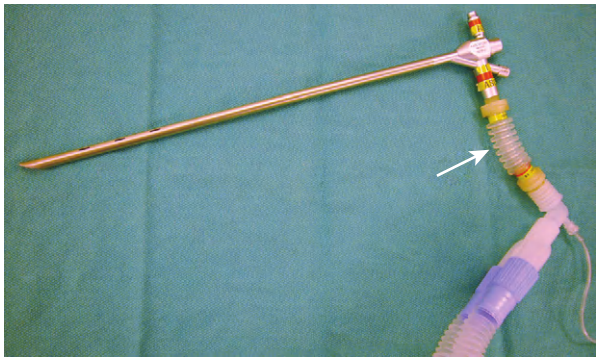

Figure 38-10 A rigid bronchoscope is connected to the anesthesia circuit by a Racine adapter *(arrow)*. A flexible diaphragm of the Racine universal adapter (SunMed, Largo, FL) connects a side arm of a rigid bronchoscope to the anesthesia breathing circuit.

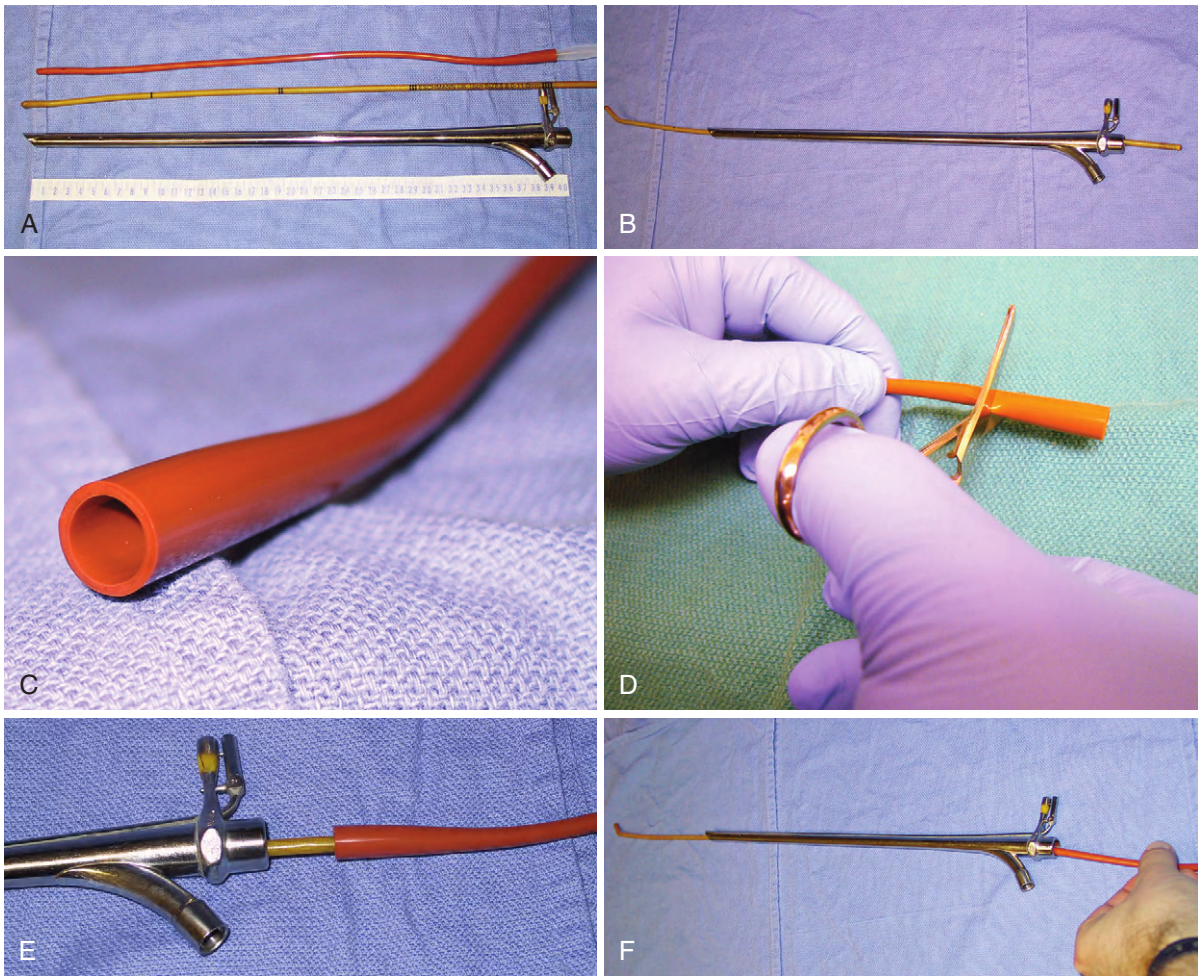

Figure 38-11 Airway exchange can be achieved with a rigid bronchoscope and a bougie introducer. **A,** The 9-F, 40-cm-long, rigid bronchoscope (CL Jackson Fiberoptic Bronchoscope, Pilling Inc., Fort Washington, PA); 15-F, 60-cm-long, multiple-use gum elastic bougie (GEB) (Eschmann Tracheal Tube Introducer, SIMS Portex Inc., Keene, NH); and 16-F, 41-cm-long, rounded, closed-tip suction catheter (Robi-Nel catheter, Kendall Dover, Mansfield, MA) are used to facilitate an airway exchange. The exchange technique involves several steps: deliberately passing the curved tip of the GEB **(B)** through the lumen of the bronchoscope into a bronchus (eliciting a distal hold up sign); stabilizing and extending a proximal straight tip of the GEB with a precut, distal, funnel-shaped end of the Robi-Nel suction catheter **(C–E);** safe removal of the bronchoscope over the extended GEB-catheter assembly **(F);** and removal of the catheter and railroading the endotracheal tube over the GEB into the patient's trachea. Anchoring a round, atraumatic tip of the GEB in a large-caliber bronchus maintains a stable position of the intubation guide and prevents its distal end from accidentally springing backward out of the trachea during bronchoscope withdrawal. This approach is superior to the use of the airway exchange catheter (AEC), whose placement below the carina is not recommended because of the recognized risk of lung perforation by the straight tip of the device. Reliably maintaining proximal positioning of the AEC tip during the airway exchange is difficult, because the AEC centimeter markings mapping the distance to the carina will become embedded inside the bronchoscope during its withdrawal. (**A, B,** and **E,** From Nekhendzy V, Simmonds PK: Rigid bronchoscope-assisted tracheal intubation: Yet another use of the gum elastic bougie. *Anesth Analg* 98:545–547, 2004.).

Patients with an advanced airway obstruction and inspiratory stridor at rest comprise some of the most feared and complicated cases for the anesthesiologist.[33] The incidence of difficult mask ventilation and impossible mask ventilation among patients with severe stridor and upper airway obstruction of more than 75% of the lumen reaches 40% and 6%, respectively,[74] compared with 1.4% and 0.15% for the general surgical population.[30,31,75] These patients frequently present for panendoscopy and microlaryngeal surgery on an emergent or semi-emergent basis, yet they require a systematic and thoughtful approach by the anesthesiologist and the surgeon.[38] The nature of the obstructing lesion (e.g., vascular, submucosal, pedunculated, inflammatory) and its location (e.g., supraglottic, glottic, subglottic, midtracheal, lower tracheal, and bronchial [mediastinal]) may require completely different intubation considerations and approaches.[17,33,34,36,38,69,71]

In the context of laryngeal surgery, the optimal technique of airway management of the stridorous patient with an advanced proximal airway obstruction (i.e., supraglottic, glottic, and subglottic levels) remains a subject of controversy. An awake flexible fiberoptic intubation, inhalational induction, and intravenous induction with muscle relaxants[17,33,74,76] have been used successfully, but none should be considered fail-safe. Thorough preoperative discussion of the surgical pathology and formulation of closely coordinated airway management plan with the surgeon are essential for safe management of these patients.

Based on our experience and review of the pertinent literature,[17,33,35,38,69,71,74,76-80] current recommendations for management of the critically obstructed airway can be outlined as follows:

1. For patients with severe stridor (e.g., symptoms exaggerated at night, hypoxemia-induced agitation or panic attacks, use of accessory muscles on inspiration, a large tumor, fixed hemilarynx, gross anatomic distortion, a larynx not visible on preoperative nasal endoscopy or flexible fiberoptic laryngoscopy), strongly consider tracheostomy under local anesthesia without sedation.
2. Patients with moderate stridor and a significant lesion seen on nasal endoscopy or flexible fiberoptic laryngoscopy, but who are considered possible to intubate, are best managed with an inhalational induction or an awake fiberoptic intubation. All airway instrumentation should proceed in a careful and gentle manner. Endotracheal intubation should be accomplished rapidly, with a small ETT. The number of attempts should not exceed two, because critical airway obstruction can quickly progress to complete as a result of manipulation of the airway.
3. If an inhalational induction is chosen, a sufficiently deep and stable plane of anesthesia is essential to avoid loss of the airway (e.g., avoidance of cough, laryngospasm). Endotracheal intubation should be performed under direct vision (e.g., direct laryngoscopy, video laryngoscopy, flexible fiberoptic bronchoscopy). Muscle relaxants should be avoided until after the intubation is completed to prevent sudden, complete airway obstruction, especially when the tumor is subglottic. The patient's neck should be prepared, and the surgical team should be present and ready to attempt an airway rescue with an anterior commissure scope or a ventilating rigid bronchoscope or by emergent cricothyrotomy or tracheostomy.
4. If endotracheal intubation under direct vision (e.g., direct laryngoscopy, video laryngoscopy, flexible fiberoptic bronchoscopy) fails in an anesthetized or awake patient or is deemed problematic, tracheostomy should be performed expeditiously, with the patient breathing spontaneously.
5. An awake fiberoptic intubation should be used with caution, because sudden loss of the airway can be precipitated by one or more of the following factors:
   - Bleeding from a friable tumor on impaction with the FFB or seeding parts of the broken tumor into the trachea
   - "Cork in the bottle" effect, when the scope is introduced into the critically narrowed airway
   - Inhibitory effect of local anesthetics on the tongue and upper airway musculature, laryngeal muscles, and function
   - Central nervous system depressant effect of local anesthetics
   - Local anesthetic-precipitated laryngospasm
   - Patient's apprehension and agitation during the procedure, resulting in hyperventilation and "sucking in" mobile, pedunculated tumors
6. Additional fallback strategies may include the following:
   - Placement of a transtracheal jet ventilation (TTJV) catheter before induction of anesthesia in an attempt to provide apneic oxygenation or high-frequency TTJV (see "Intraoperative Ventilation Techniques and Strategies for Microlaryngeal Surgery")
   - High-frequency jet ventilation (HFJV) through the supralaryngeal airway device (e.g., LMA)
   - JV approaches require caution, especially in the presence of subglottic lesions, to avoid air trapping and barotrauma
7. Patients with inspiratory obstruction due to bilateral vocal cord paralysis or fixation of cricoarytenoid joints typically do not present ventilation or intubation problems.
8. If tracheostomy is avoided, an extubation strategy must be decided on with the surgeon. Extubation should be performed over an airway exchange catheter (AEC), with the necessary reintubation equipment immediately available. Some patients should remain intubated until the airway inflammation and edema subside, and the patient's airway is then reevaluated.

2. Intraoperative Ventilation Techniques and Strategies for Microlaryngeal Surgery

Surgery can be conducted in an awake patient, frequently under conscious sedation, or with the patient anesthetized (Box 38-1). The ventilation options under general anesthesia consist of "tube" (i.e., endotracheal intubation)

Box 38-1 Ventilation Techniques and Strategies for Microlaryngoscopic Surgery

I. Awake airway surgery (conscious sedation)
II. Asleep airway surgery (general anesthesia)
  II.1. Endotracheal intubation (cuffed microlaryngeal tracheal (MLT) tube)
  II.2. Tubeless techniques
    a. Spontaneous ventilation
      Inhalational anesthesia (insufflation)
      Total intravenous anesthesia
    b. Apneic intermittent ventilation
    c. Jet ventilation
      Supraglottic
      Subglottic
      Low frequency
      High frequency
      Superimposed high frequency

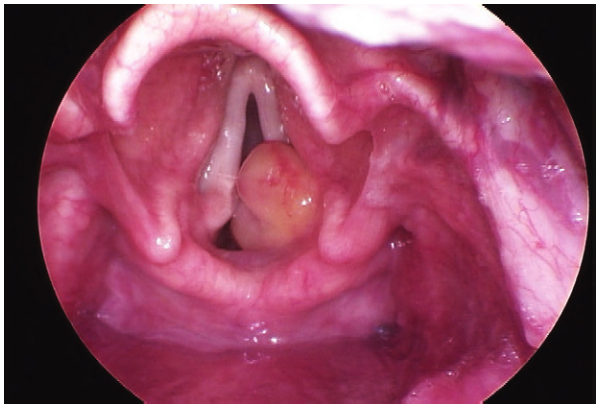

Figure 38-12 A right vocal process granuloma is located in the posterior glottis. The location and the nature of the pathology preclude the use of the microlaryngeal tracheal (MLT) tube and require the use of jet ventilation. (Courtesy of Edward Damrose, MD, Stanford University Medical Center, Stanford, CA.)

and "tubeless" techniques, with the latter represented by the techniques of spontaneous ventilation, AIV, and JV.[8,13,38,81,82]

a. AWAKE AIRWAY SURGERY WITH CONSCIOUS SEDATION

For selected patients, many laryngoscopic procedures can be safely and effectively performed in an office-based setting, including diagnostic endoscopy, laser surgery, panendoscopy for cancer screening and biopsies, and therapeutic vocal cord injections.[2-5,16] The key to success for office-based surgery remains adequate topical and regional anesthesia of the patient's airway, which is usually performed by the surgeon and typically follows preparation of the patient for awake oral and nasal flexible fiberoptic intubation (see Chapter 19). Although highly motivated patients can undergo office-based laryngoscopic surgery strictly under local anesthesia, most desire sedation and amnesia.[3]

If presence of the anesthesiologist is requested, the main objectives are to monitor for possible local anesthetic toxicity (see Chapter 19), to supplement local anesthesia with a rapidly titratable and reversible state of sedation, and to treat acute hyperdynamic responses that can occur in up to 20% to 30% of patients, despite seemingly adequate topical anesthesia of the airway.[3,83] Judicious use of intravenous opioids or sedatives/hypnotics, or both, is paramount, because a loss of patient cooperation may result in intraoperative injury.[3,16,34] Sedation of the patients with obstructive sleep apnea and morbid obesity should be performed with extreme caution.[84,85]

b. ASLEEP AIRWAY SURGERY WITH GENERAL ANESTHESIA

General anesthesia for microlaryngeal surgery represents a unique example of some of the conflicting intraoperative goals that exist between the surgeon and the anesthesiologist with regard to the patient's airway control and maintenance. For the surgeon, ideal operating conditions would be completely unobstructed surgical visualization, unimpeded surgical manipulation, and absence of movement in the surgical field. From the anesthesiologist's perspective, the ideal anesthetic technique would allow adequate protection of the patient's lower airway from aspiration and the use of stable, controlled mechanical ventilation with the ability to measure the concentration of anesthetic gases, peak inspiratory pressure (PIP), inspired oxygen concentration (FIO_2), and end-tidal carbon dioxide level ($ETCO_2$).[81] In most cases, these objectives can be balanced by the use of a small MLT tube, maximizing the patient's safety and the success of surgery.

ENDOTRACHEAL INTUBATION WITH MICROLARYNGEAL TRACHEAL TUBES. The use of a small (5.0-mm ID) MLT tube with positive-pressure ventilation remains the standard for airway management in most nonlaser microlaryngeal surgery, and it is associated with minimal or no intraoperative complications.[86,87] (For anesthetic management of the laser airway surgery see Chapter 40.) Adequate gas exchange can be maintained through small-ID ETTs in most adult patients,[88,89] unless the duration of surgery approaches 2 hours (which happens rarely).[88] Even then, despite a consistent trend toward progressive hypercapnia and respiratory acidosis, the pH and $ETCO_2$ values remain within physiologic range.[89]

With most glottic pathology originating in the anterior two thirds of the larynx,[90] consistent positioning of a small MLT tube between the arytenoid cartilages in the posterior part of the glottis leaves most of the surgical field unobstructed to the surgical view and manipulations.[4,13,16,38,91] Even with many posterior glottic disorders, it may be possible for the surgeon to gently displace the MLT tube anteriorly with the microsurgical cupped forceps or to perform the surgery using the specially designed posterior glottic laryngoscopes.[90,92]

However, if the posterior glottis is occupied by a significant surgical pathology (e.g., posterior glottic or subglottic stenosis, transglottic tumor) (Fig. 38-12), use of alternative, tubeless ventilation techniques becomes necessary.[38] Because of the surgeon's preference, tubeless ventilation can also be requested as a primary ventilation mode from the outset of the procedure.

TUBELESS TECHNIQUES

Spontaneous Ventilation. Spontaneous ventilation is rarely used in adult microlaryngeal surgery,[93-95] but it is commonly employed in the pediatric patient population,

Figure 38-13 A child in suspension laryngoscopy using the spontaneous ventilation (insufflation) technique. Notice the precut endotracheal tube connecting the anesthesia circuit to a metal cannula inserted into a side port of the suspension laryngoscope. (Courtesy of Peter Koltai, MD, Stanford University Medical Center, Stanford, CA.)

for whom it offers the additional ability to evaluate dynamic airway function and the level of obstruction (see "Anesthesia for Pediatric Airway Endoscopy and Microlaryngeal Surgery"). Anesthetic gases can be delivered (insufflated) through a nasal trumpet connected through an ETT adapter to the anesthesia circuit,[96-99] an ETT positioned in the nasopharynx,[82,100,101] a metal cannula, a side port of the rigid bronchoscope or operating laryngoscope (Fig. 38-13; see Fig. 38-10),[38] or a catheter placed through the vocal cords into the patient's trachea.[9,102,103] Scavenging of anesthetic gases can be facilitated with an open suction tube at the corner of the patient's mouth.

Although this technique offers free access to the larynx, it does not provide a still surgical field for precision surgery, it affords no protection of the lower airway, and it contaminates the OR environment.[34,87,103] Deep planes of anesthesia are usually required to blunt the laryngeal responses and to prevent patient movement, which tends to provoke cardiovascular instability and ventilatory compromise (i.e., hypoxemia, hypercarbia, and short periods of apnea).[8,39,104] With careful technique, inhalational agents can be substituted for total intravenous anesthesia (TIVA).[82,96,105] However, control of the patient's movement and a stable plane of anesthesia frequently remains problematic.[104] Monitoring an adequate hypnotic state (e.g., processed electroencephalographic activity) may be advisable for these patients.

The protagonists of spontaneous ventilation technique may wish to routinely supplement general anesthesia with topical or local anesthesia of the airway (usually

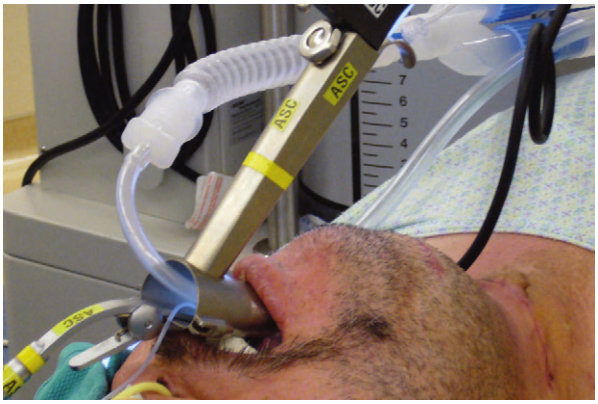

Figure 38-14 Apneic, intermittent ventilation during microlaryngeal surgery. The endotracheal tube is intermittently placed through the lumen of a suspension (Lindholm) laryngoscope by the surgeon and connected to the anesthesia breathing circuit for positive-pressure ventilation.

done by the surgeon after deployment of suspension laryngoscopy), which facilitates maintenance of a more stable and lighter plane of anesthesia, promotes hemodynamic and respiratory stability, and decreases the incidence of intraoperative laryngospasm.[39,82,96,103,105,106]

Apneic Intermittent Ventilation. AIV remains a relatively popular technique for microlaryngeal surgical procedures of short duration in some surgical centers.[87] Compared with spontaneous ventilation, it affords more stable and controlled anesthetic conditions, as well as full muscle relaxation. After induction of anesthesia, the patient's lungs are ventilated by a face mask or an LMA, which is followed by a period of apnea to allow deployment of a suspension laryngoscope by the surgeon. The patient's trachea is subsequently intubated by the surgeon with a small-diameter, preferably uncuffed ETT that is placed through the lumen of the laryngoscope,[87] and the patient's lungs are hyperventilated with an F_{IO_2} of 1.0 (Fig. 38-14). The ETT is then removed to provide a fully unobstructed and still surgical view of the larynx. The ETT is withdrawn and reinserted as frequently as necessary to maintain an oxygen saturation by pulse oximetry (SpO_2) of 90% or greater and Et_{CO_2} between 40 and 60 mm Hg,[18,87,107] allowing periods of apnea up to 5 to 10 minutes in healthy adult patients.[87,108] Apneic oxygenation through the hypopharyngeal catheter, preceded by an adequate period (10 minutes) of preoxygenation and denitrogenation of the patient's lungs, can be tried in anesthetized and paralyzed patients.[108]

TIVA is typically used for maintenance. Monitoring the hypnotic state of anesthesia is advisable during AIV, because the incidence of awareness and recall may reach 4% (30 times higher than in the general surgical population), especially when the inhalational agents are used to supplement intravenous anesthesia.[109,110]

The disadvantages of AIV include slowing the pace of surgery, disruption of the surgical field, possible trauma to the vocal cords and lower airway due to repeated endotracheal intubation, and a propensity for laryngospasm.[87] In a study of more than 350 patients,[87] the incidence of intraoperative laryngospasm with AIV was

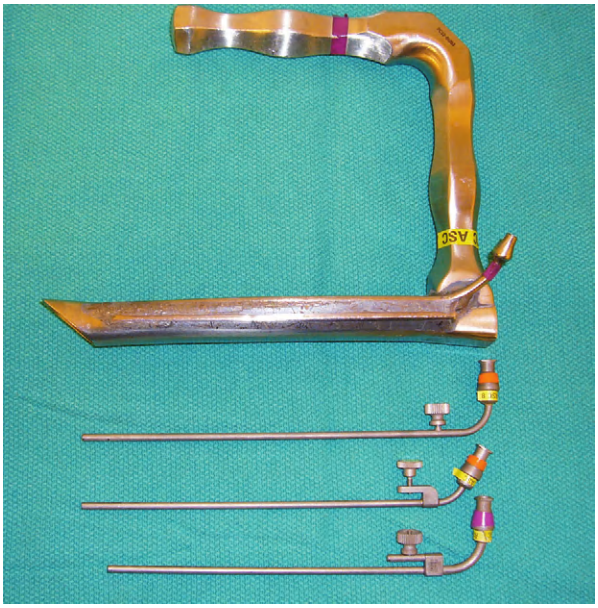

Figure 38-15 A Dedo operating laryngoscope with the integrated side port *(top)* can be used for supraglottic jet ventilation, and different jetting metal cannulas *(bottom)* can be inserted through the side ports of the operating laryngoscopes or directly through their lumen (see Fig. 38-4).

1.4%. The AIV may not be suitable for patients with significant lung or cardiovascular disease,[107] and it leaves the patient's lower airway unprotected to aspiration.[18]

Appropriate and successful phonomicrosurgery can rarely be performed using AIV, because the apnea periods are too short to permit unhurried precision surgery.[1,111] This technique may be better reserved for short, uncomplicated cases.

Jet Ventilation. Supraglottic JV (i.e., jet nozzle above the glottic opening) for microlaryngeal surgery can be performed through the side port of a suspension operating laryngoscope, with the jet cannula attached to the lumen of the laryngoscope (Fig. 38-15; see Fig. 38-4)[1,24,59,112] or through a specialized jet laryngoscope.[113,114]

Subglottic JV (i.e., jet nozzle below the glottic opening) is established by bypassing the larynx from above (i.e., translaryngeal or transglottal approach) or below (i.e., percutaneous approach) through the CTM or the upper TTJV rings.[74,86,87,111] Transglottal JV typically employs specialized, laser-safe, small-diameter, orally placed, double-lumen catheters (Fig. 38-16),[24,81,115,116] in which the large port is used for jetting and the smaller lumen

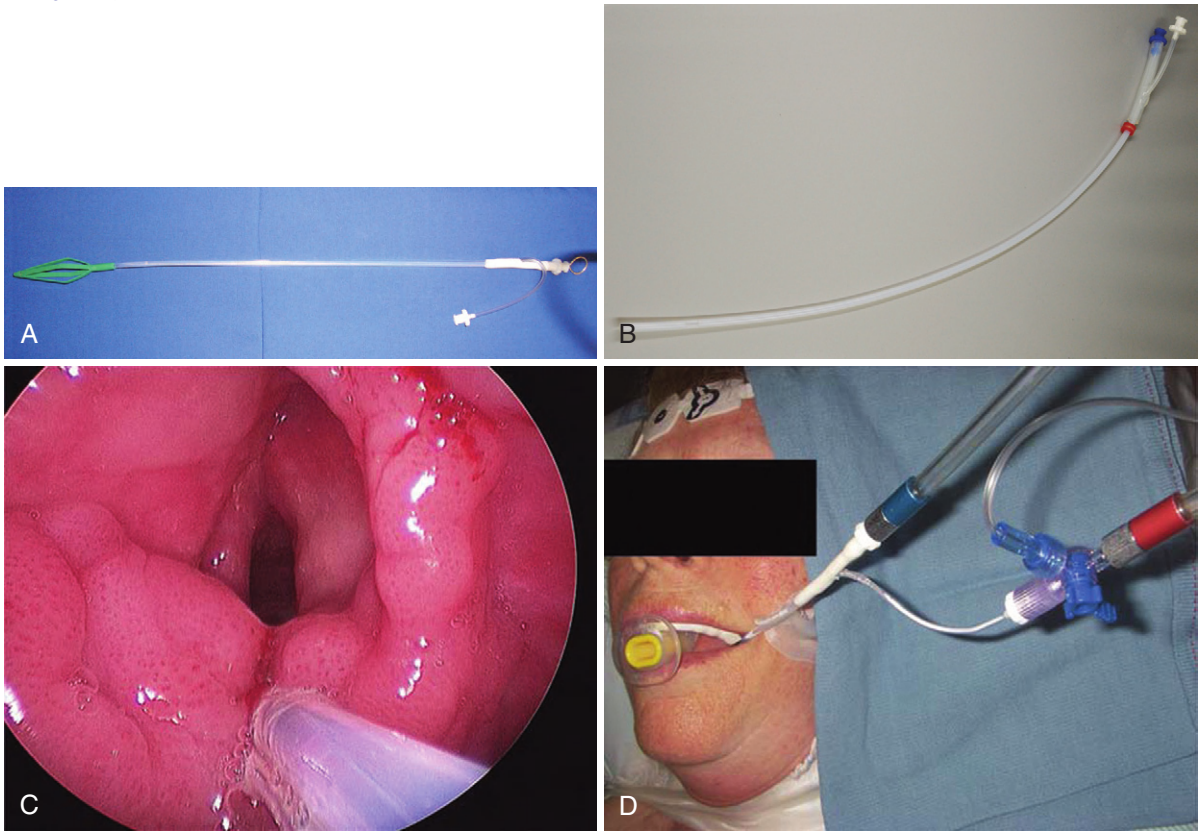

Figure 38-16 The Hunsaker Mon-Jet Ventilation Tube (Medtronic Xomed Inc., Jacksonville, FL) **(A)** and a double-lumen catheter (LaserJet, Acutronic medical systems AG, Hirzel, Switzerland) **(B)** are laser-resistant, come with the metal stylet to facilitate tracheal placement, and have a large port that is used for jet ventilation (JV) and a smaller port that is used for monitoring the distal airway pressure and respiratory gases. The green, basket-shaped distal end of the Hunsaker Mon-Jet tube **(A)** facilitates self-centering of the tube within the trachea, preventing the catheter "whip" that may lead to submucosal gas injection and possible occlusion of the distal end of the jet tube by tracheal mucosa. **C,** The small-diameter Hunsaker Mon-Jet tube is placed through the glottis to facilitate a clear surgical view and surgical access. **D,** The Hunsaker Mon-Jet tube is taped in place during JV, with the monitoring port connected to the ventilator through a three-way stopcock. The jet ventilator tubing is suspended to prevent kinking, and an oral airway is inserted to facilitate full egress of air during JV. (**B,** Courtesy of Acutronic medical systems AG, Hirzel, Switzerland; **C** and **D,** from Davies JM, Hillel AD, Maronian NC, et al: The Hunsaker Mon-Jet tube with jet ventilation is effective for microlaryngeal surgery. *Can J Anaesth* 56:284–290, 2009.).

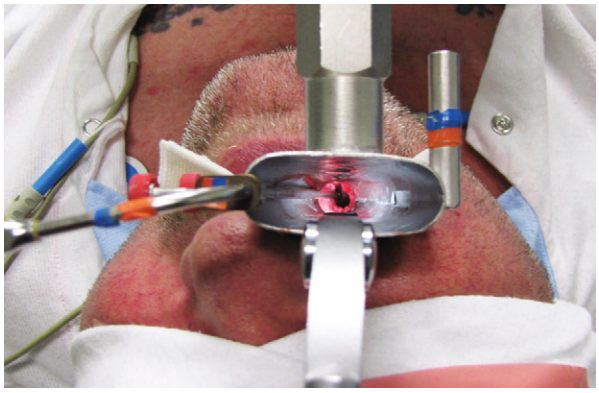

Figure 38-17 Subglottic high-frequency jet ventilation (JV) through a movable metal jet nozzle. Transglottal JV is provided through the metal jet nozzle (Brock & Mechelsen A/S, Birkerod, Denmark) and is secured on the suspension laryngoscope for the operation for vocal cord carcinoma.

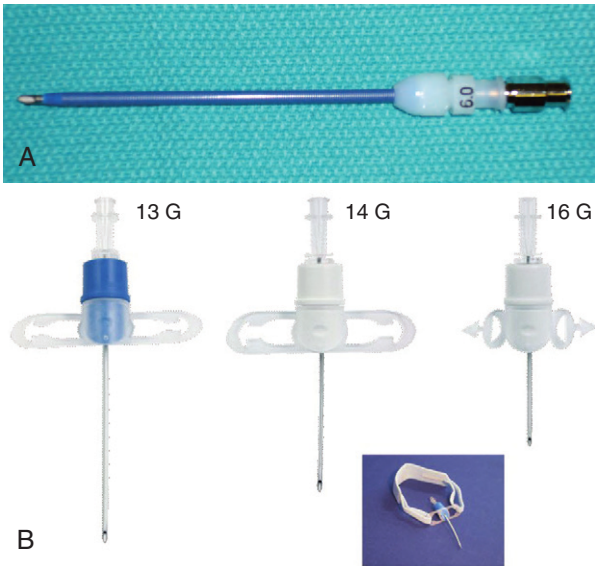

Figure 38-18 Devices for transtracheal jet ventilation (TTJV). **A,** The 7.5-cm long, 2-mm inner diameter TTJV catheter (Cook Medical Inc., Bloomington, IN) is mounted on a 14-gauge *(G)* needle. The catheter is wire reinforced to prevent kinking. **B,** Different sizes of the Ravussin-type cricothyrotomy catheter (VBM Medizintechnik GmbH, Sulz, Germany) for TTJV. The 13-gauge, 1.3-mm outer diameter catheter with the fixation flange and foam Velcro neck tape is most frequently used in adults. (Courtesy of Acutronic Medical Systems, GmbH, Salzburg, Austria.)

for monitoring the distal airway pressure and respiratory gases. Long, single-lumen catheters (typically 1.5- to 3-mm ID), some of which are laser resistant, may be used and can be placed through the oral or nasal route[24,34,87,102,117-119]; however, they lack concurrent monitoring capability. Alternatively, a small-diameter, movable, metal jet cannula can be passed through the glottis by the surgeon after the suspension laryngoscope is in position (Fig. 38-17).[87,120] For transglottal JV, midtracheal placement of the catheter or cannula is usually preferred. TTJV is typically administered through a long catheter or Ravussin-type cannula (Fig. 38-18).[74,86,121] For TTJV catheter or cannula placement, the use of an FFB or a rigid bronchoscope may be advocated to monitor the procedure[87,111,122] and to minimize the risk of unnoticed posterior tracheal wall laceration, which may lead to submucosal gas injection and barotrauma.[87,111] Use of a rigid bronchoscope with the bevel turned posteriorly may be especially efficacious, because the posterior tracheal wall is protected by the bronchoscope from the needle entry.[87] For transglottal JV and TTJV, endoscopic control also allows adjustment of the position of the distal end of the catheter or cannula to optimize HFJV.[24,86,87,122]

Compared with endotracheal intubation, supraglottic and subglottic JV techniques have distinct advantages of providing the surgeon with an enlarged, clear or minimally impeded, and undistorted view of the endolarynx, facilitating surgical access and eliminating flammable material (i.e., ETT) from the patient's airway during laser surgery.[24,115] Although supraglottic and subglottic ventilation techniques can use low-frequency jet ventilation (LFJV), HFJV, or superimposed high-frequency jet ventilation (SHFJV) modes,[34,86,111,123-125] the

TABLE 38-1
Preferred Use of Jet Ventilation Techniques for Microlaryngeal Surgery

Method of Ventilation	Low-Frequency Jet Ventilation	High-Frequency Jet Ventilation	Superimposed High-Frequency Jet Ventilation
Supraglottic Jet Ventilation			
Suspension laryngoscope	± a	± b	–
Jet laryngoscope	± a	± b	+
Subglottic Jet Ventilation			
Catheter	± c	+	–
Metal cannula	± c	+	–
Transtracheal jet ventilation	± c, d	+	–
Rigid bronchoscope	+ e	+ e	+ e

a, Probably best reserved for uncomplicated, relatively short procedures; *b,* may not be able to provide adequate gas exchange in patients with severe pulmonary disease or advanced laryngotracheal stenosis; *c,* should be used with caution; manual low-frequency jet ventilation is best avoided; *d,* also can be used as a rescue mode in "cannot ventilate, cannot intubate" situation; *e,* Used to bypass tracheal obstruction, and in central/distal airway surgery. A specially designed multilumen rigid bronchoscopes, or multilumen adapters for conventional rigid bronchoscopes, are required for high-frequency jet ventilation and superimposed high-frequency jet ventilation.

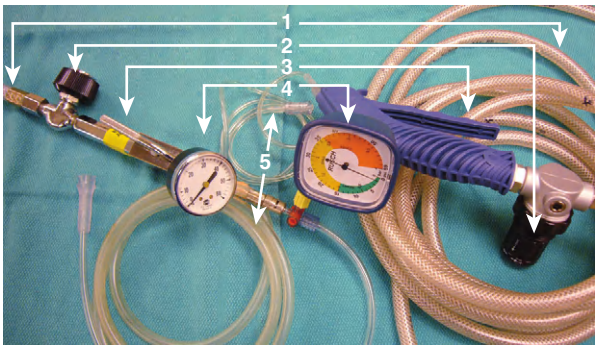

Figure 38-19 A simple Sanders-type injector (AA Jet Ventilator, Anesthesia Associates, San Marcos, CA) *(left)* and a manual jet ventilator (QuickJet, Rusch-Teleflex Medical, Durham, NC) *(right)* are used for manual (Venturi) low-frequency jet ventilation. Both devices contain a pressure hose *(1)*, an adjustable pressure-regulating valve *(2)*, a manual lever for delivering the pressurized gas *(3)*, an easily readable pressure gauge *(4)*, and noncompliant jet ventilation tubing *(5)*. QuickJet allows presetting a desired level of driving pressure, indicated by the colored scale on the pressure gauge.

use of these modes in clinical practice is usually more restrictive (Table 38-1).

The use of manual supraglottic LFJV (i.e., Venturi jet ventilation) at a rate of less than 60 breaths/min continues to predominate in clinical practice,[111] probably because of the low cost and easy accessibility of manual JV devices (Fig. 38-19) (a manual mode also can be preset on commercially available jet ventilators, where available).[59,111,126,127] Although an overall incidence of complications with manual supraglottic LFJV may be low (0.42%),[120] a survey of 229 U.K. centers revealed that it was responsible for most major complications (e.g., significant hypoxemia, barotrauma, unplanned admission to the intensive care unit) and for all deaths, especially when applied subglottically.[111] This suggests that LFJV should be reserved for uncomplicated, elective procedures of short duration and that it may not be regarded as a standard of practice for microlaryngeal surgery.[24] For increased safety, LFJV should be started with a low driving pressure (≤10 psi), which is gradually increased until visible chest excursions are observed, and adequate oxygen saturation is maintained.[24,59,111]

The subglottic HFJV mode (respiratory rate of 100 to 300 breaths/min; tidal volumes [V_T] of 1 to 3 mL/kg), delivered through specialized automated jet ventilators, is typically used.[24,34] Compared with supraglottic LFJV, in which intermittent apnea is frequently required due to significant vocal cord movement, subglottic HFJV significantly reduces laryngeal motion and affords a quiet surgical field without the need for interrupting ventilation.[125] If vocal cord movement becomes a problem, HFJV driving pressure can be decreased, and the respiratory frequency can be increased to provide a smoother gas flow, or the ventilator can be turned off during particularly delicate parts of the procedure.[24,125]

Despite very small V_T values, CO_2 elimination during subglottic HFJV is facilitated by the upstream turbulent convective flow of CO_2 along the decreasing gradient from the alveoli to the conducting airways.[34] The alveolar-arterial CO_2 gradient in patients with normal lung function is largely maintained within normal range.[34,128] Monitoring Et_{CO_2} during HFJV can be accomplished by briefly switching to LFJV mode on the ventilator to get a reliable signal or by using transcutaneous Pco_2 monitoring.[24] Administration of subglottic HFJV also results in a higher inspired O_2 concentration, because entrainment of air is reduced deep inside the airway.[24,86] Improved oxygenation is further enhanced by generation of continuous positive end-expiratory pressure in small airways (auto-PEEP), leading to alveolar recruitment and increased functional residual capacity (FRC).[24,34,119] Nevertheless, patients with severely restricted lung compliance, $\dot{V}/\dot{Q}$ mismatch or shunting, and reduced FRC (e.g., morbid obesity) remain at increased risk for hypoxemia.[86]

In contrast to supraglottic LFJV, with which contamination of the lower airway due to air entrainment is possible,[34,81] a continuous, upward-directed flow of gas during subglottic HFJV creates a positive-pressure build-up, preventing blood and surgical debris from being directed down an unprotected airway.[111,119,129] However, increased airway pressure creates concern about air trapping and barotrauma, mandating maintenance of adequate gas outflow at all times.[130]

Before the suspension laryngoscope is secured, with the patient anesthetized and a subglottic JV catheter or cannula in place, strategies for minimizing the risk of barotrauma on initiation of subglottic HFJV may include starting ventilation with low driving pressures (<15 to 30 psi), allowing sufficient exhalation time by avoiding high-frequency ventilation (i.e., starting with LFJV first), and maintaining the patient's airway patency with the assistance of an oral airway or providing a jaw lift, if needed.[74,86,87,125,131] Alternatively, initiation of the subglottic HFJV can be held off until the suspension laryngoscope is deployed, and ventilation is supported conventionally through a face mask or the LMA. It may be prudent to confirm absence of the subglottic catheter or cannula obstruction by the Et_{CO_2} return and to check the catheter or cannula position endoscopically before subglottic HFJV commences.[86,125]

On emergence from anesthesia, small V_T values and low peak and mean airway pressures associated with subglottic HFJV enable the patient to breathe spontaneously, facilitating a transition to adequate spontaneous ventilation.[24,34,86,132,133] This transition can be further assisted at the end of surgery by increasing the frequency of ventilation to 300 breaths/min, increasing F_{IO_2} to 1.0, and setting a ventilator driving pressure at about 10 psi (0.8 bar), which enables almost continuous flow of O_2 and apneic oxygenation, as well as a rise in the carbon dioxide (CO_2) level.[24] If the conversion to spontaneous ventilation through a small subglottic catheter proves difficult, the patient's airway can be supported through a face mask, LMA, or ETT, as required; these conventional bridge airway strategies equally apply to transitioning from supraglottic JV. If obstructive airway lesions exist, subglottic HFJV must be used with extreme caution. If upper airway obstruction is greater than 50%, the position of the jet nozzle should be proximal to the site of the obstruction to prevent barotrauma, or the obstruction must be bypassed by a rigid bronchoscope first.[24,79]

Total outflow obstruction with resultant barotrauma during subglottic HFJV can be quickly precipitated by

surgical instrumentation, glottic edema, laryngospasm, or closure of the vocal cords due to inadequate depth of anesthesia or inadequate muscle relaxation.[81,86,130] Modern automated jet ventilators (e.g., Monsoon III Universal Jet Ventilator [Acutronic Medical Systems AG, Hirzel, Switzerland], Twin Stream [Carl Rainer GmbH, Vienna, Austria]) incorporate multiple safety features, including automatic ventilator shutdown, if the user-preset pressure limits are exceeded.[24,74] This design has enabled some experienced providers to successfully use high-frequency TTJV in patients with massive supraglottic lesions and severe airway compromise,[74] for which the use of supraglottic or subglottic JV was not possible or surgically feasible. The presence of a second anesthesiologist to facilitate monitoring and maintenance of an upper airway was required and deemed an important safety factor in preventing intraoperative pressure-related complications in all cases.[74] Although no major complications were observed in this series of 50 patients,[74] the incidence of minor complications reached 20%, a more than threefold increase compared with the instances when high-frequency TTJV has been used in patients with less severe airway compromise.[87] Study results hold some promise that a simple,[134,135] portable expiratory ventilation assistance (EVA) device may be able to facilitate egress of gas through the jet catheter during TTJV, thereby increasing the safety of this technique; however EVA suitability for microlaryngeal surgery remains to be established.

Compared with the transglottal approach, high-frequency TTJV is associated with a significantly higher combined major and minor (e.g., transient hypoxemia) complication rate (see "Intraoperative Complications"),[86,87] and it represents an independent risk factor for complications during JV for microlaryngeal surgery.[87] Modern automated JV may not be able to remediate all possible causes of barotrauma associated with high-frequency TTJV; complications may be related to the TTJV catheter insertion problems, laryngospasm, and high-pressure episodes (e.g., coughing, active expiration) during the recovery period.[80,86] Notwithstanding the attractive features of high-frequency TTJV, such as a motionless surgical field and a particularly easy transition to spontaneous respiration,[86] it may be advisable to reserve the elective use of this technique (especially in cases of severe supraglottic airway obstruction) for the most complicated patients[74] and to designate operators with significant clinical experience and expertise.[74,80,86,111]

SHFJV, which combines high-frequency and low-frequency ventilation modes, has been used effectively in surgical treatment of high-grade laryngeal and tracheal stenosis, even with a remaining glottic opening as small as 2 to 3 mm.[136] SHFJV is delivered supraglottically through a specialized jet laryngoscope, which incorporates welded low-frequency and high-frequency jet nozzles (Fig. 38-20).[113,136,137] As the streams (LFJV of 12 to 20 breaths/min; HFJV of 100 to 900 breaths/min) get simultaneously directed from the ventilator toward the center of the distal end of the jet laryngoscope, LFJV entrains air (Fig. 38-21) and produces cyclic changes in V_T (similar to supraglottic LFJV), facilitating maintenance of $Paco_2$ at near-normal limits and allowing HFJV to be adjusted as needed.[136,137] HFJV builds up a

Figure 38-20 Jet laryngoscope for superimposed high-frequency jet ventilation. The jet laryngoscope (Carl Reiner GmbH, Vienna, Austria) incorporates a port for jet ventilation *(1)* with two welded jet nozzles for high-frequency and low-frequency ventilation and a port for pressure and gas monitoring *(2)*. (Courtesy of Carl Reiner GmbH, Vienna, Austria.)

continuous PEEP and promotes alveolar recruitment, maintaining $Paco_2$ even in the presence of the low Fio_2 required for laser surgery.[136-139] Safety of SHFJV is enhanced by an integrated port for continuous pressure (PIP and PEEP) and gas (Fio_2 and $Etco_2$) monitoring at the end of the jet laryngoscope (see Fig. 38-21)[137] and of an automatic pressure-triggered ventilator shutdown feature, similar to an isolated HFJV mode.

To achieve adequate SHFJV, it appears to be sufficient to generate a PIP of 15 to 30 cm H_2O, as measured

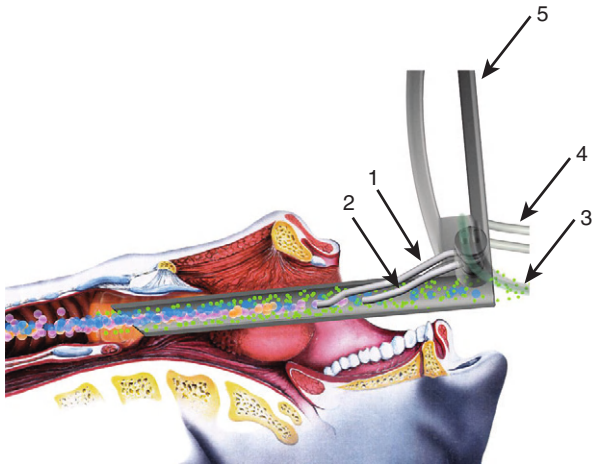

Figure 38-21 Technical diagram of the jet laryngoscope and superimposed high-frequency jet ventilation. High-frequency and low-frequency jet ventilation are simultaneously delivered to the patient from the ventilator through the high-frequency *(1)* and low-frequency *(2)* jet nozzles connected to the ventilator input tubing *(3)*. The gas flow to the patient is augmented by air entrainment *(blue circles)*. The pressure monitoring system *(4)* and jet laryngoscope handle *(5)* are indicated. (Modified image courtesy of Carl Reiner GmbH, Vienna, Austria.)

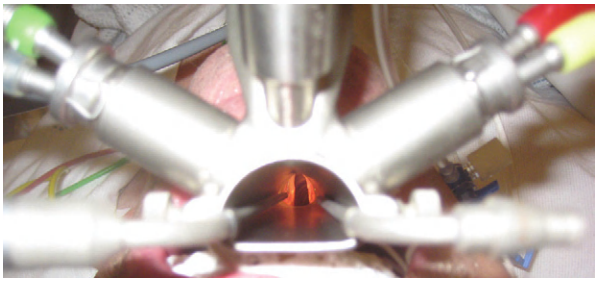

Figure 38-22 Superimposed high-frequency jet ventilation allows a completely unobstructed surgical view through the jet laryngoscope. Notice the ventilator input tubing *(green, left)* and the pressure or gas monitoring system *(red and yellow, right)* connected to the jet laryngoscope. (Courtesy of Lise Nørrekjær, MD, Department of Anaesthesia, Køge Sygehus, Køge, Denmark.)

at the end of the jet laryngoscope, which closely correlates with the PIP at the glottic and tracheal levels (i.e., no further increase in pressure occurs in the distal airway).[136,138] The PEEP values may not exceed 2.5 to 5 cm H_2O.[137,138] As a result, no adverse hemodynamic effects and barotrauma were observed in more than 1500 adult and pediatric patients who had undergone supraglottic SHFJV for laryngotracheal surgery, and endotracheal intubation was required in only 3 patients (0.2%), with concomitant significant restrictive or obstructive pulmonary disease.[136] Due to the HFJV component, vocal cord movement is greatly attenuated during SHFJV; if a perfectly still surgical field is requested by the surgeon, HFJV can be further increased, LFJV decreased or stopped, or a short period of full apnea instituted.[24,136,137]

SHFJV is a completely tubeless, laser-safe, open breathing system that allows a fully unobstructed surgical field (Fig. 38-22). It enables an easy switch between different JV modes and parameters, and it offers greater versatility and ventilation capabilities over the single-frequency JV techniques, especially in patients with preexisting compromised gas exchange. However, its effective use requires optimal laryngoscope alignment and adjustability in relation to the glottic opening.

Despite the increased safety profile of SHFJV, clinical monitoring of the patient to prevent barotrauma should remain the standard of care for all JV techniques (Fig. 38-23).[86,87] Close cooperation between the surgeon and the anesthesiologist is essential; if the operating laryngoscope moves or is removed and obstructs the airway without a warning to the anesthesia team, major barotrauma may result.[16] Ensuring an adequate level of anesthesia, analgesia, and muscle relaxation; painstaking attention to maintaining unobstructed exhalation; and close monitoring of vital signs and chest excursions are essential for the patient's safety.[59,86,87,138] The main advantages and disadvantages of the ventilation techniques used for microlaryngeal surgery are compared in Table 38-2.

C. General Anesthesia Management for Panendoscopy and Microlaryngeal Surgery

1. Premedication and Monitoring

The main anesthesia objectives and special considerations for microlaryngeal surgery are discussed in "Special Considerations and Anesthesia Objectives." Premedication can frequently be omitted. Administration of an antisialogogue (e.g., 0.2 mg of glycopyrrolate given intravenously) may be desired by the surgeon to facilitate the surgical field, especially in patients with copious secretions,[3,10] but it does not constitute the standard of care.[43] Mucosal intake of drying agents may result in increased vocal cord viscosity and impaired vibration, markedly changing the patient's voice postoperatively and contributing to postoperative dysphonia.[140] Steroids (e.g., 8 to 12 mg of dexamethasone given intravenously) are frequently used to prevent or minimize excessive postoperative swelling,[16,34] although controlled studies documenting this beneficial effect appear to be lacking.[34]

Standard OR monitors are used. Invasive arterial blood pressure monitoring is rarely indicated, and its use should

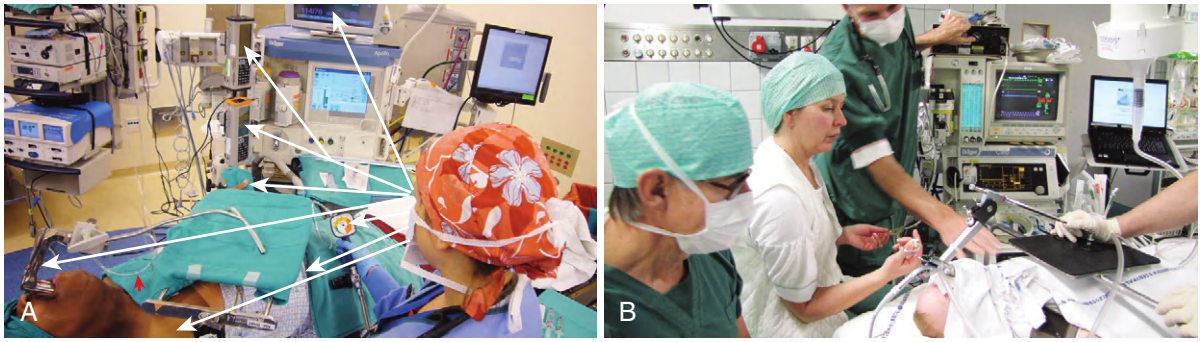

Figure 38-23 Challenges of intraoperative jet ventilation (JV). **A,** Manual, supraglottic low-frequency JV using QuickJet, connected *(red arrow)* to the suspension laryngoscope. The position and attentiveness of the anesthesiologist are required for multitasking and the challenging situations that exist. The anesthesiologist's attention *(white arrows)* must be simultaneously directed at maintaining close communication with the surgeon, observing the chest excursions, looking at the epigastric area for possible gastric distention, controlling driving pressure of the jet ventilator, maintaining adequate neuromuscular blockade (evaluated in this case at the ulnar nerve), ensuring a stable level of anesthesia delivered intravenously through the programmable infusion pumps, and observing the patient's vital signs. **B,** Automated, subglottic high-frequency JV in an 11-month-old child with recurrent respiratory papillomatosis. The JV is accomplished transglottally through a movable metal jet nozzle that is closely controlled by the anesthesiologist. Notice a different operating room setup compared with that in **A** and presence of two anesthesiologists, which increases the patient's safety.

TABLE 38-2

Advantages and Disadvantages of Ventilation Techniques Used for Microlaryngeal Surgery

Technique	Advantages	Disadvantages
Awake airway surgery	Avoidance of general anesthesia Unobstructed surgical field and free surgical access to the larynx Increased patient cooperation Ability to evaluate dynamic airway function Ability to monitor voice quality throughout the surgery Possible improvement in surgical outcomes Convenience for the surgeon and the patient Cost savings	Success depends on adequate topical and regional anesthesia of the airway Local anesthetic–induced side effects Lack of powered magnification Lack of precision afforded by a still surgical field May require conscious sedation Loss of patient cooperation may result in injury Limited ability to handle major intraoperative complications, such as bleeding and edema Limited amount of tissue biopsied or excised May not be suitable for patients with significant PD or CVD or for young pediatric patients
Endotracheal intubation (microlaryngeal tracheal tube)	Adequate surgical field and surgical access to the larynx in most cases Still surgical field Adequate airway protection Control of patient immobility and vocal cord movement with adequate NMB Stable and controlled ventilation technique Ability to continuously and reliably monitor F_{IO_2}, Et_{CO_2}, PIP, and anesthetic gases Suitable for prolonged procedures	Largely unsuitable for surgery of the posterior glottic pathology (e.g., posterior glottic or subglottic stenosis, transglottic tumor) Unsuitable for laser if the need arises May not be used according to the surgeon's preference
Spontaneous ventilation (insufflation and total intravenous anesthesia)	Unobstructed surgical field and free surgical access to the larynx Ability to evaluate dynamic airway function and obstruction Suitable for laser surgery	Unprotected lower airway Precision surgery difficult or impossible in the moving surgical field Contamination of operating room environment with anesthetic gases, if insufflation technique is used Difficulty controlling adequate depth of anesthesia and absence of patient movement Inability to continuously and reliably monitor F_{IO_2}, Et_{CO_2}, and anesthetic gases May not be suitable for patients with significant PD or CVD or for very young pediatric patients Best reserved for short, uncomplicated cases
Apneic intermittent ventilation	Unobstructed surgical field and free access to the larynx Still surgical field Control of patient immobility and vocal cord movement with adequate NMB Ability to intermittently control gas exchange Suitable for laser surgery	Unprotected lower airway Possible airway trauma and disruption of the surgical field due to repeated passage of the endotracheal tube Possible propensity for intraoperative laryngospasm Inability to continuously and reliably monitor F_{IO_2}, Et_{CO_2}, and anesthetic gases May not be suitable for patients with significant PD or CVD or for very young pediatric patients Slows the pace of surgery Best reserved for short, uncomplicated cases
Jet ventilation (JV)	Unobstructed or minimally impeded surgical field and surgical access to the larynx Still surgical field Control of patient immobility and vocal cord movement with adequate NMB Ability to monitor and control F_{IO_2}, Et_{CO_2}, driving pressure, PIP, and PEEP with automated jet ventilators Suitable for prolonged procedures	Sole dependence on total intravenous anesthesia Association with most major (e.g., barotrauma) and minor intraoperative anesthesia-related complications Dependence on sophisticated automated jet ventilators for safe use Limitations of manual JV and transtracheal JV Significant experience and presence of two operators often required May not be suitable for patients with significant PD or CVD

CVD, Cardiovascular disease; *Et_{CO_2},* end-tidal carbon dioxide; *F_{IO_2},* fraction of inspired oxygen; *JV,* jet ventilation; *NMB,* neuromuscular blockade; *PD,* pulmonary disease; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure.

be dictated by the patient's medical history, physical examination results, and special considerations such as prolonged JV or intraoperative problems (see "Jet Ventilation Problems"), for which intermittent sampling of arterial blood gases may become necessary. Monitoring the degree of neuromuscular blockade (NMB) with a conventional nerve stimulator should constitute the standard of care during panendoscopy and microlaryngeal surgery (see "Neuromuscular Blockade").

2. Anesthesia Induction and Maintenance

Conventional and advanced airway management is discussed in "Conventional and Advanced Airway Management." In most patients, standard intravenous induction can be safely performed. Difficulty in maintaining the airway during inhalational induction in patients with large, pedunculated tumors, granulomas and cysts should be anticipated, even if preoperative symptoms of airway obstruction are mild,[38] and early application of continuous positive airway pressure (CPAP) can help to stent the airway open. Another useful strategy involves preparing the patient's nares with a mixture of a vasoconstrictor and a topical anesthetic before induction, which will allow early passage of a nasal airway if the airway obstructs.[17,33]

Sevoflurane is most commonly used for inhalational induction in adult and pediatric patients.[34,141] The minimum alveolar concentration (MAC) of sevoflurane required to provide adequate endotracheal intubating (EI) conditions in 50% of unpremedicated adult patients (MAC_{EI50}) is 4.5% (95% confidence interval [CI], 3.9% to 5.2%), and the 95% effective dose (ED_{95}) for endotracheal intubation is 8%.[142] Although the ED_{95} time for achieving this target concentration in patients with normal airway is approximately 7 minutes,[143] up to 20 minutes may be required in patients with partial airway obstruction due to preexisting increase in minute ventilation and $\dot{V}/\dot{Q}$ mismatch.[17,34] This time can be shortened with the addition of small intravenous doses of midazolam or fentanyl,[141,144] although at the expense of an increased risk of apnea and loss of the airway.

If the patient's airway is reassuring, TIVA with propofol and an opioid is most commonly used during induction and maintenance of anesthesia for panendoscopy and microlaryngeal surgery.[34,74,86,87,111] TIVA offers many practical advantages, such as delivering a stable, consistent level of anesthesia in cases of JV and other settings in which the delivery of inhalational anesthetics is compromised. TIVA facilitates maintenance of induced hypotension, resulting in improved surgical visibility; ensures rapid return of protective airway reflexes; promotes rapid awakening and early postanesthesia recovery; and decreases the incidence of postoperative nausea and vomiting.[70,145-150] A propofol-based anesthetic results in profound depression of pharyngeal and laryngeal musculature and reflexes, and it effectively blocks the catecholamine release and hyperdynamic cardiovascular responses.[145,151-153] Full synergistic effect of propofol with rapidly acting opioids (e.g., remifentanil, alfentanil) allows rapid titration of anesthetic to the desired clinical effect.[154-156]

Remifentanil and alfentanil are widely used because of their favorable pharmacokinetic profile. Remifentanil is superior to fentanyl and alfentanil in promoting intraoperative hemodynamic stability, improving respiratory and general recovery, and facilitating patients' discharge after outpatient surgery.[157-162] The recommended induction doses are an intravenous bolus of 0.5 to 2 μg/kg of remifentanil and intravenous bolus dose of 1 to 2 mg/kg of propofol, followed by continuous maintenance infusions of 0.1 to 0.5 μg/kg/min of remifentanil and 80 to 180 μg/kg/min of propofol.[48,156-158,160,163] For alfentanil, an intravenous bolus of 20 to 30 μg/kg is commonly used for induction, followed by a continuous maintenance infusion of 0.25 to 1 μg/kg/min.[159,160,164,165]

Compared with conventional weight-based manual infusions, target-controlled infusions allow easier and more rapid titration of analgesia to the individual patient's responses, avoiding overshoot, improving the time course of the drug effect, and facilitating perioperative hemodynamic control.[166-168] Targeting propofol concentrations of 3 to 3.5 μg/mL and remifentanil concentrations of 2 to 5 ng/mL should be sufficient for most otherwise young (18 to 65 years old) and healthy (ASA physical class I or II) patients during the maintenance stage of anesthesia if adequate NMB is maintained.[166,169-171]

Severe bradycardic response to remifentanil should be treated promptly: activation of afferent parasympathetic fibers during direct and suspension laryngoscopy and endotracheal intubation or instrumentation may result in severe cardiac arrhythmias and asystole.[172,173] Pediatric patients and adults with high vagal tone may be at highest risk for these grave complications,[172] and pretreatment with anticholinergic agents may prevent or attenuate vagus-mediated cardiac arrhythmias. Treatment of reflex bradycardia and asystole during direct or suspension laryngoscopy must include immediate cessation of the offending stimulus, prompt administration of anticholinergics (e.g., atropine), and cardiopulmonary resuscitation, if necessary; infusion of isoproterenol or cardiac pacing may be required.[172]

Sevoflurane can be effectively combined with remifentanil and alfentanil for microlaryngeal surgery, producing good operating conditions, cardiovascular stability, and rapid emergence from anesthesia.[162] Compared with other inhalational anesthetics, sevoflurane may be preferred for outpatient microlaryngeal surgery. It improves the quality of postoperative patient recovery and shortens the discharge time, is associated with a reduced incidence of coughing compared with desflurane,[174] and produces less somnolence and postoperative nausea and vomiting compared with isoflurane.[175] Compared with TIVA, sevoflurane decreases salivary gland excretion, potentially promoting better visibility for the surgeon,[176] although clinical significance of this effect is unknown.

3. Neuromuscular Blockade

Maintenance of adequate NMB for microlaryngeal surgery is recommended,[1,34,38,86,111] but this advice is not universally followed.[111,177] Lack of appreciation for the benefits of adequate muscle relaxation constitutes a significant area for improvement in anesthesia care in general[177] and microlaryngeal surgery in particular.

Full muscle relaxation facilitates smooth endotracheal intubation, which should be accomplished in patients presenting for microlaryngeal surgery without the use of an ETT stylet when possible.[1] Maintenance of adequate NMB can prevent disastrous consequences of sudden patient movement, such as bucking or coughing while in suspension or during bronchoscopy or esophagoscopy,[43] and it can facilitate respiratory compliance during JV.[34] For some short surgical interventions, for which adequate muscle relaxation is only transiently required, combined administration of 2 μg/kg of remifentanil, 2 mg/kg of propofol, 1.5 mg/kg of lidocaine, and only one half of an intubating dose of rocuronium (0.3 mg/kg) can be administered, producing intubating conditions similar to intravenous administration of 1.5 mg/kg of succinylcholine.[178] For very short diagnostic procedures, for which muscle relaxants can be completely avoided, a bolus dose of 3 to 4 μg/kg of remifentanil (or intravenous bolus of 40 to 60 μg/kg of alfentanil), administered over 90 seconds and followed by an intravenous bolus of 2 to 2.5 mg/kg of propofol should provide excellent conditions for endotracheal intubation[179-181] or a quick "surgical look."

For most adult microlaryngeal surgical and panendoscopy procedures, maintenance of a high degree of NMB is strongly preferred and is most commonly achieved by administration of intermittent intravenous bolus doses of intermediate-acting, non-depolarizing neuromuscular blockers or succinylcholine infusion.[86] In the absence of contraindications to succinylcholine, the choice may be largely influenced by the duration of the procedure, the anesthesiologist's preference, and special surgical requirements. If rapid or intermittent return of spontaneous ventilation is required intraoperatively, an intravenous bolus of succinylcholine followed by an infusion may be preferred.[34] A succinylcholine infusion at a rate of 0.1 mg/kg/min (95% CI, 0.06 to 0.14 mg/kg/min) provides 100% twitch depression to the train-of-four (TOF) stimulation of the ulnar nerve (adductor pollicis muscle) and can be easily titrated to effect due to its linear kinetics.[182] The infusion should be started after the intubating dose of succinylcholine has dissipated and a twitch response has reappeared.[182,183] For practical purposes, it should be titrated to a barely visible single twitch during TOF stimulation of the ulnar nerve, which corresponds to 95% to 98% of twitch depression.[182] The observed increased succinylcholine requirements (i.e., tachyphylaxis) should alert the anesthesiologist to a rapidly developing transition from phase 1 to phase 2 NMB.[183,184] Similar phenomena are observed in children.[185]

In the absence of a phase 2 block, succinylcholine infusions may avoid postoperative residual curarization (PORC). The incidence of PORC with the use of the intermediate-acting, non-depolarizing muscle relaxants reaches 20% to 30% in the general surgical population.[186,187] PORC is associated with delayed discharge from the recovery room, even in the absence of respiratory compromise.[186] The use of mivacurium, despite its short duration of action, is associated with an almost 10% incidence of residual block, unless its action is pharmacologically reversed.[188] This highlights the need for vigilant intraoperative monitoring of NMB and routine reversal of NMB after microlaryngeal surgery to ensure adequate TOF recovery to a level of more than 0.9.[189-192] Even small degrees of residual paralysis (TOF of 0.7 to 0.9) are associated with impaired pharyngeal function and increased risk of aspiration, significant attenuation of the hypoxic ventilatory response, unpleasant symptoms of muscle weakness, and weakness of the laryngeal and upper airway muscles, which may contribute to the possibility of acute upper airway obstruction postoperatively (see "Postoperative Complications").[192]

During microlaryngeal surgery, access to the patient's arms is frequently difficult or impossible, and the anesthesiologist is faced with an alternative choice of monitoring NMB at the temporal branch of the facial nerve (i.e., orbicularis oculi muscle) or posterior tibial nerve (i.e., flexor hallucis brevis muscle). Monitoring TOF at the orbicularis oculi correlates best with NMB at the laryngeal adductor muscles, which are responsible for vocal cord movement and glottic closure[193] and may constitute the surgeon's preference.[43] For adequate orbicularis oculi monitoring, the following guidelines should be followed[194,195]:

1. The electrodes should be positioned just lateral to the eye or with one electrode lateral to the eye and one in front of the ear.
2. Small currents (20 to 30 mA) and small electrodes should be used to avoid stimulation of other facial muscles.
3. The responses to stimulation should be observed in the middle of the eyebrow.

The onset of and the recovery from non-depolarizing NMB at the larynx and orbicularis oculi are similar and faster than at the ulnar nerve.[191,193-196] Significantly quicker recovery of NMB is observed in adults at the flexor hallucis brevis muscle (i.e., great toe) compared with the hand muscles.[191] Assessment of the residual block at the end of the surgery must still be guided by a twitch recovery at the ulnar nerve, because the adductor pollicis muscle recovers last.[191,194,196]

The anesthesiologist must maintain constant communication with the surgeon to match the maintenance of adequate NMB with the duration of surgery. If additional muscle relaxation is requested at the end of the procedure to abolish vocal cord movement, administration of non-depolarizing muscle relaxants should be avoided, and deepening the level of anesthesia and/or administration of additional analgesia (e.g., intravenous bolus of remifentanil) should be performed instead.[43] Pharmacologic reversal of non-depolarizing NMB should be routinely done at the end of microlaryngeal surgery.

Sugammadex, a selective relaxant binding drug, can antagonize any level of NMB, including the profound blockade induced by rocuronium, adding flexibility to the use of non-depolarizing relaxants.[197] The recommended dose is 2 to 16 mg/kg, depending on the level of the block.[188,197] Profound NMB induced by rocuronium can be reversed in less than 3 minutes.[198] Sugammadex, however, has no affinity for atracurium, cisatracurium, or succinylcholine; is not widely available; and is very expensive.[197]

4. Conventional and Operative Direct Laryngoscopy

The intense sympathoadrenal response observed during direct laryngoscopy and endotracheal intubation (see "Special Considerations and Anesthesia Objectives") may be further accentuated by continuous deployment of the suspension laryngoscope and intralaryngeal or intratracheal surgical manipulations, resulting in a 10% to 17% incidence of transient intraoperative myocardial ischemia.[199] The administration of 1.5 to 2 mg/kg of esmolol by intravenous bolus, followed by continuous intravenous infusion at a rate of 100 to 300 µg/kg/min, may be particularly effective in promoting hemodynamic stability and preventing intraoperative myocardial ischemia.[200-202] Potentiation of the action of opioids and anesthetic agents by esmolol further results in decreased postoperative opioid analgesic requirements,[203-206] facilitates emergence from anesthesia, and shortens a discharge time after outpatient surgical procedures.[207-210]

5. Jet Ventilation Problems[24,34]

a. INSUFFICIENT OXYGENATION

A sudden drop in SpO_2 may be the result of acute barotrauma and pneumothorax, which should be promptly treated. A gradual decline in SpO_2 usually results from insufficient alveolar ventilation or limited lung diffusion capacity, and it is most commonly associated with preexisting restrictive or obstructive pulmonary disease. The steps of therapeutic intervention include increasing F_{IO_2} in the jet gas, gradually increasing the driving pressure, increasing the ratio of the duration of inspiration to the duration of expiration (I:E ratio), reducing the ambient air entrainment by adding an O_2 bias flow, and switching from supraglottic to the more efficient subglottic JV until the problem is corrected. Increasing the respiratory frequency or PEEP level should be avoided, because this may lead to lung overexpansion and reduced venous return. If these measures are exhausted without achieving adequate oxygenation, the anesthesiologist should switch to AIV or endotracheal intubation with an MLT tube.

b. INSUFFICIENT CARBON DIOXIDE ELIMINATION

Intraoperative hypercapnia can be observed in patients with severe COPD and reduced lung compliance. Slightly increasing the driving pressure is recommended until the problem is corrected. If Et_{CO_2} or Pa_{CO_2} levels continue to rise despite maximal driving pressure, permissive hypercapnia can be allowed in selected patients. Studies indicate that Pa_{CO_2} values as high as 100 mm Hg may be well tolerated intraoperatively.[211] A switch to conventional endotracheal intubation and intermittent positive-pressure ventilation always remains an option.

The higher ASA physical status correlates with the higher incidence of complications with transglottal and TTJV techniques,[87] and these patients should be given special attention if JV is planned. Patients with previous neck radiation therapy are at higher risk for multiple attempts at TTJV catheter placement and subsequent risk of developing intraoperative barotrauma.[86]

6. Bronchoscopy and Esophagoscopy

Diagnostic and therapeutic forms of endoscopy (i.e., bronchoscopy and esophagoscopy) are typically performed as part of the panendoscopy procedure. The use of operating flexible and rigid bronchoscopy in central and distal airway surgery, including tracheal and endobronchial stent placement, is beyond the scope of this discussion, and JV is most commonly employed for these surgical procedures. Operating esophagoscopy is commonly used for endoscopic resection of Zenker's diverticulum.

If rigid bronchoscopy is planned first, general anesthesia is induced in a standard manner, and the patient's lungs are hyperventilated through the face mask with an F_{IO_2} of 1.0. With the onset of complete muscle relaxation, the patient is immediately turned over to the surgeon without securing an airway.[43] Quick and gentle direct laryngoscopy for the purpose of applying topical laryngotracheal anesthesia (3 to 4 mL of 4% lidocaine) before rigid bronchoscopy can be tried to help blunt hemodynamic responses to subsequent surgical manipulation; however, the risk of residual laryngeal anesthesia should be kept in mind if the procedure is short.[212]

After the rigid bronchoscope is introduced into the patient's trachea, JV can be instituted, or ventilation can commence manually through the OR anesthesia circuit by using the Racine universal adapter connected to the side arm of the bronchoscope (see Fig. 38-10). A rigid telescope and many accessory instruments such as forceps, suction catheters, laser fibers, or silicone stent delivery systems can be placed by the surgeon through the central lumen of the bronchoscope.[213] Although balanced inhalational anesthesia has been used successfully in this setting,[34] TIVA can provide a more stable plane of anesthesia. With manual ventilation, high gas flows are usually required because of the variable leak around the end of the bronchoscope. Close communication with the surgeon is essential for decreasing the manual inflating pressures when the bronchoscope is introduced into a main stem bronchus and to ensure complete exhalation.[43]

After rigid bronchoscopy is completed, if endotracheal intubation is planned, a resumption of adequate mask or LMA ventilation with an F_{IO_2} of 1.0 is advisable before direct laryngoscopy. If necessary, the airway can be exchanged with the ETT through the in situ rigid bronchoscope (see Fig. 38-11).[72,73]

If endotracheal intubation is chosen, a small-diameter (e.g., 6.0 mm ID), wire-reinforced ETT may be preferred for rigid esophagoscopy to avoid possible compression of the ETT lumen; however, if suspension laryngoscopy with endotracheal intubation is planned next, a 5.0 mm ID MLT tube should be used instead. The ETT should be moved over to the left side of the patient's mouth to facilitate introduction of the surgical instruments and securely taped to the lower jaw, facilitating full opening of the patient's mouth by the surgeon.[43]

Intraoperative flexible fiberoptic bronchoscopy can be performed by the surgeon through an appropriately sized ETT, alongside the small ETT with its cuff deflated; through the LMA; or through Patil-Syracuse endoscopy mask (Ambu Inc., Glen Burnie, MD) (Fig. 38-24). If

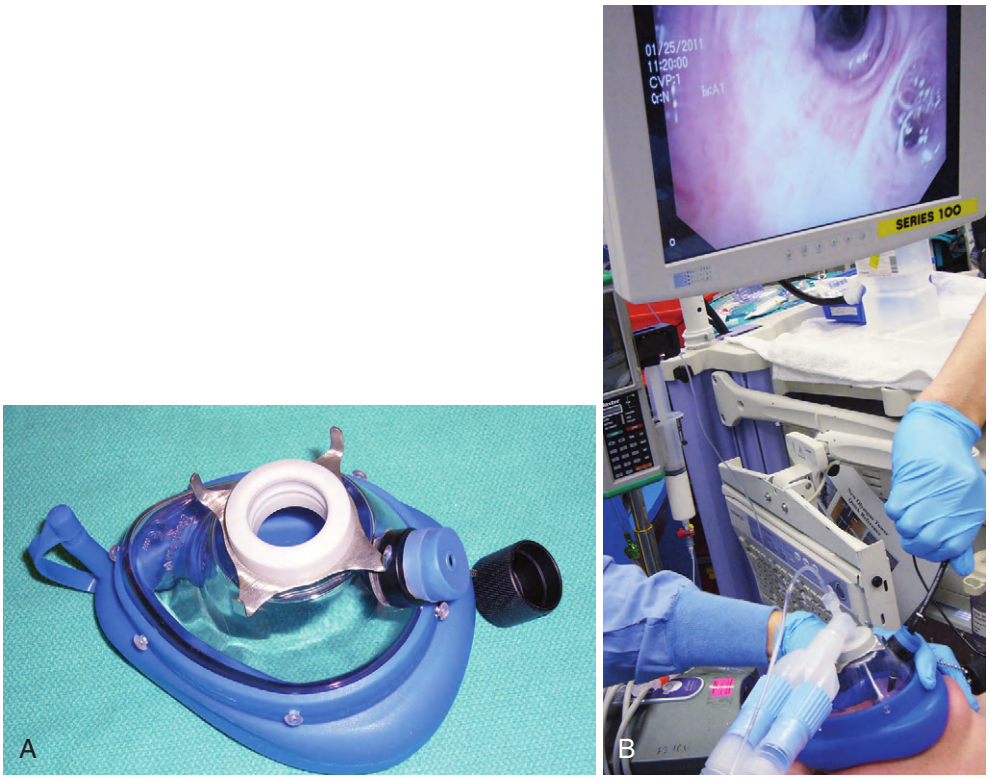

Figure 38-24 **A,** The reusable, clear-view Patil-Syracuse mask (Ambu Inc., Glen Burnie, MD) has a soft, blue, flexible diaphragm that facilitates passage of flexible endoscopes and endotracheal tubes. A black cap seals off the diaphragm and allows positive-pressure ventilation (PPV) through the anesthesia circuit when endoscopy is not in use. **B,** Flexible fiberoptic bronchoscopy is performed through the Patil-Syracuse mask. Placement and manipulation of the flexible fiberoptic bronchoscope by the surgeon is aided by a concomitant use of a pink Williams oral airway intubator, which facilitates central positioning and maneuvering of the fiberoptic bronchoscope. Maintenance of a good seal through the flexible diaphragm allows adequate PPV by the anesthesiologist.

flexible fiberoptic bronchoscopy is performed through the ETT (7.5 to 8.0 mm ID) using a swivel bronchoscopy adapter, ventilation is better controlled manually because of increased resistance to the gas flow and high PIP. Gentle, manual ventilation with small tidal volumes and an F_{IO_2} of 1.0 is usually well tolerated by the patient over the short course of the procedure. The efficacy of ventilation through the Patil-Syracuse mask during flexible fiberoptic bronchoscopy is greater than through the Classic LMA or iLMA,[214] and the Patil-Syracuse mask can be used to facilitate flexible esophagoscopy.

After endoscopy through the Patil-Syracuse mask is completed, an appropriate ventilation strategy can be instituted for the performance of operative direct laryngoscopy and suspension microlaryngeal surgery. If no further surgery is planned, the patient can be allowed to emerge from anesthesia, breathing spontaneously through the Patil-Syracuse mask or the LMA.

7. Emergence from General Anesthesia

Although highly stimulating intraoperatively, panendoscopy and microlaryngoscopic surgical procedures are typically characterized by low postoperative pain scores, even when the operation is prolonged.[43] Use of remifentanil infusions frequently allows reduction of the total dose of supplemental intravenous fentanyl to 1 to 2 µg/kg or avoidance of intraoperative use of fentanyl completely. In the recovery room, intermittent intravenous bolus doses of fentanyl in combination with oral analgesics are usually sufficient for pain control.[43] Remifentanil-induced hyperalgesia has not been an issue in our experience, possibly because of the short duration of most cases and the relatively low infusion rates that are typically required intraoperatively (0.1 to 0.3 µg/kg/min). If increased pain occurs postoperatively, it should raise an alert about possible surgical complications, such as esophageal perforation (see "Intraoperative and Immediately Postoperative Complications").

Antiemetic prophylaxis should be routine,[43] and it is most commonly achieved by intravenous administration of a serotonin $5HT_3$ receptor antagonist (e.g., ondansetron). Multimodal antiemetic prophylaxis should be employed for patients at high risk for postoperative nausea and vomiting.

If endotracheal intubation was performed, smooth, nonstimulating emergence from anesthesia constitutes one of the most challenging tasks.[1,43] Patient's straining, bucking, or coughing with the ETT in situ results in an attempted forceful glottic closure, which may provoke additional trauma to and ulceration of the mucosal surface of the vocal cords, leading to wound formation.[140,215,216] Emergence phenomena such as a patient's agitation and uncontrolled head movements and postextubation laryngospasm may exacerbate the surgically compromised vocal cords further.[140] Subsequent vocal cord wound healing leads to remodeling of the superficial

layer of the vocal cord lamina propria and the epithelium, which may result in formation of vocal cord nodules, polyps, and cysts.[215]

Three strategies can facilitate smooth tracheal extubation. First, the patient's trachea can be extubated at a deep plane of anesthesia, and the airway supported by a mask until the patient resumes spontaneous ventilation and emerges from anesthesia. Although this may be a viable approach, it is time and labor consuming, carries an increased risk of post-extubation laryngospasm, and leaves the patient's airway unprotected. It should be undertaken only if airway management on induction was uncomplicated. The second approach (i.e., Bailey maneuver), with the patient still anesthetized, involves insertion of a supralaryngeal airway (usually an LMA) behind the existing ETT, removal of the ETT, and administration of the supraglottic ventilatory support until the patient resumes spontaneous ventilation and awakens from anesthesia.[217] With the third, pharmacologic approach, the anesthesiologist relies on a low-dose remifentanil infusion to blunt the tracheal responses and to promote smooth extubation and awakening at the end of surgery.

Remifentanil is ideally suited for the control of tracheal extubation, because the return of consciousness and the cough reflex occur almost simultaneously.[17] Although the optimal dose of remifentanil required to blunt tracheal responses to extubation remains to be determined, current data indicate that a remifentanil infusion of 0.05 to 0.06 μg/kg/min (target concentration of 1.5 ng/mL) during emergence is likely sufficient; it reliably and effectively suppresses the cough reflex in awake intubated patients while promoting hemodynamic stability.[218,219]

TABLE 38-3
Complications of Panendoscopy and Microlaryngeal Surgery

Major Complications	Minor Complications
Intraoperative	**Intraoperative**
Death	Oropharyngeal mucosal trauma
Loss of the airway	Dental trauma
Major barotrauma complications	Minor barotrauma complications (subcutaneous emphysema, gastric distention)
Hypoxemia and hypercarbia	Minor hemodynamic instability (e.g., transient arrhythmias, vasovagal events)
Major hemodynamic instability (e.g., myocardial ischemia, stroke)	Laryngospasm
Intraoperative awareness	Corneal abrasion
Massive bleeding	
Tracheobronchial tree perforation	
Esophageal perforation	
Pulmonary aspiration	
Postoperative	**Postoperative**
Airway obstruction	Sore throat
Laryngospasm	Cranial nerve dysfunction (e.g., lingual, glossopharyngeal, hypoglossal)
Negative pressure pulmonary edema	Respiratory compromise
Pulmonary aspiration	Hemoptysis
	Temporomandibular joint disorder aggravation

Data from references 1, 2, 13, 33, 38, 40, 43, 213, 220-222.

IV. INTRAOPERATIVE AND IMMEDIATELY POSTOPERATIVE COMPLICATIONS

Most common, clinically relevant major and minor complications of panendoscopy and microlaryngeal surgery are summarized in Table 38-3. The incidence of complications is small and is largely related to the experience of the anesthesiologist and the surgeon, as well as their cohesive team work, the characteristics of the patient population treated, and the status of the treating institution (e.g., academic, tertiary care, private practice).[2,40,220-222]

A. Intraoperative Complications

Panendoscopy and microlaryngeal surgery remain very safe procedures. The mortality rate is exceedingly low (0.02% to 0.6%).[221,223] In a large, single-institution, retrospective review of 1093 endoscopic laryngeal surgery cases, Jaquet and colleagues[87] reported no intraoperative deaths, an incidence of major complications of 0.37% (all related to barotrauma during subglottic JV), and no major complications for 281 pediatric patients between the ages of less than 1 year and 16 years.

Loss of the airway on induction, requiring emergent cricothyrotomy or tracheostomy, can be sudden, especially in patients with critical airway obstruction. Proper preparation of the OR team is the key to promptly and efficiently dealing with intraoperative airway emergencies.[38] An overall incidence of major barotrauma complications (e.g., cervicomediastinal emphysema, pneumothorax, tension pneumothorax) is small (0.2% to 0.5%),[87,111,120] and these complications are most frequently observed during TTJV (1.1%).[87] Intraoperative bronchial or transbronchial biopsy represents an independent risk factor for intraoperative pneumothorax (about 10%).[221] These patients also carry a higher risk of developing pulmonary edema after transbronchial biopsy.[221] Although the overall incidence of cardiovascular compromise may reach 20% to 50%,[2,83,142] major cardiac and cerebrovascular complications are rarely observed (0% to 2.2%).[86,87,111,221] Massive bleeding is rare and may be encountered in patients while coring out friable vascular tumors or during inadvertent perforation of the tracheal or bronchial wall with the laser or rigid bronchoscope.[71,213] Ensuing respiratory failure with an inability to wean the patient from the ventilator has been described.[71] The rigid bronchoscope should be used by experienced operators, because improper technique frequently results in dental or oropharyngeal trauma.[213] Particular care must be exercised when introducing a rigid bronchoscope into the airway of patients considered at high risk for cervical spine (C-spine) dislocation during neck extension (e.g., elderly, patients with rheumatoid arthritis, those with congenital C-spine abnormalities).[71] Prospective trials identify the incidence of dental trauma after suspension laryngoscopy at 0% to 6.5%,[40,224] depending on the operator's experience, methodology of the study, dental injury

criteria, preexisting dentition status of the patient, and suspension technique used.[40]

Esophageal perforation is a rare event if flexible esophagoscopy is used.[2] A significantly higher complication rate (2.6%) was reported for rigid esophagoscopy, in which case patients with a history of head and neck cancer present a particular risk.[220] Pulmonary aspiration remains a particular concern when the patient's airway is left unprotected (e.g., JV), especially in patients at increased risk for aspiration of gastric contents. Intraoperative airway soiling may occur from aspiration of blood, secretions, surgical debris, or tumor cell contamination of the lower airway.[38]

Minor intraoperative anesthesia-related complications happen infrequently (2.6%).[87] The incidence of minor intraoperative laryngospasm during microlaryngeal surgery has been reported by Jaquet and colleagues as 3.1%[87]; it was exclusively related to the use of AIV and was associated with a light plane of anesthesia. In contrast, prospectively recorded, surgery-related minor complications are common (37.5% to 73%).[40,222] Minor surgical complications, such as sore throat, mucosal injury (e.g., cuts, edema, hematoma), and cranial nerve dysfunction (e.g., lingual, glossopharyngeal, hypoglossal), are most commonly observed.[1,40,221,222] The latter are likely caused by direct pressure or stretch injury associated with laryngoscopy or suspension of the laryngoscope,[40] and they are related to the size of the operating laryngoscope used and the duration of suspension.[1,40] Presenting symptoms in the recovery room may include dysesthesia and taste alteration, swallowing problems, and deviation of the tip of the tongue.[40,222]

B. Postoperative Complications

The risk of postoperative airway compromise is significantly greater among the patients who underwent diagnostic laryngoscopy and panendoscopy than those in the general surgical population.[225] The residual effects of anesthetics, analgesics, and inadequately reversed NMB may further contribute to the development of hypoventilation, atelectases, and poor mobilization of secretions in the early postoperative period.[34] Airway surgery invariably produces a certain degree of traumatic edema, which may precipitate acute airway obstruction postoperatively in an already compromised airway.[13] Development of airway obstruction should be suspected if the patient has symptoms such as dyspnea, respiratory distress, and particularly inspiratory stridor.[34] Aggressive early treatment with humidified oxygen and nebulized racemic epinephrine constitutes the first reasonable therapeutic intervention.[13,34] Postoperative laryngospasm may precede or accompany airway obstruction[226,227] and quickly lead to development of acute negative-pressure pulmonary edema.[34,226] Although the incidence of these complications in the general surgical population is small (0.3% and 0.09%, respectively),[226,228] negative-pressure pulmonary edema is preceded by laryngospasm in more than 50% of cases.[227] Treatment is supportive and consists of reestablishment of airway patency, O_2 supplementation, ventilatory support (i.e., CPAP or endotracheal intubation with positive-pressure ventilation and PEEP), management of fluid shifts, and maintenance of normal intravascular volume.[34,226-228] Postoperative hemoptysis is usually associated with interventional bronchoscopy, for which the incidence may reach as high as 41%.[221] It is common for the suspension laryngoscopy to aggravate preexisting temporomandibular joint disease, and these patients should be advised accordingly before surgery.[1]

V. ANESTHESIA FOR PEDIATRIC UPPER AIRWAY ENDOSCOPY AND MICROLARYNGEAL SURGERY

A. General Considerations

The general principles of adult airway endoscopy can be applied to infants and children, although important anatomic, physiologic, and pathologic differences in the airway exist (see Chapter 36). Some of the most common indications for flexible and rigid airway endoscopy in pediatric patients and neonates are listed in Table 38-4. Usually, examination of the entire airway, including the nasopharynx, larynx, the subglottic region, and the remaining tracheobronchial tree is indicated, because abnormalities at more than one site are found in 10% to 20% of patients.[229-231]

TABLE 38-4

Indications for Flexible and Rigid Airway Endoscopy in Pediatric Patients

Flexible Endoscopy	Rigid Endoscopy
Airway obstruction	Airway obstruction
Stridor or noisy breathing	Stridor or noisy breathing
History of laryngomalacia	History of laryngomalacia or tracheomalacia
Persistent or recurrent wheezing	Persistent or recurrent wheezing
Chronic cough	Cyanosis or apnea
Hoarseness or weak cry	Hoarseness or weak cry
Pulmonary abnormalities	Foreign body evaluation or management
Atelectasis	Evaluation and treatment of laryngeal pathology
Recurrent or persistent consolidations	Evaluation and treatment of lesions of the airway
Atypical or diffuse infiltrates	Evaluation after laryngotracheal reconstruction
Removal of mucous plugs	Aspiration or gastroesophageal reflux
Evaluation of the artificial airway	Toxic inhalation or aspiration
Assessment before extubation	Airway trauma
Confirmation of endotracheal tube position	
Tracheotomy surveillance	
Foreign body evaluation	
Toxic inhalation or aspiration	
Tracheoesophageal fistula	
Special procedures	
Bronchoalveolar lavage	
Bronchial or endobronchial biopsy	

Data from references 232, 233, and 269.

B. Patient Preoperative Evaluation and Preparation

Preoperative assessment of the pediatric patient should consider the likely diagnosis,[232,233] the extent of airway compromise, and the degree of urgency of the procedure. A complete history, including a history of prematurity, any concurrent diseases, and an overview of the child's progress since birth, should be obtained.

Preterm infants, infants whose gestational age at birth is less than 37 weeks, are at higher risk for postoperative respiratory depression and apnea when exposed to anesthesia.[234-238] The postconceptual age (PCA; i.e., gestational age plus postnatal age) is inversely related to the risk of postoperative apnea,[234,235,237] with infants younger than 44 weeks' PCA at the greatest risk.[238,239] The former preterm infant with a PCA of more than 60 weeks can be sent home safely using standard discharge criteria.[238,239] Infants with a PCA of less than 60 weeks should be admitted for monitoring at least 12 hours postoperatively or overnight.[239] Comorbidities to consider when assessing increased risk of postoperative apnea include apnea at baseline, anemia, neurologic disease, and chronic lung disease.[235,237,238,240,241] Elective procedures in preterm infants should be postponed until more than 60 weeks' PCA.[238,239] Apnea after anesthesia has also been reported in term infants,[242-244] and elective procedures should be postponed until the infant is more than 44 weeks' PCA.[239]

The physical examination should focus on the airway, respiratory system, and cardiovascular system. The patient should be examined carefully for indicators of a potentially difficult airway, such as craniofacial abnormalities, micrognathia, retrognathia, limited mouth opening, or C-spine abnormalities. Abnormal airway noises (stridor is the most common) should be evaluated carefully.

Routine laboratory studies are not indicated for most children. Preoperative hemoglobin levels should be considered for procedures with the potential for blood loss for children with hemoglobinopathies, former preterm infants, and those younger than 6 months old.[239] Preoperative fasting guidelines should be followed unless the procedure is deemed emergent.

C. Operative Pediatric Airway Endoscopy and Microlaryngeal Surgery

1. Special Considerations and Anesthesia Objectives

Some of the most commonly used general purpose (diagnostic or intubating) operating laryngoscopes are the Storz and Parsons laryngoscopes (Storz, Tuttlingen, Germany), which are available in different sizes.[245] The Parsons laryngoscope (Fig. 38-25) can also be used for bronchoscopy, and after suspension, for some types of microlaryngeal surgery.[245] The Benjamin-Lindholm laryngoscope (Storz) provides a more panoramic view of the larynx and facilitates access for microlaryngeal surgery.[246] The Parsons and Benjamin-Lindholm laryngoscopes allow continuous insufflation of O_2 or anesthetic gases through a channel on the left side of the device (see Fig. 38-13). The pediatric rigid bronchoscopes manufactured by Storz are used almost universally.[229] The OD of the bronchoscope typically is larger than an ETT with the same ID, and careful attention to choosing a bronchoscope with the appropriate OD is important to avoid damage to laryngeal structures.[247]

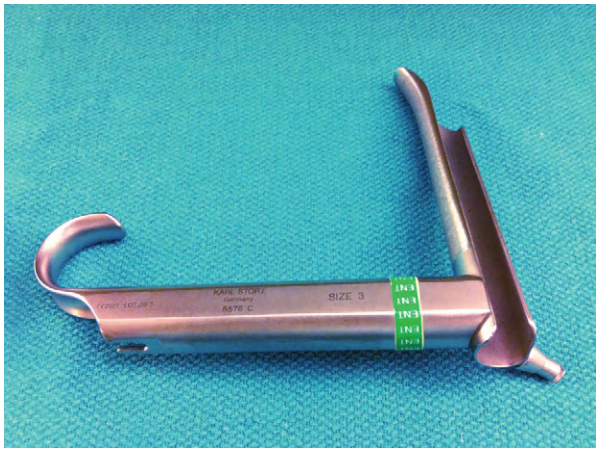

Figure 38-25 The flange of the pediatric Parsons operating laryngoscope (Storz, Tuttlingen, Germany) is open on the right side, allowing the passage of a rigid bronchoscope, if desired.

The anesthesia objectives in pediatric patients are similar to those in adults (see "Special Considerations and Anesthesia Objectives"). Because of the shared airway, communication between the surgeon and the anesthesiologist before and during the procedure is critical, and it is probably the most important factor in avoiding complications.[248]

2. Intraoperative Ventilation Techniques and Strategies

Pediatric patients undergoing upper airway endoscopy and microlaryngeal surgery frequently present with difficult airway problems. Alternative techniques for pediatric difficult airway management are addressed in Chapter 36. The approach to ventilation of the pediatric patient usually follows the one used for adults (see "Intraoperative Ventilation Techniques and Strategies for Microlaryngeal Surgery").

a. AWAKE APPROACH

In pediatric patients, the awake approach is typically limited to a diagnostic evaluation of the upper airway and its dynamic function with a nasopharyngolaryngoscope or a FFB.[249] It can be safely performed in an office setting under topical anesthesia without sedation in children of all ages, even neonates,[249-251] but it may also be performed in the OR as part of a more complete examination. The limitation of performing this procedure in an office setting without sedation is the inability to pass the scope below the vocal cords.[249,251]

b. SPONTANEOUS VENTILATION

Under general anesthesia, spontaneous ventilation is generally preferred over controlled ventilation for endoscopy of the pediatric airway.[229,247,252] However, the multiple techniques in use indicate that no single method is universally accepted.[229,247]

Spontaneous breathing techniques in neonates and infants should be limited to shorter examinations. Under anesthesia, a combination of reduced FRC, high compliance of the pediatric airways and chest wall, increased O_2 consumption, and further airflow limitations imposed by the surgical instrumentation inside and around the airway can lead to a rapid hypoxemia if spontaneous ventilation is maintained.[229,253-255] Nevertheless, successful intraoperative spontaneous ventilation has been reported in neonates as young as 2 weeks,[256-258] and it is more easily maintained during the entire procedure in older infants and children. If spontaneous ventilation fails due to apnea or hypoventilation, institution of alternative ventilation techniques must be promptly implemented.

c. APNEIC INTERMITTENT VENTILATION

For the physiologic reasons outlined previously, AIV in young pediatric patients is suitable for only very short procedures, such as a diagnostic bronchoscopy.

d. LASER-SAFE ENDOTRACHEAL TUBE

Small, laser-safe ETTs are not commercially available for infants and small children.[255] Regular pediatric ETTs can be wrapped with a fire-resistant foil for laser surgery.[254] Preparation of these wrapped ETTs is becoming less common because it is time consuming and cumbersome. Potentially dangerous gaps in the wrapping may allow ignition of the ETT, and fragments of wrapping material can serve as foreign bodies.

e. JET VENTILATION

In children, supraglottic JV is probably most commonly used.[255,259,260] Subglottic JV is used less frequently,[87] because the smaller, compliant airways of infants and small children may not allow adequate exhalation, potentially leading to a higher incidence of barotrauma.[254] In infants, even a small cannula can obstruct the surgical field. The use of TTJV in infants and small children is uncommon.[87]

3. General Anesthesia Management for Pediatric Airway Endoscopy and Microlaryngeal Surgery

a. PREMEDICATION AND MONITORING

Routine, noninvasive monitoring usually is sufficient. If quantitative assessment of CO_2 is not available due to the method of airway management, the anesthesiologist should visually monitor chest excursions and auscultate breath sounds using a precordial stethoscope.[261]

The goals of premedication in children include alleviation of anxiety, a smooth separation from parents, and facilitation of the induction of anesthesia. If the child is symptomatic and there is a possibility of airway obstruction or respiratory compromise, premedication using a smaller amount than customary should be considered. Premedication can decrease the likelihood of crying and struggling on induction and thereby prevent worsening of the airway symptoms. Infants 9 to 10 months old typically benefit from premedication.[262] Recommended dosages for midazolam are 0.25 to 0.5 mg/kg taken orally or 0.05 to 0.1 mg/kg administered intravenously.[263]

If intravenous access has already been established, an antisialagogue can be given to decrease secretions. Glycopyrrolate is preferred in children because it has no central effects, and it causes less tachycardia than atropine.[264,265] Intramuscular injections of any medication are painful and should be avoided if possible.[266] Administration of 0.5 mg/kg of dexamethasone, with a maximum dose of 10 to 20 mg, is recommended to minimize postoperative airway edema.[247]

b. ANESTHESIA INDUCTION AND MAINTENANCE

For children without intravenous access, gentle inhalational induction with sevoflurane is recommended, and the intravenous access is secured after sufficient depth of anesthesia is reached. Preserving spontaneous respiration initially is critical to allow dynamic assessment of the vocal cords, larynx, and tracheobronchial tree,[229,261,267] and it is strongly preferred when a high-grade obstruction of the upper airway is suspected or a difficult airway is anticipated.[261,268] If only a short endoscopic examination is planned, the nasopharyngolaryngoscope or FFB is passed through the nose into the pharynx by way of a bronchoscopic swivel adapter attached to a standard anesthesia mask.[269] Alternatively, the anesthesia mask can be removed to facilitate the examination. The FFB can also be passed through a laryngeal mask or an ETT if visualization of the upper airway is not required.[269]

When the depth of anesthesia is sufficient to tolerate laryngoscopy, the surgeon performs direct laryngoscopy and topicalizes the airway with lidocaine, which typically is applied to the vocal cords by atomizer or sprayed with a 3-mL Luer-Lok syringe fitted with a plastic or metal cannula.[247] The usual concentration of lidocaine is 2% for children (1% for small infants), and the maximum dose is 3 to 5 mg/kg[229,270]; toxicity is possible with excessive doses, and seizures have been reported.[271] When appropriately applied, the lidocaine provides surface analgesia to the glottis, subglottis, and proximal trachea, decreasing the chance of laryngospasm or coughing when the bronchoscope is inserted and reducing the general anesthetic requirements. After the airway has been successfully topicalized, the surgeon performs a second laryngoscopy to evaluate the larynx and the vocal cords more completely.

Depending on the pathology, the surgeon may choose to pass the telescope for a rapid assessment. This has the advantage of producing less airway trauma than by the larger bronchoscope. If there is significant narrowing, the telescope may pass beyond the narrowing more easily. The surgeon may choose to place the child in suspension at this point. A rigid bronchoscope is then passed through the vocal cords. A thinner telescope with an optical eyepiece is subsequently placed through the bronchoscope, allowing the subglottis and trachea to be examined. After the bronchoscope is introduced past the vocal cords, the anesthesia circuit is connected to the side arm of the bronchoscope, allowing gas exchange and continued ventilation, similar to the technique used in adults (see Fig. 38-10). With the optical telescope in place, gas exchange occurs in the space between the telescope and the bronchoscope sheath. Partial occlusion of the bronchoscope lumen by the optical telescope increases resistance to ventilation, especially when the 2.5-, 3.0-,

and 3.5-mm ID bronchoscopes are used.[247] The smallest optical telescope should be used to prevent increased airflow resistance.[259]

After an appropriate diagnosis has been established, the surgeon may choose to immediately initiate treatment of the pathology. Endoscopic surgery can include the use of microdebriders, dilating balloons, stents, or lasers.[272,273] Many pediatric airway centers are using laser less frequently, because alternatives such as microdebriders and balloon dilation become preferred.[272,273]

TIVA with propofol and remifentanil is used most frequently for maintenance of anesthesia, even during spontaneous ventilation. Infusions of 150 to 500 μg/kg/min of propofol and 0.05 to 0.2 μg/kg/min of remifentanil have been reported.[258,267] A bolus dose of propofol (1 to 5 mg/kg) may be administered to achieve steady-state conditions rapidly.[258,274] Remifentanil infusion may require a more dilute solution in neonates and infants to provide sufficient delivery volume.[275] Infusions must be carefully titrated to effect to avoid apnea, and they should be delivered as close to the intravenous catheter as possible to minimize delays in response to changes in infusion rates.[275]

Dexmedetomidine may be a particularly useful adjunct to TIVA when the spontaneous ventilation technique is used, because its administration is characterized by lack of respiratory depression and stable hemodynamic profile, even at high doses.[276-278] MRI of the upper airway in spontaneously breathing children with a high-dose intravenous infusion of dexmedetomidine (3 μg/kg/hr) showed only small reductions in upper airway diameter and no clinical evidence of upper airway obstruction.[279] For the preservation of spontaneous ventilation, a combination of an intravenous bolus (0.25 to 1 μg/kg) and intravenous infusion (2 to 2.5 μg/kg/hr) of dexmedetomidine with an intravenous infusion (200 to 300 μg/kg/min) of propofol appears to be well tolerated.[277,278]

Several manual infusion schemes exist for TIVA in children. Devices that allow target-controlled intravenous infusions of anesthetics in children are not widely available,[274,280] and the target concentrations for neonates and infants or for critically ill children have not been fully investigated.[281] Significantly higher propofol doses per unit of body weight are necessary in healthy children for induction and maintenance of anesthesia.[274] Compared with adults, to achieve blood concentration of propofol of 3 μg/mL, the bolus dose should be increased by more than 50%, and the infusion rate should be almost doubled (19 mg/kg/hr for 10 minutes, followed by 15 mg/kg/hr for 10 minutes and 12 mg/kg/hr thereafter).[274] Similarly, the reported target concentration of remifentanil necessary to block the response to a skin incision under target-controlled propofol anesthetic in pediatric patients between the ages of 3 and 11 years is almost twice that needed in adults (0.15 μg/kg/min, 95% CI, 0.13 to 0.17 versus 0.08 μg/kg/min, 95% CI, 0.06 to 0.12).[282]

c. EMERGENCE FROM ANESTHESIA IN THE PEDIATRIC PATIENT

After airway endoscopy is completed, an ETT can be placed in the trachea to control the airway, or more commonly, the child can be allowed to emerge breathing 100% O_2 by mask.[247,267] If the child is intubated, the usual criteria for extubation should be applied. In the recovery room, these patients should be carefully monitored for signs of airway edema or respiratory distress.

4. Complications of Pediatric Airway Endoscopy

Major and minor complications of pediatric airway endoscopy largely replicate those observed in adult patients (see "Intraoperative and Immediately Postoperative Complications").[249,267,283] No major complications were recorded with different intraoperative ventilatory techniques in more than 280 pediatric patients.[87] Intraoperatively, adverse airway events are most likely to occur with an inadequate depth of anesthesia.[267] Interventions that seem to decrease complications are careful and effective topicalization of the airway, close observation of the child for any movement or response to initial stimulation, and immediate withdrawal of the laryngoscope or bronchoscope with patient response until an adequate depth of anesthesia is reestablished.[267] In two large series of pediatric patients undergoing rigid bronchoscopy, the complication rate was 2% to 3%.[232,284] Stridor due to airway edema is the most commonly seen complication in the immediate postoperative period, and it should be treated with nebulized racemic epinephrine.

5. Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis (RRP) (Fig. 38-26) is the most common benign neoplasm of the respiratory tract in children, and it is characterized by the proliferation of exophytic squamous papillomas within the respiratory tract.[285-287] Because of the recurrent nature of the disease, most children return frequently for treatment. The average enrollee in the National Registry for Juvenile-Onset Recurrent Respiratory Papillomatosis underwent a mean of 5.1 operations annually.[288] Repeated surgical treatment may lead to laryngeal web formation and irreversible damage to the vocal cords.[287,288]

The most common symptoms of RRP are related to laryngeal obstruction and include hoarseness, abnormal cry or voice change, and stridor.[187,289] The larynx and glottis are affected in almost all cases, followed by supraglottic involvement and subglottic involvement. Distal spread to the trachea, bronchi, and lungs has been

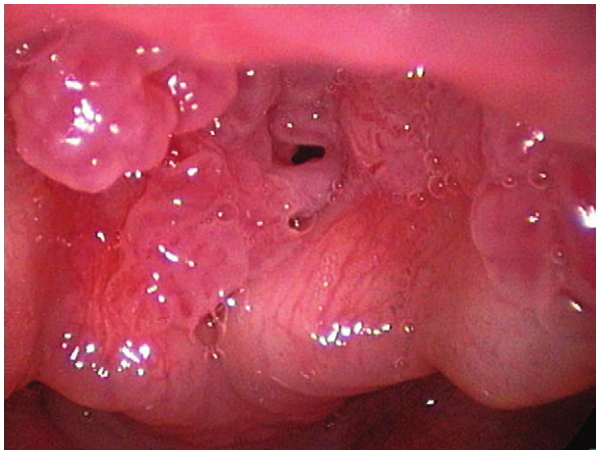

Figure 38-26 Recurrent respiratory papillomatosis. (Courtesy of Alan Cheng, MD, Stanford University Medical Center, Stanford, CA.)

reported.[286,287] Pulmonary lesions can cause bronchiectasis, pneumonia, and declining pulmonary status.[286]

Anesthesia and airway management for patients with RRP can employ tubeless spontaneous ventilation,[290] AIV, and JV[247,267,291]; the advantages and disadvantages of each technique have been discussed (see "Intraoperative Ventilation Techniques and Strategies for Microlaryngeal Surgery"). A 2002 survey of members of the American Society of Pediatric Otolaryngology showed a preference for spontaneous ventilation or AIV (63.5%), followed by JV (24.3%) and laser-safe ETTs (9.6%),[285] although a theoretical risk of carrying the human papillomavirus (HPV) particles into the distal airways with AIV or JV exists.[267,291] A higher incidence of apnea and laryngospasm may be observed during spontaneous ventilation in RRP patients under TIVA compared with positive-pressure ventilation through an ETT.[292]

Current surgical preference for debulking RRP lesions appears to favor the use of the microdebrider over the CO_2 laser,[285,286] because it shortens the operating time, eliminates the risk of a laser fire, and is associated with decreased postoperative pain.[293] With microdebrider surgery, the ETT can be used for the entire procedure, although it limits the surgeon's access to the posterior glottis.

D. Foreign Bodies in the Airway and Esophagus

1. Foreign Body Aspiration

Foreign body aspiration in the airway is most common in children 1 to 3 years old[289,294] and is a leading cause of accidental death in children younger than 5 years.[295] Food products (especially nuts and seeds) are the most commonly aspirated airway foreign bodies (77% to 86%).[296] Nuts with oils on the surface can be particularly problematic because they may stimulate a significant inflammatory response.[297]

Foreign body aspiration is suspected when a child has an acute choking event or severe coughing with respiratory distress, but in many instances, the diagnosis is delayed.[297-299] Foreign bodies in children with a delayed diagnosis may be more difficult to extract,[300] and these children are also at higher risk for complications.[300,301] Symptoms and signs associated with bronchial aspiration include coughing, wheezing, dyspnea, and decreased breath sounds on the affected side, whereas coughing, stridor, dyspnea, and cyanosis are more common with laryngeal or tracheal foreign bodies.[302]

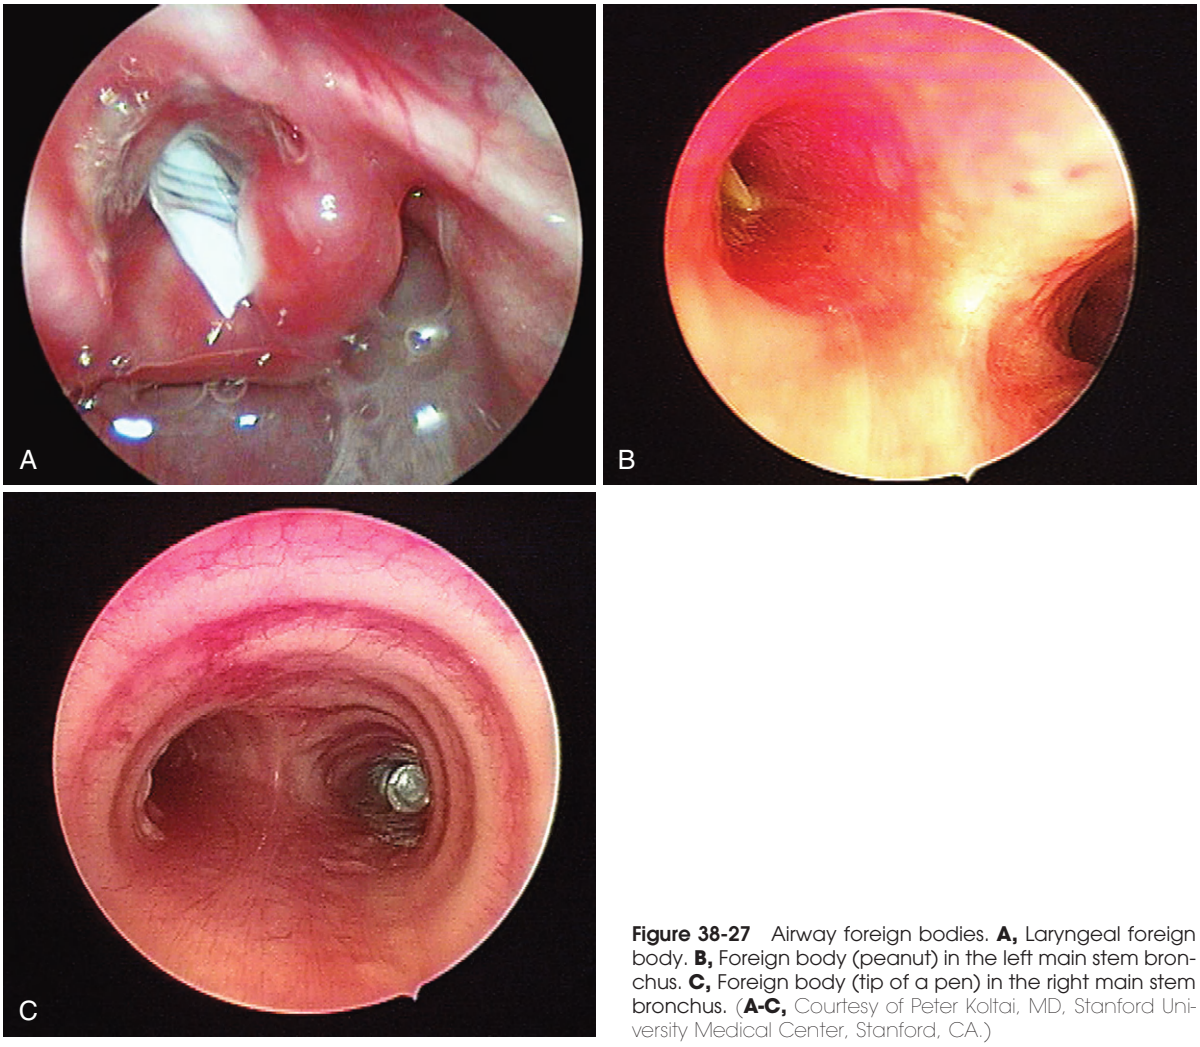

Figure 38-27 Airway foreign bodies. **A,** Laryngeal foreign body. **B,** Foreign body (peanut) in the left main stem bronchus. **C,** Foreign body (tip of a pen) in the right main stem bronchus. (**A-C,** Courtesy of Peter Koltai, MD, Stanford University Medical Center, Stanford, CA.)

Most airway foreign bodies lodge in the bronchial tree (85% to 91%), preferentially on the right side, with the remainder catching in the larynx or trachea[233,296] (Fig. 38-27). A foreign body in the bronchus can cause a ball-valve obstruction with hyperinflation of the distal lung, and if the obstruction is complete, the distal lung collapses.[229]

Preoperative assessment should consider the likely position of the foreign body, the extent of airway compromise, and the urgency of the procedure. Physical examination may reveal diminished breath sounds and rhonchi on the affected side. A chest radiograph should be obtained just before surgery to confirm that the coin, for example, has not already passed into the stomach. Because many objects are radiolucent, the chest radiograph should also be reviewed for evidence of secondary changes, such as distal air trapping, infiltrates, or atelectasis.

The treatment of choice for airway foreign bodies is prompt endoscopic removal under conditions of maximal safety and minimal trauma.[297,301] Following preoperative fasting guidelines is recommended if the procedure is not an emergency.[299] An intravenous catheter should be inserted in most cases. In an emergency situation or with a distressed infant, establishing intravenous access immediately after inhalation induction is acceptable.[299] As with most pediatric endoscopy cases, glycopyrrolate should be administered to decrease secretions, and intravenous dexamethasone is recommended to minimize postoperative airway edema.[247]

Before induction of anesthesia, the possibility of complete airway obstruction should be anticipated. Distal airway foreign bodies are more difficult to remove, whereas proximal foreign bodies are more likely to obstruct the airway.[299] A backup plan should include emergency rigid bronchoscopy, deliberate advancement of the foreign body into a main stem bronchus, tracheotomy, and thoracotomy in selected cases.

Induction and maintenance of anesthesia are similar to anesthesia described earlier for direct laryngoscopy and rigid bronchoscopy. The choice between maintaining spontaneous respiration and controlling ventilation remains controversial, with both techniques producing equally good results.[289,299,303] For airway foreign bodies, pediatric anesthesiologists seem to prefer maintenance of spontaneous ventilation,[304] because positive pressure can force the foreign body deeper into the smaller airways.[299,303] For the esophageal foreign bodies, controlled ventilation with an ETT is the preferred technique.[304]

When the airway foreign body is too large to withdraw through the lumen of the bronchoscope, the bronchoscope, forceps, and foreign body are removed as a single unit.[289,294] If the foreign body is dropped in the proximal airway and cannot be immediately retrieved, it should be pushed distally into the bronchus. If the foreign body is pushed into the contralateral bronchus, there is a potential for complete obstruction from edema in the original bronchus.[305] The FFB can be preferentially used when the foreign body is lodged far into the periphery of the lung.[297]

Esophageal foreign bodies (usually coins) are considered less serious than airway foreign bodies, and most pass through the gastrointestinal tract harmlessly.[306-308] For asymptomatic esophageal coins, an observation period of 8 to 16 hours is considered appropriate[309]; batteries and magnets are exceptions and should be removed expeditiously.[310,311] Esophageal foreign bodies most commonly lodge at the level of the cricopharyngeal muscle,[294] and foreign body impaction is most frequently associated with vomiting, gagging, odynophagia, dysphagia, poor feeding, and excessive salivation.[308] A large esophageal foreign body may cause symptoms of airway obstruction by compression or irritation of the upper airway, necessitating emergent intervention.[301]

2. Complications of Endoscopy for Foreign Body Removal

a. INTRAOPERATIVE COMPLICATIONS

Intraoperative complications during foreign body removal are usually minor, and include laryngospasm, bronchospasm, and O_2 desaturations. In a large review of almost 13,000 tracheobronchial foreign bodies in children, major complications, such as tracheal or bronchial laceration requiring repair, pneumothorax or pneumomediastinum, failed bronchoscopy requiring tracheostomy or thoracotomy, cardiac arrest, and hypoxic brain damage, occurred in about 1% of cases.[296] Fatal complications have been reported, but they are rare (0.4%).[297,298]

b. POSTOPERATIVE COMPLICATIONS

The most common immediate postoperative complications include laryngeal edema and traumatic laryngitis.[297] Long-term complications, such as granulation tissue and stricture formation, can occur at the site of the foreign body.[301] Persistent pneumonia and atelectasis may be seen after removal of long-standing foreign bodies.[294,297] After esophagoscopy, the most common complications are vomiting, aspiration, fever, and a second, missed foreign body.[301]

VI. CONCLUSIONS

The field of laryngeal surgery is complex and continues to expand rapidly. It is likely that the mounting complexity of microlaryngoscopic procedures will benefit from perioperative involvement of a dedicated anesthesia team. Lack of collaboration and planning between the surgeon and the anesthesiologist can turn even a simple microlaryngoscopic case into a chaotic, life-threatening airway crisis.[1] As anesthetic challenges continue to grow, so will the demand for a wide range of unique skills and expertise from the anesthesiologist to ensure patient safety and favorable surgical outcomes.

VII. CLINICAL PEARLS

- Close communication between the anesthesiologist and the surgeon throughout the perioperative period is critical for the success of the operation and for patient safety.
- A structured and stepwise approach to a tenuous and partially obstructed airway is necessary for successful management.

- Core surgical and anesthesia objectives include an anesthetic plan suitable for variable or unpredictable duration of surgery, an immobile and clear surgical field, absence of the patient's movement, maintenance of a stable plane of anesthesia, competent execution of different intraoperative ventilation techniques and strategies, full return of the patient's protective airway reflexes, smooth and rapid emergence from anesthesia, and fast-tracking patients for discharge.
- The principles and practice of jet ventilation must be well understood and adhered to by the anesthesiologist and the surgeon.
- Total intravenous anesthesia (TIVA) is preferred, especially when delivery of inhalational anesthetics is compromised.
- Neuromuscular blockade (NMB) should be adequately maintained.
- In pediatric patients, spontaneous ventilation technique typically is preferred over controlled ventilation.
- The possibility of post-extubation airway edema, laryngospasm, and postoperative airway obstruction should be anticipated and treated appropriately.

Chapter 39

The Difficult Airway in Conventional Head and Neck Surgery

ALEXANDER T. HILLEL | DAVID A. DIAZ VOSS VARELA | NASIR I. BHATTI

I. **Introduction**

II. **Aerodigestive Oncologic Surgery**
- A. Preoperative Airway Assessment
  - 1. History
  - 2. Physical Examination
  - 3. Laboratory and Imaging Studies
- B. Securing the Airway
  - 1. Examination of the Airway in the Awake Patient
  - 2. Choice of Endotracheal Intubation Technique
  - 3. Difficult or Failed Intubation
  - 4. Cricothyrotomy
  - 5. Percutaneous Dilatational Tracheostomy
- C. Intraoperative Airway Management
  - 1. Positioning of the Endotracheal Tube
  - 2. Surgical Field Requirements
  - 3. Considerations During a Tracheostomy

III. **Extubation in Head and Neck Surgery**
- A. Planned Extubation of the Endotracheal Tube
- B. Managing Accidental Decannulation of a Fresh Tracheostomy

IV. **Tonsillectomy and Other Oropharyngeal Procedures**
- A. Preoperative Considerations
- B. Obstructive Sleep Apnea
- C. Peritonsillar and Parapharyngeal Abscess

I. INTRODUCTION

Airway management in head and neck surgery is unique because the operative field is the upper airway itself or the adjacent structures and the anesthesiologist must share access to the airway throughout all phases of the procedure. The head and neck surgeon is uniquely qualified to help diagnose and manage the compromised airway, and a collegial relationship and ongoing communication between the surgeon and the anesthesiology team are essential.

Acute airway situations in head and neck surgery should be approached in a systematic manner. The simplest adequate form of control should be selected, and the lowest level (i.e., supraglottis, glottis, subglottis, or trachea) of airway obstruction should be ascertained; control should be established by securing an airway below that level. Acute airway problems often evolve in association with other medical problems. Obvious and potential difficult mask ventilation or difficult intubation should be discussed with the head and neck surgeon, and thoughtful discussion about sequential steps of airway management should take place before anesthetic induction and especially before attempting intubation. Ideally, if time allows, an action plan addressing airway management, including the initial strategy and two backup measures, should be communicated to all team members in the room. Maintaining lines of communication during the intubation procedure can reduce morbidity and mortality associated with difficult airway management.[1]

The spectrum of head and neck surgery is broad, including simpler procedures such as tonsillectomy, major ablative oncologic resections in the head and neck, and extensive reconstructive procedures. The risk of a difficult airway is relatively high for patients undergoing head and neck surgery. Bag-bask ventilation (BMV) and endotracheal intubation may be potentially or obviously difficult because of the nature of the patient's underlying condition.

The severity or completeness of airway obstruction is categorized as follows:

1. Complete obstruction: no detectable airflow in or out of lungs
2. Partial obstruction: patient with stridor or dyspnea from narrowing of the major airway
3. Potential or impending obstruction: concern that a patient will develop airway compromise because of a known anatomic or physical condition if the respiratory physiology or the consciousness level is altered

This chapter addresses current principles and techniques for securing and safely managing the airway of patients undergoing conventional head and neck surgery. The discussion emphasizes prevention of difficult airway events associated with common and uncommon procedures in otolaryngology and in head and neck surgery, ranging from a tonsillectomy to a resection of oral and oropharyngeal cancer.

TABLE 39-1
Evaluation of Stridor

Factor	Features
Definition	Harsh, high-pitched sound from partial obstruction of upper airway
Typical characteristics	Inspiratory Monophonic High pitched
Airway obstruction	
Inspiratory versus expiratory	Inspiratory stridor suggests that the lesion is extrathoracic. Expiratory stridor suggests that the lesion is intrathoracic.
Awake versus asleep	Obstruction that is worse when awake or with exertion suggests a laryngeal, tracheal, or bronchial origin. Obstruction that is worse when asleep suggests a pharyngeal origin.

II. AERODIGESTIVE ONCOLOGIC SURGERY

A. Preoperative Airway Assessment

The preoperative airway assessment must include a comprehensive general medical history, focused history related to upper airway symptoms, general and head and neck physical examination, a thorough assessment of previous anesthetic records, details of surgical steps and alternative plans, and when indicated, laboratory and imaging studies. Patients with an upper aerodigestive tract malignancy may have limited cardiopulmonary reserve because of the disease process, dysphagia, and toxic effects of the chemotherapeutic agents. The risk of regurgitation and aspiration should be considered at the time of induction of general anesthesia.

1. History

Tobacco and alcohol use are associated with most cases of head and neck cancer and predispose these patients to chronic obstructive pulmonary disease, pneumonia, hypertension, coronary artery disease, and alcohol withdrawal. Information about previous surgical and anesthetic procedures with an emphasis on a history of anesthetic difficulties or difficult intubations, or both, must be obtained and communicated. Previous difficult airway management is considered to be one of the most important predictors of subsequent airway management difficulties.[2,3] Patients with a history of obstructive sleep apnea (OSA), especially those without an obvious anatomic abnormality, need careful assessment because their redundant pharyngeal mucosa and soft palate anatomy may hinder BMV and the ability to intubate. Common presenting symptoms of airway obstruction include dyspnea at rest or on exertion, voice changes, dysphagia, stridor, and cough. Physical findings may include hoarseness; agitation; and intercostal, suprasternal, and supraclavicular retraction. Voice changes provide an early suggestion of the anatomic level and severity and progression of the lesion. A muffled voice may indicate supraglottic disease, whereas glottic lesions often result in a coarse, scratchy voice. If there is suspicion of an anterior mediastinal, pharyngeal, or neck mass resulting in partial airway obstruction, initiating anesthesia in the patient in the supine position without first securing the airway may lead to complete airway obstruction and therefore deserves special preoperative evaluation.

2. Physical Examination

A systematic and comprehensive evaluation of the patient's upper airway is mandatory. The condition of dentition, facial hair (beard), size and mobility of the tongue, thyromental distance, Mallampati score, and limitations in neck flexion and extension must be evaluated. A thyrocervical distance of less than 6 cm in a fully extended adult neck is a good indicator of difficult laryngoscopy and an inability to visualize the vocal cords. The presence and character of stridor should be appreciated, because it may suggest the location of airway narrowing (Table 39-1). Postirradiation changes, neck masses, and previous neck surgery may result in reduced neck mobility, causing difficult mask ventilation and difficult intubation. Findings of morbid obesity, evidence of any oropharyngeal or lip edema, and signs of upper aerodigestive tract bleeding may direct the preferred method of airway management. Lower cranial nerve dysfunction from tumor or previous surgery may also result in airway difficulty related to aspiration or obstruction.

3. Laboratory and Imaging Studies

Laboratory and imaging studies can provide additional information before definitive airway management, depending on the urgency or emergency of the situation. In nonurgent cases, assessment of pulmonary function in patients with chronic pulmonary diseases may be helpful, along with arterial blood gas and pulmonary function tests. Similarly, computed tomography (CT) and magnetic resonance imaging (MRI) may help in determining the size, location, and nature of the obstruction. Even in

airway urgencies, flexible laryngoscopy or indirect laryngoscopy performed by an otolaryngologist (i.e., head and neck surgeon) may help with anticipation and planning for a difficult airway.

B. Securing the Airway

There are many approaches to securing the airway of patients undergoing head and neck surgery in a safe manner. Determining the optimal approach may depend on the surgery being performed, location of a lesion or infectious mass, or tolerance of the patient. For example, in a patient undergoing maxillomandibular fixation to repair a fractured mandible, nasotracheal intubation is ideal to keep the endotracheal tube (ETT) out of the oral cavity. In a patient with severe supraglottic angioedema, flexible fiberoptic intubation through the nose with the patient upright is preferred to enable identification of the airway with fiberoptic visualization and to avoid pharyngeal collapse in the supine position. Establishing a sequential airway plan with backup options and open communication between the anesthesiology and surgical teams facilitate preparedness and patient safety. An analysis of anesthesia-related cardiopulmonary arrests revealed that up to one third of severe complications result from an inability to establish an optimal airway after the induction of general anesthesia.[4]

1. Examination of the Airway in the Awake Patient

For a potentially difficult airway, the anesthesiologist may elect to evaluate the airway in an awake patient with the help of judicious intravenous sedation and topical anesthesia. This assessment helps to determine the optimal approach to securing the airway without compromising the patient's spontaneous breathing. The successful execution of this technique requires constant meaningful contact with the patient and adequate use of topical agents, such as 4% lidocaine spray, with the ultimate goal of not compromising the ability of the patient to breathe spontaneously and to protect the airway. Percutaneous blocks of the superior laryngeal nerves or translaryngeal instillation of lidocaine is best avoided in patients with a head or neck tumor. After the patient is adequately prepared, careful direct laryngoscopy is performed to assess whether to proceed with an awake intubation or to induce general anesthesia for subsequent intubation. A reasonable airway in an awake patient may change to a compromised airway immediately after induction of general anesthesia, with loss of tone of the pharyngeal wall and anterior displacement of the larynx.[5] If direct laryngoscopy with sedation is too risky to perform, consideration should be given to awake, flexible fiberoptic laryngoscopy to assess the airway and the possibility of awake, nasotracheal, flexible fiberoptic intubation.

2. Choice of Endotracheal Intubation Technique

a. ENDOTRACHEAL INTUBATION AFTER INDUCTION OF GENERAL ANESTHESIA

In patients with no obvious or expected airway compromise, the ETT can be placed during direct laryngoscopy after induction with a short-acting paralyzing agent, such as succinylcholine. Because it is difficult or impossible to empty the stomach with a nasogastric tube in the case of a large pharyngeal or esophageal tumor, the patient is assumed to have a full stomach.[6] Risk of aspiration is reduced by preinduction administration of ranitidine, metoclopramide, and oral sodium citrate–citric acid buffer (Bicitra, Willen Drug Co., Baltimore, MD). The Hollinger anterior commissure laryngoscope is a valuable tool in difficult airway management, and it should be considered when other techniques have failed. This scope may accommodate a 5.0-mm or smaller cuffed ETT, but the insufflation port may become lodged in the barrel of the scope. To avoid this issue, a trial passage of the ETT through the laryngoscope should be attempted before the performance of direct laryngoscopy.[7]

b. NASOTRACHEAL INTUBATION IN THE AWAKE PATIENT

If a difficult airway or difficult intubation is anticipated from the preoperative examination or awake assessment of the airway has mandated an awake intubation, nasotracheal or orotracheal intubation of an awake patient may be performed. The choice of route is directed by the surgical requirement and by the physical condition of the patient. Continuous administration of supplemental oxygen (O_2) during the entire process is mandatory.

The nasotracheal route is useful in cases of small mouth opening, severe trismus, large tongue, receding lower jaw, large oral cavity tumor, planned maxillomandibular fixation, or tracheal dilatation. Operator and equipment positioning relative to the patient is depicted in Figure 39-1. For nasal intubation, the nose is prepared with a nasal decongestant spray, such as pseudoephedrine (Afrin) and topical 4% cocaine. Cocaine is more advantageous than lidocaine because it is a vasoconstrictor in addition to being a very effective surface anesthetic. The potential for abuse by the personnel is occasionally a deterrent for its routine use. In placing the ETT through the nose, it is necessary to remember that the nasal floor usually runs in a horizontal plane perpendicular to an

Figure 39-1 The optimal setup for fiberoptic intubation includes elevation of the patient's head to minimize airway collapse. The intubator should be facing the patient, allowing the entire team to observe the procedure on the video monitor. (From Bhatti NI: Surgical management of the difficult adult airway. In Flint PW, editor: *Cummings otolaryngology-head and neck surgery*, ed 5, Philadelphia, 2010, Elsevier, pp 121–129.)

imaginary vertical line connecting the glabella and the pogonion. The ETT is advanced to approximately the 15-cm mark, and the connector is removed. The flexible fiberoptic bronchoscope (FFB) is then used to visualize the glottic opening and to introduce the tube into the trachea.

c. FIBEROPTIC-GUIDED OROTRACHEAL INTUBATION

Orotracheal intubation is facilitated with an oropharyngeal airway (OPA), such as a Williams or Ovassapian OPA. Similar to nasotracheal intubation, optimal topical anesthesia of the oral cavity and oropharynx is warranted to overcome the patient's gag reflex. The lubricated ETT, with its connector removed, is loaded onto the proximal end of the FFB. The tip of the scope is then introduced through the OPA and passed behind the epiglottis into the glottic opening leading into the trachea. When the scope is past the vocal folds, the tracheal rings should be identified before advancing the ETT. The ETT is then eased into the trachea over the scope, and placement is confirmed with a combination of bilateral chest auscultation and end-tidal carbon dioxide (Et_{CO_2}) measurement. After confirmation of the placement, general anesthesia is induced.

d. RIGID BRONCHOSCOPY

The rigid bronchoscope, a hollow stainless steel tube through which a rigid telescope is placed, provides excellent access to the airways. The distal end of the rigid bronchoscope is usually beveled to facilitate intubation and lifting of the epiglottis. The updated American Society of Anesthesiologists (ASA) protocol states that in the "cannot intubate, cannot ventilate" (CICV) scenario, "a rigid bronchoscope for difficult airway management reduces airway-related adverse outcomes."[8] This modality is recommended as a technique for cases of difficult mask ventilation. Other indications for rigid bronchoscopy include massive airway hemoptysis, foreign body retrieval, laser or photodynamic therapy, and placement of airway stents.[9]

e. RETROGRADE INTUBATION

Though rarely used, retrograde intubation represents another alternative technique for intubation of the difficult airway in head and neck patients. This technique can also be used in patients with trismus, trauma to the cervical spine, temporomandibular joint ankylosis, upper airway masses, or failed intubation. This technique begins with puncture of the cricothyroid membrane (CTM) or cricotracheal membrane with a small needle angled superiorly to pass a guidewire through the larynx, and it is then guided through the nose or mouth. The ETT is then advanced over the guidewire with a Seldinger technique into position in the trachea.[10]

Retrograde intubation may also be used to facilitate other approaches. For example, a combination of conventional, fiberoptic, and retrograde techniques can be used to intubate successfully.[11] An FFB with a suction port can be used as an anterograde guide over a retrograde wire. A direct laryngoscopic view can facilitate placement of the tip of a fiberoptic scope into or near the glottic aperture. After the FFB is past the vocal folds and tracheal rings have been identified, the preloaded ETT may be passed over the FFB into the trachea.

f. TRACHEOSTOMY WITH LOCAL ANESTHESIA

If a patient is in acute respiratory distress because of upper airway obstruction and the patient is considered unable to be safely intubated under general anesthesia after evaluation (including FFB), the best choice is to perform a planned but urgent awake tracheostomy.[12] This should be performed under local anesthesia with minimal intravenous sedation to avoid loss of spontaneous breathing. Tracheostomy under local anesthesia in an awake patient is also an excellent method to secure the airway in the following situations: upper airway abscess that may be in the way of or distorting the pathway for endotracheal intubation; bulky, friable supraglottic or glottic mass; and glottic stenosis with presumed bilateral cricoarytenoid joint fixation. In these situations, attempts at direct laryngoscopy and intubation may result in abscess rupture or aspiration of purulent material, blood, or material from a friable tumor, or in the case of cricoarytenoid joint fixation, the fixed, medialized vocal folds do not allow passage of the ETT without severe damage to the membranous vocal folds.

3. Difficult or Failed Intubation

An unanticipated difficult intubation or failed intubation is not an uncommon occurrence in head and neck surgery. When this situation is encountered after induction of general anesthesia, a very systematic, well-designed plan should be followed. Maintenance of oxygenation is paramount, and BMV should be continued between each intubation attempt. Repeated attempts at intubation carry the risk of traumatizing the larynx and should be minimized. Trying different neck positions and different laryngoscope blades should be limited to three or four attempts, because the time and ability to think clearly are limited under these circumstances, and each anesthesiology team should have an algorithm to follow routinely. The subsequent course of action depends on the team's ability to achieve satisfactory BMV.

a. ADEQUATE BAG-MASK VENTILATION

If BMV is adequate, a potent inhalational agent is used to continue general anesthesia. The Hollinger anterior commissure laryngoscope may be used to visualize the vocal cords. This laryngoscope has a flared superior flange that can lift the epiglottis to visualize anteriorly placed vocal cords. An Eschmann stylet is passed through the glottic opening, and an ETT is then passed over it after withdrawing the laryngoscope. The anesthesiology team can practice visualizing the larynx with this tubed anterior commissure laryngoscope, which is available on the otolaryngologist's laryngoscopy cart.

As an alternative, in a patient who is adequately BMV, the ETT may be passed with oral fiberoptic-guided laryngoscopy.[13] An OPA bite block is placed in the patient's mouth, and the regular mask is replaced with an endoscopy port (i.e., Patil-Syracuse endoscopy mask).[14] The lubricated FFB is passed through the mask's diaphragm into the OPA and into the trachea through the glottis.

The ETT is then threaded over the FFB into the patient's trachea. As described earlier, a scope can also be used to pass an ETT through the nose. The nose is decongested with topical Afrin, and topical 4% cocaine is used to anesthetize the nose. The appropriately sized, well-lubricated ETT is then placed along the floor of the nose, and an FFB is passed through the tube. An assistant occludes the other nostril and the mouth, and a triple connector is used so that the scope and O_2 delivery can be simultaneously introduced.

Despite multiple attempts and use of the preceding techniques, intubation attempts may continue to be unsuccessful. If BMV is still possible, anesthesia should be discontinued and the patient allowed to awaken. The anesthesiologist should then proceed with an awake intubation.

b. FAILED BAG-MASK VENTILATION

In situations of inadequate BMV of an anesthetized patient, after unsuccessful attempts at chin thrust and placement of a nasopharyngeal airway or OPA, the ASA algorithm should be followed.[8] The laryngeal mask airway (LMA) was integrated into the ASA difficult airway algorithm in different locations in 1996,[15] as a supralaryngeal airway or ventilation device or as an intubation conduit. If LMA ventilation is not adequate or feasible, the emergency pathway should be followed, and if the patient cannot be ventilated with a bag-mask or awakened safely, emergency surgical airway remains the next option (see Chapters 10 and 31). Use of LMAs is increasing in many situations of inadequate BMV,[16,17] but they should be used with extreme caution in conventional head and neck surgery, even by those with adequate experience with these devices. If ventilation with the LMA is the only option, we recommend definitive endotracheal intubation before initiation of surgery by advancing an ETT through the LMA or advancing an Aintree intubation catheter (Cook Critical Care, Bloomington, IN) over an FFB passed through the LMA into the trachea. In the latter case, the LMA is then removed, and an ETT is passed over the Aintree catheter and into the trachea. It should be kept in mind that only ETTs 7.0 mm or larger can be used with this technique.

4. Cricothyrotomy

Cricothyrotomy (i.e., coniotomy) is a procedure for establishing an emergency airway when other methods are unsuitable or impossible. Emergency cricothyrotomy is performed in approximately 1% of all emergency airway cases in the emergency department.[18] The access site is the CTM. This procedure is especially suited for gaining control of the airway when severe hemorrhage or massive facial trauma, foreign bodies, or emesis does not permit visualized intubation. Other cases arise when teeth are clenched, when intubation repeatedly fails, and when there is a possibility of cervical spine injury. In these cases, cricothyrotomy represents the safest and quickest way to obtain an airway because minimal soft tissue dissection is required between the skin and the CTM.[19] If a patient has sustained a respiratory insult associated with burns or smoke inhalation, an elective prophylactic cricothyrotomy may be performed early to prevent fatal respiratory obstruction occurring during transport.[20]

a. SURGICAL TECHNIQUE

The CTM is identified by palpating a slight indentation in the skin superior to the prominence of the cricoid cartilage. The CTM is immediately subcutaneous with no overlying large veins, muscles, or fascial layers, allowing easy access. A vertical skin incision and a horizontal entrance into the CTM are advised. For an incision into the CTM itself, a low horizontal stab is made to avoid laterally placed vessels.[21] A small tracheostomy tube or a small standard ETT can be used in a cricothyrotomy. If an ETT is placed through the cricothyrotomy, it should be minimally advanced so it does not enter a bronchus because of the short distance between the CTM and carina. Tube size is important in ensuring successful cannulation without excessive trauma. After the patient is stabilized, the cricothyrotomy should be converted to a formal tracheotomy for adequate ventilation and to minimize risk of injury to the vocal folds, which attach into the thyroid cartilage just superior to the CTM (Fig. 39-2). This technique is contraindicated in patients who are at increased risk for subglottic stenosis, preexisting laryngeal disease, malignancy, nearby inflammatory processes, epiglottitis, severe distortion of normal anatomy, or bleeding diathesis and contraindicated in infants and children.[22]

b. NEEDLE TECHNIQUE

Needle cricothyrotomy is performed in dire emergencies when the appropriate equipment or knowledge to perform a formal emergency cricothyrotomy or intubation is unavailable or in children younger than 2 years with airway obstruction and an inability to be intubated. A large-gauge needle and cannula with a syringe attached are introduced through the CTM until air can be aspirated. The cannula is then advanced off the needle down the airway (Fig. 39-3). The cannula is connected to an oxygen supply. The patient can then be oxygenated, but ventilation to remove carbon dioxide (CO_2) is not achieved, and respiratory acidosis may ensue rapidly. A needle cricothyrotomy ensures a supply of O_2 for a short time only, and it must be converted to a surgical cricothyrotomy or tracheotomy in a timely fashion to allow adequate ventilation.[23]

The transtracheal needle ventilation technique can be used to great advantage in the emergency setting. This technique requires access to 100% O_2 at 50 psi and a Luer-Lok connector. Adequate ventilation through the catheter is not possible with a conventional ventilator or a handheld anesthesia bag.[24] The airway is controlled by puncturing the trachea or CTM with a 16-gauge, plastic-sheathed needle. The needle is withdrawn, leaving the sheath in the trachea; the sheath is then attached to the high-pressure line through a pressure regulator control, and ventilation is accomplished using a manual interrupter switch. The patient can be fully ventilated with this technique for only 45 minutes. The only way the gas or O_2 inspired through transtracheal jet ventilation (TTJV) can escape is through the patient's own airway, and attempts at securing the airway must continue. The equipment to perform adequate TTJV should be

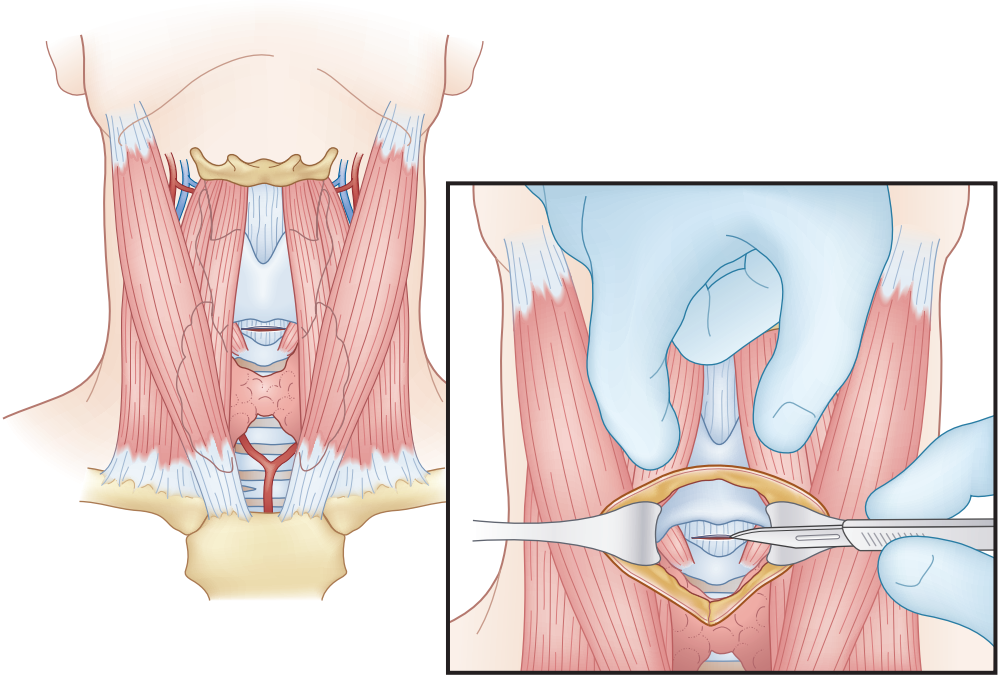

Figure 39-2 Cricothyrotomy. The cricothyroid membrane is palpated through the skin by using the thyroid notch and cricoid cartilage as reference points.

available in the operating room, and the anesthesiology team should familiarize themselves with its assembly.

5. Percutaneous Dilatational Tracheostomy

Percutaneous dilatational tracheostomy (PDT) is placement of a tracheostomy tube without direct surgical visualization of the trachea. The general consensus is that PDT should be performed only on intubated patients.[25]

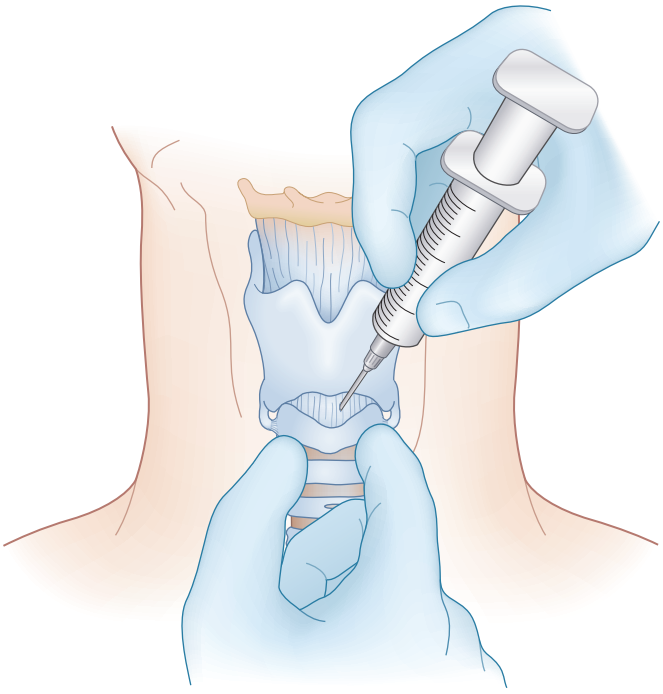

Figure 39-3 Needle cricothyrotomy. A large-gauge needle and cannula with a syringe attached are introduced through the cricothyroid membrane until air can be aspirated.

It is considered to be a minimally invasive bedside procedure that is easily performed in the intensive care unit (ICU) or ward, with continuous monitoring of the patient's vital signs.[7] The criteria for PDT are more stringent than those for open surgical tracheostomy.[26] A PDT should be performed on patients whose cervical anatomy can be clearly defined by palpation through the skin. Moreover, two preoperative criteria must be met: the ability to hyperextend the neck and ensuring that the patient can be reintubated in case of accidental extubation. Obese patients, children, and those with severe coagulopathies should not be considered candidates for this procedure (Table 39-2).[26]

Several systems and approaches for performing a percutaneous tracheostomy have been marketed since the inception of the idea, and many comprehensive accounts of the evolution of this approach are available in the literature. Controversy surrounding this procedure lingers, but there have been many large series with acceptable rates of complications as long as proper selection of

TABLE 39-2
Contraindications to Percutaneous Dilatational Tracheostomy

Absolute Contraindications	Relative Contraindications
Emergent airway access	Anatomic abnormalities (e.g., deviated trachea, enlarged superficial veins)
Infants	Enlarged thyroid or other neck mass
Infection at insertion site	Coagulopathy
High positive end-expiratory pressure (PEEP) or oxygenation requirements	Previous neck surgery
	Obesity

patients and adherence to a procedural protocol are ensured.[27]

Ciaglia and colleagues described a technique in which there is no sharp dissection beyond the skin incision.[28] The procedure is done with the patient under general anesthesia, and all steps are performed under bronchoscopic vision. The patient is positioned and prepared in the same fashion as for a standard surgical tracheostomy. A skin incision is made, and the pretracheal tissue is cleared with the help of blunt dissection. The ETT is withdrawn enough to place the cuff at the level of the glottis. The endoscopist places the tip of the bronchoscope such that the light from the tip shines through the surgical wound. The operator then enters the tracheal lumen below the second tracheal ring with an introducer needle. The track between the skin and the tracheal lumen is serially dilated over a guidewire and stylet. A tracheostomy tube is placed under direct bronchoscopic vision over a dilator. Placement of the tube is confirmed again by visualizing the tracheobronchial tree through the tube. The tube is then secured to the skin with sutures and tracheostomy tape.

In another technique for percutaneous tracheostomy, Schachner and colleagues made a small skin incision and passed a dilator tracheotome (Rapitrac) over a guidewire into the trachea to dilate the tract fully in one step.[29] The tracheotome has a beveled metal core with a hole through its center that accommodates a guidewire. Inside the trachea, the tracheotome is dilated, and a conventional tracheotomy cannula fitted with a special obturator is passed through the tracheal opening. The dilator and obturator are then removed.

A novel method called translaryngeal tracheostomy (i.e., Fantoni's technique) is different from other techniques. For Fantoni's tracheostomy, the initial puncture of the trachea is carried out with the needle directed cranially and the tracheal cannula inserted with a pull-through technique along the orotracheal route in a retrograde fashion. The cannula is then rotated downward using a plastic obturator. The main advantage of Fantoni's tracheostomy is that a minimal skin incision is required, and almost no bleeding is observed.[30,31] The procedure can be carried out only under endoscopic guidance, and rotating the tracheal cannula downward may pose a problem, demanding more experience.

The routine use of bronchoscopy during PDT, other than Fantoni's tracheostomy, is controversial.[32,33] There are reports of lower rates of acute complications under endoscopic guidance.[33] For critically ill patients or those with head injuries, it is important to consider the resultant hypercarbia when choosing to perform an endoscopically guided PDT. However, endoscopic guidance plays a critical role in the training of physicians, during percutaneous tracheostomy in patients with complex anatomy, and in removing aspirated blood. Another consideration that supports the use of bronchoscopy is the ability to better define the exact location of the tracheal puncture.[34] A cadaver study in autopsies of patients who had undergone PDT found that the tracheal puncture site varied greatly.[35] It seems logical that bronchoscopic guidance during PDT can confirm the initial airway puncture site, although a controlled study is necessary to settle this issue.[34]

The technique of PDT is relatively easy to learn, but it has been repeatedly reported that a learning curve exists, which may be overcome by performing a number of supervised procedures. The time required for performing a bedside PDT is considerably shorter than that required for performing an open tracheostomy.[36] In ICU patients, one of the major advantages of PDT is elimination of the scheduling difficulty associated with the operating room and anesthesiology teams. Bedside PDT also precludes the necessity to schedule the surgery and to transport critically ill patients who require intensive monitoring to and from the operating room.[37] PDT expedites the performance of the procedure in most cases. The cost of performing a PDT is roughly one half that of an open surgical tracheostomy. The major savings are operating room charges and anesthesia fees.[38]

C. Intraoperative Airway Management

1. Positioning of the Endotracheal Tube

Otolaryngology procedures require specific positioning of the ETT, because the operative field is shared by the anesthesiology and surgical teams. Procedures such as oropharyngeal tumor resection with reconstruction and cases requiring maxillomandibular fixation mandate the nasal placement of the ETT. The ala of the nose must be well protected from the risk of necrosis by pressure from the ETT. An alternative is placement of a tracheostomy tube at the beginning of the case. For operations with a tracheostomy, the tracheostomy tube can be exchanged for a reinforced tube (anode tube) rather than an ETT, which avoids kinking of the tube. If positive-pressure ventilation is necessary for the surgical procedure, an uncuffed tracheostomy tube should be replaced by a cuffed tracheostomy tube. A tracheostomy tube exchanger, such as the Weinmann Tracheostomy Exchange Set (Cook Critical Care) should be used to facilitate the exchange when the tracheostomy tube has been in place for 7 days or less.

2. Surgical Field Requirements

Head and neck surgery often requires the operative team to be on both sides of the table, and the operating table has to be positioned to accommodate this need. Bulky anesthetic equipment must be kept clear of the surgical field. The ETT and the connectors should be nonkinking, have a low profile, and be secured to the head so that head movement does not compromise the anesthetic circuit. Exact positioning of the ETT should be planned with the head and neck surgeon. The ETT should be taped to the oral commissure or around the nose to prevent downward pressure leading to the risk of accidental extubation or pressure necrosis of the nasal ala or the tip. The position of entry of the ETT into the airway has to be switched during certain head and neck procedures such as during a tracheostomy. Correct positioning of the second tube must be ensured before removing the first tube.

3. Considerations During a Tracheostomy

When a tracheostomy is being performed, there are important considerations that require clear communication

between the anesthesiology and otolaryngology teams. Administration of 100% O_2 is advised before tracheal opening so that, in case of loss of airway at the time of placement of a tracheostomy tube, there is sufficient reserve in the lungs to prevent hypoxemia. Most procedures on the neck and around the upper airway involve routine use of Bovie cautery. As the dissection approaches the trachea, it is advisable to avoid the use of Bovie cautery directly over the airway to avoid an airway fire. If Bovie cautery is necessary, it is mandatory to reduce the fraction of inspired O_2 to the lowest possible level compatible with optimal O_2 saturation.

As the tracheal incision is about to be made, the surgical team should communicate with the anesthesiology team to deflate the ETT cuff to prevent cutting the cuff. After the trachea is entered and the surgeon is able to visualize the ETT, the anesthesiologist should loosen the tape and should be able to withdraw the ETT so that the distal tip is just above the opening into the trachea. An adapter and a short, flexible tube (e.g., Jolly tube) are placed onto the cuffed tracheostomy tube to avoid pull on the trachea. A successful operating room tracheotomy requires excellent planning on the part of the anesthesiology and surgical teams to avoid mishaps.

Correct placement of the tracheostomy tube is confirmed by the appearance of an Et_{CO_2} waveform and by the presence of bilateral breath sounds on auscultation. To prevent contamination of the tracheobronchial tree with blood and secretions above the tracheostomy site, this area should be meticulously suctioned at the time of changing to a more permanent tracheostomy tube. When the tracheostomy is performed as part of a head and neck resection and reconstructive procedure and when a reinforced tube is placed, it is mandatory to secure it to the chest wall with sutures. This prevents accidental slipping of the tube into a main stem bronchus, which can result in oxygenation problems or bronchospasm if the anesthesia is light at that point. At the completion of the case, the anode tube is replaced with a tracheostomy tube.

III. EXTUBATION IN HEAD AND NECK SURGERY

Accidental extubation is a risk in head and neck surgery because the surgical team is frequently operating around the oral and nasal cavities. The anesthesiologist should be attentive to this possibility and remain in constant communication with the surgical team to avoid inadvertent extubation. The preparations and plans to reintubate should be in place before extubation in case the situation arises. In head and neck procedures in which the patient does not have a tracheostomy, there is risk of supraglottic and glottic edema because of the presence of an ETT and intraoperative manipulation. Intraoperative measures, such as administration of short-acting intravenous steroids (e.g., dexamethasone [Decadron]), minimizing the movement of the ETT, and keeping the head of the patient slightly elevated, can help reduce this risk. Excessive intravenous fluid administration should be avoided. Patients undergoing lengthy ablative and reconstructive procedures may benefit from remaining intubated and lightly sedated overnight in the ICU. Extubation can then be planned for the next day in the presence of experienced anesthesiology and surgical personnel with equipment available for securing the airway. Planning for extubation should include instruments to enable a bedside cricothyrotomy or a tracheostomy, if necessary.

A. Planned Extubation of the Endotracheal Tube

In most situations, extubation proceeds smoothly after patients meet extubation criteria, including spontaneous ventilation and the ability to follow commands. In others, it may be more challenging than the intubation. It may not be possible to use BMV because of postsurgical edema and changes related to the reconstruction. The use of OPA and nasopharyngeal airway devices may not be feasible because of concern about disrupting delicate surgical repair in the oropharynx or nasopharynx.

To ensure a safe extubation, the anesthesiology team should consider the following questions. First, is there an air leak around the tube after deflating the cuff? Second, if the patient develops acute airway obstruction on extubation, are the equipment and personnel available to secure an airway to prevent hypoxia? This may include options for an emergency cricothyrotomy, TTJV, or a tracheostomy. If the answer is an affirmative, extubation should proceed. If the preceding criteria cannot be met, extubation should be delayed for another 24 hours, or the anesthesiologist should consider extubating over an airway exchange catheter (AEC) or a jet stylet.[39] A hollow AEC with a small internal diameter is inserted through the ETT into the patient's trachea. The ETT is then withdrawn over the catheter; the AEC can be used as a means of jet ventilation or a reintubation guide, or both.[11] This approach is especially useful when an ETT needs to be exchanged or replaced.

B. Managing Accidental Decannulation of a Fresh Tracheostomy

Accidental decannulation of a fresh tracheostomy may be life-threatening because of the rapid closure of the tracheostomy tract in the immediate postoperative period. Options to reestablish an airway are challenging in obese patients, patients with a short thick neck, small retrognathic jaw, intermaxillary fixation, or a deep and posterior airway. Initially, an attempt should be made to immediately place a tracheostomy tube or an ETT through the tracheostomy opening. If this is unsuccessful, BMV should be applied immediately and a call for help initiated. The patient should be placed supine with the neck extended and a shoulder roll in place. A tracheal dilator or cricoid hook, or both, and ample light can enable replacement of a one-size-smaller tracheostomy tube or an ETT. No more than one or two attempts should be made, especially if the BMV is optimal. An experienced anesthesiologist should place an orotracheal tube with direct laryngoscopy. In experienced hands, a Hollinger anterior commissure laryngoscope and Eschmann stylet can be a lifesaving combination in this situation. When the airway is secured from above, the patient can be taken

back to the operating room for replacement of the tracheostomy tube.

IV. TONSILLECTOMY AND OTHER OROPHARYNGEAL PROCEDURES

A. Preoperative Considerations

Tonsillectomy is one of the most frequent procedures performed by the otolaryngologist, with about 737,000 performed in 2006.[40] Most of these operations are performed on healthy adults and children. Current indications include history of recurrent tonsillitis, tonsillar hypertrophy, OSA, asymmetrical tonsils, recurrent peritonsillar abscess, and tonsillar malignancy.[41] Performance of these procedures in patients with coagulation disorders is uncommon but can be challenging if the diagnostic workup fails to alert the surgical and anesthesiology teams about the presence, nature, and extent of the problem.

B. Obstructive Sleep Apnea

OSA can lead to serious and potentially life-threatening conditions if left untreated. They include hypertension, pulmonary hypertension, coronary artery disease, cor pulmonale, and congestive heart failure.[42] Nonsurgical options are available for patients with mild to moderate sleep apnea, but many patients with severe sleep apnea, tonsillar hypertrophy, and soft palate redundancy can benefit from tonsillectomy, uvulectomy, and uvulopalatopharyngectomy. Adults with this disorder must have a preoperative assessment of the severity of the problem with an overnight polysomnogram. The severity of OSA, the extent of desaturation, and the number and duration of apneic episodes have significant implications, especially for postoperative monitoring of these patients. Induction of general anesthesia relaxes the pharyngeal muscles in a manner similar to the effect of rapid-eye-movement (REM) sleep.[39] This makes BMV difficult to maintain, and the OPAs and nasopharyngeal airways do not always significantly improve the airway. Excessive pharyngeal tissue exacerbates the obstruction caused by the redundant soft palate and base of the tongue, hindering a good view of the cords during laryngoscopy. Patients with OSA are more sensitive to sedative and narcotic analgesics. This necessitates extreme caution and a need for slow titration in using these agents. Awake fiberoptic intubation may be considered before induction of general anesthesia.

C. Peritonsillar and Parapharyngeal Abscess

Anesthetic management of patients with peritonsillar abscess is a challenging task in head and neck surgery. These patients have severe odynophagia, upper airway edema, and distortion of the normal anatomy. The limited mouth opening resulting from local pain and inflammation increases the degree of difficulty when securing the airway. The anesthesiologist should expect a difficult airway on induction of general anesthesia and make alternative plans to be able to achieve a secure airway. Spontaneous or traumatic rupture of the abscess is a real risk, and the consequential aspiration of pus into an unprotected airway remains a possibility. The head and neck surgeon may attempt needle aspiration for decompression of the abscess under local anesthetic.[43] Awake intubation or direct laryngoscopy is a safe option only if the abscess is relatively small and does not distort the route of intubation. A possible alternative is nasal, awake fiberoptic intubation using topical anesthesia. Topical anesthesia can be accomplished using the "spray-as-you-go" technique or translaryngeal injection of 3 to 4 mL of 4% lidocaine.[13] For a sizable abscess or airway distortion, a tracheostomy done under local anesthesia with minimal or no sedation is the safest approach.

D. Airway Management During Routine Tonsillectomy and Oral Procedures

The surgeon places a mouth gag (e.g., Crowe-Davis) into the mouth to increase exposure of the oropharynx. The ETT is held in a groove under the blade of this gag. There is a small but real danger of extubation during placement, adjustment, and removal of this blade. The ETT should always be secured with a tape to the lower lip. To monitor for kinking or obstruction of the ETT, the anesthesiologist must pay close attention to Et_{CO_2}, bilateral chest auscultation, and peak airway pressures. The oral cavity and oropharynx should be gently but meticulously suctioned at the end of the procedure to prevent aspiration of blood, causing laryngospasm. The patient's head should be turned to the side at the end of the procedure to minimize blood in the endolarynx and resultant laryngospasm.[29]

E. Postoperative Airway Problems After Tonsillectomy

Monitoring patients for OSA after tonsillectomy has been a controversial issue. Children with severe and mixed (obstructive and central) sleep apnea should be monitored overnight in a postanesthesia care unit (PACU).[44] Relief of airway obstruction increases the risk of postoperative pulmonary edema and does not address central apneic episodes, which may be unmasked and result in O_2 desaturation and loss of respiratory drive.[44] The postoperative care of adults with OSA after tonsillectomy and similar procedures should be individualized. Care should be based on the severity of sleep apnea preoperatively and performance in the PACU in the immediate postoperative period.

F. Management of Bleeding After Tonsillectomy

Post-tonsillectomy bleeding may take place in the immediate postoperative period (i.e., reactionary bleeding) or 7 to 10 days after the surgery (i.e., secondary bleeding, often from infection). Preventive measures, such as meticulous hemostasis for reactionary bleeding and hydration and administration of oral antibiotics for secondary bleeding, are routinely recommended by surgeons.

Obstruction of the airway by a combination of bleeding and postoperative airway edema is the most frequent cause of post-tonsillectomy morbidity.[45] Post-tonsillectomy bleeding occurs usually at a slow rate, allowing a large volume of blood to be swallowed by the patient without awareness. Postoperative nausea and vomiting and loss of blood may result in severe hypovolemia before a fall in the hemoglobin level is detected. Reduced hemoglobin level and aspiration of blood may result in hypoxemia in the patient, especially in a young child. Careful serial monitoring of hemoglobin levels and judicious use of packed red cell transfusions are important considerations, particularly in children.

If surgical treatment is required for post-tonsillectomy hemorrhage, the patient should be assumed to have a full stomach with blood in the airway.[39] Awake intubation under direct laryngoscopy in adults or rapid-sequence induction of anesthesia with etomidate or ketamine is the preferred choice in this situation. A work-up for coagulation disorders should take place in case of recurrent hemorrhage. An angiogram or a CT scan to rule out a pseudoaneurysm of the carotid may be needed in rare cases of recurrent and severe post-tonsillectomy hemorrhage.

V. SURGERY ON THE ANTERIOR SKULL BASE

The scope of head and neck surgery has expanded to include craniofacial, maxillofacial, and anterior skull base surgery. Indications may include trauma, syndromic skeletal abnormalities, sleep apnea, orthognathic deformities, and tumor removal. The anesthetic team must discuss and understand the approach, nature, and extent of the proposed surgical procedure to be able to anticipate airway problems.[46] Most patients undergoing these procedures are previously healthy adults or children, but a few have anatomic abnormalities that predispose them to challenging airway problems, including limited mouth opening, retrognathia, protruded maxilla, and presence of orthodontic appliances.[47]

A. Airway Management

Anesthesiologists should be prepared for fiberoptic intubation if a difficult airway is anticipated during the preoperative work-up. The nasal route is preferred because access for most of these procedures involves intraoral incisions. The possibility of maxillomandibular fixation at the end of the case is another reason for considering nasotracheal intubation. Nasotracheal intubation is achieved using the technique previously described. The regular adapter of the ETT is replaced with a curved adapter with a flexible extension, which is connected to the ventilator. The extension is then padded and taped over the patient's forehead so as to come off the top of the head and not interfere with the surgical approach.

B. Extubation in Skull Base Surgery

In maxillomandibular fixation, an attempt at extubation should be considered only if the patient is fully awake, is following commands, and has intact airway reflexes. Appropriate wire-cutting instruments should always be at hand for patients with such an impediment to access to the airway. After endoscopic resection of skull base tumors or repair of cerebrospinal fluid leaks, deep extubation is recommended to keep intracranial pressures low and ensure the integrity of the repair.

VII. CONCLUSIONS

The risk of a difficult airway is relatively high in the otolaryngology patient population undergoing operative management of glottic and subglottic stenosis and among head and neck cancer patients. The anesthesiology and otolaryngology teams should consider many options to secure the airway and should communicate the airway plan of action before intubation. Applying these principles can optimize airway management in head and neck surgical patients.

VIII. CLINICAL PEARLS

- The risk of a difficult airway is relatively high for patients undergoing head and neck surgery.
- Communication during the intubation procedure reduces the morbidity and mortality associated with difficult airway management.
- The optimal approach to securing the airway of patients undergoing head and neck surgery depends on the operation being performed, location of the lesion or infectious mass, tolerance of the patient, and comfort level of the anesthesiology and otolaryngology team.
- Establishing a sequential airway plan with backup options optimizes patient safety.
- The Hollinger anterior commissure laryngoscope is one of the most useful tools for difficult airway management, and it should be considered when other techniques for orotracheal intubation have failed.
- Nasotracheal fiberoptic intubation is useful in cases of a small mouth opening, severe trismus, large tongue, receding lower jaw, large oral cavity tumor, planned maxillomandibular fixation, or tracheal dilatation.
- If a patient is in acute respiratory distress because of upper airway obstruction and is unable to be safely intubated under general anesthesia, the best choice is to perform a planned but urgent awake tracheostomy.
- Cricothyrotomy is a procedure for establishing an emergency airway when other methods are unsuitable or impossible.

X. Clinical Pearls

I. INTRODUCTION

The use of laser technology in medicine and surgery has expanded greatly since its development in the 1960s, and lasers are found in some form throughout most hospitals in the world. Laser technology has been incorporated into most aspects of modern life, from computers to supermarket bar code readers, and lasers have been used increasingly in a wide variety of clinical applications, from diagnostic medicine to laser airway surgery.

In medical practice, the type of laser used depends on the procedure to be undertaken, the type of surgery, the location, and the requirements of the physician. They are used in superficial or cutaneous procedures, such as those

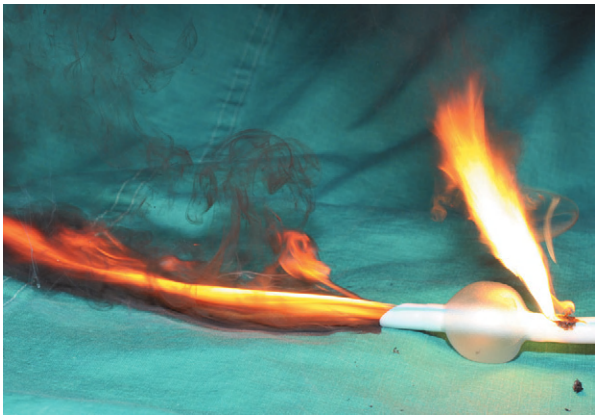

Figure 40-1 Catastrophic laser-induced blowtorch fire of a polyvinyl chloride endotracheal tube (ETT). The ETT had 100% O_2 flowing through it and had a sustained CO_2 laser strike proximal to the cuff on the outer surface, from which a second flame is emerging.

involving dermatologic, dental, opthalmic, and plastic surgery, and those involving introduction of lasers into the body, such as interventional or diagnostic cardiovascular procedures and thoracic, neurologic, urologic, gynecologic, and general surgery.

Airway surgery is unique in that it involves the anesthesiologist and surgeon working in the same anatomic field. Even without the use of a laser in a shared airway, procedures are challenging when the airway is compromised. The addition of a laser beam (i.e., ignition source) into a shared airway can cause a catastrophic fire, and to avoid these disasters, all operating room staff must recognize that a team approach is essential (Fig. 40-1).[1-39] If a high-risk situation exists, all team members must proactively agree on how a fire will be prevented and managed.[1] The importance of a team approach cannot be overstated.

For safe laser airway surgery, the surgeon and anesthesiologist should be familiar with the principles of a laser, types of laser available, hazards of laser use, and management approach for an airway fire. They should understand the advantages and disadvantages of the various anesthesia techniques available.

II. PRINCIPLES OF LASER TECHNOLOGY

A. History

Laser is an acronym for light amplification by the stimulated emission of radiation. Photons are released in a very narrow, intense, high-energy beam as a result of a stimulated emission.

The history and development of lasers parallels our understanding of electromagnetic radiation, ions, molecules, and atoms. In 1900, Max Planck revised his earlier work on radiation and the absorption of light and heat by a black body (i.e., a perfect absorber).[40] He proposed that electromagnetic energy could be emitted only in quantized form. In this process, called the *photoelectric effect*, electrons are emitted from matter as a consequence of their absorption of energy from short-wavelength electromagnetic radiation, such as visible or ultraviolet light. In 1905, Albert Einstein described how the photoelectric effect was caused by absorption of quanta of light (i.e., photons) and explained that the energy of these quanta was directly related to the frequency of the radiation absorbed. From these observations, Einstein developed his ideas on quantum mechanics, and in 1917, he developed the quantum theory of radiation,[41,42] in which he discussed the interactions of atoms, ions, molecules, photons, and electromagnetic radiation. According to the quantum theory of radiation, electrons, atoms, molecules, and photons interact with electromagnetic radiation of quantum units by absorption, spontaneous emission, and stimulated emission.[43]

In 1954, Charles Townes described the first amplification and generation of electromagnetic waves by stimulated emission by using microwaves, which he called microwave amplification by the stimulated emission of radiation (MASER). In 1960, Theodore Maiman produced light amplification by the stimulated emission of radiation (LASER) using a ruby crystal and red light. Throughout the 1960s and 1970s, many substrates and ions were tried as the laser medium. Some, such as the carbon dioxide (CO_2) laser, were successfully developed, found to be useful in medical practice, and are still used.[44]

B. Physics

An atom consists of a nucleus around which electrons orbit in discreet shells. These shells, or orbits, have specific energy levels associated with them. Electrons in the stable ground state occupy the lowest orbit, which is closest to the nucleus and has the lowest energy level. Electrons can move from one orbit to a higher-level orbit by absorbing energy, or they can move from a higher-level orbit to a lower level by emitting energy. The energy absorbed or emitted is exactly equal to the difference between the orbital energy levels, and it can take the form of a photon, which is the elementary particle of light and a quantum of electromagnetic energy.

In *absorption*, an electron is boosted to a higher energy level by absorption of the energy of a colliding photon. The natural state for matter is to be at the lowest energy level. An electron in a higher orbit will spontaneously drop back to the lowest-energy orbit possible and emit energy as a photon, which is exactly equal to the photon required to take the electron to the higher orbit. This process, known as *spontaneous emission*, occurs in a random manner that results in incoherent light.

In 1917, Einstein postulated that if a photon released from an excited atom collided with another atom already in the excited state, the second atom would release two photons with the same wavelength, phase, and direction (i.e., identical photons). If these two photons stimulated more excited atoms, more identical photons would be released. Einstein called this process *stimulated emission of radiation*, and it is the basic principle of laser physics (Fig. 40-2).[45]

The energy of a photon is proportional to the frequency of light and is described by the following equation:

$$e = h\lambda$$

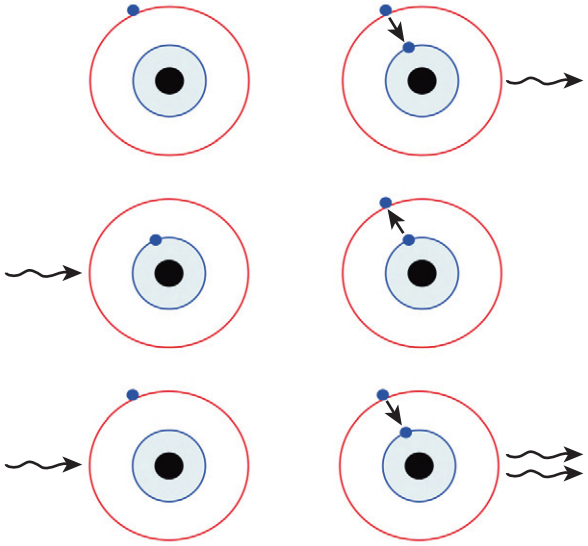

Figure 40-2 The processes of absorption, spontaneous emission, and stimulated emission are necessary for a laser to operate. *Top*: In an excited state (i.e., electron in a higher-energy orbit), the electron is unstable and reemits this energy (i.e., spontaneous emission). *Middle*: A photon or light packet with energy ($h\nu$) or another power source can provide the energy necessary to raise the energy level of electrons from the ground state to an excited state (i.e., absorption). *Bottom*: A photon of the appropriate energy impinging on an electron in the excited state causes the release of a second photon of the same energy (i.e., stimulated emission). The latter photon travels in the same direction and is in phase with the first photon.

where
e = quantum energy
h = Planck's constant
λ = wavelength

All lasers consist of a *laser medium* (e.g., CO_2, argon) contained in an *optical cavity* between *two mirrors*, one totally reflecting and one partially reflecting mirror. An *external energy source* continuously excites or pumps the laser medium, causing many of the atoms to reach a higher energy level (Fig. 40-3). When more than one half of the atoms are in an excited state, a population inversion has taken place. In this state, spontaneous emission occurs in every direction, but photons emitted in the direction of the optical cavity strike the mirror and are reflected back, striking excited atoms, and resulting in stimulated emission. This process repeats itself at an increasing rate with each passage of the photons reflected off the mirrors through the laser medium, generating a huge number of identical photons that all have the same wavelength, phase, and direction. The partially reflecting mirror lets a small amount of this energy escape through the aperture, creating the laser beam.

Laser light may be in the invisible infrared, visible, or ultraviolet part of the electromagnetic radiation spectrum. It is monochromatic, with all the photons having the same wavelength, and collimated, allowing the beam to be intense and unidirectional, with no divergence, preventing spread as the light moves farther away. The laser light is coherent spatially and temporally, with all the photons in phase, and it has high energy density.

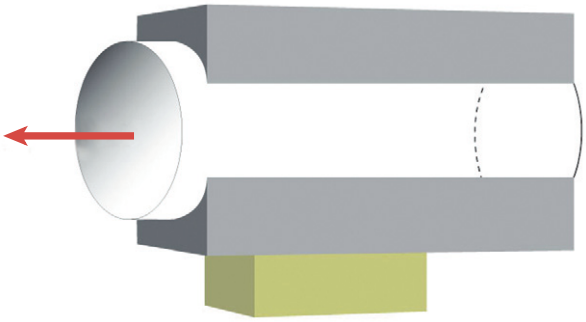

Figure 40-3 Laser apparatus. A power source (yellow box) stimulates the lasing medium (inside the cylinder within the gray box). The spontaneous emission of photons from electrons in the excited state stimulates the emission of more photons. The parallel mirrors (circles at the ends of the gray box) reflect the photons traveling along the axis of the laser, amplifying the intensity of the radiation. This results in a coherent monochromatic laser beam emerging from the partially reflective mirror *(red arrow)*.

C. Laser Parameters

The operator can select three parameters to alter the effectiveness of the laser on tissue by adjusting the exposure time, spot size, and power.

1. Exposure Time

Exposure time is the time that the tissues are exposed to the laser light. The exposure time is influenced by the pulse structure of the laser, which is influenced by the type and configuration of laser and which may be fixed. The pulse structure can be in a continuous mode, with the laser emitting continuous laser light when switched on. The pulse structure can also be in a pulsed mode in which a single, brief (0.5 microseconds to 100 milliseconds) pulse of laser light is emitted. Early versions of these pulsed-mode lasers showed that the pulse was a series of irregular spikes. Q-switching produces a very short laser pulse, reducing the interval of the pulse and increasing high peak power. By using the pulsed mode with high intensity and short pulse duration, the laser beam can ablate tissues quickly and before thermal energy spreads damaging adjacent tissues.

2. Spot Size

After the laser light has emerged from the optical cavity of a laser system, it may pass through a lens that focuses the beam to a very small diameter, or spot size, ranging from 0.1 to 2.0 mm. The optical properties of each focusing lens determine the focal length, or distance from the lens to the intended target tissue.[46]

3. Power

When using lasers in clinical practice, power often is measured in watts (W), although a more useful term is the *power density*. For a given power, the effects vary according to the spot size and the time of exposure. The relationship between power and depth of tissue injury becomes logarithmic when the power and exposure time are kept constant and the spot size is varied.[47] Power density describes the amount of power (W) arriving at a surface area (W/cm^2).

$$\text{Power density } (W \cdot cm^{-2}) = \text{Power output of laser } (W) / \text{Area of focal spot } (cm^{-2})$$

D. Laser-Tissue Interaction

When a laser interacts with tissues, the energy can be reflected, absorbed, conducted as heat, or scattered. The extent to which these processes occur depends on the type of laser used and the tissue with which it interacts. Laser wavelengths depend on the medium, and the degree of absorption depends on the target tissue components. The CO_2 laser (10,600-nm wavelength) is particularly well absorbed by water, whereas the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (1064-nm wavelength) is absorbed less by water and creates more energy scatter. The argon laser (488- and 514-nm wavelengths) and potassium titanyl phosphate (KTP) laser (532-nm wavelength) are in the visible spectrum, and their energies are absorbed well by pigments such as melanin and hemoglobin. For the most commonly used lasers in medicine, absorption of laser energy excites the atoms within tissues, which produces heat (Fig. 40-4).

The CO_2 laser heats the water within cells, and as the temperature rises to about 65° C, proteins denature and thermal necrosis occurs. As the heating continues and the temperature reaches 100° C, the water within the cell boils and produces water vapor; this leads to an explosive vaporization, and the cell explodes. The tissue surface in contact with the CO_2 laser disintegrates and undergoes charring, with carbon debris deposited at about 350° C. There is little damage to the underlying structures. Surrounding the charred area is a zone of thermal necrosis, and around this is an area of thermal conductivity and repair.[48]

E. Laser Classification

The American National Standards Institute (ANSI Z136 report on safe use of lasers) and the International Standard International Electrotechnical Commission (IEC 60825 report on the safety of laser products) define four classes of laser according to their power and wavelength:

Class 1. These lasers are considered safe, with no risk when viewed by the naked eye. Class 1M denotes that the beam is potentially hazardous if it is viewed with an optical instrument, such as a microscope.

Class 2. These lasers emit low-power visible radiation in the range of 400 to 700 nm. An aversion reaction or blink reflex limits exposure to less than 0.25 seconds and provides protection from equipment such as a laser pointer. Class 2M devices are the same as class 2, but they may be hazardous if viewed with an optical instrument.

Class 3. A class 3R laser is considered safe with restricted beam viewing, and if the maximum permissible exposure is exceeded, the risk of injury is low. Class 3B lasers are hazardous if the eye is exposed directly, and protective eyewear is required if direct viewing of a laser beam may occur. A key switch and safety interlock must be present on all class 3B lasers.

Class 4. Most medical lasers belong in this class and pose dangers to the eye, skin, and combustible material. They are a fire risk and produce air contaminants and plumes. All class 3B and class 4 lasers must be operated by trained, authorized personnel and be equipped with a key switch and a safety interlock.

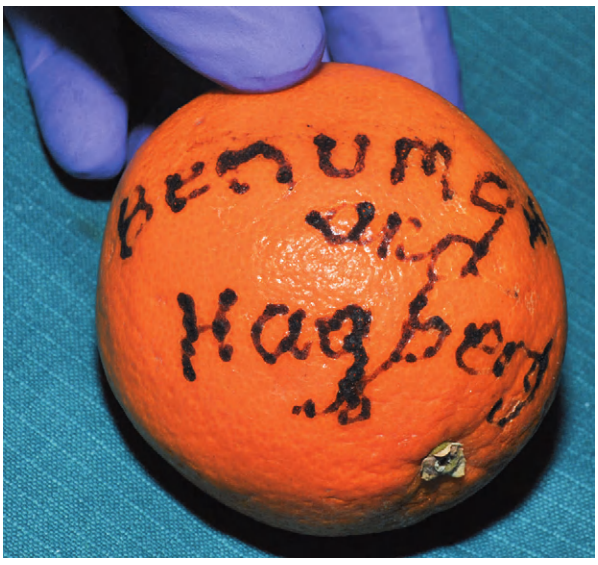

Figure 40-4 The surface of an orange after a CO_2 laser strike shows charring and carbon debris deposited at around 350° C. The words *Benumof and Hagberg* can be seen.

F. Types of Laser

Lasers are named according to their medium, which can be a gas, solid, liquid, or semiconductor. Many types of lasers exist, and their clinical application depends on their wavelength, tissue absorptive characteristics, cost, ease of use, and safety. Lasers have differences in their emitted wavelength, output power, mode of operation (i.e., pulsed or continuous mode), and application (i.e., contact or noncontact). For laser airway surgery, the CO_2, argon, Nd:YAG, KTP, and diode lasers are the most commonly used (Table 40-1).

TABLE 40-1
Characteristics of Commonly Used Medical Lasers

Type of Laser	Laser Wavelength (nm)	Color	Fiberoptic Transmission
Gas			
Helium-neon	633	Red	Yes
Argon	500	Blue-green	Yes
Carbon dioxide	10,600	Invisible	No
Solid			
Ruby	695	Red	Yes
Nd:YAG	1,060	Invisible	Yes
KTP	532	Green	Yes

Figure 40-5 The CO_2 laser (AcuPulse, Lumenis, Yokneam, Israel) has an articulating arm for attachment to a surgical microscope or handheld device. The coaxial helium-neon, low-intensity laser can be seen as a continuous, visible red light.

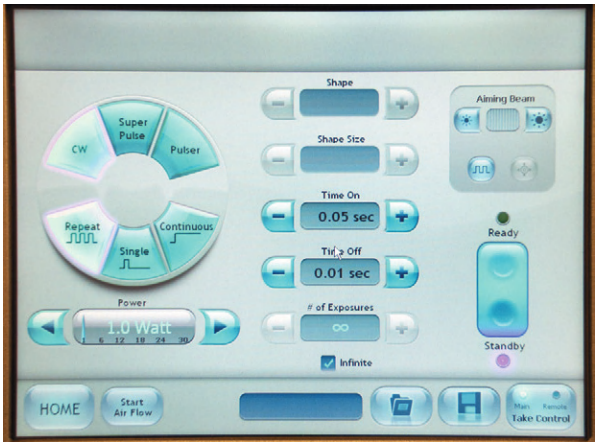

Figure 40-6 CO_2 laser parameters include continuous, pulsed, and superpulsed modes.

1. Carbon Dioxide Laser

The CO_2 laser has been used for many otolaryngology and head and neck surgical procedures and in gynecologic surgery for the treatment of intraepithelial neoplasms, condylomata acuminata, and other lesions. It is the most commonly used laser for airway surgery and is particularly suited to laryngeal and head and neck surgical procedures (Fig. 40-5).

This laser uses CO_2 mixed with nitrogen and helium as its medium. The nitrogen is used to aid in energy transfer to the upper excitation level of the CO_2 molecule. The CO_2 laser emits invisible infrared light at a wavelength of 10,600 nm in the infrared range of the electromagnetic spectrum, and the light cannot be seen by the human eye. To allow the CO_2 laser to be seen, a second, coaxial helium-neon (He-Ne) laser is incorporated into the CO_2 laser and acts as a pointer. The low-intensity (0.8-mW) He-Ne laser has a wavelength of 6328 nm, which is within the visible part of the electromagnetic spectrum, and the light is red. As soon as the CO_2 laser is switched on, this visible red light is seen continuously and independently of the status of the CO_2 laser. The He-Ne laser must be aligned with the CO_2 laser in the coaxial arrangement, and the alignment must be checked before use. If the coaxial arrangement is not aligned, the CO_2 laser and the He-Ne beam will strike different areas, resulting in destruction of healthy tissue or increasing the risk of an airway fire.

The CO_2 laser is preferred for laryngeal lesions. It is used for the treatment of benign laryngeal pathology, such as nodules, polyps, papillomas, granulomas, Reinke's edema, webs, hemangiomas, subglottic stenosis, and arytenoidectomy, and for phonosurgical procedures. CO_2 lasers allow precise cutting and shallow penetration of tissues. These qualities are imperative for removal of lesions situated in the supraglottic or immediate subglottic regions. It can be used for leukoplakia on the vocal cord and within the oral cavity. Transoral laser procedures use a CO_2 laser to excise and debulk tumors within the oral cavity and from the vocal cord itself. Many early vocal cord tumors are treated with excision by a CO_2 laser.

The CO_2 laser can be used in a continuous, pulsed, or superpulsed mode. The superpulsed mode reduces the exposure time to a few nanoseconds while delivering high energies of 400 to 500 W with each peak (Fig. 40-6). The rest time between each peak allows the tissues to cool and reduces thermal injury to adjacent tissues.

The CO_2 laser can be attached to an operating microscope or a handheld device so it can be used for intraoral procedures such as palatal surgery. CO_2 laser energy is highly absorbed by water, and because water is the primary component of most biologic tissue, CO_2 laser energy is highly absorbed by most tissues. It is readily absorbed by the first 200 μm of biologic materials, independent of tissue pigmentation.

The CO_2 laser has advantages that make it an effective surgical tool. Its use with an operating microscope allows the surgeon to precisely destroy targets approximately 2 mm in diameter under binocular vision. This degree of precision may be impossible to achieve with conventional cautery. During CO_2 laser surgery, the surgical field is usually bloodless because of the laser's considerable hemostatic action. Vessels up to 0.5 mm in diameter usually can be sectioned without bleeding.[49] The CO_2 laser has been used successfully to excise vascular lesions, even in patients with a bleeding diathesis.[50] The use of more traditional surgical tools, such as cautery, usually results in considerable postoperative edema. Edema does not usually occur after using the CO_2 laser because of the sharp line of tissue destruction, with virtually no

injury to surrounding tissue. Ninety percent of the laser's energy is absorbed within 0.03 mm.[51] There is no manipulation of tissues because laser treatment is usually a noncontact technique. Microscopic examination of tissue after CO_2 laser surgery reveals a discrete line of destruction, with preservation of capillaries and normal features of adjacent tissues. The preservation of adjacent tissues is thought to account for the rapid healing, minimal scarring, and reduced pain often observed after CO_2 laser surgery.[49]

The CO_2 laser is a safe and extremely useful surgical modality in the airways and the digestive tract.[52] It is best suited for widening benign tracheal stenoses and for removal of granulation tissues.[53]

2. Flexible-Fiber Carbon Dioxide Laser

A drawback of CO_2 lasers is that they are fixed to a line-of-site delivery mechanism and cannot be transmitted through ordinary fiberoptic bundles, which limits their use to areas accessible by a straight approach. Flexible-fiber CO_2 lasers (Omniguide, Cambridge, MA; Fiberlase CO_2 Fiber, Lumenis, CA) have been developed for use in airway procedures, including base of tongue tumors, laryngeal tumors, tracheal tumors, laryngeal papillomas, tracheal stenosis, and laryngeal lesions.[54-59]

Flexible-fiber CO_2 lasers have a photonic band gap mirror lining, which guides light through a hollow core. The mirror lining reflects the CO_2 laser energy along the hollow core to the distal tip. The hollow core also delivers a cooling flow of inert gas, usually helium, that helps to prevent the fiber from overheating, clears the surgical field of blood, minimizes tissue heating, and ensures the hollow core is clear. The flexible laser fiber can be passed through a rigid bronchoscope or flexible bronchoscope or can be used with a handpiece.

The anesthesiologist should be aware of the risk of a gas emboli, and this possibility should be monitored. Pressurized gas exiting the fiber tip during the laser procedure may cause gas emboli, and the fiber tip should not be brought into direct contact with blood vessels or vascular tissues. Pressurized gas exiting the fiber tip during the laser procedure may cause separation of submucosal flaps or mild emphysema under superficial layers of tissue, and the CO_2 fibers should not be used for lesions below the carina. The flexible CO_2 laser allows access to areas inaccessible by traditional line-of-sight CO_2 lasers, including the nasal cavity, oral cavity, tongue base, larynx, subglottis, and trachea up to the carina.

3. Potassium Titanyl Phosphate Laser

The KTP laser is strongly absorbed by hemoglobin and melanin, and it is used for otolaryngologic lesions, vascular diseases, and hemorrhages.[60] The KTP laser has been used to treat several skin conditions, including port wine stains, hemangioma, telangiectasia, spider nevi, and red scars of the skin (Fig. 40-7).

The KTP laser is generated by passing the light of a rapidly pulsed Nd:YAG laser through a potassium titanyl phosphate crystal, which doubles the frequency and halves the wavelength to 532 nm, producing a beam in the bright green visible spectrum that has a tissue penetration of 0.5 to 2 mm.[60] The radiation is able to pass through a flexible fiberoptic bundle and is used in a pulsed mode. It is used in vascular lesions within the airway, and because it can be transmitted through clear substances and can pass through a flexible fiberoptic fiber, it can be used in areas where a direct line-of-site laser cannot. The KTP laser has been used for laryngotracheal stenosis, laryngeal paralysis, and choanal atresia. The convenience of fiber delivery, concomitant telescopic control, and low-grade edematous reaction were the main advantages over the CO_2 laser. Healing time was longer for the KTP laser than for the CO_2 laser.

Figure 40-7 Potassium titanyl phosphate (KTP) laser (AuraXP, American Medical Systems, Minnetonka, MN). The flexible fiber is coiled in front of the laser.

4. Argon Laser

The argon laser contains argon gas and produces a visible blue-green beam with wavelengths of 488 nm and 514 nm, which are absorbed selectively by hemoglobin, melanin, and other pigments that lie under the retina. The beam is readily transmitted down a fiberoptic bundle, allowing endobronchial surgery (Fig. 40-8).

Applications of the argon laser include ophthalmologic surgery, especially for retinal and anterior chamber procedures. Because the laser passes readily through fluid inside the eye without damage, it is used in the treatment of retinal vascular lesions, including diabetic retinopathy, retinal detachment, glaucoma, and macular degeneration. Its applications in dermatologic and plastic surgery include the removal of port wine stains, hemangiomas, and tattoos because of the laser's absorption by hemoglobin and other pigments. Because the tissue penetration is 0.5 to 2 mm, it is useful for superficial coagulation of capillary vessels. Port wine stains are lightened without

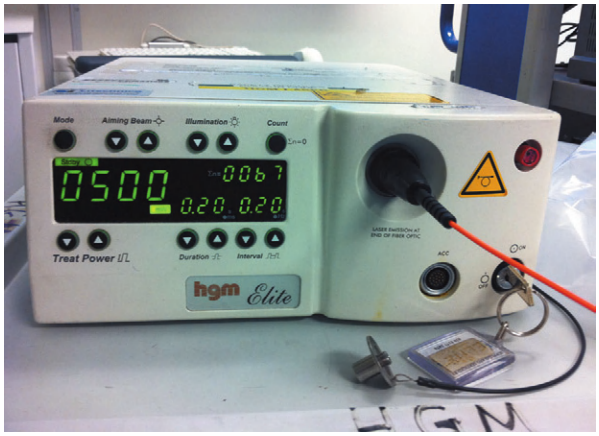

Figure 40-8 HGM Elite argon laser (HGM Medical Laser Systems, Salt Lake City, UT) has a flexible fiberoptic bundle protected by a red lead.

scarring after treatment with the argon laser.[50] To vaporize tissues, the power density is increased to produce a small focal spot; this allows argon laser stapedotomy. The argon laser has been used in infants to remove obstructive endobronchial lesions due to traumatic suction catheter injuries by passing argon laser fibers through the suction port of the fiberoptic bronchoscope (FOB) and targeting the obstructive endobronchial lesion with the argon laser beam.

5. Neodymium:Yttrium-Aluminum-Garnet Laser

The Nd:YAG laser has been used for photocoagulation and deep thermal necrosis in the treatment of gastrointestinal bleeding and obstructing bronchial lesions. The Nd:YAG laser uses a clear, solid, crystalline medium that emits radiation in the infrared region of the electromagnetic spectrum; the radiation has a wavelength of 1060 nm and is invisible (see Table 40-1). Conventional fiberoptic bundles readily transmit Nd:YAG laser radiation at high power, which is applied in a continuous or pulsed mode. The radiation is more readily absorbed by dark tissue. Blue or black pigmentation enhances Nd:YAG absorption, whereas pale colors enhance its penetration.[61,62] Nd:YAG radiation penetrates tissues to a depth of 2 to 6 mm and provides good homeostasis for blood vessels up to 0.5 cm in diameter. However, the depth of penetration is less predictable than that of the CO_2 laser. The power density below the tissue surface depends on the color of the surface, which makes laser penetration more difficult with the Nd:YAG laser than with the CO_2 laser.

The Nd:YAG laser is recommended for lesions distal to the larynx and for bulky, vascular endobronchial neoplasms. The advantage of the Nd:YAG laser is that the radiation can be transmitted through fiberoptic bundles. Excision of lesions that are located distal to the larynx is complicated because it is difficult to reach the tumor with the laser beam. In these situations, the Nd:YAG laser is preferred because it can be used with a rigid bronchoscope or an FOB.[62] Nd:YAG lasers are less precise in cutting, penetrate the tissue deeper, and have improved photocoagulation and superior hemostasis compared with other lasers.

Dumon and coworkers,[63] reporting a large series of cases, recommended the use of rigid rather than flexible bronchoscopy for treating obstructive pulmonary lesions by means of endoscopic Nd:YAG laser surgery. Brutinel and associates reported difficulty ventilating and oxygenating patients' lungs through an endotracheal tube (ETT) during Nd:YAG surgery with an indwelling FOB in place.[64] Casey and colleagues reported combustion of the FOB and ETT in a patient undergoing Nd:YAG laser airway surgery.[65] The use of a rigid bronchoscope for the treatment of obstructing pulmonary lesions facilitates the removal of tissue and the treatment of complications.[66] Power levels less than 50 W given in short pulsations decrease the chances of impingement on vital underlying structures.[66] McDougall and Cortese reported two patients who died during Nd:YAG laser endoscopic treatment of airway obstructions using very high power.[67] At high power, the penetration of tissues by the Nd:YAG laser cannot be readily controlled, and perforation of a large blood vessel is possible.

6. Ruby Laser

The ruby laser uses a solid medium of a crystal aluminum oxide (i.e., sapphire) containing chromium ions. It emits visible red radiation at a wavelength of 695 nm (see Table 40-1). The ruby laser is used only in the pulse mode. The radiation is not readily absorbed by water but is significantly absorbed by pigments such as melanin and hemoglobin. The ruby laser can easily penetrate the anterior structures of the eye. It is used to photocoagulate vascular and pigmented retinal lesions. Use of this laser has decreased with the availability of newer types, and the ruby laser is not commonly used for laser airway surgery.

7. Diode Laser

The diode laser is another addition to a growing array of tools for laser surgery. This laser is effective for treatment of hyperplastic inferior nasal turbinates and provides good hemostasis and a sufficient reduction of tumors in otolaryngology practice.[60] The continuous-wave, semiconductor diode laser emits radiation at wavelengths of 810 and 940 nm in the near-infrared spectrum. The radiation is delivered by a flexible fiber coupled with an aiming beam. The diode laser penetrates tissue to a depth of 1 to 3 mm, and it is suitable for vascular lesions. It is used to remove and debulk airway pathology, including tumors throughout the airway.

8. Other Lasers

Other lasers may have krypton, gold, copper, xenon, erbium:YAG, or holmium:YAG as their medium, but none is used for laser airway surgery.

III. LASER HAZARDS

General laser hazards exist for any type of surgery being done with a laser. Hazards include eye, skin, and drape damage; laser plumes; gas embolism; and misdirected laser beams.

Airway laser hazards exist when a surgeon is using a laser within the airway. The greatest danger is an airway

Figure 40-9 In the selection of laser glasses, notice the protection offered by the sides of the glasses, which wrap around the eye.

fire. Fires require three components known as the *fire triad*: a fuel source, an oxidant source, and an ignition source.

A. General Laser Hazards

1. Eye Damage

Lasers can easily damage the eyes by direct or indirect exposure, causing serious corneal and retinal injuries that may be irreversible. Eye protection is essential for anyone within the operating room, including the patient, auxiliary staff, nursing staff, surgeon, and anesthesiologist (Fig. 40-9). General precautions for the patient include taping the eyes closed and avoiding the use of petroleum-based eye lubricants. Further protection includes saline-soaked eye pads, protective eye glasses, or metal eye goggles, depending on the wavelength and type of laser used.

All laser glasses should be labeled clearly with the optical density value, the wavelengths against which protection is afforded, and maximum radiant exposure, or irradiance, to which the eyewear can be exposed (Figs. 40-10 and 40-11).[68] The correct protective eye glasses must be used for the type of laser used for the procedure; failure to do so provides no protection for the eyes. In hospitals where only one type of laser is in use, this is less of a problem, but care must be taken in hospitals with many types of lasers and protective eye goggles.

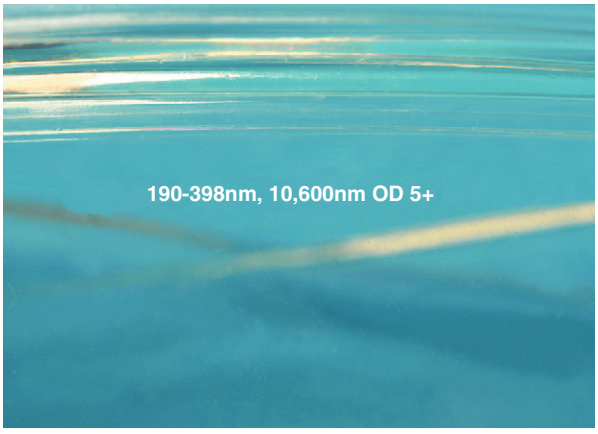

Figure 40-10 Eyes must be protected from laser energy. Laser glasses are labeled with the optical density value, the wavelengths against which protection is afforded, and maximum radiant exposure or irradiance to which eyewear is exposed.

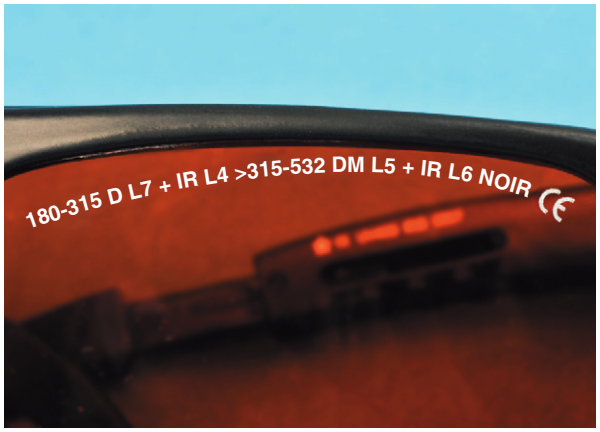

Figure 40-11 The correct protective eye glasses must be used with any given laser. The optical density value, the wavelengths against which protection is afforded, and maximum radiant exposure or irradiance to which eyewear is exposed are part of the design of laser glasses.

For CO_2 lasers, the damage to the eye is limited to the cornea because its radiation is largely absorbed by water, and the cornea is more than 75% water.[61,69] There is no risk to the retina. For airway use, the patient's eyes should be taped, protective saline-soaked eye pads placed, and surgical drapes applied and covered with another layer of saline-soaked swabs placed over the drapes. For the operating room staff, CO_2 laser–protective eyeglasses should be worn. Contact lenses protect only the area covered and provide inadequate protection. Regular conventional eyeglasses can protect against the CO_2 laser beam if the beam has been directed or reflected straight onto the eyeglass; however, if the beam is reflected accidentally into the side of the eyeglasses, damage to the eye can occur. When working with CO_2 lasers, all operating room staff should use eyeglasses that wrap around the eye, protecting from CO_2 laser entry from the side. The surgeon does not need to use CO_2 laser protective eyeglasses when working with the operating microscope because the optics of the microscope provide protection[70]; however, if the surgeon uses the CO_2 laser with a handpiece, the surgeon must also wear protective eyeglasses.

For Nd:YAG lasers, unprotected eyes may absorb and focus laser light at the ocular fundus, resulting in irreparable damage. Radiation from the KTP and other lasers such as the Nd:YAG can penetrate the cornea and lens of the eye, resulting in severe retinal damage. The endoscopist is at greatest risk because of the Nd:YAG laser's potential for backscatter.[62] The patient and all operating room staff should wear protective eyeglasses. Filters that absorb the Nd:YAG wavelength of 1.06 μm can be placed into rigid and flexible bronchoscopes. If the fibers break during laser surgery, the beam may be deflected to anywhere in the operating room.

For KTP and argon lasers, all operating room personnel require protective amber-colored eyeglasses, and for laser procedures on the face, metal goggles are used (Fig. 40-12). For rigid and flexible endoscopes and operating microscopes, filters that absorb the KTP wavelength can be introduced.

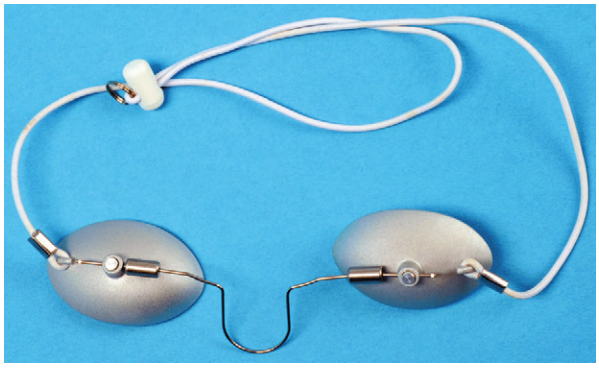

Figure 40-12 Metallic goggles are used during laser procedures on surface skin.

2. Skin and Drape Damage

Laser burns to the skin can occur, and the face or exposed areas should be protected with wet towels and drapes. For laser airway procedures involving a suspension laryngoscope, all of the area around the surgical laryngoscope and face should be completely covered with wet towels, which must be kept wet throughout the procedure. Care should be taken, particularly around the draping of the proximal portion of the surgical laryngoscope, to ensure that the lips and nose are fully protected because this region is more likely to be struck by a reflected laser beam from the proximal rim of the surgical laryngoscope (Fig. 40-13).

Preparation solution should not contain alcohol. Oxygen saturation monitors are a standard of care and should be used because detection of cyanosis is difficult with the patient's face covered. Disposable surgical drapes are a potential fire hazard. They are treated with flame-retardant chemicals and are water resistant, but all types of surgical drapes are potentially flammable. Many cases of drapes catching fire have been reported. When the drapes catch fire, it is difficult to extinguish because the drapes are water resistant, and the water rolls off them. A CO_2 fire extinguisher should be available. Drapes, once ignited, go up in flames immediately, causing the operating room to be inundated with smoke and making it difficult for everyone to see and breathe.[71-73] It is important to keep the towels moist, or they can become flammable.

Figure 40-13 Care should be taken to ensure complete coverage of the face and area around the surgical laryngoscope with wet towels. A CO_2 laser is attached to the operating microscope by an articulating arm.

3. Laser Plume

The plume of smoke produced by vaporization of tissues in electrocautery or laser surgery may be hazardous. The smoke contains fine particles (mean size, 0.31 μm; range, 0.1 to 0.8 μm) that can be efficiently transported and deposited in the alveoli.[74] In rat lungs, the deposition of laser plume particles could produce interstitial pneumonia, bronchiolitis, a reduction in mucociliary clearance, inflammation, and emphysema.[75,76] The laser's smoke plume acting as a vector for viruses is a controversial idea. Viral DNA has been detected in plumes from condylomas and skin warts but not from laryngeal papillomas.[77-80] CO_2 lasers seem to produce the most smoke from vaporization of tissue. Operating room personnel can be protected by using an efficient smoke evacuator at the surgical site (Fig. 40-14).[81,82] Ordinary operating room masks can filter particles no smaller than 3.0 μm. Laser masks that are more efficient should be used to protect the operating room personnel from plume particles.

4. Gas Embolism

Gas embolism has been reported with Nd:YAG laser resection of tracheal and bronchial tumors, and it may be a risk factor for flexible-fiber CO_2 lasers introduced into the bronchial tree.[83,84] Gas embolism has been reported in laparoscopic surgery that used Nd:YAG laser probes that required a gas cooling system.[85,86]

5. Misdirected Laser and Laser Protocol

A misdirected laser may result from equipment failure or an inadequate knowledge of that equipment. Safety protocols should be in place to prevent this problem. Burn (discussed earlier) can occur even with an unfocused laser.

The intensity of the laser and the potential for tissue damage and combustion with a misdirected beam necessitates that strict safety precautions are followed.

Figure 40-14 The AtmoSafe smoke evacuator (Atmos Medical Limited, Hampshire, United Kingdom) holds a metal coin by its suction.

Hospitals should have a laser safety officer or advisor, access to laser technicians, a laser register, and adequate staff training.

Lasers should always be set to the standby mode, except when they are ready to fire, to prevent inadvertent actuation. They should be used in the pulsed (shuttered) mode rather than the continuous mode whenever possible to limit the energy delivered by the laser and to allow the area being lasered to cool between firings. The laser radiation should never be allowed to strike highly polished or mirror-like surfaces. Most instrumentation for use with lasers has a dull or matte finish, and blackened instruments are widely used. This is important because reflection of the coherent laser beam may not disperse it, and injury to the patient or operating room personnel is possible, even from a reflected laser beam. Any instruments that become hot as a result of laser radiation may cause burns.[68,87] Tracheal laceration, tooth damage, injury to soft tissue, and cutaneous burns to operating room personnel have been described during laser surgery.[88]

The Nd:YAG and argon lasers can penetrate glass, and any windows in the operating room should have an opaque covering to prevent penetration by laser radiation. A warning sign should be placed on the operating room door so that anyone entering is informed that the laser is in use (Figs. 40-15 and 40-16). To prevent personnel inadvertently entering the operating room during laser surgery, the doors may be automatically locked when the operating room is in laser mode (Fig. 40-17). Extra goggles should be available for personnel entering the operating room.

Figure 40-16 A warning sign should be placed on the operating room door to prevent personnel from inadvertently entering during laser surgery.

B. Airway Laser Hazards

The high energy of the laser and its potential for combustion can cause an airway fire when the surgical field is near to the airway (Fig. 40-18). When a laser strikes the unprotected external surface of a tracheal tube during laser airway surgery, the surface starts to disintegrate and can catch fire. If the fire is not recognized and the laser continues to be applied, it can produce a hole in the tracheal tube and expose the burning surface to the oxidant-rich gas within the anesthesia system. At this stage, an explosive blowtorch-like fire may occur and

Figure 40-15 The sign warns personnel entering the operating room that a KTP laser is being used.

Figure 40-17 Interlock control system in the operating room prevents entry during laser use. When these systems are engaged, operating room doors are locked automatically.

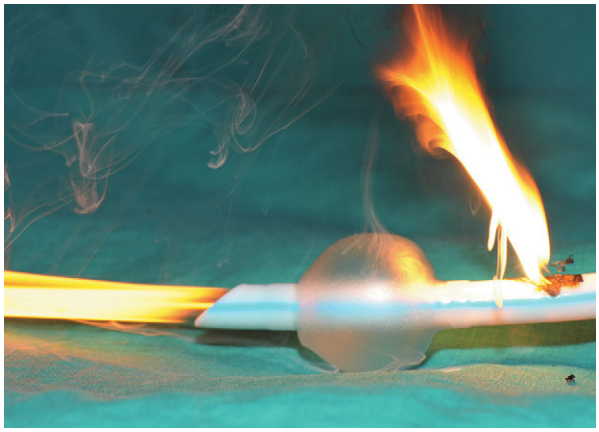

Figure 40-18 An airway fire results when a laser strikes the polyvinyl chloride endotracheal tube.

rapidly spread in a distal and proximal manner. Any airway fire is a life-threatening complication, but the blowtorch fire is especially feared (Fig. 40-19).

If the cuff of an ETT is punctured, the oxidant-rich gas within the circuit becomes exposed to the external surface of the ETT, and the risk of an airway fire, including a blowtorch fire, is increased significantly. Examination of an ETT after a blowtorch laser fire reveals total or near-total destruction of the ETT, with molten material, smoke, and other particulate material spreading out from the distal end of the tube (Figs. 40-20 and 40-21).

It is thought that operating room fires are underreported and that there are probably 100 to 200 operating room fires in the United States per year. Of the reported fires, 20% result in serious injury to the patient. One or two deaths per year are caused by airway fires.[89]

Many options are available for anesthesia management during airway laser surgery. Selection of the ventilation method and type of laser depends on the nature and location of the lesion, the condition of the patient, and the availability of equipment and expertise. Different anesthesia management techniques have been described in the treatment of recurrent respiratory papillomatosis using the CO_2 laser.[90] In a 1995 survey, 92% of otolaryngologists preferred using a CO_2 laser for removal of recurrent

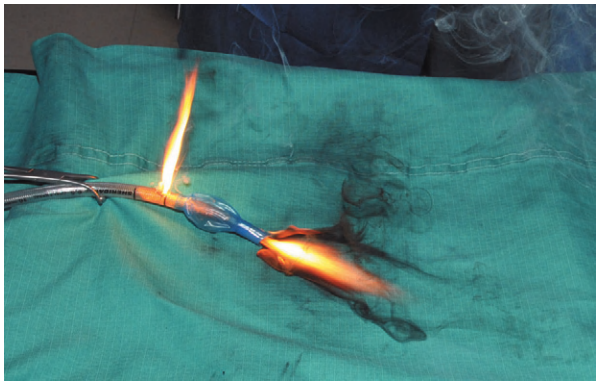

Figure 40-19 Continued laser application can produce a hole in the tracheal tube and expose the burning surface to the oxidant-rich gas within the anesthesia system, producing a blowtorch airway fire.

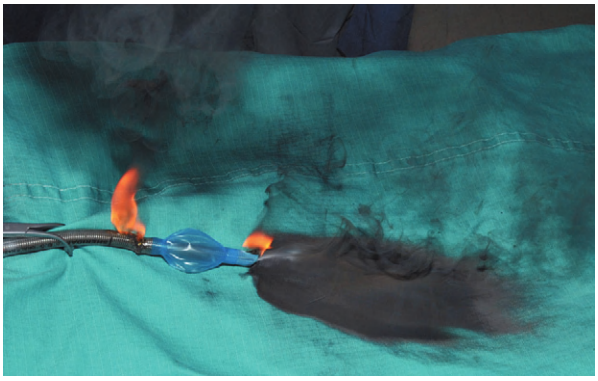

Figure 40-20 Smoke, molten material, and other particulate material spread out after an airway fire.

respiratory papillomas. However, there is no consensus with respect to anesthesia management. About 46% preferred using a laser-safe ETT, 26% favored using jet ventilation, 16% preferred an apneic technique, and 12% preferred spontaneous ventilation.[91] Other options include awake with topical anesthesia, general anesthesia through an ETT, rigid bronchoscopy with general anesthesia, and general anesthesia by a laryngeal mask airway (LMA). The possibility of complete airway collapse or an inability to ventilate must be taken into consideration when deciding on spontaneous or positive-pressure ventilation.

When general anesthesia for laser airway surgery is conducted without an ETT, special techniques are used. They include Venturi jet ventilation, intermittent apneic technique, LMA, and insufflation, which are discussed later in this chapter.

If ventilation through an ETT is proposed, prevention of an ETT fire or explosion requires the use of special techniques and appropriate ETTs. Surveys of otolaryngologists active in this type of surgery concerning the complications of CO_2 laser laryngeal surgery have found ETT fires or explosions to be the most common major complication.[52,92] Historically, the estimated incidence of airway fires was between 0.4% and 0.57% of the patients undergoing laser airway surgery.[39] The one or two deaths per year are caused by airway fires. As reported by Cozine and colleagues, patients have died because of combustion of an ETT during CO_2 laser surgery.[93]

1. Fuel Source

Fires require three components (i.e., fire triad): a fuel source, an oxidant source, and an ignition source. Fuel source includes flammable material, such as ETTs, gauze, sponges, drapes, volatile anesthetics, masks, nasal cannulas, suction catheters, gloves, gowns, endoscopes, and any material that may burn in the presence of an oxidant-rich atmosphere. The only exception is stainless steel.

2. Oxidant Source

An oxidant-rich atmosphere exists within closed breathing circuits when high concentrations of oxygen or nitrous oxide are present, and this increases the chances of an airway fire. An oxidant-rich atmosphere also can occur under drapes or masks and can increase the likelihood of a fire.

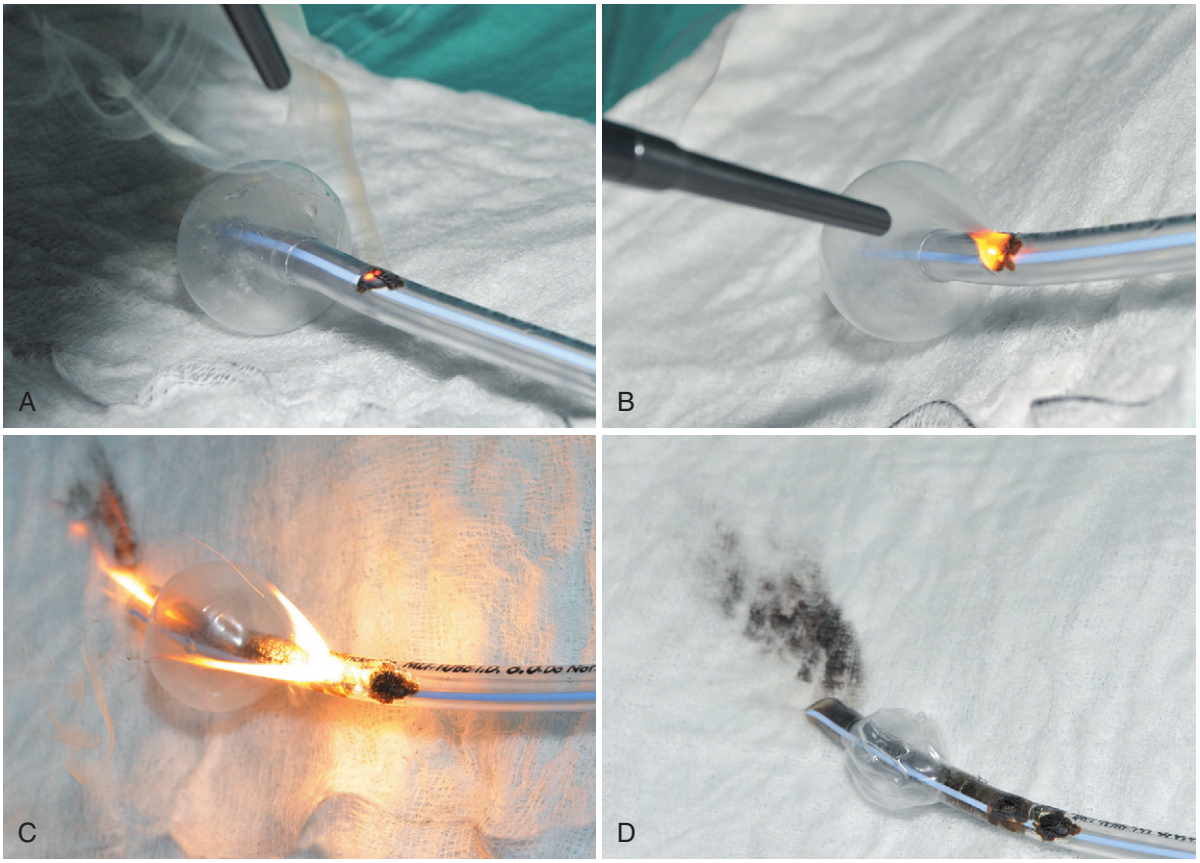

Figure 40-21 A laser striking the polyvinyl chloride endotracheal tube (ETT) created an airway fire. **A,** Smoke emerges from the outer shaft of the ETT after a continuous laser strike. **B,** The outer surface glows orange. **C,** After perforation into the inner aspect of the ETT in the presence of 100% oxygen flow, flames emerge from the puncture site and distal ETT. **D,** After the fire is extinguished, damage to ETT and material spreading out from its distal end can be seen.

3. Ignition Source

Any high-energy source has the potential to ignite a fire. During laser airway surgery, the laser is the ignition source. Other ignition sources include electrocautery devices, fiberoptic cables, light cables, defibrillator pads, heated probes, and drills. The influence of special equipment and anesthesia on airway fires is discussed later in this chapter.

IV. PREVENTING AIRWAY FIRES

The risk of an airway fire during laser airway surgery depends on the many factors that affect the three components of the fire triad. The first component is the fuel source, and the most common fuel source is the ETT. Attempts have been made to reduce the risks of a fire by protecting the tube shaft by covering it with metal foil, protecting the tube shaft by covering it with laser-protective coatings, adding saline to the tube cuff, and developing specially manufactured laser tubes suitable for laser airway surgery.

The second component is the oxidant source. An understanding of the effect of anesthetic gases on tracheal tube flammability is required, as well as an appreciation of the flammability limits of potent inhaled anesthetics.

The third component is the ignition source. The different types of lasers, power settings, modes of operation, exposure times, and spot sizes have been discussed. Most of these parameters depend on the type and site of surgery undertaken, but the anesthesiologist should understand the factors that increase the risk of an airway fire.

A. Fuel Source Considerations

1. Use of Metallic Foil Tapes to Protect Endotracheal Tubes

Metal foil tape wrapped around a standard ETT that is used during laser surgery in adults is of historical interest, but it is not commonly used for laser airway surgery. Foil tapes were first suggested as a simple, inexpensive means of protecting the shafts of combustible ETTs from laser beams by Strong and Jako in 1972.[49] Their use during laser surgery was described during the 1970s and 1980s,[94-97] when specially manufactured laser-resistant ETTs were not available or performed poorly.

Metallic foil tapes provide protection only from the direct impact of the laser beam. Indirect combustion caused by sparks or heat from gaseous or tube combustion is still possible because the ETTs used typically were combustible and usually had an enriched concentration of oxygen flowing through them. Problems with the use of metallic foil tape have included obstruction of the airway when the tape came loose from a wrapped ETT[98,99]

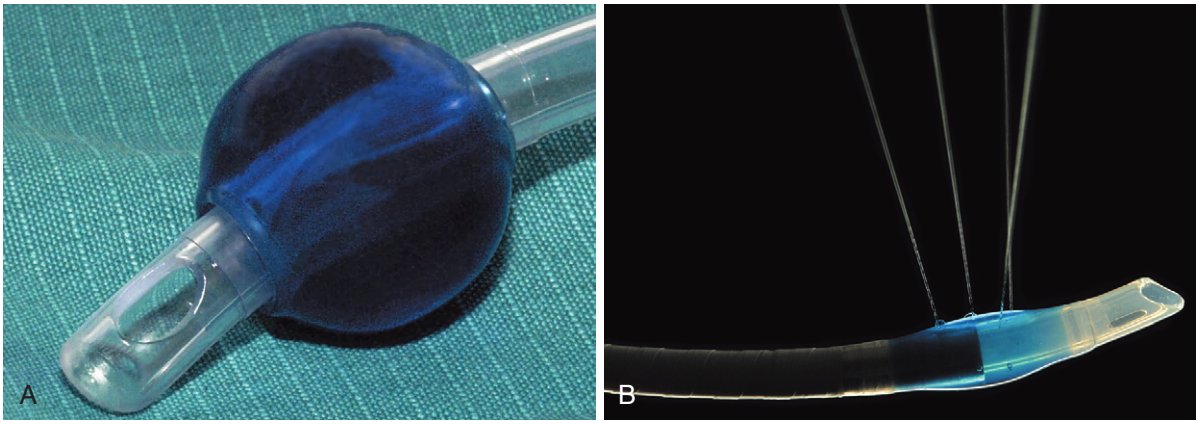

Figure 40-22 **A,** The endotracheal tube cuff is filled with saline and methylene blue dye. **B,** Perforation of the saline-filled cuff results in jets of water.

and aluminum foil tape becoming trapped in the trachea after laser airway supraglottoplasty.[100]

No metallic foil tapes are manufactured for medical applications, and the U.S. Food and Drug Administration has not sanctioned their use. The physician who wraps an ETT with metal foil tape incurs some product liability risk as a noncertified "manufacturer" if injury occurs.[101] One manufacturer, when questioned, cautioned against the use of its aluminum tape for medical purposes.[102]

Wrapping the metal foil tape in a spiral, overlapping manner should cover the shaft from the cuff to the most proximal region possible and should include the pilot tube. Poor wrapping may cause some areas of the shaft to be unprotected, and bending of the tube may expose unprotected areas. Foil-wrapped tubes may loose flexibility, and their foil edge surface may traumatize. The type of metallic tape used to protect combustible ETTs is important.[102]

The possibility of changes in the composition of any metallic foil tape requires every batch of tape to be evaluated for its incendiary characteristics before use.[95] Metal foil tape wrapped around a standard ETT is not recommended for laser airway surgery.

2. Laser-Guard Protective Coating

The Merocel Laser-Guard (Medtronic Xomed Corp, Mystic, CT) ETT protective coating is no longer available in many parts of the world and is largely of historical interest. It can be regarded as an advance from the use of metallic foil tape to cover a combustible tracheal tube, but its use has been replaced by specially manufactured tracheal tubes for laser airway surgery. The Merocel Laser-Guard consisted of a rectangular sheet of embossed silver foil covered with a thin, absorbent Merocel sponge layer on one side and adhesive on the other.

3. Prevention of Endotracheal Tube Cuff Fires with Saline

During laser airway surgery, the ETT cuff is particularly vulnerable to a laser strike. The high-volume, low-pressure cuff is thin and relatively large because the tube size chosen is undersized to provide the best exposure of the larynx for the surgeon.

The laser beam is aligned along the axis of an operating laryngoscope, which is along the same axis as the ETT but is almost perpendicular to the cuff, which expands away from the tracheal tube until it reaches the tracheal wall. Because undersized ETTs are used, the cuff size is large, and the area exposed to a laser strike is greater than for a larger ETT. A laser strike of the cuff can result in an airway fire at the cuff or lead to a leak of anesthetic gases from within the circuit and expose the outer part of the tracheal tube to an oxidant-rich environment, increasing the chance of a shaft- or cuff-related airway fire or blowtorch fire.

During the 1970s and 1980s, attempts were made to improve the laser-resistant properties of the shaft of combustible ETTs. In 1982, LeJeune and colleagues suggested that filling ETT cuffs with saline could protect them from the CO_2 laser, because a laser strike on the cuff results in a jet of water that acts as a "built-in fire extinguisher" (Fig. 40-22).[103] The saline also can act as a heat sink. Sosis and Dillon compared air-filled and saline-filled cuffs, and they found the saline-filled cuffs,[104] although perforated by the laser beam as rapidly as air-filled cuffs, were significantly slower to deflate, allowing more time before reaching the point at which airway pressure could no longer be maintained. Saline-filled cuffs prevented ETT ignition by the CO_2 laser set to 40 W (Table 40-2) in a statistically significant number of cases compared with the control group of air-filled cuffs, and saline filling of ETT cuffs was recommended for laser airway surgery. A small amount of dye, such as methylene blue, should be added to the saline so that laser-induced ETT cuff perforation becomes

TABLE 40-2

Incidence of Endotracheal Tube Combustion with Air- and Saline-Filled Cuffs with the Carbon Dioxide Laser Set to 40 W

Cuff Type	Number of Cases	Combustion (%)

obvious to the surgeon, who can immediately terminate operation of the laser. Further protection of the ETT cuffs can be obtained by placing moistened pledgets above them and keeping the pledgets moist throughout the procedure.[105]

4. Special Endotracheal Tubes for Laser Airway Surgery

Beginning in the 1970s, laser surgery of the airway became increasingly popular, and as the dangers of an airway fire became clearer, many attempts were made to reduce this risk. Two strategies were used to reduce the risk. The first involved the anesthesiologist using a standard combustible ETT and covering it in some form of protective coating. Early attempts involved protection of the shaft by metal foil and then specially designed protective coatings. The second approach involved manufacturers producing tracheal tubes that had laser-resistant properties. Some of the early manufactured laser tubes were not particularly effective, but they were thought to allow any type of laser use, and subsequently, a number of airway fires were reported. It is useful to discriminate between laser-proof and laser-resistant devices.

Laser proof implies that irrespective of the oxidant environment and the power of the laser, the ETT cannot catch fire. With a laser-proof ETT, a continuous laser strike with extremely high power in a 100% oxygen environment does not produce a fire of the tube. Only one laser-proof tracheal tube (Norton) has been designed, and it is discussed later.[106]

All other manufactured ETTs for laser airway surgery are only laser resistant. Laser-resistant tubes provide some degree of protection against a laser strike, but these tubes vary in their materials, protective coating, relative size, and number of cuffs used. Any laser-resistant tube can result in an airway fire or blowtorch fire (Fig. 40-23) if it is used outside of its limits, such as a laser strike on an unprotected area between the tube shaft distal and the cuff, at the unprotected proximal part of the shaft, or at the cuff itself. The anesthesiologist should appreciate the maximum power settings for which a laser-resistant tube has been tested, the range within which ignition does not occur, and the effect the oxidant environment has on the laser resistance characteristics. All laser-resistant tubes are not laser proof, and they must not be used outside of their limits.

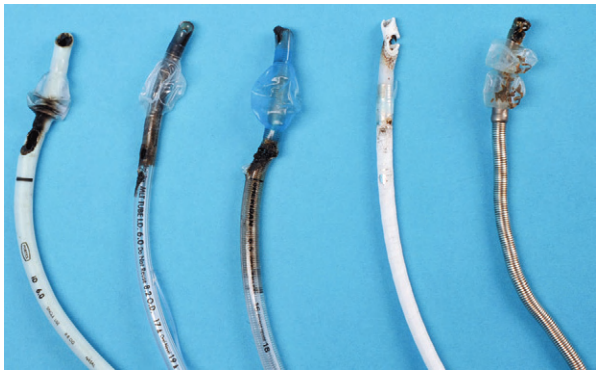

Figure 40-23 Laser-induced fire damage to endotracheal tubes (ETTs). Left to right, the first three are standard nonlaser polyvinyl chloride ETTs, and all three have been damaged by an airway fire. The two ETTs on the right are designed for laser use. Both tubes have sustained fire damage in their unprotected areas distal to the cuff by high-energy, sustained CO_2 laser strikes to the ETTs with 100% oxygen passing through them.

a. NORTON LASER ENDOTRACHEAL TUBE

The Norton ETT (V. Mueller, Baxter Healthcare Corp., Niles, IL), first described in 1978 by Norton and De Vos, was the only laser-proof tracheal tube produced (Fig. 40-24).[106] It was constructed from interlocking, spiral-wound, stainless steel parts. It is no longer manufactured. Because it was made of steel, it was extremely resistant to multiple uses and autoclaving, and it may still exist in some hospitals.

The Norton ETT had a matte or sand-blasted finish, rather thick walls, and a ribbed exterior. It came in three sizes: 4.0-, 4.8-, and 6.4-mm internal diameter (ID) (Table 40-3).[107] The matte finish diffused reflected laser beams.[106] A 4.8-mm-ID Norton ETT has a wall thickness of 1.4 mm. The thick wall of this ETT is considered a disadvantage because the tube can obscure the surgeon's view more than an ETT with the same ID but with thinner walls—an important consideration during laser airway surgery. This ETT's large size and stiffness may make surgical exposure and laryngoscope positioning

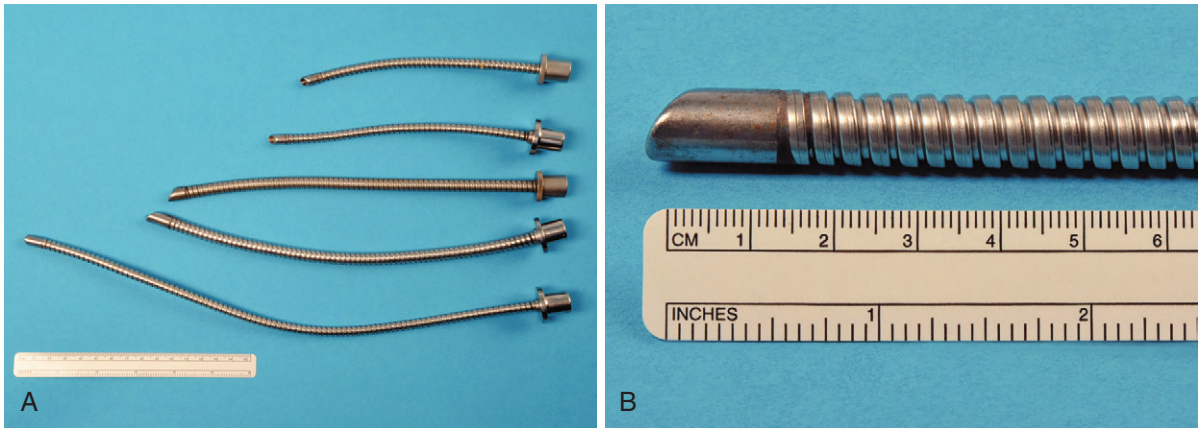

Figure 40-24 **A** and **B,** In the selection of Norton laser tubes, notice the absence of a cuff and ribbed exterior.

TABLE 40-3

difficult, and it can make passage through the glottis traumatic. It is usually necessary to use a stylet to introduce the Norton ETT.

The Norton tube had no cuff, but a separate latex cuff was available and could be attached to it. If an external cuff was added to the device, it was no longer laser proof because the cuff and pilot tube could act as a fuel source for an airway fire. The separate latex cuff is no longer manufactured, and because they degraded over time, they are not commonly found.

Alternatively, the pharynx may be packed with wet gauze, sponges, or packs to seal the system to allow positive-pressure ventilation of the lungs, but this introduces a potential fuel source and can cause an airway fire, particularly if they are allowed to dry out. Even if ventilation of the patient's lungs is not compromised by leakage, the presence of anesthetic gases in the oropharynx increases the possibility of combustion in the surgical field and increases operating room pollution.

The relatively small diameter and ridged internal surface produce turbulent airflow and an increased resistance to airflow. Woo and Strong suggested Venturi ventilation through the Norton tube in an attempt to overcome the ventilation issues of increased resistance,[108] airflow, and air leaks.

b. XOMED LASER-SHIELD I ENDOTRACHEAL TUBE

The Xomed Laser-Shield I ETT (Xomed-Treace, Jacksonville, FL) is no longer manufactured and is of historical interest only. The silicon rubber tube was coated with a silicon elastomer to which metallic particles had been added, and it was designed to be used only with a CO_2 laser. Several airway fires were reported with its use.[109-112] It is a useful reminder of the limitations of a laser-resistant ETT and the dangers of using a device outside of its intended range.

c. BIVONA LASER ENDOTRACHEAL TUBE

The Bivona (Gary, IN) laser ETT is no longer available in many parts of the world and is mainly of historical interest. It was designed to limit the effect of cuff perforation by a laser strike, because the polyurethane foam cuff with its silicone envelope maintained the cuff seal even when penetrated. The Bivona laser ETT was designed to be used only with a CO_2 laser. Blowtorch airway fires were reported with this tube.[112]

d. XOMED LASER-SHIELD II ENDOTRACHEAL TUBE

The Xomed Laser-Shield II ETT (Xomed Surgical Products, Jacksonville, FL) has a laser-resistant overwrap of aluminum foil tape and a Teflon cover. The proximal and distal ends of the silicon elastomer shaft and cuff are not protected and therefore are not laser resistant (Fig. 40-25). The metallic tape provides protection against laser impact. The Teflon tape gives the tube a smooth surface to minimize mucosal injury from tube manipulation. No adhesives are used because adhesives with metallic tape increase the risk of an ETT fire.[98] Dry methylene blue dye has been placed in the cuff inflation valve to enable detection of a cuff rupture. The Xomed Laser-Shield II comes packaged with neurosurgical cottonoid, which is used wet to protect the distal shaft and cuff for an added margin of safety.

Dillon and associates evaluated the combustibility of the Xomed Laser-Shield II ETT and compared it with 3M's no. 425 aluminum foil–wrapped, combustible, polyvinyl chloride (PVC) ETTs used with a CO_2 laser and an Nd:YAG laser.[113] Exposure of the bare silicon rubber shaft of the Laser Shield-II ETT to CO_2 laser radiation resulted in combustion in 2.1 ± 0.7 seconds; Nd:YAG laser radiation–induced combustion occurred at 3.3 ± 4.5 seconds ($P = 0.05$). The silicon rubber burned with a bright flame and disintegrated. It was difficult to extinguish. Dillon and colleagues concluded that the foil-wrapped shaft of the Laser Shield-II ETT provided adequate protection against high-power, continuous-mode Nd:YAG and CO_2 laser radiation.[113]

Ossoff and colleagues also studied the Laser-Shield II for combustibility with CO_2 and KTP lasers. They evaluated the Laser-Shield II dry, with blood, with a blood/K-Y jelly mixture, and with K-Y jelly alone on the ETT. Each tube was clamped, and 100% oxygen was delivered at 3 L/min through it. All trials were performed with 3 minutes of continuous output. The maximum power output was 40 W for the CO_2 laser and 15 W for the KTP laser. These settings far exceed the clinical settings used. With the KTP laser (13.5 to 15 W), no fires were observed, regardless of surface penetration. For the CO_2 laser, no fires were observed at 40 W for 3 minutes on continuous mode with the dry ETT. Blood or KY-jelly, or both, decreased the resistance of the ETT to CO_2 laser radiation. For the tube with blood alone, 25 W was the highest power that the tubes withstood without ignition. For the K-Y jelly/blood mixture, the maximum power was reduced to 19 W. With K-Y jelly alone, no fire occurred at the maximum power setting of 40 W.[114]

The Xomed Laser-Shield II ETT offers the potential advantage of an adhesive-free foil wrapping for ETT protection. Silicon, however, disintegrates during combustion, whereas rubber and PVC tend to retain their integrity. The Teflon overwrap around the foil raises questions because pyrolysis of Teflon may liberate toxic fumes that can cause polymer fume fever.

Medtronic Xomed recommends only the Xomed Laser-Shield II for all surgical procedures involving the use of CO_2 or KTP lasers in a normal-pulsed or continuous mode of noncontact delivery. It is contraindicated for use with any Nd:YAG laser, argon laser, or any laser other

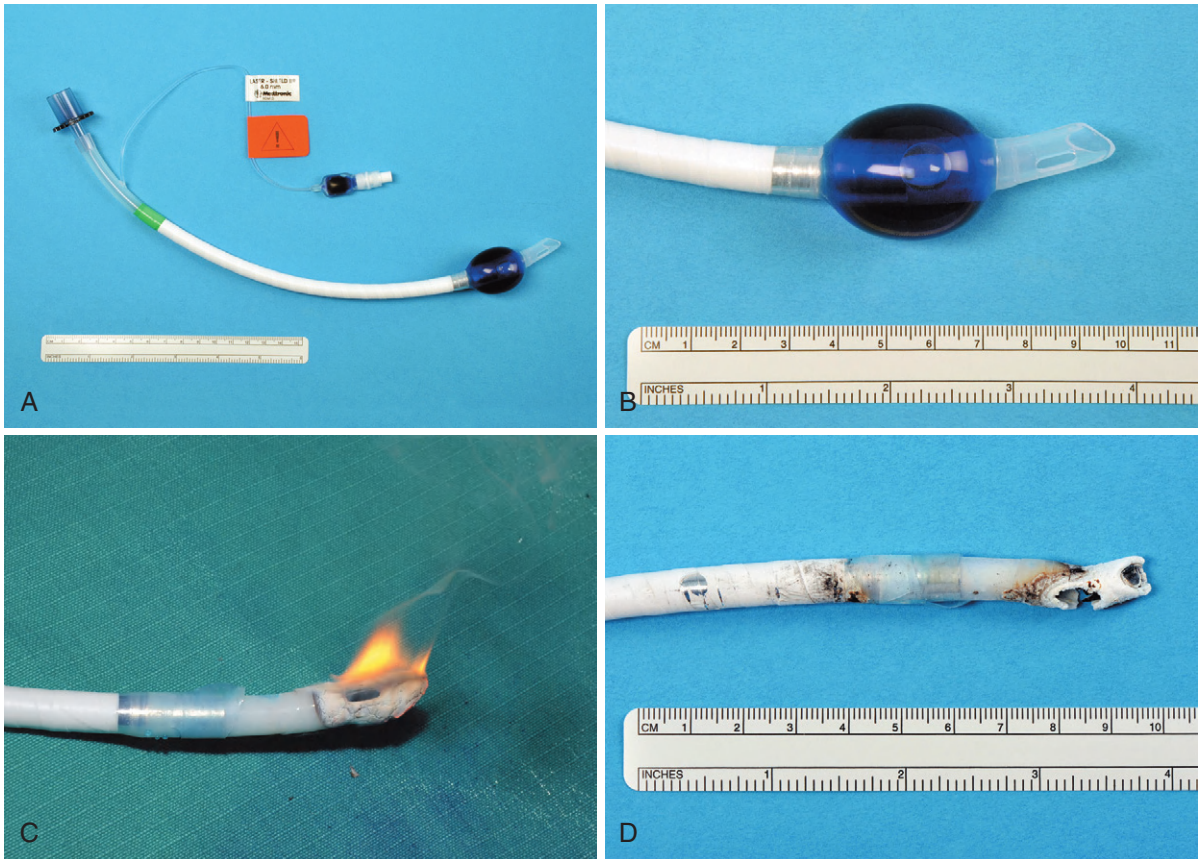

Figure 40-25 Xomed Laser-Shield II endotracheal tube (Xomed Surgical Products, Jacksonville, FL). **A,** The proximal and distal ends of the silicon elastomer shaft and cuff are not protected. **B,** The laser-resistant aluminum foil tape can be seen proximal to the cuff. **C** and **D,** An airway fire occurred in the distal, unprotected area after a sustained, high-power CO_2 laser strike in 100% oxygen.

than the CO_2 or KTP. When the laser beam hits the Laser-Shield II Teflon, the reflective aluminum wrapping may be exposed, and it is possible for the beam to be reflected into the patient's tissue. The sizes of Xomed Laser-Shield II ETTs are given in Table 40-4.

e. MALLINCKRODT LASER-FLEX ENDOTRACHEAL TUBE

Mallinckrodt (Glens Falls, NY) Laser-Flex ETTs have corrugated stainless steel shafts. They are designed as a single-use item, and the manufacturer states that this type of ETT should be used only with the CO_2 and KTP lasers. The adult version of this ETT incorporates two PVC cuffs. The manufacturer suggests that the distal cuff can be used if the laser damages the proximal one. The adult tube's distal end, including its Murphy eye and the proximal 15-mm connector, is constructed from combustible PVC (Fig. 40-26). The Laser-Flex cuffs are inflated by means of two 1-mm-diameter PVC pilot tubes that are located on the inside of the ETT. An Nd:YAG or other laser fiber should never be inserted through this tube. Heyman and colleagues found that prolonged laser impingement on the shaft of a Mallinckrodt Laser-Flex ETT could prevent cuff deflation, and they stressed the importance of aspirating the saline from the cuff in a slow, gentle manner.[115]

The adult sizes of Mallinckrodt Laser-Flex ETTs available with the double-cuff system are 4.5-, 5.0-, 5.5-, and 6.0-mm ID. Three pediatric sizes (3.0-, 3.5-, and 4.0-mm ID) of uncuffed Mallinckrodt Laser-Flex ETTs are also available. They are all stainless steel, except for a PVC 15-mm adapter. They are not equipped with Murphy eyes (Table 40-5).

Unlike the all-stainless-steel Norton ETT, the Mallinckrodt Laser-Flex ETT has an airtight shaft. However, the walls of both types of tubes are somewhat rough. In their product information for the uncuffed pediatric tubes, Mallinckrodt states, "Due to the spiral design of the tube,

TABLE 40-4

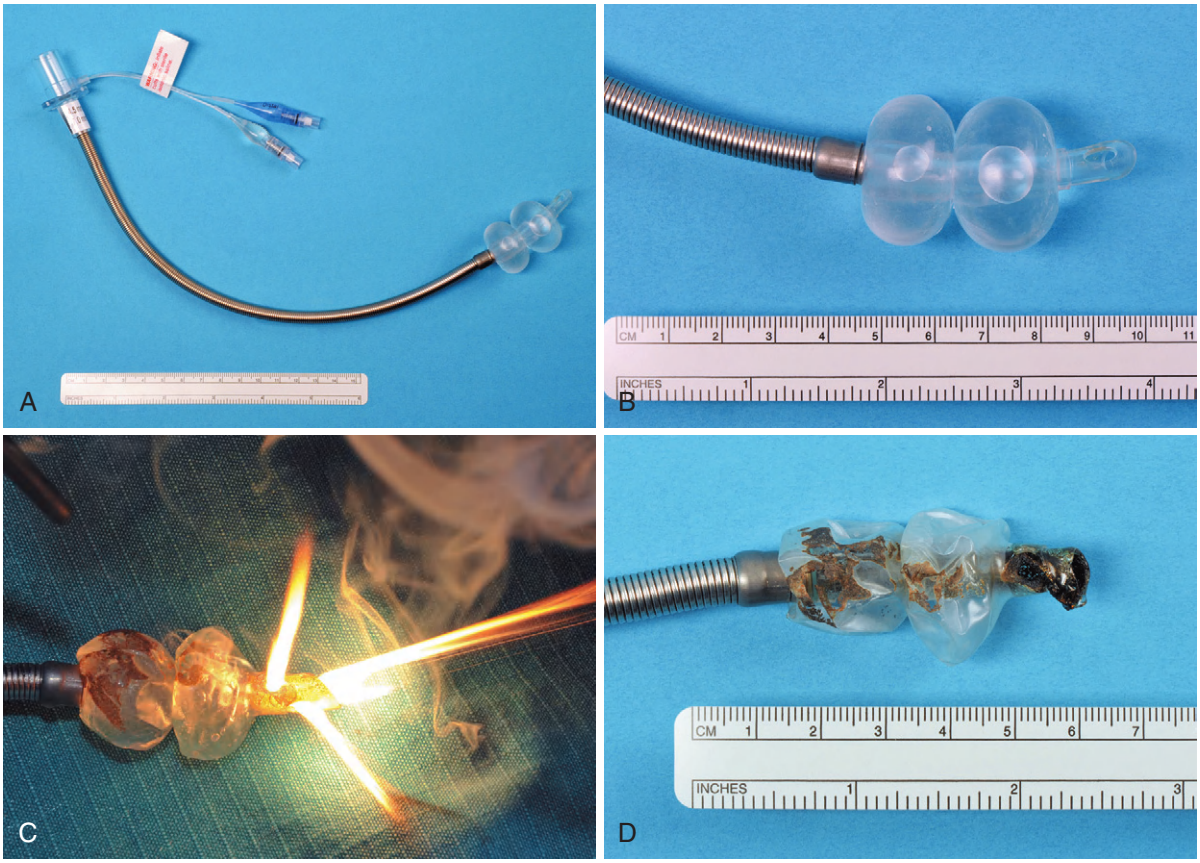

Figure 40-26 **A** and **B,** The Mallinckrodt Laser-Flex endotracheal tube (Covidien, Hazelwood, MO) has a corrugated stainless steel shaft and double cuff filled with saline. **C** and **D,** An airway fire occurred in the distal, unprotected area after a sustained, high-power CO_2 laser strike in 100% oxygen.

the airflow resistance for a given size will be approximately equal to a PVC tube, which is 0.5 mm smaller." They add, "Due to the bore size of the tube, patients should be monitored closely to guard against overinflation of the respiratory system and a build-up of expiratory gases."[116]

Sosis and coworkers studied the resistance to CO_2 laser radiation of size 4.5-mm-ID Mallinckrodt Laser-Flex ETTs.[117] The tubes were positioned horizontally on a stainless steel tabletop covered with a wet towel. An oxygen flow of 5 L/min passed through the tubes as a Sharplan (Tel Aviv, Israel) model 734 CO_2 laser was aimed at an ETT's shaft. A laser power setting of 35 W was used with a beam diameter of 0.6 mm. This resulted in a power density of 13,400 W/cm^2. The laser, set to the continuous mode of operation, was activated for 90 seconds or until combustion occurred. Blowtorch combustion occurred in one of five Laser-Flex ETTs studied. However, when human blood was applied to the shafts of four 4.5-mm-ID Mallinckrodt Laser-Flex ETTs, blowtorch combustion occurred in all cases.

In another study, Sosis and Dillon noted that there is less danger of a reflected laser beam causing damage when the Mallinckrodt Laser-Flex ETT is used compared with foil-wrapped ETTs.[118] In an evaluation of the Laser-Flex ETT with the Nd:YAG laser, Sosis found that the shaft of the Laser-Flex ETT could be ignited in all cases by the Nd:YAG laser when operated at high power.[97] Clinical Laser Monthly reported the occurrence of an airway fire during a case in which a Mallinckrodt Laser-Flex ETT was used during a laser excision of vocal cord polyps.[119] They stated that the patient had minor burns. They reported that, at the time of the fire, the cuffs of the ETT were not inflated with saline as recommended by the manufacturer.

f. SHERIDAN LASER-TRACH ENDOTRACHEAL TUBE

The Sheridan (Argyle, NY) Laser-Trach ETT is a single-use, red rubber tube that has a spiral-wrapped, nonflammable, embossed copper foil from cuff to the proximal end of the tube. The copper foil is covered by an outer, absorbent fabric. The company recommends saturating the outer layer with sterilized isotonic saline before use, and it must remain saturated during the procedure, because a laser strike on a dry outer coating of fabric will produce a fire.

The outer covering reduces heat buildup and must be vaporized before the copper foil is reached. The Sheridan Laser-Trach is recommended only for use with CO_2 and KTP lasers. The outer fabric coating adds additional size to any given internal diameter and these tubes are therefore relatively large compared to other laser-resistant tracheal tubes.

Sosis and associates compared 6.0-mm-ID Sheridan Laser-Trach ETTs with plain (bare) Rüsch red rubber ETTs of the same internal diameter.[120] Five liters per minute of oxygen flowed through the tubes being studied. The tubes were subjected to continuous radiation at 40 W from a Sharplan CO_2 laser or 40 W of continuous output from a Laserphotonics (Orlando, FL) Nd:YAG laser. The Nd:YAG laser radiation was propagated by a 600-µm fiber bundle. Each type of laser was directed perpendicular to the ETT being studied. The laser's output was continued until a blowtorch fire occurred or 50 seconds elapsed. No ignition occurred after 60 seconds of CO_2 laser fire to the shafts of eight Sheridan Laser-Trach ETTs tested. However, blowtorch ignition of all eight bare rubber ETTs tested occurred after 0.87 ± 21 (mean ± SD) seconds of CO_2 laser fire. Nd:YAG laser contact with the Sheridan copper and fabric-covered rubber ETTs resulted in perforation and blowtorch ignition in all tubes tested after 18.79 ± 7.83 seconds. This was significantly ($P < 0.05$) longer than the 5.45 ± 4.75 seconds required for blowtorch ignition of all eight plain red rubber ETTs tested with the Nd:YAG laser.

It was concluded that under the conditions of the study, the Sheridan Laser-Trach ETT was resistant to CO_2 laser radiation. It is not recommended for use with the Nd:YAG laser. Table 40-6 lists the sizes of the Sheridan Laser-Trach ETTs available.

g. LASERTUBUS ENDOTRACHEAL TUBES

Lasertubus (Rüsch, Duluth, GA) is a laser-resistant ETT with a shaft made of soft white rubber and a laser guard approximately 17 cm long, consisting of a Merocel sponge and silver foil with a double cuff. A cuff within a cuff arrangement exists and the sponge surface should be soaked to reduce the risk of an airway fire in a manner similar to that for the Sheridan Laser-Trach. According to the manufacturer, the Lasertubus offers resistance to all types of medical lasers, such as argon, Nd:YAG, and CO_2, with wavelengths ranging from 488 to 1060 nm. Sosis and colleagues evaluated the Rüsch Lasertubus in vitro.[121]

Jacobs and colleagues reported crimping of the Lasertubus, resulting in hypoxemia in a patient.[122] After placement of the Lasertubus, the surgeon extended the patient's head and neck and within 30 seconds, peak inspiratory pressures increased, oxygen saturation decreased, and no end-tidal CO_2 was evident. Immediate direct laryngoscopy confirmed that the ETT was correctly placed. On inspection, no kinks or obvious obstruction was seen. Ultimately, the laser tube was removed and the patient reintubated with a PVC ETT. The patient's oxygen saturations returned to 100%. On inspection of the Lasertubus, the tube had crimped under the tape. Although this was a small defect not obvious to cursory inspection, it resulted in complete obstruction to airflow. The investigators then experimented by bending unused laser tubes and found that a weakness within the wall of the tube remained, predisposing to crimping with minimal force and producing complete obstruction to airflow.[122]

B. Oxidant Source Considerations

1. Effect of Anesthetic Gases on Endotracheal Tube Flammability

The anesthetic gases used during airway laser surgery can profoundly influence combustibility. Nitrous oxide should never be considered an inert gas during laser airway surgery. Although nitrous oxide cannot support life, it can readily decompose into oxygen, nitrogen, and energy according to the following equation:

$$N_2O = N_2 + \tfrac{1}{2}\, O_2 + \text{energy}$$

In an experiment analogous to one with oxygen, a glowing match thrust into a vessel containing nitrous oxide bursts into flames. Nitrous oxide supports combustion to approximately the same extent as oxygen, and the addition of nitrous oxide in an attempt to dilute oxygen makes no difference to the flammability.[123]

Chilcoat and coworkers stressed that the reduction in oxygen concentration on dilution with nitrous oxide did not provide any additional safety when performing laryngeal laser surgery.[124] They recommended the use of either nitrogen, air, or helium when it was desired to reduce the oxygen concentration in anesthetic gas mixtures to levels of 30% or less for laser surgery.[124] Wolf and Simpson showed that nitrous oxide and oxygen are linearly additive in their ability to sustain combustion.[125] Nitrous oxide should not be considered safe, and careful consideration is required before using it with laser surgery.

Helium and nitrogen are inert gases, and when added to oxygen, they can delay ETT flammability (Table 40-7). Pashayan and Gravenstein and Osoff found that helium was more protective than nitrogen in retarding

TABLE 40-7
Physical Properties of Helium and Nitrogen at 26° C

Physical Properties	Helium	Nitrogen
Thermal conductivity (cal (sec•cm^2 °C•cm^{-1}•10^{-6})$^{-1}$)	360.36	62.40
Thermal capacity (cal•g^{-1}•K^{-1})	1.24	0.249
Density (g•L^{-1})	0.179	1.25
Thermal diffusivity (cm^2•sec^{-1})	1.621	0.199

From Pashayan AG, Gravenstein JS: Helium retards endotracheal tube fires from carbon dioxide lasers. *Anesthesiology* 62:274, 1985.

laser-ignited ETT fires.[110,126] The protective effect of helium is probably due to its high thermal diffusivity (i.e., quantity of heat passing through 1 cm^2 of cross-sectional area per unit of time) or thermal conductivity (i.e., time rate of transfer of heat by conduction). Presumably, helium diffusivity prevents a rise in temperature around the site of laser exposure, preventing the laser-irradiated ETT from reaching its temperature of spontaneous ignition.

Pashayan and Gravenstein studied the CO_2 laser–induced combustibility of 2-cm segments of PVC ETTs in various oxygen, helium, and nitrogen environments.[126] At oxygen concentrations of 30% and 40%, the mean time to ignition with nitrogen was significantly shorter than the time for the same concentration of oxygen in helium. Pashayan and Gravenstein concluded that helium in concentrations of 60% or greater delayed CO_2 laser–induced combustion of PVC ETTs if the laser power output was 10 W or less.[126] They also concluded that the radiopaque barium stripe on the PVC ETT was more combustible than the clear portions of the ETT and that they should be positioned away from the laser. Reflected beams may reach a stripe that appears to be out of the direct line of sight, and using an ETT without such stripes is preferred.

Ossoff compared the incendiary characteristics of three ETTs in various oxygen concentrations diluted with either helium or nitrogen using a CO_2 laser. They found that helium was better than nitrogen as an inert mixture with use of the CO_2 laser to decrease flammability. They also showed that the safest anesthetic gas mixture was 30% oxygen in helium.[110]

Al Haddad and Brenner studied the combustion of 1- to 2-inch PVC ETT segments with the KTP laser and CO_2 laser in helium-oxygen and nitrogen-oxygen atmospheres.[127] They compared these two lasers because of their different wavelengths and penetration characteristics that are commonly used in airway laser surgery. The CO_2 laser mean ignition time in helium was prolonged compared with nitrogen ($P < 0.001$), whereas increasing the oxygen concentration reduced the ignition time for both nitrogen and helium. With KTP, there was no significant difference for ignition among the five groups of oxygen concentrations or between nitrogen and helium. Al Haddad and Brenner reconfirmed that helium, as part of the mixture with 30% oxygen, is safest for the CO_2 laser but concluded that the use of helium instead of nitrogen conferred no added safety during KTP laser surgery.

Simpson and colleagues determined the flammability of four types of ETTs in mixtures of helium and oxygen or nitrous oxide compared with mixtures of nitrogen and oxygen or nitrous oxide.[128] The ETTs were initially ignited in oxygen and nitrogen, and the nitrogen was quickly discontinued and replaced with helium. The helium concentration was increased until the candle-like flame on the ETT was extinguished. The oxygen concentrations just before the flame's extinction with helium were defined as the *oxygen/helium index of flammability* by the researchers. A similar experimental design was used with mixtures of nitrogen and oxygen until the propane torch–induced combustion of the four types of ETTs was extinguished. This was defined as the *oxygen/nitrogen index of flammability*. Next, the oxygen was replaced by nitrous oxide, and the procedure was repeated to determine the *nitrous oxide/helium* and *nitrous oxide/nitrogen indices of flammability*. The indices of flammability of each type of ETT studied were averaged, and the results were compared using Bonferroni corrected *t*-tests. These results show that the PVC ETT is flammable in 27.4% oxygen with the remainder consisting of helium and in 25.4% oxygen with the remainder nitrogen. In all cases, the oxidant oxygen/helium values were statistically significantly higher than the oxygen/nitrogen values for the same type of ETT ($P < 0.05$). The oxidant nitrous oxide/helium indices were statistically higher than the nitrous oxide/nitrogen indices for all except the Xomed ETT.

Simpson and colleagues observed that the differences between helium and nitrogen indices determined in this study were not clinically significant. For example, for a PVC ETT, the difference between 27.4% oxygen in helium and 25.4% oxygen in helium needed for combustion is very small. Their study also showed that the PVC ETTs were less flammable than the red rubber, silicon, and Xomed ETTs.

In summary, oxygen and nitrous oxide support combustion very well; dilution of oxygen by nitrous oxide makes no difference to the flammability and should be avoided; helium and nitrogen are inert gases, and their use can reduce the risk of an airway fire; and helium was better than nitrogen as an inert mixture with the CO_2 laser, but this difference was not clinically significant. Moreover, in clinical practice, administration of air and oxygen is most frequently used during laser airway surgery because most anesthesia machines do not allow the delivery of helium. The oxygen concentration should be kept as low as clinically feasible while the laser is in proximity to the tube.

2. Flammability Limits of Potent Inhaled Anesthetics

In 1850 in Boston, Massachusetts, the first recorded fire occurring in the operating theater was reported during facial surgery. With the use of ether, acetylene, ethylene, and cyclopropane, many more reports followed.[129] The range of flammability of potent inhaled anesthetics used in modern practice is well above the alveolar concentrations that would be applied to patients in clinical practice.

TABLE 40-8
Minimum Flammable Concentrations of Halothane, Enflurane, and Isoflurane

Anesthetic Agent	MFC of Agent in 20% O_2/Remainder N_2O (%)*	MFC of Agent in 30% O_2/Remainder N_2O (%)*
Halothane	3.25	4.75
Enflurane	4.25	5.75
Isoflurane	5.75	7.0

*The minimum flammable concentration (MFC) was determined by igniting each anesthetic in a mixture of 20% or 30% oxygen (O_2,), with the remainder composed of nitrous oxide (N_2O).
Adapted from Leonard PF: The lower limits of flammability of halothane, enflurane, and isoflurane. *Anesth Analg* 54:238, 1975.

Leonard,[130] in investigating the lower limits of flammability of halothane, enflurane, and isoflurane, observed that halogenation rendered these compounds less flammable but might not prevent their combustion under all circumstances. He found that it was possible to ignite a mixture of 4.75% halothane in 30% oxygen with the remainder composed of nitrous oxide (Table 40-8). In 20% oxygen with the remainder nitrous oxide, halothane concentrations greater than 3.25% were combustible. In oxygen–nitrous oxide mixtures of 20% and 30% oxygen, enflurane could be ignited at concentrations greater than 4.25% and 5.75%, whereas isoflurane required 5.25% and 7.0%, respectively. These values were obtained under laboratory conditions designed to encourage flammability. A closed combustion vessel was used that contained no water vapor, CO_2, or nitrogen. Ignition was initiated with a 15-kV transformer that delivered a 60-mA current across a 0.25-inch gap. However, because the spark duration was not specified, the total energy delivered could not be calculated. The ignition power used (900 W) was, however, higher than the maximum power output delivered by most electrosurgical equipment. Leonard observed that the energy used in this experiment was much greater than that of a static discharge in the operating room. He concluded that even if the fraction of nitrous oxide administered to the patient exceeds 70%, the lowest flammable concentration of each of the three volatile halogenated anesthetic agents is above that which would be used clinically, except perhaps at the beginning of an inhalation induction.

A study by Pashayan and Gravenstein showed that the addition of 2% halothane to a mixture of 40% oxygen and 60% helium significantly decreased the mean time to combustion of PVC ETT segments that were subjected to CO_2 laser radiation.[126] Ossoff and colleagues found that the addition of 2% halothane significantly retarded the ignition of Rüsch red rubber ETTs in atmospheres of 30%, 40%, and 50% oxygen–balance helium at power settings of 10, 15, and 20 W.[95]

The ratio (3.3) of the percentage of desflurane at the lower limits of flammability in 70% nitrous oxide to the minimum alveolar concentration (6%) is not markedly different from what Leonard reported with enflurane (3.4), halothane (6.3), or isoflurane (6.1).[96,110] Sevoflurane is considered to be nonflammable over the entire anesthetizing concentration range in the presence of air, oxygen, and nitrous oxide.[96,131]

C. American Society of Anesthesiologists Practice Advisory for the Prevention and Management of Operating Room Fires

In 2008, a report by the American Society of Anesthesiologists (ASA) Task Force on operating room fires published a practice advisory for the prevention and management of operating room fires.[1] Practice advisories are systematically developed reports that are intended to assist decision making in areas of patient care.[1] They are based on scientific literature, expert opinion, clinical feasibility data, open forum commentary, and consensus surveys. They are not intended as standards, guidelines, or absolute requirements and can be adopted, modified, or rejected according to clinical needs and constraints.[1] This practice advisory looked at operating room fires, surgical fires, airway fires, and high-risk procedures.

The practice advisory defined an operating room fire as a fire that occurred on or near patients who are under anesthesia care and included surgical fires, airway fires, and fires within the airway circuit. A surgical fire was defined as a fire that occurred on or in a patient. An airway fire was a special type of surgical fire that occurred in a patient's airway and that may or may not include fire in the attached breathing circuit.[1] A procedure was designated as high risk when an ignition source came close to an oxidizer-enriched atmosphere (e.g., tracheostomy, laryngeal surgery).

The task force developed the advisory by a seven-step process that involved consensus on the criteria for evidence; systematic review of originally published, peer-reviewed studies; expert opinions of consultants asked to participate in surveys on the effectiveness of various strategies for fire prevention, detection, and management and comment on a draft of the advisory; comments of active members of the ASA on the advisory; open forum discussions at a major national meeting; survey of consultants on the feasibility of implementing the advisory; and all available information that was used to build consensus within the task force to formulate the advisory statements

The ASA Task Force's primary findings commented on education, operating room fire drills, preparation for every case, and prevention and management of operating room fires. The anesthesiologist should collaborate with all members of the procedure team throughout the procedure to minimize the presence of an oxidizer-enriched atmosphere in proximity to an ignition source.[1]

For all procedures, surgical drapes should be configured to minimize the accumulation of oxidizers (i.e., oxygen and nitrous oxide) under the drapes and to keep them from flowing into the surgical site. Flammable skin prepping solutions should be dry before draping. Gauze and sponges should be moistened before use near an ignition source.[1]

For high-risk procedures, the anesthesiologist should notify the surgeon whenever there is a potential for an ignition source to be in proximity to an oxidizer-enriched atmosphere or when there is an increase in

oxidizer concentration at the surgical site. Any reduction in supplied oxygen to the patient should be assessed by monitoring pulse oximetry and, if feasible, inspired, exhaled, and delivered oxygen concentrations.[1]

For laser procedures, a laser-resistant ETT should be used. The laser-resistant ETT used should be chosen to be resistant to the laser used for the procedure (e.g., CO_2, Nd:YAG, argon, erbium:YAG, KTP). The ETT cuff of the laser tube should be filled with saline and colored with an indicator dye such as methylene blue.[1]

Before activating a laser, the surgeon should give the anesthesiologist adequate notice that the laser is about to be activated.[1] The anesthesiologist should reduce the delivered oxygen concentration to the minimum required to avoid hypoxia, stop the use of nitrous oxide, and wait a few minutes after reducing the oxidizer-enriched atmosphere before approving activation of the laser.[1]

For cases involving an ignition source and surgery inside the airway, cuffed tracheal tubes should be used when clinically appropriate.[1] The anesthesiologist should advise the surgeon against entering the trachea with an ignition source (e.g., electrosurgery unit).

Before activating an ignition source inside the airway, the surgeon should give the anesthesiologist adequate notice that the ignition source is about to be activated. The anesthesiologist should reduce the delivered oxygen concentration to the minimum required to avoid hypoxia, stop the use of nitrous oxide, and wait a few minutes after reducing the oxidizer-enriched atmosphere before approving the activation of the ignition source.[1] In some cases (e.g., surgery in the oropharynx), scavenging with suction may be used to reduce oxidizer enrichment in the operative field.[1]

For a fire in the airway or breathing circuit, remove the ETT as fast as possible, stop the flow of all airway gases, remove all flammable and burning materials from the airway, and pour saline or water into the patient's airway.[1] If the airway or breathing circuit fire is extinguished, reestablish ventilation by mask, avoiding supplemental oxygen and nitrous oxide, if possible. Extinguish and examine the ETT to assess whether fragments were left in the airway. Consider bronchoscopy (preferably rigid) to look for ETT fragments, assess the injury, and remove residual debris. Assess the patient's status and devise a plan for ongoing care.[1]

D. Management of an Airway Fire

Many factors must be considered when an airway fire occurs. All operating room personnel must be prepared for the possibility of an airway fire during laser endoscopic surgery. If an airway fire occurs, sterile isotonic saline or water should be immediately available in a 30- or 60-mL syringe. Another laser and PVC ETT should be available. A plan of action should be rehearsed by operating room personnel so that rapid action can be taken if a fire occurs.

Schramm and colleagues discussed immediate management of an airway fire.[132] The management protocol calls for immediate removal of the ETT.[132] Sosis wrote a laser airway fire protocol in which certain steps should be taken simultaneously by the anesthesiologist and surgeon (Box 40-1).[133] In the event of an airway fire, the protocol calls for immediate cessation of ventilation and turning off of all anesthetic gases, especially oxygen, by disconnecting the hose from the common gas outlet, detaching the ETT from the anesthetic circuit, or clamping the ETT or turning off the flow meters. At the same time, the flames should be extinguished with a sterile saline or water solution. Presuming an easy airway, the protocol calls for the ETT to be removed immediately because it no longer provides an airway and may be on fire. After the ETT has been removed and the fire completely extinguished, the patient's lungs should be ventilated with 100% oxygen by bag and mask.

Box 40-1 Laser Airway Fire Protocol

- Cease ventilation and turn off all anesthetic gases, including oxygen.*
- Extinguish flames with a saline solution.*
- Remove endotracheal tube (ETT) after deflating cuff,* and ensure the whole ETT has been removed.
- Ventilate the patient's lungs by mask after all burning material has been removed and extinguished.
- Examine the airway for burns and foreign bodies such as fragments of the ETT or packing materials.

*These steps should be taken simultaneously by the anesthesiologist and surgeon.
Adapted from Sosis MB: *Probl Anesth* 7:160, 1993.

Chee and Benumof described "a patient scheduled for an elective tracheostomy whose airway evaluation revealed an in situ 8-mm-ID PVC ETT, swollen lips, an edematous tongue protruding out of the mouth and an oropharynx filled with secretions."[134] General anesthesia was induced with 300 mg of intravenous propofol and maintained with 0.4% inspired isoflurane (Forane) and a 35% oxygen-air mixture. The vital signs remained stable. Electrocautery was used for coagulation by the surgeons. The patient was administered 100% oxygen immediately before insertion of the tracheostomy tube. Suddenly, the surgeons reported a blue flame shooting up vertically from the patient's neck. The breathing circuit was disconnected immediately from the ETT, and 20 mL of 0.9% saline was flushed in the ETT. The fire was extinguished promptly. The ETT was not removed because the ability to reintubate was uncertain. Despite a leak around the perforated cuff, the seal was sufficient to generate a peak inspiratory pressure of 20 cm H_2O. Meanwhile, the surgeons were able to insert a tracheostomy tube into the trachea. Fiberoptic bronchoscopy was performed in the operating room and postoperatively revealed generalized upper airway edema consistent with prolonged intubation, no distal airway burn injury, and minimal burn injury to the proximal aspect of the tracheostomy site. The patient experienced no sequelae from the airway fire.

Each patient before laser surgery must be evaluated for risk of possible difficult intubation. If the patient is difficult to intubate or potentially a high risk for difficult intubation and an airway fire occurs, the patient will still be difficult to intubate. In these circumstances, the risk of removing the ETT and not being able to reestablish an airway outweighs the risk of leaving the tube in after the airway fire is extinguished. Van Der Spek and

coworkers suggested that if the patient is not easy to intubate,[135] a long stylet can be passed through the existing tube before removing it to facilitate the passage of a new one. Chee and Benomuf also suggested that the ETT can serve as a conduit for a tube exchanger.[134] For reintubation, an airway exchange catheter is placed through the ETT with the assistance of a laryngoscope, if possible, to facilitate the passage of a new ETT over the airway exchange catheter. To minimize the risk of failing to pass an ETT over the airway exchange catheter, the operator can use a relatively small ETT over a relatively large airway exchange catheter. The airway exchange catheter allows ventilation, which allows time for an alternative reintubation strategy, such as a surgical airway or FOB.[136]

After the airway is reestablished, the extent of the airway damage should be assessed. Foreign bodies (e.g., pieces of tube, metal foil, pledgets) should be removed. This may entail fiberoptic bronchoscopy through an ETT or rigid bronchoscopy. Careful clinical judgment must be used to decide whether to extubate. Extensive burns should be managed with controlled ventilation of the lungs through an ETT or tracheostomy. The use of antibiotic and steroids should be considered if burns are severe. All inhaled gasses should be humidified.

V. AIRWAY PATHOLOGY

Patients presenting for laser airway surgery range from young, otherwise fit, and healthy individuals with minor vocal cord lesions with no anticipated airway problems to elderly patients with advanced glottic carcinoma, stridor, and significant airway compromise. An understanding of the different types of pathology seen and the use of lasers for their resection and removal is useful.

1. Nodules are benign lesions of the vocal fold (Fig. 40-27). They can be bilateral and are usually caused by vocal abuse. They can be resected by fine surgical instruments augmented by a laser.
2. Polyps are benign lesions of the vocal fold (Fig. 40-28). They are common in adults, are usually unilateral, and can be resected surgically augmented by a laser.

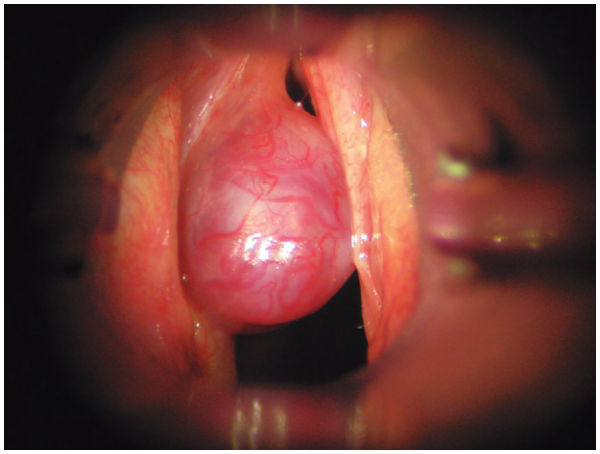

Figure 40-28 Large vocal fold polyp.

3. Cysts are benign lesions of the vocal folds (Fig. 40-29). They are commonly seen in professional voice users. They are caused by obstruction of a glandular duct, resulting in a mucous retention cyst. Surgery involves careful resection and may involve a laser.
4. Granulomas are benign lesions induced by healing granulomatous tissue that develops after microtrauma. They are usually found on the posterior third of the vocal process after trauma during intubation or extubation. Removal involves surgical instruments augmented by a laser.
5. Papillomas of the vocal folds are caused by human papillomavirus infection (Fig. 40-30). Most are benign lesions, but they rarely can undergo malignant transformation. In adults, hoarseness is usually the main symptom, although in severe cases, significant airway compromise with stridor can occur. In children, any airway obstruction has a significant effect on airflow, and near-total airway obstruction can occur. Laser resection usually involves a CO_2 laser, and after surgery, the airway obstruction and airflow are improved. Papillomas can recur, and some patients require repeated laser surgery at 1- to 12-month intervals.

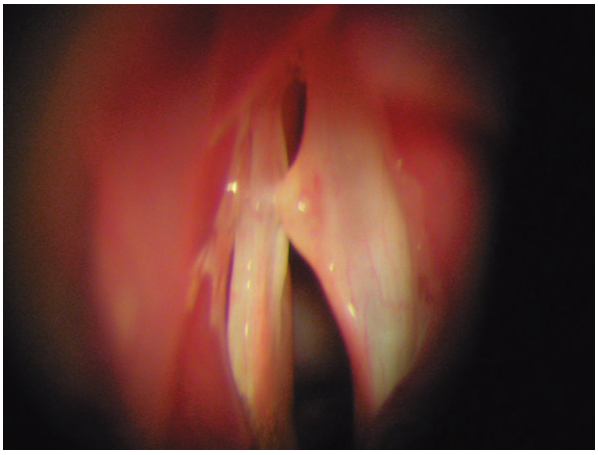

Figure 40-27 Nodule of right vocal fold.

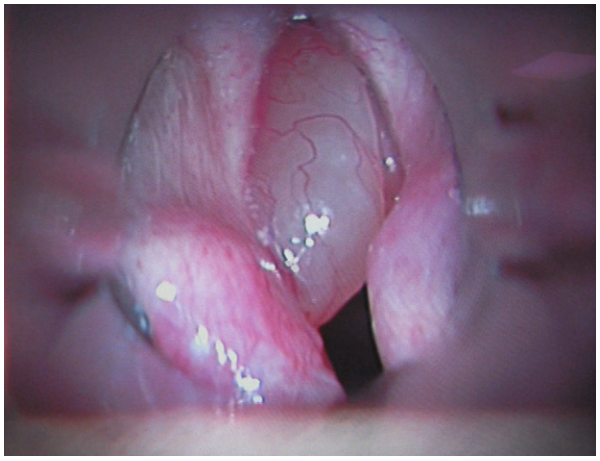

Figure 40-29 Vocal fold cyst.

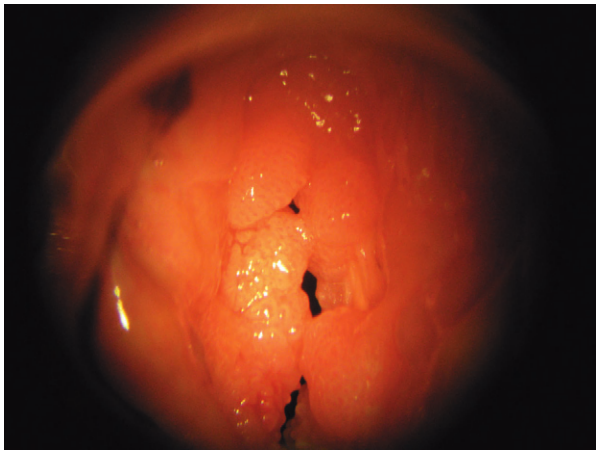

Figure 40-30 Extensive vocal fold papilloma.

6. Malignant tumors of the vocal cord are usually unilateral and occur mainly in the middle third of the vocal fold. Eighty percent are found in men 45 to 65 years old. More than 90% of patients are smokers with a high alcohol intake. Treatment depends on tumor staging and involves local resection, radiotherapy, transoral laser resection, hemilaryngectomy, or laryngectomy.
7. Other lesions on the vocal cord are caused by hemangiomas, submucous hemorrhage, Reinke's edema, chronic laryngitis, amyloidosis, sarcoidosis, tuberculosis, and rheumatoid arthritis. These lesions can be resected by a laser and any subsequent bleeding controlled with a laser.

VI. ANESTHETIC TECHNIQUES FOR LASER AIRWAY SURGERY

A. Laryngeal Mask Airway

The LMA was first described in 1983.[137] It is used in routine anesthetic practice and for management of the difficult airway.[119] The LMA and reinforced flexible laryngeal mask airway (fLMA) have been used for awake and anesthetized patients undergoing fiberoptic bronchoscopy for diagnostic and airway evaluation.[138,139] It has also been used for laser pharyngoplasty.[140] Carinal obstruction was managed using a combination of Nd:YAG laser therapy through a FOB inserted through an LMA and subsequent Nd:YAG through an FOB with a rigid bronchoscope.[141] Other reports described the use of a LMA and high-frequency jet ventilation for resection in tracheal surgery.[142]

The LMA and fLMA are constructed from silicon rubber that contains silica filler, which provides high-temperature resistance and some flame-retardation ability. The same material has been used to manufacture laser-resistant ETTs.[137] Pennant and colleagues did a limited study of the incendiary characteristics of the LMA and fLMA, suggesting that they are resistant to CO_2 lasers at power densities below 1.25 to 2.35 $\times$ 10^3 W/cm^2, but 1.2 $\times$ 10^4 W/cm^2 produced immediate ignition.[143] Brimacombe looked at the incendiary characteristics of the LMA and fLMA with the CO_2 laser and compared them with two standard PVC ETTs: Mallinckrodt reinforced armored tube and Mallinckrodt RAE tube. Continuous firing led to light smoke production and penetration of the tube in 20 to 30 seconds. Both PVC tubes were penetrated in 0.5 to 2 seconds, and ignition occurred at 2 to 6 seconds with 100% O_2 and 2 to 8 seconds with an O_2-N_2O mixture.[144]

At intermediate power density (4.7 $\times$ 10^3 W/cm^2), LMA and fLMA were penetrated at 0.5 to 2 seconds and ignited in 2 to 5 seconds with 100% O_2 and an O_2-N_2O mixture. At the highest power setting (9.8 $\times 10^3$ W/cm^2), all four (i.e., LMA, fLMA, and two PVC ETTs) ignited in 0.05 to 0.1 seconds with 100% O_2. The LMA and fLMA are more resistant to CO_2 laser fire than standard PVC tubing. The CO_2 laser at power densities below 2.35 $\times$ 10^3 W/cm^2 appears to be safe with use of the LMA and fLMA.

Pandit and colleagues showed that at laser outputs and distances of the KTP fiber tip from the fLMA normally encountered in clinical practice, the fLMA was not penetrated or ignited.[145] Keller and associates looked at the standard LMA (silicon based) and fLMA (silicon based with metal wire) and at a disposable LMA (PVC based) and intubating LMA (silicon and steel based) and PVC-based ETTs using KTP and Nd:YAG lasers at two power densities used commonly in airway surgery (570 and 1140 W/cm^2).[146] Each airway device was fixed to a table in room air and attached to a closed-circuit breathing system with 30% oxygen in air delivered at 3 L/min. The laser was fired at the same distance of 3 mm. They also evaluated the marked and unmarked parts of the airway device and the unmarked device after application of 0.1 mL of unclotted fresh human blood. They evaluated the cuff with air or undiluted methylene blue dye.

There was no ignition of any airway device. The impact sites of the silicon-based LMA for both lasers revealed a layer of silica ash just like that found by Pandit and colleagues. The silicon-based tubes were less easily penetrated than the PVC-based tubes, except for the intubating LMA, which flared sooner than with the KTP laser at both densities. The disposable LMA cuff was more resistant to penetration than the silicon LMA cuff or PVC ETT. The cuffs filled with air were penetrated more rapidly than those with methylene blue.[99]

Pandit and Keller and their colleagues showed that the cuff was more vulnerable to a laser strike with the CO_2 and KTP lasers, especially when filled with air. Pandit filled the cuff with saline, and Keller filled the cuff with nondilute methylene blue, and both found increased resistance to the laser strike. The disadvantage of using saline in the cuff is that the manufacturers recommend filling the cuff only with air. It has been reported that if not all the saline is withdrawn from the cuff after use in the standard reusable LMA, the cuff may rupture during autoclaving.[147,148] Coorey and colleagues reported a technique in which they were able to empty the saline-inflated LMA reliably by a syringe without the plunger with the cuff held above the syringe to facilitate gravitational drainage. The cuff was then manually squeezed. The LMA with the syringe barrel attached was placed in a warming cupboard at 60° C for 12 hours. They found

that filling the LMA cuff with saline was a viable option for laser airway surgery.[149]

The other option is the disposable LMA, for which filling the cuff with saline is not a concern because it is used only one time. The only concern is that the disposable LMA shaft is more easily penetrated than the silicon-based LMA, but the disposable LMA cuff was more resistant to penetration than the silicon-based LMA or PVC ETT cuffs. When filled with methylene blue dye and with the Nd:YAG laser power density at 570 W/cm^2, none of the cuffs was affected after 30 seconds.[146]

B. Management of Anesthesia

Operations on the airway are unique in that the surgeon and anesthesiologist are working in the same area. This can be challenging, and the anesthesiologist has to allow the surgeon adequate exposure to any lesions within the airway and at the same time oxygenate the patient, remove CO_2, maintain anesthesia, prevent soiling of the tracheobronchial tree, and maintain safe conditions and prevent an airway fire.

An ideal laser airway technique would be simple to use; provide complete control of the airway with no risk of aspiration; control ventilation with adequate oxygenation and CO_2 removal; provide smooth induction and maintenance of anesthesia, provide a clear and motionless surgical field that is free of secretions; not impose time restrictions on the surgeon; not be associated with the risk of airway fire or cardiovascular instability; allow safe emergence with no coughing, bucking, breath holding or laryngospasm; produce a pain-free, comfortable, alert patient at the end of the operation; and be laser proof.

The ideal technique does not exist, and some of these ideal conditions conflict. The presence of a cuffed ETT provides control of the airway and prevents aspiration but may obscure a glottic lesion and is not laser safe. A cuffed laser tube provides some protection against laser-induced airway fires but has a greater external-to-internal diameter ratio and may obscure laryngeal lesions. Jet ventilation techniques require specialist equipment and knowledge and an understanding of their limitations, and they do not protect the airway from soiling.

Safe laser airway surgery requires an understanding of the airway pathology, its location within the airway, the type of laser used, the surgical requirements, and the patient's comorbidities. It is essential that careful communication and cooperation between anesthesiologist and surgeon takes place before, during, and after any procedure.

During laser airway surgery, Rontal and colleagues used a video monitor during all laser endoscopic procedures so that the entire operating room team could observe the procedure.[150] The use of a video monitor to observe the impact of the laser beam on tissues in shared airway procedures is used by many surgical units and allows the operating room nurses to anticipate the surgeons' needs and the anesthesiologist to communicate better, adjust the anesthesia accordingly, and act quickly if there is an airway fire (Fig. 40-31). Without a video monitor, only the surgeon can see the surgical site and the impact of the laser beam; vital seconds may be lost before the team recognizes an airway fire is happening, but it would have been obvious on a monitor screen. The presence of a video monitor has no disadvantage, but its absence may be detrimental, and some units regard it as a standard requirement for shared laser airway surgery.

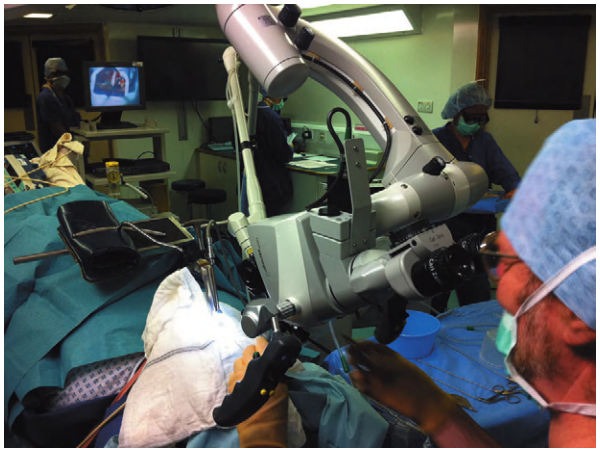

Figure 40-31 Video monitor allows all operating room staff to observe the procedure.

1. Preoperative Evaluation

The preoperative evaluation attempts to identify factors that may cause difficulty during the perioperative course and involves assessment with a thorough medical evaluation for all patients coming to surgery. Laser airway surgery is carried out on a wide spectrum of patients and airway pathologies. Some patients are young, fit, and healthy with no airway compromise and require laser removal of minor airway lesions. At the other end of the spectrum, some patients have significant tobacco and alcohol intake, cardiovascular and respiratory dysfunction, and large obstructing tumors of the airway. Laser airway surgery for cancer patients is often palliative and can be a high-risk procedure when patients present in a suboptimal state with nutritional and metabolic derangements and limited time for correction before the airway deteriorates. Optimizing nutritional, metabolic, cardiovascular, and respiratory parameters is the aim before any surgery, but in cases of critical airway obstruction, this may not be possible, and the anesthesiologist, surgeon, patient, and relatives need to be aware of and accept the increased risks.

At the end of the preoperative assessment, the anesthesiologist should have some idea of the size, mobility, and location of the lesion. Standard airway assessments to predict the ease of ventilation, visualization of the laryngeal inlet, and tracheal intubation should be performed. Airway pathology and its impact on airway management should be assessed. The severity and size of lesions at the glottic level are assessed by direct or indirect laryngoscopy, undertaken by surgeons in an outpatient setting, and a photograph or image of the findings is often added to the record. Information about subglottic and tracheal lesions is provided by chest radiography, computed tomography (CT), and magnetic resonance imaging (MRI). The size of the lesion gives an indication of potential airflow obstruction. Stridor indicates a

Box 40-2 Preoperative Evaluation

1. History of endoscopic procedures, previous difficulties, medical record, and chosen technique
2. Hoarse voice: occurs with minor vocal fold lesions and significant pathology
3. Voice changes: nonspecific symptom
4. Dysphagia: significant
5. Altered breathing position: significant
6. Inability to lie flat: significant
7. Difficulty breathing during sleep: significant
8. Stridor: significant
9. Stridor on exertion: suggests obstruction becoming critical
10. Stridor at rest: indicates critical airway obstruction
11. Inspiratory stridor: suggests extrathoracic airway obstruction
12. Expiratory stridor: suggests intrathoracic airway obstruction

significantly narrowed airway. In the adult, stridor implies an airway diameter of less than 4 to 5 mm, but the absence of stridor does not exclude a significantly narrowed airway (Box 40-2).

Very mobile lesions (e.g., multiple, large vocal cord polyps, papillomas) may cause partial airway obstruction after induction of anesthesia, but total airway obstruction is extremely uncommon. Airway obstruction is worse with a spontaneously breathing patient after induction of anesthesia because of the loss of supporting tone in the oropharynx and hypopharynx.

Supraglottic lesions, if mobile, can obstruct the airway or make visualization of the laryngeal inlet difficult. Subglottic lesions may allow a good view of the laryngeal inlet but cause difficulty during the passage of an ETT.

The recognition of a compromised or anatomically distorted upper airway is paramount in the preoperative assessment of these patients. For elective procedures, a detailed history, examination, and other investigations should be undertaken, but for more urgent procedures with severe airway compromise, investigations may not be possible. Patients' old anesthesia records should be available to obtain the history of prior intubations. The major concerns are as follows:

1. Airway or head and neck problems: The anesthesiologist should know the underlying pathology of the lesion, anatomic characteristics, and severity of obstruction. An extensive evaluation of the degree of airway obstruction should be undertaken. A history should be obtained of signs of airway obstruction possibly related to edema or tumor, such as obstructive sleep apnea, difficulty breathing, difficulty swallowing, shortness of breath, snoring, stridor, wheezing, or difficulty clearing secretions. The airway should be examined for the Mallampati classification, mouth opening, prognathia, size of the tongue, neck range of motion, prominent teeth, and tracheal deviation from external compression. The precise location and extent of the tumor should be defined by chest radiography, CT, and MRI.[151] However, the patient's general condition may preclude obtaining imaging. The test results should be reviewed for the luminal size of the trachea and tracheobronchial obstruction. These studies should include chest radiography (i.e., anteroposterior and lateral for possible pulmonary collapse and consolidation, presence of air-filled lung bullae, or pneumothorax), CT or MRI, flow-volume loops, and barium swallow.
2. Respiratory problems: The concerns are upper airway obstruction and coexisting pulmonary problems, such as a history of chronic obstructive pulmonary disease, emphysema, or newly diagnosed asthma; wheezing; and decreased exercise tolerance. Whether the patient requires home oxygen should be determined. Physical examination includes auscultation of the lungs for wheezing or decreased breath sounds and looking for clubbing or cyanosis. The examiner should review the chest radiograph, percent of oxygen saturation, baseline arterial blood gas determination, flow-volume loop, and pulmonary function tests to determine the amount of pulmonary reserve and involvement of the extrabronchial structures.
3. Cardiovascular problems: The concerns are related to potential cardioarterial disease. History of chest pain, shortness of breath with exertion, decreased exercise tolerance, and previous myocardial infarction or congestive heart failure are of interest. Examination includes auscultation of the heart for rate, rhythm, and heart murmurs and assessment of the lungs for rales. The examiner should look for jugular venous distention, for congestive heart failure, and for possible subclavian venous occlusion due to the tumor. Tests that may be needed are a 12-lead electrocardiogram, cardiac echocardiogram, dipyridamole (Persantine) thallium, and exercise stress test.
4. Other system problems: The gastrointestinal system should be assessed for aspiration potentials, such as hiatal hernia, acid reflux, nighttime cough, and obesity. Routine blood work should be done unless otherwise indicated.

The patient's physical status should be optimized before surgery. Many airway procedures can cause sustained hypertension and tachycardia, both of which stress the cardiovascular system. Patients should receive nothing by mouth according to the ASA recommendation or hospital policy.

2. Premedication

Premedication to reduce secretions and anxiety may be useful in patients with minor airway lesions but should be avoided in patients with severe airway compromise. An antisialagogue to minimize oral and tracheobronchial secretions may be given: 0.2 mg of glycopyrrolate intravenously or 0.4 mg intramuscularly or 0.4 to 0.5 mg of atropine subcutaneously or intramuscularly. Caution should be taken if the patient has difficulty mobilizing secretions because the antisialagogue thickens pulmonary secretions. Thick secretions may block narrowed airways further, may be difficult to cough out by the patient, and

may in extreme circumstances totally obstruct critically narrowed airways.

Any premedications given to patients should be given in the holding area of the operating room, where they can be monitored. During the preoperative visit, the anesthesiologist should attempt to allay the patient's fears. For patients with moderate obstruction, decreasing anxiety may be beneficial because quieter breathing results in decreased airway resistance. For patients with severely narrowed airways, respiratory depression must be avoided. Careful deliberation is needed before giving any anxiolytic or opioids or combination thereof, which can act synergistically in producing respiratory depression. Midazolam (0.5 to 1 mg intravenously, with repeated doses) may be given for anxiolysis but not for critically obstructed airways because a significant risk of total airway obstruction exists.

Patients should be monitored with a three- or five-lead electrocardiogram, depending on the cardiac history, pulse oximetry, capnography, oxygen analyzer, precordial stethoscope, peripheral nerve stimulator, and noninvasive blood pressure cuff. An invasive arterial blood pressure line should be considered for patients with cardiovascular instability to monitor closely hemodynamic changes and arterial blood gases intraoperatively.[152]

A difficult airway cart should be in the room that contains a complement of airway equipment and local anesthetics for topicalization. Airway equipment that should be available includes different laryngoscopes, oral and nasal airways, LMA, intubating LMA, fiberoptic scope, retrograde and cricothyrotomy kits, and jet ventilation. A rigid bronchoscopy and tracheostomy tray should also be in the room.

3. Induction and Maintenance of Anesthesia

a. GENERAL ANESTHESIA

The technique for induction and maintenance of general anesthesia for laser airway surgery is determined by the general condition of the patient, the location and size of the lesion, the planned surgical procedure, and most importantly, the degree of airway compromise. All patients with airway compromise should be considered as a possible difficult intubation, whereas not all patients with a difficult intubation have airway compromise.

When airway compromise is not an issue, most procedures are routine and uneventful with the use of most standard induction techniques. An intravenous induction technique is suitable for most benign and early malignant glottic lesions when airway obstruction is not present or anticipated. After intravenous induction of anesthesia and administration of neuromuscular blockade appropriate to the length of surgery, laryngoscopy is undertaken to visualize the larynx, establish laryngoscopy grade, and administer a local anesthetic. Confirmation of pathology is important because the disease may have progressed and the anesthesia plan may have to change.

When airway compromise is an issue, traditional teaching suggests any technique that uses inhalational induction and maintains spontaneous ventilation is safest in the presence of airway obstruction.[111,114] Spontaneous breathing has traditionally been thought of as critical with intrathoracic obstructive lesions of the large airways. During spontaneous breathing, large airways are stented open during inspiration by the negative intrathoracic pressure that is generated. This permits some inspired tidal volume to get past the obstruction. When the chest wall expands during inspiration, the negative pressure generated is beneficial in preventing collapse of the tumor mass onto the large airways and vessels. These two safeguards are removed when spontaneous ventilation ceases.

Traditional teaching for inhalational induction and maintenance of spontaneous ventilation in obstructed airways has been questioned. Inhalational induction for advanced laryngeal tumors with airway obstruction is difficult and challenging. Physiologic problems include a reduction in airflow with spontaneous ventilation, an increased collapsibility of the airway, increased work of breathing, critical instability at points of narrowing leading to further airway collapse, and a reduction in functional residual capacity.[113] Induction is slow with apneic periods, and episodes of obstruction are common. Controversy exists about the suitability of "taking over" the patient's own spontaneous ventilation with bag-mask ventilation. The advantage of retaining spontaneous ventilation throughout is the theoretical inherent advantage of this technique. However, taking over ventilation allows a suitable depth of anesthesia for laryngoscopy to be achieved quicker. This avoids the long periods of spontaenous ventilation while waiting for an adequate depth of anesthesia, during which the patient may become unstable.

Traditional teaching advices caution if muscle relaxants are used. The airway can collapse with loss of muscle tone, and this may not be overcome by positive-pressure ventilation, resulting in total loss of the airway. Traditional teaching advises that before abolishing the ability to breathe spontaneously by administering a muscle relaxant or inducing a deep plane of anesthesia, it is prudent to establish that patients can be ventilated with positive pressure by face mask.

The administration of a muscle relaxant provides optimal ventilation and intubating conditions. Calder and Yentis commented on the perceived safe practice of not giving muscle relaxants until face mask ventilation has been documented and argued the theoretical advantage is not fulfilled in practice.[153] They considered two studies and looked at the incidence and prediction of difficult and impossible mask ventilation in which no patient was awakened and suggested that when a patient has an obstructed airway,[154,155] it was not feasible to await awakening and something had to be done to ventilate the lungs before catastrophic desaturation occurred.[153]

General anesthesia is used in pediatric patients. In small children with airway obstruction, attempting bronchoscopic procedures with sedation alone is not recommended. General anesthesia using inhalation agents allows better airway control and permits the operator to concentrate on the procedure.[156] In a retrospective review of pediatric patients undergoing diagnostic bronchoscopic procedures in the intensive care unit with sedation, ketamine was associated with a 20% rate of adverse reactions. Complications were mostly in children younger than 3 years with severe underlying disease.[157]

A tubeless spontaneous respiration technique has been used for pediatric microlaryngeal surgery. It allows an unrestricted view and surgical access to the larynx. This can be accomplished by delivering inhalation agents proximal to the larynx or by using propofol. Halothane (0% to 5% at 4 to 10 L/min) is delivered by the suction channel of the microlaryngoscope. Propofol (2 mg/kg) as a bolus is followed by an infusion of 100 µg/kg/min. In pediatric microsurgery, satisfactory results were obtained in two groups of children using halothane or propofol.[158]

General anesthesia is preferred in most adults to the same extent. Airway control that is possible with general anesthesia is fundamental in situations of airway obstruction and severe respiratory distress. There is better control of the airway and easier clearance of blood and mucus with use of a rigid bronchoscope.[159] For the insertion of a rigid bronchoscope, general anesthesia is necessary.

Rigid bronchoscopy can be performed in a spontaneously breathing patient using an inhalation technique. This technique requires experience, particularly in the presence of significant airway obstruction. A deep plane of anesthesia is needed to prevent coughing. Laryngospasm or bronchospasm can complicate induction if the instrumentation is attempted too hastily. This can disastrously worsen the situation, causing total airway obstruction resulting in hypoxemia, hypotension, and trauma to the trachea. Because the uptake of any inhalation agent is delayed by airway obstruction, induction times are always longer than usual. Sufficient time must be spent making sure that the patient is "deep enough" for intubation. Judging the appropriate depth of anesthesia is often difficult. Excess anesthesia may result in hypoventilation in a spontaneously breathing patient.[160] Caution should be exercised in monitoring the patient when using inhalation agents at such critical periods. The concentration required for an adequate depth of anesthesia to permit instrumentation of the trachea may not be tolerated by the cardiovascular system, causing hypotension and hemodynamic instability. Consequently, the margin of safety for inhalation agents may be very narrow. This is especially true in infants and in elderly patients. In children, sevoflurane seems to cause fewer complications, such as dysrhythmias and laryngospasm, than halothane.

Patients with significant tracheal obstruction benefit from sitting up and receiving supplementary humidified oxygen. A coughing spell may critically exacerbate the obstruction and should be avoided. In the operating room glycopyrrolate (0.2 to 0.3 mg) may be helpful in controlling secretions, and midazolam (2 to 4 mg intravenously) may be used for sedation. If an inhalation induction is chosen, the patient is preoxygenated with 100% oxygen, gradually induced with sevoflurane, and allowed to breathe spontaneously. For total intravenous anesthesia, the patient is induced with a sleep bolus of 2 mg/kg of propofol followed by a propofol infusion of 100 to 150 µg/kg/min. Before administering a muscle relaxant, it has traditionally been thought prudent to establish the ability to ventilate the patient by positive pressure through a face mask, although this approach has been questioned.[153] Positive-pressure ventilation may become impossible in the presence of certain large lesions in the airway. Urgent measures are necessary when the situation deteriorates to acute central airway obstruction. An ETT may be inserted to bypass the obstruction. Positive-pressure ventilation and suctioning may not be enough in certain situations. Rigid bronchoscopy may be required urgently to force the tube and establish an airway under direct vision.[161]

Muscle relaxation is often necessary to hold a quiescent surgical field for laser excisions. Medium- or short-acting muscle relaxants are preferred. Mivacurium (0.2 to 0.25 mg/kg intubating dose, 3 to 15 µg/kg/min infusion), rocuronium (0.6 mg/kg), and cisatracurium (0.15 to 0.25 mg/kg) have been used. Anesthesia can be supplemented with fentanyl (bolus dose of 2 to 15 µg/kg, maintained at an infusion rate of 0.03 to 0.1 µg/kg/min) or remifentanil (bolus dose of 0.5 to1 µg/kg, maintained at an infusion rate of 0.1 to 0.4 µg/kg/min).

b. SEDATION AND TOPICAL ANESTHESIA

Selected adult populations undergoing flexible fiberoptic laser excision can be managed by experienced individuals with sedation and topical anesthesia. Topical anesthesia with sedation is suitable for adults who are cooperative and for a short endoscopy period with a flexible bronchoscope. This is a favored method for lesions in the middle or lower third of the trachea. Complications are rare. Bleeding seems the most life-threatening complication.[162]

Sedative drugs can decrease ventilation and should be used judiciously in small children and elderly patients. Two distinct mechanisms are accountable for this reduction: decreased respiratory drive and upper airway obstruction. Sedatives alter normal respiratory responses to hypercarbia and hypoxia, thereby decreasing the respiratory drive. Brief hypercarbia and acidosis that may develop under these circumstances are ordinarily inconsequential. However, airway obstruction is a real and more dangerous outcome of sedation because it can quickly lead to oxygen desaturation. Hypoxemia from airway obstruction can have devastating consequences.[163] The exact mechanism of upper airway obstruction during sedation or anesthesia is not clear. It may be caused by decreased muscular tone and increased collapsibility of the upper airway. Midazolam induces upper airway obstruction during deep sedation. Flumazenil relieves this obstruction in addition to reversing the sedative effects of midazolam.[71]

Introduction of additional obstruction to a patient with an airway that is already narrowed by a fixed lesion is fraught with danger. A perilous scenario can ensue, with progressively increasing obstruction resulting in total loss of the airway. Prompt measures must be undertaken to relieve the obstruction. They include asking the patient to take deep breaths, jaw thrust, chin lift, and insertion of an oral or a nasal airway. Chin lift or jaw thrust may not always relieve the obstruction. However, when these two maneuvers are combined with positive airway pressure, the pharyngeal airway is widened, counteracting airway narrowing.[164] If a procedure being performed under sedation becomes prolonged, additional,

unplanned drugs have to be administered, increasing the risk of excessive intraoperative sedation and of postoperative somnolence.

VII. ANESTHESIA MANAGEMENT FOR LARYNGEAL LASER SURGERY

Many laryngeal lesions are resected and removed with the aid of a laser, including papillomas, vocal cord cysts, vocal cord polyps, Reinke's edema, vocal cord granulomas, vocal cord microwebs, and scar tissue after intubation. For most of these lesions, airway obstruction is not significant, and several anesthesia techniques are appropriate. It is important that the preoperative assessment identifies the type and size of laryngeal lesion to establish the extent of airway compromise and establishes the general medical status of the patient. The exact anesthesia technique chosen is determined by the experience of the anesthesiologist, surgical preference and access, equipment available, type of laser used, duration of the procedure, type and vascularity of the lesion, and protection against airway soiling from blood and secretions. Two approaches are used: closed systems, in which a cuffed laser tracheal tube is used, and open systems, in which a cuffed laser tracheal tube is absent. Open systems use spontaneous ventilation or jet ventilation techniques.

The technique chosen for a procedure is not absolute and may have to change as surgical and anesthesia requirements change. For example, an open system using jet ventilation on a lesion thought to be relatively avascular may change to a closed system employing a cuffed laser tube if the lesion is bleeding and there is a risk of soiling the tracheobronchial tree. Conversely, a system employing a cuffed laser tube may have to change during surgery to an open system if the laser tube overlies a lesion, making surgery very difficult or impossible.

A. Laser Tube

Closed systems are familiar to all anesthesiologists and involve the placement of a laser tube. The different types of laser tubes and their relative laser-resistant properties have been discussed. Placement of laser tubes is routine, although care should be taken to prevent traumatizing the laryngeal lesion as the laser tube is passed through the glottis and into the trachea. After the laser tube is in position and the cuff inflated, there is protection of the lower airway from blood and secretions. Routine control of the airway and ventilation are established, and because the system is closed, there is little danger of pollution of oxygen or volatile agents unless the cuff is compromised. It is important to appreciate immediately any cuff compromise due to a laser strike because it causes oxygen and volatile agent leaks around the laser tube, increasing the fire risk. All laser tubes have a greater outer diameter for any given internal diameter because of their laser-resistant coverings, and this may limit surgical access and visualization of laryngeal lesions. Because the surgeon requires adequate exposure, small laser tubes usually are placed, which can lead to higher inflation pressures.

B. Spontaneous Ventilation and Insufflation Techniques

Open systems can be used during anesthesia for laser procedures on the vocal cords, and spontaneous ventilation techniques have been used in adults and in children. Spontaneous ventilation techniques with insufflation are particularly suitable for infants and children in whom it is not possible to pass a tube past a lesion or when a laser tube obscures the lesion.

Spontaneous ventilation and insufflation techniques are useful in the removal of foreign bodies, evaluation of airway dynamics (e.g., tracheomalacia), and laser airway surgery. The technique requires a spontaneously breathing patient and provides a clear view of an unobstructed glottis. Insufflation of anesthetic gases and agents can be achieved by several routes: a small catheter introduced into the nasopharynx and placed immediately above the laryngeal opening; a tracheal tube cut short and placed through the nasopharynx, emerging just beyond the soft palate; a nasopharyngeal airway; and the side arm or channel of a laryngoscope or bronchoscope.

The absence of any fuel source (e.g., tube) within the airway makes this a laser-safe procedure for laryngeal lesions. However, great care must be taken to prevent the catheter or nasopharyngeal airway from getting very close to or entering the larynx. This would provide a fuel source that could easily cause an airway fire if struck by a laser beam. If the catheter is inadvertently inserted too far, it may enter the esophagus, causing marked gastric distention and possible regurgitation.

Inhalational induction may be commenced with sevoflurane in 100% oxygen. At a suitable depth of anesthesia, as assessed by clinical observations of the rate and depth of respiration, pupil size, eye reflexes, blood pressure, and heart rate changes, laryngoscopy is undertaken and topical lidocaine administered above, below, and at the level of the vocal cords. One hundred percent oxygen is administered by face mask with spontaneous ventilation and anesthesia continued with inhalational (insufflation) or an intravenous route (propofol infusion). At a suitable depth of anesthesia assessed by clinical observations, the surgeon undertakes rigid laryngoscopy or bronchoscopy.

Movements of the vocal cords are usually minimal with a spontaneously breathing technique, provided an adequate level of anesthesia is maintained. If the depth of anesthesia is too light, the vocal cords may move, the patient may cough, or laryngospasm may occur. If the depth of anesthesia is too great, the patient may become apneic with cardiovascular instability. Careful observation throughout the procedure, observing movements, respiratory rate and depth, cardiovascular stability, and unobstructed breathing, is vital, with the concentration of the volatile anesthetic adjusted accordingly. The insufflation technique requires close cooperation between the anesthesiologist and the surgeon.

The limitations of spontaneous ventilation or insufflation techniques include the lack of control over ventilation and the potential for airway soiling. Operating room pollution due to insufflation of volatile agents is also an issue and requires high-intensity suction catheters near the mouth (see Fig. 40-14). Insufflation techniques may

not be suitable for large, soft, floppy lesions, particularly in the supraglottis or glottis, which may obstruct the airway after the onset of general anesthesia with spontaneous ventilation.

Rita and associates used the CO_2 laser successfully to excise subglottic stenosis in infants,[165] avoiding a tracheostomy, and reported that ETTs of any size in this group make surgery in infants difficult or impossible because the operative field is obstructed. They reported that in some infants with subglottic stenosis, even a 2.5-mm-ID ETT, was difficult to pass through the stenotic area. Rita and associates concluded that although the insufflation technique is potentially hazardous,[165] if it is done correctly, it provides an appropriate anesthetic technique for surgery on the larynx of infants.[166] They reported good results with this technique over the course of many years.

C. Intermittent Apneic Technique

Weisberger and Miner described the use of an intermittent apneic technique for laser laryngeal surgery in the resection of juvenile papillomatosis of the larynx without the use of an ETT.[167] The investigators stated that a clear, unobstructed view of the airway and complete immobility of the surgical field were essential for the surgeon during these cases (see Fig. 40-30). During a 2-year period, 51 procedures were performed by the investigators on nine patients who had juvenile laryngeal papillomatosis. Their average age was 10.5 years (range, 3.5 to 37 years). After induction of general anesthesia, the patients were paralyzed with atracurium or vecuronium and anesthesia maintained with halothane or enflurane in 100% oxygen. The patients' tracheas were intubated with small-caliber ETTs wrapped with foil tape. In cases of extensive papillomatosis, resection was started with the ETT in situ while the patients' lungs were ventilated with 40% oxygen. Otherwise, the ETTs were removed and the surgery started. The surgery was interrupted when the oxygen saturation decreased. The patients' tracheas were then reintubated, and they were hyperventilated with 100% oxygen. This resulted in a rapid rise in the oxygen saturation so that repeated extubations and surgery could continue. The median number of apneic episodes required for each procedure was two, with a range of one to five. The duration of apneic episodes was 2.6 minutes, with a range of 1 to 4.5 minutes. A suspension laryngoscope and microscope, which provided excellent visualization of the larynx, were used in these cases so that endotracheal intubation could be readily accomplished without moving the laryngoscope. The apneic technique removes all the flammable material from the larynx during laser actuation and is thought to decrease greatly the possibility of an airway fire. Weisberger and Miner stated that the apneic period should be shortened for small children because of their decreased functional residual capacity.[167] The technique is contraindicated in patients in whom visualization of the larynx is difficult.

D. Jet Ventilation Techniques

Jet ventilation techniques are suitable for ventilation during laser surgery of most adult vocal cord lesions. The main limitation for their use is the experience of the anesthesiologist and the absence of suitable equipment. Jet ventilation techniques involve the intermittent administration of high-pressure jets of air, oxygen, or oxygen-air mixtures that entrain room air and lower the delivered pressures. The risk of life-threatening barotrauma is the most serious complication, and it occurs when entrainment of room air is absent. This results in the delivery of very high driving pressures, leading to pneumomediastinum, pneumothorax, and surgical emphysema.[168-170]

In 1967, Sanders first described a jet ventilation technique using a 16-gauge, high-pressure source (jet) placed down the side arm of a rigid open bronchoscope.[171] Sanders used intermittent manual ventilation with a rate of 8 L/min and a driving pressure of 700 torr to entrain room air and showed the technique could maintain supranormal oxygen pressure and prevent a rise in the CO_2 partial pressure. Since 1967, modifications to Sanders' original jet ventilation technique have been made for endoscopic airway surgery. These modifications include frequency of ventilation (i.e., low-frequency, high-frequency, or superimposed frequency jet ventilation) and the site at which the jet emerges in the airway (i.e., supraglottic, subglottic, or transtracheal).

The frequency of ventilation and the location of the jet cannula should be selected according to the degree of airway obstruction and the location of the lesion. Specially designed catheters, laryngoscopes, bronchoscopes, and ventilators are available for the clinician to choose from. Many techniques have been described, claiming different advantages over the other methods.

There is no clear consensus about the ideal ventilation modes or the laser techniques. Selection must be done on the basis of a thorough understanding of the pathophysiology of airway obstruction and individual experience with use of these devices. Hunsaker introduced a laser-safe subglottic monojet ventilation tube.[109,172]

High jet pressure increases the risk of subcutaneous emphysema related to facial plane dissection in the neck, especially when there is disruption of the mucous membrane during surgery. If mucosal disruption is noticed, the jetting catheter should be positioned away from the mucosal opening because pressure drops rapidly with the distance from the jetting orifice. Because there is no ETT to protect the airway, vomitus, blood, smoke, or debris and seeding of papillomas down the tracheobronchial tree can occur. There is a possibility of polluting the operating room with infectious agents or the anesthetic gases. Mucosal dehydration and inspissated secretions can result from dry jetting gases. End-tidal CO_2 cannot be easily measured. Volatile agents cannot be used, and scavenging of gases is required.

1. Site of Jet Delivery

a. SUPRAGLOTTIC JET VENTILATION

Supraglottic jet ventilation describes a technique in which the jet of gas emerges in the supraglottis by attachment of a jetting needle to the rigid surgical suspension laryngoscope. High- or low-frequency ventilation can be used. Supraglottic jet ventilation techniques allow a clear, unobstructed view for the surgeon with no risk of a laser

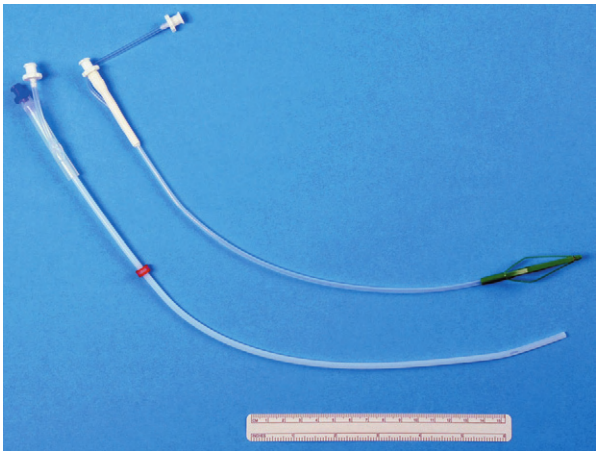

Figure 40-32 Hunsaker Mon-Jet catheter (Xomed, Jacksonville, FL) and Acutronic subglottic catheter for jet ventilation (Acutronic Medical Systems, Hirzel, Switzerland). The green basket of the Hunsaker catheter reduces catheter tip movement within the trachea.

airway fire. However, if the surgeon places surgical swabs into the operating field, there is a risk of an airway fire with the swab acting as a fuel source.

Supraglottic techniques have limitations: misalignment of the suspension laryngoscope to the glottic inlet, which results in poor ventilation and the risk of gastric distention with entrained air; blood, smoke, and debris blown into the distal trachea; considerable vibration and movement of the vocal cords, which may require ventilation to be stopped whilst operating; inability to monitor end-tidal CO_2 concentration; and risk of barotrauma with pneumomediastinum, pneumothorax, and subcutaneous emphysema.

b. SUBGLOTTIC JET VENTILATION

Subglottic jet ventilation involves placing a small (2 to 3 mm external diameter) catheter or specifically designed tubes (e.g., Benjet, Hunsaker, Acutronic, Carl Reiner) through the glottis and into the trachea, which allows delivery of a jet of gas directly into the trachea (Fig. 40-32). This means a fuel source is present within the airway, and care must be taken during laser airway surgery. Many of the subglottic catheters that are commercially available have some laser-resistant properties, but if their tolerance is exceeded, the catheters can degrade and fracture. If after a fracture of the catheter and after a laser strike, jet ventilation is resumed, the distal fragment may be forced into the distal airways. Some catheters (e.g., Hunsaker) have metal wires within the catheter to reduce the chances of this distal fragmentation.

Subglottic jet ventilation is more efficient than supraglottic jet ventilation and results in reduced driving pressures, minimal vocal cord movements, a good surgical field, and no time constraints for the surgeon in the placement of the rigid laryngoscope. The main disadvantage is the potential for a laser-induced airway fire due to the presence of a potential fuel source within the airway and a greater risk of barotrauma than in supraglottic jet techniques (Fig. 40-33).

c. TRANSTRACHEAL JET VENTILATION

Elective transtracheal catheter placement under local anesthesia in individuals with significant airway pathology or under general anesthesia for elective laryngeal surgery has been described.[173] Transtracheal jet techniques carry the greatest risks of barotrauma. Other potential problems include blockage, kinking, infection, bleeding, and failure to site the catheter. None of the commercially available transtracheal catheters is specifically designed for laser use, and transtracheal jet ventilation techniques for endoscopic laser surgery of the larynx require a careful evaluation of the potential risks and benefits.

2. Jet Ventilation Frequency

a. LOW-FREQUENCY JET VENTILATION

Low-frequency ventilation typically describes ventilatory rates of less than 60 breaths/min (1 Hz), and in practice, most low-frequency ventilation is accomplished by a manual Sanders-type device at rates of 15 to 25 breaths/min. With sufficient driving pressures, this leads to near-normal tidal volumes, visible chest inflation, and passive chest deflation. A metal jet needle or cannula is positioned inside a laryngoscope or a rigid bronchoscope and is connected to a source of oxygen. To prevent barotrauma, a reducing valve and a pressure regulator should

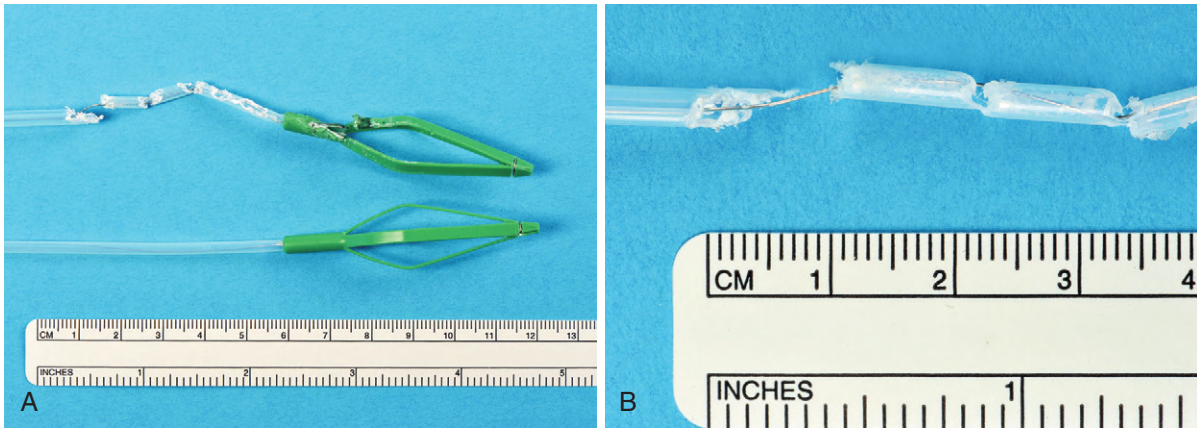

Figure 40-33 **A,** Hunsaker Mon-Jet catheter after it sustained a high-power CO_2 laser strike in 100% oxygen. **B,** The internal stainless steel wire prevented fragmentation.

be in line so that the oxygen pressure is limited to 50 psi for adults. In children, extreme caution should be used. The anesthesiologist should start with much lower values and gradually increase the pressure while observing the chest movements. Holding down the handheld lever controls the duration and frequency of the jet of oxygen. The actual delivered tidal volume, concentration of oxygen, and inspiratory pressures depend on the amount of air entrainment by the jet, length of the cannula and its alignment to the trachea, size of the laryngoscope, and lung compliance. These factors are hard to measure in a clinical situation with any great precision and at best are estimates. Adequate ventilation is accomplished in most patients who are anesthetized and given muscle relaxants.

The minimal possible pressure that can provide adequate ventilation should be used. The Venturi jet must be kept in perfect alignment with the trachea to achieve streaming of the flow into the lungs. Anesthesiologists should be watchful after any readjustment of the operating laryngoscope to which the jet is clamped, which may impair ventilation of the lungs. Oxygen saturation must be constantly monitored and chest movement continually observed.

During supraglottic jet ventilation, there is considerable movement of the laryngeal structures, and the timing of each breath can be coordinated with the surgeon operating the laser. Even small movements are magnified under the operating microscope. This movement is much less of an issue with subglottic jet ventilation. Intravenous agents, such as propofol infusions, are used to maintain anesthesia. Short-acting muscle relaxants are used to prevent movements of the patient that can be dangerous during a laser operation. Gastric distention with possible regurgitation may occur with a misaligned cannula,[174] and a nasogastric tube may be required. Adequate fluids are given intraoperatively, and gases may be humidified in the postoperative period to prevent mucosal drying.

Jet ventilation is helpful in many situations in which a laser is not used. Intermittent jet ventilation has been applied through the instrument channel of the flexible FOB to expand atelectatic lungs and through the Hunsaker jet ventilation tube for one-lung ventilation for lobectomy.[175] However, extreme care should be taken to avoid pulmonary barotrauma.

b. HIGH-FREQUENCY JET VENTILATION

During high-frequency jet ventilation (HFJV), small tidal volumes are delivered at a rate of 60 to 150 cycles per minute from a high-pressure source (5 to 50 psi), with inspiration taking 20% to 40% of each cycle. This is an effective ventilation method that provides adequate gas exchange. This method has been used in rigid bronchoscopy. Hautmann and colleagues described a technique of delivering HFJV through a noncompliant insufflation catheter.[176] The catheter can be threaded through the sidearm of the bronchoscope and positioned in the trachea or in the main stem bronchus. Medici and coworkers used an insufflation catheter with a side hole in the contralateral main stem to deliver high-frequency positive-pressure ventilation during endobronchial surgery using an Nd:YAG laser.[177] HFJV catheters can be placed transtracheally; however, in a prospective multicenter study, the rate of subcutaneous emphysema was 8.4%.[178]

An advantage of HFJV is that it provides excellent views and access to the surgical site. Catheters are small and obstruct the surgical field less than larger conventional ETTs. To-and-fro movements of the major airways that are invariably present during normal respiratory excursions are not present. Because a small tidal volume is used, there is less movement of the larynx, trachea, and lungs. This greatly facilitates the precise operation of the laser beam.

Although the reported incidence of pulmonary barotrauma in HFJV is low, it can lead to serious complications. Pulmonary barotrauma can result from high driving gas pressures and air trapping. Ventilators should initially be set at the lowest possible driving pressures and increased incrementally while carefully observing chest movements. There is a potential risk of barotrauma if the air pressures are not monitored. In addition to an injector catheter, Unzueta and associates used a second identical catheter placed 7 cm distal to the injector site to measure airway pressure continually.[146] Continuous monitoring of end-expired CO_2 and O_2 by conventional methods is difficult to interpret because of fast respiratory rates and high gas flow rates. However, there is a well-defined relationship between arterial CO_2 concentrations and end-tidal CO_2 concentration when expiratory gas is obtained by sidestream sampling during jet ventilation.[179] Observation of chest wall movements and blood gas analysis are reliable methods for assessing the adequacy of ventilation. Klein and coworkers suggested the use of a double-lumen jet catheter for respiratory monitoring.[168]

Air trapping and stacking of breaths are inherent problems in high-frequency ventilation because of short expiratory times.[180] In airways distal to the obstruction, injurious excess pressure can easily build up. Obstruction to gas outflow can easily occur because of the tumor and because of the presence of surgical instruments, bleeding, and mucosal edema. Light anesthesia or inadequate muscle relaxation can cause laryngospasm, closing the glottis and further obstructing the airflow. To prevent barotrauma, it is essential to ensure that there is adequate outflow.

c. COMBINED FREQUENCY JET VENTILATION

Oxygenation and CO_2 elimination may be improved by using low-frequency and high-frequency ventilation in combination (Fig. 40-34). In this method using combined (superimposed) frequencies of ventilation, the location of the gas inflow in the airway seems to influence the efficiency of jet ventilation. Supraglottic, combined-frequency ventilation seem to be superior to subglottic, monofrequent jet ventilation in providing an unobstructed view and access to glottis.[181] With intratracheal jet ventilation, aspiration and air entrapment are virtually absent. There is no clear advantage of one ventilation technique over the other.[182] In a study of 37 adult patients, supraglottic, combined-frequency ventilation was more efficient than subglottic, low-frequency or subglottic, combined-frequency ventilation.[181] However, in a bench model of laryngotracheal stenosis, supraglottic HFJV was

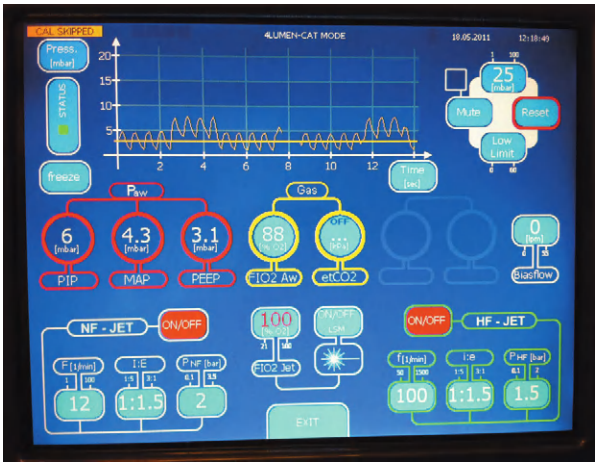

Figure 40-34 The combined-frequency jet ventilation monitor (Carl Reiner, Vienna, Austria) allows observation of the inspired oxygen concentration, measurement of end-tidal CO_2, and scrutiny of three- and four-lumen catheters. It has a laser-safe mode.

TABLE 40-9
Complications Associated with Jet Ventilation of the Lungs

Ventilation Related (*n*)*	Ventilation Unrelated (*n*)*
Major	
Pneumothorax (9)	None
Hypoxemia during anesthesia (6)	
Mediastinal air (2)	
Tension pneumothorax (1)	
Minor	
Carbon dioxide retention during anesthesia (3)	Prolonged mask support (10)
Subcutaneous emphysema (2)	Prolonged endotracheal intubation (5)
Gastric dilation (2)	Laryngospasm (5)
Airway bleeding (2)	Prolonged sleep or paralysis (2)
Recall of procedure (1)	

*Data from 15,701 patients were analyzed.

associated with significantly larger end-expiratory pressures and peak inspiratory pressures.[183] Two risks are built in because of the location of the jet cannula: aspiration at the supraglottic location and barotrauma at the subglottic location.

High-frequency ventilation should be reserved for patients with severe airway obstruction or severe pulmonary dysfunction. Most cases do well with a variety of simpler techniques that are well established. They include ventilation with a laser-resistant tube or microlaryngoscopy tube, supraglottic jet ventilation with a jet needle, and subglottic jet ventilation with a catheter.[184]

There is no perfect mode of ventilation that suits all clinical conditions. Complications have been associated with various ventilation techniques in laser resections (Table 40-9). Table 40-10 suggests a general approach that is used in the pediatric population.

VIII. ANESTHETIC MANAGEMENT FOR TRACHEOBRONCHIAL TREE LASER SURGERY

Laser resection is the preferred method for removal of obstructive lesions from the trachea and bronchus. It is a safe and effective means of relieving central airway obstruction. With more than 4000 published interventions, the safety and efficacy of laser bronchoscopy has been well established.[142] Providing safe anesthesia for laser excision of lesions that are in the tracheobronchial tree can be challenging. Maintaining unhampered views of the operative field, gaining free and safe access to the laser, and supplying adequate ventilation are essential in choosing a method of anesthetic management, and these are not easy measures to provide for patients with an obstructed airway. The challenge is to preserve adequate gas exchange while maintaining good visualization and surgical access to the lesion.

The primary advantage of using a laser for recurrent benign tumors is that multiple resections can be safely performed in outpatients. This approach avoids the increased morbidity of open thoracotomy procedures. In cancer patients, endoscopic palliation helps in evaluation and staging of malignant tumors. These treatments reduce morbidity during chemotherapy without increasing surgical complications.[185] In cases of severe obstruction by unresectable tumors, a patent airway can be cored

TABLE 40-10
Techniques for Pediatric Laser Bronchoscopy

Site	Scope	Laser	Ventilation Method
Supraglottic or immediately subglottic	Direct laryngoscope	Carbon dioxide	Venturi ventilation through safe ETTs
Trachea, main stem bronchus	Rigid bronchoscope	Flexible KTP or argon laser	Manual ventilation through side arm of bronchoscope $FIO_2 < 0.5$
Distal to main stem bronchus	Flexible bronchoscope through a standard ETT	Flexible KTP or argon laser	Manual ventilation through standard $FIO_2 < 0.5$

ETT, Endotracheal tube; *FIO_2,* fraction of inspired oxygen; *KTP,* potassium titanyl phosphate.

with a laser.[186,187] The combination of laser and rigid bronchoscopy is ideal for treating central airway obstruction.[188] Relief of acute ventilatory distress is a major benefit of bronchoscopic laser resections.[189] Therapeutic bronchoscopy should be considered even in individuals with cancer requiring intubation and mechanical ventilation. Often, mechanical ventilation is successfully discontinued and death from suffocation postponed.[190]

When anesthesiologists and surgeons simultaneously handle the airway, they must have a predetermined plan for intraoperative and postoperative management. Good communication and cooperation are important, and development of a team approach is necessary for successful results.[191] Devising such a plan is made easier if the current problems are conceptualized in two broad categories: mechanical and patient-related issues. Mechanical issues deal with attaining good surgical access while simultaneously providing adequate gas exchange and anesthesia. Distal lesions pose a greater challenge because they can cause complete airway obstruction and are difficult to reach with laser treatment. An ideal treatment modality for endoscopic ablation provides secure airway protection, excellent visualization of the lesion, and delivery of safe and effective method of treatment. Use of a contact Nd:YAG fiberoptic laser system through a rigid bronchoscope has performed well in meeting these criteria.[192] Patient-related topics such as age, size, pulmonary function, and general health status should be the basis for all final decisions. It is important first to decide on the type of laser therapy, type of scope, and technique of ventilation. An anesthesia management plan can then be formulated on the basis of patient-related factors, available equipment, and expertise.

A. Rigid Ventilating Bronchoscopy

Although the rigid bronchoscope is an old instrument, it continues to play a major role in newer therapies for access to the airway.[193] Rigid bronchoscopy is the standard technique for anesthesia management during laser resection of severely obstructing tracheal masses.[194] The main advantage of the rigid bronchoscope is complete control of the airway. The bronchoscope ultimately functions as a rigid ETT. The area and clarity of the view of the surgical field with rigid scopes are superior to those with flexible scopes. However, the view is limited to the trachea, carina, and the main bronchi. Subglottic lesions can be visualized through a rigid bronchoscope. Compared with flexible bronchoscopes, rigid bronchoscopes have large-diameter instrument side channels. A variety of baskets, forceps, and grabbers that are used for a wide range of therapeutic procedures can pass easily through these wide channels. In the event of significant bleeding or tenacious secretions, the telescope can be withdrawn and suction catheters passed directly down the bronchoscope while maintaining oxygenation and control of the airway.

The rigid bronchoscope has a side port that can be attached to any conventional anesthesia delivery system. It substitutes for the ETT during the procedure. A removable eyepiece allows surgical interventions when open and control of ventilation when in place. Usually, there is a variable leak around the scope, which can be compensated for by increasing the fresh gas flow.

The rigid bronchoscope provides an excellent view of the larynx, similar to the view provided by the direct laryngoscope. Ventilation can be provided through the rigid bronchoscope. Eliminating the ETT improves the access to the surgical field and reduces the risk of airway fire. With experience, rigid bronchoscopy is simple to use, is low cost, and is relatively safe when the proper precautions are observed.

Rigid bronchoscopy can be invaluable and life-saving in cases of severe obstruction because the bronchoscope can be pushed past the obstruction.[141,195] It is unsurpassed in evaluation, control, and therapeutic manipulation of the tracheobronchial tree.[196] A retrospective review of 300 patients over a 12-year period concluded that the use of rigid bronchoscopy offers certain advantages in ventilation during general anesthesia. Rigid therapeutic bronchoscopic intervention is increasingly accepted to treat patients with central airway obstruction. Laser resection is applicable when the obstruction is caused by malignant exophytic tracheobronchial lesions, benign granulation tissue, or tracheobronchial stenosis with scar tissue formation.[190] In one study, rigid bronchoscopy was preferred for proximal lesions and FOB used for distal lesions. Often, the rigid and flexible bronchoscopes were used together to maximum advantage.[197]

Drawbacks of rigid bronchoscopy include increased secretions and finite access to the distal airways and upper lobes. Conditions such as ankylosis of the jaw or rigid cervical spine, which make direct visualization of the larynx difficult, may preclude the use of a rigid bronchoscope. General anesthesia is often necessary for rigid bronchoscopy, whereas flexible bronchoscopy can be performed with sedation and topical anesthesia. Patients do not tolerate pressure on the soft tissues, and significant neck extensions are painful.[198]

B. Flexible Bronchoscopy

Flexible bronchoscopy is used to reach lesions in distal airways. Flexible fiberoptic scopes are more suited for procedures under sedation and local anesthesia.[161] Flexible bronchoscopes are built with bundles of optical fibers or a camera at the distal end. The fibers deliver light to the tip and transmit pixels. An image is constituted when all the pixels are reassembled. However, the image formed is not as good as the view from direct laryngoscopy. It is possible to visualize the entire airway because the tip of the bronchoscope can be flexed through an arc of 220 degrees. There is usually a working channel, which can be used for suction and for passing instruments. In adults, 5.5- to 6.0-mm flexible bronchoscopes are used, and in children, 3.6- and 2.2-mm scopes are popular. The disadvantage of the smaller scopes is that there is no instrument channel or, if present, it is too narrow. As technologic improvements occur in the design of smaller instruments and improved forceps, the therapeutic and diagnostic role of flexible bronchoscopes will become more prevalent in clinical practice.[199]

IX. CONCLUSIONS

Airway surgery is unique in that it involves an operation in which the anesthesiologist and surgeon are working in the same anatomical field. The addition of a laser beam (i.e., ignition source) into the airway may cause a catastrophic airway fire. An understanding of the fire triad and the steps that can be taken to avoid a fire is an essential requirement before undertaking laser airway surgery. General laser hazards include eye and skin injury, drape fires, and laser plumes. Airway fires occur when a laser strikes the unprotected surface of a tracheal tube or any other material within the airway that acts as a fuel source. Any high-energy source, such as diathermy, can act as an ignition source and can result in an explosive blowtorch fire.

Attempts to prevent fires from occurring have involved wrapping the tube in some form of protective covering. Metal foil tape wrapped around a standard tracheal tube is of historical interest but is not recommended. Specially manufactured laser tubes are most commonly used and vary in their protective coatings, number of cuffs, size, flexibility, and resistance to compression. All commercially available laser tubes can be involved in a laser fire if they are used outside their recommended protective range. Anesthetic gases and the flammability limits of potent inhaled anesthetics affect tube flammability.

The introduction of laser fibers through an FOB passed through an LMA was an important step, as was the use of LMAs during laser pharyngoplasty. Preoperative assessment aims to identify the size, mobility, and site of a lesion. Very mobile lesions may cause partial airway obstruction after induction of anesthesia, but total airway obstruction is extremely uncommon. Airway obstruction is worse in a spontaneously breathing patient after induction of anesthesia because of the loss of supporting tone in the oropharynx and hypopharynx. Supraglottic lesions, if mobile, can obstruct the airway or make visualization of the laryngeal inlet difficult. Subglottic lesions may allow a good view of the laryngeal inlet but cause difficulty during the passage of an ETT. The traditional teaching of inhalational induction and maintenance of spontaneous ventilation in obstructed airways has been questioned.

During anesthesia, a closed system with a laser tube may be used, or an open system may be employed using a spontaneous ventilation technique, intermittent apnea, or jet ventilation technique. With an open airway, it is not possible to produce a sustained fire, regardless of the laser power and oxygen concentration, because no fuel source is present in the airway. A tube, catheter, stent, or any foreign material introduced into the airway may act as a fuel source and complete the fire triad, which may result in a catastrophic airway fire if precautions are not taken.

X. CLINICAL PEARLS

- Good communication, cooperation, and the development of a team approach are essential requirements for successful laser airway surgery. The surgeon and anesthesiologist should be familiar with the principles of a laser, the types of laser available, hazards of laser use, the management of an airway fire, and the advantages and disadvantages of the various anesthetic techniques available.
- For an airway fire, three components of the fire triad are needed: fuel source, oxidant sources, and ignition source. Removal of one of these components prevents or reduces the risk of an airway fire, which in practice means removing or protecting the fuel sources, minimizing the oxidant sources, and not using an ignition source.
- Oxygen and nitrous oxide support combustion very well, and dilution of oxygen by nitrous oxide makes no difference to the flammability risk. In clinical practice, air and oxygen are most frequently used during laser airway surgery, with the oxygen concentration kept as low as clinically feasible while the laser is near the tube.
- All manufactured laser tubes have laser-resistant properties, providing some degree of protection against a laser strike, and these limits are provided by the manufacturer in the product literature, which describes the types of laser the tube has protection from and the limits of power settings for different lasers. Laser tubes vary in the material used, protective coating, relative size, and the number of cuffs. All laser tubes can result in an airway fire or blowtorch fire if used outside of their limits.
- The preoperative evaluation attempts to identify factors that may cause difficulty during the perioperative course. It involves a thorough medical evaluation of all patients before surgery. At the end of the preoperative assessment, the anesthesiologist should have some idea of the size, mobility, and location of the lesion. Recognition of a compromised or anatomically distorted upper airway is paramount in the preoperative assessment of these patients.
- Premedication to reduce secretions and anxiety may be useful in patients with minor airway lesions, but it should be avoided in patients with severe airway compromise. Thick secretions may block narrowed airways further, may be difficult to cough out by the patient, and may in extreme circumstances totally obstruct critically narrowed airways.
- Jet ventilation techniques are suitable for ventilation during laser surgery of most adult vocal cord lesions. The main limitation for their use is the experience of the anesthesiologist and the absence of suitable equipment. Life-threatening barotrauma is the most serious complication, and it occurs when room air is not entrained. This results in the delivery of very high driving pressures, leading to pneumomediastinum, pneumothorax, and surgical emphysema.

VI. Clinical Pearls

I. DEFINING THE PROBLEM

A. The Clinical Challenge

Airway management in the trauma patient can be particularly challenging because of the presence of a difficult airway with the need for rapid action. The traumatized airway is often anatomically disrupted, obstructing direct laryngoscopy, and the presence of blood in the upper airway confounds attempts at fiberoptic intubation. Manual in-line stabilization of the cervical spine (C-spine) is required in most patients with blunt trauma, compounding the airway difficulties. Although trauma patients are often intubated outside the operating room (OR), usually in the emergency department (ED) resuscitation area, they can also present to the OR requiring intubation for emergency surgery. In the ED, trauma patients are intubated primarily by emergency physicians, but patients with direct trauma to the airway may be managed using a team approach, with emergency physicians, anesthesiologists, and surgeons working in concert to achieve the best possible results. In the OR or other units within the hospital, trauma airway management is typically the responsibility of the anesthesiologist, although surgeons may be called on to assist when the airway is disrupted.

Trauma patients needing airway intervention require a rapid evaluation for potentially difficult airway attributes, development of an airway management plan (including rescue techniques in the event of failure), and a willingness to act quickly with incomplete information. In most cases, the need to intervene is apparent, but certain situations can mislead the evaluating physician into thinking that an airway is not at risk. Many trauma patients initially appear to be stable; they maintain a patent airway and breathe spontaneously until some process causes them to deteriorate rapidly. Soft tissue swelling, hematomas, or subcutaneous air can cause dramatic and potentially lethal airway distortion, even though external findings remain unremarkable, until the patient suddenly decompensates. Any patient with a traumatized airway requires early assessment and decisive action. Delay or observation, although initially seeming prudent, can lead to catastrophic airway compromise and make airway intervention much more difficult than if it had been undertaken earlier.

1. Emergency Department or Trauma Resuscitation Room

Patients who have been subjected to acute blunt or penetrating trauma can present with a spectrum of injuries, ranging from minor and localized insults to catastrophic and multisystem trauma. In the trauma resuscitation room, intubation may be indicated by direct trauma to the head, face, neck, or airway; respiratory compromise due to thoracic injury; or overall management strategy, as in the critically injured patient with hypovolemic shock.

In most cases, the usual paradigms of airway management used in elective anesthesia are not applicable. Care of the acute, severely injured trauma patient is best done using a team approach with a clearly designated team captain, who controls the decision making, sequence, and flow of the entire resuscitation.

Airway management decisions are not driven only by the need for operative intervention; the decision about when and how to control a patient's airway is based on a complex series of considerations related to the patient's specific injuries and overall condition, the risk of deterioration, and the need for transport to locations in the hospital where resuscitation is not easily undertaken (e.g., angiography suite). This type of decision making about the airway is often more complicated than that involved in elective surgery, and a unique approach to airway intervention is needed. In smaller hospitals, where a trauma team approach cannot be used due to staffing limitations, decisions regarding resource allocation and prioritization of interventions are even more challenging.

2. Early Hospital Care of the Traumatized Patient

Trauma and burn patients frequently undergo surgery that is not related to their acute resuscitation but is required during the first few days of their hospital stay. Burn débridement and grafting, fracture fixation, complex wound revision and repair, and other procedures are often required hours or days after the patient has been stabilized and more acute, life-threatening problems have been controlled. Decision making in this setting is easier with respect to airway management because the decision to intubate is driven by the need for surgery and anesthetic management; however, careful preoperative assessment remains essential. In addition to the usual comorbidities that can make airway management difficult, trauma patients often have other complicating factors, such as direct airway injury, pulmonary injury with rapid oxyhemoglobin desaturation, persistently tenuous hemodynamic status, or cerebral injury with elevated intracranial pressure (ICP). Patients with significant total body surface area burns, crush injuries, or spinal cord injuries develop acetylcholine receptor upregulation, with its attendant risk of hyperkalemia if succinylcholine is administered.[1] Although classic teaching posits that this vulnerability to succinylcholine-induced hyperkalemia begins on postinjury day 7, some effect is seen as early as day 3.[2] This combination of considerations—specifically unresolved or unrecognized traumatic injuries, the potential for hyperkalemia, and the patient's preexisting comorbidities—can make airway management in this intermediate-term window anything but routine. A careful approach, including detailed consideration of possible difficult airway management protocols and relevant comorbidities, is essential.

3. Delayed Surgery

Traumatized patients frequently require multiple operative repairs or revisions before and during the rehabilitation phase. Delayed operations often are performed between 1 and 6 months after injury, and they may involve many of the considerations outlined previously, particularly those related to succinylcholine-induced hyperkalemia. However, because these patients usually are stable and most have already undergone procedures that require endotracheal intubation, most airway difficulties have been identified. Although the management of these patients raises important issues, this chapter focuses on the acutely traumatized patient and issues related to airway management in that setting.

B. The Decision to Intubate

The decision to intubate is the most important resuscitative decision, but it is often the one with which the provider struggles the most. Trauma patients present anxiety-provoking situations because their airway difficulty is often exaggerated by C-spine immobility, direct airway trauma, overall physiologic compromise, and the propensity for clinical deterioration. Early definitive airway management must be performed in a logical and safe fashion to continue evaluation and resuscitative efforts for these patients. Decision making must be based on a consistent, reproducible series of principles that accounts for the patient's current condition, likelihood of deterioration, planned diagnostic and therapeutic interventions (including transport), preinjury comorbidity, and the resources and expertise available in the resuscitation area.

Answers to three fundamental questions inform the decision to undertake emergency intubation:

1. Is there a failure to maintain or protect the airway?
2. Is there a failure of oxygenation or ventilation?
3. Is there a need for intubation based on the anticipated clinical course?

Questions 1 and 2 are relatively straightforward in the setting of the trauma patient. Failure to maintain the airway is clinically obvious. Loss of airway protection usually occurs in the setting of depressed mental status caused by head trauma, hypovolemic shock, or ingestion of drugs or alcohol and is a condition with which the ED physician and anesthesiologist are familiar. Airway protection is best tested by evaluation of the patient's ability to phonate (if possible). Phonation requires an unobstructed upper airway and the ability to execute complex, coordinated maneuvers. After phonation, the patient's ability to swallow and handle secretions is assessed. The ability to sense the pooling of secretions in the posterior pharynx and to perform the coordinated series of neurologic and muscular maneuvers to swallow requires a high degree of function and connotes airway protection. The gag reflex, long advocated as the test by which the need for intubation can be judged, should never be performed in a critically injured, supine, immobilized trauma patient. The wisdom of inserting a tongue blade or other device to stimulate the patient's posterior oral pharynx in this state is questionable, because vomiting is easily provoked and difficult to deal with.

The gag reflex is much less reliable than phonation and swallowing, and it is absent in up to 25% of the normal adult population.[3] The presence of a gag reflex does not equate to airway protection, nor does its absence indicate a need to intubate. The presence or absence of the gag reflex is better thought of as a neurologic evaluation (i.e.,

cranial nerves IX and X) rather than as part of an airway evaluation. The Glasgow Coma Scale is a better tool for predicting intubation.[4]

The ability of a patient to maintain appropriate oxygenation and ventilation can be assessed clinically and supported by pulse oximetry and capnography. Although arterial blood gas values are useful in evaluating the trauma patient with respect to identification of occult acidosis that may represent more severe shock than is clinically apparent, these determinations have little or no role in the decision to intubate. Evaluation of the patient's respiratory effort and the overall sense of the patient's injuries in the context of pulse oximetry readings are more important to the intubation decision than arterial blood gas values. Patients with compromised ventilation or oxygenation should receive high-flow face mask oxygen (O_2) with a reservoir, and all reversible issues should be addressed. Hemothorax, pneumothorax, flail chest, and opioid overdose are examples of reversible conditions that compromise oxygenation and ventilation. Most cases of hypoxemia or hypoventilation in multitrauma patients are multifactorial and do not respond to simple interventions. In these cases, early intubation usually is indicated.

Most trauma patients can maintain and protect their airways and exhibit adequate or correctable oxygenation and ventilation. For them, it is the anticipated clinical course that guides the decision to intubate. This is the most sophisticated and most important of the decisions facing the airway manager or trauma captain. A patient may appear stable at the time of evaluation, but deterioration can be predicted as a natural course of the injuries. For example, the patient with burns from a closed-space fire with significant inhalation of superheated air (see Chapter 44) may present with a somewhat hoarse voice or a simple cough but has an otherwise patent airway. Failing to recognize the likelihood of progressive obstruction of the airway, which has been subjected to toxic and thermal insults, and to intervene in a timely fashion can lead to disaster. Although the patient may not meet the criteria for emergency intubation related to airway maintenance and protection, oxygenation, or ventilation, the likelihood of deterioration is alone sufficient to warrant airway intervention.[5] It is the predictability of the deterioration that determines the decision to intubate. Alternatively, the upper airway can be examined by fiberoptic laryngoscopy, informing the airway manager of the stability or fragility of airway patency. Similarly, the patient with a crushed pelvis, open femur fracture, and hypotension is inevitably intubated, even though there is no immediate threat to airway patency or oxygenation. The need for advanced imaging, aggressive pain control, and operative repair of obvious injuries dictates that the patient be intubated early and in a more controlled fashion than trying to manage a chaotic intubation from behind the computed tomography (CT) scanner.

Consideration of the patient as a whole, of the individual injuries and how they interact, of the effects of these injuries on the patient and on the patient's comorbidities, and of the need for interventions (including transport) frequently guides a prudent and rational decision to intubate, even when the patient does not have an immediate airway problem and when oxygenation and ventilation are adequate.

Preventing morbidity or mortality as it relates to trauma airway management refers to delaying intubation rather than to a mishap occurring during intubation. It is better to err on the side of intubating early and securing a potentially threatened airway than observing the patient with a false sense of security born from adequate oxygenation and ventilation at that moment. The purpose of observation is to see whether obstruction or airway failure ensues, but if either occurs, the results may be disastrous.

II. ANATOMY OF THE AIRWAY: TRAUMA CONSIDERATIONS

Although airway anatomy is discussed in Chapter 1, the following is a brief description of elements to consider in the trauma setting. The airway begins at the nares or lips and ends with the terminal bronchioles and alveoli of the lungs. The upper airway consists of the oral and nasal cavities and the pharynx, which provide a conduit for the movement of gases to the larynx, through the glottis, and into the trachea. The nasopharynx, oropharynx, and hypopharynx (Fig. 41-1) form a continuous space that conducts air from the outside world to the glottic aperture. The nasopharynx is protected anteriorly and laterally by the maxillary bones, the nasal bones, and nasal cartilage. Direct injury to the face, particularly from an impact with an object of high mass, high velocity, and low surface area (e.g., baseball bat), can collapse the maxillary structures into the nasopharynx and cause extensive hemorrhage, threatening the airway and complicating attempts to manage it. Similarly, the oropharynx is protected by the maxillary bones, alveolar ridges, and

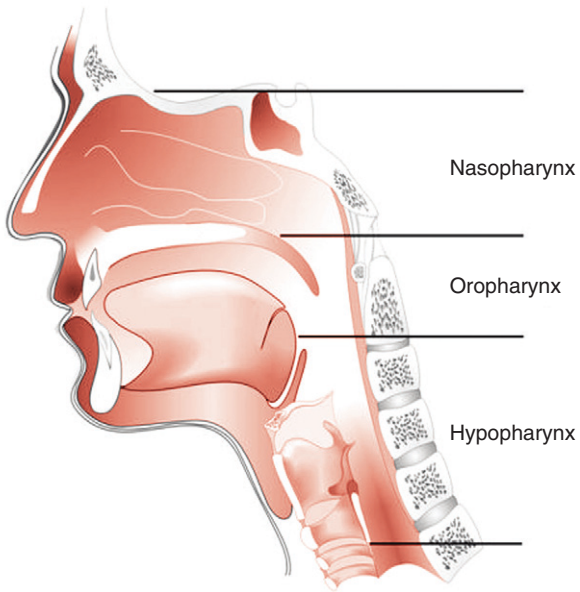

Figure 41-1 Airway anatomy. (From Redden RJ: Anatomic considerations in anesthesia. In Hagberg CA, editor: *Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone, p 11.)

mandible but is subject to the same sort of intrusive injuries. Blows to the face producing Le Fort I, II, or III fractures (Fig. 41-2) can simultaneously threaten the airway and complicate airway management.

The larynx and trachea are essentially subcutaneous structures in the anterior neck. The larynx is separated from the skin only by subcutaneous fat and the anterior cervical fascia. The thyroid notch, cricothyroid membrane, and cricoid cartilage can be easily palpated to provide the critical landmarks for surgical access to the airway (see Chapter 31). The airway is mobile in the neck but is fairly firmly anchored by the strap muscles and cervical fascia. Tracheal deviation as a result of pneumothorax or hemothorax may occur in patients who are severely compromised.[6] Tracheal deviation is not helpful as a sign of pneumothorax because it usually occurs only when the pneumothorax is at an advanced state and easily identifiable by auscultation. Tracheal deviation can result from disruption of the neck anatomy caused by hemorrhage or extensive subcutaneous emphysema. It is also seen with chronic scarring, such as that related to previous radiotherapy. In any case, palpation of the trachea and larynx is a valuable exercise in the event that surgical airway management becomes necessary. It also can establish the position of the airway in the neck, even if orotracheal intubation is contemplated. Orotracheal intubation can be extraordinarily difficult or impossible when the trachea or larynx is displaced laterally.

Vascular structures in the neck, such as the carotid artery and jugular vein, do not have a direct bearing on the airway. Nonetheless, they can be the cause of significant airway compromise when vascular injury from blunt or penetrating trauma creates hemorrhage that displaces or otherwise changes the configuration of the airway. The nerves supplying sensation to the supraglottic larynx and the remainder of the airway are rarely injured by trauma.

Knowledge of the anatomy of the upper airway is no more or less important in the management of the multitrauma patient than in any other setting in which emergency airway management is required. When specific trauma to the maxillofacial area or neck threatens and disrupts the airway, however, anatomic knowledge and the ability to improvise an approach may be key determinants of success.

III. SPECIFIC CLINICAL CONSIDERATIONS IN TRAUMA

A. Direct Airway Trauma

Direct trauma to the airway can be broadly classified as blunt or penetrating trauma. Each of these categories can be considered in the context of direct injury to the airway itself versus compromise or threat to the airway caused by the proximity of an injury in the neck. Injury to the airway can occur at one or more levels. Maxillofacial trauma can compromise the upper airway; direct injury to the neck can compromise the airway from the hypopharynx to the trachea; and injuries to the thorax can disrupt the lower trachea, main stem bronchi, or other smaller bronchi. The approach to airway management is dictated by the clinical presentation of the patient and the best judgment of the operator.

1. Penetrating Neck Trauma

Penetrating neck injuries range in scope from stab or other puncture wounds to major lacerations due to both low-velocity (e.g., BBs, pellets) and high-velocity (e.g., crossbows, firearms) projectile injury. The consequences of these various mechanisms can vary drastically. The overall mortality rate due to penetrating neck injuries is 2% to 6%, with a significantly lower mortality rate for low-velocity injuries.[7-9] The patient with a stab wound to the neck usually has identifiable anatomy and can undergo a planned airway evaluation and early intubation under controlled circumstances. Patients with high-velocity injuries often have significant vascular and hollow-structure injuries, and anatomic distortion can make airway management challenging.[10] These injuries mandate urgent airway management, but the approach is confounded by the myriad injuries caused by the missile.[11]

For the purposes of classification of penetrating injury, the neck is divided into three zones (Fig. 41-3). Zone 1 extends from the clavicles inferiorly to the level of the cricoid cartilage. Zone 2 extends from the cricoid cartilage to a line drawn through the angles of the mandible, and zone 3 is the area above the angles of the mandible. This classification is most useful for low-velocity penetration, such as from a stab or long-distance birdshot, but it has also been applied to high-velocity injuries, such as rifle wounds.[10] These zones were designated because of their unique anatomic characteristics.[12] Zone 1 is dominated by the major vascular structures at the root of the neck, specifically the carotid arteries, internal jugular veins, subclavian arteries and veins, and innominate arteries and veins. The airway at this level is relatively

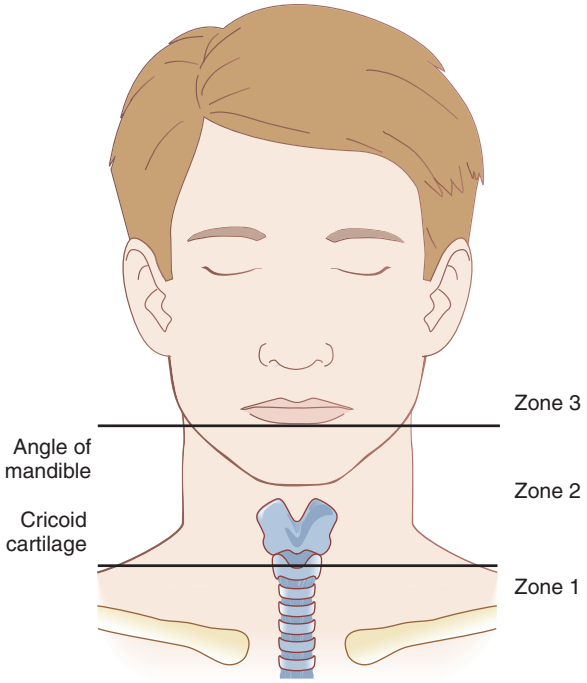

Figure 41-3 Zones of the neck.

inaccessible except by tracheotomy. Zone 1 injuries are relatively uncommon (<10% of penetrating neck injuries) but are often associated with major vascular injuries or injuries to the dome of the lung.[13] Patients with zone 1 injuries often require emergency airway management because of direct airway compromise by hemorrhage or the anticipated clinical course predicted by the profound shock that typically develops. There is little literature to guide the selection of airway management techniques for zone 1 penetrating injuries. Most information is limited to small case series of subsets of larger series that are dominated by zone 2 injuries. The approach to airway management is dictated more by the nature of the threat to the airway than by the location of the inciting wound. The overall approach to airway management in penetrating neck injuries is outlined subsequently.

Zone 2 is the most common location for penetrating neck injuries, accounting for most reported cases.[14] Zone 2 injuries require emergency airway intervention in approximately one third of the cases, with a large proportion of the remainder undergoing subsequent intubation related to evaluation or surgical repair. The area of concern in zone 2 extends from the anterior margins of the paravertebral muscles bilaterally. In this area, major vascular structures (e.g., common carotid arteries, internal jugular veins) and their associated sympathetic ganglia and the hypopharynx, esophagus, larynx, and trachea are all at risk. The most common cause of airway compromise in zone 2 injuries is external distortion by hemorrhage related to vascular injuries or direct injuries to the airway.[15]

Zone 3 injuries are uncommon (<10% of all penetrating neck injuries) because of the very small area involved and the protection provided by the mastoid processes posteriorly, the mandible anteriorly, and the base of the skull superiorly. The area, however, is rich with major vascular structures (i.e., carotid arteries and internal jugular veins) and provides easy access to the pharynx. Surgical repair of injuries in this area is difficult, and most of these patients undergo extensive evaluation by angiography, with stenting of vascular injuries often the intervention of choice. Because zone 3 injuries involve the pharynx, direct airway compromise is uncommon except by hemorrhage into the airway from a through-and-through injury to the carotid artery. In these rare circumstances, immediate airway intervention is required and may be difficult because of the torrential hemorrhage. Orotracheal intubation is usually successful in these cases, however, particularly if the patient is positioned head down to prevent the blood from entering the operator's view. After the airway is secure, the mouth can be packed tightly with gauze to control the internal hemorrhage while direct external pressure is simultaneously applied as the patient is transported to the OR.

The approach to the airway in the patient with penetrating neck trauma is guided by the same principles that were outlined earlier in this chapter. Compromised airway patency or protection because of hemorrhage, for example, is an indication for active airway management. Similarly, severe shock with overall obtundation of the patient and an inability to protect the airway or ventilate and oxygenate adequately makes the intubation decision fairly straightforward. The difficulty lies in the patient who has evidence of injury to the neck, but who does not have an obviously compromised airway at the initial evaluation. It is in these cases that judgment is most important and that most tactical errors are made.

The best approach is to consider two specific issues. The first is whether there is evidence of a direct injury to an air-containing structure in the neck. Subcutaneous air indicates injury to an air-filled structure in the neck,[16] such as the airway (including the hypopharynx or pharynx) or the esophagus. In severe cases, particularly patients with injury to both vascular and air-filled structures, airway obstruction can occur rapidly, requiring emergency cricothyrotomy.[17] In less threatening cases, it is virtually impossible to tell whether the esophagus or airway is involved, and early direct or fiberoptic examination of the airway is indicated. Sedation and topical anesthesia allows the operator to determine the severity and location of any airway injury. Preparation with a small to moderate-size endotracheal tube (ETT) (e.g., 6.0- to 7.0-mm inside diameter) mounted on the scope before initiating endoscopy facilitates prompt intubation if the injury is found to be significant. If the scope has been placed successfully distal to the injury, the patient can be gently intubated over the flexible fiberoptic bronchoscope (FFB), because it is best to secure the airway distal to the injury. This at least ensures that the patient is safe until he or she can be transported to the OR for further evaluation by an otolaryngologist or general surgeon. Although tracheostomy is often necessary, in these cases, temporary oral endotracheal intubation over an FFB ensures airway control and minimizes the subsequent leakage of air into the tissues, facilitating later repair.[16] If no airway injury is identified and there is no evidence of increase in the subcutaneous emphysema in the neck during spontaneous or assisted ventilation, the injury can

be presumed to be esophageal.[18] If, however, circumstances change and subcutaneous emphysema begins to increase, even slightly, intubation is recommended since development of large amounts of subcutaneous emphysema can distort airway anatomy such that subsequent intubation or surgical airway management becomes difficult or impossible. As with all penetrating neck injuries, early intubation, even in patients who do not appear to immediately require it, is the most prudent course.

The second issue is whether there is evidence of significant vascular injury to the neck. All penetrating neck wounds have some external bleeding, although it can be surprisingly modest. The issue with respect to airway management is whether injury has occurred to any of the major vascular structures in the neck (e.g., carotid arteries, jugular veins). A hematoma of any size, external hemorrhage, or any evidence of displacement of the airway structures can serve as evidence of direct vascular injury. As soon as it has been established that direct vascular injury has occurred, active airway management should be undertaken.[19,20] Most of these patients present early in the course of their injuries, when anatomy is preserved and orotracheal intubation is likely to be relatively easy to achieve. Waiting to determine whether the hematoma is expanding is perilous, because most of the hemorrhage into the neck occurs into the deep tissue planes, distorting and displacing the airway without external evidence until a crisis occurs. The time-honored dictum that hematomas of the neck should be observed to see whether they are expanding is not rational, and any evidence of direct vascular injury to the neck is sufficient justification for intubation. Early intubation can proceed using a rapid-sequence intubation (RSI) technique if a careful examination for difficult airway attributes fails to identify problems and there is a sound rescue strategy planned in the event of intubation failure.[21] Early intervention allows the operator to intubate in a controlled fashion rather than scrambling to secure an emergency airway later in the patient's course, when airway obstruction is imminent or has already occurred.

If there is doubt regarding oral access, three approaches can be considered. The first option is to perform oral RSI under a double setup with preparations and personnel in place to perform immediate surgical cricothyrotomy if orotracheal intubation is not successful. This approach should only be undertaken only if the preintubation airway assessment indicates that orotracheal intubation, although potentially difficult, is still likely to be successful. Similarly, there must be confidence that bag-mask ventilation (BMV) will be successful in maintaining the patient's oxygenation, if required. If visualization is suboptimal during conventional direct laryngoscopy, the use of a bougie or video laryngoscope can be considered.

The second option is to perform fiberoptic intubation under sedation and topical anesthesia, as described earlier. This allows the operator to use the FFB to identify and enter the airway, even if the anatomy has become distorted. If this is undertaken early in the patient's course, there is typically sufficient time and control to yield a high success rate. However, a distorted and bloodied airway makes fiberoptic intubation technically challenging, and the most experienced operator should perform the procedure.

The third option is to proceed directly with a planned surgical cricothyrotomy. This requires that the airway be identifiable with clear landmarks to permit a surgical approach. Local anesthetic infiltration and direct transcricothyroid puncture for instillation of local anesthesia into the airway are likely to make the procedure easier to perform (see Chapter 31).

In all cases of penetrating neck trauma, early consultation with an otolaryngologist or general surgeon is essential. Initially innocuous injuries may lead to catastrophic consequences for the patient if not identified and managed early.[22] Early airway intervention permits controlled resuscitation and prevents major morbidities related to penetrating neck injury, such as airway compromise with resultant hypoxia or anoxia.

2. Blunt Neck Trauma

Many of the management issues related to penetrating neck trauma apply in an analogous fashion to management of the patient with blunt neck trauma. The primary difference is related to the inability to precisely localize the injury (i.e., no obvious skin penetration to identify the point of injury) and the fact that blunt injury is usually more diffuse. Initial evaluation of the patient with a blunt neck trauma should include identification of bruising or ecchymosis related to the external injury. The oropharynx should be inspected to ensure that there is no injury to the tongue or dentition. The external neck should then be palpated carefully from the mandible to the clavicle. Palpation is focused on three findings:

1. Identification of swelling, hemorrhage, or subcutaneous emphysema
2. Evaluation for tenderness (if possible) of the neck, particularly the airway structures
3. Evaluation of the anatomy of the upper airway for direct airway injury and for the anatomic landmarks that are important if a surgical airway must be placed (see Chapter 31).

Because subcutaneous emphysema may be occult, it requires careful palpation. Extensive ecchymosis suggests blunt vascular injury with free hemorrhage (which is usually venous) or formation of a pseudoaneurysm. Extensive ecchymosis or extensive swelling strongly suggests impending airway compromise, and urgent airway intervention is advisable.[23] Infrequently, direct blunt neck trauma can cause laryngeal fracture or tracheal transsection. The latter is often rapidly fatal, but patients may arrive in the trauma resuscitation area alive because of incomplete transsection.[24] In these cases, there is usually subcutaneous air, often accompanied by swelling, and pain elicited by palpation of the anterior airway. Although a trial of BMV may be tempting, it is likely to exacerbate the subcutaneous emphysema and accelerate the patient's deterioration. When such an injury is identified, the best approach is prompt transfer to the OR for surgical exploration of the anterior neck and establishment of the airway by tracheostomy distal to the transsection. Often, however, airway management must be undertaken before the surgery, and careful awake

fiberoptic intubation over a small FFB after inhalational induction may be the least of all evils. If the airway must be secured in the ED, for example, before transportation to a level I trauma center, the same approach is used, substituting intravenous sedation and topical anesthesia for inhalational anesthesia because the latter is not available in the ED.

As with penetrating neck injuries, the key error in the management of the patient with blunt neck trauma is observing an already distorted airway to determine if the condition worsens. If the patient exhibits evidence of significant neck injury, it can be assumed that the airway is threatened. When this threat advances to actual airway compromise, it threatens the patient's life and thwarts subsequent attempts at airway management. As with penetrating trauma, early airway management is indicated when there is evidence of significant blunt injury to the neck.

Airway management is complicated by the fact that patients with blunt anterior neck trauma must be presumed to have a C-spine injury. Up to 50% of patients with blunt airway injury have a C-spine injury,[25] which is discussed here in the context of airway management.

In clothesline injuries, in which the neck is struck, usually transversely, by a fence wire or similar object, the central neck area may be significantly but deceptively disrupted from the impact.[17] Although these injuries can be dramatic and often require immediate airway management, the airway itself is often intact, signified by identification of intact structures and the absence of air bubbling or gurgling during negative-pressure or positive-pressure ventilation. Early intubation from above, preferably over an FFB, is best in these cases. If the airway has been breached, and gurgling or subcutaneous air is evident in the tissues of the neck, positive-pressure BMV is not likely to be successful in oxygenating the patient, and attempts at BMV may result in insufflation of large amounts of air into the soft tissues of the neck, further compromising the airway and the attempts at securing it. The best approach in these cases is to attempt to secure the airway over an FFB using sedation and topical anesthesia, with a plan to progress directly to a cricothyrotomy or emergency tracheostomy, if fiberoptic intubation is unsuccessful.

3. Maxillofacial Trauma

Mandibular fractures are usually isolated injuries, but they can occur in the setting of multitrauma, particularly in unrestrained occupants in motor vehicle collisions and victims of severe assault. They rarely threaten the airway unless the anterior mandible is fractured, which allows the tongue to fall back and obstruct the airway. Usually, this obstruction is easily relieved by pulling the anterior segment of the mandible forward. This maneuver also remedies any interference with endotracheal intubation by the posteriorly displaced tongue. Patients with fractures of the angle of the mandible or the mandibular condyles often have limited mouth opening due to pain and to anatomic restriction. Because the deformity is bony, it is often not abolished by neuromuscular blockade (NMB). Although it is always important to establish the extent of mouth opening and whether it is adequate to permit intubation before administering NMB agents, this is especially true in patients with mandibular fractures.

Maxillary fractures usually occur in one of the classically described Le Fort patterns. Although the precise location of the Le Fort fracture pattern is sometimes difficult to remember, the Le Fort I, II, and III fractures can be thought of as follows (see Fig. 41-2). The Le Fort I fracture represents separation of the roof of the mouth from the face, with the fracture extending through the alveolar ridge to the base of the nose and separating the alveolar ridge and hard palate from the rest of the face. The Le Fort II fracture is separation of the central face from the rest of the face and cranium. The fractures extend from the base of the nasal bones through the medial orbits down through the maxilla to the posterior molars, effectively creating a free-floating central face fragment. The Le Fort III fracture is separation of the face from the skull. This fracture extends from the base of the nasal bones through the orbits to the lateral orbital rims and then through the zygomatic arch and down through the pterygoid plate.

Le Fort I fractures rarely cause airway compromise. If the fracture fragment has displaced posteriorly, it can easily be pulled forward by gripping the upper incisors or alveolar ridge. Le Fort II fractures similarly do not compromise the airway unless extensive hemorrhage is present. The fracture fragment, although free floating, rarely displaces posteriorly enough to compromise the airway. In the absence of hemorrhage, the mouth and oral pharynx are usually patent and functional. However, Le Fort III fractures can significantly compromise the airway due to posterior displacement of the entire central face, compromising the oral and nasal pharynx. Similarly, extensive swelling or hemorrhage related to the fractures may threaten the airway. In all cases, careful oral inspection and suctioning to determine the patency and adequacy of the oral cavity, followed by early intubation for airway protection and overall management of the patient, are advisable.

An uncommon but disastrous presentation of maxillofacial injury occurs when an attempted suicide fails because the gun (usually a shotgun) is oriented in such a way as to have the mass of the shot pass upward through the face rather than on a posterior trajectory through the brainstem. This often happens when the patient places a rifle or shotgun under the chin and then tries to reach downward for the trigger. This movement naturally leads to extension of the neck, and the trajectory of the missile is altered, causing it to pass upward through the face (Fig. 41-4). Although such injuries occur with massive facial distortion, airway management can range from easy to virtually impossible. Destruction of the mandible, tongue, palate, and nasopharynx often makes orotracheal intubation impossible, and hemorrhage is usually extensive. Primary surgical airway management is usually the method of choice. However, the injury can be predominantly anterior, sparing the airway, and the mandible and tongue can be displaced forward, permitting adequate oral access for orotracheal intubation. Nonetheless, efficient suctioning is usually required because the hemorrhage can be significant.

Figure 41-4 Facial trauma.

B. Cervical Spine Injury

Unstable injury to the C-spine presents a particular hazard with respect to airway management because of the potential to cause or exacerbate spinal cord injury. C-spine injury usually occurs when there is high-energy transfer, such as in a motor vehicle collision, but it can occur with relatively minor trauma in patients with significant degenerative disease of the C-spine, such as rheumatoid arthritis or osteopenia. Motor vehicle collisions are the greatest cause of spinal injury, accounting for about 50% of these injuries, followed by falls, athletic injury, and interpersonal violence.[26]

In the trauma resuscitation room, all patients who have been subjected to significant blunt trauma should be assumed to have a C-spine injury until it has been excluded. Penetrating trauma can also cause spinal injury, but creation of an unstable spinal injury without concomitant spinal cord injury is exceedingly rare. With penetrating injury, it is usually apparent whether spinal injury has occurred because the patient sustained a neurologic disability. Barring this finding, C-spine immobilization in a patient with isolated penetrating trauma is typically unnecessary and may even be harmful.[27-29]

One of the significant challenges related to airway management in patients with blunt trauma is the inability to determine definitively whether the patient has a C-spine injury before intubation is required. Fortunately, most patients with a C-spine injury do not require intubation during the acute phase of resuscitation. However, those who have the most severe trauma are likely to require intubation, and this is the same population who is at highest risk for spinal injury.[30] It has been estimated that 2% to 14% of all patients with serious blunt trauma have a significant C-spine injury.[31,32]

The decision about whether to obtain portable C-spine imaging before intubation must take into account two radiographic principles. First, a single, portable, lateral, cross-table radiograph is highly insensitive for significant C-spine injury. At least 25% of lateral C-spine radiographs fail to visualize the cervical-thoracic junction (C7-T1).[33] Even if the lateral radiograph is adequate, it should be considered no more than 80% sensitive for C-spine injury.[34] A complete three-view C-spine series fails to identify about 15% of significant C-spine injuries, and it is difficult to obtain adequately for patients in cervical collars.[35] In consideration of this information, no plain radiograph should be interpreted as indicating that the C-spine is free of injury and that movement can be undertaken with impunity during intubation.

Second, the severe limitations of portable C-spine radiographs question their value before intubation. Current guidelines recommend the use of CT for C-spine evaluation of patients with trauma.[36] Given the limitations of portable cross-table plain radiographs of the spine and the danger of remote imaging before airway management, it is prudent to presume a C-spine injury and intubate with in-line C-spine stabilization without imaging.

Only patients who will not be obtaining CT imaging before emergency surgical management should have a lateral C-spine radiograph in the trauma bay. In other words, C-spine injuries should be presumed for all patients with blunt trauma needing airway management (and precautions should be taken accordingly), with CT imaging obtained for those thought to be stable enough for the scanner. However, in patients proceeding directly to the OR after intubation, a lateral C-spine x-ray (along with portable chest and pelvis radiographs) can be obtained to screen for the presence of catastrophic C-spine injury. In these cases, however, only a positive C-spine radiograph can be considered to provide additional information. The incidence of a false-negative radiograph despite significant injury is high enough that no reassurance should be taken from a negative study result.

Airway management in the patient with C-spine injury must be undertaken with strict attention to C-spine immobilization. This is best performed by a second operator whose sole function is to maintain the alignment of the head, neck, and torso. The best immobilization technique is one that allows the person performing the immobilization to have direct contact with the head and the torso.

Two common methods of immobilization are described. In one method, the assistant approaches the head from the thorax, resting his or her forearms on the upper chest and clavicles and passing the wrists and hands up alongside the neck bilaterally, so that the hands (with fingers spread) can grip and immobilize the occipital-parietal area of the head. This allows the assistant to prevent and detect any change in the angle of the head on the neck or the neck on the body during laryngoscopy and intubation. The assistant must provide direct feedback to the intubator of any motion.

In another method, the assistant crouches below the operating table, usually to the intubator's left side. The assistant then reaches up over the head of the table and immobilizes the base of the occiput with the heels of both hands. The fingers extend down alongside the neck to the top of the patient's shoulders, permitting the assistant to immobilize the head and neck and allowing detection of movement.

Intubation should be performed with the anterior portion of the cervical collar open because it may limit laryngoscopy. Leaving the collar intact has not been shown to reduce significant C-spine movement during

intubation, and is not a substitute for manual in-line stabilization.[37-39] Although cricothyrotomy can be performed through the openings in most cervical collars, it is often technically challenging, and it is preferable to remove the anterior one half of the collar before undertaking surgical airway management. The debate regarding nasotracheal intubation versus various awake intubation techniques versus RSI in the trauma patient is discussed in "Principles of Airway Management in the Trauma Patient."

C. Intracranial Injury

Intracranial injury commonly occurs with blunt and penetrating forms of trauma. In penetrating trauma, injuries are obvious because the penetration must occur proximate to the cranial vault. With blunt trauma, however, the presence of intracranial injury can be much more difficult to establish. Although the Glasgow Coma Scale (GCS) score is widely used in trauma, it is at best a crude instrument. However, in the absence of a reversible cause (e.g., opioid overdose), a GCS score of 8 or less indicates coma and mandates intubation on the basis of airway protection and anticipated deterioration. Any patient with a GCS score of 12 or less should be considered to have significant head injury until cranial CT scanning can prove otherwise. These patients may have elevated ICPs, and all patients with a GCS score of 8 or less should be presumed to have elevated ICPs with loss of cerebral autoregulation. This approach has some impact on the agents selected for intubation and, to a lesser degree, the methods used.

Airway management in the patient with intracranial injury is dictated by an often-conflicting series of choices between limiting the adverse responses in the brain related to intubation and maintaining overall management of the patient's hemodynamic status and resuscitation. In patients with an elevated ICP, stimulation of the upper airway structures by a laryngoscope or other device results in an increase in the ICP.[40] The ICP appears to increase by two mechanisms: First, a release of sympathetic adrenergic transmitters results in elevation in heart rate and blood pressure, which translates to an elevation in ICP in the nonautoregulated brain.[41] Second, a direct reflexive increase in ICP is caused by laryngeal stimulation, although the mechanism is not precisely defined.[42]

Succinylcholine, which is the drug of choice for RSI of the multitrauma patient, is believed to cause an elevation in ICP, although this has been disputed.[43-45] The mitigation of these potential elevations in ICP is an important theme in the airway management of the trauma patient with presumed intracranial injury. Avoidance of hypoxia and hypercarbia and maintenance of adequate perfusion are vital for producing the best possible patient outcome.

Lidocaine has been studied in the context of prevention of the ICP response that is sympathetically mediated and the ICP response that is considered reflexive. Its use during RSI in the context of head injury continues to be controversial. Best-evidence reviews of patient outcomes and lidocaine use during airway management in head injured patients showed that no good evidence exists evaluating this specific issue.[46-48] Several small, randomized trials have found conflicting results with respect to the ability of lidocaine to attenuate spikes in ICP during laryngoscopy and intubation.[41,49-54] Overall, there is insufficient evidence to strongly recommend the use of lidocaine for the purpose of suppression of sympathetic discharge during intubation. However, lidocaine given intravenously at a dose of 1.5 mg/kg has been shown to blunt the direct ICP response to tracheal suctioning and laryngeal stimulation in hypocarbic patients with elevated ICP.[51,53] Lidocaine's wide therapeutic margin, familiarity, safety profile, and ready availability make it a reasonable choice when administered at 1.5 mg/kg intravenously for 3 minutes before the induction agent when undertaking RSI of a patient with known or presumed elevated ICP. Used in this manner, lidocaine may have a beneficial effect on the direct ICP response to laryngoscopy and intubation.

The sympathetic response to intubation has been extensively studied, and synthetic opioids and beta-blockers have been shown to attenuate the reflex sympathetic response to laryngoscopy. Administration of a beta-blocker to a trauma patient may worsen hemodynamic instability and is rarely desirable, except in certain cases of isolated head trauma. Similarly, administration of full sympathetic-blocking doses of the synthetic opioids, such as fentanyl, can have adverse effects, particularly in patients with hypovolemia, who depend on sympathetic drive. Fentanyl, in a dose of 2 to 3 μg/kg as a pretreatment agent, has been shown to attenuate the reflex sympathetic response to laryngoscopy and should have minimal adverse cardiovascular effects.[55] Care must be used, however, to ensure that the fentanyl does not cause respiratory depression with resulting hypercarbia and that the patient has sufficient hemodynamic stability to tolerate even this small dose.

Competitive NMB agents, such as rocuronium, achieve intubating conditions almost as rapidly as succinylcholine, but without the attendant rise in ICP.[56,57] However, the duration of paralysis when 1.0 mg/kg of rocuronium is used for intubation is about 45 minutes.[58] For this reason, succinylcholine, with its ultrarapid onset and shorter duration of action, remains the drug of choice for emergency intubation of trauma patients, including those with elevated ICP. The exacerbation of the ICP elevation by succinylcholine, however, is clearly not desirable. Evidence is poor supporting the administration of a defasciculating dose of a nondepolarizing NMB before succinylcholine to attenuate an increased ICP and is not recommended.

In summary, when RSI is planned, and there is no contraindication, 1.5 mg/kg of intravenous lidocaine and 3 μg/kg of intravenous fentanyl should be considered before the administration of succinylcholine. Defasciculating doses of non-depolarizing NMB drugs should not be used until further study clarifies their role. Laryngoscopy and intubation should be as gentle and atraumatic as possible. There is evidence that minimizing laryngeal stimulation helps to reduce the hemodynamic and ICP responses to laryngoscopy and intubation. Several devices have been evaluated to see

whether they are less traumatic than direct laryngoscopy. Intubations through a laryngeal mask airway (LMA) and with the use of the Trachlight stylet appear to be less stimulating than intubation by direct laryngoscopy.[59,60] Studies comparing intubation over a lighted stylet with direct laryngoscopy indicate that the placement of the ETT into the trachea is more stimulating than the laryngoscopy itself.[61]

D. Intraocular Injury

Most patients with open globe injuries can be intubated in the OR under controlled conditions. Penetrating globe injuries usually are isolated and are caused primarily by implements (e.g., sticks, children's toys) or by low-velocity missiles (e.g., BBs, pellets). Occasionally, open globe injury occurs in the context of multitrauma and requires intubation in the trauma bay. Decisions related to overall management of the patient's multiple injuries should take precedence over management of the eye injury. Whether the intubation occurs in the trauma resuscitation bay or in the OR, the concern related to managing open globe injuries is whether succinylcholine, which causes a transient rise in intraocular pressure, may cause extrusion of intraocular contents.[62] There has never been a single case report of vitreous extrusion after the use of succinylcholine in a patient with an open globe injury.[63] The paramount consideration therefore appears to be prevention of straining, coughing, or bucking during the intubation, arguing for RSI. It has been recommended that a defasciculating dose of a competitive NMB agent be given 3 minutes before administration of succinylcholine in patients with open globe injuries to mitigate the elevation of intraocular pressure, but this approach has never been subjected to study. It appears that defasciculation is appropriate for patients with open globe injuries receiving succinylcholine unless there is a contraindication, such as severe respiratory compromise.

E. Thoracic Injury

Blunt and penetrating injuries can cause sufficient compromise of respiration or oxygenation to mandate intubation. The extent of injuries associated with penetrating trauma depends on the implement or missile used and the location and path of the object involved. High-velocity gunshot wounds to the chest are often fatal, causing disruption of the major vasculature, main stem bronchi, or the heart.[64] Lower-velocity gunshot wounds, especially those more peripherally placed, often cause much less blast injury to the chest, resulting in minor pulmonary contusions and a surprisingly low incidence of hemothorax or pneumothorax.[65] Pneumothorax is common in penetrating injury, whether caused by missile or implement, and cardiac injury with pericardial tamponade can occur. Blunt chest trauma tends to be more diffuse and is more often associated with pulmonary contusion, disruption of the chest wall with concomitant rib fractures, costochondral separation, hemothorax or pneumothorax, and if severe, disruption of a main stem bronchus or of the aorta.

In addition to a thorough physical examination and a determination of vital signs (including O_2 saturation), early, portable, anterior-posterior chest radiography is invaluable in assessing patients who are victims of thoracic trauma. However, obvious life-threatening conditions, such as tension pneumothorax, should be treated before radiographic confirmation. A patient presenting with external evidence of chest trauma (e.g., motor vehicle crash victim with multiple rib fractures and subcutaneous air) who has signs compatible with tension pneumothorax (e.g., hypotension, tachycardia, tachypnea, O_2 desaturation) should have immediate decompressive thoracostomy before radiographic studies. The finding of tracheal deviation occurs only in the final stages of tension pneumothorax when the patient is in extremis, and the presence of a midline trachea should never be used to exclude tension pneumothorax. If there are not sufficient personnel to manage all of the necessary tasks simultaneously, a needle thoracostomy can be done, pending insertion of the chest tube. Needle thoracostomy, however, is strictly a short-term temporizing measure, and tube thoracostomy with a 34-Fr or larger chest tube should be performed at the earliest opportunity. The objective is to release sufficient air such that diminished venous return and cardiac contractility are temporarily relieved. Release of tension pneumothorax also facilitates choice of the induction agent for intubation as hemodynamics typically improve significantly after needle or tube thoracostomy. Mitigation of the intrathoracic pressure helps to avoid the hypotension that may occur when positive-pressure ventilation is instituted after intubation.

Thoracic injuries have three effects on airway management. First, the intrathoracic injuries may be the primary reason for intubation. Pulmonary contusion, bilateral hemothorax, flail chest with respiratory compromise, pulmonary hemorrhage, and major life-threatening intrathoracic injury are all indications for early intubation.

Second, the thoracic injuries may compromise preoxygenation before intubation and promote rapid oxyhemoglobin desaturation after paralysis. Preoxygenation is essential when performing RSI, and patients with severe pulmonary injury may not preoxygenate well. It may be difficult to obtain O_2 saturations greater than 90%, even with high-flow O_2. Rapid oxyhemoglobin desaturation can be anticipated, and these patients may require BMV throughout the intubation sequence to maintain adequate oxygenation. This approach is particularly important in the patient with concomitant head injury.

Third, hypotension related to thoracic injuries may limit agent selection. Some induction agents, such as sodium thiopental and propofol, are potent venodilators and negative inotropes. When they are given to patients with hemodynamic compromise related to thoracic or multisystem injuries, the hypotension can be severe and prolonged. This effect often precludes the use of such agents or necessitates a significant reduction in dosage.

The intubation technique for patients with thoracic trauma is dictated by their overall status. Rarely does the thoracic trauma alone determine the technique. RSI usually is preferred, but care must be taken to

preoxygenate the patient adequately and to maintain adequate oxygenation throughout the procedure. After the patient is intubated, positive-pressure ventilation may further compromise venous return and mean arterial blood pressure, and the mechanical ventilation should be adjusted to maintain adequate oxygenation with the least effective tidal volume until the patient-specific hemodynamic effects of the positive-pressure ventilation can be determined. Patients with pulmonary injury, such as pulmonary contusion, usually do better with modest amounts of positive end-expiratory pressure (5 to 10 mm Hg), but this has the potential to further compromise venous return and must be instituted with caution.

F. Hemorrhagic Shock

The patient in profound hemorrhagic shock has significant metabolic debt, experiences rapid muscle fatigue, is susceptible to respiratory compromise and failure, and usually requires intubation with positive-pressure ventilation unless the underlying process can be reversed. In addition to contributing to the need for intubation, hemorrhagic shock greatly limits the choice of agents for intubation. Induction agents such as sodium thiopental and propofol have significant adverse hemodynamic consequences.[65] These agents should be used in greatly reduced doses or avoided altogether in patients with hemorrhagic shock. Ketamine releases catecholamines and is the most stable of the induction agents. Ketamine can be used in a reduced dose of 1 mg/kg, even in patients with significant hemodynamic compromise. In frank shock, however, ketamine, like every other induction agent, depresses myocardial contractility and must be used with extreme caution.[66,67] It has been implicated in transient elevations of ICP, but the evidence in this regard is highly conflicted.[68] In the context of head injury with significant hypovolemia, ketamine's superior hemodynamic characteristics outweigh its potential to cause small, transient rises in ICP. Although caution is advised in administering ketamine to patients with head injury and to those in shock, it may be the least of all evils if given in a reduced dose in these patients.

Etomidate, an imidazole derivative, has remarkable hemodynamic stability.[69] In the induction dose of 0.3 mg/kg, it causes virtually no change in mean arterial blood pressure in normal and hypovolemic patients. In very large doses (two or three times the induction dose), etomidate consistently causes hypotension.[70] In morbidly obese trauma patients, dosing should be based on their lean body weight, not total body weight. For patients with frank shock, the dose should be reduced to between 0.15 and 0.2 mg/kg. Etomidate appears to have some cerebral protective effect and can significantly lower ICP without adverse effects on perfusion pressure.[71] It is therefore a rational agent for use in patients with multisystem trauma and hypovolemic shock.

Midazolam is infrequently used as an induction agent in multitrauma patients. It exhibits many of the same adverse hemodynamic effects as propofol and Pentothal. If it is used, the dose should be greatly reduced to 0.1 mg/kg in patients in frank shock. However, compared with other readily available agents, midazolam has a slower onset and longer clinical half-life, and at greatly reduced doses, it may not provide adequate amnesia for the patient.[72]

In addition to influencing the decision to intubate and the choice of agents, hemorrhagic shock greatly complicates overall management. Drug circulation times can be longer, and the physician may have to allow more time between the administration of succinylcholine and the first attempt at intubation. Succinylcholine itself is remarkably stable, although an increased or repeated dose may be required because of poor drug distribution in patients who have hemorrhagic shock. Pretreatment agents usually are avoided in hemorrhagic shock, with the exception of lidocaine for elevated ICP.

Isotonic fluid resuscitation must occur in parallel with preparation for intubation. The use of a high-flow blood-infusing unit can provide warmed packed red blood cells at a rate as high as 500 mL/min.[73] Care must be taken not to overshoot the resuscitation, particularly in the presence of penetrating injuries and those thought to be associated with ongoing bleeding. The goal is maintenance of an adequate perfusion pressure to support the brain and vital organs until surgical repair can be undertaken. There is no evidence that restoration of the blood pressure to a normal range is beneficial, and evidence suggests that permissive hypotension may instead be preferable.[74-76] Crystalloid can be infused as the first 2 L of fluid during resuscitation, but it should be rapidly replaced with blood if shock is ongoing. A urinary catheter may be helpful to monitor urine output, and lactic acid or base deficit values can help to monitor the overall treatment of shock.[77] If the patient is not going to be transported promptly to the OR, placement of an arterial line is highly advisable.

IV. PRINCIPLES OF AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

A. Control of the Combative Patient

Trauma patients, particularly those who are intoxicated or who have sustained head injury, are frequently agitated or combative on arrival to the ED. In some cases, this agitation is a result of an overwhelming combination of confusing sensory inputs to the patient. Intoxication, head injury, disorientation, and severe pain can contribute to combative behavior. The patient's mental status may be an extension of a medical condition that precipitated the injury. Hypoglycemia, stroke, syncope, and seizure should be considered when the patient's mental status is significantly altered or when prehospital reports suggest a minor mechanism or minimal vehicular damage.

Initially, attempts should be made to reassure the patient and to help him or her orient to the chaotic environment of the resuscitation room. An agitated and confused patient may be helped by the physician placing his or her face relatively close to the patient's and speaking in a clear, firm, reassuring voice. Although this may have some initial calming effect, physical and chemical restraints are often necessary to facilitate an orderly, efficient, and safe trauma assessment. These patients are often restrained on a long spine board with a cervical

collar, tape, and sandbags, but these constraints are temporary, and the patient's ability to move and to exert significant forces on the potentially injured spine often warrants further action.

The decision about whether to sedate a patient or to intubate for behavioral control should be made on the basis of the patient's overall injuries. If intubation is inevitable, even without combative behavior, based on the patient's injuries and expected clinical course, early intubation is the best approach. RSI allows protection of the C-spine, complete control of the patient, and treatment of multiple injuries without further disruption or pain. If the patient's overall injuries are deemed to be relatively modest and intubation would not be indicated in the absence of the combative behavior, chemical restraint without intubation is the best approach. Repeated, titrated doses of a butyrophenone, such as haloperidol, can rapidly achieve control of the patient without compromising respiration or significantly altering the neurologic examination. In the hemodynamically stable patient, 5 mg of haloperidol can be given intravenously in repeated doses every 5 minutes, with observation for effect.[78] Most patients calm rapidly under the influence of the haloperidol, and management can then proceed in a more orderly fashion. Haloperidol has been rumored to lower the seizure threshold and therefore be contraindicated in patients with head trauma, but this is close to a medical fairy tale. There are no well-controlled studies proving this association, and the remainder of the literature is a heterogenous mixture of rat studies and case reports.[79] There is no human evidence to support this often-cited contraindication. Droperidol was equally effective and commonly used for this purpose before the U.S. Food and Drug Administration (FDA) issued a highly controversial black box warning about QT interval prolongation, which greatly curtailed its use.[80]

Benzodiazepines are often used but have the potential for significantly more respiratory depression than haloperidol. Benzodiazepines must be used with great caution, particularly in patients with concomitant alcohol intoxication. The practice of using haloperidol in combination with benzodiazepines complicates matters by giving two drugs when one drug would do. Haloperidol has stood the test of time in trauma patients, who remain hemodynamically stable, and it can be given in large doses when necessary. Haloperidol does not alter the need to investigate the cause of the patient's combative behavior with CT, neurologic examination, and metabolic testing, but it does rapidly help to achieve control of the patient and permit ongoing evaluation.

B. Prevention of Aspiration

All trauma patients are considered to be at high risk for aspiration. Compromised airway protection from head injury or from intoxication, prone position, and a nonfasted state make aspiration a paramount concern. Reasonable precautions should be taken to prevent aspiration, particularly of gastric contents, during overall trauma management and particularly during airway management. The initial intubation method depends on the constellation of patient injuries, hemodynamic status, and the equipment and expertise available. Most patients, however, will undergo RSI. Induction and the use of NMB drugs that occurs during RSI place the patient at risk for passive regurgitation. Early and generous suction, particularly when hemorrhage exists, reduces the aspiration of blood.

Routine application of posterior cricoid pressure (i.e., Sellick's maneuver) held throughout laryngoscopy was widely accepted dogma because it was thought to prevent aspiration through compression of the upper esophagus against the anterior cervical vertebral bodies. Although it seemed logical, it was never supported by firm evidence.[81,82] Misapplication of cricoid pressure is common among a variety of operators, and it can result in more difficult mask ventilation, direct laryngoscopy, and tracheal tube passage.[83-86] Moreover, regurgitation is often seen despite Sellick's maneuver being applied.[87-90] Advanced imaging suggests the cervical esophagus is positioned lateral to the cricoid ring in many patients, a relationship that is exaggerated by posterior pressure rarely resulting in esophageal obstruction.[91] C-spine motion may occur during cricoid pressure and introduce unnecessary risk for patients with known or suspected unstable C-spine injuries. If applied correctly however, Sellick's maneuver may reduce gastric insufflation during BMV.[92-94] On balance, the best approach is to consider posterior cricoid pressure optional during laryngoscopy and intubation and to remove it immediately if the laryngeal view is poor or tube passage is difficult. It should be routinely performed during prolonged rescue BMV.

If the patient vomits while on the spine board, the patient and the board should be rolled together into the right lateral decubitus position to permit suctioning and evacuation of the vomitus from the mouth. Vomiting is an indication for early intubation in patients who require immobilization on a spine board and who may be relatively helpless to manage the vomitus after it is in the mouth. When applying awake intubation techniques, adequate sedation and topical anesthesia should be used to prevent gagging and emesis. If the patient vomits during awake intubation, there is increased risk of aspiration because of the topical anesthesia of the supraglottic area and the vocal cords. Prompt suctioning and repositioning of the patient, if necessary, should help reduce this risk. There is no evidence that one particular device or technique is more likely to prevent aspiration than any other. RSI, developed as the cornerstone of emergency airway management because of its ability to reduce aspiration, has recently been challenged in this regard.[95]

C. Choice of Technique

The issues related to approach to the airway are discussed in detail in the individual sections earlier in this chapter. Overall, the choice of technique must balance the physiologic status of the patient, the nature of the injuries, predicted airway difficulty, the urgency of the airway intervention, and the availability of various devices and surgical backup. Historically, the Advanced Trauma Life Support (ATLS) course developed by members of the American College of Surgeons advocated blind nasotracheal intubation for patients with suspected C-spine

injuries because it was believed to be less likely to cause C-spine movement. This belief was unfounded, and blind nasotracheal intubation has fallen out of favor as a method of airway management in the trauma patient because of slower intubation times, higher complication rates, and greater O_2 desaturation.[96-98] RSI is the preferred method for most intubations. There was early objection, however, due to suspicion of dangerous degrees of C-spine motion during unrestricted direct laryngoscopy and that residual muscle tone in nonparalyzed patients provided valuable splinting support. As a result of these two fundamentally incorrect beliefs, trauma intubations through the 1970s and 1980s were largely performed by awake intubation. Cadaver studies and those done in living patients have failed to support this contention. There is no evidence that careful laryngoscopy performed with in-line stabilization subjects the C-spine to any risk, although intubation should not be forceful or prolonged. There is good evidence that manual in-line stabilization combined with a careful oral laryngoscopy and RSI does not pose any risk to the cervical spinal cord.[99-101]

Unrelaxed patients present the potential for significantly more C-spine motion as a result of coughing, bucking, gagging, or other movement during an awake intubation attempt. RSI has been successful and frequently used during trauma intubations. In a published report of almost 9000 ED intubations from phase II of the National Emergency Airway Registry showed that 82% of trauma patients underwent RSI and 11% were intubated with no medications; they were mostly patients in full arrest or near-full arrest who were completely unresponsive on presentation and underwent immediate direct laryngoscopy with intubation and manual in-line stabilization. Less than 1% of patients underwent unassisted nasotracheal intubation.[102]

D. The Difficult Airway

Trauma patients represent a group with high-risk, exceptionally difficult airways. Acquired characteristics, such as airway trauma, C-spine immobility, hemodynamic compromise, and other potentially life-threatening injuries, can exacerbate inherently difficult airway markers, necessitating clarity of thought and error-free decision making during intubation. An efficient but detailed difficult airway assessment is necessary before NMB in the multitrauma patient. Conventional assessments that occur during a preoperative visit may not be possible in the trauma bay. It is rarely possible to obtain a prior surgical anesthetic history from the patient. Creators of the national *Emergency and the Difficult Airway Course: Anesthesia* have developed a four-pronged rapid assessment tool that can be quickly applied to virtually any patient.[103] Portions of this tool have been externally validated in emergency populations, and it is currently subject to further validation in the third phase of the National Emergency Airway Registry multicenter registry.[104] The LEMON mnemonic is used as shown in Box 41-1 to identify one or more attributes of a difficult airway in a patient.

The tool is overly sensitive at the cost of specificity, but that is more desirable than the converse. If a difficult intubation is anticipated, physicians use an algorithmic approach that is dictated by how stable the patient is and how urgently he or she needs to be intubated (Fig. 41-5). The easiest surrogate is the best attainable O_2 saturation measurement, because it defines the time available to consider alternative approaches. If the patient is well oxygenated and is reasonably stable (i.e., does not need to be intubated in the next 2 to 3 minutes), a methodic stepwise plan can be made. If the patient is critically desaturated and highly unstable, it is probably necessary to proceed directly with some form of airway intervention promptly without the luxury of a planned approach to the difficult airway. In this scenario, a double-setup RSI, in which the anterior neck is prepared for a surgical airway as RSI drugs are administered, is most appropriate. RSI gives the operator the best chance of intubation success, and if a *cannot intubate, cannot ventilate* (CICV)

scenario develops, a cricothyrotomy should be immediately performed. Primary cricothyrotomy may be the primary method used, usually when orotracheal and nasotracheal intubation is predicted to be difficult or impossible. Rarely, other devices such as the FFB or intubating LMA (ILMA) are useful.

When there is sufficient time (Sa_{O_2} > 90%) to plan the intubation approach carefully, the patient should be evaluated for the likelihood of success with BMV and laryngoscopy. Predicted success with BMV is a necessary precursor to consideration of paralysis. The MOANS mnemonic (Box 41-2) contains a well-validated collection of patient attributes that contribute to difficult mask ventilation.[105] If it is the intubator's judgment that the patient cannot be BMV successfully, a technique using NMB is out of the question unless it is part of a double setup with an immediate ability to move to a surgical airway if the first attempt at laryngoscopy is unsuccessful. Next, the operator must decide whether laryngoscopy and intubation are likely to be successful. If it is thought that the patient is likely to be successfully intubated by direct laryngoscopy despite the difficult airway attributes, taking into consideration that the patient should successfully undergo BMV, RSI can be planned with a surgical backup, as necessary. For example, the assault patient requiring strict C-spine precautions because of a dislocated jaw and active upper airway bleeding would be challenging or impossible to manage with direct laryngoscopy because of a severely reduced mouth opening, neutral head position, and airway bleeding. However, a normal-sized patient who was stabbed in the abdomen and was placed in a C-spine collar by emergency medical services but who has little likelihood of a neck injury would routinely warrant a laryngoscopic attempt. Both patients meet criteria for a difficult airway, but successful direct laryngoscopy is reasonable in the second patient but not in the first patient. With the advent of the video laryngoscope, traditional difficult laryngoscopy predictors may not apply, and what constitutes a difficult video laryngoscopic attempt has not been defined. As our knowledge and experience with video laryngoscopy develops, our threshold for NMB in these patients may change.

In most circumstances, difficult airway attributes are identified in trauma patients, but the operator can still be confident that BMV and direct laryngoscopy will be successful, thereby permitting RSI. If, however, in the opinion of the operator, BMV or direct laryngoscopy is unlikely to be possible, it is better to proceed with an awake technique. This involves administration of sedation and use of topical anesthesia to permit awake evaluation of the airway by a direct, video-assisted, or fiberoptic technique (see Chapter 11). Awake laryngoscopy is a common approach that has three possible outcomes: the cords are well visualized, and the patient is intubated; the cords are well visualized, and the decision is made that RSI is possible (in this case, awake laryngoscopy is terminated, and the patient undergoes RSI); or awake laryngoscopy determines that orotracheal intubation will likely be difficult or impossible, and an alternative approach is necessary.

If, after awake direct laryngoscopy, it is determined that the patient cannot be intubated orally, there are several alternative techniques, which are described elsewhere in this textbook. In the trauma patient, the most useful of these is video laryngoscopy. Although it is susceptible to soiling from airway secretions and bleeding, the mechanical limitations inherent in direct laryngoscopy virtually vanish with video laryngoscopy, and glottic visualization nearly always improves.[106,107] Surgical cricothyrotomy, flexible fiberoptic intubation, video laryngoscopy, a lighted stylet technique, and an ILMA may be useful in selected cases. Supralaryngeal or retroglottic airways, such as the LMA, King LT, and others, can be used as a rescue device in the setting of a failed airway, but they are rarely preferred as a primary management tool in trauma patients because of the uncertainty about their ability to protect against aspiration. The goal in managing the trauma patient, even with an identified difficult airway, is to achieve endotracheal intubation with an inflated cuff to protect against aspiration. Placement of a device that does not achieve this is normally considered only in circumstances in which there has been a failed airway or the patient has precipitously arrested and definitive airway management is not possible (see "The Failed Airway").

E. Pharmacologic Considerations

Injured patients are most often managed with RSI and several factors commonly observed for trauma victims should be considered when finalizing the pharmacologic menu. Rapidly selecting the appropriate induction agent, NMB agent, and pretreatment agents to secure the airway with the least likelihood of adverse effect is paramount.

Trauma patients are frequently hypovolemic, even if their initial mean arterial blood pressure is normal. Drug selection must go hand in hand with volume resuscitation and other appropriate interventions, such as tube thoracostomy, control of external hemorrhage, and pelvic stabilization. The individual decisions related to choice of pretreatment and induction agents are discussed throughout this chapter, but a few points should be emphasized.

Induction agents should be chosen to provide the best possible intubating conditions (used in conjunction with succinylcholine) with the least likelihood for adverse hemodynamic consequences. Etomidate, in a dose of 0.3 mg/kg, is remarkably hemodynamically stable, appears to provide some degree of cerebral protection, and has an onset-duration profile similar to that of

succinylcholine. Although etomidate has been associated with adrenal cortical suppression, this is not clinically significant when a single dose is used for induction for intubation.[108] Its safety during RSI in trauma patients has been challenged, although these studies have fatally flawed methodology and low patient numbers, making the results hard to interpret and impossible to apply to clinical practice.[109,110] Etomidate can cause myoclonic jerks during its onset, but use of a rapidly acting NMB agent, such as succinylcholine, mitigates this effect substantially. Ketamine is an appropriate induction agent for hypotensive trauma patients. Ketamine's role in head injury has been questioned because of its tendency to cause elevated ICP, but it is likely that the preservation of cerebral perfusion by maintenance of mean arterial blood pressure in hemodynamically unstable patients is more important than any theoretical risk to the brain caused by ketamine's tendency to increase cerebral activity and ICP.[64,111] Other induction agents, such as propofol and pentothal, have much more tendency to cause hypotension and should be used in reduced doses and with caution in compromised or elderly trauma patients. Patients in shock with an immediate need for intubation should be given reduced (one-third to one-half) doses, regardless of the induction agent. Choice of a paralytic is not altered by the presence or absence of trauma. Succinylcholine and rocuronium are both appropriate and result in near-equivalent intubating conditions and first-pass success, depending on the dose used.[112,113]

The choice of agents for sedation and awake intubation is influenced by the patient's general status. It is advisable to use the agent with which the operator is most familiar for sedation. For example, if the operator typically sedates patients for painful procedures using propofol, it may be the best choice to sedate the trauma patient for awake laryngoscopy. In the absence of operator preference, ketamine may be ideally suited, especially when combined with an antisialagogue because of its ability to preserve respirations and hemodynamic status.[114] Overall, familiarity with the drugs and the ability to titrate them carefully are probably more important than the drug's pharmacodynamic characteristics.

F. The Failed Airway

In managing the severely traumatized patient, it is important to have a clear definition of airway failure and a prepared action plan. The most widely accepted definition of a failed airway and the one used in the *Emergency and the Difficult Airway Course: Anesthesia* states that a failed airway exists when "(1) there have been three failed attempts by the most experienced operator, or (2) there has been one failed attempt by an experienced intubator combined with an inability to maintain adequate oxygen saturation despite airway adjuncts, maximal supplemental oxygen, and a bag and mask."[115]

In either case, it is necessary to recognize that, with the current method and device being used, orotracheal intubation is not going to succeed, and the operator must move on to a rescue technique. If three attempts have failed, but oxygenation can be maintained with BMV, the operator should quickly evaluate why intubation was unsuccessful. Despite solid direct laryngoscopic technique, inadequate glottic exposure is often the culprit and results from the additive effect of poor C-spine mobility, reduced mouth opening, and oral secretions and blood. The modern difficult airway manager should have within his or her immediate reach a device designed to overcome these limitations and see around corners. Many options exist, although video laryngoscopy has shown the most promise, resulting in improved laryngeal views in almost every conceivable scenario in OR studies and ED populations.[106,107,116,117] In the CICV scenario, the most appropriate rescue device is surgical cricothyrotomy. One parallel attempt at oxygenation may occur by rapid, blind insertion of a rescue supralaryngeal airway, such as a King LT or LMA, but only in concert with preparation for a surgical approach. If the patient's oxygenation improves, other options can be explored. There should, however, be no hesitation for performing a cricothyrotomy if the slightest hint of supralaryngeal airway failure exists. An algorithm for managing a failed airway was developed for the *Emergency and the Difficult Airway Course: Anesthesia* and is shown in Figure 41-6.[115] The theme of the algorithm is that decisions are driven by whether there is sufficient

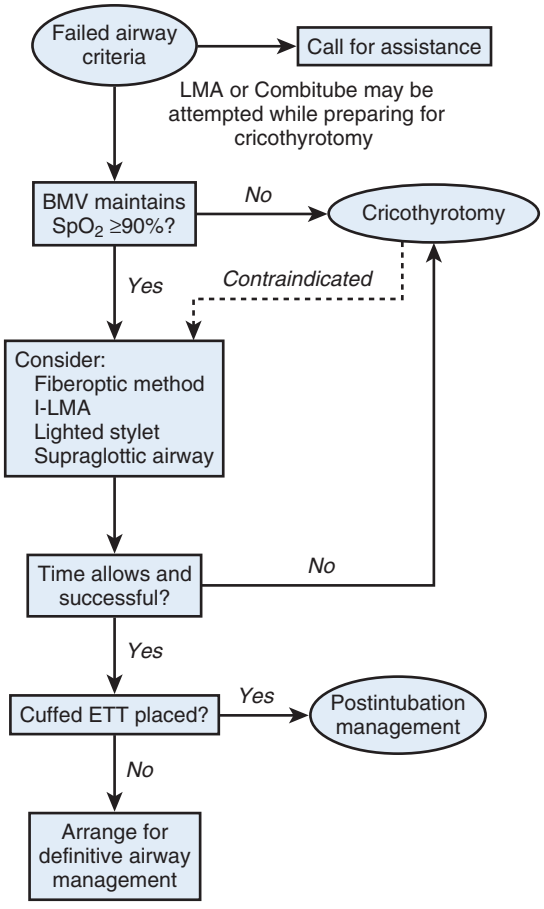

Figure 41-6 Failed airway algorithm. *BMV,* Bag-masic venfilation; *ETT,* endotracheal tube; *I-LMA,* intubating laryngeal mask airway; *LMA,* laryngeal mask airway; *SpO_2,* oxygen saturation measured by pulse oximetry. time to consider alternatives. If a CICV scenario arises at any time, the pathway leads to cricothyrotomy.

G. Rescue Techniques

The ultimate rescue technique for a failed airway in the trauma patient is surgical cricothyrotomy (see Chapter 31). When intubation has failed but ventilation is possible (i.e., *cannot intubate but can ventilate* scenario), several devices warrant consideration. They appear in the central box of the algorithm in Figure 41-6.

If direct laryngoscopy alone has been used, the operator should consider video laryngoscopy. The Glidescope video laryngoscope (GVL) and Macintosh video laryngoscope have been shown to improve laryngeal view compared with direct laryngoscopy in heterogeneous patient populations. Use of the GVL is associated with high levels of intubation success after failed direct laryngoscopy, although it may not be as effective in patients with significantly altered upper airway anatomy.[118] Video laryngoscopy should be considered early as a backup or principal intubating device for significantly difficult trauma airways. Optically enhanced devices, such as the Airtraq, are understudied in trauma populations, although, early data suggest the Airtraq may be effective for patients requiring C-spine precautions.[119]

If these tools are not available, many supralaryngeal airways can be tried. The Combitube has been evaluated as a primary airway management device and as a rescue device. Numerous studies have shown that emergency medical technicians can successfully insert Combitubes with a high likelihood of success.[120,121] When studied in a cadaver unstable C-spine model, the Combitube produced more posterior C-spine displacement than the LMA or fiberoptic methods. This suggests that in-line stabilization is equally important during Combitube insertion as during direct laryngoscopy.[122] Insertion with a cervical collar in place, however, has yielded mixed results. One study showed a high insertion success rate, and another reported successful blind insertion in only one third of patients with a semirigid collar on.[123,124] Ventilation with the Combitube, however, usually is highly successful.[124] The primary use of the Combitube is as a rescue device in the cannot intubate but can ventilate scenario in which other airway devices are thought unlikely to be successful. The Combitube is a less desirable choice because it does not place a cuffed ETT in the trachea when located in the esophageal position, but it usually suffices for ventilation and oxygenation. Another role for the Combitube is as a temporizing measure during preparations for cricothyrotomy. In this circumstance, only a single, expeditious attempt at placement is warranted.

Patients may arrive in the trauma bay with the Combitube inserted, inflated, and functioning. Because the Combitube does not provide a definitive airway (defined as a cuffed ETT in the trachea), it is advisable in most circumstances to intubate the patient and remove the Combitube. Details of insertion and use of the Combitube are discussed in Chapter 27, but there is a specific technique that must be used to intubate when the Combitube is in place. The Combitube has two cuffs, which are inflated through two separate channels. The proximal (pharyngeal) cuff is the larger of the two and is indicated by the blue filling valve. After ensuring that the patient is stabilized and adequately preoxygenated, this proximal cuff should be deflated. The Combitube should then be moved to the left corner of the patient's mouth to permit access from the right side for laryngoscopy. Because the Combitube is almost always placed in the esophagus, it can remain in place while laryngoscopy proceeds. If difficulty arises, video laryngoscopy may be performed.[125] After the patient is intubated with the ETT cuff inflated and tube position confirmed by end-tidal CO_2 detection, the distal cuff on the Combitube can be deflated, and the Combitube can be removed. In the few cases in which the Combitube is inserted in the trachea, it can serve as a definitive airway, and tracheal placement is identified because successful ventilation and CO_2 detection are occurring through its second port. It has been recommended that a nasogastric tube be passed and the stomach decompressed before removal of the Combitube. It is possible for regurgitation to occur after removal of the Combitube, particularly if BMV occurred before placement of the Combitube in the prehospital setting.

In the ED and trauma resuscitation room, the ILMA is preferable to the Classic LMA. The ILMA is equally or more easily inserted and allows a conduit for subsequent intubation, with a significantly higher success rate than for the Classic LMA.[126,127] The ILMA has also been used to facilitate fiberoptic intubation and lighted stylet intubation.[128] The standard LMA and the LMA ProSeal have reasonable insertion success rates in the context of C-spine immobilization, but this situation has not been evaluated for the ILMA.[129] The ILMA has two main uses in the trauma patient. It can be used as the primary intubation method in a patient with an identified difficult airway. In the trauma patient, however, particularly one with an immobilized C-spine, the ILMA typically is not the first device selected. More commonly, the ILMA is used as a rescue device in a cannot intubate but can ventilate scenario. Placement of the ILMA allows ongoing ventilation with a very high success rate and facilitates endotracheal intubation. Like the Combitube, the ILMA can be placed as a temporizing measure during preparation for a cricothyrotomy in a CICV situation, as long as the placement and attempted ventilation through the ILMA do not delay initiation of surgical cricothyrotomy. Although less studied, the King LT shows promise as an effective rescue device and offers advantages of speed and success over the Combitube when used by prehospital providers.[130]

The lighted stylet has not been studied specifically in trauma as a primary intubating device or as a rescue device. In controlled settings and experienced hands, the lighted stylet can have a high intubation success rate. However, the possible need for reduced lighting during a trauma resuscitation, the lack of supporting evidence in managing trauma, and the availability of more effective video devices make this tool an option best left on the shelf.

V. CONCLUSIONS

The trauma airway is a subset of the difficult airway. In addition to the standard markers, specific issues such as anatomic disruption, brisk bleeding, and polytrauma must be managed along with global trauma resuscitation, making trauma airways particularly challenging. The fundamental principles that are applied to all patients with difficult airways must be applied to trauma patients. The foundation for success is an orderly approach, including prioritization of resuscitation steps, evaluation of the specific characteristics of the difficult airway, careful selection of pharmacologic agents, early use of video or optically enhanced airway tools, and coordination with other members of the resuscitation team.

VI. CLINICAL PEARLS

- Many trauma patients may initially appear to be maintaining their airways well, but because of progressive airway obstruction or multisystem traumatic comorbidities, they can deteriorate rapidly.
- Intubating a trauma patient should be part of an overall team-based approach to resuscitation. Although intubation may not be necessary to maintain airway patency, the patient's expected clinical course or need for emergent surgical intervention may prompt intubation.
- The gag reflex should not be used to gauge airway protection in any patient, especially those with trauma, who are typically secured on a backboard in a cervical collar and prone to aspiration. If these patients do vomit, they should be rolled with the board into a lateral decubitus position.
- Current evidence supports a strategy of not immobilizing the C-spine in patients with isolated penetrating trauma who do not have signs of neurologic compromise.
- CT images, not radiographs, should be obtained for all patients with suspected C-spine injury who are stable enough for travel to a CT scanner.
- Advent of the video laryngoscope has changed the management of difficult airways. Improved glottic visualization and high success rates for intubation support its use as an early rescue tool and principal intubating device.
- Sellick's maneuver does not prevent aspiration and may make intubation more difficult. It should be routine during bag-mask ventilation (BMV) but optional (at best) during intubation.
- Proceed with caution using induction agents, such as propofol or full-dose benzodiazepines, in patients with significant hemorrhage or shock.
- Predictors of a difficult airway, such as those contained in the LEMON mnemonic, should be applied to all trauma patients.
- A variety of effective rescue airway devices are available for use in trauma patients. Airway specialists should become familiar with and practice several of them to maximize the options available in case of a failed airway.

Chapter 42

The Difficult Airway in Neurosurgery

IRENE P. OSBORN | LARA FERRARIO

I. Introduction

II. The Neurosurgical Patient
- A. Intracranial Dynamics and the Airway

III. Clinical Strategies for the Neurosurgical Patient
- A. Patient for Craniotomy
- B. Head-Injured Patient
- C. Patient with Cervical Spine Disease
  1. Management of Acute Injury and the Unstable Spine
  2. Chronic Spine Disease with Myelopathy

IV. Failed Intubation or Anticipated Difficult Airway
- A. Patient in a Halo Frame or Stereotactic Headframe
- B. Patient for Awake Craniotomy or Embolization Procedures
- C. Patient with Acromegaly
- D. Role of Laryngeal Mask Airway in Neurosurgery

V. Postoperative Considerations
- A. Airway Injury and Function after Neurosurgery
  1. After Supratentorial Craniotomy
  2. After Cervical Spine Surgery
  3. After Posterior Fossa Surgery

VI. Conclusions

VII. Clinical Pearls

I. INTRODUCTION

Airway management in the neurosurgical patient is sometimes a challenging endeavor. In achieving and maintaining a patent airway, it is important to consider its impact on the central nervous system and the well-being of the patient. This chapter reflects the authors' experiences anesthetizing neurosurgical patients in several institutions. The 1990s were declared "the decade of the brain," and since then the variety of neurosurgical procedures, anesthetic techniques, and airway devices has increased dramatically. The evolution of neurosurgical practice and the growth of complex spine surgery provide a myriad of clinical challenges.

This chapter reviews the range of airway considerations faced daily by the neuroanesthesia practitioner. The goal is to address issues specific to the dedicated neuroanesthesiologist, as well as those related to the neurosurgical patient that might be encountered by the generalist anesthesiologist. This discussion reflects the ever-changing considerations in airway management of the neurosurgical patient and offers solutions to common clinical problems that occur in this patient population.

II. THE NEUROSURGICAL PATIENT

The American Academy of Neurological Surgeons (AANS) estimates that almost 1 million neurosurgical procedures are performed annually in the United States. Spine procedures are performed at three times the rate of cranial surgeries.[1] When considering the range of potential neurosurgical procedures, the variety of patient pathophysiology is substantial. A patient presenting for neurosurgery may appear to be completely normal or can present with clinical symptoms of intracranial hypertension. The airway might be assessed as "normal" but the patient's head is fixed in a frame. Also, the patient may present with acromegaly for pituitary surgery or may have a previous history of difficult intubation. Additionally, the unanticipated difficult airway becomes an even greater challenge in patients at risk for cerebral aneurysm rupture. Other challenges include the spine surgery patient in the prone position and considerations for extubation after prolonged surgery. Patients with central nervous system (CNS) disease can be sensitive to the effects of hypnotic agents, rendering them susceptible to apnea when premedication is given.

Neurosurgical procedures comprise only 7% of cases in the American Society of Anesthesiologists (ASA) closed-claims database but are associated with settlements that are 1.6 to 4 times more than general surgical procedures.[2] Understanding the patient's physiologic requirements, in addition to the surgeon's plan, is extremely important in these patients. It is wise to have a number of techniques for achieving, maintaining, and rescuing the neurosurgical airway.

A. Intracranial Dynamics and the Airway

Intracranial pressure (ICP) is the pressure within the rigid skull. Airway management in the face of intracranial hypertension is a frequent challenge for the neuroanesthesiologist, as well as the emergency physician. The patient who does not require immediate airway control may benefit from the simple maneuver of elevating the head. The head-up position may have beneficial effects on ICP through changes in mean arterial pressure (MAP), airway pressure, central venous pressure, and cerebrospinal fluid displacement.[3] Cerebral perfusion pressure (CPP) is the effective perfusion pressure driving blood through the brain, defined as the difference between mean arterial and intracranial pressures (CPP = MAP – ICP). A frequent consideration in the neurosurgical patient is the need to balance and maintain intracranial dynamics, avoiding increases in ICP, yet maintaining cerebral perfusion. Although head elevation may reduce ICP, raising the head above 30 degrees may place the patient at risk for venous air entrainment and should be done with caution.

Ventilation is intimately related to cerebral blood flow (CBF) and is an integral part of neuroanesthesia management. The avoidance of hypercarbia is essential in management of patients with intracranial hypertension. Carbon dioxide dilates the cerebral blood vessels, increasing the volume of blood in the intracranial vault and therefore increasing ICP. Periarteriolar hydrogen ion concentration, $[H^+]$, powerfully influences cerebral arteriolar tone, and as the arterial carbon dioxide tension ($Paco_2$) rises, $[H^+]$ increases, causing arteriolar dilatation. This leads to a concomitant decrease in cerebrovascular resistance, causing an increase in CBF, and an increase in cerebral blood volume (CBV).[4] Difficult mask ventilation may quickly lead to hypercarbia, hypoxemia, and increased CBF. Hypoxia also remains one of the more potent arteriolar cerebrovascular dilators. Changes in the arterial oxygen tension (Pao_2) are associated with late increases in CBF. Hypoxia or ischemia leads to marked vasodilation, increased arterial vascular volume, and intracranial hypertension.[5]

Laryngoscopy and intubation, if performed with difficulty or improperly, can severely compromise intracranial dynamics and increase morbidity. Both the sympathetic and the parasympathetic nervous system mediate cardiovascular responses to endotracheal intubation.[6] Acute increases in ICP and MAP during laryngoscopy and endotracheal intubation have been well documented.[7] In 1975, Burney and Winn[8] measured ICP in 12 patients undergoing craniotomy and two patients for carotid arteriography. ICP did not change in response to the injection of contrast medium but increased significantly and dramatically in response to laryngoscopy and intubation. The increase appeared related to the initial ICP of these patients, possibly representing exhaustion of compensatory mechanisms. Special attention must be given to this factor during manipulation of the larynx in neurosurgical patients with initially increased ICP or space-occupying intracranial lesions.

Techniques to blunt this sympathetic response have included (1) an additional dose of thiopental or propofol, (2) use of beta-blockers or other antihypertensive agents, and (3) use of intravenous (IV) lidocaine. Esmolol or lidocaine as an IV bolus of 1.5 mg/kg before laryngoscopy and intubation did not completely prevent the increase in MAP and ICP.[9,10] Etomidate has been shown to cause an early "burst" suppression pattern on the electroencephalogram (EEG), minimal changes in CPP, and a marked reduction in ICP. This decrease in ICP was maintained during the first 30 seconds and the following 60 seconds after intubation, as MAP and heart rate remained unchanged.[11] Although not practical, this approach demonstrates the extent of efforts often made to obtund this response. Numerous methods have been advocated to prevent undesirable cardiovascular disturbances at intubation.[12] Whereas the cardiovascular response can be dramatic and substantial, the ICP response may lag behind and persist longer. Once the patient is intubated, ventilation parameters may be adjusted to the clinical situation.

III. CLINICAL STRATEGIES FOR THE NEUROSURGICAL PATIENT

Airway assessment of the neurosurgical patient requires similar considerations as described in other chapters of this textbook. The patient who has undergone previous surgery and has a history of difficult intubation warrants particular attention. A review of the anesthetic record should reveal which techniques produced success or failure. Difficult mask ventilation is of particular concern because of the potential for causing hypercarbia and the detrimental changes previously described.

A. Patient for Craniotomy

Patients who are neurologically intact may demonstrate no evidence of intracranial pathology or alteration. In addition to the history and physical examination, preoperative computed tomography (CT) or magnetic resonance imaging (MRI) scans of the head may give valuable information, because lesions associated with greater than 10 mm in midline shift or cerebral edema usually indicate intracranial hypertension.[13] These patients should be appropriately managed to avoid undue increases in ICP and CBF. Such measures include proper head positioning, preoxygenation, and appropriate dosing of induction agents and relaxants to achieve a smooth intubation. The primary challenge in anesthetizing a patient with a supratentorial mass lesion is to avoid further increases in ICP when one has limited intracranial compliance. There is no "ideal anesthetic" for this group of patients, and the perioperative management should be individualized. However, the practitioner should be aware of the effects of anesthetic agents on intracranial dynamics.

The preoperative use of midazolam for anxiety in these patients should not cause harm if they are carefully observed. A 1-mg to 2-mg dose of IV midazolam in adult patients may facilitate the induction of anesthesia without altering intracranial dynamics.[14] Opioids, on the other hand, should be restricted to very small amounts and given preoperatively under constant supervision because of possible hypercarbia and resultant effects. The efficacy

of depth of anesthesia was recognized early on as a technique for avoiding intracranial hypertension.[15] Deep inhalation anesthesia was replaced by a combination of intravenous induction agents, notably thiopental, in combination with fentanyl. Thiopental produces a dose-dependent reduction in CBF and cerebral metabolic rate of oxygen consumption ($CMRO_2$). Other barbiturates, such as pentobarbital and methohexital, essentially have similar effects. ICP is reduced by barbiturates, likely because of the reduction in CBF and CBV. *Propofol* has largely replaced thiopental as the induction agent of choice for neuroanesthesia. Despite initial concerns about decreasing MAP and CPP, propofol provides a smooth transition to unconsciousness without an increase in heart rate, as observed with thiopental. This often produces less hypertension with laryngoscopy and intubation.[16]

Clinical doses of most opioids have minimal to modest depressive effects on CBF and $CMRO_2$. Early studies demonstrate that ICP is either not elevated or slightly decreased with fentanyl alone or in combination with droperidol. Reported ICP increases in patients with space-occupying lesions have been attributed to hypercapnia. The variability in response to opioids appears to be caused by the background anesthetic. When vasodilating drugs are used as part of the anesthetic management, the effect of the opioid is consistently that of a vasoconstrictor. *Sufentanil* was thought to produce an increase in ICP in patients with intracranial mass effect, but this was later attributed to a decrease in MAP.[17] *Alfentanil* produces little changes or slight decreases in CBF.[18] The beneficial effect of synthetic opioids is their ability to blunt the hemodynamic response to laryngoscopy and intubation without affecting intracranial dynamics. *Remifentanil* produces the most profound and consistent response, with lack of hypertension, tachycardia, or increase in ICP.[19] A continuous infusion throughout induction may provide the most effective hemodynamic control, while adequate ventilation is maintained.

The volatile agents, including nitrous oxide, can be considered dose-dependent cerebral vasodilators.[20] As a component of neuroanesthesia, volatile agents are typically used in moderate doses, in combination with opioids and hypnotic agents. The effects on cerebral circulation and metabolism of sevoflurane and desflurane are largely comparable to isoflurane. Both induce a direct vasodilation of the cerebral vessels, resulting in a less pronounced increase in CBF, compared to the decrease in cerebral metabolism.

Induction may be followed by hyperventilation with a volatile agent to deepen the anesthetic, decrease $CMRO_2$ (and CBF), and provide bronchodilation in patients with asthma or chronic obstructive pulmonary disease. Sevoflurane is useful in both pediatric and adult patients by allowing inhalation induction without the adverse effects of coughing or breath-holding.[21] A frequently employed technique in the cooperative patient is the use of active hyperventilation before induction, to initiate hypocapnia and decrease CBF as the patient loses consciousness. The use of topical anesthesia applied to the larynx and trachea can also prevent further response to laryngoscopy and intubation.[22] The large number of techniques recommended to suppress cardiovascular responses indicates that no single method has gained widespread acceptance (Table 42-1).

The obtunded patient with symptoms of intracranial hypertension requires additional attention to detail, avoiding premedication and maneuvers that increase coughing. If a rapid-sequence induction is not indicated

TABLE 42-1

Anesthetic Techniques to Avoid Increased Intracranial Pressure

Technique	Precaution(s)
Avoid hypercapnia.	Be vigilant of patient's respiratory status. Avoid undue sedation.
Avoid hypoxia.	Supplemental oxygen use mandatory. Be vigilant of patient's respiratory status. Take precautions to avoid aspiration. Preoxygenation before induction of anesthesia or tracheal intubation.
Avoid marked hypertension.	Be vigilant to changes in degree of painful stimulation. Ensure adequate depth of anesthesia before intubation attempts or surgical/procedural attempts.
Avoid severe neck rotation.	Attempt to maintain neck in neutral position. Be vigilant to head positioning of patient during surgery.
Avoid compression of jugular veins.	Consider avoiding internal jugular neck lines when possible.
Elevate head.	If backup position not possible, use reverse Trendelenburg (avoid hypotension).
Decrease blood viscosity and intracerebral vascular volume.	Avoid rapid infusion of mannitol, which may paradoxically increase intracranial pressure.
Avoid sustained increases in intrathoracic pressure.	Use maneuvers or pharmacologic agents to avoid bucking, movement, and vomiting. Avoid high ventilatory pressures when possible. Avoid PEEP when possible.
Avoid cerebral venodilators.	Consider beta-blocker use to treat hypertension. Consider calcium channel blockers. Avoid nitroglycerine and nitroprusside, if possible.

PEEP, Positive end-expiratory pressure.

and the patient's airway anatomy is adequate for laryngoscopy, anesthetic induction may proceed with voluntary hyperventilation with 100% oxygen by mask, if possible. After loss of consciousness, manual hyperventilation should occur both before and after administration of muscle relaxant. Opioid administration may begin at this time to prevent the sympathetic response to laryngoscopy. IV lidocaine (1 mg/kg) may be administered to blunt the hemodynamic and ICP response to laryngoscopy. Alternatively, a beta-blocker or an additional dose of propofol may be given. Esmolol or lidocaine, 1.5 mg/kg as an IV bolus before laryngoscopy and intubation, does not completely prevent the increase in MAP and ICP. Complete neuromuscular blockade should be verified before laryngoscopy to prevent cough and associated increases in ICP. Proper airway management is essential to avoid the twin insults of hypoxia and hypercarbia. An obstructed airway may also lead to a rise in intrathoracic pressure. This may produce an elevated venous pressure, increase in intracranial blood volume, and elevated ICP. If the patient can be mask-ventilated but intubation is difficult, one may choose to proceed with an alternative device to facilitate intubation.

Alternative devices, such as the lightwand, can be useful in failed intubation, particularly in patients with a small chin or limited mouth opening. Because a lightwand is inserted without use of a laryngoscope, there is potential for less hypertension and tachycardia. This finding was demonstrated by Nishikawa and associates[23] in 60 patients undergoing awake intubation for emergency surgery. Its successful use in the difficult airway requires experience and practice. Brimacombe and Kihara[24] compared the hemodynamic responses of the lightwand and intubating laryngeal mask airway (ILMA) to direct laryngoscopy in hypertensive and normotensive patients. In their series, both the ILMA and the lightwand attenuated the hemodynamic stress response to tracheal intubation compared with direct laryngoscopy in hypertensive, but not in normotensive, anesthetized paralyzed patients. Optical stylets, such as the Shikani Optical Stylet scope or the Clarus Video System, have similar characteristics and insertion technique with the added benefit of laryngoscopic viewing (Fig. 42-1) The ILMA is particularly useful in the failed intubation sequence, and the ability to ventilate is extremely important in neurosurgical patients. The success of the ILMA as a ventilatory device has been impressive, as demonstrated in several of the early evaluation studies.[25,26] It is also extremely useful in the setting of a failed fiberoptic intubation.[27]

Figure 42-1 Intubation using the Clarus video system (Clarus Medical, Minneapolis, MN).

The patient for aneurysm surgery who presents with a difficult airway is particularly problematic. If the airway is anticipated or known to be difficult, fiberoptic intubation is often the method of choice. This is assuming that one is skillful using the fiberoptic scope and is prepared to perform this technique in the awake, cooperative patient (see Chapter 11). IV fentanyl and midazolam may be carefully administered if the patient does not exhibit signs of intracranial hypertension. An arterial line is generally placed before induction. Additional techniques include remifentanil infusion (0.05 μg/kg/min) and dexmedetomidine infusion.[28,29] Both techniques require careful patient monitoring and may be useful. Once the glottis is viewed, a dose of lidocaine may be given via the fiberoptic scope to prevent coughing and "bucking" with intubation.

Alternative techniques for failed sedation or topicalization include awake placement of the ILMA or other techniques that do not produce excessive hemodynamic responses. The concomitant administration of beta-blockers or vasodilators may be necessary for blood pressure control. Essentially, the ASA Difficult Airway Management Algorithm should be followed with close monitoring of blood pressure and heart rate at all times until the airway is secured.

B. Head-Injured Patient

Traumatic brain injury (TBI) remains a prevalent disease in the United States and the world. The incidence of TBI is 175 to 300 per 100,000 population and accounts for 56,000 deaths per year in the United States.[30] With the increased use of seatbelts, motor vehicle crashes are now secondary to gunshot wounds as the leading causes of TBI. Early intubation of the head-injured patient is critical and is often established in the field if providers are so trained. It is essential for optimal management of the patient, providing for efficient ventilation and oxygenation, helping to prevent aspiration of gastric contents, and allowing for suction of the lungs and pulmonary toilet. However, patients who are unconscious and breathing adequately may be transported with oxygen by mask throughout their initial assessment. This is intuitive in the apneic and unresponsive patient with a Glasgow Coma Scale (GCS) score of 8 or less.

The anesthesiologist caring for the patient with TBI must understand that although primary mechanisms of injury *(primary insults)* are a large determinant of patient outcome, attention to *secondary insults*, such as hypoxia, hypotension, intracranial hypertension, and decreased CPP, can impact dramatically on morbidity, mortality, and quality of life of the TBI patient.[31] Evidence supports this, with mortality from TBI nationally decreasing over the decades.[32] *Hypoxia* in TBI patients is a frequent occurrence, particularly in the prehospital setting. Interestingly, hypoxia was identified in 44% of patients with TBI on

arrival in the emergency department.[33] Similarly, Jeremitsky and colleagues[34] report that hypoxia is one of three predictors of mortality in adult brain-injured patients (with hypothermia and hypoperfusion). Hypoxia dramatically impacts morbidity and mortality in TBI, and hypercapnia further increases mortality.

Hypotension is the secondary insult that has been most frequently cited as contributing to poor outcome after TBI. Hypertension is independently related to mortality in multivariate analysis.[34] Information from the Traumatic Coma Data Bank shows that a systolic blood pressure less than 80 mm Hg was one of five factors that worsened patient outcome at 6 months.[35] Hypotension during any phase in the brain trauma patient's hospital course is associated with a greater likelihood of severe disability and vegetative state.[36] However, early in the course of brain trauma, especially when combined with hypoxia, hypotension is devastating. When hypotension and hypoxia occur together, mortality is 75%.[35]

Techniques minimizing head movement should be used in TBI patients and by the most skilled clinicians. However, concern about a cervical fracture should never take precedence over relieving hypoxemia. It is of critical importance to ensure that appropriate monitoring is present throughout airway maneuvers. Nasal intubation should be avoided in head injury, particularly in patients with known or suspected basilar skull fractures and sinus injuries. Alternative airway devices, such as video laryngoscopes, any of the indirect rigid laryngoscopes, ILMA, or fiberoptic stylets, may be useful when the head must remain immobilized.[37] Most emergency patients are assumed to have a "full stomach," so it is important to weigh the risk of aspiration, which is a potential problem during laryngoscopy and intubation. If the situation warrants, surgeons should be prepared to perform a rapid cricothyrotomy if intubation attempts fail and ventilation becomes impossible.

C. Patient with Cervical Spine Disease

1. Management of Acute Injury and the Unstable Spine

Spinal injuries occur in approximately 13% to 30% of polytrauma patients, and cervical spine injury (CSI) represents about 0.9% to 3% of all polytrauma patients.[38,39] The relative risk of CSI is increased in the presence of severe head injury by a factor greater than 8.[40] In the United States, cervical trauma has an incidence of approximately 5 per 10,000 population annually, making up 4% of all blunt trauma. In trauma victims with a GCS score of 13 to 15, the incidence of CSI is 1.4%, but this rises dramatically to 10.2% if the GCS score is less than 8. It is of vital importance to capture all injuries in the unconscious polytrauma patient within an emergent time frame. If a CSI is missed or its detection delayed, the incidence of secondary neurologic deficit increases from 1.4% to 10.5%. For this reason, the Advanced Trauma Life Support (ATLS) protocol was created, constantly updated, and broadly followed in most trauma centers.[41] When a diagnosis of CSI is delayed, almost one third of patients may develop permanent neurologic deficit.[42] One of the areas of controversy is how best to "clear" the cervical spine in the trauma patient. Detection of CSI requires a variety of modalities that vary in sensitivity, including clinical evaluation, plain radiography, CT, MRI, and dynamic fluoroscopy.

Clinical Evaluation. To clear the cervical spine clinically, the following criteria must be met:

1. GCS score of 15, with the patient alert and oriented
2. Absence of injuries that may draw attention away from a CSI
3. Absence of drugs or intoxicants that may interfere with the patient's sensorium
4. Absence of signs or symptoms on examining the neck, specifically:
   a. No midline pain or tenderness
   b. Full range of active movement
   c. No neurologic deficit attributable to the cervical spine

Clearly, there will only be a small number of trauma patients who fulfill these criteria.

Plain Radiography. The cross-table lateral view alone, even if technically adequate and interpreted by an expert, will still miss 15% of cervical injuries. Of cross-table lateral films taken in emergency rooms, approximately a quarter of the films are anatomically inadequate, necessitating further imaging modalities for evaluation, usually of the cervicothoracic junction. A three-view cervical series includes the cross-table lateral view, open-mouth odontoid view, and anteroposterior (AP) view (Figs. 42-2 to 42-4). Using these views, the sensitivity increases to detect 90% of those with an actual injury. Again, anywhere from 25% to 50% of these series may be inadequate anatomically. In low-risk patients, plain radiography is an efficient diagnostic examination with specificity of 100%. In high-risk patients, plain radiography is a good adjunctive screening test in conjunction with a CT scan, with sensitivity of 93.3% and specificity of 95%.

Computed Tomography. CT scanning, either of the entire cervical spine or directed at areas missed by plain radiographs, provides a complementary approach when used in addition to the three-view cervical series, reducing the risk of missing a CSI to less than 1%. In the evaluation of the cervical spine, a helical CT scan has higher sensitivity and specificity than plain radiographs in the moderate-risk and high-risk trauma population, but it is more costly. In fact, a helical CT scan is the preferred initial screening test for detection of cervical spine fractures among moderate- to high-risk patients seen in urban trauma centers, reducing the incidence of paralysis resulting from false-negative imaging studies and institutional costs, when settlement costs are taken into account.[42]

a. INTUBATION

The anesthesiologist or emergency physician may be confronted with a patient with CSI who requires intubation. In one series, 26% of patients admitted to a large trauma center required intubation over the first day of admission. Furthermore, a growing body of literature indicates that

Figure 42-2 Normal lateral cervical x-ray view. (Courtesy of Prasanna Vibhute, MD, Department of Radiology, Mount Sinai Medical Center.)

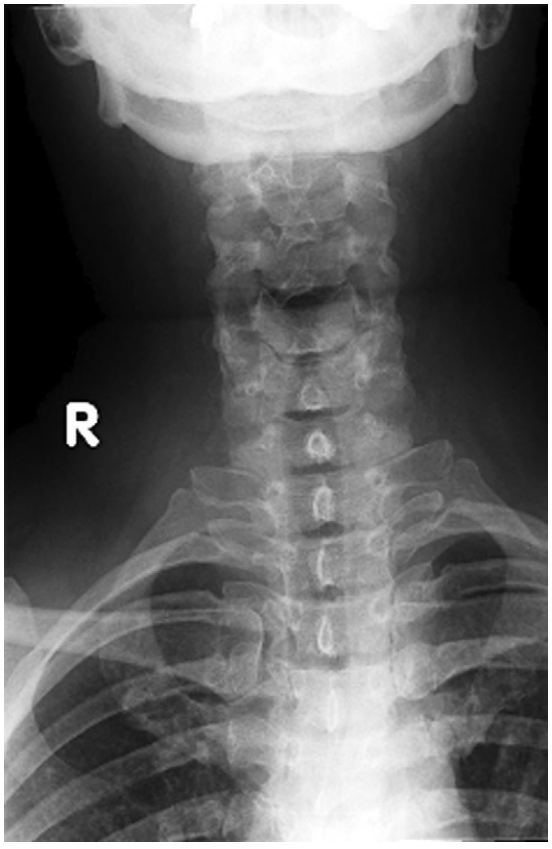

Figure 42-3 Normal anteroposterior cervical spine x-ray view. (Courtesy of Prasanna Vibhute, MD, Department of Radiology, Mount Sinai Medical Center.)

Figure 42-4 Normal odontoid cervical spine x-ray view. (Courtesy of Prasanna Vibhute, MD, Department of Radiology, Mount Sinai Medical Center.)

any patient with a CSI above C5 should be intubated electively, early in the course of presentation.[43] The following survey reviews airway devices and assigns utility based on clinical presentation of cervical injury.

i. **DIRECT LARYNGOSCOPY.** If performed appropriately, direct laryngoscopy is safe in the patient with CSI.[44-46] No neurologic sequelae were noted in a review of 73 patients with known cervical spine fractures intubated after rapid-sequence induction with the application of cricoid pressure and manual in-line stabilization (MILS) of the head and neck and direct laryngoscopy.[47] When intubating the patient with direct laryngoscopy, the anterior portion of the hard cervical collar can be removed to facilitate opening of the mouth at intubation.

The major concern during the initial management of patients with potential CSI is the further deterioration of the neurologic function caused by pathologic motion of the injured vertebrae. Therefore, to protect the spinal cord, it is crucial to maintain spinal alignment and preserve spinal stability by establishing early immobilization of the spine. Techniques to provide cervical spine immobilization include sandbag-tape immobilization and cervical collars of various consistency.[48] The same rationale is applied when management of the airway is required in the patient with suspicious CSI. The goal is to achieve endotracheal intubation as quickly as possible with the least amount of cervical motion. Although thorough evaluation for respiratory failure is necessary, current consensus is that early intubation is mandatory in patients with complete CSI, and evidence of respiratory failure should prompt immediate airway intervention.[49] As currently recommended by ATLS protocol, direct laryngoscopy with MILS is most often performed and has been extensively investigated.[50]

The effects of direct laryngoscopy have been studied in a range of patients, including those with normal neck anatomy under anesthesia, as well as in cadavers, including those with cervical lesions caused to simulate fractures at a variety of levels. In the anesthetized patient with normal cervical anatomy, using neuromuscular

blockade and a no. 3 Macintosh blade, a variety of movements occur. On elevation of the blade to obtain a view of the larynx, there is superior rotation of the occiput and C1 in the sagittal plane, C2 remains near-neutral, and there is mild inferior rotation of C3 to C5.[51] The most significant movement is produced at the atlanto-occipital and atlantoaxial joints.[45] In cadaveric models of unstable cervical segments (C1-C2), the movements associated with maneuvers such as chin lift and jaw thrust are greater than those produced by the intubation itself. The application of cricoid pressure produced no significant movement at the site of injury in these patients.[6]

ii. IMMOBILIZATION. In view of the risk of secondary neurologic injury to the acutely injured, unstable cervical spine, it is widely viewed as standard of care to immobilize the cervical spine when this is suspected. The most common measures include manual in-line immobilization, immobilization of the head between two sandbags, and placement of a rigid cervical collar and a spinal board. This management is itself associated with significant morbidity and mortality. It may increase the difficulty of intubation or increase the likelihood of airway compromise and risk of aspiration. Nonetheless, the use of manual in-line immobilization (not traction) is the best means to minimize movement of the cervical spine during airway manipulations and should always be practiced. It should be recognized, however, that the presence of a cervical collar does not necessarily protect against movement at the occipitocervical and cervicothoracic junctions.[52]

In all these studies, a certain degree of movement of the cervical spine was detected during direct laryngoscopy with MILS. The magnitude of the reported displacement was within the physiologic ranges. In addition, no difference was detected in the movements recorded by using three different blades (Macintosh, Miller, McCoy). Santoni and colleagues[53] recently reported a direct correlation between the worsening of the glottic view caused by MILS and the increase in maximum applied pressure by the laryngoscope blade. They concluded that this increase in the force applied through the laryngoscope could worsen cervical instability. In the presence of cervical instability, impaired glottic visualization and secondary increases in pressure application with MILS have the potential to increase pathologic craniocervical motion.

The laryngoscopic pressure, which reflects a degree of difficulty in glottic visualization, can be significantly diminished by using video laryngoscopes, such as the Airtraq and the Pentax AirwayScope[54,55] (Fig. 42-5). These channeled video laryngoscopes allow for indirect laryngoscopy and provide optimal view of the glottis without alignment of the oropharyngeal and orotracheal axes. For these reasons, they have been successful in allowing tracheal intubation in the presence of cervical collars. The GlideScope is a widely used video laryngoscope with a record of success in cervical spine immobilization.[56,57] Using cinefluoroscopy, Robaitaille and colleagues[58] found that the GlideScope did not produce less cervical spine movement than the Macintosh blade but did provide an improved laryngoscopic view and successful intubation (Fig. 42-6).

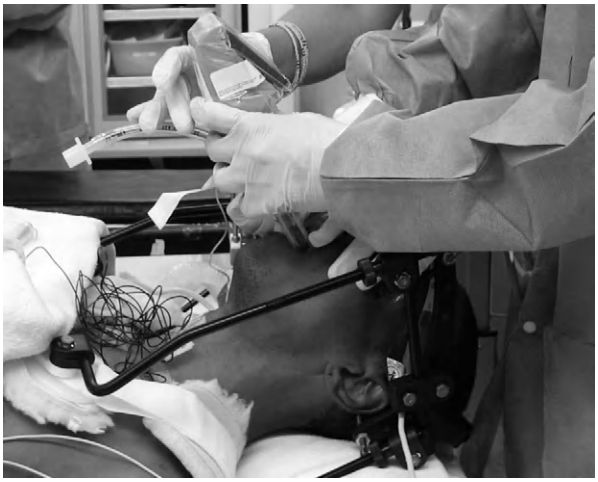

Figure 42-5 Intubation using the Pentax AWS videolaryngoscope (Pentax Ricoh Imaging, Tokyo).

iii. AWAKE INTUBATION. In a cooperative patient, awake fiberoptic intubation can be performed. One of the benefits of this technique is that it allows for the patient to be intubated without movement of the cervical spine. It may be performed with a hard collar in place. The patient's airway may be topicalized, but this may, in theory, increase the potential for aspiration in patients at risk for regurgitation and aspiration. Ovassapian and others,[59] however, found no evidence of aspiration in 105 patients at risk. Awake fiberoptic intubation may prove to be time-consuming and requires expert topicalization and operator skills for success. Because of the lack of assurance of expedient intubation and the risk of aspiration, we advocate that the fiberoptic scope be used in the cooperative patient in the urgent situation and in the nonurgent patient who is not at risk of aspiration. This recommendation is a general guideline, and expertise with any given airway device must be considered when using an airway technique in a specific clinical situation.

iv. LARYNGEAL MASK AIRWAY. Another alternative to direct laryngoscopy is the intubating LMA. Waltl and

Figure 42-6 Intubation using the GlideScope in a cervical collar (Verathon, Bothell, Wash).

associates[60] reported that the ILMA produced less extension of the upper cervical spine than direct laryngoscopy.[61] Ferson and colleagues,[62] in 254 difficult-to-manage airways, reported that 70 patients with acutely unstable necks were all successfully intubated with the ILMA, 92.6% on the first attempt and 7.4% on the second attempt.[62] There was no report of worsening neurologic outcome or aspiration as a result of this intervention. The authors were skilled users of the device and practicing anesthetists who had vast clinical experience with the ILMA. Other studies were not as successful. Bilgin and Bozkurt[63] reported that optimum conditions for ventilation through the ILMA could be achieved at the first attempt only in 59% of the patients wearing a semirigid neck collar, and that two to four attempts were necessary in 42% of the patients. Successful blind intubation could be performed in all patients, but only 53% at the first attempt. On the contrary, first-attempt and overall success rates were reported to be higher than with blind techniques using a flexible fiberoptic scope or lightwand-guided tracheal intubation under vision through the ILMA. The clear disadvantage of this approach was the prolonged intubation time.[63]

This information must be viewed, however, in light of cadaveric experiments in which the intubating LMA has been demonstrated to create posterior pressure on the midportion of the cervical spine.[64] This may be particularly relevant in cervical flexion injuries. If the ILMA is to be used in a patient in a hard cervical collar with cricoid pressure, one should be aware of difficulties described in this scenario. Wong and associates[65] presented two cases where the ILMA was used in awake topicalized patients with unstable cervical spine without difficulty. In light of these studies indicating that the ILMA may produce cervical motion and excessive pressure on the cervical spine, and that it is difficult to place with application of cricoid pressure and the presence of a hard cervical collar, the ILMA cannot be recommended as a primary device in the patient with acute cervical injury. It should be viewed as a rescue device if direct or fiberoptic intubation fails.

v. CRICOTHYROTOMY. Although suggested as an alternative to direct laryngoscopy in patients with cervical neck trauma,[66] cricothyrotomy may produce a small but significant movement of the cervical spine.[67] Although often suggested as a primary mode of intubation of the unstable patient with CSI, the procedure is associated with a high complication rate.[68] In one study of long-term complications in emergency departments in the United Kingdom, only 41.5% survived to hospital discharge. A mere 25.9% of these patients who survived experienced no long-term complications (10.9% of all patients receiving emergency cricothyrotomy).[69] This high incidence of complications may be related to the decreasing number of cricothyrotomies performed and the unfamiliarity of many physicians with the procedure. The incidence of emergency surgical airway in the setting of trauma has decreased over the past several decades. Therefore, emergency cricothyrotomy should be reserved as a rescue procedure in the management of the airway in patients with acute cervical spine injuries.

Box 42-1 Airway Techniques for Patients with Unstable Cervical Spine

- Awake fiberoptic intubation
- Nasal intubation
- Indirect rigid laryngoscopy
- Bullard, Wu, and Upsher laryngoscopes
  - Video laryngoscope and DCI systems
  - Airtraq and Pentax AWS laryngoscopes
- Direct laryngoscopy with in-line stabilization
- Fiberoptic intubation using LMA as conduit
  - LMA Classic
  - LMA-Fastrach
- Lightwand or fiberoptic lighted stylets
  - Trachlight
  - Shikani Optical Stylet, and Bonfils Retromolar Intubation Fiberscope
  - Clarus video system
- Retrograde intubation
- Surgical airway
  - Cricothyrotomy
  - Tracheostomy

DCI, Direct coupled interface; *LMA,* laryngeal mask airway.

vi. ALTERNATIVE STRATEGIES. Optimal airway management strategies in patients with an unstable CSI remain controversial. Additional alternative devices to the laryngoscopes are a lightwand or an intubating fiberoptic stylets, such as the Shikani Optical Stylet and the Bonfils Retromolar Intubation Fiberscope. These tools are designed to allow blind tracheal intubation, avoiding hyperextension of the neck. However, few objective data guide the selection of appropriate devices. Different study series report that intubation with the Trachlight was successful at first attempt in 90% of patients. Inoue and colleagues[70] conducted a prospective randomized study of 148 patients receiving general anesthesia for procedures related to clinical and radiographic evidence of cervical abnormality. Trachlight or ILMA was used for tracheal intubation, with the head and neck held in a neutral position. In the Trachlight group, intubation was successful at the first attempt in 67 of 74 patients (90.5%) and at the second attempt in five (6.8%). In contrast, in the ILMA group, 54 of 74 patients (73.0%) were intubated within the protocol. The mean time for successful tracheal intubation at the first attempt was significantly shorter in the Trachlight group than in the ILMA group. The Trachlight may be more advantageous for orotracheal intubation in patients with CSI than the Fastrach with respect to reliability, rapidity, and safety. Skill and experience with the device are essential to achieving this success (Box 42-1).

b. SUMMARY

As can be appreciated from the previous discussion, the problem with airway management in patients with CSI is that the techniques normally employed to secure the airway have the potential to cause movement and thereby risk causing secondary neurologic injury. Although a strategy for "clearing" the cervical spine is previously

outlined, the emergent nature of management of these often–multiply injured patients may mean that time does not permit this to be performed. Therefore, a group of patients remain whose cervical spinal integrity is uncertain and who must be managed as if their cervical spine is, in fact, injured. It is essential to proceed in the most expedient manner with the techniques that have been carefully practiced.

2. Chronic Spine Disease with Myelopathy

In the same manner as patients with ischemic heart disease present for noncardiac surgery, patients with cervical spine disease present for surgery for nonneurosurgical procedures. As such, their airway management is of interest to all, not solely those providing anesthesia for complex spinal surgery. One of the problems in relation to this patient group is predicting difficulty with intubation, both by direct laryngoscopy and fiberoptic intubation.[71]

Regarding fiberoptic intubation (FOI), the traditional bedside tests used to predict difficult direct laryngoscopy may not necessarily be predictive of difficulty in FOI. Difficulty with visualizing the vocal cords in FOI has been extensively documented and is most often caused by secretions and blood in the airway, distortion of the upper airway, and of particular relevance, resistance to passage of the endotracheal tube (ETT) in a high proportion of cases. This ETT problem has been linked to the size of the fiberoptic scope in relation to the ETT and indeed, the design of the ETT itself. Patients with rheumatoid arthritis may pose additional difficulty because of alteration in the plane of their vocal cords. Efforts at establishing which patient features influence difficulty in the passage of the ETT, or impingement, have been directed at examining radiologically common features. Neither the Mallampati grade nor the thyromental distance correlated with the degree of impingement on passage of the tube. There was, however, a positive correlation with the size of the epiglottis and the size of the tongue. In particular, the thickness was more important than the length of the tongue, an issue of particular relevance in patients with acromegaly.

Difficult intubation (DI) is well recognized as more common in patients with cervical spine disease. In particular, ankylosing spondylitis, rheumatoid arthritis, and Klippel-Feil abnormality present additional difficulty.[72] One of the problems with predicting DI is its incidence and the sensitivity and specificity of the tests used to detect it.[73] DI in the undifferentiated anesthesia community has an incidence of approximately 1%. The positive predictive value (PPV; proportion of difficult cases predicted to be difficult) of the common tests such as Mallampati or Wilson Risk Sum is about 8%, and the PPV of the tests used in combination is approximately 30%.[74] Tests predicting DI with sensitivity of 95% and specificity of 99% will have a 51% false-positive rate. However, if the prevalence of DI is theoretically 10%, the problem of false-positive cases would decrease to 8.7% (with sensitivity of 95% and specificity of 99%). One might therefore expect prediction of DI to be more rewarding in a patient subgroup with a high incidence of DI, such as those with cervical spine disease.

A number of important correlates have emerged from this examination. As previously discussed, when performing direct laryngoscopy, the most significant movement is produced at the atlanto-occipital and atlantoaxial joints.[45] Not surprisingly, therefore, patients with reduced mobility at this level present increased difficulty of intubation.[75] However, a highly significant association exists between disease of the occipito-atlanto-axial complex and impaired mandibular protrusion. This is mainly, but not uniquely, caused by rheumatoid disease. Also, extension at the craniocervical junction is needed to open the mouth fully, another limiting factor with direct laryngoscopy.

a. RHEUMATOID ARTHRITIS

Three especially relevant areas in which rheumatoid arthritis (RA) affects the airway and cervical spine are cricoarytenoid arthritis, temporomandibular arthritis, and atlantoaxial instability.[76] Laryngeal involvement in RA has a prevalence of 45% to 88%. Depending on the investigation, 59% of patients with RA show laryngeal involvement on physical examination, 14% show extrathoracic airway obstruction on spirometry, and 69% show one or more signs of laryngeal involvement. Of the latter, 75% have symptoms of breathing difficulty. For these RA patients, the greatest risk is after extubation. Intubation, even if of brief duration, can lead to sufficient mucosal edema to cause postextubation stridor and airway obstruction. Interestingly, the incidence of postextubation stridor is much lower after FOI (1%) than after direct laryngoscopy (14%).[77]

Up to two thirds of patients with long-standing RA may have limited temporomandibular joint (TMJ) mobility with consequent limited mouth opening. Of those with severe TMJ destruction, up to 70% may undergo episodes of airway obstruction similar to that seen in patients with micrognathia or obstructive sleep apnea syndrome.[78]

Atlantoaxial instability is present in about 25% of all patients with RA and is more likely in those with severe peripheral rheumatoid involvement. Symptoms correlate poorly with radiologic findings, and a serious concern is that some series have found atlantoaxial instability in approximately 5% of RA patients presenting for elective orthopedic surgery. The direction of the instability is variable, and a significant percentage will exhibit vertical subluxation, or cranial "settling." This can also result in impingement of the odontoid peg on the brainstem.[79]

b. SUMMARY

The patient who presents for elective surgery, with symptoms of cervical myelopathy, deserves careful airway management to avoid further injury. Intubation techniques described for the CSI patient are appropriate and best performed by experienced practitioners. When possible, awake intubation, followed by demonstration of extremity movement, is ideal and recommended. When this is not possible, a technique that produces minimal head movement and airway maintenance is acceptable. A thoughtful approach is based on patient anatomy, risk of intubation difficulty, and a rescue plan for intubation or ventilation failure.

IV. FAILED INTUBATION OR ANTICIPATED DIFFICULT AIRWAY

A. Patient in a Halo Frame or Stereotactic Headframe

Early halo immobilization is a common practice in patients with potentially unstable cervical injuries and may facilitate the diagnostic work-up and treatment of trauma patients with multiple injuries.[80] The halo device provides the most rigid form of external cervical immobilization. Although the halo frame is an effective form of cervical immobilization, complications can occur. This cumbersome device prevents easy access to the patient's airway and also prevents extension of the head.

Patients treated with halo fixation present unique challenges in terms of airway control. The halo frame prevents proper positioning for laryngoscopy by restricting atlanto-occipital extension. Oral intubation is often possible, but it is a function of other variables, such as mouth opening, tongue size, upper dentition, and ability to prognath the lower jaw forward. In the nonemergent setting, fiberoptic bronchoscopy can overcome the difficulties in intubating these patients,[81] but in an emergency setting, these intubations can be extremely difficult. Sims and Berger[82] reported a retrospective survey of 105 patients managed with halo fixation at a level 1 trauma center. In this series, 14 of the patients (13%) required emergent or semiemergent airway control with almost half the patients dying in the attempts or shortly after. Based on their findings, the authors suggest that early tracheostomy be considered in hospitalized trauma patients requiring halo fixation who present with a high Injury Severity Score (ISS), history of cardiac disease, or a condition requiring intubation on arrival. Patients who are intubated on arrival may be more likely to require emergent reintubation during their hospital stay. Older patients and those with a history of cardiac disease are more at risk for arrest-related death (Box 42-2).

Respiratory failure or airway obstruction in the patient wearing a halo frame becomes a serious emergency. If the airway needs to be secured and tracheal intubation has failed, use of adjuncts may be life-saving. The halo frame immobilizes the head and neck and prevents use of the "sniffing position" for laryngoscopy or assisted ventilation. Case reports have described a variety of techniques for airway rescue in the patient wearing halo fixation. The Bullard laryngoscope has been used after failed laryngoscopy in a patient who additionally had a difficult airway.[83]

Box 42-2 Recommendations for Early Tracheostomy in Trauma Patients with Halo Fixation

High cervical injury score
History of cardiac disease
Age >60 years
Intubated on arrival
Previous history of difficult intubation
Anticipated length of intubation greater than 1 week
Capability of surgical airway not available

The ILMA was successfully used in an awake patient when a fiberoptic scope was unavailable.[84] This device was also used by one of the authors after a failed intubation attempt following a respiratory arrest. A Combitube was used in a 78-year-old patient with respiratory deterioration after extubation when LMA insertion proved impossible.[85] In recent reports, 15 patients in halo-vest fixation were electively intubated for surgery under general anesthesia using the GlideScope, and a 14-year-old patient unable to tolerate awake FOI was successfully intubated with the Pentax AWS[86,87] (Fig. 42-7).

Patients who present for elective surgery in halo fixation should be approached carefully with a plan for intubation. The techniques described earlier for the anticipated difficult airway should be employed. It is imperative that (1) clinicians involved have skills and equipment for alternative intubation techniques, (2) a neurosurgeon or professional can safely remove the halo if necessary, and (3) a rescue plan is prepared in case of failed ventilation in these challenging patients.

Stereotactic Headframes. Stereotactic localization is widely used in neurosurgery and has revolutionized practice over the past 30 years. The term *stereotactic* originated from the Greek words *stereo* meaning "three-dimensional" and *tactos* meaning "touched." Lars Leksell is best known as the neurosurgeon who brought stereotaxis into clinical use, although it was originally described by Horsley and Clarke in 1908.[88] In 1949, Leksell designed the first instrument to be based on the arc-center principle, a system that provided precise mechanical three-dimensional control in intracranial space. It served to identify the target and to calculate the angles and distances to be used with the frame. The stereotactic system has undergone many refinements over the years. The early stereotactic frames produced by Leksell provided head fixation but significantly interfered with airway access. The later frames have a cross-bar that may be directed cephalad for easier access to the nose and mouth. The cross-bar can be removed by unscrewing two screws with an Allen wrench (which should always be available). Newer designs feature a movable front piece (Fig. 42-8).

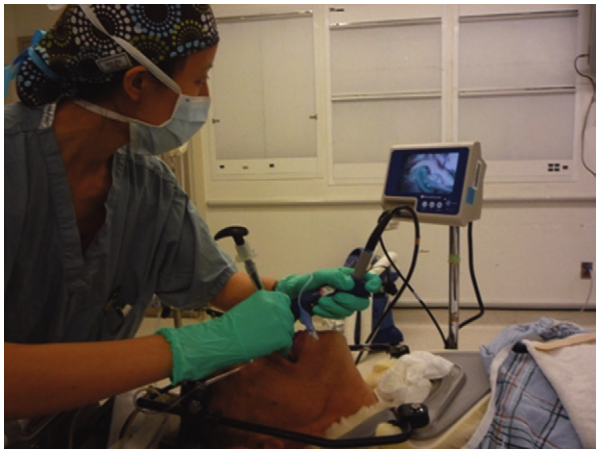

Figure 42-7 Patient in a halo fixation vest intubated using the GlideScope (Verathon).

Figure 42-8 Leksell frame allows placement of a laryngeal mask airway (LMA Supreme; LMA North America, San Diego).

Despite moderate access to the airway, head positioning and fixation to the table can make proper positioning for airway management extremely challenging.

Applications of stereotaxis are increasing and are presently used for biopsy, craniotomy, and procedures for movement disorders. Neuronavigational techniques require the acquisition of radiologic studies, such as CT or MRI, while the patient is wearing the stereotactic frame. Stereotactic neurosurgery may require general anesthesia or conscious sedation. Cooperative patients who are neurologically intact may easily tolerate frame placement under sedation with local anesthetic applied at the pin sites. Conscious sedation is desirable when patients must be transported for diagnostic radiologic procedures in the headframe (Fig. 42-9). This is the anesthetic technique appropriate for intracranial biopsies and the surgical treatment of movement disorders and Parkinson's disease. The use of intravenous sedation must be carefully monitored, and the agents chosen should provide analgesia, sedation, and cardiovascular stability.[89] Oxygen should be administered by nasal cannula, and monitoring of capnography is extremely useful. It is essential to monitor head positioning during frame fixation to the operating table. Excessive head flexion may lead to airway obstruction when sedative agents are given.[90]

Figure 42-9 Patient in Leksell frame for transport with supraglottic airway and (Patil) intubation guide, "whistle" for management during transport (Elekta, Stockholm).

Box 42-3 Airway Management Techniques for Stereotactic Surgery

Spontaneous ventilation with oxygen supplementation

Awake oral or nasal fiberoptic intubation
Spontaneous intubation and blind nasal intubation
Awake or asleep fiberoptic intubation via laryngeal mask
Awake or asleep optical stylet (lightwand) intubation
Awake or asleep video laryngoscopy intubation

Potential complications of the surgical procedure include bleeding and the potential for air entrainment. Air entrainment may occur from the surgical site if near the venous sinuses or from the pins sites if placed near diploic veins.[91] This is usually noted by the development of coughing, dyspnea, and decreased oxygen saturation. It is important to make the diagnosis and inform the surgeon, who should immediately flood the operative field to prevent further air entry. Another and more serious risk is internal bleeding. Postoperatively, patients usually undergo a CT scan to check for signs of hemorrhage or hematoma formation.

Patient cooperation is an important factor in these procedures; pediatric patients, obtunded patients, and those at risk for seizures present increased management challenges. The obese patient or the patient prone to airway obstruction requires careful consideration for the stereotactic headframe technique, perhaps performed under general anesthesia. When this decision is made, the patient is anesthetized and intubated before frame placement and must be ventilated, sedated, and monitored for transport to and from a diagnostic radiologic area. Alternatively, a cooperative patient may tolerate placement of the headframe and diagnostic radiology, although the lesion is in the occipital region, requiring prone positioning. This problem may be solved by awake intubation in the headframe, followed by positioning after anesthesia is induced. If awake intubation fails, an alternative technique may be used. The LMA is extremely useful in this scenario and may be used as the sole airway in smaller patients having the procedure in the supine position. It is important to be familiar with a number of airway techniques and to have a plan for alternative methods of airway management should these challenges occur[92] (Box 42-3).

B. Patient for Awake Craniotomy or Embolization Procedures

Craniotomy in the awake state has been performed since ancient times. Current indications include resection of a lesion in the eloquent or speech center of the brain. Surgical procedures for the treatment of epilepsy, tumors, or arteriovenous malformation are sometimes performed in the awake patient. With refinement of neurophysiologic monitoring techniques, awake craniotomies are necessary in only a small percentage of patients. However, surgery for movement disorders has again increased the use of

this technique. Intraoperative complications of awake craniotomy include restlessness and agitation.[93] This may occur when the patient is oversedated but experiences discomfort. More serious complications are hypoventilation, nausea, and seizures.[94] Changing the level of sedation will often resolve these problems. It is important to maintain the good rapport with the patient established preoperatively. Comfortable positioning of the patient to avoid discomfort, allowing surgical access and avoiding a claustrophobic atmosphere, is essential and requires cooperation of the entire operating room (OR) staff.

The evolution of anesthetic technique has progressed from fentanyl/droperidol to the current use of propofol infusion with alfentanil or remifentanil or dexmedetomidine.[95,96] Intraoperative nausea is rare with the use of propofol infusions. A newer agent is *dexmedetomidine* (Precedex), a selective α_2-adrenergic agonist used for continuous IV sedation. Dexmedetomidine has been shown to produce sedation and analgesia without respiratory depression. The onset is slower than with propofol, and dexmedetomidine must be administered by infusion. This may be beneficial for the older patient, pediatric patient, or potentially debilitated patient and has been used throughout intraoperative testing. Seizure control is sometimes necessary; methohexital (1 mg/kg) or a benzodiazepine (midazolam) is effective. Terminating the seizure requires careful titration of sedatives to avoid apnea.

If necessary, general anesthesia may be required for the uncooperative or the very young patient.[97] The "asleep-awake-asleep" technique has been used by some centers in an effort to minimize patient discomfort and provide better operating conditions for the surgeon. The patient undergoes a "light general anesthetic" with additional local anesthesia and is awakened intraoperatively for testing at the appropriate time.

Airway management can be challenging, and several maneuvers have been reported. Huncke and colleagues[98] used awake fiberoptic intubation, which was accomplished in 10 patients. This effective but arduous technique required significant skill and a special catheter to deliver local airway anesthetic. Some clinicians have also used nasal airways and blind nasal intubation, assuming that bleeding or significant discomfort is avoided. The most useful technique in recent years has been the laryngeal mask airway for control of the airway.[99] The LMA has been described in several reports and can be achieved (with skill) without having to remove drapes or change patient position.[100] In our experience, using the LMA Classic and the LMA-ProSeal, patients could be induced and re-anesthetized for the resection after intraoperative testing. This allows the surgeon a "quiet field," because many patients become hypercarbic while awake and sedated. The LMA-ProSeal is particularly advantageous for the ability to provide positive-pressure ventilation and deliberate entry into the gastric tract.[101]

Embolization Procedures. The endovascular treatment of intracranial aneurysm and arteriovenous malformation (AVM) is now an option for many patients. This new therapy offers significantly reduced morbidity, mortality, and hospital stay compared with craniotomy.[1] In patients with acute subarachnoid hemorrhage (SAH), considerations must be made for the likelihood of increased ICP, changes in transmural pressure, and cerebral ischemia. During endovascular treatment, the two most serious potential complications are cerebral infarction and hemorrhage. Endovascular coiling may be safely applied within hours of the aneurysm rupture with low probability of aneurysm perforation. General anesthesia is preferred for patients with acute SAH. Despite concern for neurologic evaluation, most neuroradiologists now prefer general anesthesia for optimal imaging of studies and techniques. Airway control through an ETT or LMA allows for improved oxygenation, anesthetic administration, and a motionless patient. Radiologic imaging methods include high-resolution fluoroscopy and high-speed digital subtraction angiography (DSA) with a "roadmapping" function.[2] The computer superimposes images onto live fluoroscopy so that the progress of the radiopaque catheter tip can be seen. Any motion during this stage of the procedure profoundly degrades the image. The anesthesiologist is typically off to the side of the patient and must negotiate around the myriad of monitors and equipment, which are part of this terrain. One benefit of this environment is the ability to obtain fluoroscopic confirmation of ETT positioning, confirm proper central line location, if placed, or make the diagnosis of atelectasis.

Although the radiology suite may be in a remote location, the patient with an anticipated difficult airway should be approached in the same manner as in the OR. A potential limiting factor is the flat table, which does not allow the patient's head to be raised. Supporting blankets should be used to produce the optimal position for laryngoscopy or awake intubation, if necessary. The techniques described earlier apply in this setting, and we have used the fiberoptic bronchoscope, ILMA, lightwand, and GlideScope in the radiology suite. Emergence from anesthesia should be smooth, avoiding excessive coughing and "bucking." Hypertension should be controlled to prevent potential cerebral edema and bleeding at the femoral cannulation site. There is minimal pain, but patients are required to remain supine for a time.

C. Patient with Acromegaly

Acromegaly is a rare condition afflicting 3 to 4 per 1 million people.[102] After Marie's 1882 description of the disease,[103] Chappel[104] reported the death of an acromegalic patient secondary to airway obstruction in 1886. Airway obstruction is one of several mechanisms associated with DI in these patients. The association between difficult airway management and acromegaly has long been recognized in the anesthesiology community. Compared with the nonacromegalic population, acromegalic patients have a higher incidence of DI, unpredictable difficult airway, and problematic mask ventilation.

The occurrence of the difficult airway in acromegaly is well described, and the incidence of difficult laryngoscopy in these patients ranges from 9% to 33%.[105] The hypersecretion of growth hormone characterizing acromegaly results in a number of alterations in airway anatomy. Patients develop hypertrophy of the facial bones with coarsening of the features. The hypertrophy of the mandibular bone leads to prognathism. In addition to

significant macroglossia, hypertrophy of laryngeal and pharyngeal soft tissues and structures (e.g., vocal cords, arytenoepiglottic and ventricular folds) is well documented. Schmitt and associates[106] found a 26% incidence of Cormack and Lehane grade III views on direct laryngoscopy in acromegalic patients.

Past case reports described the inability to ventilate and intubate the acromegalic patient, but heightened awareness and preparation have led to increased success with these patients.[107] Preinduction airway assessment may not correlate with difficulty of intubation. Although Mallampati classification may be helpful, the thyromental distance is an insensitive indicator of DI. The lack of large prospective studies on acromegaly precludes an absolute statement regarding predictive value of preoperative assessment to difficulty of intubation at this time. Sharma and colleagues[108] recently compared the modified Mallampati classification with the upper lip bite test as predictor for difficult laryngoscopy in acromegalic patients, concluding that "sensitivity and accuracy of both tests were less in the acromegalic population than the non-acromegalic controls."

Airway management in the agromegalic patient remains problematic. Some advocate the use of awake fiberoptic intubation in patients with acromegaly to avoid the creation of a surgical airway.[109,110] This approach is gradually changing. While awake FOI remains the present standard of care for difficult airways, acromegalic patients have considerable redundant tissue and large tongues. Hakala and colleagues[111] reported that FOI may prove difficult or fail in patients with acromegaly. When considering awake FOI, the increased incidence of coronary artery disease in patients with acromegaly should also be considered.[112] An anesthetic plan must be formulated to balance the risks of losing the airway and precipitating myocardial ischemia. The plan should include (1) a second anesthesiologist if a difficult airway is anticipated, (2) a difficult airway cart, and (3) a surgeon skilled in performing a surgical airway.

In addition to difficulty with intubation of acromegalic patients, ventilation may also be challenging. Various explanations have been described as the reason for difficulty in ventilating these patients. The prognathic jaw may impede proper mask placement; the large tongue or redundancy of soft tissue may lead to airway obstruction with recumbency and use of muscle relaxants; and the decreased range of neck motion secondary to cervical osteophyte formation may impede the attainment of proper sniffing position. There is a 16% to 30% incidence of upper airway obstruction diagnosed by spirometry in patients with acromegaly.[113] Additionally, the incidence of sleep apnea is increased in these patients.[114] A history of obstructive sleep apnea, hoarseness, or stridor should alert the anesthesiologist to possible glottic and infraglottic involvement and the potential for difficulty with intubation and ventilation. This propensity toward airway obstruction must also be considered in the immediate postoperative period, especially in the patient with bilateral nasal packing.[115,116] Postoperative negative-pressure pulmonary edema has been described in acromegalic patients from partial obstruction after extubation (Box 42-4).

Box 42-4 Airway Considerations in Patients with Acromegaly

- Prognathic jaw
- Macroglossia
- Osteophyte formation of cervical spine; decreased range of motion of neck
- Thickening of pharyngeal and laryngeal soft tissue
- Thickening of vocal cords
- Recurrent laryngeal nerve paralysis
- Decrease in width of cricoid arch
- Hypertrophy of arytenoepiglottic folds
- Hypertrophy of ventricular folds
- Central sleep apnea

The ILMA has been advocated as an adjunct for intubating patients with acromegaly, but the failure rate may be too high for its use as a primary tool. Law-Koune and others[117] reported a 47.4% first-attempt failure rate with the ILMA in acromegalic patients induced with propofol, concluding that the "rate of failed blind intubation through the ILMA precludes its use as a first choice for elective airway management." Further research is required to address if the use of the ILMA as a conduit for lightwand- or fiberoptic-assisted intubation will improve the success rate. As a rescue strategy in failed laryngoscopic or fiberoptic intubation, the ILMA may be an option, if awakening the patient is not a realistic alternative. Also, we used FOI with the LMA Classic (sizes 5 and 6) in two patients with acromegaly when the ILMA did not allow successful intubation.

Use of video laryngoscopy is likely to be beneficial in acromegalic patients. Prospective studies are lacking, but we continue to have excellent results at our institutions using the GlideScope and the McGrath video laryngoscopes as primary or secondary instruments for intubating patients with acromegaly (Fig. 42-10). The construction of most blade-type video laryngoscopes allows easy navigation around the large tongue and usually provides excellent visualization of the glottic opening.[118] Experience with video laryngoscopy is recommended in normal airways before attempting use in a potentially difficult airway.

D. Role of Laryngeal Mask Airway in Neurosurgery

Although use of both the LMA and the intubating LMA for neurosurgical procedures has been previously described, this section addresses additional issues and further details their use in the neurosurgical patient population. Although the LMA cannot substitute for the ETT, it can be used in a number of situations where an ETT would be difficult or impossible to insert. In addition, the beneficial effects on cardiovascular and intracranial reflexes make the LMA a wise choice in certain neurosurgical procedures. This assumes that the clinician is skilled in LMA placement and manages the anesthetic appropriately. Several case reports describe LMA use in craniotomy, but these were scenarios of failed intubation and the necessity for an airway in fasted patients.[119,120] Although the intubating LMA has been discussed

Figure 42-10 Intubation of acromegalic patient with McGrath Series 5 video laryngoscope (LMA North America).

extensively as a device for airway management in patients with limited neck movement, Combes and colleagues[121] demonstrated its role in the failed-intubation scenario. In their prospective study of unanticipated difficult intubation, they concluded that the ILMA and the gum elastic bougie effectively solve most problems occurring during unexpected difficult airway management.[121] This is particularly important for the neurosurgical patient, who may not easily tolerate repeated laryngoscopy attempts, inadequate ventilation, and excessive hypertension and tachycardia.

The LMA can also be used as a conduit for FOI and as a rescue airway technique that is preferred by some clinicians rather than the ILMA.[122] The LMA, as well as the ILMA, can be inserted in a variety of patient positions. This becomes useful in the dreaded situation of extubation in the prone position, as well as loss of the airway in a sedated patient fixed in a headframe.[120] Assuming the mouth opening is adequate, the device can be easily placed by facing the patient and using the thumb to insert along the hard palate. A case report describes anesthetic induction and management in the prone position for a penetrating spine injury at C1-C2 using a LMA.[123] Elective use in the prone position, although considered controversial by some, can be safely performed in appropriate patients with proper positioning. There is a growing body of experience and literature on the utility of this technique with the LMA Supreme. Studies have shown the ease of insertion with the patient positioned prone for surgery. This obviates the need for turning an anesthetized patient and allows for efficient use of OR time.[124,125]

Hypertension, coughing, and bucking preferably are avoided in the neurosurgical patient. When these are a particular consideration or the patient has severe asthma or chronic obstructive pulmonary disease (COPD), extubation may be facilitated by exchanging the ETT for the LMA (using LMA as "bridge to extubation").[126] This is performed while the patient is still deeply anesthetized, without airway reflexes. The exchange technique is also useful when an elaborate head draping is required and excessive neck movement will likely provoke coughing and bucking. The technique is also known as the "Bailey maneuver," used at the Royal Throat, Nose and Ear Hospital in London.[127] The laryngeal mask provides a number of airway options for the neurosurgical patient and should always be readily available.

V. POSTOPERATIVE CONSIDERATIONS

A. Airway Injury and Function after Neurosurgery

A range of airway problems is possible in the patient who has undergone neurosurgery. Potential risks include an intraoperative seizure, hypoxia, and hypoperfusion of an ischemic penumbral area, which may produce an obtunded postoperative state. These factors, along with the residual effects of anesthetic drugs, may render the patient unable to maintain the airway safely. Patients undergo neurosurgery in a variety of positions other than supine, and the effects of gravity, venous pressure, and fluid administration may alter the integrity of the airway structures. Thus, although the airway itself may not be considered a difficult airway, there are reasons why airway function may not automatically return immediately after neurosurgery. In addition to this global effect on the ability to maintain the airway, there are specific risks of alteration in airway function after neurosurgery.

1. After Supratentorial Craniotomy

In addition to general issues regarding impaired level of consciousness, as previously mentioned, patients may present with airway problems who have previously undergone temporoparietal or pterional craniotomy. When these patients subsequently present for surgery, either further neurosurgery or other non-neurosurgical procedures, they may now have a difficult airway because of limited mouth opening not evident at the original craniotomy. This is as a consequence of scar formation in the region of the temporalis muscle.[128] This is much more likely to occur in those who have had a period of sedation and ventilation in the intensive care unit following their original craniotomy, because they do not resume normal eating and talking activities. Even patients extubated immediately after craniotomy and who do resume normal eating and talking are at risk of developing restricted mouth opening if, for reasons of excessive pain, they themselves limit jaw movement and subsequently develop restrictive scarring. Kawaguchi and associates[129] were able to characterize postcraniotomy changes in mouth opening that occurred in 92 patients after surgery. The postoperative reduction in maximal mouth opening was greater in the group who underwent frontotemporal craniotomy

(vs. parietal or occipital regions). Limited mouth opening resolved after 3 months in most patients. Supratentorial craniotomies separated by short intervals can increase the risk of limited mouth opening, which may result in a difficult intubation.

There is a risk that anesthesiologists may be lulled into a false sense of security in this setting, if they limit their assessment of the airway to reviewing the previous anesthesia chart. This will only describe the grade of laryngoscopy at that time, and if they do not perform a new, postcraniotomy assessment of the airway, with particular reference to mouth opening, they may find a critical reduction in ease of laryngoscopy.

2. After Cervical Spine Surgery

The intraoperative management of the patient scheduled for cervical spinal surgery is considered in detail earlier. A significant number of the problems, however, present themselves only on completion of the surgery. Although the surgical goals included alleviating spinal cord compression, reduction of dislocation, or fixation of instability, almost invariably these procedures result in a reduced range of cervical movement. Consequently, on emergence, it may be difficult to maintain the airway in the presence of residual anesthesia because airway maneuvers possible after induction of anesthesia are no longer viable.

Anterior cervical spinal surgery may result in recurrent laryngeal nerve injury or hematoma, causing airway obstruction after extubation. The most common cause of vocal cord paralysis is compression of the recurrent laryngeal nerve within the endolarynx. Monitoring of ETT cuff pressure and release after retractor placement may prevent injury to the recurrent laryngeal nerve.[130] Edema may also develop in the tissues of the neck because the esophagus and trachea are retracted during these procedures to obtain access to the cervical spine. In contrast to problems associated with recurrent laryngeal nerve injury, such as angioedema or hematoma, which tend to occur early, this edema may not develop for 2 to 3 days postoperatively. Common features in these patients require reintubation with an increasing number of levels manipulated; the higher the operated levels, the longer the surgery, and the greater the intraoperative blood loss, the greater is the risk for reintubation. If these patients require reintubation, it is often difficult to perform, with significant rates of mortality and hypoxic sequelae. Consequently, attempts have been made to identify the risks previously described and the strategies to predict at-risk groups and plan alternative management, as discussed next.

Sagi and colleagues[131] demonstrated that 19 patients (6.1%) had an airway complication, six patients (1.9%) required reintubation, and one patient died. Symptoms developed on average 36 hours postoperatively. All complications except for two were attributable to pharyngeal edema. Variables found to be statistically associated with an airway complication were exposing more than three vertebral bodies; intraoperative blood loss greater than 300 mL; exposures involving C2, C3, or C4; and surgery longer than 5 hours. A history of myelopathy, spinal cord injury, pulmonary problems, smoking, anesthetic risk factors, and the absence of a drain did not correlate with an airway complication. Thus, patients with prolonged procedures (5 hours), exposing more than three vertebral levels that include C2, C3, or C4 and with more than 300-mL blood loss, should remain intubated or should be extubated over an airway exchange catheter and watched carefully for respiratory insufficiency.

Swallowing difficulties and dysphonia may occur in patients undergoing anterior cervical discectomy and fusion. The etiology and incidence of these abnormalities are not well defined. Once again, there is a tendency for patients undergoing multilevel surgery to demonstrate increased incidence of swallowing abnormalities on postoperative radiographic studies.[132] Patients undergoing multilevel procedures are at an increased risk for these complications, in part because of soft tissue swelling in the neck. Although more rare, the risk of migration of the bone, synthetic graft, or plate into the airway or compressing the airway with resultant obstruction may also occur. In addition to necessitating reintubation, this has the added hazards of intubation being required in a patient with a potentially unstable cervical spine and the need for further surgery.[133,134]

The issues surrounding airway complications of *posterior* cervical spinal surgery, which are additional to those of *anterior* cervical spinal surgery, relate mainly to anesthesia conducted with the patient in the prone position, as discussed next.

3. After Posterior Fossa Surgery

Because of the position of the lower cranial nerves in relation to the posterior fossa, the patient's ability to maintain the airway may be compromised postoperatively. Performance of a careful history preoperatively may unmask subtle impairment of gag reflex with increased episodes of choking on food, and family members may have noticed changes in character of speech. Duration of surgery, proximity of the surgical site to the lower cranial nerves, and the presence of either edema or hematoma in relation to these nerves may result in both loss of gag reflex and loss of the ability to maintain and protect the airway after posterior fossa surgery. Because of the proximity of the brainstem, further hazards are presented postoperatively because central control of respiration may be jeopardized, and these factors will dictate the safety of timing of extubation.[135,136]

Potential postoperative airway problems divide essentially into those of the prone and sitting position, and those related to surgery on the structures in the posterior fossa. Basically, patients are at risk even before the end of these surgeries because securing the ETT in this setting is problematic because secretions and skin preparation solutions are ongoing threats to its security. Even if securely fastened to the skin, facial edema may result in the ETT migrating out of the trachea, especially in children in whom the distance between endobronchial intubation and extubation is small. Facial edema itself is not necessarily hazardous to the airway, but macroglossia and oropharyngeal edema clearly are problematic.[134]

A variety of mechanisms have been proposed to account for the macroglossia seen after posterior cervical

spinal and posterior fossa surgery.[137] Clearly, if the tongue becomes inadvertently trapped between the teeth, lingual edema will result. The venous drainage of the tongue may be obstructed by the presence of an oropharyngeal airway, and if an esophageal stethoscope is there along with an oral ETT, these further risk impairing the venous and lymphatic drainage of the tongue in the prone position. Other factors that may contribute to the formation of edema are lateral rotation of the head and neck and flexion of the neck, because these two maneuvers may impair venous drainage of the head and neck.[138] The duration of surgery, as well as blood loss and fluid replacement, should also be taken into account as to the likelihood of developing macroglossia.[139]

In all these settings, although macroglossia may be immediately apparent and may preclude extubation, the oropharyngeal airway and the ETT may be the only elements maintaining the airway, and only on their removal does the edema become apparent, risking airway compromise. A rarer neurologic complication impacting on airway function after surgery in this position is quadriplegia. This may be caused by a combination of prolonged hyperflexion, overstretching of the cord, and compromised blood supply to the cord.[140] The devastating complication of quadriplegia has been reported as another risk of surgery in the seated position. Clearly, extubation of the neurosurgical patient after prolonged surgery requires careful consideration, a review of the patient's intraoperative course, and assessment of airway and neurologic responses. Patients who appear to have obvious facial or airway swelling with minimal response to the ETT are best left intubated until they are fully recovered and meet all criteria for extubation.

VI. CONCLUSIONS

The scope of airway considerations in the neurosurgical patient is vast. General and specific concerns in patient management include airway assessment and emergency airway algorithms. These patients often present with a number of disease processes, which must be considered in relation to the anesthetic as well as to airway management. This task becomes more challenging as patients become older, live longer, and present with multiple medical problems. Additionally, neurosurgical procedures, both in and outside the operating room, are becoming more complex with time. Some procedures will be done with the neurosurgical patient in prone, lateral, or sitting position. Others will require the patient to be awake temporarily and then anesthetized. The approach to airway control is a decision made by the anesthesiologist, often in collaboration with the surgeon. It is important for the practitioner to explore new airway devices and techniques and to gain skill in those that will benefit the neurosurgical patient population. Many problems may occur in the patient after neurosurgery, and thus vigilance both intraoperatively and postoperatively is essential. Anesthesiologists' role as perioperative physician requires that they provide close observation of the patient throughout the perioperative period and render the safest care possible.

VII. CLINICAL PEARLS

- In addition to airway assessment, a neurologic examination or communication with the surgeon is invaluable before induction of anesthesia for neurosurgical procedures.
- Patients with an unstable cervical spine may be unable to cooperate with an awake fiberoptic intubation because of intoxication, hypoxia, or head injury. The need for a CSI patient's airway to be secured is often urgent because of the cervical spine injury or associated head or facial injury.
- A rigid cervical collar may make airway management difficult, impeding mouth opening and application of cricoid pressure. Therefore, with manual in-line immobilization in place, the front part of the collar should be removed or opened before attempted intubation.
- Patients with acromegaly frequently have obstructive sleep apnea and should be induced and ventilated with caution. Direct laryngoscopy and video laryngoscopy are the most effective intubation techniques.
- Elective patients who demonstrate neurologic symptoms of the extremities with neck flexion or extension should have awake, topicalized endotracheal intubation.
- Become familiar with alternative airway devices and practice in normal airways before treating patients with difficult airways.
- Be attentive and inspect the degree of neck flexion in patients positioned prone, lateral, or in any head fixation device.
- A cuff leak test may be helpful before extubation after prolonged surgery in the prone position; always have reintubation strategies and plans.

I. INTRODUCTION

Up to 80% of people with obstructive sleep apnea (OSA) are obese, and with obesity at epidemic proportions worldwide,[1] OSA remains a major contributing factor to airway management difficulties. Numerous studies have reported major respiratory complications, including brain damage and death, in surgical patients with OSA.[2,3] These disastrous outcomes result from failure to secure the airway during the induction of anesthesia, airway obstruction immediately after tracheal extubation, and respiratory arrest after the administration of opioids or sedation in the postoperative period.

The prevalence of OSA is about 20% in the U.S. population. It occurs as a result of partial or complete airway obstruction during sleep,[4] and it is associated with episodic hypoxemia and hypercarbia.[5-7] However, with the U.S. population aging and becoming obese, the prevalence of OSA is expected to increase significantly. Among the surgical population, patients with morbid obesity and OSA tend to be overrepresented due to the higher rates of obesity and OSA-related complications requiring surgical therapy.[3,8] More than 75% of patients with OSA are undiagnosed or untreated.

II. DEFINITIONS OF OBESITY AND OBSTRUCTIVE SLEEP APNEA

Obesity is a degree of excess weight associated with adverse health consequences.[9] It is defined as a body mass index (BMI, or weight in kg divided by height in m^2) greater than 29, and overweight is defined as a BMI of 25 to 29.9.[9] A BMI of 40 or greater is classified as morbid obesity, and a BMI of 50 or greater designates super-obesity. Morbid obesity is associated with an increased risk of comorbidities,[10] which may influence perioperative morbidity and mortality.[11]

OSA is a disorder characterized by repetitive upper airway collapse during sleep. Airflow ceases for more than 10 seconds, five or more times per hour, despite continuing ventilatory effort. It usually is associated with a decrease in arterial oxygen saturation (Sa_{O_2}) of more than 4%.[12] Obstructive sleep hypopnea is a greater than 50% decrease in airflow for more than 10 seconds occurring

15 times or more per hour of sleep. It is usually associated with a decrease of 4% or more in Sa_{O_2}.

III. PATHOPHYSIOLOGY OF OBSTRUCTIVE SLEEP APNEA

A. Pharyngeal Muscle Activity and Airway Patency

Three pharyngeal segments—nasopharynx (i.e., retropalatal pharynx), oropharynx (i.e., retroglossal pharynx), and laryngopharynx (i.e., retroepiglottic pharynx)—form the upper airway, which is a long, soft-walled tube that lacks bony support on the anterior and lateral walls, which makes it collapsible (Fig. 43-1).[6] The transmural pressures across the pharyngeal walls (i.e., difference between extraluminal and intraluminal pressure) determine the patency of the upper airway. Activation of pharyngeal dilator muscles—the tensor veli palatini, the genioglossus, and the muscles of the hyoid bones (geniohyoid, sternohyoid, and thyrohyoid)—during inspiration counteracts the narrowing effects of reduced intraluminal pressure associated with inspiration. In addition to this inspiration-associated activation, tonic activity of these muscles during wakefulness helps to stabilize the pharyngeal walls.

Upper airway collapse is caused by a reduction in pharyngeal dilator muscle activation, which likely results from the loss of stimulatory effect of wakefulness (i.e., induction of sleep), reduction in respiratory drive, depression of negative pressure reflexes, and the loss of lung volume, which decreases longitudinal traction on the pharyngeal walls.

B. Sleep Pattern, Airway Obstruction, and Arousal

Normal sleep consists of four to six cycles of non–rapid-eye-movement (NREM) sleep followed by rapid-eye-movement (REM) sleep. The four stages of NREM sleep and one stage of REM sleep represent progressive slowing of the electroencephalographic waves. Rhythmic activity of the upper airway muscles decreases during deeper stages of sleep, which is accompanied by significant increase in upper airway resistance and consequent upper airway collapse.[13]

Contraction of the diaphragm during inspiration creates a subatmospheric pressure within the airway that may lead to narrowing of the collapsible segments of the pharynx.[14] As pharyngeal pressure becomes more

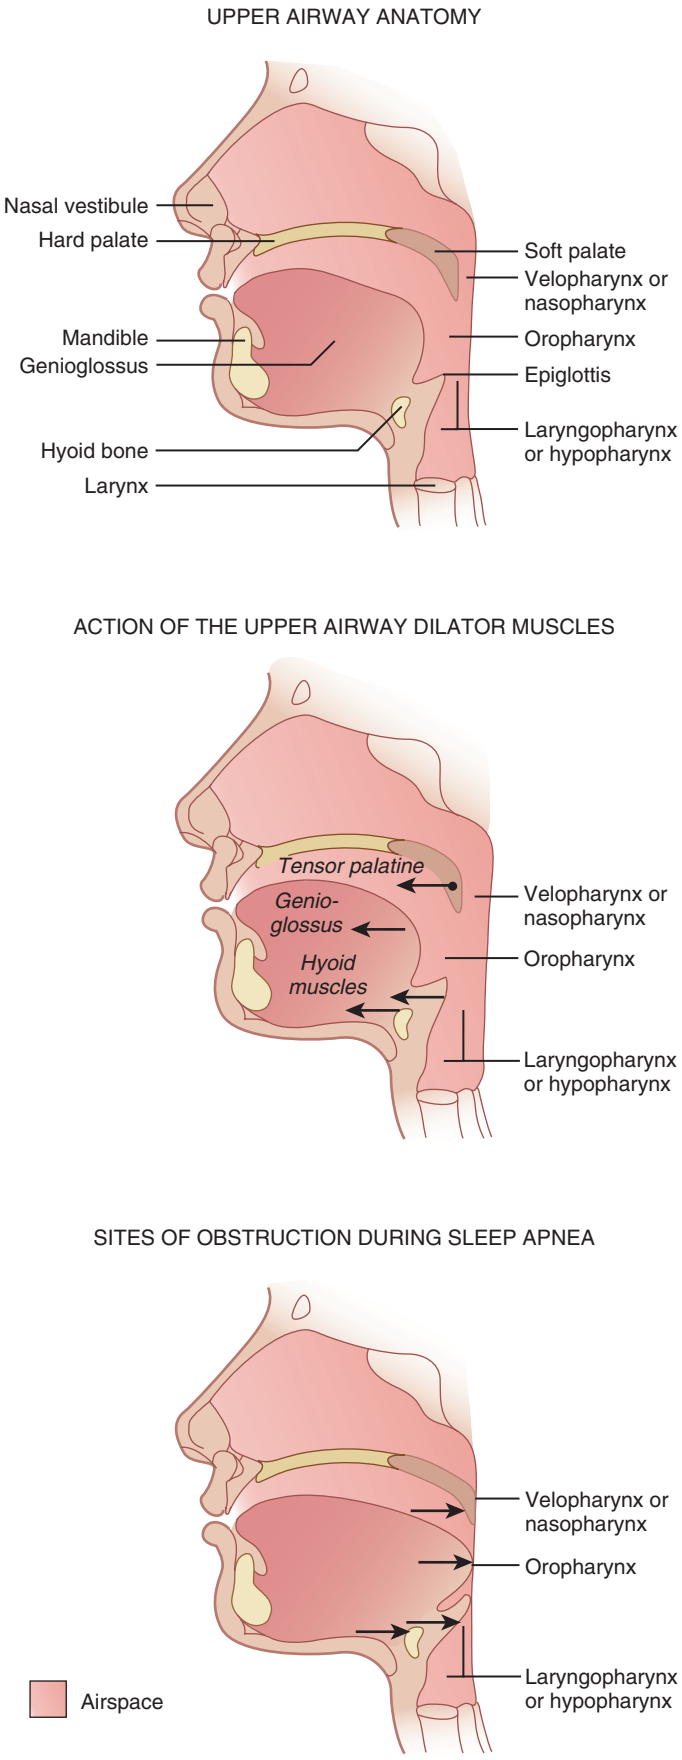

Figure 43-1 Airway obstruction during sleep apnea. *Top,* The schematic drawing shows the important upper airway anatomy. The nasopharynx ends at the tip of the uvula; the oropharynx extends from the tip of the uvula to the epiglottis; and the laryngopharynx extends from the tip of the epiglottis to the posterior cricoid cartilage. *Middle,* The drawing shows the action of the most important dilator muscles of the upper airway. The tensor palatine, genioglossus, and hyoid muscles enlarge the nasopharynx, oropharynx, and laryngopharynx, respectively. *Bottom,* The drawing shows collapse of the nasopharynx at the palatal level, the oropharynx at the glottic level, and the laryngopharynx at the epiglottic level. (From Benumof JL: Obstructive sleep apnea in the adult obese patient: implications for airway management. *J Clin Anesth* 13:144–156, 2001.)

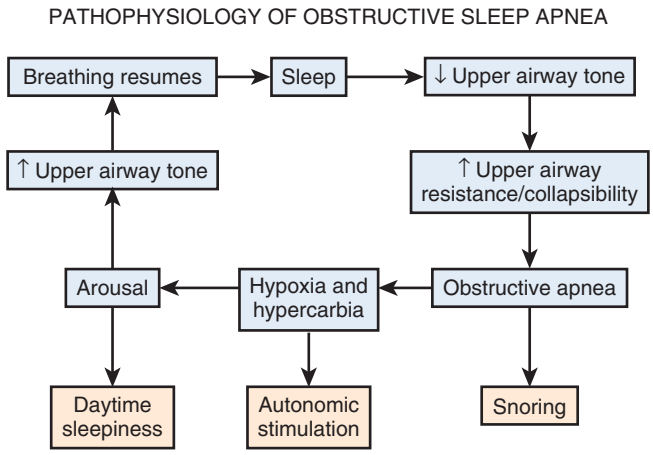

Figure 43-2 Pathophysiology of obstructive sleep apnea.

negative, pharyngeal collapse progressively increases. The lateral pharyngeal walls, a major site of pharyngeal adipose tissue deposition, are the most compliant and therefore the most common site of pharyngeal collapse.[15] In obese patients, deposition of fat around the pharyngeal walls narrows the upper airway and increases the extraluminal pressure and collapse.[16,17] For a given degree of loss of pharyngeal muscle tone and pharyngeal muscle collapse, a greater degree of pharyngeal obstruction is observed in patients with a posteriorly set tongue (caused by micrognathia and retrognathia or a receding mandible), large tongue, large tonsils, and nasal obstruction. Other factors that contribute to upper airway narrowing and subsequent collapse during sleep include: large neck circumference, anatomic or craniofacial abnormalities affecting the airway, and age.[18,19]

Airway collapse leads to obstructive apnea and consequently causes a decrease in arterial oxygen tension (Pa_{O_2}) and increase in arterial carbon dioxide tension (Pa_{CO_2}), which increases neural traffic in the reticular activating system, progressively increasing ventilatory efforts[20,21] and causing arousal from sleep. Arousal, expressed as extremity twitching, gasping or snorting, vocalization, and increased electroencephalographic activity, reactivates the pharyngeal muscles and opens the upper airway. As the upper airway opens, ventilation resumes, which corrects hypoxia and hypercarbia.[22] Hyperventilation after arousal reverses the blood gas disturbance to correspondingly decrease the central drive. The cycle repeats itself when the patient again falls asleep (Fig. 43-2).

Frequent arousals result in sleep disruption and excessive daytime somnolence, and oxygen desaturation, sympathetic hyperactivity, and a systemic inflammatory response may contribute to cardiovascular comorbidities such as systemic hypertension, cardiac arrhythmias, myocardial ischemia, pulmonary hypertension, and heart failure.[23]

IV. DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

Because OSA is undiagnosed in an estimated 60% to 70% of patients and failure to recognize OSA preoperatively is one of the major causes of perioperative complications,[5-7] all patients must be screened for OSA. Obtaining a thorough history and physical examination helps to determine a presumptive diagnosis of OSA, and polysomnography can confirm the diagnosis and severity of OSA and can determine the need for and level of continuous positive airway pressure (CPAP).

BOX 43-1 STOP-BANG Scoring System

S = Snoring. Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
T = Tiredness. Do you often feel tired, fatigued, or sleepy during daytime?
O = Observed apnea. Has anyone observed you stop breathing during your sleep?
P = Pressure. Do you have or are you being treated for high blood pressure?
B = Body mass index >35 kg/m^2
A = Age >50 yr
N = Neck circumference >40 cm
G = Male gender

Risk of Obstructive Sleep Apnea

High risk: ≥3 questions answered yes
Low risk: <3 questions answered yes

From Chung F, Yegneswaran B, Liao P, et al: STOP questionnaire: A tool to screen patients for obstructive sleep apnea. *Anesthesiology* 108:812–821, 2008.

A. Clinical Diagnosis

A presumptive clinical diagnosis of OSA may be made from an observation of components that make up the classic triad of sleep disordered breathing (i.e., history or observation of apnea or snoring with hypopnea during sleep), arousal from sleep (i.e., extremity movement, turning, vocalization, or snorting), and daytime sleepiness (i.e., easily falling asleep during quiet times of the day) or fatigue. Because arousals may not be readily apparent, diagnosis of OSA is commonly based on two of the three components, sleep disordered breathing and daytime somnolence.

A systematic review and meta-analysis of clinical screening tests for OSA reported that the STOP-BANG screening tool was easy to use and a good predictor of severe OSA (i.e., apnea-hypopnea index [AHI] >30) (Box 43-1).[24,25] The STOP-BANG questionnaire has a sensitivity of 93% and specificity of 43% at an AHI greater than 15 and a sensitivity of 100% and specificity of 37% at an AHI greater than 30.[25] Other questionnaires, including the Berlin questionnaire and the American Society of Anesthesiologists (ASA) checklist, are also in clinical use and have a similar predictive accuracy for OSA.[26-28]

When the cricomental space, defined as the perpendicular distance from a line between the cricoid cartilage and the inner mentum to the skin of the neck, is more than 1.5 cm, the diagnosis of OSA can be excluded with a negative predictive value of 100%.[29] A decision rule developed to diagnose OSA using three predictors (i.e., cricomental space ≤1.5 cm, pharyngeal grade greater than II, and presence of an overbite) has a positive predictive value of 95% and may provide an alternative to polysomnography.[29]

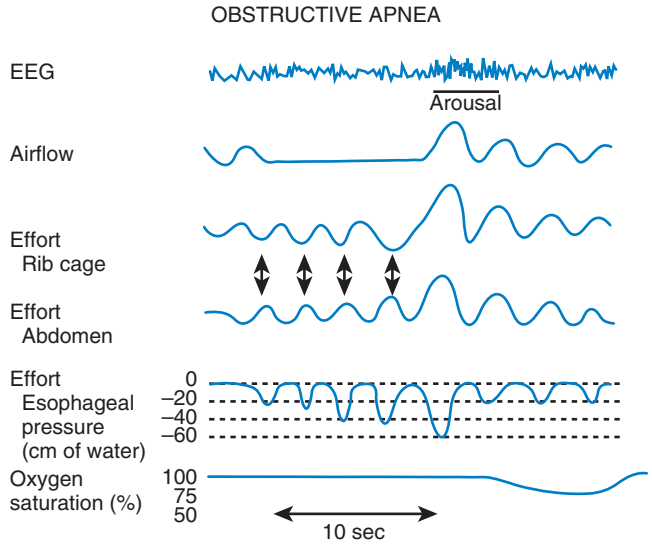

Figure 43-3 Upper airway closure with obstructive apnea. Increasing ventilatory effort is seen in the rib cage, the abdomen, and the level of esophageal pressure (measured with an esophageal balloon), despite lack of oronasal airflow. Arousal recorded on the electroencephalogram *(EEG)* is associated with increasing ventilatory effort, as indicated by the esophageal pressure. Oxyhemoglobin desaturation follows the termination of apnea. During apnea, the movements of the rib cage and the abdomen *(effort)* are in opposite directions *(arrows)* as a result of attempts to breathe against a closed airway. After the airway opens in response to arousal, rib cage and abdominal movements become synchronous. (From Strollo PJ, Rogers RM: Obstructive sleep apnea. *N Engl J Med* 334:99–104, 1996.)

B. Polysomnography

Polysomnography remains the gold standard in the diagnosis of OSA. Polysomnography consists of monitoring the electroencephalogram (EEG), electrooculogram (EOG), and submental electromyogram (EMG) for staging sleep. Oral and nasal airflow, respiratory efforts (i.e., inductance or impedance pneumography to monitor thoracoabdominal motion or the diaphragmatic EMG), oximetry, and capnography are also monitored. Body position, sound, arterial blood pressure, and the electrocardiogram are monitored (Fig. 43-3).[30]

The results of a sleep study are reported as events and indices. Events include apnea (no airflow ≥10 seconds), hypopnea (tidal volume [V_T] ≤50% of the control awake value ≥10 seconds), desaturation (>4% decrease in Sa_{O_2}), and arousal, which may be detected clinically (i.e., vocalization, turning, or extremity movement) or by an electroencephalographic burst.[12] Indices are measured as events per hour, which include the AHI (i.e., number of times a patient was apneic or hypopneic per hour), oxygen desaturation index (i.e., number of times a patient had a more than 4% decrease in Sa_{O_2} per hour), and arousal index (i.e., number of times a patient was aroused per hour). If the patient has OSA, the entire sleep study is repeated with CPAP titration to determine the level of CPAP that causes a significant decrease in the AHI.

Because polysomnography may not always be available, other screening devices with single or multiple channels have been explored and may represent alternative methods to diagnose OSA. One study suggested that an O_2 saturation value of more than 94% on room air in the absence of other causes should lend consideration to the diagnosis of long-standing OSA.[31] The American Academy of Sleep Medicine recommended that the portable monitoring used as an alternative to a polysomnogram must record airflow, respiratory effort, and blood oxygenation. The device also must allow display of raw data with a capability for manual scoring or editing of automated scoring.[32]

It is unclear whether a routine preoperative sleep study (i.e., polysomnogram or home sleep study) could improve perioperative outcomes, because the optimal duration of preoperative CPAP therapy before proceeding with elective surgical procedures is unknown, and compliance with CPAP varies. For those suspected of having OSA based on clinical criteria, anesthesiologists may elect to proceed with a presumptive diagnosis of OSA, unless the patients have significant comorbidities.[5,7]

The severity of OSA is best expressed in terms of the AHI; an AHI of 6 to 20 is considered mild, an AHI of 21 to 40 is moderate, and an AHI greater than 40 is severe OSA. Different sleep laboratories use different criteria for defining the severity of OSA. Because determination of OSA severity based on clinical criteria may be difficult, it may be prudent to treat these patients as if they have moderate or severe OSA.

V. OBESITY, OBSTRUCTIVE SLEEP APNEA, AND THE AIRWAY

Obesity (determined by the BMI) is considered a predictor of difficult mask ventilation (DMV) and difficult intubation (DI).[33] Morbidly obese patients have deposits of excess adipose tissue in the neck, breast, thoracic wall, and abdomen that may impede patency of and access to the upper airway. Magnetic resonance imaging studies of obese patients found greater amounts of fat in areas surrounding the collapsible segments of the pharynx in those with OSA,[34,35] which may explain the difficulty in airway management in obese patients with OSA but not in all obese patients. The distribution pattern of body fat may be a more relevant factor contributing to difficult airway management than the BMI itself.[34] Clinical studies have found that BMI alone is not a good predictor of a difficult airway.[36-40]

Patients with severe OSA (AHI ≥40) have been shown to be at a significantly higher risk for DMV and DI, leading to speculation that they may have different anatomic characteristics compared with patients who have less severe OSA.[41] Obese patients with OSA have larger neck circumferences than equally obese patients (i.e., similar BMI) without OSA.[16,42] This neck "mass loading" (up to 28% increase in neck soft tissue) may be responsible for a more collapsible airway, leading to DMV and DI.[16] Men have a higher percentage of soft tissue and fat in the neck compared with women,[43,44] which may explain greater airway difficulties in male OSA patients compared with female OSA patients. A logistic regression model identified neck circumference at the level of the thyroid cartilage as the single most predictor of problematic intubation.[45] Probability of a DI increases significantly with a neck circumference of 40 cm or more.[45,46]

Neck circumference corrected for height (i.e., neck circumference/height) is sensitive and specific for detecting OSA compared with neck circumference alone.[47] Racial differences in craniofacial anatomy may contribute to the severity of OSA and to a DI.[48,49] Other factors that may contribute to difficult airway management include diabetes mellitus and abnormal facial morphology.[50,51]

Ultrasonography has been used to quantify neck soft tissue at the level of the vocal cords and suprasternal notch to determine potential predictors of difficult laryngoscopy in morbidly obese patients.[52] The amount of pretracheal soft tissue was found to be a strong measure distinguishing an easy laryngoscopy from a difficult one.[52] Lateral head and neck radiography can easily identify caudal soft tissue displacement, which shifts the hyoid bone caudally to increase the distance between the mandible and the hyoid bone. When this distance is more than 20 mm, the presence of OSA and a possible difficult airway should be suspected.[53] Radiographic evaluation has affirmed strong relationships among DI and higher Mallampati scores, OSA, greater mandibular depth, and smaller mandibular and cervical angles.[54]

VI. EFFECTS OF ANESTHESIA AND SURGERY ON POSTOPERATIVE SLEEP

Sedatives/hypnotics, opioids, and muscle relaxants impair neural input to the upper airway muscles and therefore may worsen or even induce OSA. These drugs also decrease the ventilatory response to hypoxemia and hypercarbia, further exaggerating OSA. In contrast to natural sleep, in which OSA patients are aroused in response to asphyxia, drug-induced airway obstruction and apnea lack the ability to arouse and respond adequately to asphyxia. This situation may have life-threatening consequences.

Other factors that influence sleep patterns and can exacerbate sleep disorders include the stress response to surgical insult and postoperative anxiety, pain, and opioids.[55] These factors reduce REM sleep in the immediate postoperative period, which is followed by a rebound REM sleep that can last for several days after surgery.[56] The rebound REM sleep makes patients with OSA even more vulnerable to airway obstruction. Postoperative sleep disturbances appear to be related to the location and invasiveness of the surgical procedure.[57] For example, fewer sleep disturbances occur after mild or moderately invasive surgery than after major surgical procedures.

VII. PERIOPERATIVE RISKS OF OBESITY AND OBSTRUCTIVE SLEEP APNEA

Factors that determine the perioperative risks in obese and OSA patients include the degree of obesity (i.e., BMI) and the severity of OSA, invasiveness of anesthesia and surgery, and postoperative opioid requirements.[27] The ASA practice guidelines propose a scoring system that may be used to estimate whether an OSA patient is at increased risk for perioperative complications[27] and to determine perioperative management (Box 43-2).

Patients who are at significantly increased risk for perioperative complications (score ≥ 5) are not considered to be good candidates for ambulatory surgery. Patients with mild OSA who are undergoing superficial or minor surgical procedures under local, regional, or general anesthesia and who are expected to have a minimal postoperative opioid requirement may undergo ambulatory surgery. Ambulatory surgery is not recommended for patients undergoing airway surgery or upper abdominal laparoscopic surgery. Because the ASA scoring system needs validation, it should serve only as a guide.

BOX 43-2 American Society of Anesthesiologists Scoring System for Estimating Perioperative Complications

A. Severity of sleep apnea is based on sleep study (i.e., AHI) results or clinical indicators if a sleep study is not available:
   - None = 0
   - Mild OSA = 1
   - Moderate OSA = 2
   - Severe OSA = 3
   - Subtract a point for patients using CPAP or BiPAP preoperatively and postoperatively.
   - Add a point for a patient with a $PaCO_2$ greater than 50 mm Hg.

B. Invasiveness of surgery and anesthesia:
   - Superficial surgery under local or peripheral nerve block anesthesia without sedation = 0
   - Superficial surgery with moderate sedation or general anesthesia or peripheral surgery under spinal or epidural anesthesia (with no more than moderate sedation) = 1
   - Peripheral surgery with general anesthesia or airway surgery with moderate sedation = 2
   - Major surgery or airway surgery under general anesthesia = 3

C. Requirement for postoperative opioid:
   - None = 0
   - Low-dose oral opioids = 1
   - High-dose oral opioids or parenteral or neuraxial opioids = 3

D. Estimation of perioperative risk:
   - Overall score = score of A plus larger score of B or C.
   - Patients with an overall score of 4 may be at increased perioperative risk from OSA.
   - Patients with an overall score of 5 or greater may be at significantly increased perioperative risk from OSA.

AHI, Apnea-hypopnea index; *BiPAP,* bi-level positive airway pressure; *CPAP,* continuous positive airway pressure; *OSA,* obstructive sleep apnea; *$PaCO_2$,* arterial partial pressure of carbon dioxide.

Adapted from Gross JB, Bachenberg KL, Benumof JL, et al: Practice guidelines for the perioperative management of patients with obstructive sleep apnea: A report by the Task Force on Perioperative Management of patients with obstructive sleep apnea. *Anesthesiology* 104:1081–1093, 2006.

VIII. INTRAOPERATIVE CONSIDERATIONS

The major concerns during induction of anesthesia or sedation/analgesia technique in obese and in OSA patients include DMV, DI, and increased risk of regurgitation of gastric contents and potential pulmonary aspiration.[58] General anesthesia with a secure airway is

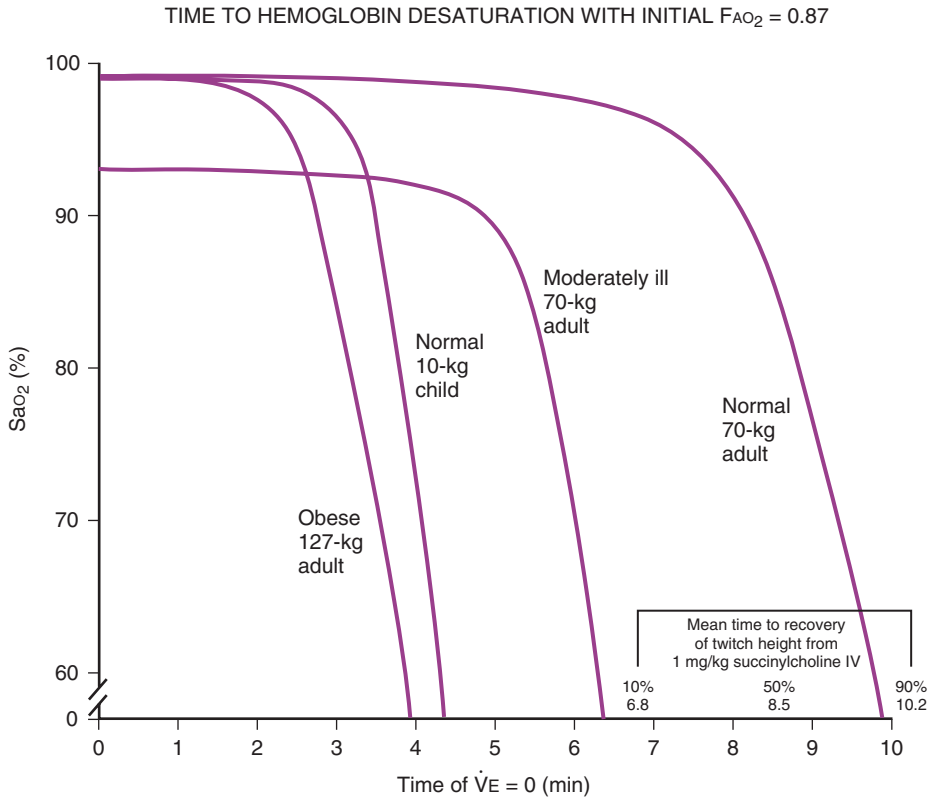

Figure 43-4 Arterial oxygen saturation *(Sa_{O_2})* versus time of apnea for various types of patients. Mean times to recovery from 1 mg/kg of intravenous succinylcholine *(lower right corner)*. Critical hemoglobin desaturation occurs before return to an unparalyzed state after 1 mg/kg of intravenous succinylcholine. (From Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology* 87:979–982, 1997.)

considered preferable to deep sedation without an airway,[27] which is increasingly used in modern anesthesia practice.[59]

A. Preinduction Considerations

Alterations in pulmonary function (e.g., reduced functional residual capacity [FRC] and O_2 reserves) in obese patients may result in severe hypoxemia even after short periods of apnea (Fig. 43-4).[60,61] Positioning of the patient in the head-elevated laryngoscopy position (HELP), which can be achieved by stacking blankets or a specially designed foam pillow (Troop Elevation Pillow, CR Enterprises, Frisco, TX)[62] or the inflatable Rapid Airway Management Positioner (RAMP, Airpal Inc., Center Valley, PA),[63] can compensate for the exaggerated flexed position from posterior cervical fat. The objective of this maneuver is to elevate the head, upper body, and shoulders above the chest so that an imaginary horizontal line connects the sternal notch with the external auditory meatus to create a better alignment among the oral, pharyngeal, and laryngeal axes (see Fig. 9-1 in Chapter 9). This position structurally improves maintenance of the passive pharyngeal airway, facilitates bag-mask ventilation, and improves the success of endotracheal intubation.

Other techniques used to avoid postinduction hypoxemia include preoxygenation with 100% O_2 until the end-tidal oxygen value is at least 90% and use of 10 cm H_2O of CPAP or bi-level positive airway pressure (BiPAP) ventilation (i.e., intermittent positive-pressure ventilation [PPV] with positive end-expiratory pressure [PEEP]) with the patient in a 25-degree head-up position.[60,64-66] Preinduction techniques followed by 10 cm H_2O of PEEP during bag-mask ventilation and after intubation can reduce post-intubation atelectasis and improve arterial oxygenation.[67] A poorly sealed preoxygenation system results in difficulty with achieving adequate preoxygenation within a reasonable period of time (Fig. 43-5).[6]

B. Awake Endotracheal Intubation

One of the critical decisions regarding induction of general anesthesia in the obese patient with OSA is to determine whether awake intubation should be performed. Awake intubation should be considered when any component of the triple maneuver (i.e., mandible advancement, neck extension, and mouth opening) is unattainable.[68] Obese OSA patients typically are more difficult to intubate than their non-OSA counterparts,[51] but obesity by itself has not been largely associated with difficult laryngoscopy or DI.[36,37,41,68] A retrospective analysis performed to identify patient characteristics that influence the choice of awake fiberoptic intubation or intubation after general anesthesia in obese patients revealed that awake intubation patients were more likely to be male, have a BMI of 60 kg/m^2 or greater, and be assigned to a Mallampati class of III or IV.[69] Because no single factor predicts DMV or DI, it may be prudent to combine multiple predictors, such as Mallampati class III

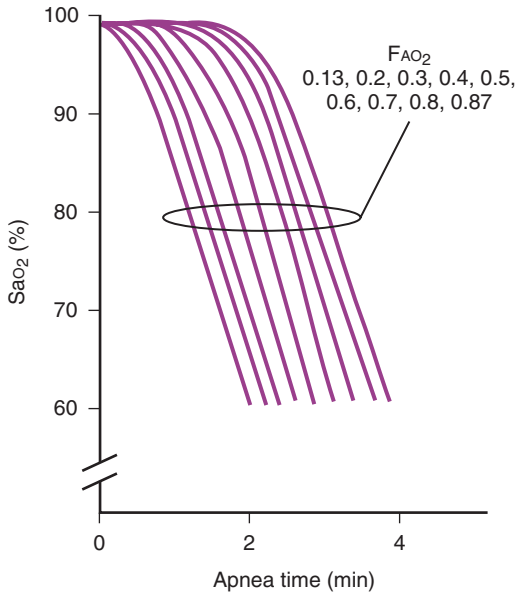

Figure 43-5 Arterial oxygen saturation *(Sao_2)* versus time of apnea for a patient with a body mass index of 40 kg/m^2 for various initial preapnea concentrations of the fraction of alveolar oxygen *(F_{AO_2})*. An F_{AO_2} of 0.87 *(right-most curve)* corresponds to a fraction of inspired oxygen (F_{IO_2}) of 1.0, and an F_{AO_2} of 0.13 *(left-most curve)* corresponds to an F_{IO_2} of 0.21. (From Benumof JL: Obstructive sleep apnea in the adult obese patient: Implications for airway management. *J Clin Anesth* 13:144–156, 2001.)

or IV,[70] neck circumference of 40 cm or larger, limited mandibular protrusion,[38] and severe OSA (AHI ≥40), to determine the need for awake intubation.

During awake intubation, sedatives and opioids, although desirable, should be minimized or totally avoided if possible, because airway obstruction can occur while the airway is being secured.[6] Dexmedetomidine is a highly selective α_2-adrenergic agonist with sedative, amnestic, analgesic, and sympatholytic properties that does not cause respiratory depression.[71] It reduces salivary secretions through sympatholytic and vagomimetic effects, which should improve visualization during fiberoptic intubation and facilitate awake intubation. The addition of ketamine with dexmedetomidine may further improve a patient's tolerance to awake intubation without impairing respiration.[72]

Topical anesthesia applied to facilitate awake intubation may compromise the airway patency.[73,74] In the upper airway, topical anesthesia may impair neural compensatory mechanoreceptors necessary for the arousal response and cause narrowing of the pharyngeal cross-sectional area, which may induce and prolong apneic episodes.[73,74] The spray-as-you-go technique for topicalization of the local anesthetic during awake intubation is often performed to minimize the time of obtundation of laryngeal reflexes.

C. Endotracheal Intubation After Induction of Anesthesia

If endotracheal intubation is planned after induction of anesthesia, adequate preparation must be made for a difficult airway based on the ASA difficult airway management guidelines.[75] Emergency airway equipment (e.g., video laryngoscopes, supralaryngeal airways, flexible fiberoptic bronchoscopes) and additional help must be immediately available. Video laryngoscopes offer superior viewing of the glottis and reduce the duration of performing endotracheal intubation, thereby preventing significant desaturation in morbidly obese patients.[76-78] The laryngeal mask airway is an effective rescue device for the difficult airway or failed airway, even in obese patients.[79,80] However, the increased intra-abdominal pressures associated with obesity may increase the risk of gastric aspiration with the use of the laryngeal mask airway, because it does not completely seal the airway. Restrictive pulmonary disease in obese patients can increase the peak inspiratory pressures and cause leaks around the laryngeal mask airway cuff, leading to hypoventilation and gastric insufflation.[81,82]

Because of concerns about aspiration and a difficult airway, rapid-sequence induction of general anesthesia with propofol and succinylcholine or rocuronium and cricoid pressure constitute the standard of care for morbidly obese patients. However, it is important to ensure sufficient depth of anesthesia, because inadequate anesthesia predisposes to regurgitation of gastric contents and pulmonary aspiration.

A short-acting muscle relaxant (e.g., succinylcholine) is recommended because it allows a rapid recovery, which may allow rapid return of spontaneous breathing. However, even with low-dose succinylcholine, recovery of breathing and pharyngeal patency may not occur before development of severe hypoxemia because morbidly obese patients can desaturate rapidly.[61] A higher dose of succinylcholine has been recommended for optimal intubating conditions in morbidly obese patients.[83,84]

Use of high-dose rocuronium may allow rapid intubating conditions, but its longer duration of action may be detrimental during a DI or DMV. Sugammadex (not available in the United States) can rapidly reverse rocuronium-induced muscle relaxation in case of impossible bag-mask ventilation or endotracheal intubation to avoid disastrous consequences.[85] However, it does not reverse unconsciousness induced by the intravenous anesthetic agent, and airway patency therefore may not be restored.

The need for rapid-sequence induction in the obese patient with no other risk factors (e.g., diabetes, history of significant reflux) is being questioned.[5,86] Controlled induction of general anesthesia allows appropriate titration of intravenous anesthetic, prevents hemodynamic instability that can occur from a predetermined dose, allows adequate ventilation, and avoids hypoxia between induction and endotracheal intubation. However, these benefits should be weighed against the risks of DMV and DI with rapid development of severe O_2 desaturation when faced with minimal risk of aspiration.

D. Mechanical Ventilation

The aim of mechanical ventilation in obese patients is to prevent progressive atelectasis that is commonly seen in this patient population.[87] Proposed ventilatory strategies

for obese patients include the use of lower inspired oxygen concentrations (F_{IO_2}) to maintain physiologic oxygenation,[88] low V_T (6 to 8 mL/kg ideal body weight),[89] application of PEEP (5 to 10 cm H_2O), and inclusion of recruitment maneuvers (i.e., large manual or automatic lung inflations).[90-93] Recruitment maneuvers to adequately open up the collapsed alveoli may require airway pressures of up to 55 cm H_2O, which may have deleterious effects on hemodynamics and therefore should be performed only after hemodynamic stabilization and be maintained for only a short period.[94] Use of pressure-controlled ventilation may allow improved distribution of gases and lower peak airway pressure.[95,96] Hyperventilation should be avoided because hypocapnia may cause metabolic alkalosis and postoperative hypoventilation.[87]

IX. POSTOPERATIVE CONSIDERATIONS

There is a high risk of post-extubation airway obstruction in obese patients with OSA, which is further increased after airway surgery with subsequent nasal packing. The ASA Closed Claims Project database analysis of lawsuits involving loss of airway after tracheal extubation found that those cases resulted in higher incidences of brain death and death than loss of airway during induction of anesthesia.[97] In 67% of the lawsuits, the patients were obese, and 28% had a history of OSA.[97]

The effects of obesity on respiratory mechanics, including a reduction in FRC, a decrease in lung compliance, expiratory flow limitation, and development of intrinsic PEEP, act together to elevate the work of breathing at rest and increase the risk of perioperative pulmonary complications.[98,99] This situation may be compounded by the negative respiratory effects induced by sedative/hypnotics and muscle relaxants that can persist for several hours after anesthesia.[100,101]

Factors to consider when determining whether to leave the patient intubated after surgery include BMI, severity of OSA, associated cardiopulmonary disease, ease of bag-mask ventilation and intubation at induction of anesthesia, type and duration of surgical procedure, and the intraoperative course. Patients with OSA should be extubated in a semirecumbent position after they are fully awake (i.e., rational, oriented, and responding to commands in a quick and unambiguous manner) and after verification of complete reversal of neuromuscular blockade. A nasopharyngeal or oropharyngeal airway may prevent post-extubation airway obstruction.[102]

A. Postoperative Noninvasive Positive-Pressure Ventilation

CPAP is the most commonly used form of noninvasive PPV in OSA patients. It works by acting as a pneumatic splint to prevent airway collapse during sleep, thereby reducing the work of breathing by counteracting auto-PEEP to reduce respiratory muscle load, improving lung function (particularly FRC), and improving gas exchange.[103,104] Auto-CPAP, delivered by a self-titrating device, uses algorithms to detect variations in the degree of obstruction and adjusts to the pressure level to restore normal breathing, thereby compensating for factors modifying upper airway collapsibility, including stage of sleep, posture during sleep, and the use of drugs that affect upper airway muscle tone.[105] However, it has not been confirmed that auto-CPAP is more effective than fixed CPAP.[106,107]

CPAP or BiPAP should be applied as soon as possible after surgery to patients who are receiving it preoperatively. It should be instituted when nausea, vomiting, post-extubation suctioning, level of consciousness, communication, facial edema, and drug depression issues are minimal or nonexistent.[27] The use of CPAP immediately after tracheal extubation may improve postoperative pulmonary function.[108]

B. Postoperative Disposition

Requirements for postoperative monitoring depend on patient-specific factors (e.g., high BMI, severe OSA, associated cardiopulmonary disease), invasiveness of the anesthetic technique, the type and duration of surgery, and the intraoperative course.[31] Patients with severe OSA undergoing an extensive surgical procedure that requires significant opioid analgesia may require close monitoring in a monitored environment (e.g., intensive care unit, step-down unit). Creation of intermediate care (observational) units with higher nursing ratios has been suggested as the most rational solution for postoperative care of morbidly obese patients with OSA who have moderate disease and whose conditions are not severe enough to qualify for an intensive care unit.

The scientific literature regarding the safety of ambulatory surgery in OSA patients is sparse and of limited quality,[5] and the suitability of these procedures remains controversial. The ASA practice guidelines propose a scoring system that may be used to determine the suitability for ambulatory surgery (see Box 43-2).[27] Patients who are at significantly increased risk for perioperative complications (score ≥ 5) are not good candidates for ambulatory surgery.[27] OSA patients should be monitored for a median of 3 hours longer than their non-OSA counterparts before discharge from the facility.[27] Monitoring should continue for a median of 7 hours after the last episode of airway obstruction or hypoxemia while breathing room air in an unstimulated environment. Unfortunately, the recommendation for longer postoperative stays is not based on any scientific evidence and may be the major limitation on performing surgical procedures in an ambulatory setting.

X. CONCLUSIONS

Airway management and general anesthesia for patients with obesity and OSA remains a challenge to anesthesiologists and other health care professionals. Understanding the pathophysiology of the disease with respect to how OSA complicates the status of various body systems and presents difficulties to the anesthesiologist is important in providing optimal care and improving perioperative outcomes. Because life-threatening situations may be encountered in this patient population, adequate preparation cannot be overemphasized.

The possible presence of OSA must be confirmed by a proper diagnosis obtained clinically or through a comprehensive sleep study. This is a primary step in ensuring that adequate surgical preparation is made. Preoperative diagnosis may improve the perioperative outcome because perioperative management can be modified appropriately, including delay of surgery to confirm and quantitate the diagnosis with a sleep study and use of appropriate anesthesia technique. It is necessary to develop protocols that allow much earlier identification and evaluation of OSA and preparation of an appropriate perioperative management plan. Postoperatively, the OSA patient must be watched closely because the risk of pharyngeal collapse and life-threatening airway obstruction lingers for several days after surgery, especially when opioids are used.

XI. CLINICAL PEARLS

- Clinical diagnosis of obstructive sleep apnea (OSA) may be made by observing the components of the classic triad of sleep-disordered breathing (i.e., history or observation of apnea or snoring with hypopnea during sleep), arousal from sleep (i.e., extremity movement, turning, vocalization, or snorting), and daytime sleepiness (i.e., easily falling asleep during quiet times of the day) or fatigue.
- A high body mass index (BMI) is a weak but statistically significant predictor of difficult intubation (DI) or failed endotracheal intubation and of difficult mask ventilation (DMV). The distribution pattern of body fat, rather than the BMI value, may be a more relevant factor in a difficult laryngoscopy. Measuring the neck circumference at the level of the thyroid cartilage is a useful addition to the normal daily practice of measuring weight or BMI during preoperative airway evaluation.
- A lateral head and neck radiograph demonstrating caudal soft tissue displacement that shifts the hyoid bone caudally to increase the distance between the mandible and the hyoid bone to more than 20 mm suggests the presence of obstructive sleep apnea (OSA) and possible difficult airway.
- General anesthesia with a secure airway is preferable to deep sedation without an airway for superficial procedures and for OSA patients undergoing procedures involving the upper airway.
- Intubation under general anesthesia should be carried out with the patient fully preoxygenated to prevent hypoxia because the relatively low functional residual capacity (FRC) found in obese patients causes them to desaturate more rapidly.
- The head-elevated laryngoscopy position (HELP) significantly elevates the head, upper body, and shoulders above the chest so that an imaginary horizontal line connects the sternal notch with the external auditory meatus to create a better alignment among the three axes.
- Intravenous anesthetic agents, except for ketamine, significantly decrease inspiratory negative airway pressure by depressing the chemical drive. Ketamine has a less depressant effect on pharyngeal dilating muscle activity, but it increases pharyngeal secretions, thereby offsetting the beneficial effect.
- A short-acting muscle relaxant, such as succinylcholine, does not ensure recovery of muscle function or pharyngeal patency before development of severe hypoxemia in morbidly obese patients with significantly decreased FRC.
- Rapid-sequence intubation is often recommended in obese patients because of the high prevalence of lower esophageal sphincter hypotonia, which increases the prevalence of gastroesophageal reflux disease, but the benefits should be weighed against the risks of DMV or DI.
- The aim of mechanical ventilation in obese patients is to keep the lungs open during the entire respiratory cycle to counteract the negative effects of respiratory modifications induced by general anesthesia and paralysis, which can persist for a few days postoperatively.
- The endotracheal tube should be left in place, or extubation should be carried out over an airway exchange catheter if any doubt exists about the ability of the patient to breathe spontaneously or the ability of the practitioner to reintubate in an emergency.
- Tracheal extubation should occur in the semi-upright or head-up position only after the obese OSA patient regains full consciousness after general anesthesia and after confirming airway patency and verification of complete reversal of neuromuscular blockade. Continuous positive airway pressure (CPAP) should be applied as soon as possible after surgery in patients who are receiving it preoperatively, but it should be instituted when nausea, vomiting, post-extubation suctioning, level of consciousness, communication, facial edema, and drug depression issues are minimal or nonexistent.
- Obese OSA patients should be cared for in a monitored environment because of an increased risk of opioid-induced postoperative upper airway obstruction.

III. Airway Management During the Later Stages of Burn Management
IV. Conclusions
V. Clinical Pearls

I. INTRODUCTION

The airway of the burn patient presents ongoing challenges and special considerations during the period of initial burn injury and throughout the patient's hospital course. As a consequence of their injuries, some burn patients have airway difficulties throughout the remainder of their lives.

The National Burn Repository reports 181,000 hospital admissions for burn injury for 1998 through 2007 in 73 U.S. burn centers. The overall mortality rate during this period was 4.9%.[1] A 2006 report of the National Burn Repository indicated an incidence of inhalational trauma of 5.7% during the previous 10 years.[2] Inhalational burn trauma was associated with a 27.3% mortality rate, compared with a rate of 4.5% for burned patients without inhalational injury.[2] A review of 850 children admitted with inhalational injury during a 10-year period at the four Shriner's Pediatric Burn Centers in the United States found a mortality rate of 16.4%.[3] Consequently, inhalational burns contribute significantly to mortality among the burn population. Although the outcomes for survival after burns and the quality of life of burn victims have improved, respiratory complications are an ongoing source of burn morbidity and mortality.

II. AIRWAY MANAGEMENT IN THE ACUTELY BURNED PATIENT

A. Evaluation of the Patient after Acute Burn Injury and Indication for Airway Management

1. Assessment at the Scene

First responders have a crucial role in the early management of burn patients. In addition to the usual trauma assessments, emergency medical service (EMS) staff must determine whether the patient's condition warrants immediate intubation in the field or the patient can be observed. Indications for intubation at the trauma scene include the following[4,5]:

- Unconsciousness and altered mental status (with incumbent aspiration risk)
- Respiratory distress (e.g., desaturation with supplemental oxygen [O_2], tachypnea)
- Thermal airway injury
- Hoarseness, stridor, dysphagia, or drooling
- Burn injury to the neck and face after fire or smoke exposure in a closed space or carbonated sputum

Figure 44-1 Carbonaceous sputum, singed nasal hairs, and facial burns indicate possible upper airway thermal injury.

- Prolonged transport to the hospital of the patient with possible airway injury
- Extensive burn injury
- Additional traumatic injuries

Patients with a flame injury from a barbecue or fire in an open space may have burns to the neck and face but no airway involvement and therefore do not require early intubation.

In addition to initial medical management of the patient, EMS staff gathers information about the type of injury and the patient's medical history. The information should be recorded for transport with the patient to a specialized burn center.

The practice of prehospital intubation of the burned patient has been questioned. Eastman and colleagues[6] reviewed the charts of 1272 patients admitted after field intubation over a period of 23 years and found that 69% of them survived. However, 30% of the survivors were extubated on admission or on the second day after the burn. None required reintubation. Klein and associates[7] reviewed the charts of patients admitted to the Washington Burn Center after a transport of more than 90 miles for the period of 2000 through 2003. They examined parameters such as duration of transport, error in burn severity estimation, fluid management, appropriateness of intubation, and transport complications. Of 1877 patients, 424 were transported more than 90 miles to the burn center. No patient died during transport, and 111 patients arrived intubated, with only 61% having inhalational burns. More than 50% of patients were extubated within the first 24 hours after admission.

Failure to secure an airway was one of the most common complications occurring during patient transport. The fact that airway obstruction can develop very quickly in burn patients and that the experience and equipment of EMS are often limited supports intubation in the field before transport in the patient with a potential for respiratory compromise.

2. Assessment in the Hospital

Roughly 10% of burn patients also present with other traumatic injuries. All burn patients are considered trauma patients and consequently undergo a primary trauma survey (i.e., the ABCDE algorithm: airway, breathing, circulation, disability, and exposure).[8] The extent and surface area of the burn are noted, other traumatic injuries identified and treated, and the airway secured if indicated. The incidence of inhalational trauma, length of hospital stay, and mortality rate are increased for patients presenting with burns and other traumatic nonburn injuries.[9]

On arrival of the patient at the burn center, the tube position is confirmed with carbon dioxide (CO_2) monitoring and auscultation of the lung fields. Uncertainty about endotracheal tube (ETT) placement should be remedied by direct laryngoscopy or fiberoptic bronchoscopy. The mouth, pharynx, and larynx are examined by laryngoscopy to assess edema and identify any burned mucosa and the presence of soot (Fig. 44-1). A radiograph is obtained to verify the ETT position and identify other potential injuries, such as a pneumothorax. Lung parenchymal injuries usually are not immediately detectable by radiography immediately after injury. Patients presenting with a supralaryngeal airway (SLA) on arrival at the hospital require endotracheal intubation or a surgical airway.

In the unintubated patient, the presence of soot in the sputum, dyspnea, tachypnea, hoarseness, and stridor are signs of impending airway obstruction. Fiberoptic endoscopy is the gold standard for the diagnosis of inhalational trauma.[10-17] In the awake patient, a nasal fiberoptic examination under local anesthesia can be performed to evaluate the larynx and confirm the presence or absence of edema and soot. Patients with altered mental status, dyspnea, hoarseness, or stridor require immediate intubation.

A relevant history for airway management after burn injury includes the following information:

- Location and type of injury (e.g., flame, steam, chemical, electrical, vehicular)
- Mental and physical condition at the scene of injury and changes during transport
- History of a difficult airway
- Circumstances of the burn (e.g., open space, closed space)
- Other traumatic injuries
- Other medical history[10,12,18,19]

Rarely, inhalation of hot steam and hot fluids can lead to a rapidly progressive upper airway edema. Chemical fires can have more complex sequelae because the chemicals themselves can injure tissues after extinction of the fire. The circumstances of the burn injury and its duration can help to discern the likelihood of carbon monoxide (CO), cyanide (CN), and other toxicities.

3. Altered Mental Status

An isolated burn injury usually does not produce a mental status change early in the disease course. A disoriented, stuporous, or unconscious burn patient should be closely examined for additional trauma. Burn-related reasons for altered mental status include inhalation-induced hypoxemia, CO poisoning, CN toxicity, and electrical injury. Other sources of altered mental status include head trauma, alcohol or drug ingestion, metabolic disorders, seizures, and psychosis. Patients with altered mental status should be intubated and ventilated with 100% O_2 until CO poisoning and CN toxicity can be ruled out. Intubation should be performed using maneuvers to stabilize the cervical spine (C-spine) if neck injury has not been ruled out.[10,12,17,20,21]

4. Cardiovascular Abnormalities

Cardiovascular instability, dysrhythmia, and cardiac arrest can be consequences of CO intoxication. Cardiac disturbances can also result from innate cardiac disease combined with the response to traumatic injury. Hypotension is often caused by fluid loss associated with burns. Hemorrhagic and neurogenic shock can also lead to hypotension in these patients as a consequence of nonburn injuries. The airway should be secured in hemodynamically unstable patients.[10,17,22]

5. Neck and Face Burns

Extensive burns of the face and neck produce facial edema, making direct laryngoscopy difficult or impossible. These patients may have pharyngeal and laryngeal edema, further complicating intubation (Fig. 44-2). Delay in securing the airway can lead to a "cannot intubate, cannot ventilate" situation. Surgical airways must be performed in this instance.[10,17,21,23]

6. Extensive Burns

Patients with large body surface area burns frequently have airway burns as well (Fig. 44-3). Edema after resuscitative efforts can make intubation impossible. After massive burns, patients develop a hypermetabolic state leading to increased CO_2 production requiring ventilator support. Some physicians suggest prophylactic intubation for total body surface area burns greater than 30%.[10,12,17,22]

Figure 44-2 Severe airway edema continues to progress for several days after initial injury and intubation.

7. Additional Injuries

Burn injuries can occur in explosions. In this setting, blast injuries, including pneumothorax and eardrum perforation, must be addressed. To escape a fire, victims often jump from windows, sustaining fractures. Burns caused by vehicular trauma can be associated with other traumatic injuries. Electrical high-voltage contact can be accompanied by brain edema, cardiac dysrhythmias, myonecrosis, and rhabdomyolysis with renal injury. C-spine injury should be ruled out as expeditiously as possible in the course of patient management, depending on the nature of the primary injury.

B. Inhalational Injury

Approximately 20% to 30% of patients admitted to regional burn centers have some degree of inhalational injury and are at risk from toxic gases.[19,24] Edelman and colleagues[25] reviewed 829 patients admitted to a burn center between 2000 and 2004 and found that 28% had an inhalational injury. Although the mortality rate for patients with solely a thermal injury was 3% and was 12% for those with an isolated inhalational injury, patients with combined thermal and inhalational injuries had a mortality rate of 14.6%.[25] Box 44-1 summarizes smoke inhalational injuries.

Figure 44-3 Extensive burns to the chest and neck can require immediate escharotomy to facilitate ventilation.

1. Injury to the Respiratory Tract

a. UPPER AND LOWER AIRWAY INHALATION SMOKE INJURY

Inhalational injury of the airway can be caused by steam, carbenoids, chemicals, and the toxic products of combustion. In most patients, the entire airway is involved, and several toxic agents are inhaled. Inhalational injury results from thermal injury (heat) to the upper airway, toxic chemicals in the respiratory tract, and CO and CN toxicities.

Thermal injury and inhaled chemical toxins cause burn injuries by different mechanisms. In an enclosed environment, temperatures can exceed 800° C, with an O_2 concentration of just 10% and CO concentrations greater than 0.5%.[26,27] Injuries are often described by the area of the tracheobronchial tree affected. The upper airway lies above the vocal cords, whereas the lower airway consists of the tracheobronchial tree, including the terminal bronchi and alveoli.

The upper airway consists of the nasal and oral cavities, the pharynx, and laryngeal structures such as the epiglottis, false vocal cords, and true vocal cords. Direct injury of the upper airway with steam, superheated air, or hot liquid is rare. The heat-conducting capacity of air is low, reducing the potential for injury. Reflex closure of the glottis usually protects the structures below the vocal cords from steam injury. Signs of upper airway injury by heated air and steam include erythema, edema, ischemia, and pharyngeal ulcerations. Although the initial presentation of injury may be unimpressive, these lesions can quickly lead to airway edema and obstruction.

The lower airway includes the tracheobronchial system and the lung parenchyma. Most injuries of the upper and lower airway result from the chemical toxins produced by combustion. Burned rubber and plastics release ammonia, chloride, sulfur, and nitrogen dioxides. Cotton and wool fires produce toxic aldehydes, including formaldehyde. Laminated structures produce cyanide.[16,21,22,28-30]

BOX 44-1 Smoke Inhalational Injuries

- Inhalation injury occurs in 20% to 30% of burn patients.
- Inhalation injury increases burn mortality.
- The leading cause of immediate death from burns is inhalational injury, not the burn itself.
- Heat injury is confined above the vocal cords.
- Inhalation damage is caused by toxic chemicals and thermal injury.
- Sequelae of inhalational burns include pulmonary edema, $\dot{V}/\dot{Q}$ mismatch, atelectasis, airway obstruction, and pneumonia.
- Carbon monoxide (CO) and cyanide (CN) systemic toxicities should be suspected with burns in confined areas.

b. PATHOPHYSIOLOGY OF SMOKE INHALATIONAL INJURY

Different mechanisms contribute to the pulmonary changes after smoke inhalation. An increase in bronchial perfusion contributes to the development of pulmonary edema, as does the increased permeability of the pulmonary vasculature caused by an increase in nitric oxide (NO).

NO formed from arginine by nitrous oxide synthetase (NOS) has an important role in pulmonary changes after smoke injury. Smoke inhalation stimulates vasomotor and sensory nerve endings in the tracheobronchial tract, releasing neuropeptides with bronchoconstricting properties. Neutrophil activation produces reactive oxygen species (ROS), increasing the activity of NOS.[31]

Increased NO in the lung reduces hypoxic pulmonary vasoconstriction, leading to ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and edema formation. O_2 and NO react to form peroxynitrite. Peroxynitrite causes cellular injury and damage to cell membranes that results in increased pulmonary vascular permeability and pulmonary edema.

Peroxynitrite, other reactive O_2 species, and reactive nitrogen (N_2) species damage DNA. In an effort to repair damaged DNA, poly(ADP-ribose) polymerase (PARP) is activated. PARP uses ATP energy reserves to repair damaged DNA. Depletion of ATP by PARP activity results in cell death.[32-35]

The coagulation cascade is activated, leading to fibrin deposition in the airway. Airway casts are formed, often obstructing the airway and impairing gas exchange in the lungs. Inhibition of surfactant leads to alveolar collapse, atelectasis, and $\dot{V}/\dot{Q}$ mismatch.[11,16,21,28,34,36]

c. SYMPTOMS

Ninety percent of patients with burns to the face and neck have an airway injury. Indicators for airway injury after burn include the following:

- Facial burn with singed nasal and facial hair
- Soot in the oropharynx
- Soot in the sputum
- Dysphonia
- Stridor
- Rhonchi
- Bronchospasm
- Respiratory distress
- Hypoxia
- Loss of consciousness

Absence of facial burns does not rule out an airway injury. However, carbonated sputum does not necessarily indicate injury below the vocal cords, because it can be drained from the nasal cavity.[10,12,13,16,17,21,23]

d. DIAGNOSIS

The gold standard for the diagnosis of an inhalational injury is direct or fiberoptic inspection of the larynx and tracheobronchial tree. Initial evaluation should document the presence and extent of injury to establish a baseline of the airway injury. Recurrent examinations are needed to evaluate the course of injury and to remove necrotic tissue to prevent airway obstruction and atelectasis.[10-17]

Flow-volume curves are difficult to obtain and depend on the patient's effort, making them less useful for discerning airway obstruction and compromise in the acute burn patient.[10,16] The arterial blood gas determination may not demonstrate any abnormalities during the early stage of airway injury,[10,16] and the radiograph obtained at presentation may not reveal any pathologic changes caused by the burn. Previous changes and nonburn injuries, however, are evident. Radioisotope evaluation of the lungs can demonstrate injury to the lung parenchyma and small airways. After intravenous injection of xenon 133 or inhalation of technetium 99, the healthy lung can rapidly clear the isotopes, but injured parenchyma clears isotopes in a delayed and uneven manner. This type of testing is not practical in the acutely injured patient.[16,17,21]

2. Systemic Toxicity from Inhalational Injury

a. CARBON MONOXIDE POISONING

CO is a product of combustion. It is a colorless, odorless, tasteless gas. Burn victims injured in a confined space should always be evaluated for possible CO poisoning. CO has great avidity for the iron of hemoglobin and cytochrome oxidase. CO's affinity for hemoglobin is 200 times greater than that of O_2. Moreover, carboxyhemoglobin shifts the O_2 dissociation curve to the left, impeding the delivery of O_2 to the tissues. CO binds to cytochrome oxidase in the mitochondria, impairing O_2 use on a cellular level and producing tissue hypoxia and acidosis.[6,10,13,21,28]

CO poisoning is the leading cause of poisoning death in the United States.[37] It is often missed because the signs and symptoms are nonspecific, including fatigue, headache, weakness, dizziness, confusion, and loss of consciousness.[10,38] A history, examination, and laboratory studies are required to make the diagnosis of CO poisoning and to plan treatment.[39-43]

The history should elicit the circumstances of burn (e.g., closed-space fire), time of exposure, and source (e.g., internal combustion engines in closed space, smoke inhalation, stoves, furnaces). The examination should take into account the pathophysiology of burn injuries, including an affinity of CO for hemoglobin that is 240 times more than that of O_2, reduced hemoglobin O_2 carrying capacity, tissue hypoxia, and the leftward shift of the hemoglobin dissociation curve.

Laboratory tests include pulse oximetry and O_2 saturation, but O_2 partial pressure does not reflect CO poisoning.[10,13,17] Carboxyhemoglobin is measured and normally is less than 2% in nonsmokers. The carboxyhemoglobin level is slightly higher in pregnant patients due to fetal CO. The concentration of carboxyhemoglobin is chronically 3% to 8% in smokers and more than 10% to 15% after smoking.

Symptoms of CO poisoning include headache, nausea, fatigue, and dizziness with carboxyhemoglobin levels between 10% and 20%. Few symptoms occur with levels lower than 10%. Disorientation may occur with carboxyhemoglobin levels between 20% and 40%; stupor or coma with levels between 40% and 60%; and death with levels greater than 60%. Pets exposed to CO can likewise be affected.

Treatment includes 100% O_2 administered to all burn victims. This level of O_2 accelerates the dissociation of CO from hemoglobin by 50% every 30 minutes. Patients with CO-hemoglobin levels between 20% and 25% should be intubated. Hyperbaric O_2 therapy increases the elimination of CO and can be considered for unconscious patients.[11,13,22,28] No data suggest that hyperbaric O_2 therapy mitigates any long-term sequelae of CO poisoning. Limited availability of these chambers and difficulties accessing the patient while in the chamber impede the use of hyperbaric therapy for acute care of burned patients.

Sequelae include delayed neurologic symptoms such as ataxia, mental degradation, and incontinence, which are seen in 12.5% of patients with high initial CO-hemoglobin levels. Computed tomography (CT) can demonstrate decreased density of the globus pallidus.[10,11,13,16,17,21]

b. CYANIDE POISONING

CN is the product of burning plastics containing high amounts of nitrogen, such as polyurethane, polyacrylonitrile, and acrocyanate. CN causes asphyxia at the cellular

level by inhibiting cytochrome oxidase and preventing mitochondrial respiration. O_2 consumption is reduced through interruption of the tricarboxylic acid cycle, and anaerobic metabolism occurs with the development of a lactic acidosis.[10,11,13,16,44]

A history, examination, and diagnostic studies are required to determine CN poisoning and its treatment. Inhalational injury in a confined space makes CN poisoning more likely, as does an increased CO-hemoglobin concentration. Measurement of blood CN concentration can be made but may not be immediately available. Levels between 0.5 and 1 mg/L are considered toxic, and levels above 1 mg/L are thought to be lethal.[13,44,45]

The symptoms, including headache and confusion, are similar to those of CO poisoning. Electrocardiographic changes may be seen, and seizures may occur. Loss of consciousness is often transitory in CO poisoning but is sustained in CN poisoning. Bradypnea occurs in CN poisoning but is not found in CO poisoning. Pupillary dilatation may occur in CN poisoning but is not frequently found in CO poisoning.

Therapy includes amyl nitrite and sodium nitrite to induce methemoglobinemia, which binds with CN. Thiosulfate is a substrate in the metabolism of CN into less toxic thiocyanate by hepatic rhodanese. Hydroxycobalamin also binds with CN, forming nontoxic cyanocobalamin. Hydroxycobalamin has minimal side effects, whereas methemoglobinemia reduces tissue O_2 delivery to patients with impaired use of O_2 at the cellular level.[44,46-51]

C. Airway Management Approaches

1. Airway Management in the Field

Intubation when indicated should be performed at the scene according to locally established management protocols. Video-assisted intubation can be performed if the equipment is available. Depending on the nature of the injury, C-spine precautions should be employed. All patients should have a rapid-sequence induction.

If intubation is difficult in the upper airway patent, an SLA (e.g., laryngeal mask airway [LMA], King LT, Easytube, Combitube) can be employed as needed. Unfortunately, none of these devices protects the airway from aspiration. Moreover, with time, airway and laryngeal edema make ventilation with an SLA progressively difficult, and when necessary, a surgical airway should be employed.[30]

2. Airway Management in the Hospital

Airway assessment is performed as previously described using fiberoptic bronchoscopy. Signs of airway injury include the following:

- Airway soot
- Erythema, edema, or ulceration
- Mucosal fragility
- Increased secretions
- Loss of cough reflex (indicates greater depth of mucosal injury)
- Mucosal necrosis

Evaluation of the lower airway requires airway topicalization and sedation. Evaluation of the upper airway can determine the need for intubation. After intubation, fiberoptic evaluation of the tracheobronchial tree can proceed. Patients with significant soot, hyperemia, and edema are intubated immediately. Patients without such symptoms can be observed and undergo serial airway examinations. Anesthetic agents to facilitate intubation must be selected on an individual basis. Combined propofol and ketamine may be useful to facilitate intubation with minimal perturbations of the patient's hemodynamics.

Rapid-sequence intubation techniques should be employed because the patients are unlikely to have been fasted before their burn. Succinylcholine is considered safe to administer in the first 24 hours after a burn. After this 24-hour window, succinylcholine use is contraindicated due to the development of immature nicotinic receptors over the muscle membrane, which can lead to hyperkalemia after succinylcholine administration.[52] These receptors occur at the neuromuscular junction and over the entire muscle membrane. Moreover, the prolonged channel opening time of these receptors contributes to the release of potassium from the myocyte. Over time, the number of receptors returns to baseline as the burn heals; however, the patient may be at risk for hyperkalemia for up to 2 years.[53,54]

In patients with severe neck burns, laryngoscopy can be impossible, necessitating a surgical airway. The precise airway tools to employ depend on the individual practitioner's preference. Fiberoptic intubation limits movement of the head and neck but may be impossible in the sooty, bloody airway of the burn patient with a smoke inhalation injury. Various video laryngoscopes can be used to provide airway visualization, especially when in-line stabilization is employed for patients at risk for C-spine injury. Surgical airway approaches should always be considered and employed when needed.

In patients presenting with a LMA in place, fiberoptic intubation through the LMA can be performed. The Aintree intubation catheter can be placed with fiberoptic endoscopy into the trachea, the LMA removed, and an ETT passed into the trachea. Chapter 50 further explains this technique.

In patients arriving with an Easytube, Combitube, or VBM Laryngeal Tube in place, an Airtraq intubation device can be inserted between the tongue and the laryngeal tube, and after partial deflation of the laryngeal tube cuff, the Airtraq can be advanced until the cords are visualized. Other devices, such as any of the video laryngoscopes, flexible fiberoptic laryngoscopes, or fiberoptic stylets can be used in the same fashion. Leaving the SLA in place permits O_2 delivery while intubation is attempted. Direct laryngoscopy with in-line stabilization when indicated can also be employed. Surgical airways should be performed when intubation appears doubtful and is needed. Surgical airways should not be delayed for multiple attempts at direct or video laryngoscopy. The same considerations that complicate intubation also complicate the performance of a surgical airway in the burn patient. An SLA often can be employed to provide ventilation while a definitive surgical airway is obtained. A

cart for the management of a difficult airway should be available with a variety of devices, catheters, video laryngoscopes, and a surgical airway tray when inhalation burn patients are treated.

3. Airway Management in Burned Children

Because of their small airway diameters, even a modest degree of airway edema in pediatric patients can lead to airway collapse. Because the resistance to flow is inversely proportional to the fourth power of the radius of the tube, decreasing the radius by one half increases resistance 16-fold.

Loss of airway and aspiration is the fourth most common cause of death cited in a study of pediatric burn patients.[55,56] Intubation may be indicated when the amount of resuscitative fluid is predicted to be more than 180 mL/kg.[57] Intubation with a Miller blade is often successful in children because the high position of the larynx requires lifting of the epiglottis. Cuffed ETTs are preferred because they allow the delivery of higher ventilator pressures and eliminate the need for repeated laryngoscopy and exchanges of the endotracheal tube if the leak is too great.[56,58]

4. Tracheotomy

Tracheotomy is performed in burn patients when laryngoscopy and intubation attempts fail. Elective tracheotomy for burn patients who need prolonged periods of positive-pressure ventilator support has been associated with airway strictures and stenosis after recovery.[10,13,37,59] However, most studies do not identify an increased risk of tracheotomies in burn patients compared with other populations.[60-63] In a retrospective study, Namdar and colleagues[64] demonstrated that tracheotomy permitted the use of lung-protective ventilation strategies in burn patients. However, Saffle and assocates[65] found no benefit for early tracheotomy as far as duration of ventilator support, length of stay, infection complications, or survival. In the pediatric population, tracheotomy caused no increased risk of complications.[38,66,67] The potential loss of the airway is less in children with a tracheotomy than those with an ETT in place. Some studies have found that percutaneous tracheotomy has reduced mechanical ventilation, hospital stay, and cost compared with traditional surgical tracheotomy.[61,68-71]

5. Securing the Artificial Airway

Securing the ETT of the burned patient can be challenging. Ideally, the ETT should be fixed without producing additional facial injuries and adjust to facial swelling. Taping usually is ineffective in securing the ETT. Suturing the tube to the gums, wiring it to a tooth, wiring it to brackets anchored to the enamel of the incisors, and circumferential fixation devices have all been employed.[72] Tying the tube with sling ribbon (umbilical tape) or even use of a disposable surgical free mask can secure it to the head. Care must be taken so that the items tied about the head do not lacerate the corners of the mouth or the ears. The tape stops must be checked routinely because facial edema can expand and pull the tube out of the trachea. If a leak develops, fiberoptic laryngoscopy can be used to guide the ETT back into the trachea. The ETT's position and taping should be checked frequently, especially during changes in patient position and after patient transport.

6. Extubation of the Burn Patient

a. EXTUBATION OF THE BURNED PATIENT AFTER 12 HOURS OF INTUBATION

After a burn injury, patients are at risk for strictures, granulomas, and airway stenosis. Patients can be symptomatic immediately after ETT removal, or strictures can develop over time, leading to progressive airway stenosis.

Before extubation, the upper airway should be assessed for patency. Fiberoptic inspection of the larynx and airway is useful to identify potential sources of immediate extubation airway loss. The patient's other critical illnesses also should be corrected before considering extubation. Any gastric feedings should be discontinued at least 4 hours before extubation, and the patient should be free of ileus and gastrointestinal bleeding. All burn patients should pass a CPAP trial, fulfill routine extubation criteria, and have a leak around the deflated ETT cuff.[73]

Extubation should be delayed if the patient requires an increased fraction of inspired oxygen (FIO_2) of more than 40%, pressure support of more than 10 cm H_2O, high minute ventilation, or a positive end-expiratory pressure (PEEP) greater than 5 cm H_2O to maintain an arterial oxygen saturation (SaO_2) of 94%. Routine intensive care unit ventilatory management parameters must always be considered.

In patients at high risk for airway compromise after extubation, the anesthesiologist and surgeon can be at the bedside to reintubate or provide a surgical airway if the extubation effort fails. A Cook catheter can be placed in the airway and left in position after extubation to serve as a reintubation guide.

After extubation, speech and swallowing consultants can help to restore the voice and assist in preventing aspiration. Because airway stenosis can occur, prolonged extubation follow-up and fiberoptic evaluation is indicated.[14,16,20,28,60,69,74-76] Video stroboscopic vocal cord evaluation can be used as a screening tool to decide whether further airway evaluation by an ear, nose, and throat specialist is required.

Extubation failure occurs with a higher incidence in the burn population than among other critically ill patients (30% versus 23%).[77] Usually, the cause of failure is poor pulmonary toilet. Extubation failure is associated with burn size, inhalational trauma, and age of the patient.

b. EXTUBATION AFTER BURN SURGERY

Patients without airway injuries can be managed according to usual anesthesia practices. If significant edema exists in the face or airway, extubation after surgery is delayed until it subsides. If other airway difficulties occur, extubation in a controlled manner is undertaken as described earlier.[13,16,78]

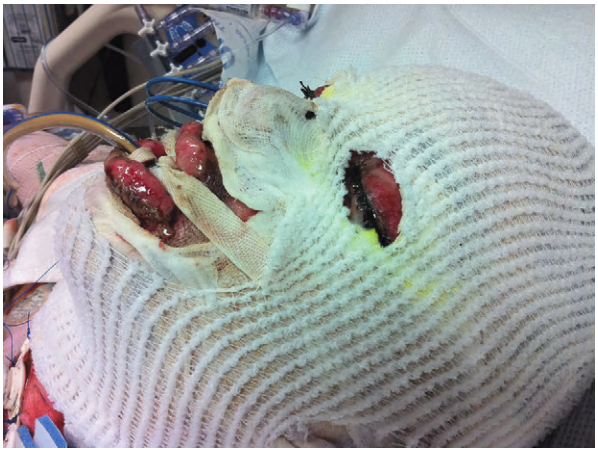

Figure 44-4 Dressings on the face can make bag-mask ventilation difficult or impossible. A supraglottic device can be used to ventilate the patient until the muscle relaxant takes effect and the trachea can be intubated.

III. AIRWAY MANAGEMENT DURING THE LATER STAGES OF BURN MANAGEMENT

Burn patients require multiple procedures after their initial intensive care course. Close airway evaluation is required in this population. SLAs and regional anesthetics can be employed when indicated.[79-81] As always, the patient's airway history is reviewed and an examination completed. Even weeks after extubation following a prolonged intubation, a patient can develop strictures and granulomas, which can complicate airway management.[71] Availability of adjuvant airway management devices should be considered when the recovering burn patient is brought to surgery during a long-term convalescence (Fig. 44-4).

IV. CONCLUSIONS

Burn patients present challenges in management in the field, in the hospital, in the intensive care unit, and during recovery. All burn patients are considered to have difficult airways, and management protocols are adjusted accordingly.

V. CLINICAL PEARLS

- Additional traumatic injuries should be ruled out in every burn patient.
- Intubation in the acutely burned patient with a traumatic C-spine injury should be performed using C-spine precautions.
- A variety of devices, including video laryngoscopes and fiberoptic endoscopes, should be available for intubation of the acutely burned patient and the previously burned patients; the ASA difficult airway algorithm should be applied in treating a patient with a difficult airway.
- Direct thermal injury to the upper airway can result in a fast-developing massive edema, compromising the airway and impeding intubation.
- Inhalation smoke injury causes direct injury to the upper and lower airways and can cause systemic toxicity through toxic smoke components, such as carbon monoxide and cyanide.
- Fiberoptic endoscopy is the gold standard for the diagnosis of inhalation smoke injury.
- Airway obstruction through edema formation can rapidly develop in children because of their smaller-diameter airways.
- Meticulous endotracheal tube (ETT) fixation and adjustment is crucial in the presence of facial edema formation. Loss of airway at the peak of edema formation can easily result in a "cannot ventilate, cannot intubate" situation.
- Before extubation, pathologic changes such as scars, stenosis, and webs should be excluded in patients after direct thermal or inhalation smoke injury to the upper airway.
- Airway management in the later stages after a burn injury can be complicated by pathologic changes such as scars and webs in the airway and by scars and contractures of the face and the neck.

V. Clinical Pearls

I. INTRODUCTION

Regional anesthesia is recognized as an effective alternative to general anesthesia and is included in the American Society of Anesthesiologists (ASA) difficult airway algorithm as an alternative to failed intubation (Fig. 45-1).[1] The anesthesiologist should carefully balance the risks and benefits of using regional anesthesia compared with those of securing the airway before the administration of anesthesia in a patient with an established difficult airway. The anesthesiologist has a responsibility to provide safe anesthetic care, including maintaining appropriate conditions to manage the airway effectively during the perioperative period. Morbidity and mortality as a consequence of mismanagement or lack of proper management of the airway represent major concerns for anesthesiologists worldwide.

Many factors must be considered by the anesthesiologist managing a patient with a difficult airway. Although management of the airway is most often easily performed before surgery, serious consideration should be given to the increased difficulty associated with the need to control the airway during the course of surgery, especially in a patient with an established difficult airway. Intraoperative block failure because of a change in the surgical plan or excess duration of surgery is a concern that must be taken into consideration when considering the use of regional anesthesia on the difficult airway patient. The anesthesiologist must determine on an individual basis what is most appropriate, whether it is preoperative management of a difficult airway or the use of regional anesthesia, and must assess the risks associated with management of the airway during the course of surgery.

II. PRACTICE GUIDELINES FOR MANAGEMENT OF THE DIFFICULT AIRWAY

Irrespective of the final decision, an appropriate assessment of the patient's airway represents the first step. Although the ability to predict accurately a difficult airway preoperatively would be of great value, it is evident from the literature that no single airway assessment can reliably predict a difficult airway.[2] Nevertheless, a preoperative airway history and physical examination should be performed in order to facilitate the choice and management of the difficult airway, as well as reduce the likelihood of adverse outcomes (see Chapter 9).[3]

Langeron and colleagues have established five factors that are frequently associated with difficult airway management.[4] They separated difficult airway into difficult mask ventilation and difficult intubation; the former is the more deleterious of the two. It is well established that airway management may be more difficult in trauma cases and in patients with comorbidities, such as severe rheumatoid arthritis, morbid obesity, metabolic diseases, deformities, or pregnancy. Rocke and colleagues demonstrated that the incidence of difficult airway is 10 times higher during pregnancy than in the general population. They documented the potential risk factors for difficult airway in the obstetric patient.[5] The risk factors included short neck, missing protruding incisors, receding mandible, facial edema, and high Mallampati scores. The relative risk of experiencing a difficult intubation compared with an uncomplicated class I airway assessment has been established as follows: class II, 3.23; class III, 7.58; class IV, 11.3; short neck, 5.01; receding mandible, 9.71; and protruding maxillary incisors, 8.0. Using the probability

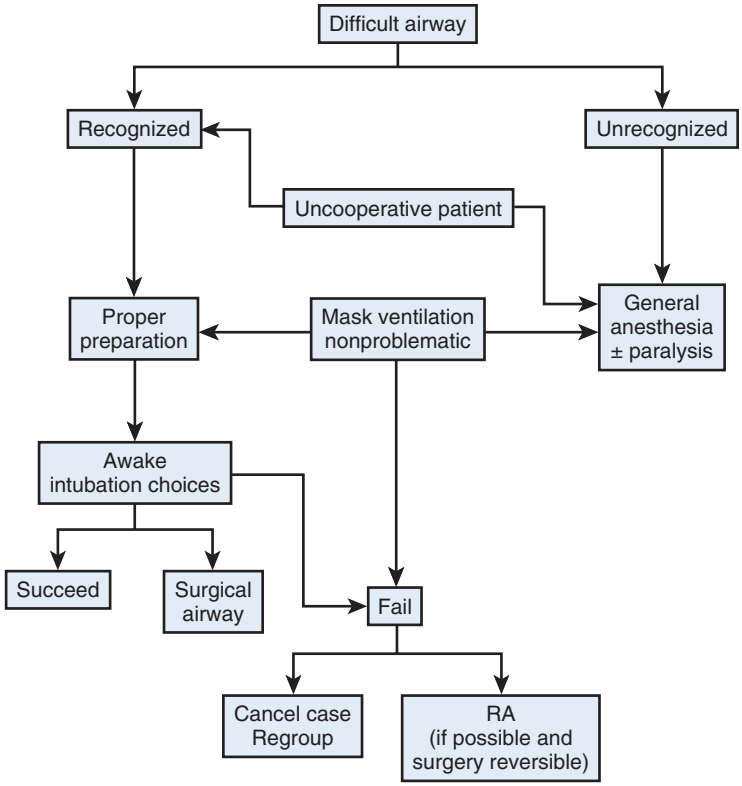

Figure 45-1 In the airway algorithm, regional anesthesia *(RA)* represents an acknowledged alternative to a failed intubation. (From Hagberg CA, editor: *Handbook of difficult airway management*, Philadelphia, 2000, Churchill Livingstone.)

index or a combination of risk factors, or both, showed that for a combination of class III or IV plus protruding incisors, short neck, or receding mandible, the probability of difficult laryngoscopy was more than 90%.

The concept of a difficult airway has different meanings for different physicians. Although most anesthesiologists agree that a patient with very limited mouth opening, Mallampati IV classification, and a very short neck has a difficult airway, there is more controversy about the relative difficulty of managing the airway in a patient with cervical trauma or obesity. This in part reflects the increased expertise in airway management of anesthesiologists and the increased number of airway devices designed to facilitate airway management. For example, Hagberg and colleagues demonstrated that Cormack-Lehane grade 3 airways assessed by laryngoscopy were reduced to grade 2 and even grade 1 when using the video laryngoscope.[6,7] The experience of the anesthesiologist with difficult airway management and access to certain airway management devices represent important factors in establishing the relative difficulty of managing the airway of a given patient.

Kheterpal and colleagues followed Langeron's work by determining the incidence and predictors of difficult mask ventilation and impossible bag-mask ventilation in relation to a difficult intubation.[8] Kheterpal later observed in more than 50,000 patients[9] that 25% of impossible bag-mask ventilations ($n = 19$) also had difficult intubations and that 10% ($n = 2$) required surgical airways. The incidence of impossible bag-mask ventilations was 0.15%. Radiation-induced changes in the neck, male sex, obstructive sleep apnea, Mallampati class III or IV, and presence of a beard were identified as independent predictors. Despite the low incidence, the anesthesiologist must anticipate and recognize differences for difficult mask ventilation and difficult intubation while also exercising sound judgment in conducting regional anesthesia in this patient population.

III. USE OF REGIONAL ANESTHESIA VERSUS PREOPERATIVE MANAGEMENT OF THE AIRWAY

In the past few years, interest has increased in using regional anesthesia as the primary anesthesia technique, especially in patients undergoing gynecologic or obstetric; plastic; ear, nose, and throat; trauma; and orthopedic surgery. The literature supports using various techniques for performing regional anesthesia as the primary anesthetic on patients with difficult airways.[10-12] We do not recommend performing these cases unless the anesthesiologist has a level of certainty about performing the block. Because of the more expanded use of regional anesthesia, anesthesiologists have become better accomplished at these techniques (e.g., higher success rate, lower frequency of complications). However, no regional technique provides a 100% success rate or is completely free of complications. Regional anesthesia complications include hematoma, nerve injury, and local anesthetic–associated complications, such as cardiac arrest, seizures, and death. When deciding whether to perform a regional technique in lieu of securing the airway preoperatively, these complications should be considered because they may trigger the need for immediate and urgent control of the airway because of a sudden loss of respiratory function (total spinal) or the development of local anesthesia–related complications (e.g., cardiac arrest, seizures).

Occurrence of these complications may be delayed, even if in most cases they occur within minutes after performance of a block. Anesthesiologists must be prepared to control the airway during the entire perioperative period. Although any regional technique intrinsically carries the risk of complications, the relative risk is different for each regional technique. For example, the use of an ulnar block at the wrist for an open reduction and internal fixation of the fifth finger performed using 5 to 6 mL of 0.5% ropivacaine is associated with a much lower risk of local anesthetic toxicity than the use of a transarterial axillary block performed with 40 mL of 0.5% bupivacaine. The specific type of approach, technique (e.g., transarterial, neurostimulator, paresthesia), volume of local anesthetic, and relative proximity of the injection site to a vessel or the central nervous system are some of the factors associated with the risks of toxicity associated with the use of regional anesthesia. Several considerations are important in making the decision to use regional anesthesia in a patient with an established difficult airway (Box 45-1). Knapik and colleagues demonstrated the ability to perform regional anesthesia for valvular heart surgery using a thoracic epidural on a patient with severe pulmonary disease, precluding the use of general endotracheal anesthesia.[13] However, during cardiopulmonary bypass, the patient required ventilatory support with a mask technique, a feat that would have been ill advised if difficult mask ventilation was anticipated.

BOX 45-1 Regional Anesthesia Versus Control of the Airway in Patients with Established Difficult Airways

Patient

Informed consent
Cooperative and calm
Hemodynamically stable
Ability to tolerate sedation, if required
Ability to communicate with anesthesiologist throughout procedure
No history of claustrophobia
Adequate intravenous access

Anesthesiologist

Expertise in both RA and DA management
Enough preoperative time to perform RA technique
Appropriate RA technique for surgical procedure
Prepared for alternative plans for DA

Surgeon

Dependable and reliable
Willing and able to supplement RA with local anesthetics, if necessary
Cooperative with primary and alternative plans for DA management

Types of Surgery

Nonemergent (except cesarean section)
Short duration
Patient's position allows good airway access
Can be interrupted for DA management
Limited or moderate blood loss

Support

Availability of appropriate equipment for RA and DA management
Staff (anesthesiologists, operating room nurses)

DA, Difficult airway; *RA,* regional anesthesia.

A. Selection of Patients

Not all patients are good candidates for regional anesthesia, especially anyone with an established difficult airway. The use of regional anesthesia as the plan of anesthetic management rather than securing the airway may be considered in adult patients who are calm, possess good communication skills, and understand and accept the risks and benefits of a regional technique over general anesthesia. Consent for regional anesthesia should include consent for the perioperative management of the airway in the case of a failed block or other uncertainty arising during surgery. It is therefore important to consider the patient's psychological status and not perform regional anesthesia in a patient who consents to regional anesthesia to avoid an awake fiberoptic intubation (e.g., negative previous experience); has a history of claustrophobia, a condition that may be exacerbated by the need to place a surgical sheet over the face of the patient; is unable to remain still, especially in the context of minimal sedation use, because of preexisting medical or surgical conditions (e.g., severe rheumatoid arthritis, back pain, prostate hypertrophy, hyperactive bladder, poor peripheral circulation); or has a psychiatric condition, such as severe depression, hysteria, psychosis, or Alzheimer's disease. It is also important to evaluate the patient's sensitivity to sedation. For example, it is unlikely that opioid-tolerant patients with a history of chronic or cancer pain would be sensitive to sedation. The increased requirement for the sedative or anesthetic may represent a contraindication for the use of regional anesthesia.

B. Anesthetic Environment

1. Anesthesiologist's Expertise

The use of regional anesthesia as an alternative to the preoperative management of the airway in a patient with a known difficult airway can be considered only if the anesthesiologist has appropriate expertise with regional techniques and difficult airway management. Peripheral nerve blocks can be classified according to the degree of difficulty (Box 45-2).

a. REGIONAL ANESTHESIA

Before considering the use of regional anesthesia in patients with an established difficult airway, it is necessary to verify that regional anesthesia is not contraindicated. General contraindications for the use of regional anesthesia include coagulopathy and infection. Specific contraindications must also be considered, such as chronic obstructive pulmonary disease (COPD) for an interscalene block. Although the use of regional anesthesia is associated with intrinsic risks, evidence also supports the concept that appropriate expertise in regional anesthesia represents an important determinant for the success of the procedure and for reducing the risk of complications.

BOX 45-2 Peripheral Nerve Block Classification According to Difficulty

Basic Blocks

Femoral
Axillary
Superficial cervical
Intravenous
Posterior sciatic
Posterior popliteal sciatic

Intermediary Blocks

Interscalene
Lateral sciatic
Infraclavicular
Anterior sciatic
Continuous femoral
Continuous axillary
Lumbar plexus
Parasacral
Paravertebral

Complex Blocks

Continuous paravertebral
Continuous infraclavicular
Continuous lumbar plexus
Continuous anterior
Parasacral sciatic block
Pediatric blocks

Expertise includes proper experience in the chosen technique; appropriate knowledge of the relevant anatomy, especially innervation; knowledge of the equipment; and knowledge of the pharmacology of local anesthetics and any medications added to a local anesthetic mixture or given for sedation.

The use of neurostimulator and ultrasound techniques is preferred to the use of paresthesia or transarterial techniques, or both, in the performance of regional anesthesia to increase the likelihood of success and minimize the required dose of local anesthetics, thereby minimizing the risk of seizures related to an intravascular injection. The smallest needle possible should be used to avoid intrathecal placement of the needle when performing an interscalene or a lumbar plexus block. Table 45-1 shows the needle sizes related to the practice of the most common peripheral nerve blocks.

TABLE 45-1
Needle Length for Most Common Peripheral Nerve Blocks

Type of Block	Length (cm)
Interscalene and supraclavicular blocks at the elbow and the wrist	2.5
Axillary, high humeral, posterior popliteal	
Infraclavicular (coracoid) and femoral blocks	5.0
Lumbar plexus, lateral sciatic, gluteal, and infragluteal	10.0
Posterior sciatic, anterior sciatic, and high lateral sciatic blocks	15.0

Although the literature provides information about the relative success rate of each technique for a given surgical procedure, the anesthesiologist's personal experience is more important in deciding which regional anesthesia technique is most appropriate. To optimize the success rate and minimize the risk of complications associated with the use of regional anesthesia in a patient with an established difficult airway, the anesthesiologist should favor the techniques that he or she is most comfortable with for a given surgical procedure rather than base the choice on the literature. For example, it is established that most shoulder or knee operations can be performed using an interscalene or a combined sciatic and femoral nerve block, respectively. However, if the anesthesiologist responsible for the care of the patient does not routinely use peripheral nerve blocks for these operations, preoperative management of the airway is preferable.

REGIONAL ANESTHESIA COMPLICATIONS. In the case of a patient with an established difficult airway, the likely complications are those that would lead to the immediate need to secure the airway because of total spinal block, cardiac arrest, or seizure. Among regional techniques, neuraxial blocks have a higher rate of complications.[14-19] Closed claim studies have demonstrated that young, healthy patients undergoing surgery during spinal anesthesia can experience sudden cardiac arrest.[20] In obstetrics, 70% of the regional anesthesia–related deaths occurred among women who had epidural anesthesia, and the remaining 30% were associated with spinal anesthesia. These deaths resulted when the block became too high for adequate ventilation, and the airway could not be secured, leading to hypoxia or aspiration, or both.[21,22]

The ASA study of closed claims in obstetrics also showed that about 25% of the anesthesia-related maternal deaths were associated with regional anesthesia. Ananthanarayan and associates presented a case of difficult intubation with brainstem anesthesia after retrobulbar block.[23] After failed endotracheal intubation, the airway was secured using a laryngeal mask airway.[23] Among the peripheral nerve blocks, lumbar plexus block,[24-26] interscalene and axillary brachial plexus block,[27-34] intercostal block, and retrobulbar block are those most often associated with complications requiring immediate control of the airway.[23] This possibility also exists with the performance of any peripheral nerve block, especially when relatively large volumes of local anesthetic are injected rapidly or when there is a vein or artery located near the nerve.

LOCAL ANESTHETICS. The choice of the local anesthetic mixture, its volume and concentration, and the mode of administration deserve serious consideration. Although the choices are dictated by the technique (e.g., major conduction blockade versus peripheral nerve blocks), selection of the local anesthetic mixture should be based even more on the safety of patients with a difficult airway, with special focus on possible complications requiring immediate airway intervention. Local anesthetics that have the highest safety profile and provide adequate anesthesia covering the entire surgical period are most

TABLE 45-2
Maximum Dose of Commonly Used Local Anesthetics

Anesthetic	Maximum Dose (mg)	pH
Lidocaine	300	6.5
Mepivacaine	500	4.5
Bupivacaine	150	4.5-6
Ropivacaine	225-300	4.6

suitable. The maximum dose of local anesthetics should be determined to decrease the risk of toxicity. Table 45-2 shows various local anesthetics and their maximum accepted doses.

b. EXPERTISE IN MANAGEMENT OF THE DIFFICULT AIRWAY

Because perioperative management of the airway may be required during the course of the procedure in a patient undergoing surgery under regional anesthesia, the anesthesiologist should be appropriately trained and experienced in difficult airway management. Use of regional anesthesia in a patient with an established difficult airway cannot be considered an appropriate alternative for the inexperienced or unprepared anesthesiologist.

2. Proper Anesthetic Setting

In addition to proper expertise in regional anesthesia and difficult airway management, the proper equipment for difficult airway management should be in good order and readily accessible during the entire perioperative period. Support should be available because calling for help is one of the first steps according to the revised version of the airway algorithm.[3] The time commitment to manage the airway appropriately should be weighed against the relative availability of the anesthesiologist during the entire perioperative period, because management of the airway may be required intraoperatively. This is especially important when the anesthesiologist supervises more than one location. An anesthesiologist who is supervising residents or certified registered nurse anesthetists or who is on call is not as available as when he or she supervises one location.

C. Surgical Environment

1. Type of Surgery

Use of a regional anesthesia technique is not appropriate for all types of operations. For a patient with an established difficult airway, a successful block does not obviate intraoperative management because the patient becomes uncomfortable or there are major hemodynamic changes or bleeding. Regional anesthesia should be considered for shorter procedures with minimal expected blood loss. For example, a short abdominal procedure may benefit from a spinal, epidural, or in some cases, bilateral paravertebral blocks. Diaphragmatic function is not blocked by a spinal or epidural anesthetic, which explains why most anesthesiologists favor the use of neuraxial blocks for low abdominal procedures. In orthopedics, it is important to consider all surgical requirements, especially those related to the use of a tourniquet. Although in surgical procedures of less than 30 minutes' duration, tourniquet pain is usually not an issue, the mechanism of tourniquet pain should be well understood and managed, because it usually requires sedation or analgesics, or both, that are often contraindicated in patients with unsecured difficult airways (Table 45-3).

TABLE 45-3
Regional Anesthesia Versus Preoperative Management for Difficult Airways

Approach	Surgical Application
Surgeries That Might Be Performed Using Regional Anesthesia	
Peripheral nerve blocks	Minor orthopedic trauma of the upper and lower extremity Open reduction with internal fixation of the small finger, elbow, and ankle and wrist fracture Minor arthroscopy surgery (e.g., shoulder, knee, ankle)
Neuraxial blocks	Gynecologic surgery Cesarean section
Surgeries More Suitable for Preoperative Management	
Airway management for long operations associated with major blood loss	Major or multiple trauma Major abdominal surgery Revised total hip surgery Major orthopedic oncology surgery
Airway management for long operations performed in the prone position	Spinal surgery Achilles' tendon surgery
Airway management for blocks unlikely to provide adequate anesthesia	Interscalene block for high humeral fracture Lumbar plexus block for hip surgery

2. Cooperation Between Surgeon and Anesthesiologist

Especially in the case of a patient with an established difficult airway, the anesthesiologist and the surgeon must agree that the operation can be performed using regional anesthesia alone or with supplementation of the block by local anesthesia during the procedure. The anesthesiologist should be familiar with the surgeon, the surgical procedure, and the surgical environment, including the availability of surgical equipment and support staff. For example, for joint replacement procedures, many hospitals and surgery centers depend on the presence of a prosthesis representative. Availability of these representatives may involve significant time delays, imposing significant limitations on the use of regional anesthesia. In a patient with an established difficult airway, the use of regional anesthesia requires the surgical procedure to be well defined, because prolonged surgical time, hemodynamic instability, or blood loss can lead to significant problems. If regional anesthesia is preferred, the surgeon should proceed only after careful determination that the patient is properly anesthetized and that inflation of a

tourniquet, if used, is well tolerated. Because of the relationship between cuff inflation pressure and tourniquet pain, it is important to minimize the pressure level at which the tourniquet is inflated. Although it is well established that pain associated with a tourniquet can occur immediately at the time of the inflation or be delayed, it is critically important to verify that the tourniquet is tolerated at the time of inflation. In short procedures, delayed tourniquet pain represents a lesser concern.

3. Positioning of the Patient

The patient's position during surgery is a critical element in the choice between preoperative management of the airway and the use of regional anesthesia. Prone and lateral positions are more likely to make management of the airway during surgery more difficult. The sitting position is also unfavorable for the use of regional anesthesia unless it is possible to convert quickly to the supine position (e.g., patient undergoing shoulder surgery in a beach chair position under an interscalene block). Although it is always possible to change to the supine position urgently, it is far from optimal medical management. Of all the positions, the supine position allows the best access to the airway. When considering the patient's positioning for a surgical procedure, it is important to consider the relationship between the surgical preparation and the patient's positioning, even when supine. For example, during an open reduction and fixation of an elbow fracture, the elbow is often elevated and flexed over the patient and then draped. Pediatric or claustrophobic patients may react to this positioning with significant stress and anxiety, a situation favoring preoperative management of the airway rather than regional anesthesia.

The anesthesiologist can proceed with the performance of regional anesthesia if it is found to be an appropriate alternative to preoperative management of the airway. The chosen technique can be physically performed outside or inside the operating room, depending on the specific block and the facility's preference. Enough time should be available for performance of the block and evaluation of its effects. Because complications do occur, it is necessary to be prepared for cardiovascular and central nervous system resuscitation. Certain positions, such as sitting for epidural or paravertebral blocks, have risks of serious complications, such as vasovagal syncope, that may require ventilatory support.

IV. CONCLUSIONS

The use of regional anesthesia in patients with an established difficult airway remains the exception rather than the rule in current practice. Regional anesthesia represents an acceptable alternative to preoperative management of the airway if certain conditions are met: establishment of proper indications for the use of regional anesthesia, appropriate consent obtained from the patient, an anesthesiologist who is experienced in regional anesthesia and difficult airway management and who is available during the entire perioperative period, and equipment and support that are readily available during the full perioperative period.

V. CLINICAL PEARLS

- The decision to perform regional anesthesia should include the surgeon's opinion.
- Choosing regional anesthesia is easier when intraoperative management of the airway can be easily accomplished during surgery (e.g., lower extremity surgery with the patient in the supine position).
- Performing a regional technique before surgery may help to assess the patient's level of anxiety and agitation and to confirm whether the choice is the right one.
- The reliability of the surgeon and the type of surgery should weigh heavily in determining whether a regional anesthesia approach is appropriate.
- If regional anesthesia is chosen, it is important to wait for the surgical block to be confirmed.
- The block should be performed as close as possible to the start of surgery.
- The duration of a block is shorter in young patients than in elderly patients.

Chapter 46

Airway Management in Intensive Care Medicine

KURT RUETZLER | PETER KRAFFT | MICHAEL FRASS

I. Introduction

II. Noninvasive Airway Management
- A. Indications and Contraindications of Noninvasive Ventilation
  - 1. Acute Respiratory Failure
  - 2. Weaning Strategy
  - 3. Difficult Airway Management
  - 4. Contraindications
- B. Different Types of Noninvasive Devices
  - 1. Noninvasive Positive-Pressure Ventilation via Face Mask
  - 2. Noninvasive Positive-Pressure Ventilation via Helmet

III. Endotracheal Intubation in Intensive Care
- A. Prelaryngoscopy Airway Assessment
- B. Oral vs. Nasal Endotracheal Intubation
- C. Choosing the Correct ETT Size
- D. Drugs Used for Sedation and Analgesia
- E. Awake Endotracheal Intubation
- F. Assessment of Correct ETT Placement

IV. Difficult Airway Management in Intensive Care
- A. Esophageal-Tracheal Combitube
- B. Laryngeal Mask Airway
- C. Transtracheal Jet Ventilation
- D. Emergency Surgical Airway
  - 1. Percutaneous Cricothyrotomy
  - 2. Surgical Cricothyrotomy

V. Complications of Translaryngeal Intubation

VI. Airway Management for Prolonged Mechanical Ventilation (Tracheostomy)
- A. Reasons for Performing Tracheostomy
- B. Timing of Tracheostomy
- C. Tracheostomy Techniques
  - 1. Conventional Surgical Tracheostomy
  - 2. Percutaneous Dilatational Tracheostomy Techniques
- D. Airway Management During Tracheostomy
- E. Perioperative and Early Complications of Tracheostomy
- F. Late Complications of Tracheostomy
- G. Conventional (Surgical) vs. Percutaneous Tracheostomy

VII. Routine Airway Care in Mechanically Ventilated Patients

VIII. Difficult Extubation in Critically Ill Patients

IX. Conclusions

X. Clinical Pearls

I. INTRODUCTION

A major responsibility of the anesthesiologist or critical care physician is the maintenance of adequate ventilation and pulmonary gas exchange in critically ill patients. In the operating room (OR) the incidence of airway catastrophes resulting in emergency tracheostomy, brain damage, or death ranges from 0.01 to 2 cases per 10,000 procedures. Emergency airway management is often even more challenging in the intensive care unit (ICU) setting. The increasing demand for critical care medicine makes it necessary to focus on specific airway problems encountered in ICU patients.

Major differences exist between airway management in a controlled setting such as the OR and airway management in the ICU. Difficult laryngoscopy and endotracheal intubation is often successful after multiple attempts in the OR because of adequate patient preparation and positioning. To the contrary, endotracheal intubation of the "crashing" critically ill patient with poor cardiopulmonary reserve in a relatively uncontrolled environment requires a different approach to prevent serious problems.

This chapter briefly describes noninvasive and "invasive" airway management with special respect on the recommendations of the American Society of Anesthesiologists Task Force on Management of the Difficult Airway (ASA algorithm) first presented in 1991.[1] The basic principles of the ASA algorithm are meticulous patient evaluation before sedation or anesthesia

induction, awake intubation if problems are suspected, and preparation of an alternative approach in case of failure.

Those recommendations are at least in part valuable for the management of ICU patients as well. Unfortunately, the ASA algorithm has a number of characteristics that prevent direct application to the ICU situation. Airway management in ICU patients is usually urgent or emergent, often depriving the physician of the time necessary to evaluate the patients and plan the life-saving intervention. The patient is presumed to have a full stomach and must therefore undergo awake airway management or rapid-sequence induction. The option of reemergence from anesthesia to resume spontaneous ventilation if difficulty is encountered is mostly unfeasible. However, at least part of the algorithm is of major importance for ICU airway management and is therefore presented in detail.

Intensive care unit airway management is complex; this chapter focuses on the most important topics to provide the reader with the information required for daily ICU practice. The chapter begins with a brief overview over noninvasive airway management (including continuous positive airway pressure via mask or helmet) and proceeds with prelaryngoscopic airway assessment. This special aspect is extensively addressed because many airway catastrophes can be prevented only by adequate evaluation and preparation of the patient before the administration of sedatives. The gold standard techniques for the performance of direct laryngoscopy and oral or nasal endotracheal intubation are then presented. Alternative methods to direct laryngoscopy (especially awake endotracheal intubation!) are discussed and the control of patients' airways in emergency situations is presented: One of four emergency techniques must be chosen immediately—laryngeal mask airway, esophageal-tracheal Combitube, transtracheal jet ventilation, or surgical airway—to prevent cerebral hypoxia. For planned as well as emergency ICU airway management, the alternative methods or techniques must be readily available before sedation and must be practiced in routine cases.

Long-term translaryngeal intubation might result in serious laryngeal damage, including ulcer formation or tracheal stenosis. Therefore, indication, timing, and recent techniques of tracheostomy are discussed, with advantages and drawbacks. Airway management in ICU patients is a matter of ongoing research and discussion. For example, the percentage of patients undergoing tracheostomy and the timing of tracheostomy underwent dramatic changes after the introduction of percutaneous dilatational tracheostomy (PDT) in the 1980s. Regardless of the technique used, PDT can quickly be performed at bedside, has a relatively low incidence of complications in trained hands, and is cost-effective, with excellent cosmetic results. After presenting routine airway care maneuvers (e.g., tracheal suctioning), this chapter closes with an often-overlooked problem in ICU airway management, difficult extubation, often encountered in patients after ear-nose-throat (ENT) procedures or other causes of pharyngeal-laryngeal swelling or distortion. Close interaction is needed with the attending ENT specialist, with coping strategies to prevent catastrophes during extubation. Special topics of ICU airway management are also detailed in other chapters (see Contents and Index).

II. NONINVASIVE AIRWAY MANAGEMENT

Invasive ventilation using an endotracheal tube (ETT) was once the gold standard for ventilatory support of critically ill patients. However, longer duration of invasive ventilation increases the risk of complications such as ventilator-associated pneumonia (VAP).[2] Noninvasive ventilation (NIV) preserves the patient's ability to speak and cough and has been shown to reduce complications related to intubation, especially VAP.[3-5] For this reason, use of NIV has become widely accepted, especially in patients with chronic obstructive pulmonary disease (COPD) and patients with cardiac failure, since weaning from respirator and ETT may become extremely difficult. In selected patients with respiratory failure, noninvasive positive pressure ventilation helps to reduce an increased respiratory rate, augments tidal volumes and reduces work of breathing.[6,7] Therefore, NIV is a promising approach to ventilatory support of ICU patients and might become even more important as a "weaning as well as a therapeutic procedure" in the near future.

A. Indications and Contraindications of Noninvasive Ventilation

Basically, NIV is applied in three different areas: in acute respiratory failure, as a weaning strategy, and in the management of the difficult airway.

1. Acute Respiratory Failure

Over the past decade, *noninvasive positive-pressure ventilation* (NPPV) has increased in popularity in the patient with acute exacerbations of COPD. In these patients, based on evidence derived from multiple randomized trials, NIV should be considered as first-line therapy.[8-12]

In a systematic review, Keenan and colleagues[13] assessed the effect of NPPV on rate of endotracheal intubation, length of hospital stay, and in-hospital mortality in patients with an acute exacerbation of COPD. The addition of NPPV to standard care in patients with COPD exacerbation decreased the rate of endotracheal intubation (risk reduction [RR], 28%; 95% confidence interval [CI], 15%-40%), length of hospital stay (absolute reduction, 4.57 days; CI, 2.30-6.83 days), and in-hospital mortality rate (RR, 10%; CI, 5%-15%). However, subgroup analysis showed that these beneficial effects occurred only in patients with severe exacerbations, not in those with milder exacerbations of COPD.

A similar approach was used by the Cochrane Database group, presenting a systematic review on the effectiveness of NPPV in management of acute COPD exacerbations.[14] Only randomized controlled trials (RCTs) were selected by two independent reviewers. NPPV not only decreased mortality (RR 0.41; 95% CI 0.26, 0.64), but also decreased the need for intubation (RR 0.42; CI 0.31, 0.59) and treatment failures (RR 0.51; CI 0.39, 0.67). In addition, complications associated with treatment (RR 0.32; CI 0.18, 0.56) and length

of hospital stay (–3.24 days; CI –4.42, –2.06) were also reduced in the NPPV group. The reviewers concluded that NPPV should be used as the first-line intervention in all patients with respiratory failure secondary to an acute exacerbation of COPD. NPPV should be considered early in the course of respiratory failure, to avoid endotracheal intubation, reduce mortality, and avoid treatment failure.

Carlucci and associates[15] evaluated the changes in the practice of NIV for the treatment of COPD patients between 1992 and 1999. In this special patients' collective, the failure rate of NPPV was constant over the years (17%). Although the severity of acute respiratory failure (ARF) episodes increased (defined by pH and APACHE II at admission), the risk of failure for a patient with pH less than 7.25 was threefold lower in the period 1997-99 compared with 1992-96. Furthermore, a significantly higher percentage of patients (pH >7.28) were treated at the normal ward and not in the ICU, which allowed a significant cost reduction.

Based on strong evidence (level 1), recent clinical studies support the use of NIV to treat ARF related to COPD exacerbations, treat cardiogenic pulmonary edema, and facilitate weaning and extubation in patients with COPD and immunosuppressed patients.[8,16] The future will show whether this trend away from "invasive" toward noninvasive ventilatory support in routine patient care will be sustained.

2. Weaning Strategy

Weaning from the ventilator is difficult in up to 20% of all patients. Already the consequent use of standardized weaning strategies (regardless of their content) has increased the success rates after extubation. In this context, Udwadia and coauthors[17] described the use of NIV as a weaning strategy first in 1992. In 2003, Burns and coworkers[18] performed the first meta-analysis of NIV as a weaning strategy, including five clinical trials and 171 patients. NIV showed significant benefit for duration of in-hospital-stay, total duration of ventilation, reduced mortality, and lower VAP rate compared with conventional weaning using endotracheal intubation. In a 2010 systematic review that included 12 randomized and quasi-randomized studies, Burns and others[19] compared NIV and invasive weaning strategy in 530 COPD patients.[19] This meta-analysis showed that NIV weaning in COPD patients is associated with decreased mortality, decreased incidence of VAP, reduced length of stay in ICU and hospital, and decreased total duration of ventilation and duration of endotracheal intubation.

Current studies on NIV weaning, predominantly focused on COPD patients, propose a potential reduction in mortality and VAP.[20] In fact, further clinical research is necessary to clarify potential benefits of NIV as weaning strategy versus conventional weaning via ETTs or cannulas.

3. Difficult Airway Management

Critically ill patients are characterized by limited physiologic reserves, possibly resulting in catastrophic complications during airway management, including cardiac arrest. After a systematic review of airway management in critically ill patients in 2007, Walz and colleagues[21] proposed adaptations to the ASA Difficult Airway Algorithm. In this algorithm, NIV serves as a valuable adjunct to conventional invasive airway management.

4. Contraindications

Absolute contraindications to NIV include respiratory arrest and the inability to tightly fit the face mask. The physician must consider potential clinical benefits as well as potential drawbacks for the following relative contraindications:

- Hemodynamic instability or uncontrollable dysrhythmias
- Any type of coma
- Mentally confused, agitated, or uncooperative patient
- Swallowing impairment or excessive secretions
- Increased risk of pulmonary aspiration
- Injuries or upper airway surgery

B. Different Types of Noninvasive Devices

Various types of face masks and helmets are widely used for administering NIV (Fig. 46-1).

1. Noninvasive Positive-Pressure Ventilation via Face Mask

Noninvasive PPV can be administered by face masks covering the mouth and nose (and eyes) or by nasal masks covering only the nose. Either technique includes a mask that is pressed against the patient's face using an elastic band (e.g., Classen band). The patient may now be supported by either continuous positive airway pressure (CPAP), pressure support ventilation (PSV), or volume-cycled or pressure-cycled systems, such as bi-level positive airway pressure (BiPAP). However, dyspneic ARF patients tend to breathe through their mouth, causing air leaking and reducing the efficacy of nasal NPPV. Face masks are preferable in these patients, and application seems to be easy. However, the pressure of the face mask against the face, especially the root of the nose, causes significant discomfort and skin lesions, and several patients refused prolonged application.[22,23] Further disadvantages are potential gastric inflation followed by vomiting (risk of aspiration), claustrophobia, and difficult speaking.[16]

2. Noninvasive Positive-Pressure Ventilation via Helmet

The helmet consists of a cylindrical transparent part that is drawn over the patient's head (e.g., CaStar, Starmed, Italy). While the helmet is closed, the lower part contains an elastic ring to ensure a tight seal at the patient's neck (Fig. 46-2). Two openings with sideways fittings to ventilatory tubing allow supportive ventilation such as continuous flow or pressure support. The helmet is a noninvasive means of ventilation; the patient has a free view through the transparent helmet and can even wear glasses, with no fogging from the circulating air. A new model of the Castar helmet includes an additional round opening with a diameter of about 10 cm for nursing the patient's face. This helmet was used as first-line intervention to treat patients with hypoxemic ARF, compared with NPPV via standard face mask.[24] Thirty-three

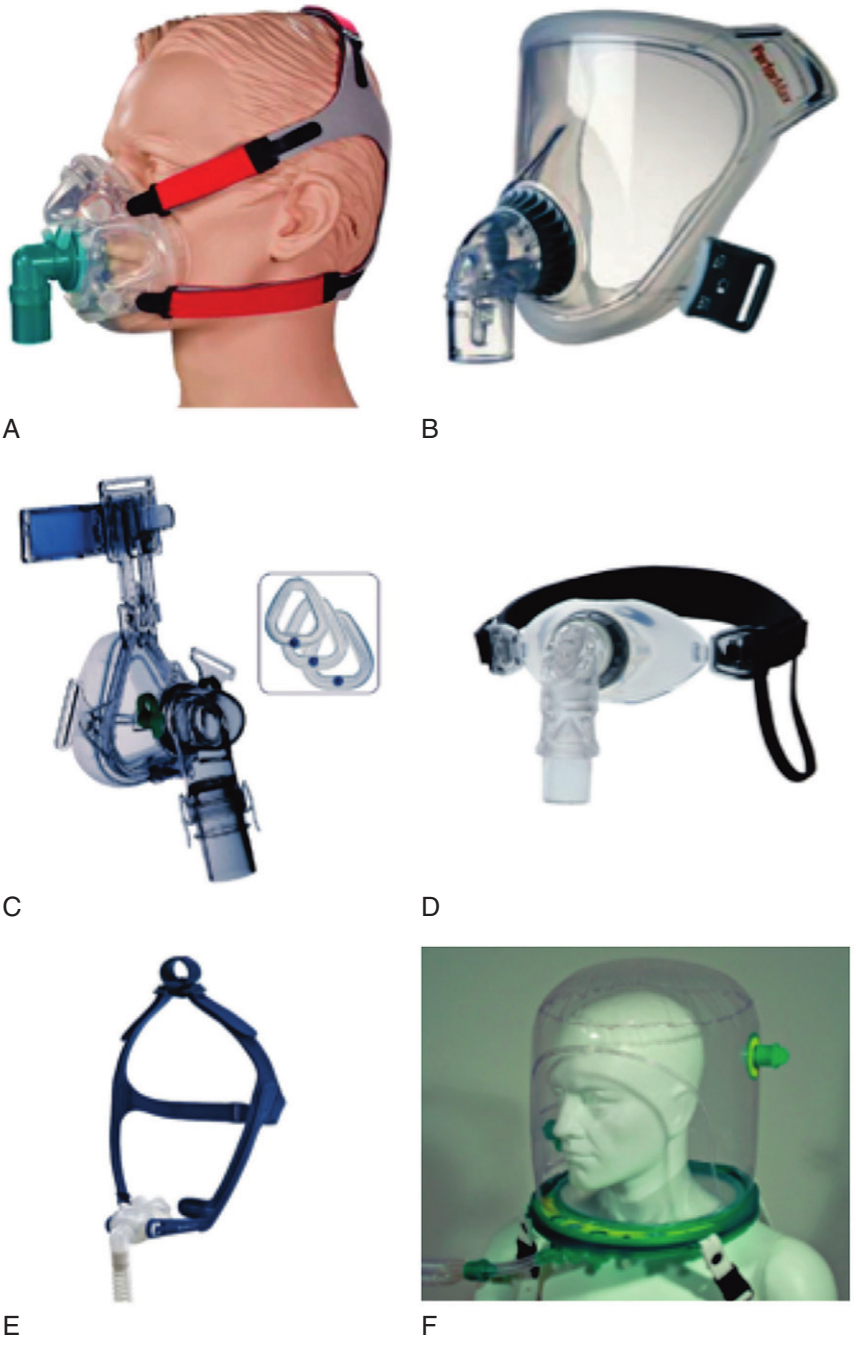

Figure 46-1 **A,** Full face mask; **B,** total face mask; **C,** nasal mask; **D,** mouthpiece; **E,** nasal pillows; **F,** helmet. (From Nava S, Hill N: Noninvasive ventilation in acute respiratory failure. *Lancet* 374:250–259, 2009.)

consecutive patients without COPD and with hypoxemic ARF (defined as severe dyspnea at rest, respiratory rate >30 breaths/min, Pa_{O_2}/F_{IO_2} <200, and active contraction of the accessory muscles of respiration) were enrolled. The 33 patients and the 66 controls had similar characteristics at baseline. Eight patients (24%) in the helmet group and 21 patients (32%) in the facial mask group (P = .3) failed NPPV and were intubated. No patients failed NPPV because of intolerance of the technique in the helmet group, versus eight patients (38%) in the mask group (P = .047). Complications related to the technique (skin necrosis, gastric distention, eye irritation) were fewer in the helmet group compared with the mask group (no patients vs. 14 patients (21%), P = .002). The helmet allowed continuous application of NPPV for a longer period (P = .05). NPPV by helmet successfully treated hypoxemic ARF, with better tolerance and fewer complications than face mask NPPV.

In another prospective clinical investigation in a general ICU, the feasibility and safety of fiberoptic bronchoscopy (FOB) with bronchoalveolar lavage (BAL) was tested during NPPV delivered by helmet in patients with ARF and suspected pneumonia.[25] Four adult patients with ARF underwent NPPV via the helmet and required fiberoptic BAL for suspected pneumonia. NPPV was delivered through the helmet in the pressure support ventilation mode. The specific seal connector placed in the plastic ring of the helmet allowed the passage of the

Figure 46-2 Application of Castar helmet in healthy volunteer.

bronchoscope, maintaining assisted ventilation. Arterial blood gas levels, pH, oxygen saturation, respiratory rate, heart rate, and mean arterial blood pressure (BP) were monitored during the study. Helmet NPPV avoided gas exchange deterioration during FOB and BAL, with good tolerance. During the procedure, heart rate increased by 5% and mean arterial BP by 7% over baseline; these levels returned to prebronchoscopy values immediately after the withdrawal of the bronchoscope. Endotracheal intubation was never required during the 24 hours after the procedure. BAL yielded diagnostic information in three of four patients. NPPV through the helmet allows a safe diagnostic FOB with BAL in patients with hypoxemic ARF, avoiding gas exchange deterioration, and endotracheal intubation.

Several special aspects of the helmet, such as the effects of direct exposure of external and middle ear to positive airway pressure, remain to be determined. Cavaliere and others[26] recommended earplugs in select NPPV patients treated with the helmet, especially during long-term support at high airway pressures. NPPV has become an integral part of daily ICU care for many patients with acute and chronic respiratory failure. However, the potential effectiveness of NPPV varies among different patient populations. The greatest benefit is seen in patients with pure *hypercapnic* respiratory failure, as seen in COPD patients. The more severe hypoxemia becomes, the less beneficial the effects observed. Clearly, further studies are necessary to identify patients with hypoxemic ARF who might benefit from NPPV.[27]

The Rüsch 4Vent (Kernen, Germany) allows unrestricted field of view and minimum level of noise. Tubing and accessories are connected to the rigid ring of the 4Vent. Diffusers prevent the stream of gas from blowing directly into the patient's face. Filters reduce the noise inside the helmet. Similar to the Castar helmet, the patient is able to speak and take liquid food and drinks. The supple material allows the helmet also to be worn lying down (Fig. 46-3).

Advantages of NPPV include few air leaks, minimal cooperation required, and absence of nasal or facial skin damage. Disadvantages include rebreathing, gastric inflation followed by vomiting, dry eyes, noise, and asynchrony with pressure support ventilation, as well as shoulder discomfort induced by the straps.[16]

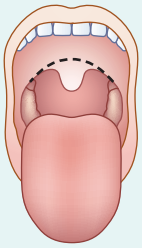
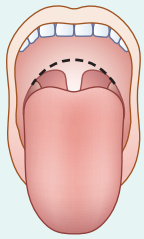
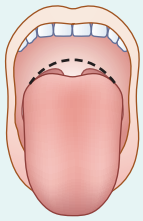
III. ENDOTRACHEAL INTUBATION IN INTENSIVE CARE







A. Prelaryngoscopy Airway Assessment

Any factor in the patient's history suggesting a difficult airway must be known before anesthesia induction, especially all diseases resulting in pharyngeal or laryngeal deformities (congenital abnormalities, surgical or traumatic deformities, laryngeal trauma, edema or tumors, goiter). As a first and rapid orientation, the simple "rule of threes" can be applied: if three fingers can be placed between the teeth, between the mandible and the hyoid bone, and between the thyroid cartilage and the sternal notch in neutral position, direct laryngoscopy should be straightforward.[28] Furthermore, more or less complex tests and scoring systems have been suggested to predict a difficult airway before anesthesia induction. The most frequently used tests are the Mallampati classification, thyromental distance, mobility of the cervical spine, and combined scoring systems (e.g., Wilson test) or multivariate risk indices[29-31] (Table 46-1).

Mallampati classification is the most common diagnostic test and is based on the evaluation of the relationship of tongue size relative to pharynx size, as follows[31]:

Class I: uvula, faucial pillars, and soft palate visible
Class II: faucial pillars and soft palate visible
Class III: only soft palate visible

TABLE 46-1
Airway Assessment

Assessment	0 Points	1 Point	2 Points
1. Interincisor gap	>4 cm	<4 cm	Cannot open mouth
2. Mallampati classification	Class I	Class II	Class III
	 A Class I	 B Class II	 C Class III
3. Head/neck movement	>90 degrees	90 degrees	<90 degrees
4. Buck teeth	Can be prognathic or edentulous	Can approximate teeth only	Cannot approximate teeth
5. Thyromental distance	>6.5 cm	6.0-6.5 cm	<6.0 cm
6. Body weight	<90 kg	90-110 kg	>110 kg
7. History of difficult intubation	None	Questionable	Definite
Airway score (AS) range: 0-14	0	7	14

The operator should be aware that the risk of difficult airway is increased in class II and especially class III patients. In the original publication, Mallampati and colleagues[31] reported excellent statistical results on the performance of the classification system. However, later investigations could not replicate these findings and report a high incidence of false-positive results.[32,33]

Thyromental distance (according to Patil) is defined as distance between thyroid cartilage (Adam's apple) and the mandible with the patient's head and neck maximally extended. The authors measured thyromental distance before anesthesia induction in 75 patients and reported a minimum distance of 6.5 cm being necessary for a successful laryngoscopic approach. At a thyromental distance less than 6.0 cm, direct laryngoscopy is impossible; between 6.0 and 6.5 cm, the operator should be prepared for a difficult airway. Sensitivity of this test varies according to definition of the "danger zone" (i.e., thyromental distance <7.0 or <6.5 cm) and is reported in the range of 30% to 90%. In most studies, specificity ranges between 80% and 97%.[32,34] Thyromental distance is a useful diagnostic test with a relatively low intra- and inter-observer variation. However, the lacking stratification for patient height and weight makes data interpretation difficult.

Direct laryngoscopy without *extension of the atlanto-occipital joint* is impossible. Decreased mobility of the upper cervical spine (e.g., in patients with rheumatoid arthritis) is a major factor responsible for failed attempts of endotracheal intubation.[35] Nichol and Zuck[30] clearly demonstrated that a reduced atlanto-occipital distance is a major factor for a limited extension of head and neck. Assessment of cervical spine mobility is performed with the patient looking straight ahead and maximum mouth opening. The patient is now urged to flex and extend the head and neck. The angle between the extreme positions should be at least 90 degrees; otherwise, a difficult laryngoscopy must be assumed, with high specificity in the 90% range.

The range and freedom of mandibular movement and the architecture of the teeth have pivotal roles in facilitating laryngoscopic intubation, so Khan and colleagues[36] proposed the *upper lip bite test*. Patients were grouped according to the following findings: lower incisors can bite the upper lip above the vermilion line (class I); lower incisors can bite the upper lip below the vermilion line (class II); and lower incisors cannot bite the upper lip (class III). In 300 elective patients, the authors evaluated the new test with the Mallampati classification. Negative predictive value for both test groups was similar (98%), but the positive predictive value of the lip bite test was better (29% vs. 13%). To improve positive and negative predictive values of those screening tests, several authors proposed the combination of various risk scores. In 1988, Wilson and associates[29] published a screening test system, including patient weight, mobility of the cervical spine, and anatomic-physiologic parameters of the stomatognathic system (Table 46-2). According to the authors, difficult airways must be suspected with 2 or more cumulative points. This scoring system requires more extensive evaluation but results in improved statistical performance. In patients with a cumulative result of 2 points, sensitivity of 75% was observed.[29] Oates and coauthors[32] reported specificity of 92%.

El-Ganzouri and associates[37] proposed a *multivariate risk index*, similar to the Wilson test. The authors recommended the following approach:

- Airway score (AS) of 0: proceed with routine management, no difficulties are expected.
- AS of 1 to 2 points: proceed with routine management, check fiberoptic availability, and prepare a special plan B.

TABLE 46-2
Wilson's Test

Risk Factor	Criterion	Points
Body weight	<90 kg	0
	90-110 kg	1
	>110 kg	2
Head and neck movement	>90 degrees	0
	90 degrees (±10)	1
	<90 degrees	2
Jaw movement	MMO >5 cm or LJ in front of UJ	0
	MMO <5 cm and LJ = UJ	1
	MMO <5 cm and LJ behind UJ	2
Receding mandible	Normal	0
	Moderate	1
	Severe	2
Buck teeth	Normal	0
	Moderate	1
	Severe	2

MMO, Maximum mouth opening; *LJ,* lower jaw; *UJ,* upper jaw.
From Wilson ME et al: Predicting difficult intubation. *Br J Anaesth* 61:211–216, 1988.

- AS of 3 to 4 points: have the fiberoptic scope on standby at bedside, and call for help; prepare for asleep or awake fiberoptic intubation.
- AS greater than 5 points: perform awake intubation (most practitioners prefer awake fiberoptic intubation).

Statistical results demonstrate a relatively weak performance in clinical routine. Even combinations of tests or scoring systems combining several risk factors are prone to misjudgment for the individual patient.[34] The upper airway is a complex structure and consists of many anatomically relevant variables. Also, statistical performance of these tests is still unsatisfying; the operator might be warned of trouble. Closely evaluating the patient before anesthesia induction might prevent catastrophic "cannot intubate, cannot ventilate" situations.

B. Oral vs. Nasal Endotracheal Intubation

Oral intubation and especially nasal intubation are characterized by special advantages and complications, with orotracheal intubation being currently favored by most anesthesiologists. Box 46-1 lists the contraindications for nasal intubation in critically ill patients.

The most common complication of *nasotracheal intubation* is nasal bleeding, occurring in about 45% of patients.[38] The incidence of bleeding can be reduced with adequate preparation (vasoconstrictors). In most cases, bleeding is self-limited, and no further intervention is needed. Other complications are necrosis of the tip or wing of the nose (up to 4% of patients) and complications induced by the impaired drainage of paranasal sinus secretions.[39] Nasotracheal intubation impairs the drainage of the maxillary sinus, resulting in congestion of secretions, followed within a few days by bacterial overgrowth and sinusitis. This typical complication of intensive care occurs within 8 days in 25% to 100% of transnasally intubated patients.[40,41] The incidence is closely related to the duration of endotracheal intubation, from 37% after 3 days to 100% after 1 week, with the majority resolving within 1 week after extubation.[42] Therefore, in all ICU patients presenting with fever of unknown origin, a high index of suspicion for sinusitis must be maintained. Radiologic or ultrasound studies, including computed tomography (CT) scans, may be necessary to demonstrate the presence of fluid or inflammation. Bacterial sinus infection may ultimately lead to bacteremia and systemic inflammatory response. These infections tend to be polymicrobial, but often display a predominance of gram-negative bacilli (particularly *Pseudomonas aeruginosa*), *Staphylococcus aureus,* or fungi. Treatment includes removal of all nasal tubes and institution of appropriate antibiotic therapy, along with decongestant therapy. In some cases, surgical drainage may be necessary. Serious, but rare complications after nasotracheal intubation are accidental turbinectomy, intracranial placement, and retropharyngeal dissection.[43-45]

Oral intubation, on the other hand, interferes greatly with oral and pharyngeal hygiene, and even small lesions of oral soft tissues may result in extensive bacterial or viral soft tissue infections (e.g., herpetic lesions).[46] Most authors agree that all complications typically seen with nasal intubation may also occur during orotracheal intubation, although at a significantly lower incidence. Therefore, *oral endotracheal intubation* is the preferred route of tube passage, and nasal intubation is reserved for special indications, mainly short-term ventilatory support in oral surgery. For patients requiring intubation for more than 7 days, the nasotracheal route should always be avoided.[47]

Box 46-1 Contraindications to Nasal Intubation

Severe coagulopathy
High-dose systemic anticoagulation
Known nasal or paranasal pathologies
Infection of paranasal sinuses
Basilar skull fractures
Traumatic brain injury with leakage

C. Choosing the Correct ETT Size

According to literature, there is a clear association between endotracheal tube diameter and the incidence of laryngeal complications. Injury is located mainly in the posterior part of the glottis, where pressures up to 200 or 400 mm Hg are exerted by poorly deformable ETTs.[48] This pressure is reduced by the use of softer ETTs with a smaller diameter. In routine anesthesia patients, use of a smaller ETT reduces the incidence of postoperative sore throat, presumably because of the decreased pressure at the ETT-mucosal interface. Stout and associates[49] studied 101 patients randomized to larger (9 mm for male, 8.5 for female) or smaller (7 mm for male, 6.5 mm for female) endotracheal tubes, and the incidence of postoperative sore throat was 48% (large ETT) versus 22% (small ETT). No ventilatory difficulties were observed in either group.

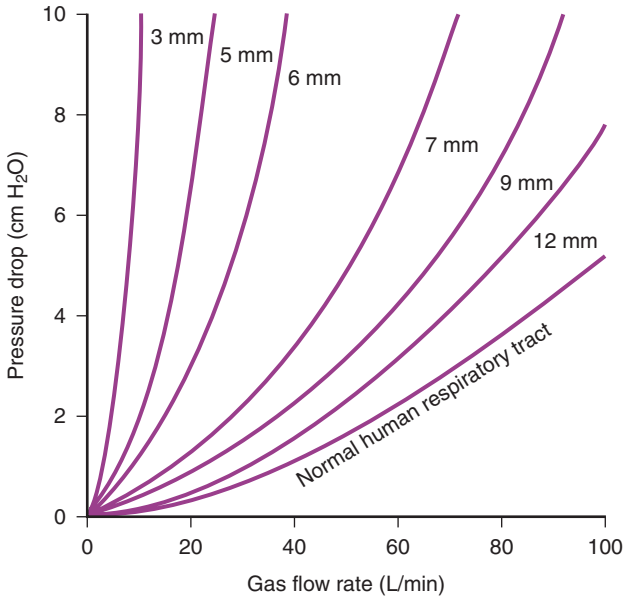


Figure 46-4 Driving pressure required to produce a flow rate of air versus internal diameter (ID) of endotracheal tubes. (From Nunn JF: *Applied respiratory physiology*, ed 3, Boston, 1987, Butterworths.)

The limiting factor for minimizing ETT diameter is the increased flow resistance and work of breathing. The pressure gradient required to generate gas flow can be calculated according to the Hagen-Poiseuille relationship, in which the rapidity of gas flow is directly proportional to the square of the ETT diameter (D) and the pressure (P) and indirectly to the ETT length and gas viscosity (valid only in laminar flow conditions). In other words, the pressure gradient through the airways proportionally rises with flow, viscosity, and ETT length but increases exponentially when ETT radius decreases. Viscosity of the gas administered has clinical consequences; with lower viscosity, a lower pressure gradient necessarily results in a lower airflow resistance. For example, gas mixtures with a high percentage of helium are often used to overcome upper airway obstruction (e.g., from tracheal compression or stenosis) and to treat the most severe status asthmaticus.[50,51]

In all patients, endotracheal intubation artificially increases airway resistance, because ETT inner diameter (ID) is smaller than tracheal diameter. Usually, ETT length exceeds length of the natural airways. Resistance is further increased by the curved design of the tubes necessary to resemble the patient's airway. Resistance measured using curved tubes is about 3% higher compared with straight tubes.[52] Therefore, the pressure gradient to generate gas flow is minimized by using an ETT with a larger diameter, short length, and straight design. Flow resistance can be translated in work of breathing, which is inversely proportional to ETT diameter (Fig. 46-4). The non-elastic work of breathing is increased twofold by using 7.0 mm–ID ETT and onefold by using an 8.0 mm–ID ETT versus a 9.0 mm–ID ETT.[53] With respect to gas flow, it is warranted to use as large an ETT as is practical for patients presenting with respiratory dysfunction; a short tracheal cannula with ID of 9.0 to 10 mm is best.

Clinical Implications. Using a smaller ETT seems to reduce laryngeal damage. The use of an ETT with an ID of 6.0 mm or less does not present a problem in anesthetized patients without spontaneous ventilation, because relatively low gas flow velocities are necessary to maintain adequate ventilation. However, gas flow resistance drastically increases, especially in spontaneously breathing patients in respiratory distress, who benefit from larger ETTs. Therefore, ETTs with ID of 7.0 to 8.0 mm seem appropriate for women and 8.0 to 9.0 mm for men.

An interesting aspect of ETT selection is airway management for professional singers. Powner[54] sent a written survey to all physician members of the Voice Foundation on airway management in professional singers. A strong consensus (76%) favored a smaller ETT for singers (6- to 7-mm ID for males and 6.0-mm ID for females) via the oral (46%) versus nasal (36%) route. Intubation/extubation by the most expert/experienced personnel was emphasized to minimize laryngeal trauma. Preferences for an early tracheostomy (6 days) versus their usual time (10 days) were approximately equal (44% vs. 50%, respectively).

The tracheal cuff has also been implicated as a cause of tracheal damage following long-term ventilatory support. Red-rubber ETTs equipped with low–residual volume, high-pressure cuffs exert high pressures to the tracheal mucosa and are thought to be damaging.[55] Using an experimental study design in rabbits, Nordin and coauthors[56] investigated tracheal mucosal perfusion and cuff-to-tracheal wall pressures exerted by low–residual volume, high-pressure cuffs and compared the results to those obtained with high-volume, low-pressure cuffs. Blood flow to the tracheal mucosa adjacent to the high-pressure cuff ceased beyond 30 mm Hg. Using high-volume cuffs, mucosal blood flow did not cease up to intracuff pressures of 80 to 120 mm Hg. However, cautious recommendations were made, and cuff pressure should be maintained below 30 cm H_2O.[55]

Conditions in ICU patients differ from routine anesthesia patients. ICU patients are mainly breathing spontaneously or on partial ventilatory support. Spontaneous breathing results in cuff pressure changes; cuff pressure decreases during inspiration and increases during expiration. Active changes in pleural pressure by forced inspiratory efforts combined with direct modulation of tracheal musculature result in marked increases of tracheal diameter and a fall in cuff pressure, even toward 0 cm H_2O.

Prolonged airway support using ETT or tracheal cannula might result in severe damage to the tracheal mucosa and increased incidence of late complications. Tracheal stenosis might be induced by direct trauma or by the pressure exerted by the ETT cuff. The presence of an ETT sutured to canine tracheal mucosa induced erythematous laryngeal mucosa in less than 1 day, proceeding to mucosal ulceration and loss of airway architecture in less than 1 week.[57] Damage was generally severe after 1 week, but no further tendency to aggravation after 1 week was observed.

The tracheal vascular supply to the tracheal submucosa is oriented in a circumferential direction anteriorly and longitudinally in the posterior part of the trachea. Seegobin and van Hessalt[58] investigated tracheal mucosal

blood flow in 40 routine surgery patients using an endoscopic photographic technique while varying cuff inflation pressure. They suggested that tracheal blood flow is almost normal at 25 cm H_2O. Increasing cuff pressure results in a pale appearance of the tracheal mucosa at 40, blanched at 50, and flow is completely absent at 60 cm H_2O. Thus, it was recommended that cuff inflation pressure should not exceed 30 cm H_2O (22 mm Hg).

Joh and colleagues[59] observed similar results, measuring tracheal mucosal blood flow in an experimental model using the hydrogen clearance method. No significant depression in mucosal blood flow was observed with the cuff inflated to a maximum of 20 mm Hg. Increasing cuff pressures to 30 or even 45 mm Hg resulted in significant reduction in mucosal blood flow, and the authors concluded that cuff pressures should be kept at or below 20 mm Hg. Incorrect cuff pressure settings may result in tracheomalacia and subglottic stenosis (too high pressures) or late-onset nosocomial pneumonia (insufficient pressures). Several authors suggested that microaspirations might thereby be facilitated and recommended the use of automatic cuff-pressure regulators.[60] In a randomized study in 130 patients, Pothmann and associates[61] reported a significant reduction in late-onset pneumonias by a microprocessor-controlled automatic cuff-pressure regulator. However, the few studies covering small numbers of patients means that the devices described cannot currently be recommended for routine patient care.[60,62]

D. Drugs Used for Sedation and Analgesia

In general, less is more in conscious sedation for airway management. Drugs must be administered in dosages not interfering with protective reflexes and patient cooperation. Therefore, short-acting drugs with a potential antidote should be used.

The presumption of a "full stomach" in emergency intubations dictates the use of a rapid-sequence induction (RSI) technique. Cricoid pressure and laryngoscopy at the earliest possible moment place increased demands on the physician preparing to intubate the patient.[63] The ICU patient presents with even more risk factors than the routine OR patient. With facial distortion, swelling, secretions, and mandibular or cervical spine injury, ICU patients present the most challenging airway management problems.

Stimulation of the airway with a laryngoscope and ETT presents an extremely noxious stimulus.[64] This stimulation causes "pressor response" and results in hypertension and tachycardia. In critically ill patients with limited reserves for adequate tissue oxygenation, this pressor response may induce myocardial and cerebrovascular injury.[65] This physiologic stress after airway management may unmask relative hypovolemia or vasodilatation and may result in post-intubation hypotension.[66] Endotracheal intubation also can provoke bronchospasm and coughing, possibly aggravating underlying conditions such as asthma, intraocular hypertension, and intracranial hypertension. Patients at risk for adverse events from airway manipulation benefit from pre-induction drugs.[67]

We prefer the combination of low-dose midazolam (0.1 μg/kg) and an opioid such as fentanyl (2 μg/kg). *Fentanyl* is the most frequently used opioid because of its rapid onset and short duration of action. Fentanyl and its derivatives, sufentanil and alfentanil, can cause rigidity of chest wall, but this rigidity seems to be associated with higher doses and rapid opioid injection. Fentanyl can be antagonized rapidly using naloxone,[68] whereas midazolam can be antagonized using flumazenil.

Remifentanil is a novel μ-receptor agonist that has been used in surgical and obstetric analgesia for more than a decade. Its pharmacokinetics suggests that remifentanil may be an ideal opioid. Notably, its unique features include rapid onset of action (~1 minute), rapid degradation by tissue and plasma esterases, and half-life of approximately 3 minutes.[69,70] Infusion of 0.05 to 0.1 μg/kg/min produces blood concentrations of 1 to 3 ng/mL. Rapid onset and elimination of remifentanil facilitate its effective and safe use during airway management in the ICU. Several studies focused on remifentanil as a sole sedative and analgesic agent in the ICU setting. Puchner and coworkers[71] prospectively studied remifentanil (0.1-0.5 μg/kg/min) alone versus fentanyl plus midazolam for fiberoptic intubation. Fiberoptic nasal intubation was possible in all patients, with a better-suppressed hemodynamic response and tolerance of ETT advance in the remifentanil group. Recall was significantly more common in the remifentanil group. A combination of remifentanil and midazolam or propofol is a valuable approach.[72]

Lallo and coworkers[73] recently studied 60 patients requiring fiberoptic nasotracheal intubation, randomized to target-controlled infusions of propofol or remifentanil. Both agents can be rapidly titrated to achieve good intubating conditions and patient comfort. In addition, remifentanil preserves patient cooperation, making it safer when spontaneous ventilation is paramount. Yeganeh and associates[74] enrolled 22 patients who had cervical trauma and semi-elective maxillofacial surgery and administered remifentanil with target-controlled or manually controlled infusion techniques. They recommended remifentanil infusion to provide good conscious sedation, but target-controlled remifentanil infusion seems to provide better conditions compared with manually controlled remifentanil infusion and is easier to use.

Alternative drugs suitable for ICU airway management and even awake fiberoptic intubation are (S+)-ketamine and propofol.[75] *Propofol* is a rapid-acting, lipid-soluble induction drug that induces hypnosis in a single arm-brain circulation time. In patients with cardiac comorbidities and limited physiologic reserve, the use of propofol can be associated with significant hypotension. Causes of hypotension are reduced systemic vascular resistance and possibly depressed inotropy.[76] In an analysis of 4096 patients undergoing general anesthesia, Reich and associates[77] reported that the use of propofol was a statistically significant predictor of hypotension. Furthermore, in 2406 patients with retrievable outcome data, prolonged in-hospital stay and death were more common in those who experienced hypotension.[77] Therefore, use of propofol may have special risks in high-risk patients with known cardiac dysfunction.[78]

Ketamine is a rapid-acting, dissociative anesthetic agent (similar to phencyclidine) with potent amnestic, analgesic, and sympathomimetic effects.[67] Ketamine can cause realistic hallucinations and extreme emotional distress. This may be prevented with the obligatory combination of a benzodiazepine. The sympathomimetic effects of ketamine may produce cardiac ischemia by increasing cardiac output. Consequently, use of ketamine should be avoided in patients with cardiac dysfunction. Leykin and others[79] found that the administration of ketamine resulted in excellent intubation conditions in patients undergoing elective surgery compared with sodium pentothal. In a prospective, randomized clinical trial, Ledowski and Wulf[80] reported that the combination of ketamine with rocuronium and etomidate resulted in superior intubation conditions. This combination may be useful in treating hemodynamically unstable patients in the ICU setting, when succinylcholine is contraindicated.[21] The use of ketamine in patients with increased intracranial pressure is only recommended in mechanically ventilated patients.[81] Ketamine is associated with realistic and truthful nightmares. In this context, the combination with midazolam seems to be an obligatory recommendation. Currently, an S(+) enantiomer of ketamine is available. This enantiomer seems to be free of these clinically relevant side effects although use of these S(+) enantiomers is still recommended in combination with midazolam.

Etomidate provides good intubation conditions with only moderate hemodynamic depression in patients undergoing RSI.[82] Etomidate inhibits adrenosteroid production through the inhibition of mitochondrial hydroxylase, after continuous or even single administration.[83-85] Cuthbergson and colleagues[86] recruited 500 patients to a multicenter, randomized, double-blind, placebo-controlled trial. The use of bolus etomidate was associated with an increased incidence of inadequate response to corticotrophin and is likely associated with an increase in mortality. Therefore, the authors recommend extreme caution in the use of etomidate in critically ill patients with septic shock.[86] Roberts and Redman[87] and Bloomfield and Noble[88,89] also questioned any use of etomidate in critically ill patients.

Dexmedetomidine is increasingly used as a sedative for monitored anesthesia. Advantages include its analgesic properties, "cooperative sedation," and lack of respiratory depression. Dexmedetomidine is also increasingly used in RSI and awake intubation, with promising studies showing a beneficial effect.[90,91] However, long-term observational studies are still lacking, and the current scientific level is too weak to recommend routine use of dexmedetomidine.

Muscle relaxants are also used in emergency airway management in the ICU. If endotracheal intubation fails, the merits of preserving spontaneous ventilation versus optimized intubating conditions using non-depolarizing muscle relaxants should be considered.

Succinylcholine is a very-rapid-acting, polarizing muscle relaxant enabling excellent intubation conditions in less than 1 minute.[92] Unfortunately, it has serious side effects, including the possibility of triggering malignant hyperthermia. The use of succinylcholine is contraindicated in patients with acute major burns, upper or lower neuronal lesions, prolonged immobility, massive crush injuries, and various myopathies.[21] Benumof and associates[93] clearly demonstrated that even the short duration of action of succinylcholine is too long, and critical hemoglobin desaturation will occur before return to an unparalyzed state, even after a 1-mg/kg dose.[93]

Rocuronium is the most widely used non-depolarizing neuromuscular blocking agent. The recommended dosage of "normal" intubation is 0.6 mg/kg. For RSI, higher dosages up to 1.2 mg/kg are necessary and provide excellent intubation conditions within 1 minute.[94] A meta-analysis by the Cochrane Collaborative Group concluded that succinylcholine created superior intubation conditions compared with rocuronium.[95] The only absolute contraindication against the use of rocuronium is allergy to aminosteroid neuromuscular drugs. A major advantage of rocuronium is the possibility of rapid and complete reversal of even deep neuromuscular block by the administration of sugammadex.[96] Based on a systemic review by Chambers and others,[97] the use of sugammadex in combination with high-dose rocuronium is efficacious.

E. Awake Endotracheal Intubation

Successful awake intubation depends on proper patient preparation. Extensive psychological support and clear explanation about reason for and management of awake intubation are necessary and helpful in the ICU setting.

The airway is topically anesthetized with 5% to 10% lignocaine, which is sprayed with a flexible nozzle into the posterior pharynx to reduce coughing and buckling during intubation. If a fiberscope is used, the larynx is then sprayed with 2 mL of lignocaine 2% administered through the working channel of the fiberscope, after which the scope is advanced into the trachea. Thereafter, a second spray is applied into the trachea before the ETT is advanced. Alternative approaches include blockade of superior laryngeal nerve or lingual nerve and transtracheal anesthesia.

Once the patient is properly prepared, any of the intubation techniques listed in Box 46-2 can be chosen according to the operator's preference.[98-102]

In case the first attempt of awake intubation fails because of equipment/operator failure or poor patient cooperation, the following options should be considered: a modified method for awake intubation (e.g., change from blind nasal to fiberoptic approach), induction of general anesthesia, and transition to a fiberoptic-guided

Box 46-2 Nonsurgical Techniques for Awake Intubation

Fiberoptic intubation (oral, nasal)
Intubation using rigid fiberoptic scopes (e.g., Bullard, Wu)[98,99]
Blind intubation through LMA Fastrach[100]
Direct rigid laryngoscopy
Retrograde techniques (with or without fiberoptic scope)
Trachlight or other lighted stylets (lightwands)[101]
Blind nasal intubation[102]

intubation method. We believe that the first choice for awake airway management is fiberoptic oral or nasal intubation. If oral intubation is performed, a conduit (i.e., Ovassapian fiberoptic intubating airway) may be used to facilitate fiberscope and ETT insertion. Additionally, a 4 × 4 gauze pad may be used to pull the tongue forward.

A valuable alternative approach is the insertion of the intubating laryngeal mask airway (ILMA) under local anesthesia and light sedation. Intubation is then performed blindly or using a fiberscope inserted through the LMA. Langeron and coworkers[103] prospectively compared ILMA intubation with fiberoptic intubation in patients with difficult airway and reported similar success rates (>90%) and durations for both techniques. Another interesting approach is the combination of Fastrach and lighted stylet. Dimitriou and associates[104] studied 44 of 11,621 patients in whom three attempts of direct laryngoscopy failed. In all these patients, an ILMA was inserted and sufficient ventilation was possible in all patients after a maximum of two attempts. Thereafter, a well-lubricated silicon ETT loaded with a flexible lightwand was introduced. Lightwand intubation was successful at the first attempt in 38 of 44 patients, at the second attempt in three patients, and at the third to fifth attempt in two. Intubation failed in only one patient. Finally, if all those alternatives fail, the establishment of a surgical airway should be considered.

F. Assessment of Correct ETT Placement

Esophageal intubation is a major complication of airway management and can result in severe brain damage or even death. Evaluating the U.S./American closed-claims database (5480 claims), Cheney and colleagues[105] reported the changing trends in anesthesia-related death and permanent brain damage. In the 1980s, 11% of claims associated with death or brain damage involved esophageal intubation, fortunately decreasing to 3% in the 1990s. This reduction was attributed to the introduction of end-tidal carbon dioxide partial pressure (P_{ETCO_2}) monitoring in the 1990s (Fig. 46-5).

Esophageal intubation is an issue even in sufficiently equipped ICUs. Schwarz and colleagues[106] studied almost 300 emergency intubations in an ICU setting and reported esophageal intubation in 8% of cases (ETT misplacement was corrected in all patients before the onset of hypoxemia).

Techniques for clinical evaluation of ETT position include the following:

- Direct visualization of the ETT between the vocal cords[107,108]
- Ventilation-bag compliance[109]
- Auscultation of breath sounds over lungs and epigastrium[110]
- Observation of symmetrical chest excursions
- ETT condensation[111]
- Lighted stylet (lightwand)[112]
- Esophageal detector device and self-inflating bulb[113-115]
- Acoustic reflectometry[116,117]
- Fiberoptic bronchoscopy
- Chest radiograph

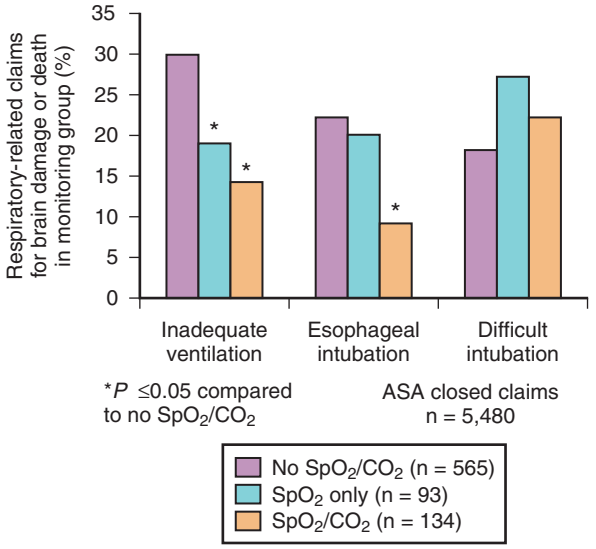

Figure 46-5 Percentage of inadequate ventilation, esophageal intubation, and difficult intubation events associated with death or brain damage in anesthesia-related insurance claims. (From Cheney FW. Changing trends in anesthesia-related death and permanent brain damage. *ASA Newslett* 66:6–8, 2002.)

- Colorimetric end-tidal CO_2 detector and P_{ETCO_2} measurement[115,118]

Radiographic investigation is of limited value because of the delay in diagnosis. Fiberoptic evaluation needs special equipment and preparation and is time-consuming. Acoustic reflectometry is a promising new approach with excellent results, at least in experienced hands. Rafael and coworkers[117] studied acoustic reflectometry in 200 adult intubated patients and reported a 99% correct tracheal and a 100% correct esophageal identification rate. Currently, CO_2 monitoring comes closest to the ideal monitor of correct ETT positioning. CO_2 monitoring can be performed either colorimetrically by relatively inexpensive single-use CO_2 detectors (e.g., Easy Cap, Tyco Healthcare; or Colibri, ICOR AB, Bromma, Sweden) or by capnography using infrared absorption.[118,119] Ventilation is assessed as P_{ETCO_2} approximates arterial CO_2 partial pressure (P_{aCO_2}) within 2 to 6 mm Hg in normal lungs. Unfortunately, in many disease states, this discrepancy increases significantly. The concentration of CO_2 expired is determined by CO_2 production (e.g., body temperature, muscle tone), CO_2 transport (e.g., circulation, pulmonary perfusion), and CO_2 elimination (pulmonary and airway integrity). Therefore, absence of P_{ETCO_2} indicates esophageal intubation, circuit disconnection, cardiac arrest, or airway obstruction. A false-positive result may be obtained after gastric inflation with CO_2 containing gas or digestion of carbohydrate-enriched beverages. ETT-misplacement can be excluded by observing a normal P_{ETCO_2} waveform for three to six consecutive breaths.

Knapp and associates[120] investigated four different methods—auscultation, capnographic P_{ETCO_2} determination, self-inflating bulb, and transillumination using Trachlight—for the verification of correct ETT positioning in 152 examinations in an ICU setting. Only P_{ETCO_2}

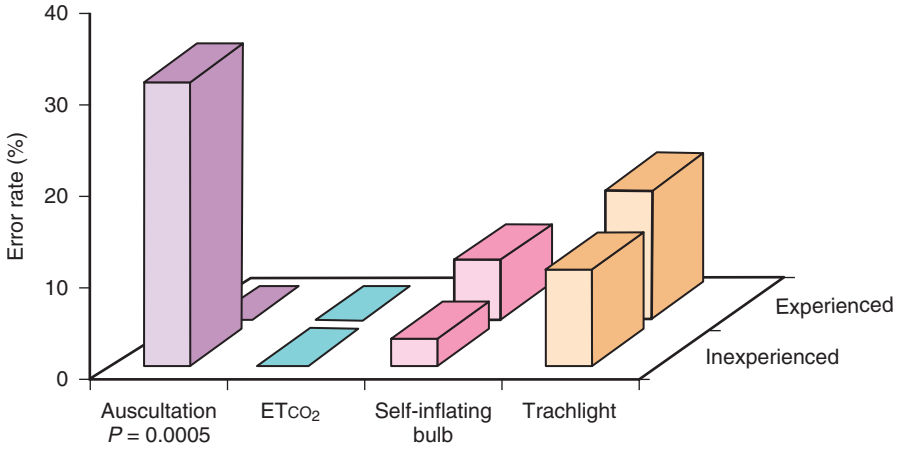

Figure 46-6 Error rates of experienced and inexperienced examiners obtained by evaluating endotracheal tube placement using one of four methods: auscultation, end-tidal carbon dioxide pressure *($ETCO_2$)*, self-inflating bulb, and Trachlight. (From Knapp S, Kofler J, Stoiser B, et al: The assessment of four different methods to verify tracheal tube placement in the critical care setting. *Anesth Analg* 88:766–770, 1999.)

monitoring was reliable for the verification of tracheal ETT placement (Fig 46-6). A poorer performance was only reported for prehospital and in-hospital cardiac arrest patients. However, end-tidal CO_2 concentrations are closely correlated with resuscitation outcome in this special setting.[121]

In conclusion, correct tracheal ETT placement can therefore only unequivocally be assured by a physiologic $PETCO_2$ signal for several consecutive breaths (eventually combined with an esophageal detector device in the prehospital setting), by direct visualization of the ETT between the vocal cords, or by fiberoptic visualization of tracheal cartilaginous rings and carina. All other techniques may provide useful additional information but are prone to errors and misinterpretation.

IV. DIFFICULT AIRWAY MANAGEMENT IN INTENSIVE CARE

Critically ill patients with preexisting hypoxia and poor cardiopulmonary reserve have a higher risk of adverse events during airway management.[122] Consequently, emergency endotracheal intubation in critically ill patients is associated with a significant incidence of major complications. Airway management in intensive care patients differs significantly from endotracheal intubation done for routine surgical procedures in the OR. Airway management in the ICU is often carried out in deteriorating patients in respiratory failure, shock, or cardiopulmonary arrest, and little time may be available for patient evaluation, examination, and preparation. Therefore, the ICU physician should approach the patient with the following four questions in mind[123]:

- Will mask ventilation likely to be successful, when general anesthesia is induced before securing the airway?
- Will endotracheal intubation likely to be successful, when general anesthesia is induced before securing the airway?
- Are there any obstacles making awake fiberoptic intubation difficult?
- In case troubles are encountered, what is plan B?

In a prospective investigation of 297 endotracheal intubations in an emergency ICU setting, Schwartz and coauthors[106] reported major complications in a significant number of patients. Among the problems encountered were difficult intubations (8%), esophageal intubations (8%), pulmonary aspiration (4%), and an associated mortality of 3%. The authors also reported that 3% of hospitalized critically ill patients die within 30 minutes of emergency intubation.

In another observational multicenter study performed in French ICUs, at least one severe complication occurred in 28%: severe hypoxemia (26%), hemodynamic collapse (25%), and cardiac arrest (2%).[124] The other complications were difficult intubation (12%), cardiac dysrhythmia (10%), esophageal intubation (5%), and aspiration (2%).

The initial step in difficult airway management might be the most important: assessing the patient's airway. Afterward, the determination of need for invasive or noninvasive ventilatory support must be done. If invasive airway management is needed, the physician performing airway management must be prepared for two serious complications.

Difficult Mask Ventilation. Difficult ventilation has been defined as the inability of a trained anesthetist to maintain the oxygen saturation greater than 90% using a face mask for ventilation and 100% inspired oxygen, provided that the preventilation oxygen saturation level was within the normal range.[125] Langeron and coauthors[126] prospectively studied 1502 patients and observed difficult mask ventilation (DMV) in 75 patients (5%). DMV was anticipated by the anesthesiologist in only 13 patients (17% of DMV cases). Using a multivariate analysis, five criteria were recognized as independent factors for a DMV (age >55, BMI >26 kg/m^2, beard, lack of teeth, history of snoring), with the presence of two indicating high likelihood of DMV (sensitivity, 0.72; specificity, 0.73). The implication for clinical practice is to avoid the administration of intravenous induction agents in patients with a high risk of DMV and secure the airway awake (Table 46-3). The risk factors for DMV include age over 55 years, body mass index (BMI) greater than 26 kg/m^2, lack of teeth, male gender, Mallampati class IV airway, presence of beard, and a history of snoring.[21,126,127]

TABLE 46-3
Anatomic Factors Associated with Difficult Ventilation

Site	Airway Issue	Intervention
Face	Facial wasting, beard, edentulous, snoring history	Patient positioning: sniffing position, and/or jaw thrust; ensure proper fit of mask to face; variety of different mask sizes; oropharyngeal and nasopharyngeal airways; team ventilation, with one person "bagging" while other ensures proper seal; leave in dentures while ventilating patient.
Upper airway	Abscess, hematoma, neoplasm, epiglottitis	Assist ventilation and avoid neuromuscular paralysis; awake intubation, possible fiberoptic with preparation for emergency cricothyrotomy; call for help if upper airway obstruction is suspected.
Lower airway	Reactive airways	Preinduction administration of bronchodilators, nitrates, and diuretics
	Airspace disease: pneumonia, ARDS, pulmonary edema, hemo/pneumothorax	PEEP valve for oxygenation in pulmonary edema, ARDS, and pneumonia; decompress pneumothorax if you are going to apply positive-pressure ventilation.
Thorax-abdomen	Ascites, obesity, hemoperitoneum, abdominal compartment syndrome	Use of bag-valve-mask with PEEP valve may help oxygenation and ventilation.

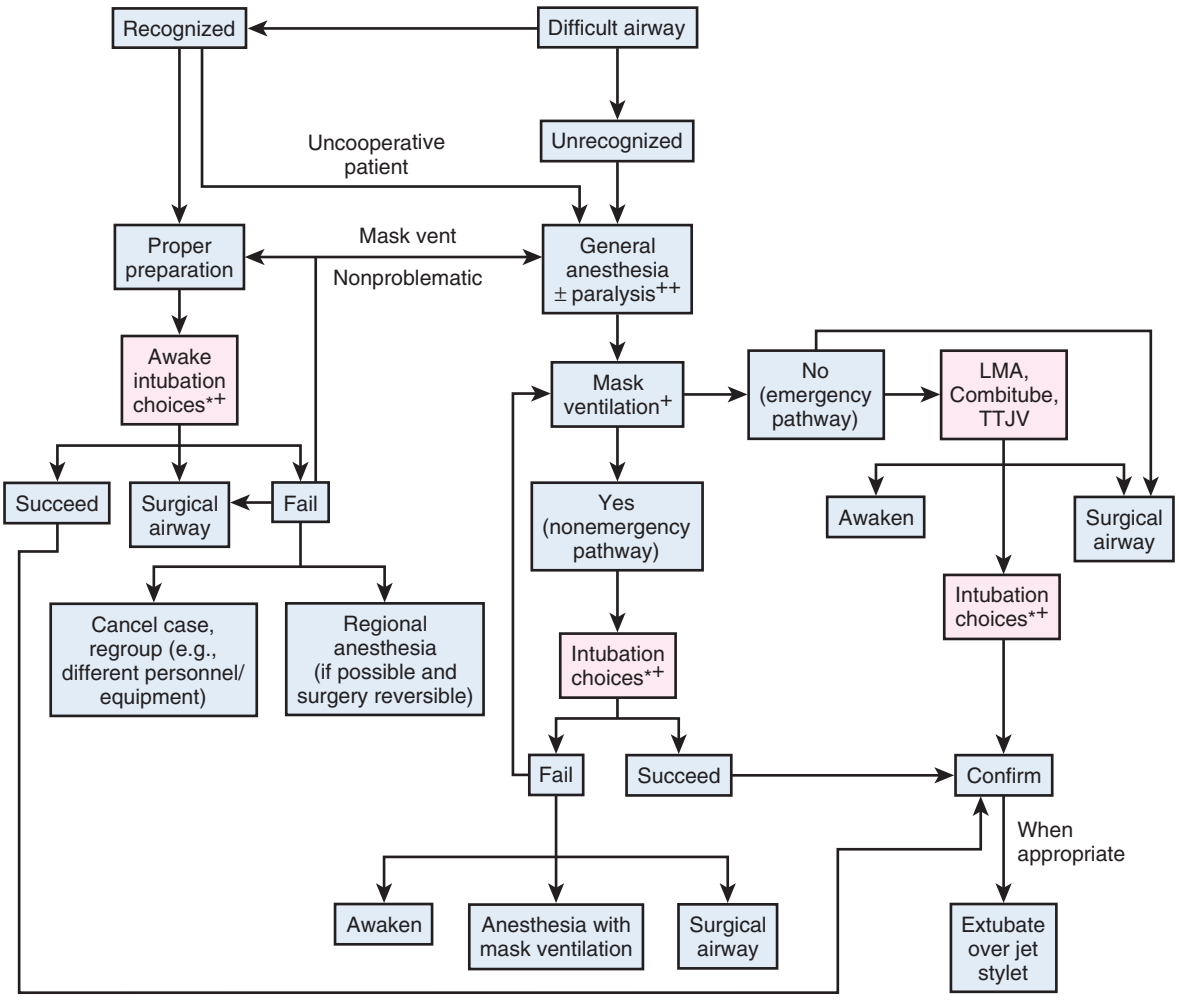
ARDS, Adult respiratory distress syndrome; *PEEP,* positive end-expiratory pressure.
From Reynolds SF, Heffner J: Airway management of the critically ill patient: rapid-sequence intubation. *Chest* 127:1397–1412, 2005.

Difficult or Impossible Intubation. Difficult intubation (DI) has been defined by the need for more than three intubation attempts or attempts at intubation that last more than 10 minutes. Difficult laryngoscopy and intubation are common phenomena even during routine patient care in the OR. Several investigations clearly demonstrated that minor problems necessitating a second intubation attempt are encountered in up to 8% of patients.[128-130] Grade 3 laryngoscopy, requiring multiple attempts at intubation, occurs in 1% to 4% among all patients.[131-133] Inability to intubate due to grade 3 or 4 laryngoscopic views is present in 0.05% to 0.35% of routine anesthesia cases.[131,134,135] Fortunately, the "cannot ventilate, cannot intubate" situation is rare in the OR and occurs in approximately 2 in 10,000 cases.[125,136,137] Christie and others[138] recapitulated several clinical indicators (Table 46-4).

In addition, Reed and colleagues[139] demonstrated that patients with large incisors, a reduced mouth opening and a reduced thyroid-to-floor-of-mouth distance are more likely to have a poor glottic view during laryngoscopy.

Management of the difficult airway in the emergency department (ED) and in the ICU has not been studied as well as in the OR. Sakles and associates[140] performed a 1-year study on 610 patients requiring airway control in the ED. Rapid-sequence induction was used in 84%, and a total of 98.9% were successfully intubated. In 33 patients (5.4%), inadvertent esophageal intubation occurred. Seven (1.2%) patients could not be intubated and underwent cricothyrotomy. Three patients experienced sustained cardiac arrest after intubation. In a prospective observational study on failed intubation attempts in the ED, Bair and colleagues[102] identified 7712 patients undergoing emergency intubation. In seven patients, a definitive airway could never be established. A total of 207 patients (2.7%) with failed endotracheal intubation were then included in the study. The majority of failed intubations occurred when RSI was not used as first choice (i.e., oral intubation under sedation, oral

TABLE 46-4
Clinical Indicators for Difficult Intubation



Airway Exam Component	Non-Reassuring Findings
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent "overbite" (maxillary incisors anterior to mandibular incisors)
Relation of maxillary and mandibular incisors during voluntary protrusion	Patient cannot bring mandibular incisors anterior to (in front of) maxillary incisors
Interincisor distance	<3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class >II)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
Thyromental distance	Less than three ordinary finger breadths
Length of neck	Short
Thickness of neck	Thick
Range of motion of head and neck	Patient cannot touch tip of chin to chest or cannot extend neck.

intubation without sedation, or blind nasotracheal intubation). The most common rescue technique was RSI (49%), followed by a surgical airway (21%). The authors concluded that invasive airway techniques are still important, and rescue airway techniques should be emphasized in ongoing medical education.

Schwartz and others[106] investigated the complications of 297 consecutive endotracheal intubations in 238 adult critically ill patients in the ICU, studied prospectively over 10 months; 89% of intubations were accomplished at the first attempt, and 8% of patients met criteria for DI. Four percent of intubations were only possible after four or more attempts. Esophageal intubation was observed in 8% of intubations but all were recognized before any adverse sequelae resulted. New and/or unexplained pulmonary infiltrates were regarded as indicative for pulmonary aspiration of gastric contents and occurred in 4% of patients. Seven patients (3%) died during or within 30 minutes of the procedure.

The ASA Difficult Airway Algorithm helps reduce the incidence of severe or catastrophic events during airway management, especially for anesthesia patients.[1] The basic principles of this approach are meticulous patient evaluation before anesthesia induction, awake intubation if problems are suspected, and preparation of an alternative approach in case of failure (Fig. 46-7). Those recommendations are also valuable for the management of critically ill patients. As mentioned, the ASA algorithm has characteristics that prevent direct application to the practice of ICU airway management. Airway management in the ICU is usually urgent or emergent, often depriving the physician of the time necessary to evaluate

+Always consider calling for help (e.g., technical, medical, surgical etc.) when difficulty with mask ventilation and/or tracheal intubation is encountered

++Consider the need to preserve spontaneous ventilation

*Nonsurgical tracheal intubation choices consist of laryngoscopy with a rigid laryngoscope blade (many types), blind orotracheal or nasotracheal technique, fiberoptic/stylet technique, retrograde technique, illuminating stylet, rigid bronchoscope, percutaneous dilational tracheal entry.

Figure 46-7 American Society of Anesthesiologists Difficult Airway (DA) Algorithm. *LMA,* Laryngeal mask airway; *TTJV,* transtracheal jet ventilation. (From Benumof JL: Laryngeal mask airway and the ASA Difficult Airway Algorithm. *Anesthesiology* 84:686–699, 1996.)

the patient and plan the life-saving intervention. The patient is presumed to have a full stomach and therefore must undergo awake airway management or RSI. The option of reemergence from anesthesia to resume spontaneous ventilation if difficulty is encountered is often impossible. Therefore, modified algorithms with more specific considerations of the special circumstances encountered in ICU and emergency patients have been suggested ("crash airway" or "failed airway" algorithm).[141] Although lacking prospective evaluation, these guidelines might represent a more appropriate application of principles and constraints to airway management in the ED setting.[63]

The best means for coping with the problem of *failed airway* is to prevent its occurrence. This requires the optimization of the initial attempt of laryngoscopy, to prevent multiple attempts causing bleeding and swelling. The net result might be a vicious circle, with each attempt leading to greater likelihood of failed intubation and ventilation, with potentially disastrous consequences. Optimizing laryngoscopy requires appropriate positioning of the patient, use of a laryngoscope blade best fitting the situation, optimal external laryngeal pressure (BURP maneuver: backward, upward, rightward pressure on cricoid cartilage), and eventually effective muscle relaxation.[63] When all these factors are taken into account, the first attempt of laryngoscopy is likely to be the best attempt.

According to the ASA Difficult Airway Algorithm and most other recommendations, there are only four appropriate options for the management of "cannot mask-ventilate, cannot intubate" situations[142] (Fig. 46-7): immediate insertion of laryngeal mask airway or esophageal-tracheal Combitube, manual transtracheal jet ventilation, or surgical access to the patient's airway (tracheostomy or cricothyrotomy).[1] A rational and well-considered approach in difficult airway management is elementary. Strict adherence to airway management guidelines (e.g., ASA algorithm) is essential and reduces failed airway attempts.

A. Esophageal-Tracheal Combitube

The esophageal-tracheal Combitube (ETC) is a double-lumen airway ("pharyngeal" and "distal" lumen) invented by Frass and coworkers,[143] equipped with a pharyngeal balloon and a distal cuff (Covidien, Mansfield, Mass). The ETC is designed for blind insertion into the patient's esophagus or trachea. In more than 95% of all *blind* insertions, the ETC enters the esophagus. After insertion, the pharyngeal balloon is inflated (maximum, 85/100 mL air) and seals against the oral cavity, while the distal cuff (5-12/15 mL air) prevents gastric inflation. Test ventilation is started via the pharyngeal lumen (i.e., supraglottic ventilation). Absence of breath sounds and gastric inflation indicate the rare case where the ETC has blindly entered the trachea. Ventilation is attempted via the distal lumen, the distal cuff blocked with the minimum amount of air providing adequate seal, and the ETC used as a conventional ETT. Two different ETC sizes are available: a small-adult model (37 French, Combitube SA) for women and men ranging in height from 120 to 200 cm and a 41-F model for taller patients.[144,145]

The ETC has been used extensively in emergency situations, as well as during routine surgery.[144,146,147] The authors recommend sufficient training during elective surgery before using the airway in emergency situations.[145,148,149] In routine cases, the ETC might be inserted using a standard laryngoscope to reduce the risk of tissue injury.[150,151] Contraindications for the use of the ETC are esophageal pathologies, ingestion of caustic substances, and central airway pathologies. Disadvantages are the lack of access to the patient's airways (suctioning of tracheal secretions impossible), lack of a pediatric ETC, and risk of venous stasis and soft tissue (tongue) swelling after prolonged use. The former limitations will be eliminated by the introduction of a redesigned ETC enabling fiberoptic access to the patient's airways and a pediatric version of the ETC.[152,153]

Advantages of the Combitube include protection against aspiration of gastric contents and the applicability of high airway pressures.[154] The ETC might stay in place for up to 8 hours, providing time for further decision making.[155] Changing the ETC for a definitive airway (regular ETT or tracheal cannula) might be done by an attempt of direct laryngoscopy, fiberoptically, or surgically (elective tracheostomy or cricothyrotomy).[152,156]

Recently, the EasyTube has been released (Teleflex-medical Ruesch). It is similar to the Combitube but offers certain advantages: The "pharyngeal" lumen of the EasyTube ends just below the oropharyngeal balloon. Therefore, the "tracheo-esophageal" lumen is thinner than that of the Combitube, which carries the two lumens down to the end. Since the distal single lumen of the EasyTube is significantly thinner, the potential danger of mucosal damage is minimized. Furthermore, the oropharyngeal balloon is latex free. The EasyTube comes in two sizes. The 28-F EasyTube ("pediatric size") is available for patients ranging in height from 90 to 130 cm; the 41-F EasyTube is designed for patients taller than 130 cm. A fiberscope can be passed through the so-called pharyngeal lumen because it is open at the distal end. This feature allows inspection of the trachea and possible replacement of the EasyTube using a guidewire, in addition to a larger suction catheter via both lumens (14-F suction catheter in 41-F EasyTube). The EasyTube has been used in a few cases of difficult intubation at the ICU (see Chapter 27).

B. Laryngeal Mask Airway

The laryngeal mask airway (LMA North America, San Diego) was presented in 1983, gained widespread popularity, and is currently used extensively during general anesthesia.[142,157,158] The LMA may be placed for three different reasons: as a routine airway and ventilatory device, as an emergency airway in cannot-intubate, cannot-ventilate situations or as a conduit for endotracheal intubation. Advantages of LMA use as a routine airway have been demonstrated clearly over conventional face mask ventilation. Tidal volumes administered were higher and problems associated with airway management (difficulties in maintaining airway or Spo_2 ≥95%) less

frequently encountered during LMA use compared with regular face mask.[159] LMA works well under these circumstances, because exact positioning is not crucial for a clinically acceptable patent airway.

Furthermore, the potential use of this recent airway in respiratory emergency situations has been recognized early.[160] Leach and associates[161] described use of the LMA as the immediate airway in cardiopulmonary resuscitation, and their findings were confirmed by a larger investigation.[162] A multicenter study was undertaken to assess the potential value of the LMA when inserted by ward nurses during resuscitation as a method of airway management, prior to the arrival of the advanced life support team with endotracheal intubation capability; 130 nurses were trained and 164 cases of cardiac arrest studied. The LMA was inserted at the first attempt in 71% and at the second attempt in 26% of patients. Satisfactory chest expansion occurred in 86%. The mean interval between cardiac arrest and LMA insertion was 2.4 minutes. Regurgitation of gastric contents occurred before airway insertion in 20 patients (12%) and during insertion in three (2%).[162]

Therefore, the LMA has been incorporated into the ASA algorithm and might be inserted as a conduit for fiberoptic endotracheal intubation in the awake or anesthetized patient who cannot be conventionally intubated (mask ventilation may or may not be possible) and as a non-emergency or emergency airway in the anesthetized patient[142] (Fig. 46-8).

Especially for those patients with supraglottic pathologies and unfavorable anatomy for face mask ventilation or endotracheal intubation, an early LMA insertion should be considered. Drawbacks of the LMA include the lack of access to the patient's central airways, risk of aspiration, limited positive airway pressures due to the often inadequate seal, and the need for training. Moreover, the LMA is a supraglottic airway device and thereby unable to establish adequate gas exchange in patients with central airway obstruction.

In the meantime, several modifications of the LMA have been proposed and have been or will be introduced into clinical routine. The ILMA differs from conventional LMAs by having a wider, shorter stainless steel tube; a handle to steady the device; and an epiglottic elevating bar (movable flap fixed to upper rim of mask). The ILMA is accepting cuffed ETTs up to ID of 8.5 mm, enabling blind or fiberoptic intubation using the correctly placed ILMA as a conduit. Success rates for blind ILMA intubation in the 75% to 90% or greater range have been reported.[103,163,164]

The ILMA has therefore been recommended as a rescue device for emergency airway management. Ferson

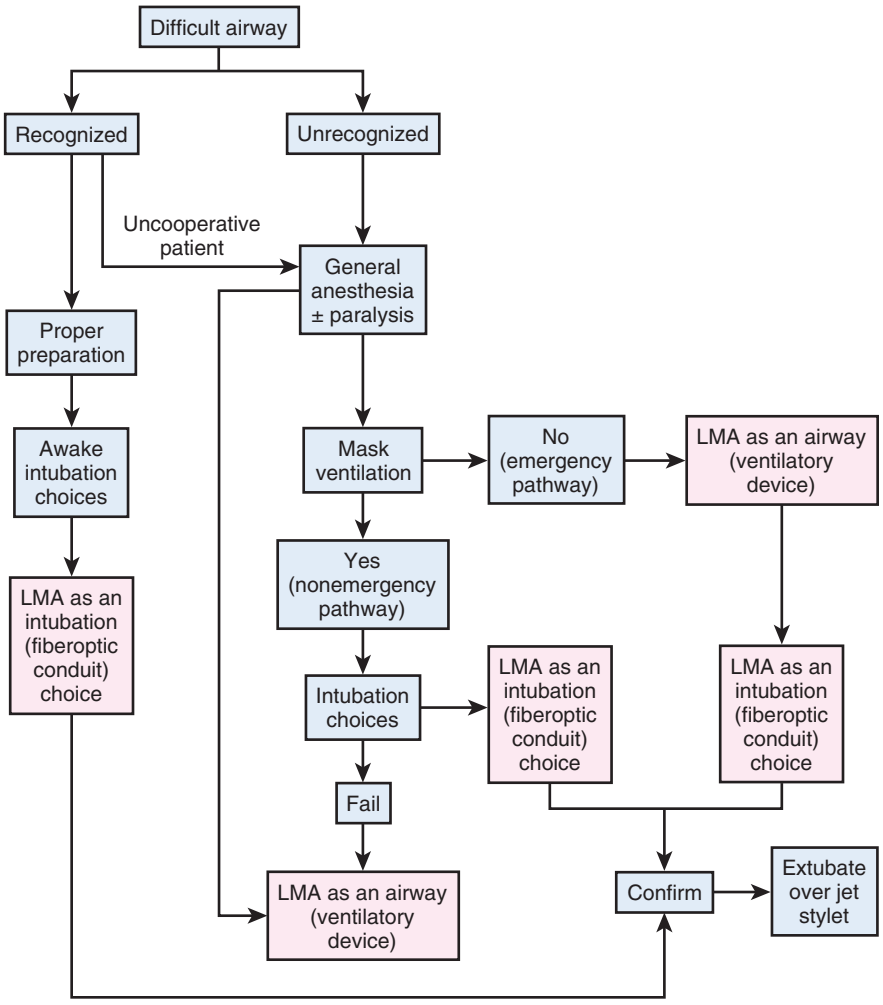

Figure 46-8 Laryngeal mask airway *(LMA)* and ASA DA algorithm. (From Benumof JL: Laryngeal mask airway and ASA Difficult Airway Algorithm. *Anesthesiology* 84:686–699, 1996.)

and colleagues[163] used the ILMA in 254 patients with different types of difficult airway. Insertion of the ILMA was accomplished in three attempts or fewer in all patients. The overall success rates for blind and fiberoptically guided intubations through the ILMA were 96.5% and 100.0%, respectively. Repeated "blind" intubation attempts with the ILMA resulted in esophageal perforation in one elderly patient.[165] Therefore, for blind ILMA intubation, the specially designed silicon tube with rounded bevel should be preferred, because success rates exceed those encountered with standard reinforced tubes.[166] Muscle relaxation is not needed for blind ILMA intubation but increases success rates.[166]

Laryngeal Mask Airway vs. Combitube. Sealing capacities and protection against regurgitation of gastric contents of the intubating LMA seem to be inferior to those of the Combitube (ETC), with average leak fractions of the LMA of 20% to 25% during positive-pressure ventilation and airway pressures of 20 to 30 cm H_2O.[167] Use of the ETC offers higher peak airway pressures and permits positive end-expiratory pressure (PEEP) ventilation, thereby enabling higher tidal ventilation and maintenance of adequate gas exchange, even in those patients with severe underlying pulmonary pathology (e.g., aspiration of gastric contents).[168] In contrast to the ETC, blind or fiberoptic intubation is possible through the LMA lumen (using conventional ETTs up to ID of 6.5 mm) and especially through the ILMA (up to 8.5 mm). With the currently available ETC model, no blind or fiberoptic access to the patient's airway is necessary. Krafft and others[152] modified the standard ETC model and created a larger ventilation hole, which can be used for fiberoptic intubation or tracheal cleansing. However, the redesigned model is currently not available, and it is uncertain whether it will be produced in the near future.

C. Transtracheal Jet Ventilation

In brief, transtracheal jet ventilation (TTJV) is performed using a 16- or 14-gauge catheter, and a 1.5- to 3.5-bar oxygen source (equipped with pressure regulator) in combination with noncompliant tubing. The TTJV catheter is inserted through a cricothyroid puncture, and correct tracheal placement is verified by the aspiration of 20 mL of free air. Noncompliant tubing is then connected and manual oxygen inflation started at an inspiratory rate less than 1 second (~0.5 second) and an inspiratory/expiratory time ratio of 1:3 (to ensure enough time for passive exhalation). Alveolar ventilation is achieved by bulk flow of oxygen through the cannula, as well as translaryngeal entrainment of room air (Venturi effect). For example, use of a 16-gauge cannula and a driving pressure of 3.5 bar results in a gas flow of approximately 500 mL/sec.[169] Therefore, facilitation of passive exhalation by maintaining patency of natural airways is of major importance to avoid overinflation and pulmonary barotrauma. Therefore, nasopharyngeal and oropharyngeal airways are inserted, maximum jaw thrust is well maintained throughout the entire procedure, and expiratory chest movements are observed continuously.

Performed in elective as well as emergency situations, the major indications for TTJV are lack of equipment for conventional airway management, the "cannot ventilate, cannot intubate" situation, ventilatory support during upper airway surgery, or support during endotracheal intubation by other techniques (e.g., ventilation during prolonged fiberoptic intubation). Complications of TTJV during *elective* application are rare but occur frequently during *emergency* TTJV (mainly limited to tissue emphysema). Monnier and colleagues[170] used high-frequency TTJV for ventilatory support during elective laser surgery for laryngeal and subglottic lesions and observed only one complication in 65 patients (mediastinal emphysema). Smith and coworkers,[171] however, reported a 29% complication rate in 28 emergency TTJV patients (exhalation difficulty in 14%, subcutaneous emphysema in 7%, mediastinal emphysema in 4%, arterial perforation in 4%). Other complications of TTJV (e.g., esophageal puncture, bleeding, hematoma formation) have been reported but rarely occur.

D. Emergency Surgical Airway

Rapid-sequence induction is the standard for emergency airway management in ICUs and EDs. Reported success rates of RSI are 97% to 99%, and an emergency surgical airway is only necessary in 0.5% to 2% of patients.[140,172] Sakles and associates[140] evaluated 610 patients requiring emergency airway management in the ED during a 1-year period; RSI was used in 515 (84%). A total of 603 patients (98.9%) were successfully intubated, and only seven patients could not be intubated and underwent cricothyrotomy. Therefore, anesthesiologists and intensive care physicians have only limited experience with surgical airway management. The ASA algorithm has proved to be an invaluable tool, but only briefly addresses the circumstances when a patient must be intubated immediately regardless of the difficulties presented. Since performance of a surgical airway is the final pathway of all airway algorithms, cricothyrotomy must be mastered by all clinicians involved in emergency airway management. Surgical airway management comprises percutaneous dilatational cricothyrotomy or tracheostomy using the Seldinger technique, surgical cricothyrotomy, or surgical tracheostomy. In emergency situations and in cases of unexpected intubation failure in the ICU, surgical or percutaneous cricothyrotomy using the Seldinger technique is preferred over tracheostomy and enables rapid and easy airway access and restoration of adequate gas exchange and ventilation.

1. Percutaneous Cricothyrotomy

Several commercial kits are available for emergency cricothyrotomy, implying easy insertion and high success rates (e.g., Melker or Arndt set, Cook Critical Care, Bloomington, Ind). *Seldinger technique* cricothyrotomy is achieved by performing cricothyroid puncture with a medium-sized needle, passing a wire through the needle, and then passing a dilator and airway over the wire (analogous to insertion of central venous line). Advertisement and promotion claim that percutaneous cricothyrotomy is a quick and easy procedure; in fact, after identification

of the cricothyroid membrane, the Seldinger approach is no faster than open cricothyrotomy.[173] Furthermore, none of the percutaneous techniques provides a cuffed tube within the trachea.

Eisenburger and colleagues[174] compared Seldinger technique emergency cricothyrotomy with conventional surgical approach in human cadavers. Tracheal placement of the tube was achieved in 60% ($n = 12$) in the Seldinger group versus 70% ($n = 14$) in the open group (P = ns). Furthermore, five attempts in the Seldinger group had to be aborted because of kinking of the guidewire. No differences in the time necessary to perform the procedures were registered. Chan and coworkers[173] performed a similar study in cadavers but observed higher success rates. Airway placement was accurate in 13 of 15 cases for the standard technique (87%) and in 14 of 15 cases for the wire-guided technique (93%). Comparing wire-guided versus standard techniques, no differences were seen in complication rates or performance times. However, one must remember that all these results are obtained in an unstressed elective situation in the morgue; one assumes that results in true emergency situations might be even poorer.

A newer cricothyrotomy device, the Portex Cricothyrotomy Kit (PCK), is based on the concept of mechanical detection of the posterior wall of the larynx (see Chapter 30, Fig. 30-15). In a comparison of two emergency cricothyrotomy kits in 40 human cadavers, the use of PCK was responsible for more lesions and more failures than the standard set, in which cricothyrotomy was based on the Seldinger technique.[175]

2. Surgical Cricothyrotomy

The vasculature is rich overlying the cervical trachea but is strikingly absent over the cricothyroid membrane (CTM). Surgical cricothyrotomy can be performed only after correct identification of the CTM between thyroid and cricoid cartilage; the vertical length of the membrane is about 0.7 to 1.0 mm. The set of instruments used should be simple: scalpel with no. 11 blade, tracheal hook, Trousseau dilator, and cuffed tracheostomy tube. The most common technique is the "no drop" technique, where the larynx and trachea are immobilized by the operator's hand throughout the procedure. Other techniques have been proposed (e.g., four-step technique), but the no-drop technique has proved its value with the following six steps (Fig. 46-9)[176]:

Step 1: Identify the CTM. Key landmark is the laryngeal prominence (Adam's apple), which is easier to palpate in men than in women. It can be identified in the midline at the junction of upper and middle third of the anterior neck. Thumb and long finger stabilize the larynx, while the index finger is run down the anterior surface of the thyroid cartilage until the concavity of the CTM is reached.

Step 2: Immobilize the larynx by holding the superior horns of the thyroid between thumb and long finger, and incise the skin *vertically* (vertical incision 2-3 cm in length provides maximum flexibility and minimum trauma). Vertical skin incision should be made through skin and subcutaneous tissues and not into the airway. Thereafter, the CTM is again identified using the index finger. Several authors prefer to leave the index finger in the wound even during the dissection of the membrane (enables the membrane incision directly caudal to the index finger).

Step 3: Incise the CTM transversely in its distal third whenever possible (avoidance of superior thyroid artery). The incision should be wide enough to permit easy insertion of the cannula (1.5-2 cm).

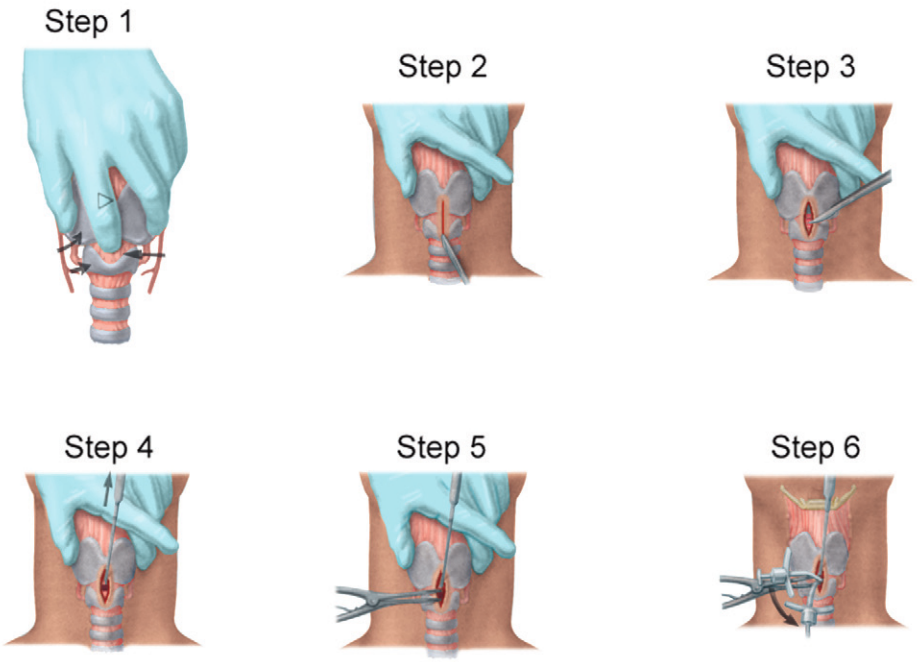

Figure 46-9 Six steps in performing surgical cricothyrotomy. (From Walls RM, Gibbs MA: Surgical airway. *Semin Anesth Periop Med Pain* 20:183–192, 2001.)

Step 4: Insert the tracheal hook transversely into the incised membrane, then rotate it 90 degrees to the midline (some authors waive use of tracheal hook in open cricothyrotomy). The hook strictly immobilizes the larynx and brings the opening within the membrane closer into the field of view.

Step 5: Insert the Trousseau dilator into the airway for several millimeters, then open it to dilate the airway. Some prefer opening the branches in a rostrocaudal direction because most resistance to cannulation is encountered between thyroid and cricoid. However, transverse dilation is also possible.

Step 6: Insert the respective tracheal cannula with the right hand between the prongs opened with the operator's left hand. Slight twisting of the cannula, with a 90-degree rotation of the Trousseau dilator, may be necessary to advance the tracheal cannula safely.

As mentioned, Seldinger as well as open cricothyrotomy are characterized by several pitfalls; both techniques require training in the manikin or better, in human cadavers, and the individual operator must choose the preferred technique. Several authors prefer the open approach because a cuffed cannula can be used, and endotracheal suctioning or bronchoscopy is possible.

In conclusion, the ASA Difficult Airway Algorithm was approved by the ASA House of Delegates in October 1992 and became effective July 1993.[1] Every patient needs to be screened for difficult airways before anesthesia induction, and when difficulties are expected, airways need to be secured with the patient still awake (using fiberoptic scope in most cases). If difficulties are encountered with the patient already anesthetized, refrain from repeated and forceful attempts at direct laryngoscopy, and instead consider alternative methods. If a "cannot ventilate, cannot intubate" situation is encountered, either LMA or Combitube must be inserted immediately. Further alternatives are institution of TTJV or immediate surgical access to the patient's airway. The most important point is to be alert and have a plan B and C prepared in case difficulties arise.

V. COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

In a recent report on 3423 emergent non-OR endotracheal intubations, Martin and associates[177] found that the total incidence of difficult intubations was 10.3%. Complications occurred in 4.2%, including aspiration (2.8%), esophageal intubation (1.3%), dental injury (0.2%), and pneumothorax (0.1%). This report confirms that airway management in the hospital environment is also associated with increased risk of airway complications.

Hoarseness is a common complication after translaryngeal intubation and is reported to occur in 20% to 42% of patients.[55,178] Jones and colleagues[179] prospectively studied the incidence of hoarseness in 167 patients undergoing anesthesia, endotracheal intubation, and surgery. Fifty-four patients (32%) complained about postoperative hoarseness, with all except five returning to normal within 7 days. Vocal cord granuloma was observed in two patients. The site of granuloma is typically at the tip of the vocal processes of the arytenoid cartilages because of their incessant movement.[180]

In a prospective study of 226 endotracheal intubations in 143 adult patients, Stauffer and associates[46] reported that 62% of all patients developed at least one complication of long-term translaryngeal intubation. The main complications, in anatomic order, are nasal and paranasal as well as laryngeal and tracheal injuries. Laryngeal injury is a common complication even after short-term translaryngeal intubation. Kambic and Radsel[181] examined 1000 patients at the end of anesthesia. Severe intubation lesions were registered in 6.2% of patients, with most injuries resolving within a few days. However, 1% of patients sustained vocal cord dysfunction even after short-term translaryngeal intubation (Table 46-5).

In about 4% to 10% of patients, severe damage to the vocal apparatus is encountered (e.g., vocal cord paralysis, granuloma, subluxation of arytenoid cartilage).[182] Most severe complications are observed within the trachea itself (e.g., ulcerations, hematomas up to necrosis, tracheomalacia).[39,46] These complications occur infrequently but may require extensive surgical interventions (i.e., resection of trachea)[183] (Figs. 46-10 and 46-11).

Laryngeal or tracheal trauma is even more common during acute airway management in emergency situations. Maxeiner[184] performed postmortem examinations involving 294 cases of emergency intubation. Acute macroscopic sequelae (mucosal hemorrhage or injury, deeper tissue hemorrhage in false vocal cords) were observed in 18% of those resuscitated outside the hospital and in 16.9% of in-hospital patients. Soft tissue hematomas were observed at the laryngeal opening (31%), vocal cords (37%), laryngeal opening and vocal cords (17%), in the subglottic region (17%), and in the hypopharynx (29%). Lesions at the laryngeal aperture were mainly located at the right part of the larynx.

TABLE 46-5

Outcome of Laryngeal Injury 3 Months after Short-Term Intubation

	Total	Cured	Cicatrix	Synechia
Vocal cord hematoma	45	38	7	—

Other serious complications of translaryngeal intubation have also been reported. Lim and coworkers[185] reported three cases of recurrent laryngeal nerve palsy in three patients after short-term intubation for surgery unrelated to the neck. Pressure neuropraxia resulted from an overinflated ETT cuff compressing the peripheral anterior branches of the right recurrent laryngeal nerve. Frink and Pattison[186] and Castella and coworkers[187] reported posterior arytenoid dislocation after uneventful endotracheal intubation and anesthesia. Furthermore, both pharyngeal and esophageal perforation have been reported after repeated attempts at intubation, especially using a rigid stylet.[188] The tip of the rigid stylet therefore should never protrude from the distal tip of the ETT.

In addition, endotracheal intubation may result in reduced clearance and retention of mucous secretions, bacterial colonization, and ventilator-associated pneumonia.[189] In a survey of 9080 ventilated patients, VAP developed in 842 patients (9.3%).[190] The mean interval between ICU admission and diagnosis of VAP was 4.5 ±7.5 days, and independent risk factors for the development of VAP were male gender and trauma admission. However, VAP seems to be a complication more of endotracheal intubation and not of ventilatory support, because recent studies show a reduced incidence in patients undergoing noninvasive mechanical ventilation.[191] A prospective, randomized study evaluated whether a closed suctioning (CS) system (TrachCare) influences crossover contamination between bronchial system and gastric juices, as well as frequency of VAP, compared with an open suctioning (OS) system. Five cross-contaminations were observed in the OS group on day 3 versus day 1; the 5 strains shared common genotypes as determined by random amplification of polymorphic DNA. No cross-contaminations were seen in the CS group ($P = 0.037$). VAP occurred in five patients of the OS group but in none of the CS group patients ($P = 0.037$). Arterial oxygen saturation (Spa_{O_2}) decreased significantly in the OS group compared with presuctioning values, the opposite of the CS group. Whereas presuctioning values were comparable between groups, postsuctioning Spa_{O_2} was significantly higher in the CS group. CS significantly reduced cross-contamination between bronchial system and gastric juices and reduced the incidence of VAP when compared with OS. Hypoxic phases can be reduced by the help of CS.[192]

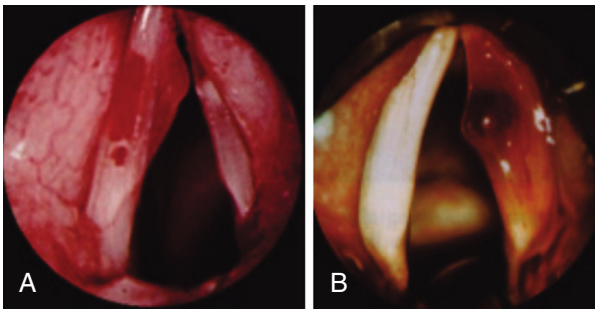

Figure 46-11 **A,** Acute laryngeal damage during airway management; **B,** hematoma of the true vocal cords after traumatic intubation attempts.

VI. AIRWAY MANAGEMENT FOR PROLONGED MECHANICAL VENTILATION (TRACHEOSTOMY)

Tracheostomy is one of the oldest surgical procedures performed in history. Transcutaneous insertion of a cannula into the patient's trachea was first described in Egyptian and Hinduistic literature between 2000 and 1000 BC.[193] The first description of "modern" tracheostomy was by the Italian surgeon Fabricius of Aquapendente in the 17th century using a tracheal cannula.[194] Development of tracheostomy continued, with many case reports on alternative techniques reported in the next three centuries.[195,196]

The currently used technique for "conventional" surgical tracheostomy was first described by Jackson[197] in 1909. Until several years ago, "open" surgical tracheostomy was the one and only method and therefore the gold standard for the long-term airway management in intensive care medicine. However, the conventional approach has several disadvantages, such as need to transfer the patient to the OR and early and late complications (e.g., bleeding, stoma infection). Therefore, Shelden and colleagues[198] reported a percutaneous access to the trachea. However, this procedure was relatively complicated and was followed by deadly complications.[199] Not until 1985 did Ciaglia and associates[200] propose a percutaneous approach using the Seldinger technique and increasingly larger-sized dilators for progressive tracheal dilation, as supposed by Sanctorius[201] in the 17th century.

Note the following definitions:

Tracheostomy: Surgical incision of the upper third of the anterior tracheal wall to insert a cannula.

TABLE 46-6

Major Complications of Prolonged Translaryngeal Intubation

Complication	Rate (%)	Reference
Supraglottic Laryngeal Injury (Ulceration, Scarring, Stenosis)		
Laryngitis	3	323
Mucosal ulceration/edema of epiglottis	7-12	46
Mucosal ulceration/edema of larynx	29-51	46
Submucosal hemorrhage of epiglottis/larynx	5-12	46
Supraglottic laryngeal stenosis	12*	260

Bilateral vocal cord paralysis (rare)	Few reported cases	323
Posterior commissure syndrome	6	260
Subglottic Injury		
Subglottic stenosis/scarring	12*	260
Tracheal injury		
Tracheal stenosis (<50% stenosis)	19	46
Tracheal dilation/tracheomalacia	N/A	N/A
Tracheoesophageal fistula†	0.5-5*	324

*After 10 days of endotracheal intubation.
†From 0.5% to 5% of all tracheoesophageal fistulas are caused by endotracheal intubation.
NA, Not available.
From Shirawi N, Arabi Y: Bench-to-bedside review: early tracheostomy in critically ill trauma patients. *Crit Care* 10:201, 2006.

Tracheostoma: Artificial opening into the trachea through the neck to the outside created by tracheostomy or tracheotomy.
Tracheotomy: Surgical technique to create a permanent epithelialized tracheostoma.
Cricothyrotomy: Surgical incision of the cricothyroid membrane for the insertion of a cannula.
Coniotomy: Percutaneous emergency cricothyrotomy using special single-use sets.

A. Reasons for Performing Tracheostomy

Tracheostomy (or tracheotomy) is one of the most frequently performed elective surgical procedures in ICU patients, done in almost 10% of intubated patients. Tracheostomy is generally done for the following four reasons[202]:

- To relieve upper-airway obstruction caused by tumor, surgery, trauma, foreign body, or infection
- To prevent laryngeal and upper airway damage caused by prolonged translaryngeal intubation
- To allow easy or frequent access to the lower airway for suctioning and secretion removal
- To provide a stable airway in a patient who requires prolonged mechanical ventilation or oxygenation support[203] (Table 46-6)

The issue of long-term translaryngeal intubation versus tracheostomy now favors secondary tracheostomy, although the adequate time point is still under discussion. In 2010, Durbin[202] listed benefits of changing from a translaryngeal ETT to a tracheostomy tube in patients who require prolonged intubation. However, the evidence level for most topics discussed is "poor" and comes mainly from uncontrolled trials (Table 46-7).

B. Timing of Tracheostomy

In 1989, at the Consensus Conference on Artificial Airways in patients receiving mechanical ventilation, the indications for nasal or oral ETTs and tracheostomy tubes were forged; "if the need for an artificial airway is

TABLE 46-7

Benefits of Changing from Translaryngeal Endotracheal Tube to Tracheostomy Tube in Patient Requiring Prolonged Intubation

Benefit	Type/Quality of Evidence Showing Benefit
Improved patient comfort	Uncontrolled reports, clinical opinion
Less need for sedation	Several RCTs
Lower work of breathing	Theoretical analysis, one small study
Improved patient safety	Clinical belief but minimal data, some contradictory
Improved oral hygiene	Clinical observation
Oral intake more likely	Opinion only
Earlier ability to speak	Uncontrolled reports
Better long-term laryngeal function	Large uncontrolled reports
Faster weaning from mechanical ventilation	One RCT
Lower risk of ventilator-associated pneumonia	Controversial, data support for both sides
Lower mortality	One RCT supports, many do not, but large RCT supports no increased mortality with tracheostomy
Shorter intensive care unit and hospital stay	Several meta-analyses

RCT, Randomized controlled trial.

*P <.005.
†P <.001.
There was a significant difference between the early tracheotomy groups and the prolonged translaryngeal intubation group in outcome measures. Some patients were sent to a step-down while still on mechanical ventilation.
From Rumbak MJ et al: A prospective, randomized study comparing early percutaneous dilational tracheotomy to prolonged translaryngeal intubation (delayed tracheotomy) in critically ill medical patients. *Crit Care Med* 32:1689-1694, 2004.

anticipated to be greater than 21 days, a tracheostomy should be preferred."[204] With the introduction of percutaneous methods, the issue of translaryngeal intubation versus tracheostomy shifted to the best time point to perform tracheostomy.

In a prospective multicenter randomized trial, Rumbak and coworkers[205] assigned 120 patients to *early* (within 48 hours after arrival at ICU) and *delayed* (14-16 days after arrival) percutaneous dilatational tracheostomy. Early tracheostomy was associated with significantly less mortality, nosocomial pneumonia, unplanned extubation, oral and laryngeal trauma, and a shorter duration of mechanical ventilation and ICU admission (Tables 46-8 and 46-9). Prospective studies by Arabi,[206] Bouderka,[207] and Rodriguez[208] and their associates approved the shorter duration of mechanical ventilation in patients with earlier tracheostomy. In a systemic review and meta-analysis of five randomized trials, Griffith and colleagues[209] found that early tracheostomy is associated with 8.5 fewer days of mechanical ventilation and 15 fewer days in the ICU. However, there were no significant differences in mortality or nosocomial pneumonia rates.

TABLE 46-9

Cause of Death in Critically Ill Medical Patients Receiving Early Tracheotomy or Delayed Translaryngeal Intubation*

Cause of Death	Early Tracheotomy ($n = 19$)	Delayed Translaryngeal Intubation ($n = 37$)
Ventilator-associated pneumonia	2	9
Gastrointestinal bleed	1	3
Acute myocardial infarction	2	4
Pulmonary embolus	1	1
Intractable septic shock	4	8
Withdrawal of life support	2	1
Respiratory failure	7	11

*More patients died of ventilator-associated pneumonia in the prolonged translaryngeal group than the early tracheotomy group.

In contrast, most studies could not demonstrate definitive advantages of early (days 3-5) versus later (days 10-14) tracheostomy.[210,211] In a systematic review, Maziak and colleagues[212] identified 48 possibly relevant articles of 8153 citations; five of the 48 articles met the inclusion criteria. After data review, the authors found no significant advantages of early (days 2-7) versus late (>days 4-14) tracheostomy, concluding insufficient evidence exists to support that the timing of tracheostomy alters the duration of mechanical ventilation or extent of airway injury. In a 2006 meta-analysis comparing early and late tracheostomy in ICU trauma patients, Dunham and Ransom[213] found no differences in mortality, nosocomial pneumonia, duration of mechanical ventilation, laryngotracheal pathology rates, or length of stay in hospital.

In a questionnaire answered by 48 Swiss ICUs (1995-1996; 90,412 patients and 243,921 ventilator-days), 10% of all patients who were ventilated longer than 24 hours underwent tracheostomy.[214] The majority of tracheotomies (35%) were performed in the second week of critical illness. However, 68% of all interviewed physicians would also perform an early (<day 7) tracheostomy if indicated (expected longer ICU course). The authors concluded that tracheostomy in Swiss ICUs is far from being standardized with regard to indication, timing, and choice of technique.

A randomized prospective study is required to examine the need for and the timing of tracheostomy in patients requiring prolonged mechanical ventilation. The findings of such a study would have significant impact on the clinical practice and hospital costs.[212] Until then, the following recommendations of the Consensus Conference of 1989 are still valid[204]:

- Patients with an estimated duration of intubation longer than 7 to 10 days are managed by translaryngeal intubation.
- Reevaluation of the patient at day 7: extubation possible within the next 7 days? If yes, continue

translaryngeal intubation (cumulative duration of translaryngeal intubation <14 days).
- All patients with slow recovery or deterioration with an estimated duration of intubation longer than 14 days should undergo tracheostomy.
- Early elective tracheostomy (days 3-5) in patients with an estimated duration of intubation longer than 21 days
- Patients in whom estimation of ventilator days is difficult should undergo daily evaluation of the pros and cons of tracheostomy and continued translaryngeal intubation.[215]

C. Tracheostomy Techniques

Basically, two approaches are available for performing tracheostomy: conventional *surgical tracheostomy* (ST) and *percutaneous dilatational tracheostomy* (PDT). During the past 15 years, standard tracheostomy using an open surgical approach and the percutaneous techniques were used in parallel. Meanwhile, the use of PDT is still expanding, and several experts suggest PDT as the new gold standard for securing definitive airways in prolonged-ventilated adult patients. This might be true, but exceptions include neuroscience patients requiring prolonged cannula care. Furthermore, anesthesiologists must keep in mind that any procedure in airway management is influenced by individual experience and preference.

1. Conventional Surgical Tracheostomy

Tracheal dissection to provide relief from airway obstruction resurfaced in the diphtheria epidemic in the 19th century. The current technique for "conventional" ST was first described by Jackson[197] in 1909. Many variations exist in technique, but ST is preferably performed in the OR.[216] In critically ill patients for whom transport seems too risky, tracheostomy can also be performed in the ICU bed, although mainly under inferior surgical conditions. Positioning the patient with head and neck extended and a small pillow under the shoulders is a major part of successful technique. Overextension of the head should be avoided; the airway might be narrowed further, and the tracheostomy site might be erroneously too low (near innominate artery). The operating field should be prepared according to aseptic conditions. Patients who do not tolerate this position may assume a sitting or semirecumbent position.

After proper preparation, palpate the landmarks (e.g., thyroid and sternal notch, cricoid cartilage), and make a 3-cm vertical skin incision extending inferior to the cricoid cartilage. Some advocate a horizontal incision because of the better cosmetic results. Subcutaneous fat can be resected using electrocautery, and the inferior limit of the surgical field should be screened for the proximity of the innominate artery. Dissect platysma until the midline raphae between the strap muscles are identified. Strictly adhere to the midline to avoid bleeding and paratracheal structures. After retracting the strap muscles laterally, the pretracheal fascia and the thyroid isthmus are exposed. The thyroid may be retracted out of field, but a resection is recommended due to the reduced incidence of postoperative bleeding complications. Securing the cricoid cartilage with a hook and superior traction improves control of the tracheal entry. Tracheal incision should be performed between the second and third or the third and fourth tracheal rings. The first tracheal ring should always be left intact to protect the cricoid cartilage.

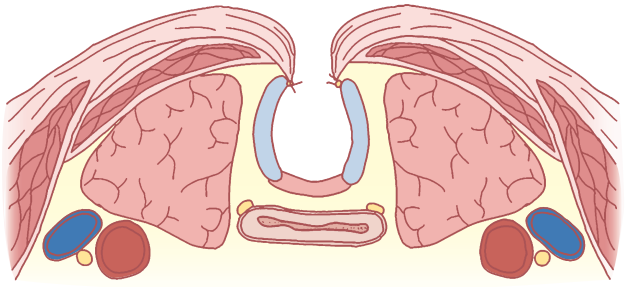

Figure 46-12 Permanent epithelialized tracheostoma. (From Hartung, Osswald, Petroianu, editors: *Die Atemwege*. Wissenschaftliche Verlagsgesellschaft, Stuttgart, 2001, p 159.)

Several options for a semipermanent tracheostomy exist; a T-, U-, or H-shaped tracheal opening can be made, with the tracheal flaps sutured to the neck skin. Creation of a U-shaped flap ("Björk flap") is not recommended because of the increased risk of flap necrosis. No tracheal cartilage should be resected, to reduce the risk of tracheal stenosis.

A permanent tracheostoma is necessary for patients who indefinitely require secure transluminal access (e.g., head injury). For the creation of a permanent stoma, a small portion of the anterior tracheal wall is resected, and skin flaps are sutured to the rectangular tracheal opening (Fig. 46-12).

2. Percutaneous Dilatational Tracheostomy Techniques

During the 1990s, a dramatic change in airway management for long-term ventilatory support occurred with the introduction of percutaneous approaches to the trachea. Percutaneous tracheostomy was first described by Shelden and colleagues[198] in 1955, but the approach never became popular because of severe complications.[199] With the introduction of the Seldinger technique by Ciaglia and others,[200] a triumphant advance of percutaneous tracheostomy began because of presumed advantages (Box 46-3).

Simpson and associates[217] showed that the number of critically ill patients at their facility undergoing tracheostomy had increased from 8.5% to 16.8% of all critically ill patients since the introduction of PDT. This represents a doubling of the proportion of ICU patients undergoing tracheostomy. Tracheostomy was

Box 46-3 Major Advantages of Percutaneous Approach to Tracheostomy

1. Bedside procedure
2. Easy to learn
3. Reduced personnel
4. Reduced incidence of wound infection

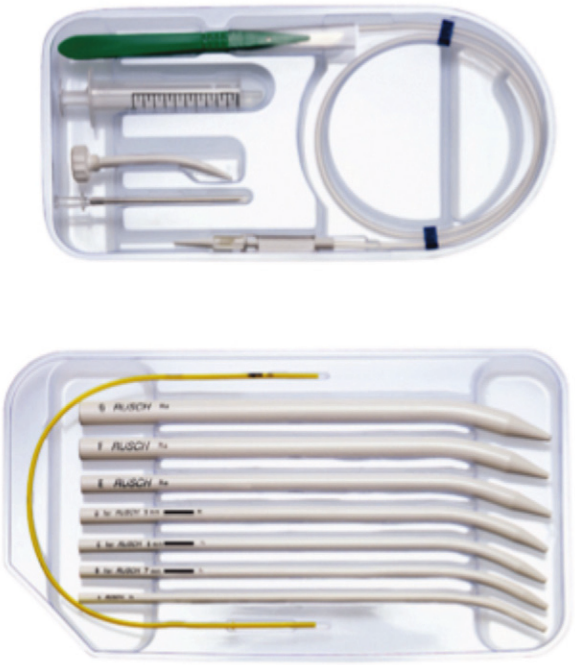

Figure 46-13 PercuQuick set for percutaneous tracheostomy. (Courtesy of Rüsch, Essilengen, Germany.)

also performed significantly earlier, at a median of 4 days versus 8 days of mechanical ventilation. Of approximately 31,000 tracheostomies performed in Germany (~80 million population), more than 50% were PDTs.

The question of which technique, ST or PDT, is better for tracheostomy remains to be answered definitively.

a. PERCUTANEOUS DILATATIONAL TRACHEOSTOMY ACCORDING TO CIAGLIA

Pasquale Ciaglia introduced PDT in 1985 as an alternative approach to conventional ST.[200] Using the original Ciaglia technique, the correct puncture site in the midline between first or third tracheal ring is identified, the trachea punctured (free aspiration of 20 mL air possible), and a guidewire inserted. Over this guidewire, special dilators are introduced, and the anterior wall of the trachea is dilated until an opening with a diameter of approximately 36 French is achieved (Fig. 46-13). Advantages of this method are short duration of the procedure and bedside performance. However, contraindications must be considered (Box 46-4).

Box 46-4 Contraindications to Percutaneous Dilatational Tracheostomy

1. Trauma or infection in region of presumed stoma, with inability to localize trachea
2. Palpable vessels at puncture site
3. Coagulation disorders (PLT <30,000/µL; PTT >50%)
4. FIO_2 >0.8
5. Known or suspected difficult airway

To enhance patient safety, Marelli and colleagues[218] proposed that the entire procedure be monitored fiberoptically. The use of a FOB prevents endotracheal insertion out of the anterior midline or injury to the posterior tracheal wall, particularly during dilatation. A drawback of FOB control is that its insertion into the airway results in a partial obstruction of the ventilatory path thereby compromising ventilation.[219]

For performing PDT, the anesthetized patient is positioned with the head and neck extended. The anterior part of the neck is cleaned and draped in accordance with thyroid surgery guidelines. The FOB is then introduced through the tracheal tube in place, and the correct puncture site is identified. For this purpose, the ETT must be drawn back toward the glottic opening, and the FOB must be inside the ETT to prevent erroneous puncture of the scope (after the procedure, the scope must undergo a complete evaluation to prevent water intrusion).[220]

After puncturing the trachea in the midline between the first and third tracheal ring, a guidewire is inserted under fiberoptic vision (Fig. 46-14A). Puncturing must be done in the midline, in the middle between the tracheal cartilages. Puncture near a tracheal ring must be prevented because cartilage damage or fractures are associated with late complications such as tracheal stenosis (Fig. 46-14B). Thereafter, a guidance cannula is slid over the guidewire and a 1.5-cm skin incision made. The puncture site is then dilated with seven (hydrophilic) plastic dilators up to a diameter of 36 F (12 mm) (Fig. 46-14C). Lastly, the tracheal cannula (maximum ID of 9 mm) is inserted as guided by a medium-sized dilator (Fig. 46-14D). A slight resistance is often encountered during cannula insertion, which is overcome by using sufficient

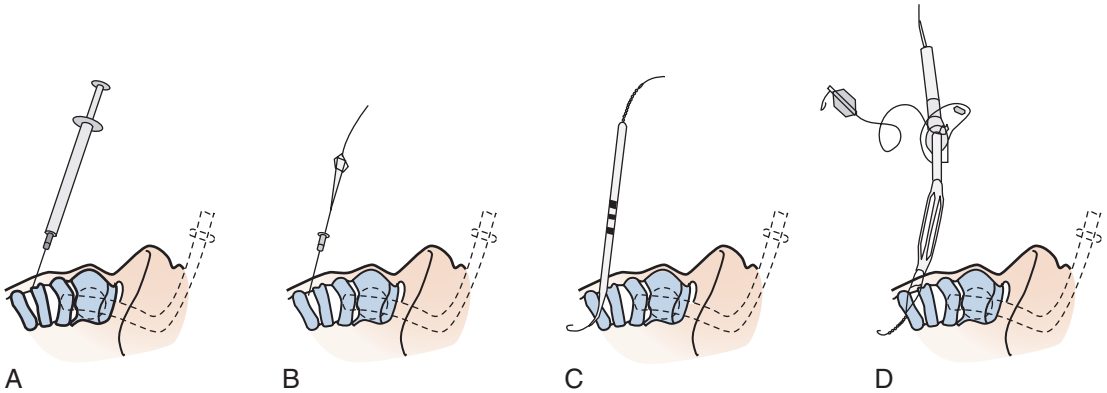

Figure 46-14 Percutaneous tracheostomy according to Ciaglia. See text for details. (Courtesy of Rüsch, Vienna. Modified from Ciaglia P et al: Elective percutaneous dilatational tracheostomy: a new simple bedside procedure—preliminary report. *Chest* 87:715–719, 1985.)[201]

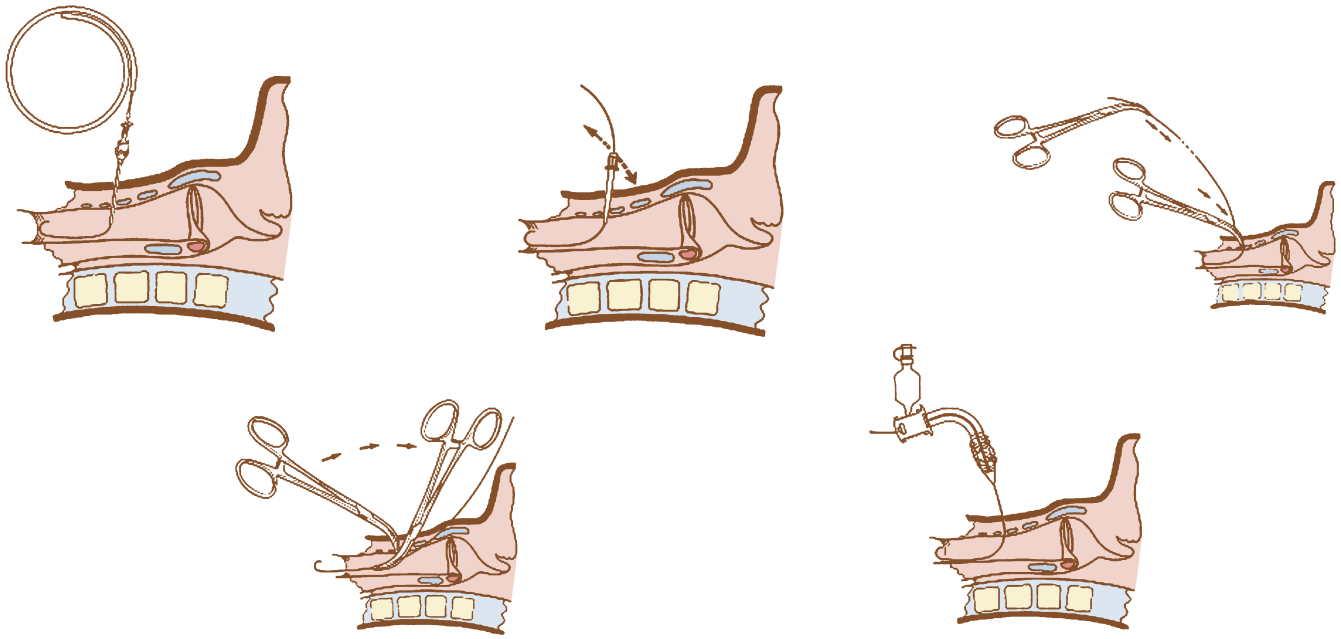

Figure 46-15 Percutaneous tracheostomy according to Griggs. (Courtesy of Rüsch, Vienna. Modified from Griggs WM et al: A simple percutaneous tracheostomy technique. *Surg Gynecol Obstet* 170:543–545, 1990.)

lubricating fluid and rotating movements during insertion. After cannula insertion, the FOB is removed from the ETT and inserted into the tracheal cannula, to verify correct placement, optimize cannula insertion depth, and remove bloody secretions from trachea and bronchi.

b. PERCUTANEOUS DILATATIONAL TRACHEOSTOMY ACCORDING TO GRIGGS

In 1989, Schachner and associates[221] presented a single-dilatation tracheostomy forceps over a guidewire (Rapitrach; Fresenius, Runcom, Cheshire, UK), which carried a relatively high incidence of injury of the posterior tracheal wall. In 1990, Griggs and coauthors[222] developed another guidewire dilating forceps (Portex, Kent, England) with a smooth rounded tip (modified Howard-Kelly forceps with blunt edge). The procedure is characterized by a similar approach as the Ciaglia technique with transillumination (diaphanoscopy), puncturing of the trachea (18-gauge needle), guidewire insertion, and skin incision (Fig. 46-15). All neck structures are slightly dilated by one small dilator. Next, the specially designed forceps is inserted through the guidewire until the trachea is reached, and the skin and pretracheal tissues are dilated by opening the blades. The forceps is carefully advanced into the trachea under fiberoptic control, with the tip of the forceps pointing toward the carina. By pulling both branches of the forceps apart, the trachea is also dilated. According to the Ciaglia technique, the tracheal cannula chosen is then inserted by means of an adequate dilator over the guidewire.

c. TRANSLARYNGEAL TRACHEOSTOMY ACCORDING TO FANTONI

The translaryngeal approach for tracheostomy (TLT) was introduced in 1996 by Fantoni and coworkers.[223,224] In contrast to all other percutaneous techniques, the initial puncture of the trachea is directed cranially (Fig. 46-16). After tracheal puncture, a guidewire is passed through the needle and passed toward the oropharynx alongside or inside the tracheal tube. The patient is then reintubated with the kit's 5-mm-ID tube, and the wire is connected with the tracheal cannula. The cannula is then advanced through the pharynx into the trachea by constantly pulling on the guidewire. The pointed head is then pulled out the anterior tracheal wall and soft tissues of the neck. Next, the pointed head is cut off, and the cannula is to be rotated 180 degrees downward using a plastic obturator. Thereafter, the fiberoptic scope is inserted through the cannula to check correct positioning in the trachea.

The major advantage of this approach is that minimal or no skin incision is necessary, minimizing the bleeding risk. Typical problems encountered with TLT are: difficulties with the intratracheal rotation of the cannula, the need for changing the ETT, and potential contamination of the tube during oropharyngeal passage.

Byhahn and coworkers[225] investigated practicability and early complications of Fantoni's TLT technique in 47 ICU patients. No severe complications (aspiration or bleeding) were observed; only oxygenation deteriorated in about one fourth of the patients. The authors concluded that TLT is a valuable alternative technique to Ciaglia's approach, but should be performed only in patients requiring a fraction of inspired oxygen concentration (F_{IO_2}) of less than 0.8. Westphal and associates[226] compared TLT with the Ciaglia approach in a prospective study of 90 patients. Although success and complication rates were similar between the groups, problems during the procedure were far more common with the TLT technique, especially in positioning the guidewire correctly. Cantais and others[227] prospectively compared forceps-dilational and translaryngeal technique in 100 adult critically ill patients. Fantoni's translaryngeal

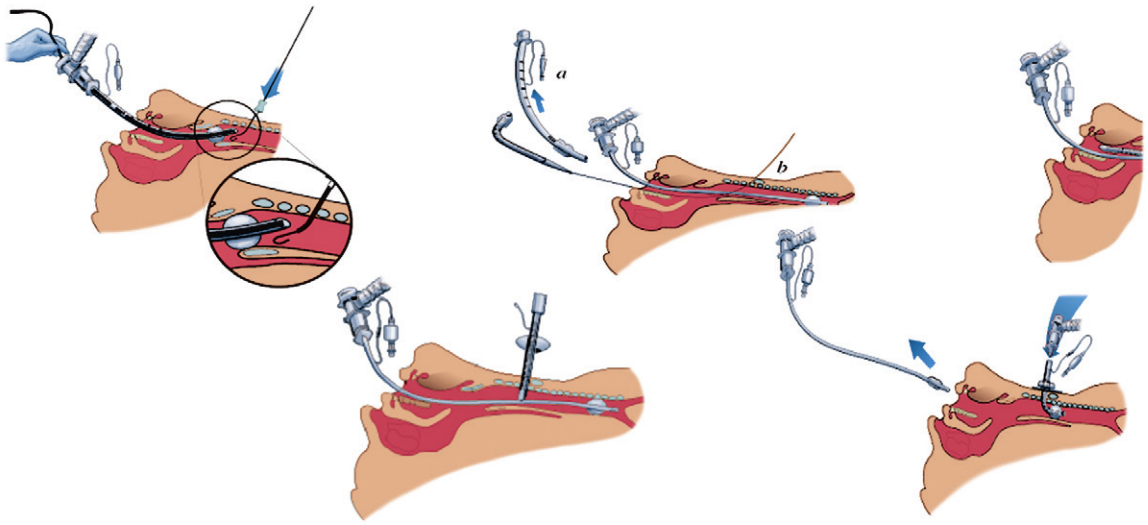

Figure 46-16 Percutaneous tracheostomy according to Fantoni. (Courtesy of Rüsch, Vienna.) (Modified from Fantoni A, Ripamonti D: A non-derivative, non-surgical tracheostomy: the translaryngeal method. *Intensive Care Med* 23:386–392, 1997.)

technique took nearly twice as long as forceps-dilation (13 vs. 7 minutes, respectively). Although minor bleeding episodes were less in the Fantoni group, major complications were more common, and unsolvable technical problems were encountered in 23% of patients. Nevertheless, the authors concluded that both techniques are safe, and physicians should be able to choose their preferred technique.

d. ROTATING DILATATIONAL TRACHEOSTOMY (PERCUTWIST)

The PercuTwist technique (Teleflexmedical Ruesch, Kernen, Germany) offers an alternative real single-step percutaneous tracheostomy approach (Figs. 46-17 and 46-18). Preparation, puncturing of the trachea, and guidewire insertion are performed according to the Ciaglia and Griggs techniques (Fig. 46-17, *1* and *2*). After needle removal, an 8-mm to 10-mm skin incision is made (Fig. 46-17, *3*), and a special hydrophilic dilation screw (suited for either 8 or 9 mm ID tracheal cannulas) is slid over the guidewire until the skin incision is reached (Fig. 46-17, *4*). Using slight pressure, the dilator is turned clockwise until the first threads are advanced into the pretracheal soft tissues (Fig. 46-17, *5*). The PercuTwist is then carefully advanced without pushing until the tip of the screw is fiberoptically visualized inside the trachea (Fig. 46-19). The screw is then advanced into the trachea twist by twist under gentle elevation of the anterior tracheal wall. The dilator is removed by counterclockwise rotation, and the tracheal cannula is inserted using an insertion dilator guided by the in situ guidewire (Fig. 46-17, *6* and *7*).

Frova and Quintel[228] reported the use of the PercuTwist system in 50 consecutive ICU patients and found a 100% success rate without serious complications. Tracheal ring fractures were observed in 4 of 50 patients (8%), but no posterior tracheal wall injury. Westphal and coworkers[229] studied 10 consecutive patients and reported no early complications besides minor bleeding (<20 mL) in two patients. In a prospective randomized study in 70 consecutive patients, Byhahn and associates[230] compared safety and efficacy of PercuTwist and Blue Rhino tracheostomy. In the PercuTwist group, complications occurred in 12 patients, including posterior wall tears, tracheoesophageal fistula, false cannula passage, and four failures to insert the cannula, compared with seven complications in the Blue Rhino group. However, no statistically significant differences in minor and overall complications were observed between the two techniques. This major complication rate of 33% in the PercuTwist group was in vast contrast with the results of Sengupta and coauthors,[231] who observed about 90 patients over 20 months of routine use of PercuTwist. All procedures performed were graded as having absent or minimal bleeding, although six patients had abnormal clotting profiles. Grundling and colleagues[232] also reported no severe complications in 54 patients of a prospective observational clinical study. A rare complication of tracheostomy is tracheal ring fracture, which was also described with the PercuTwist technique.[233]

Yurtseven and others[234] reported on 130 patients undergoing tracheostomy using three different techniques. The main finding was that PercuTwist (n = 45) was associated with minimal complications (two patients with longitudinal tracheal abrasion) and appears to be an easy to perform and practical alternative to standard PDT (n = 44, four longitudinal abrasions, one posterior tracheal wall injury, and one tracheal ring rupture) and the guidewire dilating forceps (GWDF) group (n = 41; two cases of longitudinal tracheal abrasions, one posterior tracheal wall injury). Furthermore, operating times using PercuTwist were significantly shorter than in the other groups (9.9 ±1.1, 6.2 ±1.4, and 5.4 ±1.2 minutes in PDT, GWDF, and PercuTwist groups, respectively).

Imperiale and associates[235] reported on intracranial pressure changes during tracheostomy using PercuTwist. Use of PercuTwist did not cause secondary intracranial hypertension insult and therefore could also be considered safe in a select population of brain-injured patients.

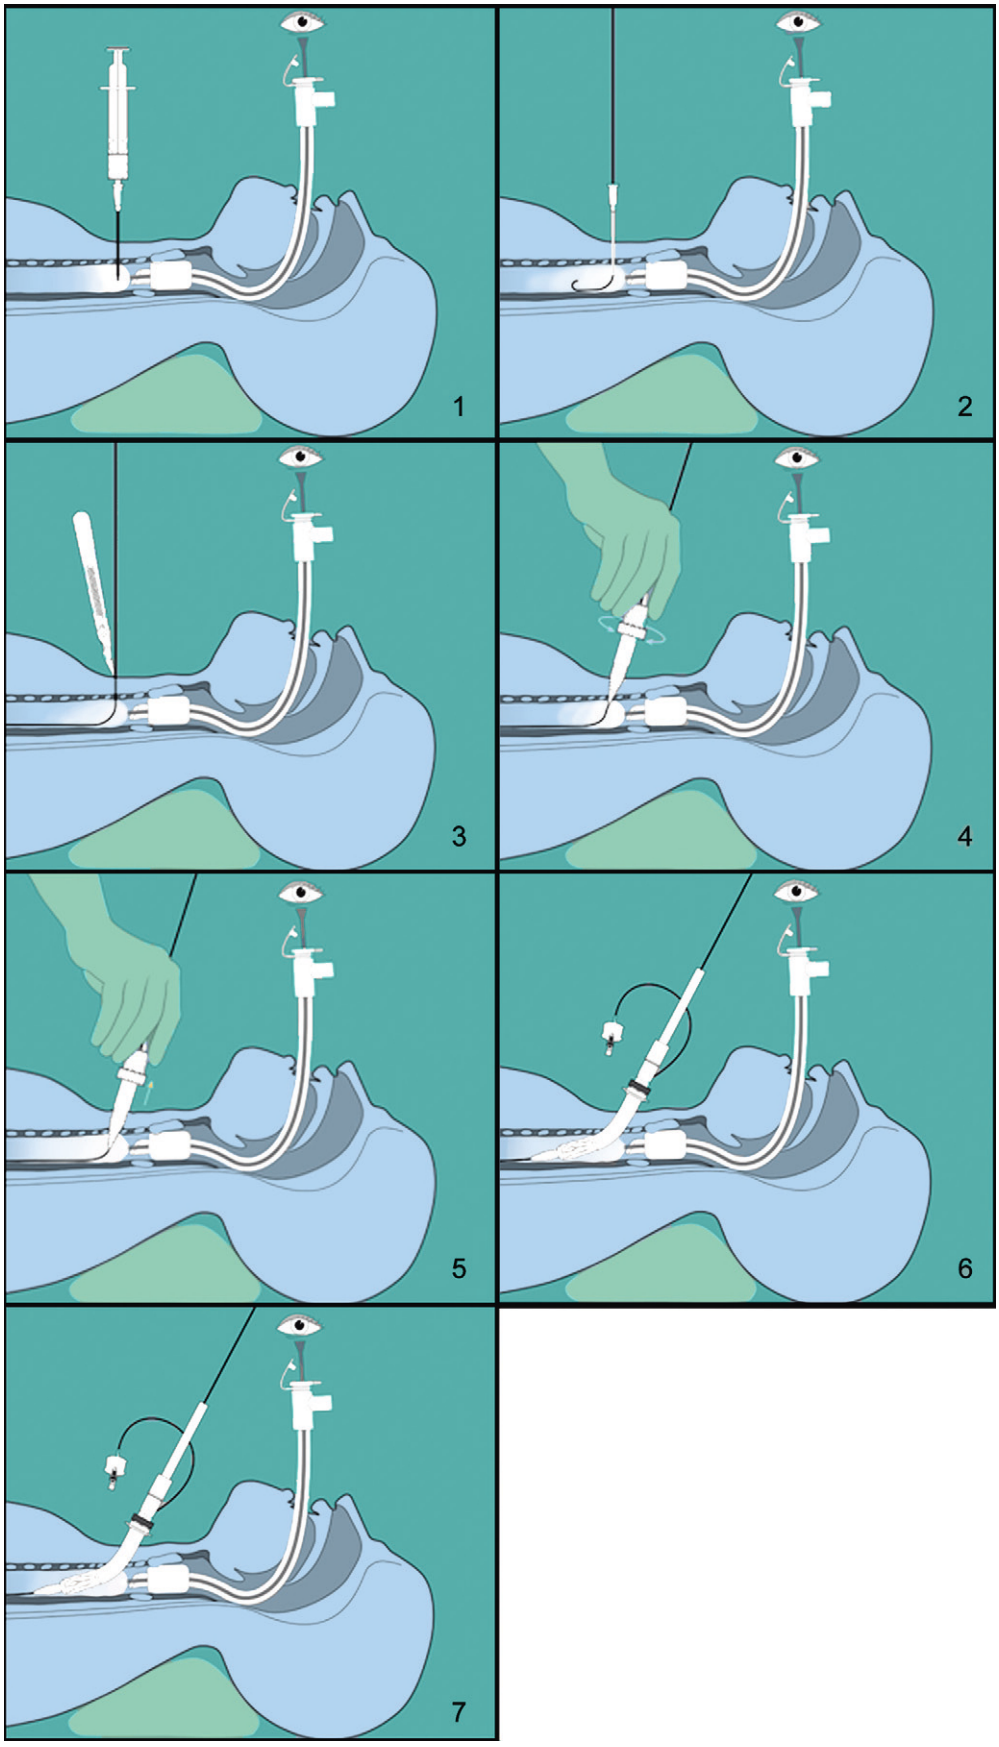

Figure 46-17 PercuTwist. See text for details. (Courtesy of Rüsch, Vienna.)

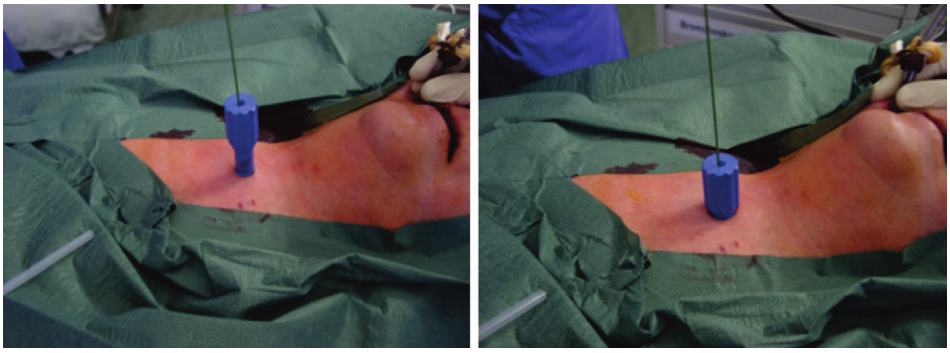

Figure 46-18 Performance of PercuTwist tracheostomy. (Courtesy of Rüsch, Vienna.)

A distinct advantage of the PercuTwist technique over all other percutaneous approaches is that the stoma remains open after removal of the screw, and immediate emergency intubation of the stoma with a small tracheal tube is possible. With all other devices, dilated stoma closes by the tissue pressure immediately after removal of the dilators.

e. CIAGLIA BLUE RHINO

The technique of PDT has constantly been evolving. In 1998 a modification was introduced called Ciaglia Blue Rhino (Percutaneous Tracheostomy Introducer Kit, Cook Critical Care). The standard multiple dilators were replaced by a single, sharply tapered dilator shaped similar to the horn of a rhino (Fig. 46-20). The dilation process can be performed in a single step, without the need to change dilators (Fig. 46-21). Therefore, the risk of injury to the posterior tracheal wall, bleeding episodes, and impaired oxygenation by repeated airway obstruction during the dilation process may be reduced.[236]

The Percutaneous Tracheostomy Introducer Set consists of a puncture needle, guidewire, small dilator and special Blue Rhino dilator, and three curved stylets for placement of the tracheostomy tube. Instructions are as follows[237]:

1. Withdraw the ETT under fiberoptic control to a level above the assumed puncture site.
2. Make a horizontal skin incision and puncture the trachea in the midline between the second and third tracheal cartilage rings.
3. Introduce the guidewire using the Seldinger technique.
4. Withdraw the needle, and introduce the guiding catheter.
5. Predilate the puncture canal with the small dilator.
6. To increase the dilator's external smoothness, moisten the Blue Rhino dilator with a few milliliters of saline solution or distilled water.
7. Advance the wet dilator over the guidewire and guiding catheter through the soft tissues and into the trachea up to its marking of 38-F external diameter. The dilation should require a minimum of force because of the dilator's smoothness (Fig. 46-21A and B).
8. Ensure the Blue Rhino PDT set contains three hard-rubber stylets of different sizes with cone-shaped tips. The tracheostomy tube should be armed with its corresponding stylet.
9. Advance this perfectly fitting unit into the trachea (Fig. 46-21C).
10. Afterward, withdraw the stylet and confirm the correct position of the tracheostomy tube using fiberoptic bronchoscopy.
11. Connect the tube with the respirator, and remove the ETT.

In a small, prospective, randomized study in 2000, Byhahn and others[237] compared the classic PDT with the Blue Rhino in 50 critically ill patients and reported a relatively high incidence of cartilage damage (9 of 25 cases), but no life-threatening complications with either

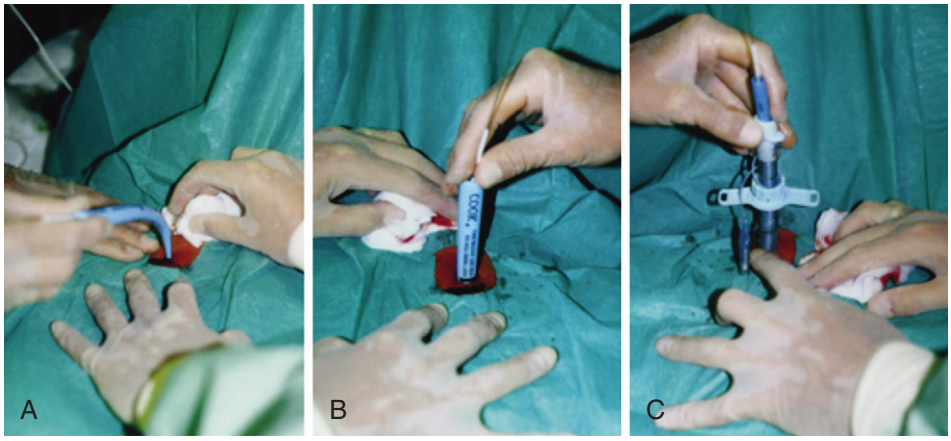

Figure 46-21 Single-step Ciaglia Blue Rhino: a modified technique for percutaneous dilatational tracheostomy. See text for details. (Modified from Byhahn C et al: (Ciaglia Blue Rhino: a modified technique for percutaneous dilatation tracheostomy—technique and early clinical results). *Anaesthesist* 49:202–206, 2000.)

method. In 2002, Fikkers and associates[238] assessed perioperative, early, and late complications in 100 consecutive Blue Rhino tracheostomies. Success rate was 98%, with minor and major complications observed in 30% and 12%, respectively. Tracheal stenosis was observed in one patient (over 6-12 months). In 2003, Dongelmans and others[239] showed that the use of Blue Rhino in an ICU environment is associated with a very low rate of major and minor complications.[240] In a retrospective study of 318 tracheostomies, Bhatti and associates[240] reported a low complication rate similar to open surgical tracheostomy, concluding that the complication rate of PDT can be reduced further with experience and use of strict protocols, making it even safer than an open ST.

In 2005, Kost and colleagues[241] evaluated 500 adults; 309 underwent PDT using Ciaglia Blue Rhino (single dilator), and 191 used the Ciaglia Percutaneous Tracheostomy Introducer Kit (multiple dilator). Total complication rate was 9.2% (6.5% in Blue Rhino and 13.6% in multidilator group). The most frequent intraoperative complications were brief oxygen desaturation (14 patients) and bleeding (12 patients). This study also identified ASA class IV patients as having a significantly increased risk of complications. Johnson[242] and Ambesh[243] and coworkers showed that the single-dilator technique decreased operative time compared with the serial-dilator technique. In both studies, complication rates were not increased by single-step dilation. In 2007, De Leyn and colleagues[244] performed a systematic review and recommended the modified Blue Rhino as the technique of choice, based on its simplicity and short procedure time (level 2c). In 2010, Dempsey and colleagues[245] reported a prospective evaluation of the single-tapered-dilator technique, with tracheostomies performed in 589 patients (2003-2009). PDT was attempted in 576 patients and successfully completed in 572. Four attempts were stopped due to bleeding. In 149 patients (26%) intraoperative technical difficulties were encountered. Early complications occurred in 16 patients (3%). Significant late complications occurred in four patients; in two patients, a trachea-innominate fistula was found and led to the death of both patients. The mortality directly attributable to PDT was 0.35%.

Based on clinical studies and personal experience, the single-step PDT currently is the most widely used technique.[245-248]

f. CIAGLIA BLUE DOLPHIN

In 2009, Gromann and associates[249,250] studied a modified PDT called Blue Dolphin, a balloon dilation technique that exerts mainly radial force to widen the tracheostoma. This force may reduce complications such as fracture of tracheal cartilage rings or injuries to the posterior tracheal wall (Fig. 46-22).

Surgical Procedure

1. Ensure optimal placement of patient with full extension of head and neck.
2. Perform surgical disinfection and sterile covering of the operative area.
3. Manually examine the cricoid cartilage.
4. Make a 1-cm to 2-cm, horizontal surgical incision.
5. Puncture the trachea at the level between the second and third tracheal cartilages.

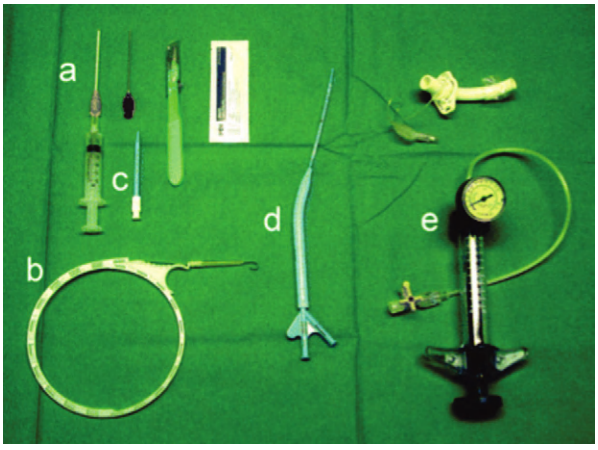

Figure 46-22 Ciaglia Blue Dolphin set balloon percutaneous tracheostomy introducer: *a,* introducer needle; *b,* wire guide; *c,* 14-F dilators; *d,* balloon-tipped catheter loading dilator assembly; *e,* Cook inflation device. (From Gromann TW et al: Balloon dilatational tracheostomy: initial experience with the Ciaglia Blue Dolphin method. *Anesth Analg* 108:1862–1866, 2009.)

6. Ensure puncture of the trachea using bronchoscopy.
7. Place the guidewire using the Seldinger technique.
8. Enlarge the puncture canal with the blue, short introducing dilators.
9. Attach the prepared inflation device to the balloon port on the balloon-catheter assembly.
10. Remove the introducing dilators; the guidewire remains in situ.
11. Introduce the prepared tracheostomy tube.
    a. Fill up the balloon with normal saline using the inflation pump (max pressure, 11 atm).
    b. Hold this pressure for at least 15 seconds.
    c. Deflate the balloon.
    d. Simultaneously insert the balloon-catheter assembly, loading dilator, tracheostomy tube, and guidewire.
    e. When tracheostomy tube is in place, remove the rest of the assembly.
    f. Inflate the tracheal tube–balloon cuff.
    g. Verify by bronchoscopy.

Tracheoesophageal fistula
Tracheomalacia

In the primary study by Gromann,[250] 20 patients underwent this procedure at the ICU bedside, and surgery averaged 3.3 ±1.9 minutes. There were no injuries of the posterior tracheal wall, no bleeding requiring treatment, or wound infections. One patient had a fracture of a tracheal ring, and another patient had subcutaneous emphysema.

In 2010, Cianchi and others[251] compared this new Blue Dolphin system with the Ciaglia Blue Rhino system in 70 ICU patients. Surgical procedure time in the Blue Rhino group was significantly shorter than in the Blue Dolphin group (1.5 vs. 4 minutes). Limited intratracheal bleeding requiring no intervention was more frequent in the Dolphin group. Although Blue Rhino was associated with fewer tracheal injuries and time for procedure was shorter, the authors concluded that PDT using the Ciaglia Blue Dolphin technique is a feasible and viable option in ICU patients.

D. Airway Management During Tracheostomy

During puncture of the trachea, the endotracheal tube must be withdrawn just below the vocal cords to protect the bronchoscope and tube cuff. Therefore, alternative approaches such as ventilatory support using a laryngeal mask airway or a Fastrach have been suggested.[252-254] In an RCT, Dosemeci and colleagues[255] studied LMA as an alternative airway for management during PDT in 60 patients, concluding that LMA is an effective and successful ventilatory device. It improves visualization of the trachea and larynx during fiberoptic-assisted PDT and prevents the difficulties associated with use of the ETT, such as cuff puncture, tube transection by the needle, and accidental extubation. However, Ambesh and associates[256] clearly demonstrated that changing ETT to LMA might result in potentially life-threatening complications, including loss of the airway during PDT. In a prospective randomized study, they compared the safety and efficacy of ETT versus LMA ventilation during PDT in 60 critically ill patients. Although the complication rate was low in the ETT group (7% ETT impalement, 7% cuff puncture, and 3% accidental extubation), a high rate of complications was observed in the LMA group (33% incidence of airway loss, inadequate ventilation, and gastric distention). A change of the ETT for an LMA during the performance of tracheostomy therefore cannot be recommended and may only be an alternative method for patients not intubated before the procedure.

E. Perioperative and Early Complications of Tracheostomy

A number of potential complications may occur during or immediately after PDT (Box 46-5). Bleeding is the most common perioperative complication, with incidence up to 4%.[257] After controversial statements, routine chest radiography for identifying complications at an early stage is not longer recommended after tracheostomy placement, unless there are signs of unexpected compromise of air exchange.[258,259] Ambesh and associates[243] compared two percutaneous single-dilator techniques (Blue Rhino, Griggs dilating forceps) in 60 consecutive patients. Percutaneous access to the trachea was possible in all patients, with significantly more difficult cannulations in the Griggs group (30% vs. 7%). Overdilatation of the stoma occurred more frequently in the Griggs group (23% vs. 0%), whereas Blue Rhino was often associated with tracheal ring fractures (30% vs. 0%). Some variation in complications is seen with different techniques for PDT. The single-dilator technique (Blue Rhino) appears to be fast and incurs no more risk than the multiple-dilator technique of Ciaglia.[238,242]

F. Late Complications of Tracheostomy

Many mechanisms may cause late complications after tracheostomy.[46] The most important factors may be placement of the tube, especially prolonged intubations; leaving the tube in place for prolonged periods, possibly related to inflated cuff; and abnormal healing at the site of injured tracheal mucosa. Clinically relevant late

*Airway symptoms included hoarseness, feeling of a lump in the throat, cough, dyspnea, and subjective phonetic or respiratory problems.
From Delaney A et al: Percutaneous dilatational tracheostomy versus surgical tracheostomy in critically ill patients: a systematic review and meta-analysis. *Crit Care* 10:R55, 2006.

complications after tracheostomy occur in up to 65% of patients.[260-263] The most common and important complication is development of granulation tissue. *Granulation tissue* occurs subclinically or presents as failure to wean patients from ventilator, failure to decannulate, or as upper airway obstruction with respiratory failure after decannulation.[264] Further late complications include tracheal stenosis, aspiration pneumonia, tracheomalacia, and tracheoesophageal fistula[265] (Table 46-10).

After its introduction by Ciaglia in 1985,[200] many investigators have reported their experience with the technique and have concluded that PDT is safe and cost-effective. Vigliaroli and others[266] reported their clinical experience with Ciaglia's dilational tracheostomy over 6 years in 304 patients, 41 of whom were evaluated for late complications. No perioperative death occurred, and early complication rate was 5%. No late complications (e.g., tracheal stenosis) were observed in any of the fiberoptically investigated patients during follow-up to 180 days.

Escarment and associates[267] evaluated the safety and complication rates of the Griggs technique in a consecutive series of 162 ICU patients. Early intraoperative complications occurred in 17%, being minor technical difficulties without morbidity (e.g., inadvertent extubation, difficult cannulation, hemorrhage). Average cannulation duration was 25 days, and stoma closure was effective in all patients after about 3 to 4 days. Follow-up was available in 81 patients, and endoscopic evaluation of the airways 3 months after decannulation was performed in 73 patients; 62 (85%) were normal, seven (10%) had granulation tissue at the stoma site, and four (5%) had tracheal stenosis, with dyspnea in two patients (3%).

Norwood and colleagues[268] determined the incidence of tracheal stenosis and other late complications after PDT in 422 patients undergoing tracheostomy between 1992 and 1999 (Ciaglia approach). Of the 340 survivors, 100 were interviewed and further evaluated by fiberoptic laryngotracheoscopy and tracheal computed tomography. CT scans identified mild stenosis (11%-25%) in 21% of patients (all asymptomatic), moderate stenosis (26%-50%) in 8%, and severe stenosis (>50%) in 2% of patients (Fig. 46-23; see also Fig. 46-11A).

Hotchkiss and coworkers[269] performed a cadaver study to evaluate the stoma and surrounding insertion site for laryngotracheal injury in six fixed cadaver specimens. Puncture and dilation were performed using the Blue Rhino technique, and no fiberoptic control of the procedure was used. Puncture level was accurately predicted in only 50% of cadavers. Anterior tracheal internal wall mucosal injury was observed in all specimens. Cartilaginous injury was severe in five of six specimens that sustained multiple comminuted injuries to two or more adjacent tracheal rings. The authors concluded that the injuries observed may significantly contribute to the development of tracheal stenosis. However, no data are presented on the potential impact of bronchoscopic guidance on the incidence of these complications.

(From Norwood S et al: Incidence of tracheal stenosis and other late complications after percutaneous tracheostomy. *Ann Surg* 232:233–241, 2000.)

Leonard and others[270] assessed the late outcome following forceps tracheostomy in a prospective observational study of 49 patients. Tracheal stenosis was observed in one patient (2%), whereas other, minor complications (e.g., change in voice, 49%) were observed frequently. However, whether this was caused by the preceding translaryngeal intubation or the technique of tracheostomy could not be determined.

The main problem of PDT leading to tracheal stenosis is that tracheal rings are forced into a position that creates the opening for the cannula. This maneuver is capable of deforming the tracheal cartilage so that it protrudes into the airway (Fig. 46-24).

Koitschev and associates[271] reported on three patients with severe tracheal stenosis/obliteration after PDT (Figs. 46-25 and 46-26). In all patients, tracheal narrowing occurred above the level of the stoma. The authors speculated the cause was a procedure-related mechanism (tracheal ring invagination and consecutive development of granulation tissue) rather than a mechanism based on the duration of cannulation (normally producing stenosis below the stoma).

In conclusion, PDT seems to be a safe, relatively simple, and quick procedure that can performed at bedside. Early complications and infection rate (~2%) might be even lower and cosmetic results better than with surgical tracheostomy. However, PDT must be performed by an experienced operator at the correct puncture site, straight in the midline between two tracheal rings, and may never be performed without fiberoptic guidance.[272] All special techniques proposed are characterized by special drawbacks or complications. The Blue

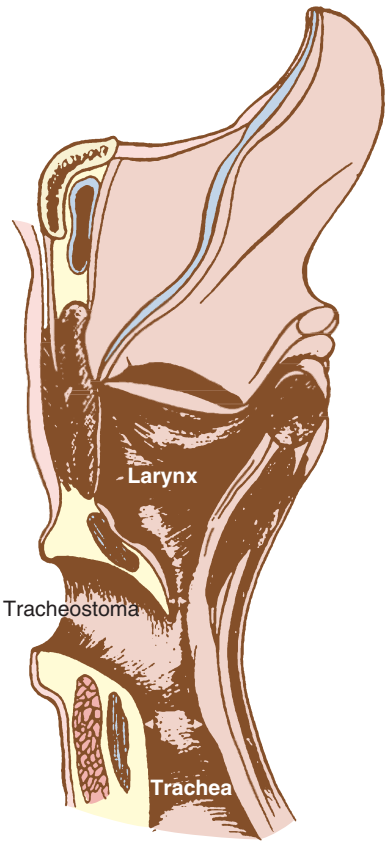

Figure 46-24 Suprastomal stenosis. Anterior tracheal wall is invaginated into the lumen. (From Koitschev A, et al: Tracheal stenosis and obliteration above the tracheostoma after percutaneous dilational tracheostomy. *Crit Care Med* 31:1574–1576, 2003.)

Rhino technique is associated with a relatively high incidence of tracheal ring fractures (~30%), whereas the PercuTwist approach has a higher risk of posterior tracheal wall injury. It is therefore difficult to compare "percutaneous dilatational tracheostomy" to the conventional surgical approach, since these are completely different techniques with different success and complication rates. Much larger studies over a longer time studying clearly defined patients and techniques are necessary to clarify the incidence of late complications after PDT. Currently, it is too early to draw definitive conclusions on PDT versus surgical tracheostomy.

G. Conventional (Surgical) vs. Percutaneous Tracheostomy

Comparing PDT with historical data of complications of ST is erroneous and may give a biased picture. Moreover, varying definitions and different techniques used by the authors make interpretation of data difficult. Complication rates for ST vary widely, between 6% and 66%, with mortality of 2%.[273] To reduce this incidence of complications and to perform a bedside procedure, the different percutaneous techniques have been proposed.

Special reference to early complications shows that serious bleeding can occur with either ST or PDT, but appears to be less frequent with PDT.[274] Considerable danger arises in the significant rate of posterior tracheal wall perforation with development of tension pneumothoraces when using PDT.[275] To avoid posterior tracheal wall injury, guidewire and guiding catheter should be firmly stabilized during PDT, and fiberoptic visualization of the entire process is obligatory. In common, pneumothorax is infrequent when using PDT but occurs in 1% to 3% when using ST.[276]

Numerous studies suggest minimal difference in acute serious complications between ST and PDT,[277] while others propose a learning curve and a significantly lower complications rate thereafter. Petros[257] clearly showed a learning curve in performing tracheostomy after prospectively evaluating 234 PDTs (Fig. 46-27).

Massick and colleagues[278] performed a prospective analysis of complication incidence for the first 100 PDTs (Ciaglia) performed in a local community hospital. The authors clearly demonstrated a learning curve, with the first 20 patients exhibiting a significantly higher incidence of perioperative as well as late complications. Furthermore, patients with suboptimal anatomy were found to have significantly increased complication rates independent of operator and institutional experience. PDT has a steep learning curve, with most perioperative, postoperative, and late complications occurring in the first 20 patients.

Beiderlinden and others[279] assessed the incidence of early complications of fiberoptically guided PDT beyond the learning curve (all investigators performed >100

PDTs). With 133 consecutive patients undergoing PDT (114 conventional Ciaglia technique and 22 Blue Rhino), tubes were fixed at the skin, and no routine tube exchanges were performed. Insertion of the tracheal tube was easy or modestly difficult in 87%, and no procedure-related deaths occurred. The incidence of tube-related complications (e.g., tracheal wall lesion, bleeding, cannula misplacement) was low, 0.7%. Fracture of tracheal rings was observed in 24%. Despite this finding, the authors concluded that with experience in performing PDT, fixation of the tracheal cannula, and omission of routine tube changes, the complication rate is low.

Several studies compared ST and PDT technique, in addition to multiple reviews and four meta-analyses.[265,280-282] At present, no consensus exists as the optimal approach in terms of minimizing complications.

Dulguerov and associates[280] performed a meta-analysis comparing surgical and percutaneous access to the trachea. Study patients were grouped as having surgical tracheostomy from 1960 to 1984 (17 investigations in 4185 patients), surgical tracheostomy from 1985 to 1996 (21 studies in 3512 patients), or PDT (27 studies in 1817 patients). The highest perioperative and postoperative complication rates were observed in the "older" surgical studies (9% and 33%, respectively). Although perioperative complication rates were higher in the percutaneous studies (10% vs. 3%), postoperative complications were lower compared with the surgical approach (7% vs. 10%). However, this meta-analysis was criticized because studies on percutaneous tracheostomy without fiberoptic control were also included. Furthermore, it is difficult to perform a meta-analysis on this topic because not only percutaneous versus surgical approaches were compared. The percutaneous group is a mix of several different procedures and techniques used (i.e., with or without fiberoptic control, Ciaglia or Griggs technique).

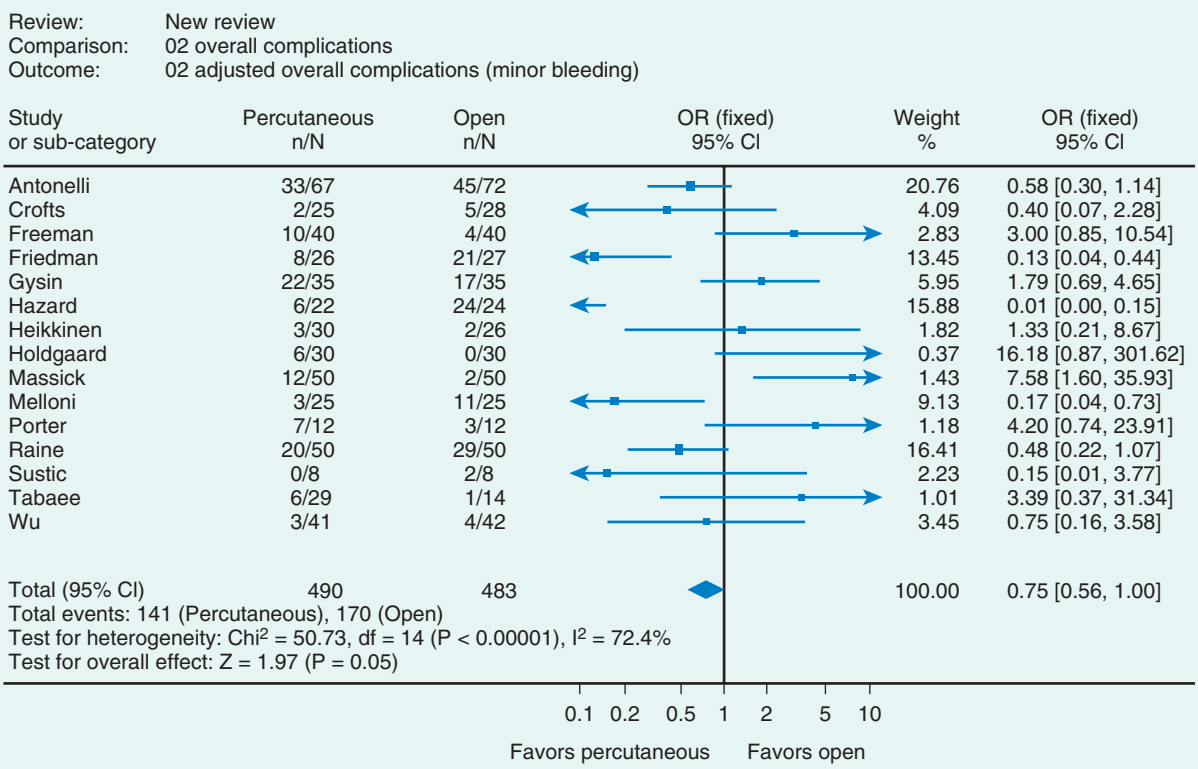
Subsequently, Delaney and coauthors[265] performed a systematic review and meta-analysis, including 17 RCTs involving 1212 patients. Pooled analysis showed no statistical difference in mortality or major complications. The rate of wound and stoma infections was low, 6.6%, but infections were significantly less common in the PDT group. Unfortunately, studies rarely include long-term follow-up, and significant late complications may be missed.

In a meta-analysis, Freeman and associates[281] examined five studies (236 patients) and found that PDT was associated with a lower overall postoperative complication rate, less perioperative bleeding, and lower incidence of stomal bleeding and stomal infection. In addition, PDT was quicker than ST by 9.84 minutes. The meta-analysis of Higgins and Punthakee[282] included 973 patients from 15 RCTs (490 PDTs and 483 STs). The author found significantly fewer complications in PDT with respect to wound infection and unfavorable scarring. Consequently, overall complications trended toward favoring the percutaneous technique. PDT appeared to be more cost-effective by freeing up OR resources, including time and personnel; providing greater feasibility in terms of bedside capability; and allowing nonsurgeons to perform the procedure safely[282,283] (Tables 46-11 and 46-12). Most authors reported lower complication rates with the individual percutaneous technique used[272,284] (Table 46-11). Tracheostomy is increasingly performed outside the OR and by PDT rather than ST technique.[285]

Bowen and colleagues[286] performed a retrospective medical chart review. Over 23 months, 213 patients received ST (n = 74) or PDT (n = 139). Perioperative complications occurred in five of 74 patients (6.76%) during PDT (whereas three patients, 4.1%, required emergent operative exploration of the neck) versus three of 139 patients (2.2%) during ST. Surgical time for PDT in the ICU was significantly shorter and cost less than ST performed in the OR.

In conclusion, all studies clearly show that adequate training and teaching is the major factor reducing complications with PDT. Until those issues are cleared, PDT can be recommended with some exceptions. Especially in patients presenting with a short thick neck, goiter, or difficult airway, PDT should be performed only by an experienced physician, with a physician prepared for ST present.[287] The most important part is fiberoptic control of the entire procedure, since erroneous punctures or direct trauma of the esophagus or tracheal wall are prevented or recognized early.[288]

VII. ROUTINE AIRWAY CARE IN MECHANICALLY VENTILATED PATIENTS



Tracheal suctioning is an intervention to remove accumulated mucus from endotracheal tube, trachea, and lower airways in patients requiring intubation for mechanical ventilation. Intubation, ventilation, and especially sedation impair the transport of mucus in the airways. Accumulated mucus in the subglottic space is a well-proven cause of ventilator-associated pneumonia. Prevention of VAP includes aspiration of secretion by suctioning.[289-291] Furthermore, coughing is impaired from ETT interference with glottic closure.

Tracheal suctioning, an essential aspect of airway management, is a potentially life-threatening procedure that can lead to hypoxia, cardiac dysrhythmias, trauma, and atelectasis.[292] Traditionally, tracheal suctioning is performed by disconnecting the patient from the respirator, applying manual hyperinflation ("bagging"), inserting a suctioning catheter into the patient's airways, and applying negative pressure to remove secretions.[293] Saline may be instilled to dilute secretions and facilitate suctioning. Tracheal suctioning is intended as a beneficial procedure, but few studies have been performed on this topic. To the contrary, several investigations reported adverse effects.[294,295] Stone and colleagues[294] reported cardiac dysrhythmias in post–cardiac surgery patients. Aldkofer and Powaser[295] reported a decrease in oxygen tension of 20 mm Hg.

Therefore, tracheal suctioning should be performed "on demand," and the need for suctioning and the effectiveness of the procedure must be determined by chest auscultation.[1] Suctioning on a routine schedule (e.g., every 4-6 hours) should be abandoned. Prior to the procedure, the patient must be properly informed, because tracheal suctioning is a frightening and unpleasant

TABLE 46-11

experience; for many patients, it is the only remembrance on their ICU stay.

To prevent hypoxemia and resulting complications, preoxygenation at an F_{IO_2} of 1.0 should be started 1 minute before suctioning. Suctioning is an invasive procedure, and sterile gloves should be worn during the process. Catheter selection is also important; the external diameter of the suction catheter should not exceed one-half the ETT internal diameter.[296] Larger catheters are traumatic, whereas smaller catheters are often insufficient at removing viscous secretions.

Much confusion surrounds normal saline instillation (NSI) to facilitate tracheal suctioning. NSI is reportedly beneficial in removing thick, tenacious secretions in patients receiving mechanical ventilation. Currently, no data confirm beneficial effects of saline irrigation. To the contrary, increasing literature focuses on harmful effects of routine tracheal NSI.[297,298] Despite the use of NSI for 25 years, many questions remain, such as the volume of saline to instill. Volumes instilled in adult patients vary between 2 and 5 mL, 5 and 10 mL, and up to 40 mL.[298] Volume of saline used has never been evaluated in controlled research studies. Investigating unretrieved saline, Hanley and others[299] instilled saline tagged with technetium 99m in two subjects. Only 20% of saline instilled was retrieved by suctioning, and the authors concluded that NSI at the proximal end of the ETT only sprinkles the trachea. Part of the remaining saline may be "blown out" during brisk coughing, and instillation at the distal end of the ETT might minimize this risk.

Furthermore, NSI has a major impact on physiologic parameters: Gray and coauthors[300] assessed minute volume and forced vital capacity in 15 patients suctioned with or without NSI. No statistically significant differences were found between the groups. However, Kinloch[297] could show that oxygenation status (i.e., mixed venous oxygen saturation) of patients suctioned using 5 mL of normal saline was poorer than in patients suctioned without saline instillation. In a systematic review, Blackwood[298] concluded that after 25 years of inconsistent practice in trying to remove tenacious secretions, it is time to focus on techniques to prevent thick and tenacious secretions.

Suctioning should be performed with continuous negative pressure at 80 to 150 mm Hg applied only during catheter withdrawal.[292,301] Higher pressures can cause hypoxemia, atelectasis, or catheter adherence to the tracheal mucosa. Duration of a single suctioning pass should not exceed 10 to 15 seconds, and the number of suctioning passes should not exceed three during one suctioning episode.[302] To minimize the risk of postsuctioning desaturation, the patient should be reconnected to the oxygen supply immediately (maximum, 10 seconds) after suctioning. To evaluate effectiveness of suctioning, a

comprehensive respiratory assessment is recommended after suctioning.[301]

Minimally invasive endotracheal suctioning has been recommended as an alternative approach. "Minimally invasive" means that the suction catheter never reaches the trachea, no saline is installed, no bagging is performed, and suctioning is only performed when clinically indicated. In an RCT of 383 ICU patients, van de Leur and associates[293] compared routine suctioning (n = 197) with the proposed minimally invasive approach (n = 186). No differences were found in duration of intubation, ICU stay, pulmonary infection, or mortality. However, suctioning-related adverse effects (e.g., desaturation, BP elevation, blood in mucus) were significantly less in the minimally invasive group. In another study, the same group evaluated patients' recollection of the suctioning procedure; 208 patients were interviewed within 3 days after ICU discharge, and the level of discomfort was quantified using a visual analogue scale.[303] A significantly lower prevalence of recollection of airway suctioning was found in the minimally invasive treated patients. Further studies are needed to prove those findings, but reconsidering the individual suctioning techniques seems to be valuable.

Furthermore, closed suctioning (CS) systems have been recommended. A reduced incidence of VAP was reported.[304] "Classic" open suctioning (OS) is routinely performed by disconnecting the patient from the ventilator and introducing a regular suctioning catheter through the ETT into the upper airways.[305] Alternatively, suctioning can be accomplished with a CS system attached between ETT and ventilatory tubing, allowing introduction of the suctioning catheter into the airways without disconnecting the patient from the ventilator.[306,307] CS has some advantages compared to the conventional OS technique. CS can be helpful in limiting environmental, personnel, and patient contamination and in preventing the loss of lung volume and the alveolar derecruitment associated with standard suctioning in the severely hypoxemic patient. However, the impact of CS on the incidence of ventilator-associated pneumonia, as well as its cost-effectiveness, remains to be determined.[305]

An interesting approach using a visualized ETT has been suggested by Frass and colleagues.[308] The so-called visualized endotracheal tube (VETT system; Pulmonx, Palo Alto, Calif) corresponds to a standard ETT with incorporated fiberoptic fibers, continuously displaying a view of patient's trachea and carina. The device worked effectively until extubation (mean duration, 137 hours), although the lens had to be rinsed approximately four times daily. Online monitoring of ETT position and amount of retained secretions is possible. Furthermore, targeted suctioning of right or left lung can be performed under visual control. The authors assumed that the frequency of suctioning maneuvers can be reduced by using this new technique.[308] However, the VETT system is not commercially available.

In recent years, *continuous aspiration of subglottic secretions* (CASS) has become increasingly popular, although few randomized prospective studies have compared CASS and conventional suctioning.[309-312] The results have been inhomogeneous and the conclusions on VAP prevention contradictory, with most studies based on a limited number of patients. Bouza and associates[291] performed a randomized comparison of conventional aspiration and CASS during a 2-year period; 359 patients underwent CASS, and 331 patients underwent conventional suctioning. The results of this important study are

presented in Table 46-13. No agreement has been reached in this area, however, and more research is needed to clarify the potentially beneficial effects of CASS. Furthermore, prospective research is needed to clarify the role of continuous cuff pressure monitoring, removal of biofilm formation in the ETTs, and routine saline instillation before tracheal suctioning.[313]

VIII. DIFFICULT EXTUBATION IN CRITICALLY ILL PATIENTS

Extubation of the trachea of ICU patients represents a special challenge to the attending physician. Every routine extubation (difficult airway absent) can be associated with severe complications, including hemodynamic decompensation and cardiac failure, breath-holding, laryngospasm, aspiration, or increased intracranial pressure. Factors that result in a relatively high incidence of difficult extubation in intensive care include special surgical procedures (head and neck surgery), swelling of laryngeal or pharyngeal tissues, limited airway access (maxillomandibular fixation, cervical immobilization, tracheal resection), and long-term ventilatory support with muscle fatigue.

In patients with preexisting difficult airway, one should be aware that emergent reintubation is an entirely different situation. Extubation of these patients might result in airway catastrophes. However, few studies have focused on this integral part of difficult airway management, and evidence is insufficient to permit critical evaluation of extubation strategies. The ASA Task Force on Management of the Difficult Airway recommended that each anesthesiologist and critical care physician have a preformulated strategy for extubation of patients with a difficult airway.[314] The preformulated strategy should include the following:

- Evaluation for general clinical factors that may produce an adverse impact on post-extubation ventilation
- Formulation of an airway management plan that can be implemented if the patient is not able to maintain adequate ventilation after extubation
- Consideration of short-term use of a guide that can serve as guidance for reintubation

By decreasing upper airway tract diameter, laryngeal edema increases airway resistance and manifests as stridor and respiratory distress. Reintubation may be required if the patient is unable to sustain the increased respiratory work. To discern patients with and without significant laryngeal edema, de Bast and associates[315] described the "cuff leak test." Leak was evaluated immediately before extubation in 76 patients, expressed as the difference between expired tidal volume (assisted control mode) measured with the ETT cuff inflated and deflated. The authors concluded that a cuff leak greater than 15.5% can be used as a screening test to limit the risk of reintubation in laryngeal edema.

Reintubation under emergency conditions in the ICU-bed is entirely different from the controlled circumstances in the OR. In ICU patients, use of "tracheal tube exchangers" (e.g., Cook Critical Care) may be indicated. This type of device is lubricated and then inserted through the lumen of the ETT into the trachea before the tube is removed. Oxygen may be delivered continuously through the hollow lumen of a tracheal tube exchanger using the by-packed adapter. If severe respiratory insufficiency occurs, another ETT is slid over this guiding bar into the trachea, blindly or under direct laryngoscopy. Alternatively, extubation may also be performed using a fiberoptic bronchoscope left inside of the trachea, in addition to a bite block. This procedure enables directed suctioning of tracheal secretions, especially during the sensible post-extubation phase. Fiberoptically controlled reintubation is possible at any time point; this approach may be advantageous in ENT and maxillofacial patients.

Not only the extubation procedure, but the entire post-extubation period, approximately 48 hours, is of utmost importance for patient outcome. It is well known that the receptors associated with swallowing are altered by the presence of an ETT.[316] The reason for swallowing dysfunction after extubation of the trachea seems to be a combination of "muscle freezing" from non-use and loss of proprioception from superficial mucosal lesions. Leder and others[317] investigated the incidence of aspiration after extubation in 20 consecutive trauma patients. All subjects underwent bedside transnasal fiberoptic endoscopic evaluation of swallowing 24 ±2 hours after extubation to determine objectively aspiration status. Aspiration was

identified in 9 of 20 subjects (45%) and 4 of these 9 (44%) were silent aspirators. The authors concluded that trauma patients have an increased risk of aspiration after orotracheal intubation and prolonged mechanical ventilation. Moreover, silent aspiration was suggested as an occult cause of post-extubation pneumonia. This high incidence of aspiration could not be verified by a consecutive prospective study by the same group. Barquist and coworkers[318] found an aspiration rate of only 10% and delayed enteral nutrition in those patients. However, no beneficial effect of fiberoptic post-extubation monitoring was observed in this small prospective study of 70 patients.

Another important factor is the impact of accidental extubation (with or without reintubation) on pneumonia risk and patient outcome. *Unplanned extubation* (UEX) accounts for about 10% of extubations and requires reintubation in 60% of cases.[138,319] In a prospective multicenter trial on predisposing factors and complications of UEX in more than 400 patients, Boulain[319] reported an incidence of 10.8%, which means 1.6 UEXs per 100 ventilated days. Multivariate analysis determined four factors contributing to UEX: chronic respiratory failure, ETT fixation with only thin adhesive tape, orotracheal intubation, and lack of intravenous sedation. The rates of mortality, laryngeal complications, and length of mechanical ventilation were similar in UEX and non-UEX patients. Patients were more often reintubated after UEX, every second versus every tenth non-UEX patient. The authors hypothesized that simple measures such as strong fixation of ETT, adequate sedation, and particular attention to orally intubated patients should minimize UEX.

Reintubation has been identified as a major risk factor for nosocomial pneumonia.[320] In a case-control study, Epstein and associates[321] found that either form of UEX (successfully tolerated or failed during weaning or ventilatory support) was associated with longer ICU stay but did not increase mortality. Recently, de Lassence and colleagues[322] prospectively evaluated a 2-year database, including 750 mechanically ventilated patients from six ICUs. *Accidental extubation*, but not self-extubation or reintubation after weaning, increased the risk of nosocomial pneumonia. It is essential to recognize that the difficult airway has not been successfully managed until the trachea is safely extubated and reintubation is prevented for at least 48 hours.

IX. CONCLUSIONS

Critical care physicians manage the airway with great efficacy for the vast majority of patients. However, in up to 10% of patients, difficulties in laryngoscopy occur, caused by unfavorable anatomy of face, airway, or cervical spine. Failed intubation can result in life-threatening hypoxia and must be prevented by strict adherence to recent recommendations (ASA algorithm). The main factors for successful emergency airway management are being prepared and having a plan B ready and securing the airway awake when trouble is suspected. Awake airway management using the fiberoptic scope is the most secure technique, leaving the patient's protective reflexes intact and exerting only minor effects on the cardiocirculatory system.

Recognizing the difficult airway situation only after anesthesia induction may result in "cannot intubate, can ventilate" or catastrophic "cannot intubate, cannot ventilate" situations. The latter situation requires immediate intervention (LMA, Combitube, TTJV) or performing a surgical airway (mainly emergency cricothyrotomy). All those techniques must be practiced in routine cases in order to be performed successfully in emergency situations.

Concerning airway management for long-term ventilatory support, tracheostomy is currently popular because of the introduction of percutaneous dilatational tracheostomy into clinical routine. Long-term translaryngeal intubation might cause severe damage to the laryngeal apparatus and trachea (granuloma formation, stenosis). In patients requiring long-term ventilatory support, we recommend tracheostomy between the first and second week on the ventilator, to reduce the incidence of long-term damage to the laryngeal structures. The technique of tracheostomy used depends on physician preference and experience. However, one should be aware that both conventional surgical tracheostomy as well as PDT require training and knowledge and are characterized by distinct learning curves. PDT should only be performed by experienced operators and under continuous fiberoptic control (best using a TV monitor to observe the entire procedure). Complications of long-term airway management are common and have a discernible morbidity.

Therefore, from the decision to intubate until extubation of the patient, we should always keep in mind that *first, do no harm*.

X. CLINICAL PEARLS

- Noninvasive ventilation techniques in the ICU are increasingly used.
- Adequate and proper positioning of patients for airway management is essential.
- A thorough airway assessment should be performed on all patients before any airway intervention.
- Never act before adequate preoxygenation.
- Each intubation could be a difficult intubation; stay attentive.
- Endotracheal intubation remains the gold standard in invasive airway management, but alternate devices (e.g., supraglottic) are potentially live-saving alternatives.
- Medications are often needed, but be prepared for any potential side effects.
- Awake tracheal intubation is an established approach, but skill and experience are required.
- Timing for tracheostomy remains controversial.
- From intubation until extubation of the patient, do no harm.

Chapter 47

Endotracheal Tube and Respiratory Care

THOMAS C. MORT | JEFFREY P. KECK JR. | LEAH MEISTERLING

I. Introduction

II. Properties of the Endotracheal Tube
- A. Anatomy of the Endotracheal Tube
- B. Development and Properties of the Endotracheal Tube
- C. Physiologic Effects of Endotracheal Tube Placement
- D. Complications of Endotracheal Tube Placement

III. Endotracheal Tubes and Other Airway Adjuncts
- A. Choice of Endotracheal Tube Size
  1. Small Tubes and Airway Resistance
  2. Large Tubes and Trauma
- B. Potentially Beneficial Alternatives to the Standard Endotracheal Tube
  1. Preformed and Reinforced Tubes
  2. Laser Tubes
  3. Subglottic Suctioning Evac Endotracheal Tubes
  4. Double-Lumen Endotracheal Tubes
  5. Supraglottic Airways

IV. Proper Safeguarding of the Airway
- A. Airway Evaluation: Predicting the Difficult Airway
- B. Identifying Proper Position of the Endotracheal Tube
  1. Detection of Esophageal Intubation
  2. Confirmation of Appropriate Depth of Insertion
  3. Cuff Pressure Monitoring
  4. Evaluation of an Audible Cuff Leak
  5. Documentation of Placement
- C. Stabilization of the Endotracheal Tube
  1. Taping
  2. Commercially Available Devices
  3. Stapling for Facial Burns
- D. Rapid Response Cart for Airway Emergencies

V. Maintenance of the Endotracheal Tube
- A. Heat and Humidity of Inspired Gas
- B. Suctioning
- C. Subglottic Care
- D. Bronchoscopy
- E. Biofilm Management

VI. Respiratory Therapies for the Intubated Patient
- A. Secretion Clearance and Control Therapies
  1. Mucolytic Agents
  2. Chest Physiotherapy
- B. Overcoming Work of Breathing Imposed by Endotracheal Tubes, Tracheostomy Tubes, and Ventilator Circuits
  1. Pressure Support
  2. Continuous Positive Airway Pressure
  3. Automatic Tube Compensation
- C. Pharmacologic Treatments
  1. Inhalation Drug Delivery
  2. Inhaled Bronchodilators
  3. Anticholinergics
  4. Corticosteroids
  5. Inhaled Antibiotics
- D. Positioning of the Patient

VII. Conclusions

VIII. Clinical Pearls

I. INTRODUCTION

The earliest recorded use of airway manipulation with an artificial device dates back to early Roman civilization when Asclepiades performed a tracheostomy for laryngeal edema. Today it is clear that the role of the endotracheal tube (ETT) in medicine is as invaluable as that of any other medical device created to date. The establishment of a definitive airway via the ETT in both elective and emergency situations has allowed for the delivery of immediate life-sustaining therapies during resuscitation, the maintenance of oxygenation and ventilation in prolonged illness, and the (temporary) delivery of inhaled anesthesia.[1] This chapter begins with a brief history of the development of the ETT. It describes the various ETTs available along with their indications for use and respective limitations. It reviews basic airway anatomy

with regard to ETT placement, proper positioning and stabilization of the ETT, and complications attributed to its use. Finally, it addresses respiratory care of the intubated and mechanically ventilated patient.

II. PROPERTIES OF THE ENDOTRACHEAL TUBE

A. Anatomy of the Endotracheal Tube

Between the time of Asclepiades and the present, ETTs have been constructed of a variety of materials, including reed, brass, and steel. Eventually, in 1917, Magill and Rowbotham manufactured them from rubber for the purpose of administering anesthesia.[2] In 1928, when Guedel and Waters added a protective cuff to prevent aspiration, the modern ETT was born. Rubber, however, had limitations in this application, such as increased stiffness with rising temperature and limited adhesive properties with different polymers, which required the cuffs to be manufactured from the same polymer as the tube.[3] These shortcomings led to the search for alternative materials. In 1967, polyvinyl chloride (PVC) was popularized by Dr. S.A. Leader, and it has since been the material most commonly used. One property that makes PVC attractive is that it provides stiffness to an ETT at room temperature to assist with intubation yet becomes more malleable with the increased temperature in situ. Other properties include the ability to embed radiopaque lines in the material to assist with positioning and recognition on a radiograph. Because it accepts many materials, the addition of an exteriorized inflation line to connect the pilot balloon to the cuff can allow for varied cuff materials. Finally, it simply is much lower in cost than other available materials.[3]

The 15-mm adapter allows for universality between ventilating devices such as a bag-mask ventilation system, anesthesia circuit, or ventilator circuit. The adapter fits ETTs as large as 12 mm internal diameter and as small as 3 mm, thereby providing further commonality among multiple ETTs and ventilating devices. Having one standard size also allows for interchange between devices made for tracheostomies or ETTs. The adapter is removable to allow for passage of intraluminal devices (e.g., bronchoscope, suction catheter) or to allow passage of the ETT via a supraglottic airway device such as a laryngeal mask airway (LMA, LMA North America, San Diego, CA). Adapter removal may facilitate the extraction of extensive biofilm accumulation or mucus plugs. Additionally, some clinicians choose to resize (shorten) the ETT.[4]

The Murphy eye, so named for Peter Murphy, an English anesthetist, is designed to provide an extra (secondary) portal for ventilation should the most distal lumen become opacified by bodily fluids, foreign bodies, or soft tissue prolapse. The most typical manifestation of this phenomenon occurs when the distal lumen abuts soft tissue of the tracheal tree, thereby occluding distal flow, or when secretion build-up occludes the distal opening. However, both native and foreign materials are also capable of creating such a dilemma, including mucus, blood, and foreign bodies. Management of such an obstruction is discussed later in this chapter.

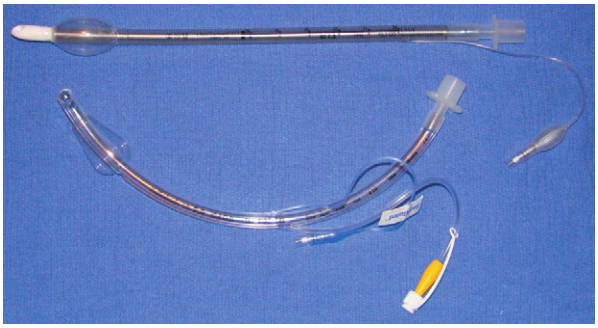

Figure 47-1 Structural comparison of the intubating laryngeal mask airway (ILMA) high-pressure, low-volume (HPLV) cuff *(top)* and a high-volume, low-pressure (HVLP) cuff *(bottom)*. (Courtesy of LMA North America, San Diego, CA.)

The cuffs on the early ETTs were, like the tubes themselves, composed of rubber. The rubber ETT cuffs had limitations such as the need for elevated inflation pressures (high pressure, low volume [HPLV]) to fill the cuff and occlude the airway surrounding the ETT. These high inflation pressures result in the transmission of high lateral pressures to the tracheal wall, albeit in a very minimal contact area, to maintain a seal. The trachea is not circular but rather D–shaped. HPLV cuffs inflate in a circular manner, thereby altering the structure of the trachea; the high pressure exerted on the tracheal wall impairs capillary pressure and possibly results in greater mucosal ischemia.[5] The most commonly used HPLV cuffs in today's practice are the reusable silicone ETTs found with intubating LMAs (ILMAs) (Fig. 47-1). Caution should be exercised when using these ETTs for prolonged periods, given their inherent risk of tracheal mucosal damage. The introduction of PVC-based cuffs reduced this problem because the cuff wall was more supple and thinner, allowing the cuff to accommodate high volume and low pressure (HVLP) and thus providing an adequate seal with lower lateral wall pressures.[3,5,6] The main value of the HVLP cuff is its ability to conform to the irregular borders of the trachea.[7-9] Polyurethane is even thinner and more pliable, with increased tensile strength, allowing for higher volumes, larger contact areas, and minimal mucosal pressures.[10] Foam-based cuffs exist and provide maximal conformation to the tracheal walls, but they do little for the prevention of microaspiration.[9]

Remodeling of the cuff has been particularly driven by the desire to improve prevention of ventilator-associated pneumonia (VAP), and the shape of the cuff has also been altered. The Mallinckrodt TaperGuard Evac ETT (Covidien, Boulder, CO) is a new option that has been demonstrated in randomized, controlled trials to reduce microaspiration by as much as 83%, compared with traditional HVLP barrel shaped cuffs (Fig. 47-2).[8] It is postulated that a barrel-shaped tube tends to wrinkle and fold in an attempt to conform to the tracheal wall, allowing small channels for potential microaspiration, whereas the bulbous, conical shape of the TaperGuard ETT may reduce wrinkling and thus decrease the incidence of microaspiration. Continued work in this area may lead to improved tracheal wall sealing capabilities at safe levels

Figure 47-2 Taperguard endotracheal tube cuff. (Courtesy Covidien, Boulder, CO.)

of pressure while minimizing potential pathways for the translocation of oronasal and gastric secretions, which is thought to be the prime etiologic pathway for VAP.[11]

The pilot balloon of an ETT functions as an indirect volume gauge for the ETT cuff, relative to the amount of air located in the cuff (inflated or deflated). The pilot balloon does not provide information about the absolute volume insufflated or the pressure exerted on the tracheal mucosa. When a pilot balloon fails or is an impediment to an intubation, options are generally limited to a tracheal tube exchange.[12-14] Pilot balloon failures have multiple causes. Shearing along the ETT connection (usually due to contact with dentition), cracked inflation valves (from syringe manipulation or trauma), material aging, and pilot tubing laceration due to biting all cause the ETT cuff to lose air over time.[15-18] Simple techniques have been described to replace a pilot balloon in a variety of clinical situations using equipment readily available in the operating room. Needles or intravenous catheters with stopcocks or claves, epidural clamp connectors, and commercially available repair kits (Fig. 47-3) provide reliable

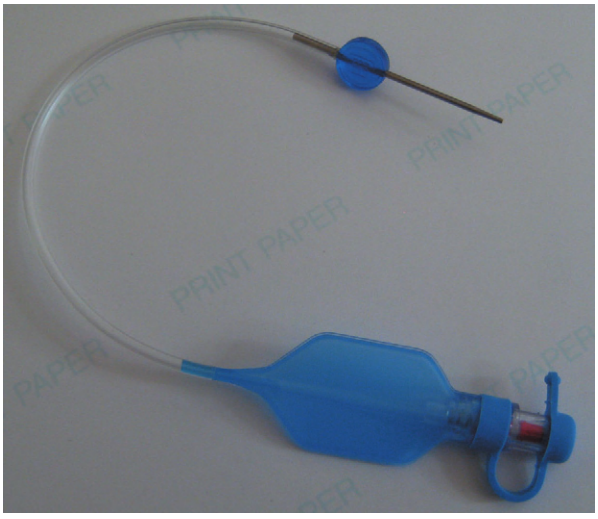

Figure 47-3 Pilot balloon repair device. (Courtesy Instrumentation Industries, Bethel Park, PA.)

substitutions for incompetent pilot balloons when they are connected to the pilot-cuff inflation line.[19,20] The procedure for replacing an incompetent valve is as follows: cut the inflation tube distal to the pilot balloon; insert a needle or intravenous catheter into the cut end (or affix the hub of an epidural catheter to the cut end); and use a stopcock or clave (an item capable of stemming the entrance of air) on the needle or catheter after insufflation, paying careful attention not to overinflate.

B. Development and Properties of the Endotracheal Tube

The purpose of the ETT has always been the same, and it has always had the same inherent problems. Technology continues to advance the standard ETT for improved function and decreased physiologic insult. Rather than compensate for the resistance produced by a rubber or PVC ETT, a newly designed ETT has been produced of ultrathin polyurethane that is reinforced with wire to resist collapsing and kinking. This wire is unique in that it has an elastic shape memory to prevent deformation. The internal diameter is increased without compromising the rigid shape of the ETT. The result is a tube with a resistance similar to that of the upper airway that is lighter, offers less airflow resistance, and, when compressed, forms an egg shape rather than an oval.[21] Experimentally, this new design has been shown to decrease inspiratory and expiratory resistance by 60% each and the inspiratory, expiratory, and total work of breathing (WOB) by 70%, 47%, and 45%, respectively.[22,23]

The use of the ETT continues to expand. No longer is it expected to be simply a conduit for ventilation. As the technology has advanced, the original ETT has steadily been outfitted with a host of successful innovations to improve patient care, whether for convenience or necessity. For example, modifications to the cuff to improve occlusion of the trachea in an effort to prevent microaspiration, coupled with an extra subglottic suctioning port (and other patient care maneuvers), have served to vastly reduce the incidence of VAP.[7-9] Another example is the modification of the surfaces of the ETT to minimize bacterial adhesion and thereby minimize biofilm accumulation.[24] As for bells and whistles, there are ETTs with fiberoptic cameras distally, allowing for ease of placement and the possibility of continued intratracheal surveillance. Another example is the addition of multiple sensors, for so-called bioimpedance cardiography, that are capable of monitoring stroke volume variation, cardiac output, systemic vascular resistance, and arterial pressures (due to the close proximity of the ETT and the aorta) and thereby, at least theoretically, preventing the need for further invasive technologies. Continued study of these modifications may provide justification to adapt these technologies to patient care.

C. Physiologic Effects of Endotracheal Tube Placement

The placement of an ETT, whether oral, nasal, or translaryngeal, is unnatural. Certain physiologic changes occur that must be addressed, including those created by the

ETT itself and those modified by its presence. The properties inherent to the ETT are relatively obvious: it causes a partial obstruction, resulting in a decrease in the normal airway circumference and the possibility of turbulent air flow patterns. Additionally, the narrowed conduit leads to higher pressure relationships with lower flows, possibly leading to damaged mucosa distally. The presence of the ETT is a nidus for the inflammatory cascade. Despite its relatively hypoallergenic profile, it is still a recognizable foreign body and as such triggers well-defined host responses. Placement of the device, regardless of the care used in placing it, still results in mechanical trauma to all of the periglottic mucosalized regions and therefore decreases the ability of the respiratory mucosa to protect itself. Finally, the ETT may cause airway alteration secondary to pressure injury.

The body's response to the ETT is also multifaceted, affecting mechanics, structure, and physiologic function. Loss of humidity and heat is the most obvious effect of replacing the regular mucosa with a foreign conduit. The gas that is delivered is already dry and cool, but bypassing the patient's natural ability to heat and humidify leads to problems more distally, including reduced ciliary function, inspissated secretions, and increased mucus plugging. The normally motile respiratory cilia are essentially paralyzed, leading to impaired secretion management. The body lacks its normal ability to move debris in a proximal direction, and collection sites develop within the tracheobronchial tree, leading to multiple potential areas for infection. Additionally, these partially or completely occluded areas may result in lobar collapse and, consequently, a ventilation-perfusion mismatch. This obstruction can also create an inability to completely exhale, leading to breath stacking and auto-PEEP (positive end-expiratory pressure) and possibly resultant barotrauma.

D. Complications of Endotracheal Tube Placement

Complications associated with ETT placement should be grouped into three major subcategories: those that occur at intubation, those that occur with the ETT in situ, and postextubation sequelae.[25] The problems associated with placement are numerous and can be worsened in emergencies, with multiple attempts, use of a variety of devices, or inexperience of the operator.[26] Problems at placement include dental and oral problems, maxillofacial damage, displacement of the arytenoid cartilages, vocal cord ulceration or dysfunction, airway perforation, autonomic hyperactivity, and, of course, failed intubation. Structural damage is unlikely to be repaired until the patient no longer requires intubation, unless the damage interferes with ventilation and oxygenation. Problems that occur as a result of an in situ ETT include those related to the ETT, such as aspiration, vocal cord paralysis, or transient nerve palsy; ulceration and granuloma formation in the trachea and on the cords; tracheal synechiae; subglottic stenosis; laryngeal webbing; tracheomalacia; tracheoesophageal, tracheoinnominate, or tracheocarotid fistula; and recurrent and superior laryngeal nerve damage.[27] Other complications are related to mechanical ventilation facilitated by the ETT and include aspiration, barotrauma (pneumothorax, pneumomediastinum), VAP, and dislodgement.[28] Finally, postextubation complications can lead to long-term morbidity or the urgent need for reintubation. Many of the postextubation culprits have already been encountered as complications of ETT placement or presence, particularly subglottic stenosis, vocal cord injury, and hoarseness.[28,29]

III. ENDOTRACHEAL TUBES AND OTHER AIRWAY ADJUNCTS

A. Choice of Endotracheal Tube Size

In selecting an ETT, consideration must be given to the functional reason for placement as well as patient-specific factors such as body height, gender, airway integrity, airway pathology, and previous airway manipulation or instrumentation. Theoretically, short-term placement for anesthesia should be different than placement for prolonged support with mechanical ventilation or for fiberoptic bronchoscopy to aid therapy. Generally, the trachea of an adult female accepts a tube of 7.5 to 8.0 mm and that of a male accepts one of 8.5 to 9.0 mm, but typically a 7.0-mm ETT is used for females and an 8.0-mm tube for males, at least in the United States. It is also generally accepted that an ETT of at least 8.0 mm is needed for competent use of an adult-based bronchoscopic investigation.[30]

1. Small Tubes and Airway Resistance

The physics of laminar gas flow through a conduit are described by the Hagen-Poiseuille equation, which reflects the relationship of resistance varying inversely with the fourth power of tube radius. Despite the fact that gas flow through ETTs is often turbulent rather than laminar, the effect on resistance to gas flow represented by each millimeter decrease in tube size is considerable, ranging from 25% to 100%.[31] Airway resistance is affected by more than tube diameter: the presence of secretion within the tube, ETT kinking, and positioning of the head and neck can also increase the tendency for turbulent flow.[32,33] The fundamental principle of which to be mindful is that airway resistance induced by an ETT is inversely proportional to the tube size—hence, the mantra that the largest tube is usually the best size.[34]

Airway resistance increases with decreasing ETT diameter, whether due to internal occlusion, smaller size, or external compression. As airway resistance increases, WOB also increases.[31] The increase in WOB associated with a 1-mm reduction in ETT diameter varies in accordance with tidal volume and respiratory rate at a given minute ventilation and can range from 34% to 154%.[31] When ventilation is controlled, the increase in WOB related to ETT resistance is seldom of any consequence, because it is overcome by ventilator adjustments. However, small-diameter tubes create greater difficulty for patients in weaning from ventilatory support due to the higher levels of resistance encountered when attempting to breathe spontaneously.[35,36] It has been suggested that an inability to spontaneously ventilate due to the increased WOB imposed by a 7-mm ETT might indicate that extubation will fail regardless of tube size.[37,38]

Increased airway resistance associated with a smaller-diameter ETT may also be associated with inadvertent PEEP. Patients with high oxygen consumption, increased carbon dioxide production, or ventilation-perfusion relationships that produce high dead space ventilation often require higher minute ventilations to achieve appropriate ventilation and oxygenation. The gas flows necessary to maintain such a minute ventilation are also quite high, and the resistance imposed by a smaller-diameter ETT further prohibits the completion of expiratory flow before initiation of the subsequent inspiration. This breath stacking results in air trapping and unwanted PEEP, magnifying the risk of mechanical ventilation because barotrauma and subsequent intrathoracic overpressure could result in circulatory compromise.[39]

The restriction to gas flow through any ETT increases dramatically when devices such as a suction catheter or bronchoscope are placed in the lumen. The cross-sectional area of the tube is effectively reduced by an amount equal to the cross-sectional area of the device inserted into the tube. The limitation of gas flow has consequences for both the inspiratory and expiratory phases: inspiratory flow may be inadequate to maintain oxygenation and ventilation during the procedure, and retarded expiratory flow may lead to overdistention resulting in barotrauma or circulatory compromise.[40]

2. Large Tubes and Trauma

Whereas smaller-diameter ETTs have disadvantages related to gas flow and airway resistance, larger tubes are more frequently associated with traumatic placements and damage to both the laryngeal structures and the tracheal mucosa.[37,38,41] Larger ETTs are associated with a higher incidence of sore throat after general anesthesia, compared with smaller-diameter tubes, but this difference is relatively negligible with long-term intubation.[42] With prolonged intubation, laryngeal trauma is more likely. Women, because of the inherently smaller size of their airway, are more susceptible to injury than men.[43,44]

Laryngeal structures at particular risk for trauma are the arytenoid cartilages and the cricoid cartilage. Trauma results not only from the shape discrepancy between the round ETT and the angular, wedge-shaped glottic opening but also from direct contact and pressure on these structures and from repetitive tube movement, which leads to ulceration or erosion of the protective mucosa.[44-46] Tracheal mucosal injury can also occur because of the irregular surfaces created by wrinkling and folding of the ETT cuff or the externalized pilot tube used to fill the ETT cuff. If the tracheal lumen is "overcrowded," airway injury is more likely to occur when large tubes are used and little cuff volume is required to seal the airway.[47]

B. Potentially Beneficial Alternatives to the Standard Endotracheal Tube

1. Preformed and Reinforced Tubes

Modifications to the ETT that are made in the operating room setting to accomplish specific surgeries are often developed in response to interference and access issues. The ability to work without disturbing the ETT has led to several variations of the ETT that can be placed safely and remove the risk of inadvertent advancement, dislodgement, kinking, or obstruction. ETTs used in remote locations also have airway access issues associated with tube kinking and partial occlusion, which typically are related to positioning problems and associated comorbidities. In part because of less stringent vigilance, unintended consequences of ETT use outside the operating room may result in more drastic outcomes. In response to these dilemmas, a variety of tubes have been developed to maintain their shape and patency in locations where distortion might cause kinking and occlusion.

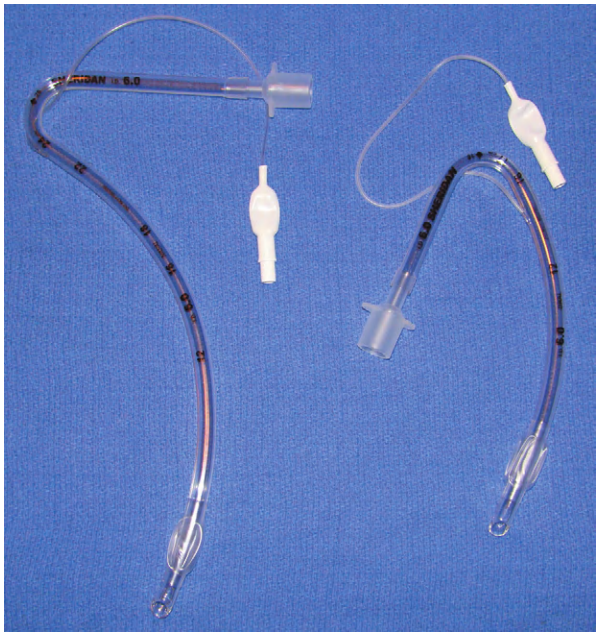

Figure 47-4 Nasal *(left)* and oral *(right)* Ring-Adair-Elwyn (RAE) preformed endotracheal tubes. (Courtesy Covidien, Mansfield, MA.)

Rigid, preformed tubes such as those developed for long-term use in tracheostomy were known to maintain their patency despite the need for angulation. Preformed tubes have been developed for specific application in anesthesia practice as well. The Ring-Adair-Elwyn (RAE) tubes (Mallinckrodt Inc., Pleasanton, CA), both oral and nasal (Fig. 47-4), maintain a fixed contour similar to the average facial profile, allowing for head and neck surgery while minimizing surgical field interference. Their contour also reduces the risk of pressure injury to the posterior pharynx when repositioning is desired. The intra-airway length is tied to the size of the ETT, with a relatively appropriate depth based on the average size of a patient for whom the tube might be selected.[48,49]

An anode or armored tube with an embedded wire coil is designed to minimize kinking even with quite severe position-induced angulation. Armored tubes are popular for use in head and neck surgery where remote airway access and the potential for kinking of the ETT are concerns. Placement of an armored tube through a tracheostomy for procedures such as laryngectomy is a common practice; it allows placement during surgical procedures such that the tube can be mobilized or the circuit draped away from the field without a high risk of tube kinking. The other common use of a wire-reinforced tube is with the ILMA. These tubes are designed to

facilitate placement through the device and to be used for short periods of time. The HPLV cuff and the theoretical possibility of kinking and resultant airway obstruction make the long-term use of ILMAs risky.

The embedded wire concept of the armored ETT has also been developed for long-term tracheostomy use. Although the armored tracheostomy tube is not free of risks, one advantage is that its flexibility allows its length and intratracheal depth to be adjusted, which may be beneficial if tracheomalacia at the level of the cuff develops.[50] These tracheostomy tubes are also popular for use in morbidly obese patients, in whom, because of the depth of tissue, preformed tracheostomy tubes may not have the shape required to fit an individual patient. One major consequence of this type of reinforced ETT may occur when external pressure is applied to the wire-reinforced component (i.e., by patient biting). Once a compression threshold is reached, the luminal support provided by the wire may be compromised, and a permanent, irreparable dent remains that can significantly endanger ventilation and suctioning capabilities.

2. Laser Tubes

Progress in laser technology has advanced surgical capabilities, particularly for airway surgery. To protect patients and health care providers from laser-induced injury to eyes and airways, special precautions are required. Fire is the most serious danger associated with the use of lasers in the operating room, especially when a laser is used in airway surgery.[30,51-53] A major complication related to the use of lasers for laryngeal surgery is ignition of the ETT.[54] The laser beam may ignite the tube by direct penetration or indirectly if burning tissue is inhaled into the tube.[30,51,52,55] The ease of ignition is related to the ETT material, the concentration of oxygen in use, and any other adjunctive materials or gases that could support combustion.[30,52,55] Most ETTs are constructed of PVC, which is highly flammable. Ideally, PVC tubes should not be used for airways when a laser is employed.[51,55,56]

ETTs can be laser-proofed or protected from the laser beam by wrapping them with either reflective metal tape or muslin. Ideally, they should be constructed from noncombustible materials. In particular, the ETT cuff is vulnerable to puncture by the laser beam and should be filled with saline or water, which allows more energy to be absorbed before disruption.[30,52,55] One trick to enhance appreciation of a penetrated, defective cuff, is to place a dye indicator, such as methylene blue, into the solution that is instilled into the cuff. Any leakage will clearly mark the airway and alert the provider to the potential dangers.[57] Protecting the tube from the laser beam by wrapping it with a foil tape has proved effective (commercial devices are available) (Fig. 47-5).[58] Tubes made of materials such as metal and silicone and those with special double cuffs also reduce the risk of airway fires and injury during laser airway surgery.[51,58]

3. Subglottic Suctioning Evac Endotracheal Tubes

Hospitalized patients who require mechanical ventilation are susceptible to the development of aspiration pneumonia. VAP is known to increase hospital length of stay, health care costs, and mortality.[59] Organisms that grow in pooled subglottic secretions above the inflated cuff of the ETT, but beneath the glottis, have previously been unmeasurable with any reliability and are now demonstrated to be a major impetus for VAP. Several nursing care measures may be taken to reduce the incidence of VAP caused by this route, including improved oral care, patient positioning by elevating the head of the bed past 30 degrees, frequent suctioning, and ensuring postpyloric tube feedings, but none of these measures completely stops the production.[60]

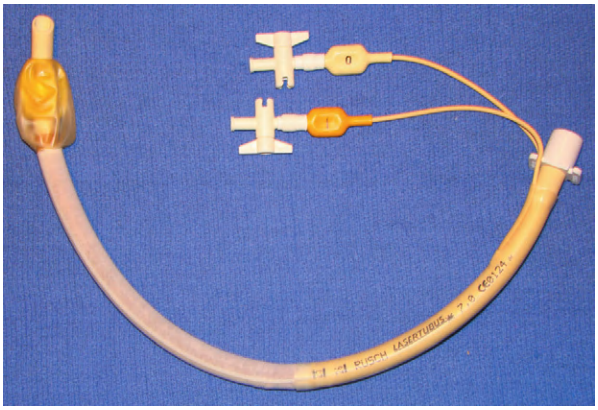

Figure 47-5 Rusch Lasertubus laser-safe endotracheal tube. (Courtesy Teleflex Medical, Durham, NC.)

The presence of these pooled collections has led to the development of specific ETTs that possess a dedicated suction system capable of emptying this area of debris. Drainage of subglottic secretions has been shown to prevent VAP.[61-64] The currently available subglottic drainage ETTs have a suction lumen that opens on the external (posterolateral) surface of the ETT immediately above the cuff (Fig. 47-6). The lumen is attached to constant or intermittent suction for active drainage of the space. Although these ETTs are beneficial, their efficacy is not 100%, and therefore all of the aforementioned nursing care actions remain vital to good hygiene and prevention of VAP. The subglottic drainage tubes have been further developed to include variations in cuff construction (materials, shapes, volumes, locations) that help to prevent aspiration of the subglottic debris.

Subglottic secretions are not the only recognized cause for VAP. Biofilm is an accumulation of debris adhered to the internal circumference of the ETT that is composed of tissue, secretions, mucus, and undetermined bacteria load. Biofilm can be aspirated, leading to a nidus for infection or causing an area of obstruction to airflow. Biofilm removal and reduction by hygiene care are currently

better researched than prevention. However, there is a growing interest in the reduction of biofilm through construction of ETTs impregnated with antimicrobial agents.[65-67] The ability of such developments to affect the incidence of VAP has not yet been proved.

4. Double-Lumen Endotracheal Tubes

The uses of a double-lumen endotracheal tube (DLT) (Fig. 47-7) can be separated into relative and absolute indications. The absolute indications are isolation, to avoid soilage or contamination of the contralateral lung tissue when dealing with infections or frank hemoptysis from a unilateral location, bronchoalveolar lavage, and one-lung ventilation (OLV). The most common reason for placement is OLV for surgical exposure, but OLV can also be important in cases of bronchopleural or bronchocutaneous fistula, unilateral pulmonary hemorrhage, giant unilateral bulla or cyst, and severe unilateral ventilation-perfusion mismatch. The relative indications all deal with surgical exposure. Complementing the DLT as another option for lung isolation, particularly if a DLT cannot be placed, are bronchial blocking devices. However, the DLT has an advantage because of the ability to pass suctioning catheters or fiberoptic devices into the area on collapse without drastically jeopardizing OLV or contaminating the contralateral side.

Relative contraindications to the placement of a DLT are fairly minimal. They include patient refusal (likely due to risk of trauma secondary to the large size), a known difficult airway, and the speed with which an isolated airway must be established. In patients with difficult airways, specially designed airway exchange catheters (Cook Medical, Bloomington, IN) (Fig. 47-8) can be used after placement of a conventional ETT to facilitate DLT placement. Additionally, some makers of video laryngoscopic technologies have developed specific DLT devices. The time required for placement is usually the biggest detractor to their use. Situations such as frank hemoptysis may be better served by a rapid-sequence induction and placement of a contralateral, main stem, single-lumen ETT for stabilization.

This technique is not ideal for long-term management. The long-term use of the DLT in the intensive care unit (ICU) setting (>24 to 48 hours) must be approached with caution, because the two smaller-diameter lumens are at significantly increased risk for partial or complete occlusion. Consideration should be given to close monitoring of luminal patency with fiberoptic evaluation on a regular basis and optimization of luminal hygiene to reduce mucus or biofilm accumulation.

5. Supraglottic Airways

Supraglottic devices are continually coming onto the market. Largely designed for shorter surgical procedures to deliver general anesthesia, their use seems to be growing past their original intent. Supraglottic airways (Fig. 47-9) such as the LMA, the esophageal-tracheal Combitube (ETC, Tyco Healthcare, Mansfield, MA), the King LT (King Systems, Noblesville, IN), and other variants have provided valuable means of establishing an (unsecured) airway in an emergency. Equally important is their ability to function as a conduit for endotracheal intubation. For example, the ILMA is a blind passage

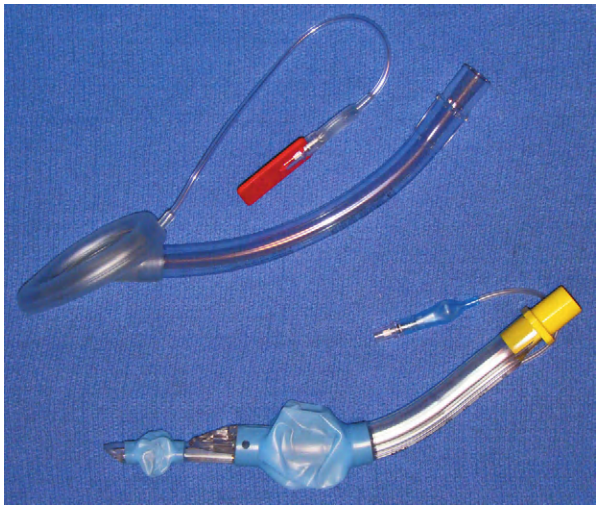

Figure 47-9 Supraglottic devices. LMA Unique *(top)*, (Courtesy USA) King LT Supraglottic Device *(bottom)*. (LMA Unique courtesy LMA North America Inc., San Diego, CA; King LT courtesy King Systems, Noblesville, IN.)

device that is designed to place an ETT through the LMA. Recently, use of the LMA as a conduit for fiberoptic bronchoscopy and subsequent ETT placement has also been demonstrated in emergency situations.[68] Although these devices do not provide classically definitive airways, their utility is unsurpassed in helping to manage the difficult airway.

IV. PROPER SAFEGUARDING OF THE AIRWAY

A. Airway Evaluation: Predicting the Difficult Airway

The decision to intubate, whether for airway protection, ventilatory failure, inadequate oxygenation, or medication delivery, is often difficult, but equally difficult can be the decision of how to intubate. Each patient and airway is unique, as is the clinical setting and the judgment, skill, and equipment of the airway team that responds. Outside the operating room, time often does not allow a comprehensive evaluation and establishment of a plan complete with contingencies before the decision to intubate must be made. Performance of a proper airway evaluation before intubation is attempted can dramatically improve outcomes.

However, a difficult airway should be assumed when one approaches the patient outside the controlled setting of the operating room. An airway physical examination is paramount to predicting a successful attempt. Criteria such as dental status, mouth opening, thyromental distance, cervical range of motion, Mallampati score, and neck circumference are all standard examination points. However, the emergent intubation presents a host of new, potentially detrimental issues not seen in operating room intubations. For example, hemodynamics may not allow for the controlled process typically seen in the operating room. Trauma patients may have actively unstable facial fractures or cervical vertebral injuries that merit inline stabilization and modified techniques for tube placement. Neurosurgical patients may have external fixators to stabilize injuries or intracranial monitoring devices that make it difficult to position the head. The type of bed a patient is in can also create access issues with intubation. A bariatric bed with an inflatable mattress can be very difficult to properly ramp, thereby making positioning suboptimal. Last, but not least, is the patient with failed extubation who must be reintubated. Issues with anxiety, hypoxemia, decreased functional residual and closing capacities, copious secretions, residual airway edema, and subglottic stenosis all make a repeat attempt more difficult than the first pass.[28]

B. Identifying Proper Position of the Endotracheal Tube

1. Detection of Esophageal Intubation

Once the clinician has deemed intubation necessary and has performed the intervention, confirmation of proper ET placement must be provided expeditiously. An incorrectly positioned ETT can produce adverse effects, especially in an already apneic patient. Unrecognized esophageal intubation can have disastrous consequences with a reported incidence as high as 8% in critical patients.[69] Therefore, a brief discussion of verification of ETT placement is warranted.

Once intubation has been accomplished, confirmation of proper placement of the ETT in the trachea needs to be achieved, ideally by the detection of end-tidal carbon dioxide (Et_{CO_2}) in expired gases using capnography or other capnometric (colorimetric) methods.[70] The detection of Et_{CO_2} is not fail-safe and does not guarantee that the ETT is positioned within the tracheal lumen (e.g., the tip may lie above the vocal cords). After three to five breaths, the absence of Et_{CO_2} suggests a nontracheal placement. Blockage or soilage of the Et_{CO_2} detection device can hamper efforts. Et_{CO_2} detection should be complemented with indirect maneuvers such as auscultation, ETT misting or fogging, bag compliance, chest wall excursions, lack of phonation, and improved oxygen saturation. The dependence of any Et_{CO_2} detection device on adequate cardiac output has spurred utilization of an esophageal detector device (Fig. 47-10). It is essentially an air-filled bulb placed on the end of an in situ ETT. After a vacuum has been created by squeezing the bulb, immediate re-expansion should occur when the bulb is placed on an ETT in the trachea (any column of air). If the ETT is esophageal, the suction created by the bulb will draw the pliable esophageal tissue into the distal lumen of the ETT, preventing full expansion of the bulb on top of the ETT (column of soft tissue).[71-73]

If intubation is to occur in a patient with cardiac arrest, capnometry may be fallible given the amount of down time and the lack of any life-sustaining cardiac output. If cardiopulmonary resuscitation (CPR) is adequate, this technicality is likely to be moot. However, esophageal bulb detectors can be helpful in this situation, although false-positives and false-negatives do occur and confound ETT verification. Still other methods that are independent of carbon dioxide and cardiac output exist, such as a tracheal whistle to verify correct placement (Box 47-1), but not one is without limitations.[72-77] Ideally, two methods are to be considered fail-safe: direct or indirect visualization of the ETT traversing the vocal cords and fiberoptic verification via the ETT lumen. The limitation of direct laryngoscopy is the operator's line of sight to the glottic opening. The key is to identify the ETT

Figure 47-10 Esophageal bulb detector and a homemade syringe device. (Courtesy Wolfe-Tory Medical, Inc.)

Box 47-1 Methods Used to Verify Endotracheal Tube Placement

- Sustainable, exhaled CO_2 by capnography or colorimetric methods
- Fiberoptic visualization of carina
- Videolaryngoscopic visualization of translaryngeal endotracheal tube position
- Direct laryngoscopic visualization of translaryngeal position
- Positive response with esophageal bulb detector device or syringe method
- Auscultation of breath sounds in bilateral lung fields and absence of same in epigastric area
- Visualization of chest wall movement with spontaneous patient efforts
- Reservoir bag synchrony with spontaneous patient efforts
- Palpable ballottement of cuff in suprasternal notch
- Acoustic reflectometry
- Transtracheal illumination
- Chest roentgenogram
- Condensation in endotracheal tube
- Lack of phonation in the nonparalyzed, semiconscious patient
- Bougie passage to distinguish between tracheobronchial tree and esophagus

positioned in the glottis, not simply to see it go in. An indirect method such as video laryngoscopy does improve the validity of ETT passage. Fiberoptic verification is hampered by equipment availability at the bedside, any airway or ETT soilage, time constraints, and operator skill. Chest rise and condensation from expired gas found in the ETT have also been used, but these signs may occur in esophageal intubations as well.[77] Therefore, the gold standard used today is the presence of $Etco_2$ in expired gases as demonstrated by capnography or other colorimetric techniques.[70]

Capnography yields quantifiable measurements of inspired and expired gases in addition to a waveform generated with each tidal volume. Although not without limitations (e.g., lack of portability, need for a power source), capnography reliably identifies initial proper placement of the ETT (nonesophageal) and provides a continuous verification of ETT security. If esophageal intubation has occurred, a gradual reduction in height of the capnograph waveforms is observed with successive breaths. False-positive results during esophageal intubations may occur in situations of ingested CO_2-containing or -liberating substances (e.g., carbonated beverages) before intubation, bag-mask ventilation with inflation of expired air into the stomach, or intubation of the supralaryngeal hypopharynx.[78] Inappropriate extubations may occur due to misinterpretation of a false-negative situation because an $Etco_2$ waveform is lacking despite proper placement. This error may occur with unrecognized circuit disconnections, an obstructed or kinked ETT, a disconnected or contaminated gas sampling line (water, secretions, entrainment of room air), equipment failure, severe bronchospasm, or inadequate cardiac output. Unquestionably, capnography is dependent on pulmonary blood flow. In the absence of perfusion (e.g., cardiac arrest), the utility of capnography can be limited; however, even in very low-flow states (e.g., CPR, separation from cardiopulmonary bypass), it has been shown to provide effective detection. Ornato and colleagues used an animal model to evaluate the relationship between cardiac output (CO) and $Etco_2$. Through manipulation of CO, with inotropes or controlled hemorrhage, a logarithmic relationship between CO and $Etco_2$ was demonstrated.[50] This finding shows that capnography is useful in cardiac resuscitation to assist with evaluation of low-flow states and adequacy of perfusion.

Figure 47-11 Example of a colorimetric capnometric device. (Courtesy Mercury Medical, Clearwater, FL.)

To alleviate the logistic concerns with capnography in emergency situations—mainly the lack of portability and the need for a power source—a portable and reliable means of detecting $Etco_2$ was developed. Colorimetric $Etco_2$ uses a detector impregnated with metacresol purple (Fig. 47-11). This indicator is pH sensitive and changes color, from purple to yellow, in the presence of CO_2. The devices are disposable, attach between the ETT and the circuit or bag, and provide a rapid and reliable indication of CO_2 concentration on a graded scale: A (purple) corresponds to an $Etco_2$ level of 0.5%, B (tan) to a level of 0.5% to 2%, and C (yellow) to a level greater than 2%.[70,77] Limitations of this method are that it is ineffective with exposure to humidified gases, vomitus, or secretions and in cases of prolonged cardiac arrest or low-perfusion states. False-positive results can occur as well, just as in capnography. Delays in recognition of esophageal intubation with colorimetric capnometry have been reported far more often than with capnography, particularly in patients with prolonged bag-mask ventilation or ingestion of $Etco_2$-containing substances before intubation. Therefore, capnography simply is the best method for detection of esophageal intubation.[79]

As mentioned previously, the esophageal bulb detector capitalizes on the physical characteristics of the esophagus, which, unlike the trachea, collapses when negative pressure is applied. Commercial devices exist, but a homemade version can be improvised using a syringe that attaches to the end of the ETT. When the plunger is withdrawn, resistance is appreciated if an esophageal intubation has occurred, because the walls of the esophagus collapse around the ETT. Unencumbered aspiration of the plunger occurs with proper tracheal placement.[71] Bulb detector devices are reported to be reliable and effective, with one study demonstrating a sensitivity of 100% and a specificity of 99%.[72] However, other studies have reported limitations and false-negative results in patients with copious or aspirated secretions, gastric distention, vomitus in the airway, morbid obesity, or reduced functional residual capacity.[71,80-83]

A little used but highly effective method of detecting proper ETT location is the passage of a catheter (e.g., bougie) via the ETT to decipher a straight smooth muscle pathway (esophagus without pathology) or a more rigid, angulated tube with reduction in the luminal diameter (tracheobronchial tree). A bougie can be used in this fashion, particularly at the time it is being used as an adjunct to intubation, or later if necessary. Gentle advancement to 28 to 34 cm (in adults) typically results in contact with the carina or a main stem bronchus. Further advancement down a main stem bronchus should be limited by the secondary lobar carina. Gentle unopposed advancement of the bougie beyond 35 cm suggests esophageal placement (assuming no esophageal pathology).

2. Confirmation of Appropriate Depth of Insertion

After correct tracheal placement of the ETT has been verified, it is imperative to identify the correct depth of the ETT to ensure adequate ventilation of each lung.[49] Before addressing the various methods that assist in confirmation of appropriate ETT depth, a brief discussion of what is considered to be the correct depth is warranted. Malpositioning of ETTs occurs frequently, with unrecognized right main stem intubation occurring in approximately 4% of chest radiographs.[49,69,84] The generally accepted depth of insertion of the ETT is between 2 and 7 cm above the carina, optimally between 4 and 7 cm above the carina with the head and neck in a neutral position.[49,77,85-87] It is important to realize this, because flexion-extension movements of the neck can displace the ETT upward or downward with resultant extubation or main stem intubation, respectively. Typically the right main stem bronchus is entered, given its straighter trajectory in relation to the trachea. If endobronchial intubation remains undetected, an inadvertent hyperinflation of the ipsilateral lung can occur with subsequent pneumothorax and concomitant atelectasis of the hypoventilated contralateral lung. Indeed, it has been reported that up to 15% of chest radiographs reveal malpositioned ETTs in intubated patients.[84,88,89] This is more frequently seen after difficult airway management.

In the operating room, chest radiographs are not used to confirm proper position; rather, indirect clinical assessment methods are used (i.e., auscultation of bilateral breath sounds, visualization of equal chest expansion, and direct visualization of the ETT tip placed just below the vocal cords). The ETT is also manufactured with distance measurements to aid with the depth of insertion. In orally intubated patients, a depth of 23 cm at the teeth or corner of the mouth has been advocated for men and 21 to 22 cm for women.[90,91] In nasotracheal intubations, a depth of 26 cm at the nares in women and 28 cm in men should be sufficient for proper tracheal position.[92] Other methods used include direct visualization of the ETT tip in reference to the carina with a fiberoptic scope or catheter,[69] transtracheal illumination, and ballottement of the ETT cuff in the suprasternal notch.[93-96]

3. Cuff Pressure Monitoring

Probably the most often overlooked parameter in daily airway care is cuff pressure.[97,98] Almost universally, this measurement is neglected in operating room intubations. However, it is well documented that excessive forces applied to the tracheal mucosa can cause necrosis and ulceration.[9,99,100] Cuff pressures of 30 cm H_2O for 4 hours have been shown to damage ciliary motility for at least 3 days.[100-102] In addition, animal studies have revealed diminished circulation in the tracheal mucosa with a pressure of just 20 cm H_2O, exaggerated greatly in the presence of hypotension.[103]

Normal occlusive pressures should be between 20 and 30 cm H_2O to avoid complications while maintaining an adequate seal in the tracheal lumen circumferentially around the cuff to prevent microaspiration and ultimately VAP.[100] Depending on the type of cuff used, the same pressure range seems to be effective at accomplishing this task both in vitro and during in vivo animal studies. For example, standardized HVLP cuffs have been demonstrated to be ineffective at preventing microaspiration with pressures as high as 60 cm H_2O,[7] whereas polyurethane tubes seem to be effective down to 15 cm H_2O.[7,10,104]

As was previously discussed, ETTs are not without risks. However, it appears that most of the morbidity is related to either inappropriate inflation of an ETT cuff or a defective ETT cuff.[98-100] An often dreaded scenario that leads to increased morbidity is frequent ETT exchanges for suspected cuff leaks. Trended values for cuff pressure could help to alleviate some of these unnecessary procedures. Most importantly, it has been demonstrated that manual palpation of the cuff or instillation of a standard volume of air often underestimates the actual occlusive pressure delivered, leading to unrecognized complications.[97,98,100] Therefore, it is recommended that frequent examination of the cuff pressure be documented and trended using manometry.

Reusable aneroid manometers can be onerous to calibrate and are often difficult to locate; in addition, they pose a recurring risk of cross-contamination for each patient. The manometers currently in use in most ICUs provide only a single data point at the time of collection. A commercially available disposable, precalibrated device that constantly measures airway cuff pressures is available. The PressureEasy device (Smiths Medical, St. Paul, MN), among others, attaches to the pilot balloon and exhibits a mark in a fixed window when the measured

Figure 47-12 Posey Cufflator aneroid manometer *(left)* and the PressureEasy Pressure Controller Device *(right)* for monitoring endotracheal tube cuff pressure. (Cufflator courtesy Posey Company, Arcadia, CA; PressureEasy courtesy Smiths Medical, Dublin, OH.)

cuff pressure is in the optimal range of 20 and 30 cm H_2O (Fig. 47-12).[97-100]

4. Evaluation of an Audible Cuff Leak

Although ETT cuff leaks pertain most often to the ICU or postanesthesia care unit (PACU) setting and longer-duration intubations, short-term tracheal intubation in the operating room may also fall prey to an apparent leak. The most relevant question is, When is a cuff leak really a cuff leak? The audible leak implies that air is escaping from the presumably closed ETT system. The leak may be caused by a defective ETT cuff that has failed, ripped, or is microperforated (in which case the pilot balloon deflates spontaneously). Equally possible is a defective pilot balloon–line assembly. The valve on the pilot balloon may be faulty and incompetent, the balloon may have a perforation, the line may be cracked or broken or may become disjointed at the tube end or the valve end. Moreover, the intermittent or continuous audible leak may represent an ETT cuff that fails to seal the airway due to malpositioning, deranged shape, or laxity and deformation of the tracheal wall (e.g., tracheomalacia, tracheitis, tracheal erosion). The ETT cuff (intact pilot balloon) may be subglottic, between the vocal cords, or supraglottic, having been displaced during patient movement, transport, repositioning, "tonguing" (dislodging the ETT by moving it with the tongue) of the ETT, excessive coughing, excessive tension on the ETT by the ventilator circuit, or, commonly, positioning for radiography. Once the ETT is partially displaced upward, an audible leak may prompt further ETT cuff insufflation, leading to further displacement. Head and neck movement by the patient may be all that is required to further displace the ETT into the hypopharyngeal region. This must be diagnosed before disaster strikes.

The various sources of a suspected cuff leak require investigation because each necessitates a different solution. Any one solution, incorrectly applied, may lead to morbidity or mortality. For example, a cuff leak resulting from a herniated cuff above the vocal cords may prompt the team to order a chest radiograph. Further displacement may take place during lifting and repositioning of the patient for the examination. Conversely, if an ETT is malpositioned in the hypopharynx (intact pilot balloon) but is assumed to be a properly positioned ETT with a cuff perforation, an exchange catheter passed via the ETT (presumably into the trachea) may exit the supraglottic ETT and enter the esophagus, leading to airway compromise. Table 47-1 highlights the possible causes and potential solutions, with relevant risk assessments for an apparent cuff leak evaluation.

5. Documentation of Placement

Clinicians who care for patients who are intubated for long periods in the ICU may find it onerous to obtain pertinent airway management details. This can be especially detrimental to future care providers who are faced with a patient with a known or suspected difficult airway. This situation could result for a number of reasons: lack of relevance (routine intubation before the patient's surgery), lack of continuity (the intubator is no longer involved in the patient's care), or an incomplete or total lack of documentation.

As an ICU course progresses, the details surrounding the original ETT placement may prove less relevant

TABLE 47-1

Causes and Solutions for Apparent ETT Cuff Leaks

Problem	Solution	Risk Level
Cuff perforation (pilot balloon deflation)	Exchange ETT (only feasible choice)	High
Incompetent pilot valve	Exchange ETT	High
	Clamp line (Kelly, hemostat)—short term solution	Low
	Place stopcock or cap on valve	Low
	Replace pilot balloon–line assembly	Low
Broken pilot line	Exchange ETT	High
	Clamp line (Kelly, hemostat)—short-term solution	Low
	Replace pilot balloon line assembly (homemade vs. commercial)	Low
Displaced ETT (intact pilot balloon)	Perform fiberoptic evaluation—diagnostic	Low-moderate
	Blindly advance ETT	Very high
	Videolaryngoscopy evaluation	Low-moderate
	Blindly pass airway exchange catheter	High
	Perform direct laryngoscopy (suboptimal line of sight)	Low-moderate

ETT, Endotracheal tube.

because the patient's clinical status and airway are dynamic, not static. A previously easy airway may remain so, but difficulty often increases as edema, trauma, secretion management, and patient status decline to confound an airway intervention. Anatomic abnormalities may be hidden or exaggerated by excessive fluid administration or a capillary leakage phenomenon in the critically ill patient, and examination of the airway may become impossible. Appreciation of the airway adjuncts that have been attempted is imperative for the incoming airway team. Immediate availability of pertinent historical airway management details may prove helpful in delivering better care. Documentation of airway interventions and procedures on a specific sheet (Fig. 47-13) may provide the incoming airway team perspective on what to expect in a single concise location.

C. Stabilization of the Endotracheal Tube

After verification and confirmation of proper tracheal placement and position have been achieved, care should be focused on securing the ETT in its proper position, and frequent assessments should be made to recognize malpositioning.[105,106]

At the most basic level, recording and confirming the depth of the ETT at the patient's teeth or lips in centimeters should be routine. This measurement should be documented on the respiratory care flow sheet. In patients requiring prolonged mechanical ventilation, the depth should be assessed and documented frequently (e.g., every shift, every 4 hours), along with clinical assessments of ETT patency and hygiene, appropriate chest expansion, and auscultation findings.

Securing and surveillance of the ETT are important not only to ensure proper depth and positioning but also to reduce the incidence of inadvertent extubation.[105] Unplanned extubation is primarily a problem in the ICU. It has a reported incidence of approximately 2% to 16%, with 80% of those extubated requiring reintubation, and contributes to a higher rate of airway-related complications, hemodynamic alterations, patient morbidity, and mortality.[48,107-109] The most frequently identified cause is inadequate sedation of a mechanically ventilated patient, and only a few studies have specifically addressed techniques used to secure ETTs. In a study comparing four such techniques, Levy and Griego concluded that the use of simple adhesive tape split at both ends and secured to both the ETT and patient's face was more effective than proprietary methods and allowed more effective nursing care, improved oral hygiene, and greater comfort for the patient.[106] However, Barnason and colleagues found no statistical difference between two methods studied in preventing unplanned extubation, allowing oral hygiene, or maintaining facial skin integrity.[110]

Attention to proper ETT stabilization primarily focuses on the reduction of unplanned extubation, improved comfort for the patient with prolonged ventilatory requirements, minimization of iatrogenic complications related to the method of fixture, and ease of nursing and respiratory care. One study addressed massive air leaks and contributing factors. The authors defined a massive air leak as one that requires extubation. Over a 2-year period, 18 ETTs were removed for massive air leaks, of which 61% were found to be free of mechanical defects (intact cuff). Fourteen of the 18 patients required reintubation; 2 of them aspirated gastric contents on replacement, and 1 suffered severe epistaxis from a blind nasal reintubation, resulting in a 21% complication rate.[111] The authors concluded that malpositioning was the most plausible explanation for the apparent air leaks. This study reinforces the importance of securing the ETT and daily vigilance to ensure that proper depth and positioning are confirmed and maintained.

Despite these studies, no consensus exists concerning the best method of securing the ETT.

1. Taping

The classically described methods are a "barber's pole" technique for operating room intubations , a simple split tape technique (Fig. 47-14), and a more secure "four-point" technique for intubations anticipated to last for 24 hours or longer. In each of these methods, tape is used to anchor the ETT to the face. Moisture, in the form of sweat, secretions, or vomitus, can jeopardize the integrity of the bond between adhesive and skin, putting the security of the ETT at risk.[105] Additionally, patient comfort is an issue when tape is used for this purpose. Skin breakdown due to allergic reactions, pressure necrosis, or repetitive trauma has been documented as a potential problem from the use of this method. The four-point method is more secure than the barber's pole technique because the tape encircles the patient's head and is not as susceptible to moisture because it is anchored to itself as well as to the patient's skin.

2. Commercially Available Devices

Although several options are available, a proprietary device has been developed to help secure the ETT and provide increased patient comfort while facilitating airway care. This device, the AnchorFast (Hollister Inc., Libertyville, IL) (Fig. 47-15), incorporates an ergonomically designed frame to minimize well-known pressure points, a latex-free adhesive on a pad, and a padded Velcro-style retaining strap that encircles the head. Preliminary studies comparing this device against classic adhesive tapes showed reduced skin breakdown, fewer lip ulcers, and improved patient comfort.[106,112]

Another commercial device used to secure the ETT has been postulated; it mimics the nasal bridling technique used for nasogastric tubes. This product is still in development.

3. Stapling for Facial Burns

The overall incidence of burn patients in most practices is very small, and this creates an unfamiliarity with their care, particularly as it relates to airway management. The focus of this section is to discuss the unique situation presented by the facial burn. Aside from the obvious difficulties of tube placement initially, replacement of an ETT after a burn resuscitation is far more challenging due to a multitude of unique injuries. The two major problems with securing an ETT for the patient with a facial burn are the increased (and increasing) edema due to ongoing inflammatory processes and continued

resuscitation, which makes the face ever expanding, and the actual burned skin, which is constantly weeping and often débrided or sloughing. It should be obvious that adhesive devices, both simple tape and proprietary devices, are ineffective in this situation. A well-documented and accepted method in these patients is to secure the ETT with tape and anchor it to the skin by stapling the tape to the burned areas. This is surprisingly well tolerated, but more importantly it is very reliable to maintain the airway and is easy to care for.

One important airway management caveat should be understood regarding proper ETT position at the gum line or lips in all intubated patients: the ETT marking at these locations only assures the location of the proximal end; it does not guarantee the depth and location of the distal ETT tip. Although this problem pertains most often to the ventilated PACU or ICU patient, an ETT located at 25 cm at the gum line and seemingly secured by tape or a commercial device does not guarantee tracheal intubation (with or without a cuff leak). Typically, a continuous or intermittent apparent cuff leak leads to further insufflation of the pilot balloon to fix the leak. An intact (inflated) pilot balloon, in this clinical situation, should arouse suspicion that the distal tip is abnormally located outside the glottis. The potential for an airway catastrophe is extreme, especially in the patient with a difficult airway, compounded by significant mechanical ventilatory requirements. Proper assessment of the ETT position, preferably with flexible bronchoscopy for diagnostic and therapeutic maneuvers, is indicated.

D. Rapid Response Cart for Airway Emergencies

Areas in which care for intubated patients is provided need to have a dedicated set of supplies to establish emergency airways in the event of primary respiratory failure or cardiac arrest to reestablish lost, previously secured airways. The responding airway team must be knowledgeable and competent in advanced management techniques and provided with immediate access to such equipment. Infrequent or casual airway managers should ask for assistance early in the management process or even immediately, before starting. The American Society of Anesthesiologists difficult airway algorithm (Fig. 47-16) should be close at hand to guide less experienced individuals who encounter problems.[113] Supplies on the cart may differ based on personal preference and facility purchase, but there are some items that must be present to help save a life.

Laryngoscopy, ETT exchange, pulmonary toilet, and a "cannot intubate, cannot ventilate" (CICV) scenario must all be covered in the equipment selection. Laryngoscopy includes both conventional (direct) and video laryngoscopy; it is used to assist the team with replacing the ETT after an inadvertent extubation, augmenting the exchange of a damaged ETT over an airway exchange catheter, improving the ability to assess ETT location within the airway, and interrogating the physiologic integrity of an airway slated for extubation.[114]

An airway exchange catheter, coupled with video laryngoscopy, greatly reduces the complication rates for necessary airway exchanges in ICU patients, thereby earning its place in an airway response cart within the ICU.[114] A fiberoptic bronchoscope should be available for confirmation purposes, for awake intubation procedures, and for deeper pulmonary toilet needs to improve ventilation and oxygenation.[115] Supraglottic airway devices should be available for situations in which mask ventilation is difficult or as a conduit to facilitate the placement of an endotracheal airway.[116] Lastly, equipment for the placement of a surgical airway must be provided. Despite all of the options available, a scalpel may be the only device capable of establishing the airway. In cases of a known or suspected difficult airway, it is helpful to immediately contact someone with the ability to place a surgical airway should other conventional or advanced noninvasive means fail.

Box 47-2 delineates the contents of a proposed difficult airway cart, which should be readily available in case of any airway catastrophe.

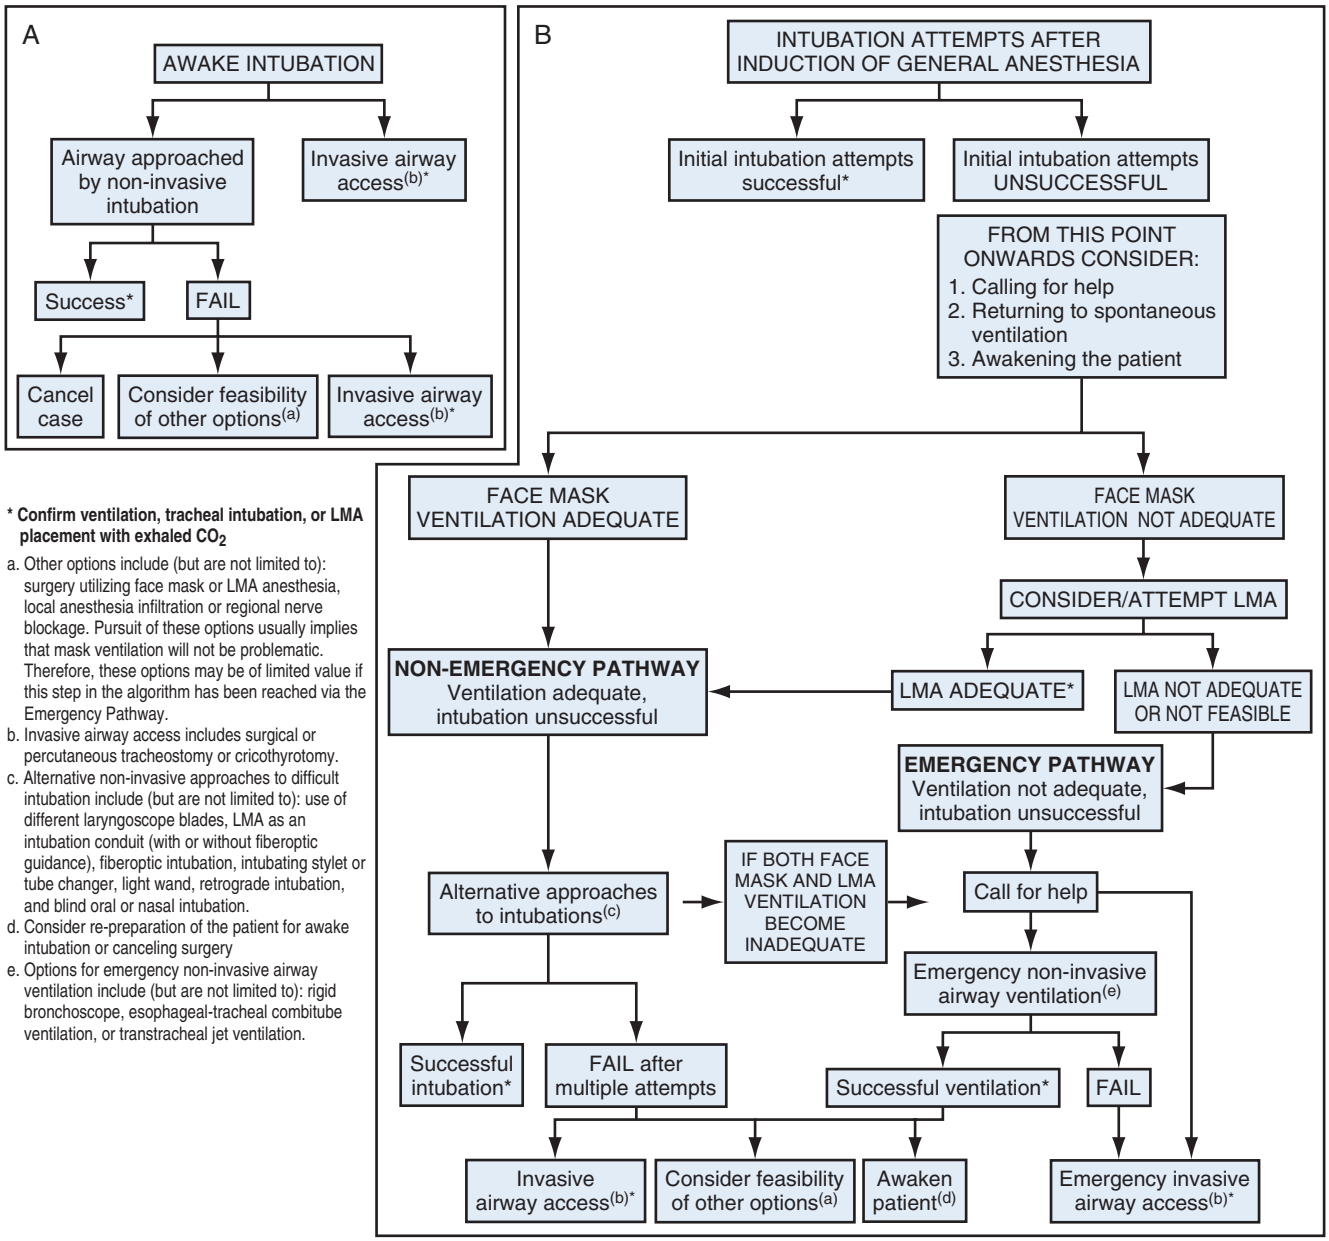
V. MAINTENANCE OF THE ENDOTRACHEAL TUBE

There is currently no alternative to the placement of an oral, nasal, or transtracheal ETT, whether to maintain airway patency, perform ventilation, improve oxygenation, remove secretions, or deliver necessary therapies. However, the ETT is only as good as its most pristine state. Despite the unavoidable decision, some still look on the placement of an ETT as a necessary evil. The conundrum arises in preserving or remastering the physiologic function of the host tissues while combating their inherent defenses aimed at reacting to the new artificial airway and protecting the new foreign device to maintain its optimized function as in its original condition.

The presence of the ETT bypasses the host defenses of the upper airway, eliminates the humidification of inspired gases, increases the WOB, limits the administration of medications, and prevents prophylactic oral hygiene. All of these changes promote bacterial colonization, inflammation, and sputum production. Inability to actively clear secretions because of a poor cough or increased difficulty of passive removal by health care personnel can lead to plugging of proximal and distal airways as well as the ETT. These retained secretions may result in the formation of atelectasis, ventilation-perfusion mismatching in the form of a shunt or dead space, hypoxemia, and increased respiratory load, thereby prolonging the duration of mechanical ventilation.[117,118] Therefore, aggressive respiratory care must be provided for the intubated patient to avoid these complications and further morbidity.

A. Heat and Humidity of Inspired Gas

During normal breathing, the air is delivered to the carina at a temperature of 32° C and an absolute humidity of 30.4 mg H_2O/L.[119] The insertion of an ETT via the nose, mouth, or trachea bypasses the upper airway and causes the natural ability to heat and humidify inspired gas to be lost. The American Association for Respiratory Care states that devices should provide a minimum of 30 mg



AMERICAN SOCIETY OF ANESTHESIOLOGISTS

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficult with patient cooperation or consent
   - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:

A.	Awake intubation	vs.	Intubation attempts after induction of general anesthesia
B.	Non-invasive technique for initial approach to intubation	vs.	Invasive technique for initial approach to intubation
C.	Preservation of spontaneous ventilation	vs.	Ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

*** Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2**

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockage. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

Figure 47-16 American Society of Anesthesiologists difficult airway algorithm. *LMA,* Laryngeal mask airway. (Courtesy of American Society of Anesthesiologists, Park Ridge, IL.)

- Percutaneous tracheostomy kit
- Medications kit (etomidate, propofol, ketamine, succinylcholine, rocuronium, intravenous and viscous lidocaine, atropine)

of H_2O/L of delivered gas at 30° C.[120] If inspired air is not warmed and humidified, the result is a dry, cool gas that is damaging to the respiratory tract and impedes mucociliary function. Secretions may become dry and inspissated, possibly leading to partial or complete occlusion of the ETT lumen. If left unrecognized, this occlusion may lead to barotrauma and death.[93] The most common method to protect against this situation is the use of an active heated humidifier or a passive heat and moisture exchanger (HME) (Fig. 47-17).[121]

HMEs are typically cylindrical devices that are fitted to the ventilator circuit, usually just proximal to the ETT connector and the Y-piece, with limited changes on airway mechanics.[122,123] This is the most effective HME placement for maximizing humidity and temperature retention in the patient circuit.[121,124] The materials provide heat, humidification, and filtering properties, earning the device the nickname, "artificial nose."[125] They are lightweight and inexpensive, require no power source, and reduce circuit condensation, making them attractive alternatives to the more expensive heated humidifiers.

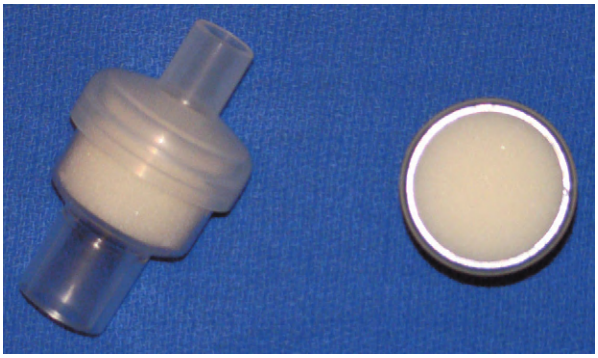

Figure 47-17 A heat and moisture exchanger.

Use of heated humidifiers is associated with the production of almost 100% humidity in the inspiratory gas and is thus more effective than use of HMEs. These units require an external power source and additional circuitry, increasing cost. Accidental overheating can occur and may create additional damage to the airway if temperatures are not frequently monitored. There is no consensus about the proper duration of use of these implements. Multiple studies have failed to show a correlation of increased incidence of pneumonia with heated humidifiers versus HMEs or with frequent changes of HMEs or heated humidifiers. Therefore, frequent changes (i.e., more often than every 7 days) of ventilator circuits, unless they are visually soiled, is neither cost-effective nor medically efficacious.[73,126-129]

B. Suctioning

Perhaps the simplest and most logical means of assisting with secretion clearance is direct suctioning. This modality is safe, but when it is performed carelessly, complications may occur, including soft tissue or airway trauma, aspiration, laryngospasm, increased intracranial pressure, bronchospasm, hypoxemia, and cardiac dysrhythmias.[130] Hypoxemia can be minimized with preoxygenation using a fraction of inspired oxygen (F_{IO_2}) of 100%. In patients with intracranial hypertension, mild hyperventilation or blunting of the cough reflex with instilled intravenous lidocaine just before suctioning may reduce the risks of additional increases in intracranial pressure. The evacuation procedure should be brief and intermittent. The vacuum should be applied only after the suction catheter has been advanced to its distal position. After each pass of the catheter, lung re-expansion with a few gentle manual breaths should be administered. Suctioning can be applied by a single-use open system in which the catheter is unprotected and open to the environment or by a closed system (Fig. 47-18) that sheathes the catheter in a sterile protective covering.

Closed systems are usually incorporated into the ventilator breathing circuit at the junction of the Y-piece and

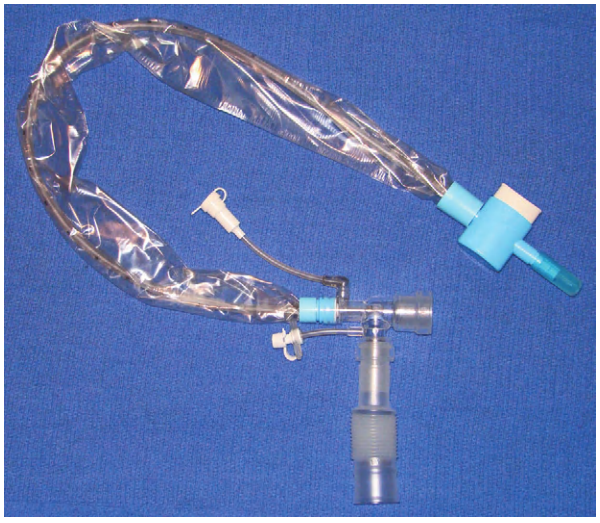

Figure 47-18 The Ballard closed endotracheal tube suctioning system.

the ETT or tracheostomy tube, allowing continued ventilation during suctioning with no need to disconnect the circuit. The advantage of not having to disconnect is important for patients who require aggressive ventilator management (e.g., high PEEP therapy), making them less susceptible to alveolar derecruitment compared with open suctioning. The retractable catheter does not add any additional restriction to airflow (when not deployed). There are concerns that colonization of these devices with aspiration of bacterial particles and cross-contamination may predispose to VAP.[131] Such concerns have led to differing opinions on the appropriate timing of any system changes. Kollef and coworkers randomly assigned patients to scheduled changes every 24 hours or to no change except when there was a malfunction or visible soiling.[132] In both groups, 15% of patients developed VAP. The only difference was in total cost: $11,016 USD in the group with scheduled changes and $837 USD in the group with no scheduled changes.[132,133]

C. Subglottic Care

Secretion management has, by necessity, moved beyond the ETT lumen. Suctioning of secretions that are pooled above the ETT cuff, in the subglottic space, is an important step in good tracheal care and is paramount in the prevention of VAP.[111,132-137] Subglottic suctioning has been shown to decrease the incidence of VAP in the ICU from 16% to 4%.[135] Specialized ETTs with dedicated subglottic suctioning ports are more expensive ($15 compared with $1 for a standard ETT).[138] An interesting cost analysis done in 2003 demonstrated that despite this increased cost, the estimated cost benefit of an ETT with a subglottic suction port was $4,992 per case of VAP saved.[138] The U.S. Centers for Disease Control and Prevention (CDC) universally recommends the use of subglottic suctioning tubes in the ICU to help reduce the rate of VAP.[139]

Subglottic suctioning can be done with small suction catheters that are advanced down the trachea until resistance is met from the ETT cuff. Another option is using ETTs with a subglottic port positioned just above the cuff. These specialized ETTs are certainly not infallible and do not replace vigilant airway care. It has been demonstrated that dysfunction of the suction lumen can occur almost 50% of the time.[140] In 43% of cases, the cause of the suction loss was determined to be prolapse of the tracheal mucosa into the subglottic suction port.[140]

D. Bronchoscopy

The use of fiberoptic bronchoscopy for routine secretion management is not advocated. It is expensive, requires proficient training, and may produce complications such as barotrauma secondary to a marked reduction or cessation in expiratory airflow (depending on the relative airway caliber) in intubated patients.[4] It should be reserved for assisting with lobar collapse caused by mucus plugging or inspissated secretions not amenable to conventional mucolysis, to perform so-called pulmonary toilet bronchoscopy that may be needed after an inhalation injury to evaluate for tracheobronchial injury, to aid in the diagnosis of significant hemoptysis, or to assist with specimen procurement when clinical suspicion merits sampling.

E. Biofilm Management

Biofilm and adherence of secretions (Fig. 47-19) within the ETT have been implicated in the development of VAP, increased WOB, delays in extubation, and other complications.[141-144] Biofilm can easily be identified by bronchoscopy on insertion of the scope into the ETT. Newer technologies using acoustic reflectometry have also been developed to help with monitoring the accumulation of biofilm and evaluating the integrity of the intubated airway. The SonarMed airway monitoring device (SonarMed, Indianapolis, IN) employs this technology to assess ETT positioning and movement as well as ETT patency hampered by either internal or external agents.

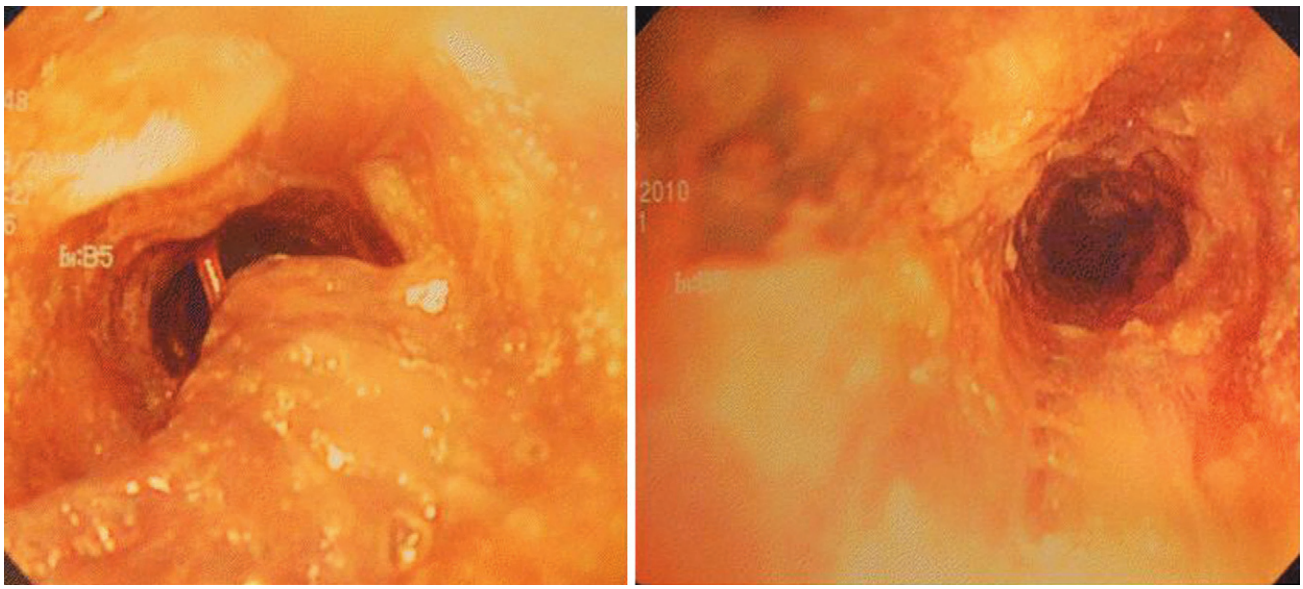

Figure 47-19 Examples of biofilm accumulation inside the lumen of an endotracheal tube.

Figure 47-20 The Omneotech Complete Airway Management (CAM) Rescue Cath catheter. (Courtesy of Omneotech, Tavernier, FL.)

Traditional methods used to manage biofilm include catheter suctioning, bronchoscopic lavage, and ETT exchange. Catheter suctioning is often ineffective for biofilm removal, because its presence frequently evades detection as the suction catheter navigates the patent channel formed by the biofilm concretions, thereby leaving the impression that the lumen is patent. Bronchoscopic lavage and ETT exchange are hampered by significant costs and hazards for both practitioners and patients. Another option is a device that essentially scrapes the biofilm from the luminal surface of the ETT. The Complete Airway Management (CAM) Rescue Cath by Omneotech (Tavernier, FL) (Fig. 47-20) resembles a Fogarty catheter used to remove a thrombus. This product has an inflatable balloon at the distal end of a catheter that is encased in a latticed netting to provide "traction" and atraumatic "abrasion" of the lumen. It is introduced into the ETT and advanced to the distal end (based on ETT and CAM depth markings); the balloon is then inflated, and the catheter is fully withdrawn back out through the proximal end of the catheter, along with any luminal biofilm. This device and procedure may prove to be a useful option in already hypoxic or PEEP-dependent patients in whom time-consuming bronchoscopies could be hazardous. The CAM Rescue Cath is also a good option for patients with a potentially difficult airway, in whom ETT exchange can pose a considerable risk.[145]

Information on the prevention of biofilm formation is rife with conflicting data. One study showed no difference in rate of *Pseudomonas aeruginosa* and *Staphylococcus epidermidis* biofilm formation among different ETT materials including PVC, silicone, stainless steel, and sterling silver.[146] More recently, however, ETTs coated in silver and chlorhexidine showed significantly reduced rates of biofilm colonization in a nonclinical setting.[23,147] The preventive management of biofilm may not be far in the future, but chlorhexidine-coated ETTs are currently not available. For now, the best strategy to manage biofilm is increased vigilance, fastidious respiratory care, and new technologies aimed at minimization and safe clearance.

VI. RESPIRATORY THERAPIES FOR THE INTUBATED PATIENT

A. Secretion Clearance and Control Therapies

1. Mucolytic Agents

Agents used to decrease the viscosity of tracheobronchial secretions and assist with their reduction and clearance have been used for decades. The primary agent in use is *N*-acetylcysteine (NAC, Mucomyst). NAC is a sulfhydryl-containing compound; therefore, it is classified as a thiol. It has extensive first-pass metabolism in the gastrointestinal tract and liver when administered orally and is almost completely absorbed; only minimal amounts are excreted in the feces. The plasma half-life is approximately 2 hours, with virtually no detectable NAC at approximately 12 hours.[148]

Most of NAC's biochemical effects appear to be related to its sulfhydryl group, which reduces the production hydroxyl radicals.[148,149] This effect has provided many uses for NAC beyond that of a mucolytic agent, including hepatic protection in acetaminophen overdose and renal protection against contrast-induced nephropathy.[52,150] NAC's effects on mucus viscosity result from its ability to disrupt the disulfide bridges and render them more liquid.[133,148] NAC is usually delivered by nebulizer in combination with a β_2-adrenergic agonist because it can induce bronchospasm.[151] Clinically, its effects have been variable in patients with chronic bronchitis, for whom oral NAC is used to assist with exacerbations and symptomatic relief.[152-154] Direct instillation of NAC during bronchoscopy may assist in secretion removal.

Another important factor in mucus viscosity is DNA content. DNA contributes to secretion viscosity because it accumulates from the degradation of bacteria and neutrophils. An agent that is considered mostly a mucokinetic agent, recombinant deoxyribonuclease (DNase, Pulmozyme), has been used in nebulized form in patients with bronchiectasis caused by cystic fibrosis with good results; however, it is expensive, and its use beyond this population of patients is not indicated.[117,155,156]

One interesting therapy used in the population of burn patients who have an associated inhalation injury is nebulized heparin. Heparin assists with decreasing and removing bronchial casts that form with inhalation injury. Heparin's anticoagulant effects assist with removal of casts, and it may act as a free radical scavenger with anti-inflammatory effects. Although studies have not consistently shown a significant change in pulmonary function, cast formation and removal are favorably altered.[157,158]

2. Chest Physiotherapy

Chest physiotherapy encompasses a variety of techniques that include position changes, percussion and vibration of the chest wall, and stimulation of a cough response. These are relatively dogmatic approaches that have historically provided poor results. They also tend to be burdensome to both the respiratory therapist and the patient. Newer, alternative techniques show promising results.

a. PERCUSSION AND POSTURAL DRAINAGE

Used extensively in patients with cystic fibrosis, the technique of percussion with postural drainage utilizes external percussion of the chest wall overlying the affected lung region. Percussion can be applied manually with a cupped hand or by an automated, usually pneumatic, device. The application of percussion or vibration, or both, to the chest wall functions to loosen the secretions in the bronchi and facilitate their mobilization.[94,159] A steep Trendelenburg position of 25 degrees or more is employed—less if the patient cannot tolerate that angle—to facilitate the gravitational effects on mucus clearance.[77,160]

Relative contraindications to the postural component of this therapy are the presence of increased intracranial pressure; the possibility of an unprotected airway and the potential for aspiration; recent esophageal, ophthalmic, or intracranial surgery; congestive heart failure; and uncontrolled hypertension.[120] As for the application of percussion or vibration, placement of the technique over recent surgical sites (e.g., split-thickness skin grafts, rib fractures or chest trauma, pulmonary contusions, burns, unstable spine fractures) or in the presence of coagulopathies, subcutaneous emphysema, or bronchospasm are all relative contraindications.[160] Hazards include hypoxemia and accidental extubation.

Clinically and experimentally, the use of percussion with postural drainage in cystic fibrosis patients is well supported.[161-163] However, patients' compliance remains a concern, because the technique is burdensome for patients and caregivers.

b. POSITIVE END-EXPIRATORY PRESSURE THERAPY

PEEP therapy, as a secretion clearance technique, creates a restriction to expiratory flow by means of a face mask or mouthpiece. The resistance is adjusted to 10 to 20 cm H_2O of back pressure during expiration, which allows airflow to move into distal airways and associated lung units, forcing past secretions and causing them to move toward the larger airways, where suctioning is more feasible. The maneuver is used with gentle and forceful coughs lasting up to 20 minutes and aerosolized medications that can be administered concurrently. Patients with an increased WOB or severe dyspnea may have difficulty performing this technique due to temporary lapses in ventilation. PEEP therapy is at least as effective for secretion clearance as percussion with postural drainage, if not more effective, and patient satisfaction is markedly more favorable.[125,164,165]

c. INTRAPULMONARY PERCUSSIVE VENTILATION

Intrapulmonary percussive ventilation (IPV) can be delivered through a mouthpiece or to the end of the ETT. Its high-frequency percussive oscillations function to loosen retained secretions, expand airways and lungs, and reduce atelectasis. Conceptualized and designed by Dr. Forrest Bird, IPV uses a "phasetron"—a sliding venturi device capable of providing 5 to 35 cm H_2O pressure during oscillations of 2 to 5 Hz.[166] Aerosolized medications may also be delivered during IPV treatments. Favorable results have been reported for secretion clearance and lung expansion in patients with cystic fibrosis, as well as in other disorders with an increased incidence of thickened secretions.[167,168] IPV offers an advantage to patients who lack the ability to perform percussion with postural drainage or high PEEP therapies.

d. HIGH-FREQUENCY CHEST WALL COMPRESSION

Therapy with high-frequency chest wall compression entails the wearing of an inflatable vest around the chest. Air is instilled into the vest bladder and then rapidly withdrawn in a cyclic manner, essentially creating an artificial cough. The high-frequency oscillations that are produced range from 5 to 25 Hz and can generate pressures as high as 50 cm H_2O. These oscillations create a gentle "squeezing" of the patient's chest that mimics small coughs. The frequency of the oscillations can be adjusted, and sensors in the vest can reduce the pressure delivered when the patient's chest expands (as with a sigh breath or a deep cough).[141] Secretion clearance and improvement in mucus rheology have also been reported.[169,170] Perhaps the biggest drawback of this method is its cost, estimated at $15,900 USD for each unit.

B. Overcoming Work of Breathing Imposed by Endotracheal Tubes, Tracheostomy Tubes, and Ventilator Circuits

With any translaryngeal intubation, the upper airway is bypassed and the resistance it imparts is thereby removed; however, there is still a substantial amount of work performed by the patient in an effort to ventilate. WOB is minimal during normal, quiet breathing, accounting for about 5% of the total oxygen consumption at rest. With increases in WOB, oxygen consumption can be markedly increased to as much as 30% or more.[155] This newly acquired increased demand may not be well tolerated by the critically ill patient. The additional WOB (WOB_{add}) imposed by the artificial airway and ventilator apparatus not only hinders weaning and liberation from mechanical ventilation but also impairs tissue oxygenation and alters critical blood flow, which may lead to worsened organ dysfunction.[86] To initiate a "breath" from the ventilator, a pressure differential across the ETT and circuit must be produced. The patient must overcome this resistance to initiate the demand flow needed for ventilation to occur. It has been shown experimentally that the ETT, the ventilator circuit, and the ventilator itself all add varying degrees of additional work for the patient to overcome, on top of the problems that initially necessitated intubation and mechanical ventilation.[32,171]

1. Pressure Support

Various modalities have been designed to overcome WOB_{add} imposed by the artificial airway and ventilator.[155]

One is pressure support (PS), which is used as either an adjunct or as a mode of ventilation to help the spontaneously breathing patient overcome the WOB_{add} imposed by an artificial airway.[21,168,172] A preset, flow-triggered inspiratory pressure chosen by the clinician is added to the airway opening pressure when inspiration is triggered by the patient. Because it is flow cycled, the patient can control the duration and depth of inspiration, and the PS ceases when some preset gas flow has diminished, usually about 25% of the maximal peak flow achieved.[173] PS has been shown to decrease WOB_{add} even with normal lungs.[173,174] However, in patients with obstructive pulmonary disease and expiratory flow limitation, breath stacking, or auto-PEEP, flow may not decelerate quickly enough, and active exhalation may be necessary to terminate the PS, thereby creating additional WOB.[175] The amount of inspiratory pressure added is usually 4 to 15 cm H_2O. Currently, it is recommended that PS be applied for all spontaneously breathing, intubated patients to assist with overcoming the resistance of the ETT or tracheostomy tube.[176] Additional PS may be necessary if tidal volumes or respiratory rates, or both, are inadequate to support oxygenation. Most patients tolerate PS well, but decreased tolerance in patients susceptible to expiratory flow limitation must be appreciated and accounted for in any management strategy.

2. Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) is applied at end-exhalation in spontaneously breathing patients. Much like PEEP, CPAP is designed to offset the degree of atelectasis that occurs inherently in the intubated, supine patient. CPAP ranging from 4 to 10 cm H_2O should be provided for all spontaneously breathing patients in an effort to compensate for the loss of expiratory lung volumes and further promote oxygenation. So-called physiologic PEEP, an amount thought to rectify the aforementioned atelectasis, is theoretical but is estimated to be equivalent to 4 cm H_2O in the normal lung. The reduction in WOB seen with CPAP has been appreciated primarily in the setting of expiratory airflow reductions; in such cases, CPAP offsets the auto-PEEP, thereby reducing the work required to generate the next inspiratory effort.[177] The type of flow-triggered mechanism and the location at which the flow differential is measured (typically at the tracheal end of the ETT) have been shown experimentally to decrease the inspiratory WOB as well.[178] CPAP is usually applied in combination with added PS.

3. Automatic Tube Compensation

As stated previously, the ETT imposes a substantial degree of resistance to inspiration. The modalities described thus far assist with decreasing some of the work needed to overcome this burden. Added PS and PS ventilation help compensate for the resistance primarily encountered during inhalation but not during exhalation, and they are not consistently provided because of the varying flow across the ETT during normal breathing.[179] Much resistance to exhalation is also produced by the presence of an ETT. Indeed, the internal diameter of the ETT greatly affects this phenomenon, as do other factors such as gas flow rates, gas density and viscosity, and luminal secretions adherent to the ETT wall. Automatic tube compensation (ATC) is a feature on some newer ventilators. It is designed to assist with the resistance imposed by the ETT or tracheostomy tube during both the inspiratory and expiratory phases of the respiratory cycle. By altering the PS delivered—raising it during inspiration and lowering it during expiration according to the pressure-flow characteristics of the ETT—ATC adjusts for the resistance and the pressure drop across the ETT during spontaneous breathing. A computer assists by calculating the pressure difference across the ETT (ΔP^{ETT}) based on ETT size, measuring gas flow and airway pressure, and selecting the resistive properties of the ETT.[179] Unlike PS, ATC cannot be used as a ventilatory mode; it is merely an adjunct component to mechanical ventilation.

One drawback to ATC is the inability to correct for the reductions in airway diameter that can occur with secretions or kinking. This limitation results in an inaccurate measurement of ΔP^{ETT} such that ATC undercompensates for the pressure difference across the airway. A high index of suspicion is necessary to monitor for this possibility. Clinically, ATC has been shown to decrease the WOB_{add} encountered with ETTs and tracheostomy tubes.[28] When these modalities were used to assist with weaning and extubation of patients in a T-piece trial, there was no difference in the workload encountered with ATC and T-piece alone, whereas adding PS to the T-piece trial at 7 cm H_2O unloaded this additional work.[180]

C. Pharmacologic Treatments

1. Inhalation Drug Delivery

The presence of an ETT does not limit drug delivery to the lungs and may actually enhance it. Many clinicians take advantage of this route of administration. The two predominant methods used to deliver agents are metered-dose inhalers (MDIs) and nebulizers. The drugs delivered by these devices are most commonly bronchodilators, mucolytics, corticosteroids, and antibiotics. For pulmonary ailments, inhaled drugs achieve efficacy comparable to or exceeding that of systemically delivered drugs with a smaller dose.[181-183] Tracheal administration of some traditionally systemic drugs often requires much higher doses to ensure absorption.

Inhalation drug delivery has other advantages over systemic administration. Systemic side effects can be reduced, because systemic absorption is markedly decreased. Variable reports regarding penetration and distribution of an aerosol to the lower respiratory tract range from 0% to 42% with nebulizers and 0.3% to 98% with MDIs. However, when the delivery method was standardized, the amount delivered in either method was similar, about 15%.[184-186]

Particle size also plays an important role in delivery. The larger the particle, the less likely it is to be delivered distally to the alveoli. Aerosol particles ranging between 1 and 5 μm are optimal for proper deposition.[181,182,185,187] The density of the gas carrying the aerosol also influences the delivery in an inverse relationship. Improvement in

delivery has been reported when a mixture of helium and oxygen was used in the ventilator circuits of both MDIs and nebulizers.[183,188]

a. NEBULIZERS

The performance of a nebulizer depends on multiple factors including the model, operating pressure, flow rate, and volume of diluent utilized. Nebulizers are capable of generating aerosols with particle sizes of 1 to 3 μm, and the size produced is inversely influenced by the flow rate or pressure used: the greater the flow rate, the smaller the particle.[181,182] Nebulizers may be used continuously or intermittently. Intermittent use appears to be more efficient than continuous delivery, with less waste of aerosol demonstrated.[189] Placing a nebulizer upstream from the Y-piece and ETT also increases drug delivery.[187,189,190] Interestingly, the use of continuous drug nebulization may impair the ability of the patient to initiate a negative-pressure inspiratory effort in the PS mode of ventilation, thereby leading to hypoventilation.[168,191]

b. METERED-DOSE INHALERS

An MDI delivers medication in combination with a mixture of pressurized propellants, preservatives, flavoring agents, and surfactants. The final concentration of active drug constitutes about 1% of the total volume in the canister.[181] When the stem on the MDI canister is depressed, a finite amount of drug is released at a certain velocity, and a spray cloud develops. Various adapters are available that fit in line with the ventilator circuit or on the end of the ETT as so-called elbow adapters to aid in the administration of inhalational therapies. Chambers or spacers appear to provide better delivery of aerosol compared with the more commonly used elbow adapters.[192] MDIs typically cause more aerosol deposition on the ETT than nebulizers do, decreasing the amount of drug delivered. These particles, in turn, adhere to the ETT. This problem can be reduced by using a spacer and performing the administration with meticulous attention to timing of the ventilatory cycle: it is most effective during inspiration and when synchronized with the patient's spontaneous effort. Dhand and Tobin reported excellent results with their technique of MDI delivery.[189]

When comparing the overall efficacy of nebulizers versus that of MDIs, several factors favor the use of MDIs in mechanically ventilated patients. Nebulizers may become colonized with bacteria and help to deliver an aerosolized inoculum. Bowton and colleagues reported a potential saving of $300,000 USD annually with the use of MDIs compared with nebulizers.[193]

2. Inhaled Bronchodilators

Airway reactivity is a ubiquitous consequence of airway manipulation that hinders respiratory function and prolongs the duration of mechanical ventilation. Additional pathophysiologic processes attributed to persistent bronchospastic disease that serve to prolong mechanical ventilation include mucosal inflammation that persists and promotes further mucus production, airway hyperemia and resultant edema, and the consequent narrowing of small airways leading to an increase in closing volume. These processes adversely affect oxygenation as functional residual capacity is decreased and CO_2 elimination, as expiratory flow, is limited. At extremes of expiratory flow limitation, generous amounts of intrinsic PEEP (auto-PEEP) are generated; this can impede cardiac filling by reducing preload, and hypotension and cardiac arrest may result. The physical effects of auto-PEEP are not limited to the cardiovascular system. The obvious effects of alveolar overdistention include an increased physiologic dead space and the potential for barotrauma, especially when controlled positive-pressure mechanical ventilation is instituted. Pneumothorax, pneumomediastinum, and pneumoperitoneum may all occur as a result, as may patient-ventilator dysynchrony.

Many maneuvers are available to reduce the effects of bronchospasm (and higher airway pressures), including decreasing the respiratory rate, prolonging the expiratory time, decreasing the tidal volume, and increasing the inspiratory flow rate. Pharmacologically, the use of β-adrenergic agonists, specifically β_2-agonists such as albuterol, is the mainstay therapy. β_2-receptors on bronchial smooth muscle promote relaxation and dilation of the airway diameter when stimulated. Systemic methylxanthines such as theophylline do not add much benefit in the acute stage of treating bronchospasm or reactive airways. Their narrow therapeutic window and vast side effect profile increase potential toxicity.

β_2-agonists also have a beneficial effect on respiratory cilia in that they cause an increase in ciliary beat frequency.[194] This phenomenon is mediated by β-adrenergic receptors and can be attenuated with nonselective beta-blocking agents. An increase in the frequency of ciliary beating promotes mucus clearance over the respiratory epithelium. Other effects include increased water secretion onto the airway surface, which facilitates mucus clearance.[195] Indeed, the beneficial effects of β-agonists on bronchial reactivity and mucociliary clearance are evident. However, there are data suggesting a more robust effect in healthier airways than in chronically diseased airways such as those seen in patients with chronic bronchitis, possibly due to downregulation and chronic attenuation.[196] Newer formulations of inhaled β-agonists such as levalbuterol may have reduced side effect profiles and possibly improved outcomes.

3. Anticholinergics

Although inhaled β-agonists are pivotal in the reduction of airway reactivity, the use of inhaled anticholinergics such as ipratropium bromide or the newer tiotropium bromide needs to be emphasized, given their obvious synergistic effect with β-agonists. It is well appreciated that many of the mechanisms of airway reactivity and inflammation associated with bronchospastic disease are cholinergically mediated. In patients with chronic obstructive pulmonary disease, the use of these agents alone or in combination with β-agonists is the foundation for rescue therapy and a mainstay in chronic management.[183]

4. Corticosteroids

Inhaled glucocorticoid therapy has become a mainstay of treatment in various obstructive respiratory ailments,

including chronic obstructive pulmonary disease and asthma. This class of medicines unquestionably has disease-specific effects at the target organ. Equally interesting is the fact that administration in an aerosol preparation magnifies their effects while markedly reducing their side effect profile, leading to a lower risk-benefit value. Targeted efficacy with minimal adverse effects helps to quantify an appropriate risk-benefit value.[197,198] High lung deposition or targeting, high receptor binding, longer pulmonary retention, and high lipid conjugation are among the pharmacokinetic parameters that lead to improved efficacy of these compounds and should be considered. A low or negligible oral bioavailability, smaller particle size leading to a relatively inactive drug at the oropharynx, higher plasma protein binding, increased metabolism rates, higher clearances, and lower systemic concentrations are associated with lower risks for adverse effects.[197-199]

For individuals who require long-term care with inhaled glucocorticoids during ventilator dependency, therapy should be continued to minimize the underlying disease process and thereby decrease the number of new variables, including adrenal insufficiency, in the treatment equation with inhaled or intravenous formulations.[200] Despite all of these perceived benefits, inhaled glucocorticoids do not seem to reduce mortality.[201] Acute exacerbations tend to be treated with intravenous or oral preparations due to the higher doses required.

5. Inhaled Antibiotics

Inhaled antibiotics have been used for decades, falling in and out of favor over the years. They are used primarily for treatment and suppression of chronic airway bacterial colonization. Their theoretical advantages are improved drug delivery and higher concentrations at the site of infection, leading to improved efficacy and better bacterial eradication compared with systemic administration.[90,202-204] The primary concern with this therapy is development of bacterial resistance.

Results differ on efficacy. Inhaled antibiotics, mainly aminoglycosides, have been used extensively in cystic fibrosis patients with good results.[90,202-205] Palmer and colleagues reported a marked reduction in the volume of airway secretions and a decrease in the laboratory markers of inflammation in a prospective study of mechanically ventilated patients with chronic respiratory failure.[90,205] However, their study lacked power and was not randomized.

Other studies have failed to show similar benefits but rather have demonstrated poor, unpredictable drug delivery.[206] Unequal ventilation, atelectasis, lobar collapse, and consolidation impair even drug distribution. Bronchospasm with chest tightness has also been reported.[134] Use of inhaled antibiotics should be limited to selected patients, such as those with cystic fibrosis. Routine use to assist with secretion reduction and clearance in the mechanically ventilated patient is not recommended.

D. Positioning of the Patient

The appropriate position in which to maintain the patient requiring mechanical ventilation has been debated. Current recommendations from the CDC state that elevating the head 30 to 40 degrees reduces the risk of VAP. A study examining head elevation and the rate of VAP concluded early after interim analysis showed an incidence of microbiologically confirmed pneumonia of 5% in semirecumbent patients versus 23% in supine patients.[207] The semirecumbent position has also been supported with regard to facilitating nursing care and decreasing gastric reflux and resultant aspiration. It has not been shown to have an effect on the hemodynamic status of the patient, although this remains a common theoretical concern.[208]

Special beds that provide continuous lateral rotation have been used for patients who cannot be repositioned easily, such as those with severe head or traumatic brain injury, bariatric patients, and those who are pharmacologically paralyzed (e.g., patients with acute respiratory distress syndrome [ARDS]). These beds are advertised to enhance skin care, reduce thrombotic events, and improve pulmonary function. Their use is proposed to reduce atelectasis and, hence, pneumonia formation; however, studies' results have remained conflicting.[209,210]

Occasionally, in severe cases of ARDS, alternative positioning (prone) may be necessary to facilitate ventilation and oxygenation. This method attempts to combat the physiologic shunt that is responsible for the observed hypoxemia. The prone position improves oxygenation by increasing lung volume, recruiting posterior lung fields, and redistributing perfusion.[211] No statistical difference was shown in a meta-analysis of the data for prone positioning of patients, although a small subset of patients with severe ARDS has been shown to benefit.[212,213] However, prone positioning is not without risks, particularly an increased risk for bed sores and ETT complications such as dislodgement.[212] Recently, a bed has become commercially available that possesses the ability to fully prone the patient, making use of this potentially beneficial intervention more dependent on necessity than caregiver feasibility. (Rotoprone, KCI Therapeutic Support Systems, San Antonio, TX.)

VII. CONCLUSIONS

The establishment and maintenance of a secure and dependable airway is paramount in the care of the critically ill patient. From the very onset of admission to the ICU, care of the airway should begin with surveillance and a determination of which airways will be difficult to secure or difficult to maintain. The proper choice of an artificial airway not only facilitates ventilatory requirements for improved oxygenation but protects the patient from untoward iatrogenic problems encountered with instrumentation. Regardless of the intervention, an unfettered vigilance is the key to improved outcomes. Proper ETT care, early performance of a tracheostomy (when indicated), frequent pulmonary hygiene, and the use of established protocols and proven preventive measures should help to ensure safe and successful outcomes in critically ill patients.

VIII. CLINICAL PEARLS

- Polyurethane endotracheal tube (ETT) cuffs that have high-volume, low-pressure (HVLP) cuffs are capable of conforming to the irregular borders of the tracheal lumen and therefore are more effective at preventing microaspiration.
- ETT placement has mechanical and physiologic consequences. Vigilant surveillance of skin hygiene, airway patency, cuff integrity, and ventilatory support must be realized to minimize injury and maximize support.
- Confirmation of ETT placement is necessary to aid in proper resuscitation efforts. Verification by the presence of end-tidal carbon dioxide, whether by capnography or capnometry or by direct or indirect visualization, is mandatory to ensure appropriate placement.
- Cuff leak evaluation is a multifaceted endeavor requiring vigilance, diligence, and skill. An appropriate analysis of the potential cause, scrutinized against the risks and benefits of ETT exchange, must occur with limited interference to homeostasis.
- ETT exchange, whether for biofilm accumulation and luminal obstruction, ETT cuff damage (cuff leak), or other ETT mechanical failure (e.g., kinking) is a high-risk ordeal. The decision to exchange an ETT should be assessed against newer, currently available technologies, such as biofilm extraction, that are designed to salvage damaged ETTs. Should the decision to perform an exchange arise, airway adjuncts such as an airway exchange catheter and video laryngoscopy have proved invaluable for achieving higher success rates.
- Once an ETT is in place, efforts must be aggressive and perpetual to decrease the risk of ventilator-associated pneumonia (VAP); these efforts range from acid-suppression therapies to use of specially designed ETTs to advanced nursing care regimens. VAP appears to be more multifaceted than previously believed. Subglottic suctioning and biofilm management are just the beginning steps.
- Any area of a facility that deals with intubated patients should have a readily accessible difficult airway cart. The cart should be well outfitted but tailored to the types of airways managed and familiar as well as specific for the providers who respond to such emergencies.
- As with pulmonary artery catheters, it is not the difficult airway cart that manages the airway but the personnel who utilize it.
- It is better to investigate any perceived ETT problem electively than to deal with its consequences after it becomes an acute emergency.
- The landscape of ETT design, construction, and maintenance has changed and will continue to change over the next decade. Not all variations will prove effective, but improved patient care will take place.

VIII. Conclusions

IX. Clinical Pearls

I. INTRODUCTION

Mechanical ventilation is frequently used to provide respiratory support in times of critical illness or in patients undergoing general anesthesia. The main goals of mechanical ventilation are oxygenation and carbon dioxide elimination, which are ensured by maintaining adequate tidal volumes and respiratory rates. Since the foot-pump ventilation apparatus was designed by Fell O'Dwyer in 1888, significant advances have been made in positive-pressure ventilation. Because the mechanical ventilator can injure the lung, safe application to limit ventilator-induced lung injury (VILI) and negative interactions with other organ systems is fundamental in managing patients. This chapter reviews different modes of mechanical ventilation and describes their characteristics, attributes, and shortcomings.

When describing mechanical ventilation, we refer only to positive-pressure ventilation, which is used in contemporary settings. Negative-pressure ventilation was employed with the advent of mechanical ventilation to treat patients affected by poliomyelitis, but it is no longer used and not discussed in this chapter.

Esteban and colleagues reviewed the use of mechanical ventilation in intensive care units (ICUs) in North America, South America, Spain, and Portugal. Among the indications for mechanical ventilation, acute respiratory failure was the most common (66% of patients), followed by coma (15%), exacerbation of chronic obstructive pulmonary disease (COPD, 13%), and neuromuscular weakness (5%). The principal causes of acute respiratory failure across all centers were pneumonia (16%), sepsis (16%), postoperative infection (15%), heart failure (12%), acute respiratory distress syndrome (ARDS, 12%), trauma (12%), unspecified causes (13%), and aspiration (3%). Endotracheal tubes were used three times more often than tracheostomies to provide artificial airways. There was some variability in the modes of ventilation used in the different countries participating in the study. Assist-control ventilation (ACV) was the most common worldwide, followed by synchronized intermittent mandatory ventilation (SIMV) with pressure support and by pressure-support ventilation (PSV) alone. However, in North American ICUs, ACV and SIMV were used equally.[1]

To initiate mechanical ventilation, the patient must have in place an artificial airway with which to interface with the ventilator. Various types of airway devices are discussed in other chapters of this textbook. Patients are connected to a mechanical ventilator with an orotracheal tube (i.e., endotracheal tube), nasotracheal tube, or tracheostomy.

Common reasons for insertion of an artificial airway are to maintain airway patency, to prevent aspiration, to facilitate clearance of secretions, and to allow mechanical

ventilatory support.[2] There are several indications for mechanical ventilation:

- Hypoxemic respiratory failure
- Hypercapnic respiratory failure
- Mixed respiratory failure
- Altered mentation with inability by the patient to protect the airway
- Hemodynamic instability
- Maintenance of adequate oxygenation and ventilation during deep sedation, anesthesia, or neuromuscular blockade

II. INITIATION OF MECHANICAL VENTILATION

Mechanical ventilation can be delivered to the patient by invasive or noninvasive methods. Noninvasive positive-pressure ventilation (NIPPV) is delivered by an external nasal or a naso-oral interface such as a face mask. The decision to use invasive or noninvasive mechanical ventilation depends on the severity and rapid anticipated reversibility of the underlying condition and the mental status of the patient. NIPPV is useful in cases of hypercapnic respiratory failure, especially associated with COPD; obstructive sleep apnea; cardiogenic pulmonary edema; and hypercapnic respiratory insufficiency in persons with adequate mental status to remain communicative.[3-5] Application of NIPPV requires frequent assessments to ensure that the desired goal of oxygenation or ventilation is being achieved.

After the deciding to initiate invasive positive-pressure mechanical ventilation, several variables must be considered for effective implementation. They include tidal volume, respiratory rate, positive end-expiratory pressure (PEEP), fraction of inspired oxygen (F_{IO_2}), peak flow, plateau pressure, trigger sensitivity, flow rate, and flow pattern.

A. Tidal Volume

Tidal volume is the volume of air delivered to the lungs with each breath by the mechanical ventilator. Historically, initial tidal volumes were set at 10 to 15 mL/kg of actual body weight for patients with neuromuscular diseases. Over the past 2 decades, VILI has been associated with excessive tidal volume leading to alveolar distention.[6,7] The mechanism of lung injury includes regional overinflation,[8] stress of repeated opening and closing of lung units,[9,10] and sheer stress between adjacent structures with differing mechanical properties.[11]

The low-tidal-volume strategy, which uses 6 mL/kg of predicted body weight, has become the standard of care for patients with ARDS, following the Acute Respiratory Distress Syndrome Network (ARDS Network) publication in 2000.[12] The ARDS Network prospectively studied intubated patients with acute lung injury (ALI) or ARDS to determine whether a low-tidal-volume strategy, compared with a traditional-tidal-volume strategy, could improve mortality and decrease the total number of ventilator days. The final analysis showed a 23% reduction in all-cause mortality and a 9% absolute decrease in mortality with the use of a tidal volume of 6 mL/kg of predicted body weight and plateau pressures of 30 cm H_2O or less, compared with the usual practice of 12 mL/kg of predicted body weight and plateau pressures of 50 cm H_2O or less. Low tidal volume or so-called lung protective ventilation is recommended for all patients with ARDS. In patients without ARDS, a retrospective review demonstrated the relationship between ALI and the use of tidal volumes greater than 10 mL/kg of predicted body weight.[13] Considering the current evidence, tidal volumes greater than 10 mL/kg of predicted body weight should not be routinely used in the care of the mechanically ventilated patient.[12,13]

B. Respiratory Rate

The respiratory rate setting depends on the desired minute ventilation. Minute ventilation is a product of the respiratory rate and the tidal volume, and it is expressed in liters per minute. After a patient is intubated and placed on the mechanical ventilator, it is important to ensure adequate minute ventilation since the underlying pathophysiology or pharmacologic interventions can suppress the patient's ability to compensate for metabolic demands. In most scenarios, the rate is determined by observing the patient's native respiratory rate before intubation. The normal rate of minute ventilation is 5 to 7 L/min. In patients with sepsis or diabetic ketoacidosis, the native minute ventilation may be as high as 12 to 15 L/min, requiring a high respiratory rate. To adequately compensate for the acid-base derangements and ensure adequate minute ventilation, it is necessary to titrate the set respiratory rate until the desired pH and Pa_{CO_2} goals are met. Permissive hypercapnia (i.e., allowing the Pa_{CO_2} to increase intentionally to achieve other goals) may be appropriate in certain clinical conditions. Auto-PEEP (i.e. intrinsic PEEP) must be evaluated to ensure it remains at less than 5 cm H_2O. After the goal is achieved, it is a safe practice to set the rate at 4 breaths/min below the spontaneous breathing rate in the event that intrinsic or extrinsic factors suppress respiration. In patients on SIMV, the rate is initially set to meet up to 80% of the minute ventilation demands. Initial respiratory rates are usually 12 to 16 breaths/min, but rates of breaths per minute in the high 20s to low 30s may be required in patients with ARDS. In those with obstructive lung disease (e.g., asthma), a lower respiratory rate is desired, with significant risk of developing auto-PEEP. Assessment and management of auto-PEEP are discussed separately.

C. Positive End-Expiratory Pressure

PEEP is the alveolar pressure above the atmospheric pressure at end-expiration. Applied PEEP (i.e., extrinsic PEEP) through mechanical ventilation allows delivery of positive pressure at the end of expiration to keep the unstable lung units from collapse.[14] PEEP increases the peak inspiratory pressure, which directly overcomes the opening pressure of the unstable lung units. Low levels of PEEP (3 to 5 cm H_2O) are routinely used in patients on mechanical ventilation. It can decrease alveolar collapse at end-expiration and may reduce the incidence of

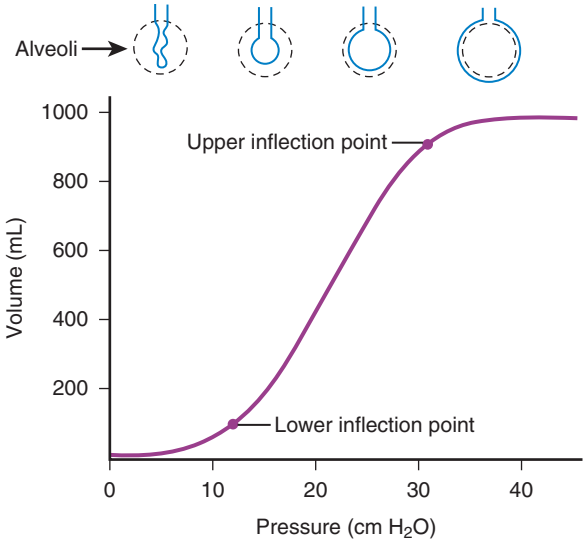

Figure 48-1 Calculation of optimal positive end-expiratory pressure (PEEP). Mechanical ventilation delivers low levels of PEEP to keep unstable alveoli from collapse at end expiration. The volume-pressure curve can be used to assess changes in lung compliance and to determine a ventilation strategy by identifying the lower inflection point, which is the critical opening pressure of collapsed alveoli, and the upper inflection point, which indicates a state of lung overinflation. (From Haitsma JJ: Physiology of mechanical ventilation. *Crit Care Clin* 23:117–134, 2007.)

ventilator-associated pneumonia.[15] Higher levels of PEEP are employed to improve oxygenation in patients with hypoxic respiratory failure. Goals in managing ARDS are to optimize alveolar recruitment and decrease cycles of recruitment and derecruitment of alveolar lung units. Several strategies are used to determine optimal PEEP, but there are limited data to support their routine use. Determining the lower inflection point of the pressure-volume curve (P_{flex}), which reflects the transition from low to higher compliance, and applying PEEP of 2 cm H_2O greater than this point may be used to estimate the appropriate level of applied PEEP (Fig. 48-1).[16]

Because it is often impractical to routinely obtain pressure-volume curves, algorithms have been developed (e.g., in ARDS Network trials), with Pa_{O_2}/F_{IO_2} ratios to set the recommended PEEP (Table 48-1).[12] Measuring esophageal pressures to estimate transpulmonary pressures has been studied as a method to determine the appropriate applied PEEP in patients with ARDS, and this approach has demonstrated improvement in oxygenation and compliance.[17] Trials of increasing or decreasing PEEP can also be used.[18,19] Higher levels of PEEP in postoperative patients have had no benefit.[20]

Lung injury in patients with hypoxic respiratory failure is heterogeneous. Since the collapse and repeated opening and closing of unstable lung units leads to further injury, its prevention would be the optimal ventilator strategy. High PEEP has been used mitigate alveolar collapse and cyclic alveolar stress. Several trials demonstrated that high PEEP increased oxygenation but did not improve mortality rates.[21,22] However, a meta-analysis of high PEEP trials indicated a mortality benefit for patients with a Pa_{O_2}/F_{IO_2} ratio of less than 200.[23] The optimal method of applying adequate PEEP has not been established.[14] Trials in ARDS patients demonstrate PEEP requirements are usually between 12 and 20 cm H_2O.

D. Fraction of Inspired Oxygen

On initiation of mechanical ventilation, the F_{IO_2} usually is set at 1.0. The goal is to rapidly reduce the F_{IO_2} to the target Pa_{O_2} and Sp_{O_2} to limit the consequences of supplemental oxygen. In most patients, a target Pa_{O_2} of 60 mm Hg and Sp_{O_2} of 90% meets oxygenation requirements. However, some patients may have higher Pa_{O_2} targets based on their underlying cardiopulmonary status (e.g., myocardial ischemia, pulmonary hypertension). In patients with ARDS, targeting a Pa_{O_2} as low as 50 mm Hg may be appropriate to limit alveolar injury.[24] A prolonged high level of F_{IO_2} has been associated with airway and parenchymal injury, atelectasis from nitrogen washout, and increased risk of diffuse alveolar damage, which is even higher in patients receiving bleomycin therapy.[25,26] If the need for supplemental F_{IO_2} remains greater than 0.6, F_{IO_2} should be reduced with strategies such as applied PEEP and alternative ventilator modes.

E. Peak Pressure

Peak airway pressure is a measurement of the maximum pressure felt by the airways on inspiration. In the passive patient, peak airway pressure, or peak pressure, depends on the respiratory rate, tidal volume, and inspiratory flow rate in volume-targeted modes of mechanical ventilation. When awake and active, the patient's effort contributes to the peak pressure. In pressure-targeted ventilator modes, the peak pressure is directly related to the inspiratory pressure that is set and the inspiratory flow rate.[27] Studies have not consistently shown barotrauma to be an adverse consequence of increased peak pressures.[28,29] The peak airway pressure typically is higher than the plateau pressure, and the difference indicates airway resistance.

F. Plateau Pressure

Plateau pressure is the pressure that is applied by the mechanical ventilator to the small airways and alveoli. The plateau pressure is measured at end-inspiration with an inspiratory hold maneuver on the mechanical ventilator that is 0.5 to 1 second. Meta-analysis demonstrated a significant correlation between plateau pressures greater than 35 cm H_2O and the risk of barotrauma.[30] In the ARDS Network trial, lower tidal volume ventilation with plateau pressures less than 30 mm Hg was associated with a lower mortality rate than that found for conventional tidal volume using plateau pressures less than 50 mm Hg.[12]

Common reasons for increased plateau pressures are the use of high PEEP, inspiratory flow, and tidal volume. Adverse consequences of high plateau pressures are barotrauma, resulting in ventilator-associated lung injury, pneumothorax, pneumomediastinum, and subcutaneous emphysema. If barotrauma develops, it may be beneficial to reduce the plateau pressures further by decreasing the tidal volume, PEEP, or flow or by increasing the patient's sedation.

G. Trigger Sensitivity

Sensors on the ventilator detect the patient's effort in terms of negative inspiratory pressure applied to the circuit by the patient or inspiratory flow of air from the patient. This is referred to as "triggering the ventilator" or "triggering a breath." Pressure trigger sensitivity typically is set between –1 and –3 cm H_2O, and a breath is triggered when a negative inspiratory effort is greater than the set sensitivity. A flow-triggered breath is delivered when the return flow is less than the delivered flow. When the patient does not provide adequate negative inspiratory pressure or flow rate to trigger breaths, the ventilator provides mandatory breaths to the patient at the set parameters. The breaths are initiated by the ventilator at the set time, as determined by the set respiratory rate, and it delivers the breath at the prescribed flow rate until the desired tidal volume has been achieved, after which the ventilator cycles off for passive exhalation.

H. Flow Rate

Flow rate, or peak inspiratory flow rate, is the maximum flow at which a set tidal volume breath is delivered by the ventilator. Most modern ventilators can deliver flow rates between 60 and 120 L/min. Flow rates should be titrated to meet the patient's inspiratory demands.[31] If the peak flow rate is too low for the patient, dyspnea, patient-ventilator asynchrony, and increased work of breathing may result. High peak flow rates increase peak airway pressures and lower mean airway pressures, which may decrease oxygenation.[27]

In most patients, peak flow rates of 60 L/min are adequate. Higher flow rates are required in patients with higher ventilator demands.[31] Higher peak flow rates may also be necessary in patients with obstructive lung disease to decrease inspiratory time, thereby increasing the expiratory time and reducing the risk of developing auto-PEEP.[32,33]

I. Flow Pattern

Modern mechanical ventilators can deliver various inspiratory flow patterns. The constant or square waveform is a description of the inspiratory flow that is delivered by the mechanical ventilator. It correlates with volume-cycled breaths, in which the inspiratory flow remains constant until the desired tidal volume is delivered and then remains at that level until expiration. In this pattern of inspiratory flow, the airway pressure varies and depends on the patient's effort and compliance of the lung. The sinusoidal wave flow gradually increases and decreases throughout the respiratory cycle. In the decelerating ramp wave (i.e., saw-tooth wave), the flow rate begins maximally and decreases until the end of inspiration. It parallels normal inspiratory pattern most closely. The ramp wave yields the most homogenous distribution of ventilation in most conditions, decreases peak airway pressures, and improves carbon dioxide (CO_2) elimination.[34] For patients who are triggering the ventilator, this strategy of ventilation is recommended (Fig. 48-2).

III. COMMON MODES OF MECHANICAL VENTILATION

The three most commonly used modes of mechanical ventilation are ACV, SIMV, and PSV. Each mode describes whether breaths are volume constant or pressure constant; which are mandatory or spontaneous, or both; and which variables determine a change in function. All three modes have uses throughout the spectrum of stabilization of ventilation, maintenance of ventilation, and weaning from mechanical support.

Choice of the type of mechanical ventilation is most often determined by whether resting of respiratory muscles is indicated. Patients who are hemodynamically compromised, patients with severe oxygenation or ventilation derangements, and those undergoing general endotracheal anesthesia qualify for a rest of respiratory muscles. In these cases, it is prudent to choose a mode of ventilation that accomplishes ventilation without the need for

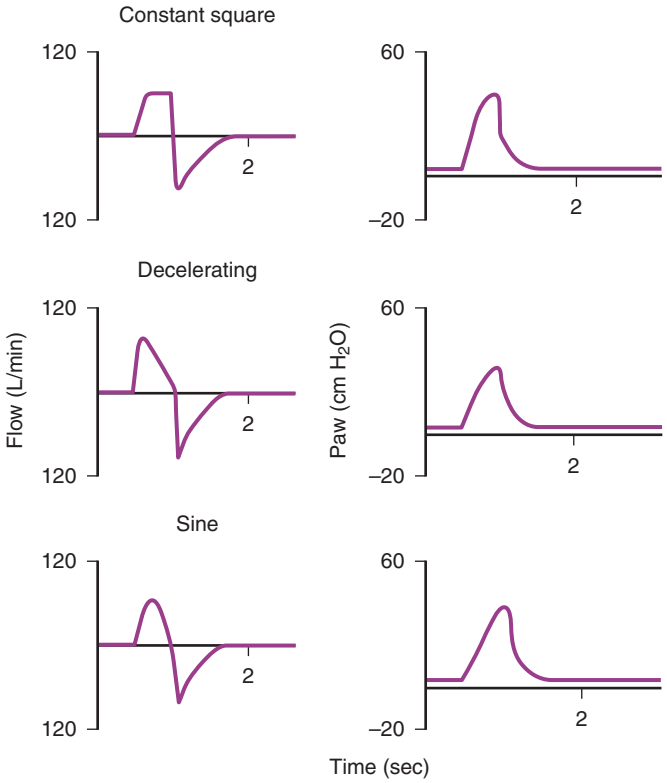

Figure 48-2 The three most common inspiratory flow patterns in humans *(left)* are compared with their corresponding pressure versus time curves *(right)*. (From Yang SC, Yang SP: Effects of inspiratory flow waveforms on lung mechanics, gas exchange and respiratory metabolism in COPD patients during mechanical ventilation. *Chest* 122:2096–2104, 2002.)

spontaneous respirations; ACV is most often used. However, if use of muscles of respiration is desired, SIMV or PSV should be considered. Patients in whom the use of respiratory muscles is desired are usually those being weaned from mechanical ventilation or undergoing assessment of muscle strength and adequacy of spontaneous work of breathing. PSV is the only mode of the three that entirely relies on the patient spontaneously breathing. Table 48-2 shows the set and variable parameters in each common mode of ventilation. Control mode of ventilation (CMV) is the original mode of ventilation. In CMV, the patient receives a positive-pressure breath at a set rate without the ability to influence how it is delivered.

A. Assist-Control Ventilation

Volume assist-control ventilation (VACV) is the most frequently used initial mode of ventilation, and it has several advantages in stabilization and maintenance of adequate ventilation. Using VACV allows adequate oxygenation and ventilation, and it decreases the work of breathing while treating a pathologic process. It is commonly used in patients expected to be passive, as in routine use in the operating room for general anesthesia and in comatose patients.

VACV is a combination mode of ventilation in which the preset tidal volume is delivered in response to the inspiratory effort or if no patient effort occurs within a set period of time. The period is determined by the backup respiratory rate set on the ventilator. A patient-triggered breath is sensed by a change in airway flow or pressure. When the change reaches the trigger threshold, the ventilator delivers the predetermined tidal volume. In ACV, the limit variable that increases to the set threshold before inspiration ends is volume or flow, or both. The cycle variable that ends inspiration is volume or time. Peak inspiratory airway pressure and plateau pressure are variable in this setting. In patients with deep sedation or neuromuscular blockade, the ACV mode functions like CMV. The advantage of ACV is that it substantially decreases the work of breath and decreases myocardial oxygen demand. The disadvantages of ACV in the active patient are that it is less comfortable than spontaneous breathing and that it can induce respiratory alkalosis and breath-stacking (Table 48-3).

When ACV is used in a volume-targeted mode, airway pressures vary. When patients with severe hypoxemia (e.g., ARDS) require high PEEP and F_{IO_2} settings to maintain adequate oxygenation, the airway pressures that are generated to deliver the desired tidal volume increase. This increasing pressure can be measured as the peak inspiratory pressure, the mean airway pressure, or the plateau pressure, all of which attempt to describe the pressures that are transmitted through the airways at different levels and at different points in the respiratory cycle. As the plateau pressures increase, reflecting increasing alveolar pressure, it may be prudent to use a pressure-control variant of the ACV mode.

Similar to volume-targeted ACV, the pressure-targeted ACV mode requires the user to input the frequency (i.e., desired respiratory rate), PEEP, and F_{IO_2}, but instead of a desired tidal volume, the user sets the upper limit of the inspiratory pressure that is allowable. As the ventilator delivers a breath, the inspiratory flow continues until the maximum pressure or allotted time is reached, and the flow then ceases. In pressure-targeted ACV, the tidal volume varies, and consistency is sacrificed to prevent barotrauma by high pressures (Table 48-4).[35] Figure 48-3 depicts the differences in VACV and pressure

assist-control ventilation (PACV) in graphs of pressure versus time and airflow versus time.

ARDS is commonly seen in medical and surgical patients and presents dilemmas in treatment.[36] According to the 1994 American-European Consensus Conference definition, ARDS is recognized as a spectrum, which includes ALI, as defined by a ratio of the partial pressure of arterial oxygen to the fraction of inspired oxygen (P_{AO_2}/F_{IO_2}) of 300 or less, and ARDS, which is defined as a P_{AO_2}/F_{IO_2} ratio of 200 or less. Other characteristics of ARDS are the acute onset of bilateral pulmonary infiltrates and a pulmonary capillary wedge pressure of less than 18 mm Hg (or no evidence of elevated left atrial pressure). ARDS is synonymous with noncardiogenic pulmonary edema.[37] ALI has many direct and indirect causes. Examples of direct injury are pneumonia, orogastric fluid aspiration, and inhalation injury; indirect causes of injury include severe sepsis, shock, pancreatitis, blood product transfusion, and narcotic overdose.[38]

Ventilatory strategies for the management of ARDS rest on the results of the ARDS Network studies, which demonstrated that patients given tidal volumes of 6 mL/kg of predicted body weight had improved mortality rates compared with patients with tidal volumes of 12 mL/kg of predicted body weight. Another finding was that plateau pressures less than 30 cm H_2O protect the lung (Fig. 48-4 and Table 48-5).[12] In 1998, Amato and colleagues demonstrated the mortality benefit of lower tidal volumes and a lower rate of barotraumas (Fig. 48-5).[16] Two meta-analyses demonstrated decreased mortality rates with the use of low tidal volume ventilation (i.e., lung-protective ventilation).[39,40] In ARDS management, plateau pressures should be less than or equal to 30 cm H_2O or the lowest possible level. A high-PEEP strategy decreased the mortality rate in a meta-analysis of 2299 ARDS patients.[23] Randomized trials of ventilation in ARDS patients are summarized in Table 48-6.

B. Synchronized Intermittent Mandatory Ventilation

SIMV is a frequently used mode of ventilation in hospital medical and surgical units. SIMV has some features that incorporate characteristics of ACV and PSV. SIMV uses

(From Al-Saady N, Bennett ED: Decelerating inspiratory flow waveform improves lung mechanics and gas exchange in patients on intermittent positive-pressure ventilation. *Intensive Care Med* 11:68-75, 1985.

the same settings as ACV: frequency, tidal volume, PEEP, and F_{IO_2}, but it also has a setting for a prescribed pressure support for a spontaneous breath. The purpose of the two types of breaths (i.e., mandatory and spontaneous) is to allow increased diaphragmatic activity and increased work of breathing by the patient when triggering spontaneous breaths. SIMV is sometimes used as a weaning mode, but it can prolong mechanical ventilation and is therefore not routinely recommended for weaning.[41]

When a patient is deeply sedated or paralyzed, SIMV functions the same as ACV. The patient receives the set number of mandatory breaths as determined by the set frequency at the prescribed tidal volume with the set PEEP and F_{IO_2}. However, in patients who are more awake, SIMV can assist the patient when he or she triggers a mandatory breath and can support the patient with the prescribed pressure support and PEEP in spontaneous breaths that are above the number of mandatory breaths set. The advantage of this mode is that it allows the patient to get the set number of mandatory breaths by controlling the breaths (if the patient is not initiating inspiration) or assisting breaths (if the patient is triggering the start of inspiration), and the patient is allowed to make an effort at spontaneous breaths. The use of SIMV also may reduce sedation requirements (see Table 48-3).[42]

TABLE 48-5

Main Outcome Variables in the Acute Respiratory Distress Syndrome (ARDS) Network Trial of Low Tidal Volumes versus Traditional Tidal Volumes in Patients with ARDS

Outcome Variable	Group Receiving Lower Tidal Volumes	Group Receiving Traditional Tidal Volumes	*P* Value
Death before discharge home and breathing without assistance (%)	31.0	39.8	0.007
Breathing without assistance by day 28 (%)	65.7	55.0	<0.001
No. of ventilator-free days, days 1 to 28 (%)†	12 ± 11*	10 ± 11*	0.007
Barotrauma, days 1 to 28 (%)‡	10	11	0.43
No. of days without failure of nonpulmonary organs or systems, days 1 to 28§	15 ± 11*	12 ± 11*	0.006

*Mean ± SD.

†The number of ventilator-free days is the mean number of days from day 1 to day 28 during which the patient had been breathing without assistance for at least 48 consecutive hours.

‡Barotrauma was defined as any new pneumothorax, pneumomediastinum, or subcutaneous emphysema or a pneumatocele that was more than 2 cm in diameter.

§Circulatory failure was defined as a systolic blood pressure of 90 mm Hg or less or the need for treatment with any vasopressor; coagulation failure as a platelet count of 80,000/mm^3 or less; hepatic failure as a serum bilirubin concentration of at least 2 mg/dL (34 µmol/L); and renal failure as a serum creatinine concentration of at least 2 mg/dL (177 µmol/L).

†Precise comparison of resulting settings across the studies is difficult, because there is variation in the schedule of reporting; we attempted to compare mean values on days 1 through 3.

‡Barotrauma was defined by Amato and coworkers as clinical barotrauma; by Brower and colleagues as pneumothorax; by Stewart and coworkers as pneumothorax, pneumomediastinum, subcutaneous emphysema, and lung cysts on a chest radiograph; and by Brochard and colleagues as pneumothorax requiring a chest tube.

Adapted from American Thoracic Society, European Society of Intensive Care Medicine, and Societé de Réanimation de Langue Française: International Consensus Conference in intensive care medicine: Ventilator-associated lung injury in ARDS. *Am J Respir Crit Care Med* 160:2118–2124, 1999.

C. Pressure-Support Ventilation

PSV is used for patients who are awake enough to accomplish spontaneous breathing. PSV was initially developed to reduce work of breathing in SIMV but evolved into a stand-alone mode of ventilation. PSV augments the patient's spontaneous inspiratory efforts with the selected level of positive airway pressure. The inspiratory pressure is delivered until the flow decreases to a predetermined level (usually 25% of peak flow). PSV allows the user to control the desired pressure support, PEEP, and F_{IO_2}. This mode relies entirely on spontaneous breaths by the patient, who must have an intact ventilatory drive. The work of breathing of PSV is inversely proportional to the level of pressure support and the flow rate.[43] Because no tidal volume is guaranteed by this mode of ventilation, pressure support must be titrated to help the patient achieve an adequate tidal volume. However, any change in lung compliance or airway impedance results in a change in tidal volume. A certain level of pressure support is needed to overcome the resistance of the ventilator circuit and endotracheal tube. This typically is less than 10 cm H_2O, but it can be higher with narrower endotracheal tubes.[44] Pressure support above that needed to overcome resistance supplements the achieved tidal volumes. Typical pressure support settings are 5 to 25 mm H_2O. When full ventilator support is needed for the patient, PSV may not be the ideal mode because it requires a higher work of breathing and minute ventilation is not guaranteed (see Table 48-3).

D. Pressure-Regulated Volume Control

Pressure-regulated volume control (PRVC) can be employed with ACV or SIMV. With PRVC, the ventilator monitors the patient's effort and varies the peak inspiratory pressure that is allowed with the inspiratory flow to achieve the set tidal volume. The ventilator provides a breath at a low pressure and then calculates the peak pressure necessary to deliver the set tidal volume. That pressure level is delivered during the next breath. If the target is not attained, the peak pressure is adjusted by 1 to 3 cm H_2O for the next breath. This allows breath-to-breath correction and enables increased airway pressure control. Because the inspiratory time and flow are autoregulated, it results in a smaller increase in plateau airway pressures with a given tidal volume. Because the ventilator responds to the patient's effort in PRVC, as the patient's ventilator demand increases, the inspiratory pressure decreases, thereby increasing the patient's work of breathing.[45]

IV. UNCOMMON MODES OF VENTILATION

A. Inverse-Ratio Ventilation

Inverse-ratio ventilation (IRV) is positive-pressure ventilation with an inspiratory-expiratory (I:E) ratio of greater than 1. It has been used in the management of severe ARDS to improve oxygenation when PEEP has been optimized.[46] I:E ratios usually range from 1.2 to 1.5, whereas in IRV, they may be 1:1, 2:1, or higher. Increasing the inspiratory time increases mean airway pressure without increasing the inspiratory plateau pressure, which may improve oxygenation.[47,48] This application is most commonly used with time-cycled pressure-control ventilation (PCV), but it can also be used with volume-cycled ventilation. The improvements in oxygenation are modest, and carbon dioxide elimination is preserved or enhanced[48,49]; however, not all studies have shown benefit.[50] Development of auto-PEEP is common in IRV, and it may be responsible for some of the improvements in oxygenation, but it also increases the risk of barotrauma. Because the benefits of IRV are controversial, it should be limited to use in patients with severe ARDS with refractory hypoxemia.[51]

B. Airway Pressure–Release Ventilation

Airway pressure–release ventilation (APRV) is similar to a blend of inverse-ratio PCV and SIMV. APRV offers two levels of continuous positive airway pressure (CPAP) ventilation, in which it uses high and low pressures to aid in recruitment of atelectatic lung units and allows spontaneous breathing.[52,53] The continuous high positive pressure (P_{high}) is delivered by the ventilator for a prolonged duration (T_{high}) and then drops to the lower pressure (P_{low}) for a short duration (T_{low}). Spontaneous breathing can occur during high and low pressures. Overall, the lower pressure is set to manage hypoxemia and the upper level to promote CO_2 elimination. When the patient cannot initiate breaths, the mode is identical to inverse-ratio PCV.[54] One study of 24 patients with ARDS showed that when APRV was compared with PSV, APRV improved oxygenation and cardiac parameters, along with improvements in ventilation-perfusion matching in the lung.[55]

APRV can decrease peak airway pressures, improve oxygenation, improve alveolar recruitment, and improve cardiac output, but the findings have been inconsistent, and there has been no evidence of mortality benefit.[56-59] During periods of transition between low and high pressures, patient ventilator dyssynchrony can occur. APRV is not recommended for patients with obstructive lung disease or high levels of minute ventilation (Figs. 48-6 and 48-7).

Bi-level ventilation is similar to APRV but has additional features.[60] The transitions from low and high pressures are coordinated with the patient's effort to reduce dyssynchrony. T_{low} usually is longer in bi-level ventilation, which allows for more spontaneous breaths to occur at this pressure level. As in APRV, bi-level ventilation has been used primarily in patients with ALI or ARDS, and it should be avoided in patients with obstructive lung disease because of the risk of auto-PEEP due to shortened expiratory times.

C. High-Frequency Ventilation

There are many types of high-frequency mechanical ventilation. High-frequency ventilation is positive-pressure ventilation with tidal volumes near the anatomic dead space and flow rates greater than 60 breaths/min. The

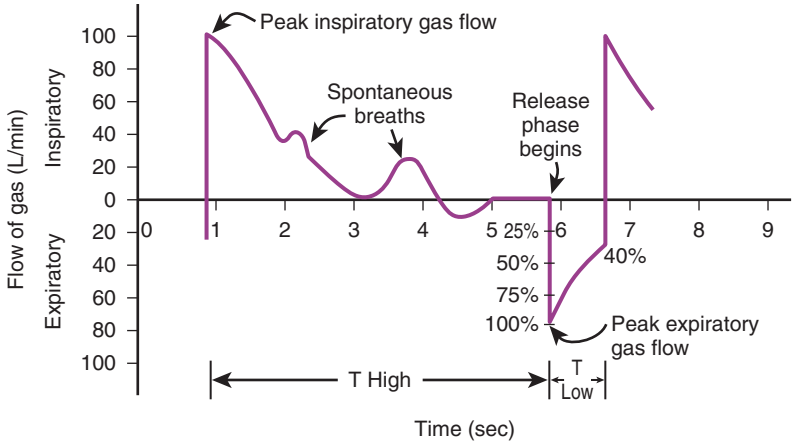

Figure 48-6 Inspiratory and expiratory flow of gas in airway pressure release ventilation. *T High,* Number of seconds spent at the higher pressure; *T Low,* number of seconds spent at the lower pressure. (From Frawley PM, Habashi NM: Airway pressure release ventilation: Theory and practice. *AACN Clinical Issues* 12:234–246, 2001.)

theoretical advantages over conventional ventilation are that the tidal volumes of 1 to 3 mL/kg and the higher levels of PEEP reduce the risk of cyclical alveolar injury and collapse and limit alveolar overdistention. The ability to maintain high mean airway pressures and lower plateau pressures can improve oxygenation.

High-frequency oscillatory ventilation (HFOV), sometimes called the *oscillator,* is a means of improving oxygenation by providing an oxygen-rich and CO_2-poor gas at high respiratory rates that rapidly mixes with sinusoidal flow at stroke volumes that approximate anatomic dead space. HFOV is the most commonly used high-frequency ventilator in adults. HFOV uses a pump to generate a respiratory frequency of 3 to 6 Hz or 180 to 360 breaths/min. In a 1984 publication, Chang described five mechanisms of oxygen delivery by high-frequency oscillation: direct alveolar ventilation of proximal airways; bulk convective gas mixing in conductive airways by recirculation of air among neighboring airways in different cycles of opening and closing of the alveolus; convective transport of gases; longitudinal dispersion by airway turbulence; and molecular diffusion.[61] Additional work is needed to delineate the exact mechanisms involved in gas exchange in high-frequency ventilation.

Selection guidelines for HFOV do not exist, but patients with ARDS who develop refractory hypoxemia on conventional ventilation are sometimes considered.[62-64] In patients with ALI that progresses to ARDS, high PEEP and F_{IO_2} values may be required to sustain oxygenation. HFOV uses high airway pressures during very short time intervals to help recruit and oxygenate atelectatic lung. The mean airway pressure is set by manipulation of the inspiratory flow rate and an expiratory back-pressure valve. A multicenter trial of 148 patients with ARDS compared conventional ventilation with high-frequency oscillatory ventilation. Patients were randomized to receive conventional mechanical ventilation or high-frequency oscillatory ventilation and were followed to compare 30-day ventilator-free survival. Results demonstrated improved 30-day mortality rates in the HFOV group, but it did not rise to statistical significance, nor did various secondary end points, including rates for 6-month mortality and duration of mechanical ventilation.[63] HFOV in patients with obstructive lung disease (e.g., COPD, asthma) may lead to significant auto-PEEP.

The oscillator requires vigilance on the part of the physician and respiratory therapist because patients are usually hypoxemic at the initiation of HFOV. Because the oscillator is uncomfortable for patients, they usually require increased sedation and often need pharmacologic paralysis. Careful titration of inspiratory pressure and frequency are needed to obtain optimal settings. During HFOV, ventilation is a passive process, and the patient must have the endotracheal tube cuff deflated to allow for passive exhalation of CO_2. Overall, HFOV appears to be equivalent to conventional ventilation in ARDS patients and useful in the management of refractory hypoxemia and severe air leaks (Fig. 48-8).[65]

In high-frequency jet ventilation (HFJV), a pressurized gas is introduced by inserting a cannula from the HFJV device into the endotracheal tube. An initial pressure of 35 pounds per square inch is set with a rate of

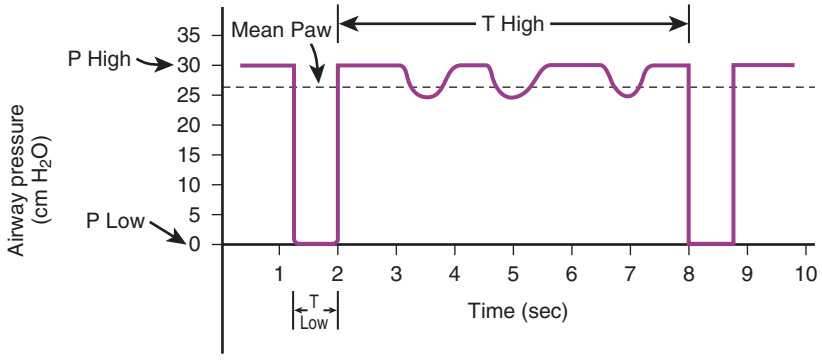

Figure 48-7 Pressure-time curve for airway pressure release ventilation. *Paw,* Airway pressure; *P High,* higher pressure used for respiration on bilevel (e.g., 30 cm H_2O); *P Low,* lower pressure used on bilevel (e.g., 0 cm H_2O); *T High,* number of seconds in the respiratory cycle spent at the higher pressure; *T Low,* number of seconds spent at the lower pressure. (From Frawley PM, Habashi NM: Airway pressure release ventilation: Theory and practice. *AACN Clinical Issues* 12:234–246, 2001.)

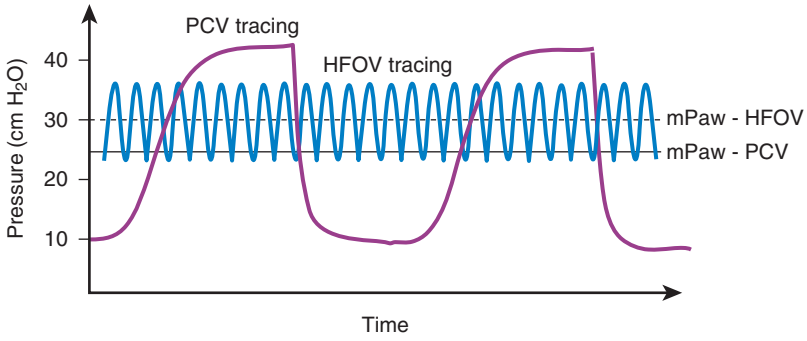

Figure 48-8 The pressure-time curve for high-frequency oscillatory ventilation *(HFOV)* is superimposed on the tracing for pressure-control ventilation *(PCV)* for comparison. (From Chang KP, Stewart TE, Mehta S: High-frequency oscillatory ventilation for adult patients with ARDS. *Chest* 131:1907–1916, 2007.)

100 to 150 breaths/min and an inspiratory fraction of 30%.[66] HFJV is more commonly employed in pediatric patients, but it has some use in laryngeal surgery. The drawback of conventional jet ventilators is there is not an adequate measure of intrapulmonary pressure in the circuit, and the patient may be at risk for volutrauma from overdistention of distal airways.

High-frequency pressure ventilation (HFPV) is a time-cycled, pressure-limited mode of ventilation that delivers subphysiologic tidal volumes at rates as high as 500 breaths/min.[67] HFPV has been used in burn units, specifically for patients with inhalation lung injury, and for salvage therapy in patients with severe ARDS.[68] The basic tenets are the same as for HFOV, but it oscillates at two different pressure levels. A Phasitron valve at the end of the endotracheal tube delivers small tidal volumes at frequencies of 200 to 900 breaths/min superimposed on PCV. Whereas the HFOV uses rapid oscillations of small volumes at high frequencies that transiently reach high airway pressures, the HFPV prolongs the application of high airway pressure at high frequencies to assist in clearance of mucus and in sloughing airway secretions. A single-center, prospective, randomized trial comparing HFPV with low tidal volume ventilation in burn patients with ALI demonstrated no difference in mortality rates or ventilator-free days.[69]

V. NONINVASIVE VENTILATION

NIPPV provides ventilatory support through an external interface such as a nasal or oronasal mask that is firmly secured to the face. The physiologic effect of NIPPV rests in its ability to provide positive pressure into the nasopharynx or oropharynx that splints open the airway and is then transmitted downstream to the lungs, where it increases lung volume. Several cardiovascular effects are seen with NIPPV in this setting. Decreased venous return occurs, and the increased intrathoracic pressure can decrease afterload and thereby increase cardiac output. Figure 48-9 details the interaction of the effects of NIPPV on the cardiopulmonary system.

Patient selection is paramount in the decision to initiate NIPPV. NIPPV is not recommended for patients with upper airway obstruction, cardiac arrest, hemodynamic instability, respiratory arrest, injury of the face, massive gastrointestinal bleeding, a high risk of aspiration, significantly depressed mentation, or an inability to clear secretions (Table 48-7).[70-72]

NIPPV has been useful in many situations, including exacerbations of COPD with hypercapnia,[73-75] cardiogenic pulmonary edema,[76-79] hypercapnic respiratory failure (i.e., Glasgow Coma Scale score greater than 10), and hypoxic respiratory failure.

NIPPV can be delivered by a standard ventilator through a face mask, nasal mask, or nasal plugs. Heated humidification increases the patient's comfort.[80] Common modes of ventilation used to deliver NIPPV are CPAP, bi-level positive airway pressure (BPAP), PSV, proportional-assist ventilation (PAV), and ACV. Modes of NIPPV may be selected on the basis of patient characteristics. For example, patients who require greater support in reducing the work of breathing should be placed on ACV mode, or the patient's comfort may be increased with PSV.[81] There was no difference in mortality rates between these modalities for various disease states.[82-85] The patient should be monitored very closely after initiation of NIPPV. If prompt improvement is not evident within 1 or 2 hours, the physician should proceed to intubation.[86] In a prospective, multicenter, cohort study, NIPPV failed in 30% of patients. The highest intubation rates occurred in patients with ARDS (51%) or community-acquired pneumonia (50%), and the lowest rates were for those with pulmonary contusion (18%) or cardiogenic pulmonary edema (10%) (Fig 48-10).[87]

NIPPV improves mortality rates and length of stay for patients with severe COPD exacerbations.[4] A meta-analysis

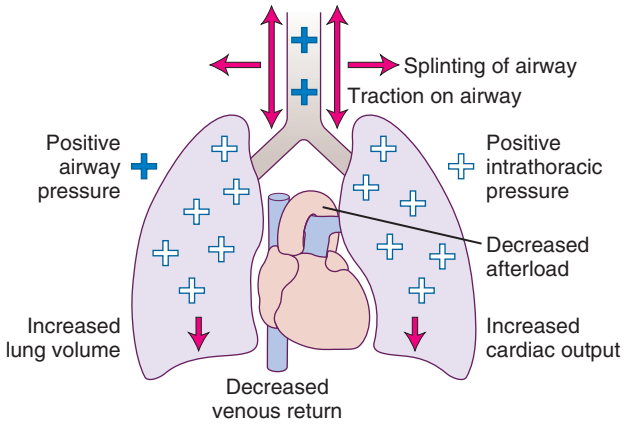

Figure 48-9 Physiologic effects of positive airway pressure. (Adapted from Antonescu-Turcu A, Parthasarathy S: CPAP and Bi-level PAP therapy: New and established roles. *Respir Care* 55:1216–1228, 2010.)

TABLE 48-7
Factors for Success or Failure of Noninvasive Positive-Pressure Ventilation

Success	Failure
• High $Paco_2$ with low A-a gradient • Improvement in pH, $Paco_2$, and decreased respiratory rate after 1 hour of NIPPV • Good level of consciousness	• High APACHE score • Pneumonia on chest radiograph • Copious secretions • Edentulous • Poor nutrition status • Confusion or delirium

of patients with severe COPD exacerbations and mild COPD exacerbations demonstrated no mortality benefit for the patients with milder COPD exacerbations.[74] In cases of cardiogenic pulmonary edema, NIPPV decreases the rate of intubation, but the mortality benefit is uncertain because of conflicting study results.[3,88] Patients with hypoxic respiratory failure and asthma exacerbations may benefit from NIPPV. NIPPV use in post-extubation failure has been studied.[89,90] If NIPPV is used immediately on extubation in patients with hypercapnia during the spontaneous breathing trial, it may prevent reintubation and is associated with a reduction in mortality rates.[91] NIPPV use in patients after the development of post-extubation failure did not reduce reintubation rates and increased mortality rates, with a longer median time from failure to reintubation in the NIPPV group.[92]

In patients with severe COPD exacerbations and cardiogenic pulmonary edema, NIPPV should be attempted if no contraindications exist. In other causes of respiratory failure, such as hypoxic respiratory failure, NIPPV can be considered if the patient does not meet the criteria for intubation. However, if the patient does not stabilize in the first 2 hours, management should rapidly progress to intubation and invasive mechanical ventilation.

VI. WEANING FROM MECHANICAL VENTILATION

The process of weaning from mechanical ventilation is a continuum from decreasing support provided by the ventilator to assessment of readiness using multiple variables, and discontinuation from the mechanical ventilator.

In 2001, a collective task force from the American College of Chest Physicians, the American Association of Respiratory Care, and the American College of Critical Care Medicine examined the issue of discontinuation of mechanical ventilation and defined patients who required prolonged mechanical ventilation and strategies to liberate them from the mechanical ventilator. They found that patients who are mechanically ventilated spend approximately 42% of their ventilator time undergoing the weaning process. The task force offered 12 recommendations to standardize practice for discontinuing mechanical ventilation, including searching for causes of respiratory failure; early discontinuation of sedation of postoperative patients; ensuring daily spontaneous breathing trials for patients who meet the criteria for hemodynamic, pulmonary, and mental stability; outlining criteria for evaluation of patients on a spontaneous breathing trial; and strategies for prolonged weaning and daily spontaneous breathing trials assisted by nonphysician practitioners within the health care organization.[93] The clinical criteria outlined by the task force includes clinically improving cause of respiratory failure, adequate oxygenation (defined as Pao_2/Fio_2 greater than 150 mm Hg or oxyhemoglobin saturation greater than 90%, while receiving Fio_2 less than or equal to 0.4 and a PEEP less than or equal to 5 cm H_2O); hemodynamic stability (absent or low-dose vasopressors and no signs of myocardial ischemia); arterial pH greater than 7.25; and a patient that is able to initiate a spontaneous inspiratory effort.[93]

A study of 300 patients published in 1996 demonstrated the value of daily screening of patients by trials of spontaneous breathing. In the study, patients were assessed daily by the nurse and respiratory therapist, and if preset guidelines were met, patients underwent a 2-hour spontaneous breathing trial. If the patient passed the trial, the physician was notified, and the patient was extubated. The study demonstrated a decrease in ventilator days; a decrease in the number of complications, including reintubation; and lower hospital cost.[94] Another study showed a decrease in the number of ventilator days and ICU days with daily weaning of sedation.[95]

In 2007, a second task force produced the Statement of the Sixth International Consensus Conference on

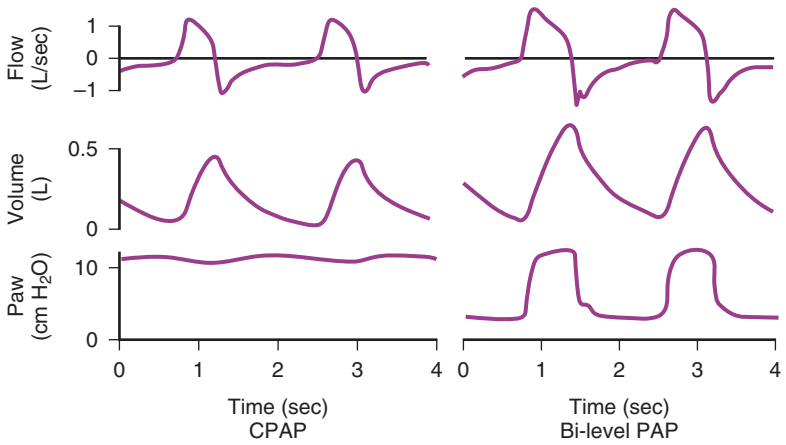

Figure 48-10 Airflow, volume, and airway pressure *(Paw)* versus time tracings for continuous positive airway pressure *(CPAP)* and bi-level positive airway pressure *(Bi-level PAP).* (From Antonescu-Turcu A, Parthasarathy S: CPAP and Bi-level PAP therapy: New and established roles. *Respir Care* 55:1216–1228, 2010.)

TABLE 48-8
Time from Initiation of Weaning to Successful Extubation with Various Ventilation Modes

Weaning Technique	Median (days)	First Quartile (days)	Third Quartile (days)
Intermittent mandatory ventilation	5	3	11
Pressure-support ventilation	4	2	12
Intermittent trials of spontaneous breathing	3	2	6
Once-daily trial of spontaneous breathing	3	1	6

From Esteban A, Frutos F, Tobin MJ, et al: A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *N Engl J Med* 332:345–350, 1995.

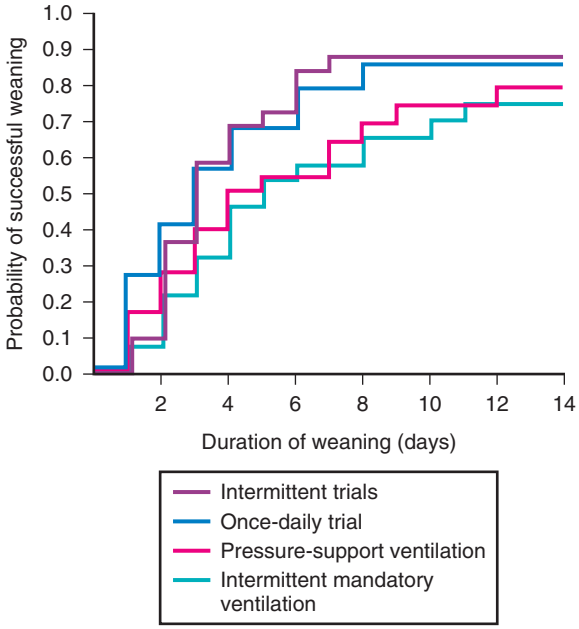

Figure 48-11 The Kaplan-Meier curve shows the probability of successful weaning from mechanical ventilation for pressure-support ventilation versus intermittent mandatory ventilation and for intermittent trials of spontaneous breathing versus once-daily trials of spontaneous breathing. (From Esteban A, Frutos F, Tobin MJ, et al: A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *N Engl J Med* 332:345–350, 1995.)

Intensive Care Medicine, which answered five important questions about ventilator weaning: What is known about the epidemiology of weaning problems? What is the pathophysiology of weaning failure? What is the usual process of initial weaning from the ventilator? Is there a role for different ventilator modes in more difficult weaning? How should patients with prolonged weaning failure be managed? Based on the answers to these questions, important recommendations were made to help identify the characteristics that predicted favorable and unfavorable weaning outcomes and determine which modes of ventilation should be used when a patient fails the spontaneous breathing trial.

The task force also addressed the use of noninvasive ventilation and prolonged ventilator dependence. Successful weaning was defined as 48 hours free of the ventilator; weaning as early as possible, using spontaneous breathing trials; avoidance of SIMV as a weaning mode; and use of PSV or AC after a failed weaning attempt. NIPPV should not routinely be used after failed extubation; it should be used only in patients with hypercapnia, although CPAP may be useful in preventing hypoxemia in postoperative patients (Table 48-8).[96]

In 1995, the Spanish Lung Failure Collaborative Group prospectively compared the use of intermittent mandatory ventilation (IMV), PSV, intermittent trials of spontaneous breathing, and once-daily spontaneous breathing trials. The study showed that spontaneous breathing trials in either form were superior to IMV or PSV in terms of time from initiation of weaning to successful extubation and probability of successful weaning (Fig 48-11).[41]

To illustrate the interaction of spontaneous breathing trials with daily interruption of sedation, the Awakening and Breathing Trial in 2008 showed that after randomizing 336 patients to the standard protocol or to daily discontinuation of sedation and daily spontaneous breathing trials, the intervention group had 3 fewer days on the mechanical ventilator, fewer ICU days, shorter hospital days, and improved survival rates compared with the standard protocol (Figs. 48-12 and 48-13).[97] Numerous weaning parameters have been studied to hasten liberation from mechanical ventilation, but none have been shown to be superior to using clinical criteria combined with an algorithmic approach to discontinuation of sedation and ventilation.

VII. COMPLICATIONS OF MECHANICAL VENTILATION

A. Mechanical Complications

Mechanical ventilation may produce complications from use of an orotracheal or nasotracheal tube and complications of using positive-pressure ventilation. Common complications of artificial airways are laryngeal edema and irritation, tracheal stenosis, sinusitis, vocal cord damage, and paralysis. Complications of positive-pressure ventilation include barotrauma, which may lead to alveolar rupture and a continuum of pneumothorax, pneumomediastinum, and subcutaneous emphysema. The lungs are susceptible to alveolar distention due to high tidal volumes delivered by the ventilator to alveoli as a result of preset volumes. Due to the heterogenous nature of the lung, even lower volumes may be disproportionally delivered to open alveoli. Atelectotrauma, or cyclic atelectasis, is sheer-force trauma resulting from repeated opening and collapsing of the alveolus in response to positive-pressure ventilation (Fig. 48-14).

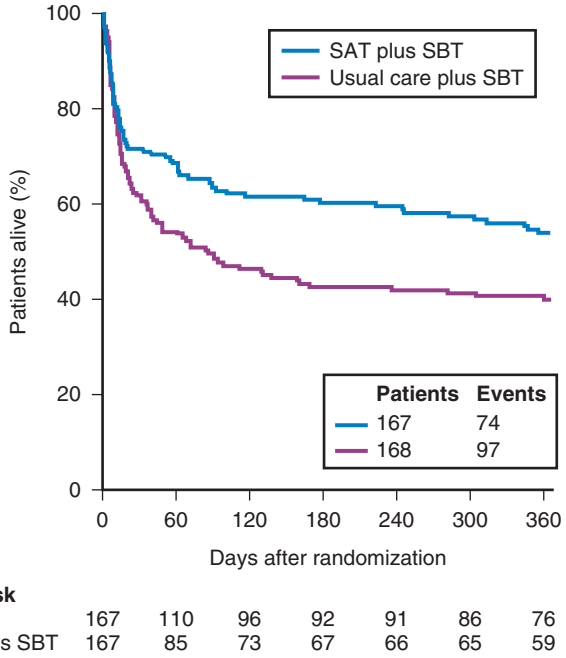

Figure 48-12 Survival at 1 year after randomization to usual care with trails of spontaneous breathing *(SBT)* or to trials of spontaneous awakening *(SAT)* with SBT. (From Girard TD, Kress JP, Fuchs BD, et al: Efficacy and safety of a paired sedation and ventilator weaning protocol for mechanically ventilated patients in intensive care (Awakening and Breathing Controlled trial): A randomised controlled trial. *Lancet* 371:126–134, 2008.)

Volutrauma and atelectotrauma are within the spectrum of ill-defined entities of ventilator-associated lung injury (VALI), which appears to be more common in lungs of patients with ARDS or ALI. Although causation has not been determined, VALI has been observed in patients who have undergone mechanical ventilation. VILI is an entity well described in animal models. It is a syndrome of diffuse alveolar damage that is morphologically identical to ARDS and that is caused by mechanical ventilation.[98] Alveolar injury results in increased permeability, loss of functional surfactant, release of cytokines, and alveolar collapse (Fig. 48-15). Other factors that may be associated with an increased risk for VALI include immunosuppression,[99] high ventilator rates,[100] supine body position, and hyperthermia.[101]

1. Auto-PEEP

Intrinsic PEEP or auto-PEEP results from incomplete alveolar emptying before the initiation of the next breath.[102] The alveolar pressures remain positive relative to atmospheric pressures at end-expiration. High minute ventilation from high tidal volumes or respiratory rates is a common cause. When high respiratory rates exist, expiratory time may be decreased to a point at which the full tidal volume is not exhaled before the next breath. High tidal volumes are less likely to be exhaled entirely before the next breath. Patients with obstructive lung diseases such as COPD and asthma often have auto-PEEP while on mechanical ventilation due to disease-related limited expiratory flow.[103] Expiratory resistance from any obstruction of the endotracheal tube (e.g., kinks, secretions) or patient-ventilator asynchrony can lead to auto-PEEP. Auto-PEEP can result from high tidal volumes, a high respiratory rate, or a decreased expiratory time relative to inhalation time in any disease state (Table 48-9).

2. Consequences of Auto-PEEP

Auto-PEEP can decrease venous return, reduce ventricular compliance, and induce hypotension.[104] Hypovolemic patients are at increased risk for PEEP-related hypotension. Alveolar distention from auto-PEEP can lead to barotrauma, worsening oxygenation from ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, and VALI. Auto-PEEP increases the work of breathing by raising the pressure the patient must generate to trigger a ventilator breath. If the breath is triggered at –2 cm H_2O and the auto-PEEP is 6 cm H_2O, the patient needs to overcome both (–8 cm H_2O of negative pressure) to initiate a breath. Auto-PEEP increases peak and plateau pressures in volume-controlled modes and decreases tidal volume in pressure-cycled ventilation.[24] Auto-PEEP also increases peak and plateau pressures, which can lead to an overestimation of thoracic compliance. Increased plateau pressures can be transmitted to the intrathoracic vessels and can lead to an overestimation of the central venous pressures and the pulmonary artery occlusion pressure (Table 48-10).

Auto-PEEP can be monitored in several ways but sometimes can be difficult to detect. The graphs of flow versus time demonstrate initiation of a new breath before the expiration reaches zero flow. End expiratory alveolar pressure, measured by introducing an end-expiratory breath-hold and subtracting applied PEEP, can quantitate auto-PEEP. The breath-hold allows the pressure in the proximal airways to equilibrate with alveolar pressure. Auscultation for airflow at the end of expiration is also useful.[105]

Management of auto-PEEP is targeted at promoting alveolar emptying and increasing expiratory time. Reducing minute ventilation by targeting tidal volume or the respiratory rate, or both, and by increasing inspiratory flow can be effective measures in reducing auto-PEEP.

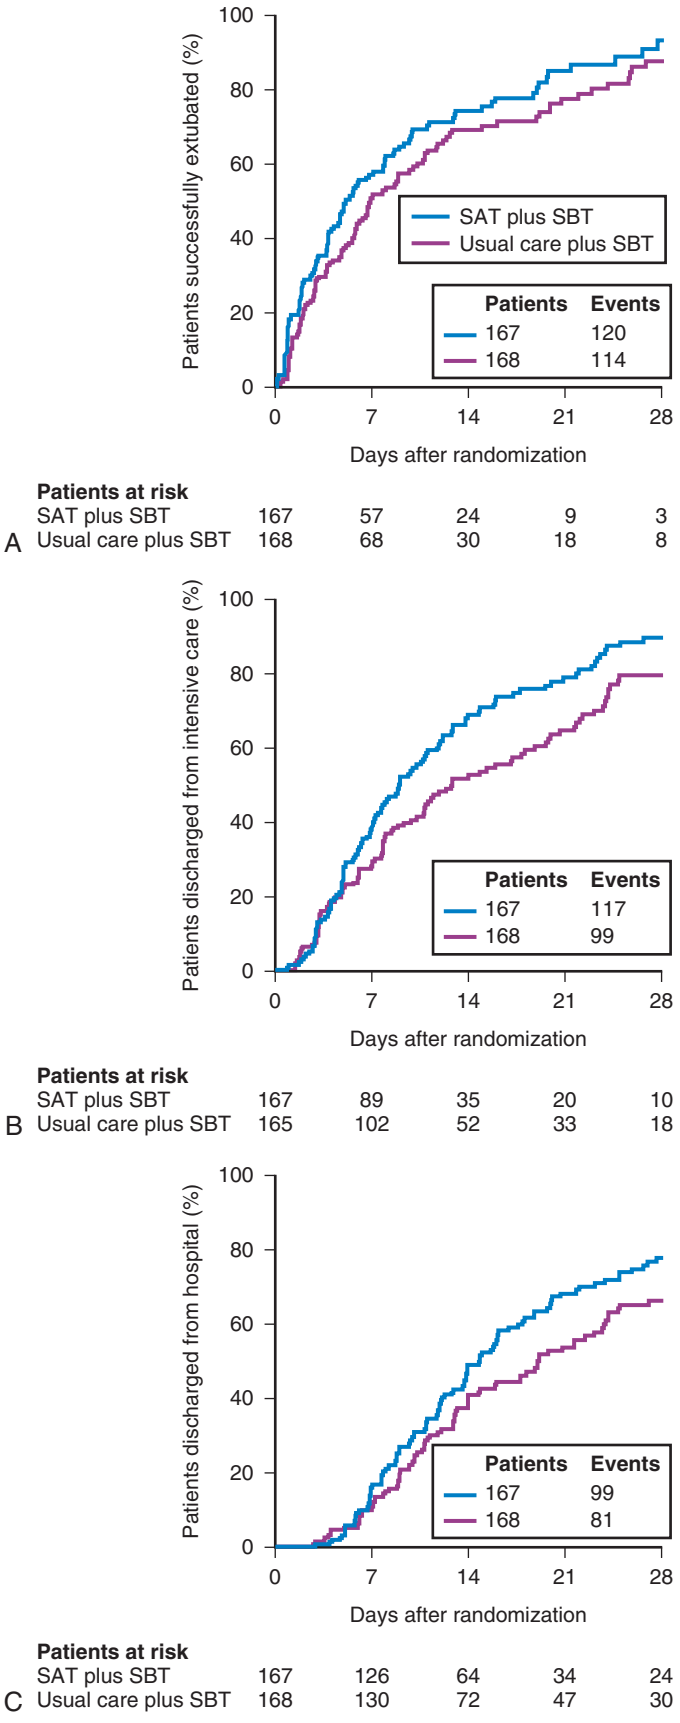

Figure 48-13 Probability of successful extubation **(A),** discharge from intensive care **(B),** or discharge from hospital **(C)** within the first 28 days after randomization. *SAT,* Spontaneous awakening trials; *SBT,* spontaneous breathing trials. Figure 48-14 A telectotrauma (i.e., cyclic atelectasis) results from the sheer forces generated by repeated opening and collapsing of the alveoli in response to positive-pressure ventilation. (From Papadokos PJ, Lachmann B: The open lung concept of mechanical ventilation: The role of recruitment and stabilization. *Crit Care Clin* 23:241–250, 2007.)

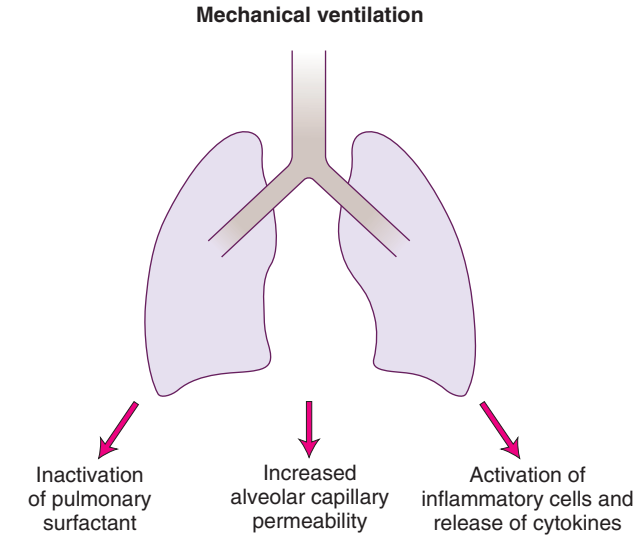

Figure 48-15 Downstream effects of lung injury from mechanical ventilation. (From Papadokos PJ, Lachmann B: The open lung concept of mechanical ventilation: The role of recruitment and stabilization. *Crit Care Clin* 23:241–250, 2007.)

TABLE 48-9
Auto-PEEP Factors

Causes of Auto-PEEP	Factors
High minute ventilation	High tidal volume High respiratory rate
Expiratory flow limitation	Airway narrowing from bronchospasm, collapse, inflammation, or remodeling
Expiratory resistance	Patient-ventilator asynchrony Narrow or obstructed endotracheal tube Secretions

PEEP, Positive end-expiratory pressure.

Management of the underlying condition is important, especially for patients with obstructive lung diseases treated with bronchodilators, steroids, and antimicrobial therapies. In patients with COPD or asthma, the limited expiratory flow can be counterbalanced by application of extrinsic PEEP.[106] Small amounts of extrinsic PEEP can decrease intrinsic PEEP by keeping the small airways open at end-expiration. However, the applied PEEP should be less than intrinsic PEEP to prevent an increase in alveolar pressures.[107]

B. Infectious Complications

Ventilator-associated pneumonia (VAP), a type of hospital-acquired pneumonia (HAP), is defined as a diagnosis of pneumonia 48 to 72 hours after endotracheal intubation. Studies of management with noninvasive ventilation show a decreased incidence of pneumonia when endotracheal intubation is avoided.[91] The earlier pneumonia is diagnosed after onset of mechanical ventilation, the better the prognosis. Pneumonia diagnosed later in the course of mechanical ventilation is more likely to be caused by a drug-resistant organism and carries a worse prognosis. Several practices can help to minimize the occurrence of pneumonia on the ventilator, including elevating the head of the bed to the semirecumbent position of 30 to 45 degrees, aggressive weaning of sedation, use of orotracheal and orogastric tubes to decrease the potential for sinusitis, daily assessments to liberate from mechanical ventilation, avoiding gastric overdistention, avoiding unplanned extubations, oral care with antiseptic solution, and limiting contamination of ventilator tubing.[108,109] Once a VAP occurs, there is no difference in mechanical ventilation–free days, the length of ICU days, the number of organ failure–free days and mortality rates on day 60 between the groups receiving between 8 days and 15 days of treatment with appropriate antibiotics.[110]

TABLE 48-10
Consequences of Auto-PEEP

Affected System	Consequences
Cardiac	Decreases venous return Hypotension Overestimation of CVP and PCWP
Pulmonary	Alveolar overdistention Barotrauma or pneumothorax Increases peak and plateau in pressure ventilation Increases work of breathing Underestimation of thoracic compliance

CVP, Central venous pressure; *PCWP,* pulmonary capillary wedge pressure; *PEEP,* positive end-expiratory pressure.

VIII. CONCLUSIONS

Various modes of mechanical ventilation can be used to provide respiratory support in critical illness or in patients undergoing general anesthesia. Safe application to limit VALI and negative interactions with other organ systems is fundamental in managing patients receiving mechanical ventilation. NIPPV can be safely and effectively applied to patients with acute respiratory failure from COPD, pulmonary edema, or other diseases. Mechanical ventilation selection using common or uncommon modes is determined by several factors, including hemodynamical instability, severe oxygenation or ventilation derangements, general anesthesia, and patient comfort. A lung-protective strategy incorporating tidal volumes of 6 mL/kg of predicted body weight and plateau pressures of 30 cm H_2O or improves outcomes in ARDS. Tidal volumes greater than 10 mL/kg of predicted body weight should not be routinely used in managing other lung states. PEEP can be applied to improve oxygenation and to limit collapse and repeated opening and closing of unstable units, which can lead to lung injury. Plateau pressures greater than 35 cm H_2O have been associated with increased risk of barotrauma and VALI. Auto-PEEP should be monitored to avoid related complications. Measures to reduce the risk of VAP should be instituted on initiation of mechanical ventilation.

Daily trials of spontaneous breathing expedite weaning and liberation from mechanical ventilation. Ventilator weaning algorithms that allow for non-physician providers to assess the readiness of patients for extubation when they meet certain preset criteria are often useful. Daily interruption of sedation facilitates liberation from the mechanical ventilation.

IX. CLINICAL PEARLS

- The indications for mechanical ventilation include hypoxemic and hypercapnic respiratory failure, altered mentation with patient inability to protect the airway, hemodynamic instability, and to maintain adequate oxygenation and ventilation during deep sedation, anesthesia, or neuromuscular blockade.
- Positive end-expiratory pressure (PEEP) improves oxygenation in patients with hypoxic respiratory failure, optimizes alveolar recruitment and decreases cycles of recruitment and derecruitment of alveolar lung units.
- Assist-control ventilation (ACV) can be volume targeted, upon initiation of mechanical ventilation, or pressure targeted when increased oxygenation is required, but there is concern about increasing airway pressures.

- A lung-protective strategy should be employed in all patients with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). Using low tidal volumes of 6 mL/kg of predicted body weight with plateau pressures of 30 cm H2O or less has become the standard of care for patients with ARDS.
- Synchronized intermittent mandatory ventilation (SIMV) incorporates some characteristics of ACV and pressure-support ventilation (PSV). The purpose of the two types of breaths (mandatory and spontaneous) is to allow increased diaphragmatic activity and increased work of breathing when triggering spontaneous breaths.
- Airway pressure–release ventilation (APRV) uses high and low pressures to aid in recruitment of atelectatic lung units and allows spontaneous breathing. It can decrease airway pressures and improve oxygenation, alveolar recruitment, and cardiac output.
- High-frequency ventilation, sometimes called the *oscillator*, improves oxygenation by providing oxygen-rich and CO_2-poor gas that rapidly mixes with sinusoidal flow at stroke volumes that approximate anatomic dead space. Each type of high-frequency ventilation—high-frequency jet ventilation, high-frequency oscillatory ventilation, and high-frequency percussive ventilation—has its subtleties and specific indications.
- Noninvasive positive-pressure ventilation (NIPPV) is useful in many situations, including exacerbations of COPD, cardiogenic pulmonary edema, and hypercapnic respiratory failure in patients with a Glasgow Coma Scale score of more than 10.
- During weaning from mechanical ventilation, daily interruption of sedation (unless contraindicated by severe hypoxemia or the need for neuromuscular blockade) and daily trials of spontaneous breathing should be employed for all patients.

Chapter 49

Monitoring the Airway and Pulmonary Function

NEAL H. COHEN | DAVID E. SCHWARTZ

I. Introduction
II. Monitoring the Airway
A. Non-intubated Patient
B. During Endotracheal Intubation
C. During Weaning
D. After Tracheal Decannulation
III. Monitoring Respiratory Function
A. Clinical Assessment
B. Radiologic Evaluation
C. Assessment of Gas Exchange
1. Blood Gas Monitoring
2. Noninvasive Monitoring
IV. Monitoring Respiratory Function During Mechanical Ventilatory Support
A. Assessment of Pulmonary Mechanical Function
1. Airway Resistance and Lung-Thorax Compliance
2. Intrinsic Positive End-Expiratory Pressure
3. Ventilatory Waveform Analysis
4. Work of Breathing
B. Assessment of Pulmonary Function During Weaning
1. Weaning Indices
2. Breathing Pattern Analysis
3. Airway Occlusion Pressure
V. Conclusions
VI. Clinical Pearls

I. INTRODUCTION

The patient with a potentially compromised airway or altered respiratory function presents many clinical challenges, such as identifying the cause of the derangement and choosing the most appropriate therapeutic and supportive interventions. Although a comprehensive physical assessment remains one of the most valuable methods for assessing the patient and determining whether the patient is responding appropriately to clinical interventions, several monitoring techniques can be valuable adjuncts to the clinical assessment.

During the past 20 years, the number and variety of monitors have increased, providing clinically relevant and useful information about gas exchange, pulmonary function, and the ventilator-patient interface. Some monitors, such as the pulse oximeter, have become routine equipment in the operating room (OR), intensive care unit (ICU), and other clinical settings. Others are used more selectively to monitor specific clinical situation or physiologic changes. To select the right device and use it to its full potential, the physician should understand the mechanism, benefits, and limitations of each monitor. The clinician should know how to interpret the information provided, correlate the data with the clinical situation, and in some cases, reconcile differences in information about the patient that is provided by different monitors to make appropriate clinical decisions.

Although most monitoring devices provide useful information, some are easier to use than others. Some data suggest that the devices that are easiest to use and for which the data are easiest to interpret are the most clinically useful devices.[1] In many situations, the information provided by monitors that is thought to be straightforward requires a comprehensive understanding of its physiologic basis. For example, although the pulse oximeter provides a straightforward measurement of oxygen (O_2) saturation, which can be easily interpreted in most cases, the information in many clinical situations does not accurately reflect the O_2 saturation (in the presence of carbon monoxide) or O_2 tension (when the patient is severely acidotic or alkalotic).[2,3] Interpretation requires an understanding of the patient's physiology and the method by which the monitor reports the data. The same caveats are true for almost every monitor that is used clinically to guide diagnosis, management, and response to therapy. The clinician must know what monitors are available and when the information provided by the monitor is clinically useful and must know how to interpret the data and understand the limitations of each device.

This chapter describes techniques for monitoring and evaluating the airway, gas exchange, and pulmonary function. It provides an overview of the monitors used to assess the patient and describes specific monitors that are useful in assessing the appropriateness of mechanical ventilatory support. Because the modes of ventilation have changed considerably and the options for providing mandatory and spontaneously initiated modes of ventilation have become available, monitoring pulmonary function and the patient-ventilator interface has become increasingly important.[4] The benefits and limitations of each monitoring technique are discussed.

II. MONITORING THE AIRWAY

A. Non-intubated Patient

Monitoring the airway is a critical component of clinical assessment for any patient requiring sedation, analgesia, or ventilatory support. As a result of underlying anatomic abnormalities, physiologic alterations in the level of consciousness, edema of the airway, or administration of respiratory depressants, a patient can develop upper airway dysfunction with life-threatening consequences. Assessment of the airway should include the clinical evaluation that is routinely performed by the anesthesiologist before initiating anesthesia or by the critical care practitioner before performing endotracheal intubation. In many cases, the assessment must be performed rapidly under challenging circumstances, but if possible, the evaluation should include a brief and focused history and physical examination. The patient should be asked about snoring or episodes of airway obstruction during sleep; previous experiences with endotracheal intubation, including difficult intubation, hoarseness after airway manipulation, and hoarseness with exercise; previous lengthy endotracheal intubation; and a history of tracheostomy or tracheal abnormalities, including stenosis or tracheomalacia. Patients with rheumatoid arthritis should be questioned about upper airway problems, particularly those related to potential arthritic changes in the cricoarytenoid joints. Patients who have had previous neck or mediastinal surgery should be carefully evaluated for evidence of unilateral or bilateral vocal cord dysfunction. For patients unable to provide a history, discussion with family members or the nurse caring for the patient, a review of the medical record, or direct observation of the airway and ventilatory pattern while preparing equipment for intubation or other interventions can provide useful information to guide management decisions. In selected patients, a lateral neck radiograph can provide useful information about the upper airway and presence of masses in the airway or epiglottic edema, although in most cases, upper airway compromise necessitates emergent intubation without the benefit of a radiologic evaluation.[5]

Examination of the airway for any patient presenting with respiratory insufficiency mandates a thorough assessment of the upper airway, including evaluation of mobility of the jaw, chin, and neck, and estimation of the potential ease or difficulty of endotracheal intubation based on the size of the mandible and visualization of the airway (i.e., Mallampati classification). The clinical assessment usually can be performed while providing supplemental O_2 or positive airway pressure by mask while preparing for the intubation. For patients with challenging abnormalities of the upper airway that may make routine laryngoscopy difficult, alternative methods to secure the airway should be considered, and the appropriate equipment should be readily available to allow rapid control using a standard laryngoscope, laryngeal mask airway (LMA), fiberoptic technique, lightwand, video laryngoscope, or in emergent situations, cricothyroidotomy or tracheostomy.

B. During Endotracheal Intubation

Although there are several situations in which the airway can be monitored and noninvasive ventilatory support provided, many patients require placement of an artificial airway for airway protection or to facilitate ventilatory support. A variety of airway devices are available, including different types of LMAs, endotracheal tubes (ETTs), and tracheotomy tubes. In some cases, the LMA can provide initial airway support to facilitate subsequent endotracheal intubation. In other cases, such as for selected surgical procedures, the LMA is sufficient to provide partial protection of the airway while allowing spontaneous ventilation. When an LMA is placed, positioning of the airway must be verified. Direct visualization of LMA placement is usually not required, and positioning can be confirmed on the basis of clinical signs. If the patient is breathing comfortably without evidence of obstruction, the LMA is usually in a good position. For the spontaneously breathing patient, this clinical assessment is sufficient. When positive-pressure ventilation may be required, better confirmation of the correct position is desirable because of the potential risks. Positive-pressure ventilation may cause a leak around the LMA, compromising the ability to provide an adequate tidal volume (V_T). Ventilation through the LMA does not prevent entrainment of gas into the stomach, and the risk of regurgitation and aspiration must be considered. In this situation, the correct position of the LMA must be confirmed, and if there is any question about the appropriate placement, its position must be verified by direct visualization, or the LMA must be replaced with an ETT by placing the ETT through the LMA or removing the LMA and intubating the trachea directly.

Although a variety of masks and other devices are available to facilitate ventilatory support without tracheal instrumentation, the patient requiring airway protection or positive-pressure ventilation usually undergoes endotracheal intubation through transoral or transnasal routes or through a surgical airway (see Chapter 17). When endotracheal intubation is required, confirmation of correct placement is essential. The most reliable method to assess the location of an artificial airway within the trachea is direct visualization of the tube passing through the vocal cords at the time of intubation. Physical examination is also important to ensure that both lungs are being ventilated after placement of the airway. Auscultation over the lung fields (particularly the apices of the lungs) and stomach should routinely be performed to

assess ETT placement. When the ETT is within the trachea, equal breath sounds should be heard over both lung fields while listening over the apices. Auscultation over the upper lung fields minimizes the likelihood of hearing sounds transmitted from the stomach. For most adult patients, if the ETT is located within the trachea, no breath sounds should be heard over the stomach. Unfortunately, auscultation can be misleading. Occasionally, particularly in children, breath sounds are transmitted to the stomach even when the ETT is properly positioned. For patients with extensive parenchymal lung disease, effusions, or endobronchial lesions, breath sounds may not be heard equally over both lung fields even when the ETT is properly positioned within the trachea.

Other clinical signs can be useful in determining whether the ETT is within the trachea. They include identifying mist within the lumen of the ETT during exhalation, palpation of the cuff of the ETT in the suprasternal notch, and the normal "feel" of a reservoir bag during manual ventilation. Despite the clinical usefulness of these methods, none is infallible, and false-positive and false-negative evaluations have been reported.[6]

A more reliable monitor for confirming that the artificial airway is within the trachea is identification of carbon dioxide (CO_2) in exhaled gas. If the airway is within the trachea and the patient is ventilating spontaneously or receiving positive-pressure ventilation, CO_2 should be eliminated by the lungs. The presence of CO_2 or measurement of CO_2 concentration can be used to determine the location of the ETT. Several devices are available to monitor CO_2 in expired gases. In the OR, CO_2 can be measured using an infrared device,[7] Raman effect scattering, or mass spectrometry. In the ICU, emergency department (ED), or other settings, including out-of-hospital locations, colorimetric techniques can successfully estimate the CO_2 concentration, or infrared devices can accurately measure the CO_2 concentration in expired gases.[8,9] As a result of the ease of use and widespread availability of these devices, the documentation of CO_2 in exhaled gas after placement of an artificial airway (i.e., capnography) has become the standard of care in anesthesia practice and is routinely used during emergency airway management in many hospitals and emergency settings. A detailed description of capnography is provided on page 1011. Unfortunately, even these devices can provide misleading information, and the information they provide is not foolproof.[10,11]

Capnography is a useful monitor to confirm correct placement of the ETT, but it is not uniformly reliable and can be misleading.[12] For example, when the patient has been ventilated by mask before intubation, CO_2-containing gas may remain in the stomach. A capnograph may indicate the presence of CO_2 in the expired gas, but it does not reflect CO_2 from the airway. This problem is even more common when capnography is used to monitor the patient who has recently received bicarbonate-containing solutions or has been drinking CO_2-containing beverages before placement of the artificial airway. In these situations, CO_2 is eliminated from the stomach during the first few breaths provided through the ETT. The presence of CO_2 from exhaled gas therefore should be monitored for at least a few breaths. If CO_2 continues to be eliminated through the ETT after four or five breaths, endotracheal placement of the tube can be ensured.[11] Another problem with capnography when used to confirm ETT placement is that CO_2 elimination occurs only if the patient has sufficient cardiac output to deliver CO_2 to the lungs. If the patient has suffered a cardiac arrest and cardiac output is very low or absent, no CO_2 is delivered to the lung. The capnogram reveals neither a digital display of CO_2 from exhaled gas nor, if the CO_2 waveform is being monitored, a capnographic display, even when the ETT is within the trachea.[13-16] During cardiopulmonary resuscitation, the presence of CO_2 in exhaled gas provides confirmation that the cardiac output has improved and CO_2 is being eliminated from the lungs. Sometimes, even when cardiac output is inadequate, chest compressions are effective at eliminating enough CO_2 from the lungs to confirm ETT placement.

Another technique to confirm placement of the ETT in the trachea at the time of intubation is use of a self-inflating bulb. This technique was advocated as an easy way to confirm the proper position of the ETT in out-of-hospital intubations. The technique uses a bulb that is applied to the ETT. Self-inflation of the bulb within 4 seconds determines that the ETT is in proper position. Although the technique has some proponents, most studies are unable to confirm that this is a reliable method to verify ETT placement.[17]

When the position of the ETT within the trachea has been confirmed, it is important to assess the exact location of the tube within the trachea to avoid placement too proximal (increasing the risk of accidental extubation) or too distal (endobronchial). Incorrect positioning of the ETT has been associated with several complications, including pneumothorax and death.[18] The location of the ETT should be confirmed at the time of placement and be regularly assessed while the artificial airway remains in place, because the position can change even after the ETT is secured. Flexion of the neck moves the ETT toward the carina, and extension moves the tube up toward the vocal cords. In adult patients, flexion and extension of the head changes the position of the ETT tip by as much as 2 cm.[18] As the ETT softens or the patient manipulates the ETT with the tongue, the tube position changes. As a result of changes in ETT position, patients are at risk for self-extubation, even when the tube is secured at the mouth and the extremities are restrained.

Several techniques can be used to assess the correct position of the ETT within the trachea. For example, placement of the ETT to a predetermined distance has been advocated as a way to minimize the likelihood of endobronchial intubation. Owen and Cheney suggested that the tube be placed to a depth of 21 cm in women and 23 cm in men when referenced to the anterior alveolar ridge or the front teeth. In their study using this approach, endobronchial intubation was avoided.[19] Subsequent studies have not confirmed that this technique prevents endobronchial intubation in critically ill adults or that it is predictive of the relationship between the position of the ETT at the teeth and the tube's position relative to the carina.[20-22]

Fiberoptic bronchoscopy has been used to determine proper positioning of the ETT.[23] When a flexible fiberoptic bronchoscope is readily available, it can be used to confirm the location of the tip of the ETT within the trachea.[24] Because many ORs and ICUs have "difficult airway carts" readily available, the use of the flexible fiberoptic bronchoscope to assist with intubation and confirm the tubes's location has become more common. The technique is useful, although it is not without some risk. Insertion of the flexible fiberoptic bronchoscope reduces the effective cross-sectional area of the ETT, potentially compromising ventilation and oxygenation.[25] Peak inspiratory pressure increases. Partial obstruction of the ETT results in an increase in airway resistance, which may lead to the development of occult end-expiratory pressure and increase the risk of pneumothorax or cause hemodynamic compromise.[26] Despite these limitations, in experienced hands, the assessment can be completed rapidly and without complications. It is a particularly useful way of documenting the location of the ETT within the trachea in the patient for whom the specific location of the tube is critically important, such as one with abnormal tracheal anatomy, the patient at risk for obstruction of the right upper lobe bronchus, or one with specific needs related to the planned surgical procedure.

Capnography can be used to identify endobronchial migration of an ETT.[27] With distal migration of the tube, the Et_{CO_2} falls. The change is usually associated with an increase in peak inspiratory pressure. These changes, although not always reliable, can provide early evidence of ETT migration because the CO_2 changes precede a change in arterial blood gases (ABGs) or other signs of displacement.

Probably the most commonly used method to assess the location of the ETT within the trachea is the routine post-intubation chest radiograph. The distance of the ETT from the carina can be measured from a portable anteroposterior radiograph obtained at the bedside. Although many clinicians have questioned whether the cost of chest radiography warrants its routine use for documentation of ETT placement, it remains the most useful and reliable method to determine the appropriate depth of the ETT within the trachea.[20-22]

One special clinical situation warrants additional monitoring of the artificial airway. Some patients require placement of a double-lumen tube to facilitate a unilateral surgical procedure of the lung, to provide differential lung ventilation, or to protect one lung from contamination with blood or infected secretions from the other lung. In these cases, proper placement of the double-lumen tube must be ensured. Physical examination alone and other monitoring techniques are usually insufficient to confirm proper positioning. Fiberoptic evaluation is most often required to confirm the ETT position after initial placement and to reevaluate placement after the patient is repositioned for a surgical procedure or while requiring differential lung ventilation in the ICU.[28] Direct visualization of the tip of the double-lumen tube and the relationship between the tracheal and bronchial lumens ensures that the tube is in the proper position and that the two lungs are isolated. Other techniques can be used to diagnose malpositioning of double-lumen tubes, although there are few studies that confirm their value. Capnography, which has been useful in identifying endobronchial migration of a single-lumen ETT,[27] may provide information about the location of a double-lumen tube, particularly if only one lung is being ventilated at the time of evaluation. Spirometry, which can be obtained from in-line monitoring devices added to the anesthesia circuit or monitoring techniques provided by critical care ventilators, can also provide early detection of double-lumen tube malpositioning.[29] As the ETT migrates, expiratory flow obstruction, as can occur with malpositioning of the tube, can be detected as a change in the shape of the expiratory limb of the flow-volume loop. Inspiratory obstruction is best diagnosed by a change in the pressure-volume loop.

C. During Weaning

Careful evaluation and monitoring of the patient's airway are required before and immediately after tracheal extubation. After the patient is weaned from ventilatory support and is being prepared for extubation, the patient's ability to protect and maintain the airway after tracheal extubation must be assessed, although it can be difficult to do so with the ETT in place. Various clinical criteria have been used to determine whether the intubated patient can protect the airway. The most common criteria are a normal gag response and a strong cough. If the patient gags when the back of the throat is stimulated and coughs during suctioning, most clinicians feel confident that the patient will be able to prevent aspiration after extubation. These criteria, however, have never been subjected to scientific evaluation. Some patients who have a poor gag or cough with the ETT in place are able to handle secretions and to cough effectively after endotracheal extubation. Others, who seem to have a satisfactory cough or gag before extubation, are still unable to protect the airway when extubated. The problem with airway protection may become clinically apparent only when the patient begins to eat, because pharyngeal function may remain abnormal for several hours to days after endotracheal intubation.[30] Nonetheless, these criteria continue to be the most commonly used to determine whether the patient can be extubated safely.

After a decision is made that the patient can protect the airway, the airway size and vocal cord function must be assessed before ETT removal. Most commonly for patients intubated for a straightforward surgical procedure, routine clinical evaluation is sufficient; no formal assessment of airway size is required before extubation. However, if the patient develops significant edema of the head and neck during surgery or has a surgical procedure of the head or neck that may compromise the airway, a more thorough assessment is required. A common technique used to assess airway size is to determine whether the patient can breathe around the ETT when its cuff is deflated and the tube occluded. When the patient is able to breathe around the ETT, the patient can be successfully extubated; however, this approach may not provide sufficient justification for keeping the patient intubated.

Many patients cannot breathe around the occluded ETT because of the increased resistance with the tube in place. As a result, alternative methods have been suggested. The leak test assesses the airway pressure required for a leak to develop around the cuff when positive-pressure ventilation is applied through the ETT with the cuff deflated.[31] Although the specific pressure at which the leak develops has not been well correlated with successful extubation, some clinicians require that a leak occur when the airway pressure is low, usually less than 15 cm H_2O, before extubation. Unfortunately, some studies, including a systematic review of the literature that included more than 2300 patients, have been unable to confirm the value of the leak test at all nor a specific leak pressure or volume above which extubation is contraindicated.[32] If the airway pressure required to identify a leak during positive-pressure inspiration is high, probably 20 to 25 cm H_2O, the patient may have sufficient upper airway edema to warrant leaving the ETT in place until the edema resolves.

D. After Tracheal Decannulation

After the ETT is removed, the airway must be closely monitored. For most surgical patients, the risk of airway compromise after extubation of the trachea is small. Occasionally, airway edema can become a problem. Less commonly, vocal cord dysfunction or cricoarytenoid dislocation can cause hoarseness or airway obstruction. Patients at risk for upper airway edema include those who have required large amounts of fluid or blood products for resuscitation in the OR or ICU and patients who were cared for in the prone position.

Most of these patients do not have the ETT removed until the edema resolves. However, even after external signs of edema resolve, assessment of the airway lumen and competency can be challenging. With the ETT in place, the airway is stented open; after removal, the airway may no longer be patent or of sufficient size to allow normal spontaneous ventilation. Sometimes, the narrowing of the airway becomes apparent only when the patient's inspiratory flow increases, resulting in stridor and increased airway resistance. If stridor develops and edema of the airway is suspected, aerosolized vasoconstrictors can be used to reduce airway swelling. Nebulized racemic epinephrine has been used successfully. The vasoconstrictive effects of the epinephrine reduce the edema and improve the cross-sectional area of the airway. When epinephrine is required, it must be administered with caution. After discontinuation of the epinephrine, rebound hyperemia can occur. If repeated epinephrine treatments are required, the epinephrine dose and frequency of treatment should be tapered (in frequency or dose) rather than abruptly withdrawn. Systemic steroids can be used to reduce upper airway edema, but their onset of action is slow. If upper airway edema is suspected and steroids are to be administered, they should be administered 6 to 8 hours before the anticipated extubation. When edema does not respond to therapy or the patient has evidence of other abnormalities, including tracheomalacia, emergent intubation may be required. For patients for whom the clinical assessment is not entirely clear but the risks of extubation are outweighed by the benefits, special equipment, including fiberoptic intubation equipment and cricothyroidotomy kits, should be readily available to facilitate emergent intubation.

Vocal cord function can be impaired after surgery. Postoperative vocal cord dysfunction can be caused by direct trauma at the time of endotracheal intubation or edema. Recurrent laryngeal nerve dysfunction can also occur, most commonly caused by nerve retraction or transection during surgery or direct trauma from high intratracheal pressure transmitted from the ETT cuff.[33] Unfortunately, it is difficult to assess vocal cord function with the ETT in place. The evaluation usually requires that the ETT be removed (see Chapter 50). After extubation, evaluation of laryngeal and vocal cord function can be assessed fiberoptically. In some patients, evaluation of the airway can be performed by inserting the fiberoptic device through the ETT and then removing the tube over the fiberoptic shaft to allow visualization of the airway. Assessment requires that the patient breathe spontaneously, so that the movement of the vocal cords can be visualized. Although the assessment can be performed in the ICU, the more common approach is to perform the evaluation under more controlled conditions in the OR, where all of the emergency airway and surgical equipment is available to secure the airway. Evaluation and extubation can be performed after the patient is anesthetized with a volatile anesthetic agent and is breathing spontaneously. If severe stridor or airway obstruction develops with removal of the ETT, the patient can be reintubated or have a tracheostomy performed for long-term airway maintenance (see also Chapter 31). In most cases, even when there is injury to a recurrent laryngeal nerve or one vocal cord, the patient is able to breathe normally without stridor, unless the patient's inspiratory flows are excessive. The greater risk exists for the patient who suffers bilateral vocal cord palsies. While still sedated, the patient may not have stridor or evidence of airway obstruction. However, as the patient awakens and inspiratory flows increase, the stridor becomes obvious and usually requires emergent endotracheal intubation or, more commonly, tracheostomy.

Stridor can occur as a result of dislocation of the cricoarytenoid joint. The risk of cricoarytenoid dislocation is greatest in patients with rheumatoid arthritis, in whom the joint may be affected. However, dislocation should be suspected in any difficult intubation patient who requires multiple attempts and extensive manipulation of the airway.

III. MONITORING RESPIRATORY FUNCTION

A. Clinical Assessment

The clinical examination remains one of the most important and valuable methods to monitor a patient's respiratory status. Too often, attention is placed on technologically sophisticated monitoring devices, and the physical examination is cursory, or the clinical findings are undervalued. Nonetheless, much information about actual or potential airway problems and abnormalities in pulmonary

mechanical function or gas exchange can be obtained from a carefully performed and thorough examination. Many of the early signs of respiratory failure are apparent on physical assessment (see Chapter 9) before the abnormalities are apparent by other means. For example, the respiratory rate provides important information about respiratory reserve, dead space, and respiratory drive, particularly when interpreted in conjunction with arterial carbon dioxide tension (Pa_{CO_2}). Tachypnea is frequently the earliest sign of impending respiratory failure. The patient's pattern of breathing should be evaluated. Subtle changes in the respiratory rate, V_T, and pattern of breathing may provide an early indication of increased work of breathing (as may occur with reduced lung compliance, increased airway resistance, or phrenic nerve dysfunction) or altered ventilatory drive. Although inspiratory flow and minute ventilation ($\dot{V}_E$) are difficult to quantify by clinical examination alone, respiratory distress often manifests as the patient attempts to increase alveolar ventilation by taking larger, more rapid inspirations.

Upper airway obstruction, as may occur after manipulation of the airway, in association with epiglottitis or a mass in or around the airway can be assessed by careful clinical evaluation. Nasal flaring, stridor, and chest wall movement in the absence of airflow suggest upper airway obstruction. If the patient is making respiratory efforts and has abdominal expansion during inspiration without chest excursions, he or she has upper airway obstruction and may require manipulation of the upper airway, including a jaw thrust, initiation of positive-pressure ventilation support with continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP), and endotracheal intubation. When the patient presents with stridor, the physical evaluation is also useful in identifying the location of airway compromise. When the stridor occurs primarily during inspiration, it is caused by extrathoracic obstruction; when it occurs during exhalation, it reflects an intrathoracic obstruction. If the stridor occurs during both inspiration and exhalation, the obstruction is fixed, such as may occur with tracheal stenosis. The fixed obstruction is rarely amenable to conservative treatment, and endotracheal intubation is most likely to be required until a more definitive therapy can be provided. In selected patients, helium therapy can be used as a temporizing intervention until a more definitive treatment can be provided.[34]

Respiratory dyssynchrony is an early and critical indicator of respiratory muscle fatigue and impending respiratory failure.[35,36] Respiratory dyssynchrony (when the patient has no evidence of upper airway obstruction) is identified by assessing chest wall and abdominal movement during normal tidal breathing. A paradoxical respiratory pattern suggests that the patient may have inadequate muscle strength to sustain spontaneous respiration and that positive-pressure ventilation support may be required. Tobin and colleagues found that respiratory muscle dyssynchrony could occur before the development of fatigue,[37,38] although fatigue of the respiratory muscles did not always result in the development of dyssynchrony.[39]

Clinical observation of the patient should include careful assessment of the respiratory muscles as a way of assessing the patient's respiratory reserve. Use of accessory muscles, including the sternocleidomastoid and scalene muscles, is commonly seen in patients with longstanding respiratory failure associated with chronic obstructive pulmonary disease (COPD).[40] The position of the diaphragm and diaphragmatic motion are also affected in patients with severe COPD. The patient who relies on accessory muscles and has minimal diaphragmatic excursion does not have any respiratory reserve. The patient is at risk for recurrent respiratory failure and presents a significant challenge during weaning when mechanical ventilatory support is required.

The routine physical examination of the lungs should be performed as part of the assessment for every patient. The examination can provide evidence of parenchymal lung abnormalities and cardiopulmonary pathology. Palpation of the chest and auscultation of the lungs can provide useful information about the presence of pleural effusions, pneumothorax, or other extrapulmonary air, and it can assess the location of the diaphragms. The examination can provide information about potential physiologic abnormalities and guide the selection of other monitoring techniques, including ABGs and chest radiography.

Although the physical examination is useful and should be performed routinely, some of the physical signs and symptoms of respiratory failure are not diagnostic, but instead reflect the physiologic manifestations of the underlying problem. The greatest value of the physical examination is that it provides an initial baseline assessment of the patient, and subsequent examinations can clarify the response to clinical interventions. The physical examination combined with other monitoring modalities remains an important monitor of respiratory status.

B. Radiologic Evaluation

The chest radiograph is another important monitor of the pulmonary status, although it represents a static picture of the clinical situation. The chest radiograph can confirm proper placement of central venous and other catheters, the ETT,[22] and pacemakers. Routine portable chest radiography usually provides evidence of pulmonary infiltrates and pulmonary edema. Radiographic findings that suggest pulmonary edema include bronchial cuffing, perihilar pulmonary infiltrates, and Kerley B lines. Although these findings are helpful, in many critically ill patients, differentiation of diffuse, bilateral infiltrates caused by infection from pulmonary edema can be difficult. When underlying pulmonary diseases such as COPD coexist with acute pulmonary edema, the classic bilateral, fluffy pulmonary infiltrates may not be present. In these circumstances, the x-ray findings must be correlated with other clinical data to explain the radiographic findings.

The chest radiograph can occasionally identify possible abnormalities in the larger airways, including tracheal stenosis and dilatation (as may occur when the ETT cuff is overinflated), although confirmation of the suspected findings usually requires computed tomography (CT) or magnetic resonance imaging (MRI). The presence of tracheomalacia is more difficult, because the airway may look normal on a routine chest radiograph. The tracheal

abnormality is more evident on clinical examination (i.e., stridor with forced exhalation) or on a dynamic radiographic study, such as a cine-CT scan.

The routine chest radiograph has limitations when used as a monitor of respiratory status. Radiographic findings do not always correlate with other clinical and physiologic monitors because the radiologic changes can be delayed in onset and resolution. The radiologic technique also influences the value of the chest radiograph as a monitor. Most commonly, a portable anteroposterior radiograph is obtained with the patient in the supine position. When it is performed in this manner, interpretation of heart size, differentiation of atelectasis and pleural effusions, and detection of pneumothoraces may be difficult. When trying to identify any of these abnormalities, other views, including upright or lateral decubitus x-ray films, should be requested, depending on the suspected pathology. Occasionally, an ultrasound or CT scan of the chest may be required to confirm the presence of pleural effusions, pulmonary abscesses, or other abnormalities.

Other radiologic evaluations can be useful to assess abnormalities observed on the chest radiograph or physical examination. Ventilation-perfusion ($\dot{V}/\dot{Q}$) scans have been used to detect pulmonary emboli, although the $\dot{V}/\dot{Q}$ scans are often inadequate or impossible when assessing a mechanically ventilated, critically ill patient for possible pulmonary emboli. For the ICU patient with suspected pulmonary emboli, pulmonary arteriograms or, more commonly, spiral CT scans are performed because they can be completed quickly and provide better diagnostic information than the $\dot{V}/\dot{Q}$ scan alone.

CT and MRI can assess the airways and pulmonary parenchyma. They can identify the location, extent, and character of upper airway abnormalities, including mass lesions, pulmonary intraparenchymal lesions, pleural effusions, and other pulmonary and extrapulmonary abnormalities.

C. Assessment of Gas Exchange

One of the most important goals in monitoring pulmonary function is to determine whether the lung is able to sustain satisfactory oxygenation and ventilation. Invasive and noninvasive monitors of gas exchange are used routinely. Although noninvasive devices are useful and provide important information about oxygenation and ventilation, the ABG determination remains the most frequently used monitor of oxygenation, ventilation, and acid-base abnormalities.[41]

1. Blood Gas Monitoring

ABG measurement remains an essential component of respiratory monitoring. It provides direct measurement of arterial oxygen tension (Pa_{O_2}), Pa_{CO_2}, and pH. From these measured parameters, bicarbonate concentration (HCO_3^-), oxygen saturation (Sa_{O_2}), and base excess or base deficit are calculated. The measured and calculated parameters define adequacy of gas exchange, acid-base balance, and overall cardiorespiratory status.

ABGs, including Pa_{O_2}, Pa_{CO_2}, and pH, are used routinely in the OR, ICU, and ED and occasionally in other clinical settings to evaluate gas exchange and respiratory reserve. Direct measurement of Pa_{O_2} from a sample of arterial blood obtained from a direct arterial puncture or from an indwelling arterial catheter has been the traditional method for assessing oxygenation. To interpret Pa_{O_2} accurately requires an understanding of normal pulmonary physiology and the influences of alterations in ventilation and perfusion on the predicted value of arterial oxygen tension. Normal Pa_{O_2} declines with age. The normal Pa_{O_2} can vary over time by as much as ±10%, and the Pa_{O_2} measured by a blood gas machine can vary by ±10%. Hypoxemia can result from several factors, including inadequate inspired O_2 (i.e., low Pa_{O_2}), $\dot{V}/\dot{Q}$ mismatch, shunt, or inadequate cardiac output (i.e., low mixed venous oxygen tension [$P\bar{v}_{O_2}$]). Documentation of an acceptable Pa_{O_2} is reassuring, although it is important to put the Pa_{O_2} value into context. It alone does not ensure that a patient's O_2 delivery is sufficient. To assess the adequacy of O_2 delivery, additional studies are necessary, including evaluation of acid-base status, measurement of serum lactate and mixed venous O_2 content, and cardiac output measurement.

The Pa_{CO_2} is used to assess adequacy of ventilation, differentiating whether ventilation is normal or abnormal (too high or too low). The normal Pa_{CO_2} is 40 mm Hg. If the Pa_{CO_2} is less than 40 mm Hg, the patient is hyperventilating; if the Pa_{CO_2} is more than 40 mm Hg, the patient is hypoventilating. However, the Pa_{CO_2} alone is only one measure of the adequacy of ventilation. It must be interpreted in relation to the pH. In response to changes in pH, ventilatory drive changes. When a patient develops a metabolic alkalosis, as might occur after a bicarbonate infusion or the administration of large quantities of citrated bank blood, the ventilatory drive is decreased. The Pa_{CO_2} rises, but the decrease in $\dot{V}_E$ is appropriate and is not an indication of respiratory failure. Similarly, the patient who has a significant metabolic acidosis should increase $\dot{V}_E$ to normalize the pH. In interpreting whether the patient is ventilating appropriately and has a normal ventilatory drive, the Pa_{CO_2} and pH must be evaluated simultaneously. For example, if a patient has a normal Pa_{CO_2} of 40 mm Hg, but the pH is below normal (e.g., 7.25), the ventilatory effort is inadequate, suggesting inadequate respiratory compensation due to drugs that are suppressing ventilatory drive or underlying respiratory failure.

When arterial blood cannot be obtained, venous blood sampling (peripheral or central) has been used to estimate arterial Pa_{CO_2}, although it is not a useful way to evaluate oxygenation. In some clinical situations, the difference between Pa_{CO_2} and $P\bar{v}_{CO_2}$ is small, and $P\bar{v}_{CO_2}$ can be used as an estimate of Pa_{CO_2}. However, the exact relationship between arterial and venous Pa_{CO_2} is not consistent from patient to patient or within a single patient as the clinical conditions change. $P\bar{v}_{CO_2}$ cannot be used as a substitute for Pa_{CO_2}.

Although monitoring gas exchange using ABG measurements is important, the technique has some limitations. Blood gas monitoring is invasive, and samples must be drawn from an indwelling arterial catheter or an arterial puncture. Frequent blood gas sampling can result in significant blood loss, which may be a clinical problem for any unstable patient, particularly the pediatric patient

or anemic adult. Placement and maintenance of an arterial catheter have associated risks, including hemorrhage, hand ischemia, arterial thrombosis and embolism, infection,[42,43] and development of a radial artery aneurysm.[44]

Blood gas monitoring usually is obtained by intermittent sampling from an arterial puncture or indwelling arterial catheter. When a patient's respiratory status is unstable or is rapidly evolving or when frequent adjustments in ventilatory support are required, intermittent monitoring may be insufficient. In these clinical situations, continuous monitoring is preferable. Continuous intra-atrial blood gas monitors can provide useful real-time data regarding gas exchange and acid-base status,[45,46] although the clinical utility of these monitors has not been validated, and the technology is not widely available.[47,48] These monitors use fluorescence-based probes placed through an arterial catheter to provide a continuous assessment of Pa_{O_2}, Pa_{CO_2}, and pH. The information obtained from these instruments should provide more immediate information about changes in gas exchange or acid-base balance. However, the probes and monitors are more expensive than intermittent blood gas analysis and have not become routine monitors.

2. Noninvasive Monitoring

Assessment of gas exchange using noninvasive techniques has revolutionized clinical care, particularly for anesthesiologists and intensive care providers. Because clinical evaluation of gas exchange is unreliable and often a late sign of deterioration,[49] noninvasive devices that continuously monitor oxygenation and ventilation are valuable tools. Several noninvasive methods are available for evaluating oxygenation and ventilation. The most commonly used devices include the pulse oximeter for monitoring oxygenation and the capnograph for evaluating ventilation.

a. PULSE OXIMETRY

Pulse oximetry provides a rapid, continuous, and noninvasive estimation of the O_2 saturation of hemoglobin in arterial blood, and it is used routinely to monitor clinical care involving airway management in the OR, ED, and ICU.[50-53] It has become the standard monitor of oxygenation during administration of sedation for procedures and during general medical care.[54-57] With routine use of this monitor, a high prevalence of clinically undetected hypoxemia in adults and children has been demonstrated.[50,57-59] These episodes of desaturation may affect morbidity and mortality.[60,61] With severe and sustained hypoxemia (i.e., oxygen saturation from pulse oximetry [Sp_{O_2}] is less than 85% for more than 5 minutes), patients with known cardiac disease were twice as likely to have perioperative ischemia after noncardiac surgery.[61] Among medical patients, those who experienced episodes of hypoxemia within the first 24 hours of hospitalization were three times more likely to die 4 to 7 months after discharge.[60]

It is logical to assume that the routine use of pulse oximetry has made caring for patients safer by increasing the detection of hypoxemia, better understanding its causes, and allowing more rapid and effective interventions to correct the pathophysiologic causes. Some clinicians have suggested that the early detection of arterial oxygen desaturation with the use of pulse oximetry may improve outcomes.[61-64] Although clinical studies do not confirm this belief, they do not negate the presumed benefit of this monitoring tool.[65-68] A systematic review of the Cochrane database found no evidence of an outcome benefit of the use of pulse oximetry in anesthesia practice.[69] Despite the lack of good outcome data to document that value of pulse oximetry, its use is considered standard of care for critically ill patients and patients receiving moderate or deep sedation or anesthesia.

To measure the O_2 saturation of hemoglobin in arterial blood, pulse oximetry uses two fundamental principles: the differential light absorption of oxyhemoglobin (O_2Hb) and reduced hemoglobin (Hb) and the increase in light absorption produced by pulsatile blood flow compared with that of a background of connective tissue, skin, bone, and venous blood.[56,70] The spectrophotometric principle that forms the basis for oximetry is the Lambert-Beer law (Equation 1), which allows determination of the concentration of an unknown solute in a solvent by light absorption.

$$I_1/I_0 = e^{-alc} \quad (1)$$

where
I_1 = intensity of the light out of the sample
I_0 = intensity of the incident light
a = absorption coefficient of the substance
l = distance the light travels through the material (i.e., path length)
c = concentration of the absorbing species
e = base of the natural logarithm

Use of the Lambert-Beer law allows the determination of the concentration of a solute in a solvent as long as the extinction coefficient is known. It also follows that for a solution with multiple solutes, a separate wavelength of light is needed for differentiation of the solutes. For a solution with four solutes, four wavelengths of light are required.

The commercially available pulse oximeters use light-emitting diodes (LEDs) that transmit light at specific wavelengths: 660 nm (red) and 940 nm (infrared). These wavelengths were selected because the absorption characteristics of O_2Hb and reduced Hb are sufficiently different at these wavelengths to allow differentiation of O_2Hb and Hb (Fig. 49-1).

The pulse oximeter determines arterial saturation by timing the measurement to pulsations in the arterial system. During pulsatile flow, the vascular bed expands and contracts, creating a change in the light path length.[51] These pulsations alter the quantity of light transmitted to the sensor and provide a plethysmographic waveform.[71] This timing of the signal allows the pulse oximeter to differentiate arterial oxygen saturation from venous saturation on the basis of the ratio of pulsatile and baseline absorption of red and infrared light (Fig. 49-2).

The pulse oximeter displays the O_2 saturation based on a ratio (R) of pulsatile and baseline absorption at the two wavelengths transmitted (i.e., 660 and 940 nm) in the tissue bed. The relationship is shown in Equation 2:

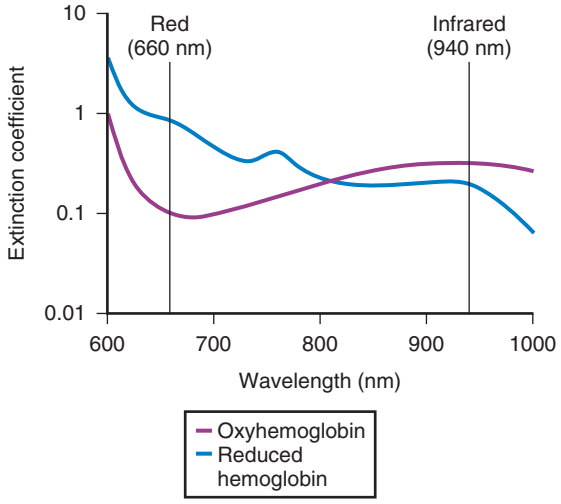

Figure 49-1 Absorption (extinction) characteristics of oxyhemoglobin and reduced hemoglobin are shown. There are marked differences between the two at light wavelengths of 660 nm (red) and 940 nm (infrared). (From Tobin MJ: Respiratory monitoring. *JAMA* 264:244–251, 1990.)

$$R = \frac{\text{Pulsatile absorbance at 660 nm/nonpulsatile absorbance at 660 nm}}{\text{Pulsatile absorbance at 940 nm/nonpulsatile absorbance at 940 nm}} \quad (2)$$

The O_2 saturation displayed by the pulse oximeter is empirically related to this calculated value on the basis of calibration curves derived for healthy, nonsmoking adult men breathing O_2 at various concentrations. Most commercially available pulse oximeters are calibrated over the range of 70% to 100%. The accuracy of pulse oximetry in determining the Sa_{O_2} of Hb has been excellent over this range,[51] with an error of ±3% to 4%.[57]

Although pulse oximetry has become a ubiquitous monitoring device, particularly to confirm adequacy of oxygenation during airway management, it has limitations. First, the measurement of O_2 saturation does not provide a direct assessment of oxygen tension. Because of the shape of the oxygen-hemoglobin dissociation curve, at higher levels of oxygenation measurements of SpO_2 are insensitive in detecting significant changes in Pa_{O_2} (Fig. 49-3). Second, the pulse oximeter is not accurate when oxygen saturation is less than 70%. The inaccuracy results from the limited range of O_2 saturations

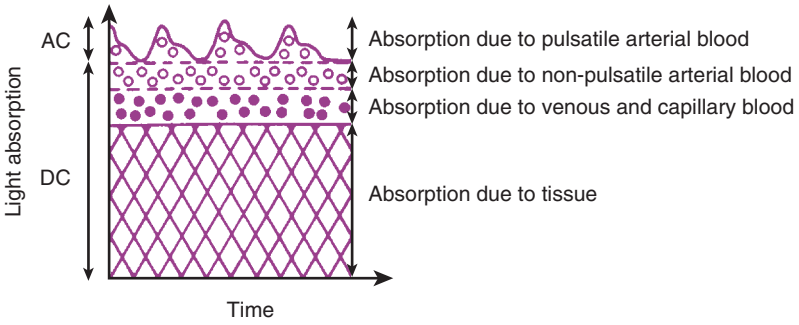

Figure 49-2 Schematic representation of light absorption through living tissue. Notice that the alternating current *(AC)* signal results from the pulsatile component of arterial blood and that the direct current *(DC)* signal comprises all the nonpulsatile absorbers of light in the tissue, including nonpulsatile blood in the veins and capillaries and nonpulsatile blood in all other tissues. (From Tremper KK, Barker SJ: Pulse oximetry. *Anesthesiology* 70:98–108, 1989.)

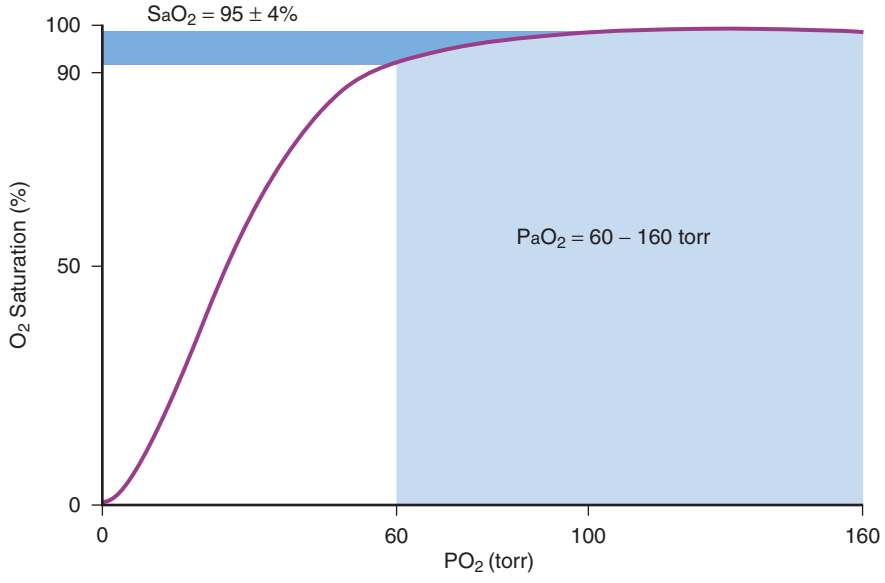

Figure 49-3 Oxygen dissociation curve. Because pulse oximeters have 95% confidence limits for Sa_{O_2} of ±3% to 4%, an oximeter reading of 95% can represent a Pa_{O_2} of 60 mm Hg (saturation of 91%) or 160 mm Hg (saturation of 99%). (From Tobin MJ: Respiratory monitoring in the intensive care unit. *Am Rev Respir Dis* 138:1625–1642, 1988.)

used in the calibration process and the difficulty in obtaining reliable human data at these low oxygen saturations.[71,72]

The accuracy of pulse oximeters during hypoxemia has been extensively studied and reviewed.[37,73-76] Most of these studies have been performed on healthy volunteers who had desaturation induced by breathing hypoxic gas mixtures for short periods. Pulse oximeters from different manufacturers varied in their accuracy during hypoxemia; the direction of error differs among these devices, with some overestimating and some underestimating true arterial O_2 saturation. Some study results documented problems with the calibration curves and caused revision of the algorithms by the manufacturers.[72-77] These modifications to the algorithms have improved performance of the oximeters.[57]

Other factors affect the performance of pulse oximeters. The response characteristics of pulse oximeters are clinically important, particularly in situations in which the saturation may be changing rapidly, as can occur during management of the difficult airway. Investigators have studied the response characteristics of pulse oximetry in clinical practice.[72-77] West and colleagues studied five obese, nonsmoking men with sleep apnea syndrome.[78] During spontaneous desaturation, the pulse oximeter underestimated the minimum Sa_{O_2}, and during spontaneous resaturation, there was an overshoot of the maximum SpO_2. The location of the probe also influences the response time for the pulse oximeter. Probes placed on the ear respond more quickly to sudden decrease in Sa_{O_2} than probes placed on a digit.[75] The response time to changes in O_2 saturation of the pulse oximeter also depends on heart rate. For fingertip sensors, as heart rate increases, the response to an acute change in saturation is faster; for ear or nasal probes, the relationship is reversed, and as heart rate increases, the response to changes in Sa_{O_2} is slower.[78]

Accuracy of the pulse oximeter is altered in several situations (Box 49-1). Excessive light, such as fluorescent or xenon arc surgical lights, bilirubin lights, and heating lamps, can cause falsely low or high SpO_2 values.[57,72,79] Covering the probe with an opaque material helps to eliminate this problem. Electrocautery devices can produce significant electrical interference, which results in improper functioning of the pulse oximeter.[56] The infrared pulse waves used by neurosurgical image guidance systems interfere with the signal quality and O_2 saturation detection by pulse oximetry.[80] The use of aluminum foil as a shield was effective in restoring the accuracy of six brands of pulse oximeters when exposed to the infrared signal generated by a neuronavigation device.[81] Misalignment of disposable pulse oximeter probes may cause falsely low O_2 saturation to be displayed by pulse oximeters, even though the plethysmographic tracing is of excellent quality, and this can change anesthetic management.[82] In 100 patients entering the postanesthesia care unit (PACU) at Massachusetts General Hospital, only 6 had perfect placement of the probes, and for the remaining 94, the average misalignment distance was 5.4 mm (range, 0 to 23 mm).[82] In a single case report, a Massimo Signal Extraction Technology (Massimo SET; Irvine, CA) pulse oximeter using SatShare technology with a Datex-Ohmeda AS/3 monitor displayed an uninterrupted waveform and normal O_2 saturation during asystole in a patient undergoing abdominal surgery.[83]

BOX 49-1 Conditions Affecting the Accuracy of Pulse Oximetry

- External light sources
- Electrocautery
- Motion of the probe
- Dyshemoglobinemias: carboxyhemoglobin, methemoglobin
- Dyes and pigments: indocyanine green, methylene blue, indigo carmine
- Nail polish
- Severe anemia
- Low perfusion, low perfusion index
- Excessive venous pulsations

Motion of the probe, such as when a patient or caregiver moves the digit on which the oximeter probe is placed, can cause artifactual readings from the pulse oximeter. Vibration of the sensor delays the detection time for hypoxemia and causes spurious decreases in SpO_2.[84] Movement can result in errors of as much as 20%.[85] In a large, prospective study, patients' motion was the major reason for abandoning the use of a pulse oximeter in the PACU.[86] In pediatric patients, 71% of all alarms were false.[87] Attempts have been made to minimize the effect of motion by timing the measurement of SpO_2 to the electrocardiogram (ECG). Pulse oximeters that possess ECG linkage and time the measurement of arterial saturation to the ECG have performed better during vibration than those without this feature.[84] Although this ECG interface is helpful, it has not completely eliminated motion as a problem, particularly in very active or agitated patients. Another approach to decreasing the effect of patients' motion on the accuracy of oximetric data has been to reject motion artifact retrospectively using changes in the plethysmographic waveform that immediately preceded the questionable event.[85] This results in fewer detected episodes of false O_2 desaturation, although at the price of missing true events.[88]

Several manufacturers have added technology designed to minimize motion artifact and to extract a more accurate (true) signal. The Masimo SET uses unique sensor designs and software algorithms to reduce the incidence of false alarms. When the performance of oximeters using this technology was compared in volunteers with that of the Nellcor N-3000 Symphony with improved low-signal performance (Oxismart) and the older Nellcor N-200, the oximeters using Masimo SET were superior in error and signal dropout rate.[89] Baker and colleagues compared the functioning and accuracy of 20 pulse oximeter models in volunteers with hypoxemia during motion and found that the Masimo SET had the best overall performance.[90] When used in the neonatal ICU, Masimo SET resulted in dramatically fewer false alarms and captured more true events than the Nellcor N-200.[91] Oximeters using Masimo SET were more reliable in detecting bradycardia and hypoxemic episodes in patients in the neonatal

ICU than the N-3000.[92] This is evidence that more reliable data from oximetry can improve the process of care in a cost-effective manner. In adults after cardiac surgery, the use of more reliable oximeters (those with Masimo SET) compared with conventional oximeters resulted in a more rapid reduction in fraction of inspired oxygen (FIO_2) and the need for fewer ABG determinations during mechanical ventilation.[93] Petterson and colleagues have reviewed the various technologies used to prevent the effects of motion artifacts on the accuracy of pulse oximeters.[94]

Another problem with the pulse oximeter is its inability to differentiate oxyhemoglobin from other hemoglobins, such as methemoglobin and carboxyhemoglobin. An oximeter is able to differentiate only as many substances as the number of wavelengths of light it emits.[56,77] Commercially available oximeters can detect only two types of hemoglobin, reduced and oxygenated (Hb and O_2Hb). Pulse oximeters derive a functional saturation of hemoglobin, which is defined in Equation 3:

$$\text{Functional saturation} = \frac{O_2Hb \times 100\%}{O_2Hb + Hb} \quad (3)$$

This functional saturation does not account for other hemoglobins, such as methemoglobin (MetHb) or carboxyhemoglobin (COHb). To assess the presence of these other hemoglobin species, two additional wavelengths of light must be incorporated into the measuring device. Spectrophotometric heme oximeters (CO-oximeters) that use four or more wavelengths of light are able to measure other hemoglobin species and calculate the fractional saturation using Equation 4:

$$\text{Fractional saturation} = \frac{O_2Hb \times 100\%}{O_2Hb + Hb + MetHb + COHb} \quad (4)$$

When COHb or MetHb is present, the pulse oximeter does not provide a true measurement of oxygen saturation.[95,96] The presence of COHb causes a false elevation in the SpO_2 measurement.[95] As shown in Figure 49-4, COHb has minimal light absorption at 940 nm, and at 660 nm, its absorption coefficient is almost identical to that of O_2Hb. The pulse oximeter cannot differentiate COHb from O_2Hb; it overestimates the O_2Hb.[95] The SpO_2 displayed by the pulse oximeter approximates the sums of COHb and O_2Hb. This problem with pulse oximeters is important to consider when assessing oxygenation in patients who have sustained smoke inhalation or patients who have smoked just before proposed airway management. COHb can also be present in long-term ICU patients because carbon monoxide (CO) is a metabolic product of heme metabolism.[97,98] The influence of this potential endogenous source of CO on the accuracy of SpO_2 in the critically ill patient requires further evaluation. In any case, when high CO levels are suspected, O_2 saturation should be measured using a CO-oximeter rather than a pulse oximeter.

MetHb also interferes with pulse oximeter measurements.[96,99] As MetHb levels exceed 30% to 35%, SpO_2 becomes independent of the MetHb level, approaching

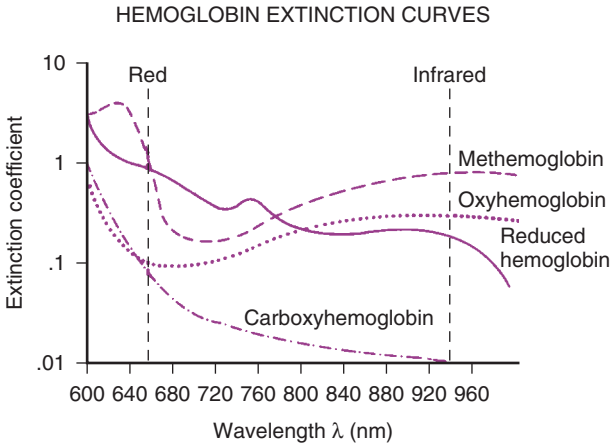

Figure 49-4 Transmitted light absorbance spectra of four hemoglobin species: oxyhemoglobin, reduced hemoglobin, carboxyhemoglobin, and methemoglobin. (From Tremper KK, Barker SJ: Pulse oximetry. *Anesthesiology* 70:98–108, 1989)

85%. This inaccuracy occurs because the MetHb absorption coefficient at 660 nm is almost identical to that of reduced hemoglobin, whereas at 940 nm, it is greater than that of other hemoglobins (see Fig. 49-4). The pulse oximeter therefore overestimates or underestimates the true SaO_2, depending on the level of MetHb.[77] Some causes of high MetHb levels include administration of nitrates, local anesthetics (e.g., lidocaine, benzocaine), metoclopramide, sulfa-containing drugs, ethylenediaminetetraacetic acid (EDTA), and diaminodiphenylsulfone (Dapsone) and primaquine phosphate used to treat patients with acquired immunodeficiency syndrome (AIDS). Some patients can also have congenitally high MetHb levels.

The continuous and noninvasive detection of oxygenated and deoxygenated hemoglobin, as well as COHb, MetHb, and total hemoglobin, has become possible with the development of oximetric technology. The devices used to monitor these parameters are referred to as pulse CO-oximeters. These newer devices use 8 to 12 wavelengths of light. Devices developed by Massimo Corporation, the Rainbow Set Radical 7 pulse CO-oximeter and the Rad 57 pulse CO-oximeter, can detect and accurately measure the concentrations of COHb and MetHb.[100] An advantage of these devices is the ability to continuously monitor the level of dyshemoglobinemia and monitor the response to treatment.[101-105] The clinical value of this technology has been documented in numerous case reports of detection of carboxyhemoglobinemia and methemoglobinemia. However, the specific algorithms used to detect the dyshemoglobins impacts the accuracy of these devices. For example, the accuracy of the Massimo Radical 7 Pulse CO-oximeter in measuring MetHb during coincident hypoxemia (SaO_2 < 95%) was poor in 14 healthy adults with overestimation of MetHb levels by 10% to 40%.[106] After the company made modifications of the software and separated the optical sensors for MetHb and COHb, the accuracy for measuring MetHb concentrations improved considerably.[107]

Pulse CO-oximetry can also be used to continuously determine the hemoglobin concentration in arterial blood

(SpHb).[108] Macknet and colleagues used a Masimo Radical 7 with a spectrophotometric adhesive sensor using 12 wavelengths of light to measure SpHb in 20 healthy volunteers undergoing hemodilution (with removal of 500 mL of whole blood) compared with the standard total hemoglobin (tHb) measurement using a laboratory CO-oximeter.[109] The investigators found that the average difference between SpHb and tHb to be –0.15 g/dL, with a standard deviation of 0.92 g/dL, and they concluded that SpHb is accurate within 1.0 g/dL. In 20 patients undergoing spinal surgery, Miller and colleagues compared SpHb with tHb and with hemoglobin measured with a point-of-care device, the HemoCue.[110] There was an overall tendency for the SpHb to overestimate the corresponding tHb, especially when the perfusion index (PI) was higher than 1.4, the manufacturer's threshold value for accuracy of SpHb. This study also calls into question the utility of using SpHb in making clinical decisions, because 22% of the pulse CO-oximeter tests determined hemoglobin values were more than 2.0 g/dL different from the tHb values.[110] However, other investigators have found the monitor to be a useful guide to clinical decision making. In a preliminary study of 350 patients undergoing orthopedic surgery, the use of noninvasive, continuous hemoglobin monitoring reduced the frequency of blood transfusions and decreased the number of units of blood transfused compared with standard hemoglobin measurement.[111] Although these studies have documented the value of SpHb monitoring in some clinical situations, the clinical value for guiding transfusion decisions for the patient with rapid, acute blood loss, large fluid shifts, or poor PI will require further investigation.

Fetal Hb does not affect the accuracy of the pulse oximeter.[56,57,79] The effect of other dyshemoglobinemias, such as sulfhemoglobin, on the accuracy of pulse oximetry has not been investigated.[79] Other pigments that interfere with the accuracy of pulse oximeter measurements include indocyanine green, methylene blue, and indigo carmine.[79] These dyes cause transient artifactual falls in saturation; the extent of the problem depends on the absorption characteristics of the dye. Skin pigmentation has minimal effect on pulse oximeter readings, although very dark pigmentation can result in a slight decrease in accuracy.[112,113] Jaundice has caused artificially low and artificially high pulse oximeter readings.[94] In most studies, however, even very high bilirubin levels have had no effect on the accuracy of the SpO_2.[103,114]

Certain shades of nail polish can alter significantly the accuracy of pulse oximetry when the sensor is placed directly over the nail bed. The extent to which accuracy is affected depends on the absorption characteristics of the nail polish at 660 and 940 nm. Black, blue, and green polishes can falsely lower the measured SpO_2 by up to 6%; red nail polish has little effect on pulse oximeter measurements.[79,115,116] If a patient has a darkly pigmented polish, it should be removed from the nail bed that is going to receive the probe, or the probe should be placed over the sides of the digit, thereby avoiding transmission of the signal through the nail bed.[79,116] Darker skin pigments can produce falsely high readings of arterial O_2 saturation by many pulse oximeters during hypoxemia. The positive bias in patients with dark skin may be as much as 8% when arterial O_2 saturation is less than 80%, and it is less pronounced in patients with intermediate pigmentation and smallest in those with the lightest skin.[117] This may be explained by the use of light-skinned individuals for the testing and calibration of pulse oximeters. However, not all oximeters produce this result. The Masimo Radical oximeter with an adhesive, disposable probe was found to underestimate oxygen saturation in hypoxic subjects.[118]

Severe anemia can affect the accuracy of the pulse oximeter. Lee and coworkers demonstrated that the pulse oximeter was inaccurate when the hematocrit was less than 10%.[119] Vegfors and colleagues also found that the pulse oximeter is not accurate when the hematocrit is very low,[120] but they suggested that the problem was caused by poor perfusion rather than the hematocrit level alone. Of more importance in the management of the severely anemic patient is the assessment of O_2 delivery, rather than O_2 saturation, even when the pulse oximeter is accurate. SpO_2 reflects only O_2 saturation and does not provide a guide to adequacy of the oxygen-carrying capacity of the blood or O_2 delivery. In patients with sickle cell anemia, pulse oximetry correlates well with Sa_{O_2} measured by CO-oximeter, although with a clinically insignificant bias toward underestimation.[121]

When patients become hypotensive, hypovolemic, or markedly vasoconstricted, the peripheral pulse diminishes. This results in an additional problem with the performance of the pulse oximeter because the monitor works only when the patient has adequate arterial pulsations. When the patient's peripheral perfusion is poor, the pulse oximeter may be unable to measure SpO_2. In one study of patients with poor perfusion after cardiopulmonary bypass, only 2 of 20 brands of pulse oximeters were able to give SpO_2 values within 4% of that obtained using a CO-oximeter.[122] Attempts to improve the accuracy of pulse oximeters in hypoperfused conditions have not adequately solved the problem. Alternative probe locations, such as the nose or ear, and reflectance, rather than transmittance, techniques have been tried with various degrees of success.[123,124] Investigators have evaluated pulse oximetry using probes placed in the esophagus.[125-127] When placed esophageally or in other internal tissue sites, the measurement of SpO_2 depends on reflectance and not on detection of the transmitted signal on the side opposite the emitter, as in standard transmission pulse oximetry.[128,129] Esophageal location of the pulse oximeter probe in critically ill surgical patients results in more consistent Sa_{O_2} readings than with standard surface probes, and the function of probes was not affected by changes in perfusion or temperature.[127] Esophageal pulse oximetry has also been used successfully in neonatal and older pediatric patients.[130] Fetal pulse oximetry uses reflectance technology.[131] Unfortunately, the expected reduction in the rate of cesarean delivery with the use of fetal oximetry has not occurred.[132] In patients with peripheral vascular disease undergoing vascular surgery, the use of a forehead reflectance probe was shown to be an acceptable alternative to the standard transmission probe placed on the earlobe.[128]

The accuracy of SpO_2 measurements in hypothermic patients has not been rigorously evaluated, but it seems to depend primarily on the presence or absence of an adequate pulse signal rather than temperature itself.[133] In one study, active warming of patients improved the ability of pulse oximeters to detect a signal and decreased the incidence of false alarms.[134]

Pulsations other than arterial pulsations interfere with the performance of the pulse oximeter. When venous pulsations are pronounced, for example, the pulse oximeter may underestimate the true arterial oxygen saturation of hemoglobin.[135] In a group of patients with severe tricuspid insufficiency, pulse oximetry underestimated the O_2 saturation by up to 11%. Other clinical situations in which venous pulsations may be important include patients with severe congestive heart failure and patients who require very high venous pressure, such as after a Fontan procedure performed as treatment for tricuspid atresia.

Severe burns and injury to the digits of both hands and feet have been reported from the application of pulse oximeter probes.[136-138] Frequently rotating the site of application and increasing vigilance can minimize these events. Burns of the skin have occurred with the application of pulse oximeters to patients after photodynamic therapy with the porfimer sodium (Photofrin).[139] During intraoperative photochemotherapy with verteporfin, frequent rotation of the site of the pulse oximeter at intervals of 7 to 15 minutes during the 6-hour procedure prevented cutaneous injury.[140]

The plethysmographic waveforms produced by many pulse oximeters have been evaluated as a noninvasive method to determine blood pressure, intravascular volume, and perfusion.[115,141-147] Respiratory-induced changes in photoplethysmography, as a predictor for volume responsiveness in mechanically ventilated patients, is similar to that seen in the arterial pressure waveform, and these dynamic measurements are superior to the static measurements obtained from intravascular catheters.[148-150] Some patient conditions may limit the use of these dynamic indicators of volume responsiveness, including dysrhythmias, a requirement for positive-pressure ventilation with a V_T greater than 8 mL/kg, and low levels of positive end-expiratory pressure (PEEP).[151] Plethysmographic variations induced by the use of positive-pressure ventilation were more reliable in predicting fluid responsiveness than central venous pressure or pulmonary artery occlusion pressure in mechanically ventilated cardiac surgery patients postoperatively.[152] Photoplethysmographic pulse variation of more than 9% produced by mechanical ventilation identified patients who were likely to respond to fluid administration with an increase in cardiac output.[148] In this study, there was no relationship between arterial pressure measured directly and the amplitude of the photoplethysmogram. Respiratory changes in the amplitude of the plethysmographic pulse were found to be as accurate as changes in pulse pressure from an arterial catheter produced by mechanical ventilation in septic patients for the prediction of fluid responsiveness.[153] The use of respiratory variations in photoplethysmography has been as reliable and as accurate an indicator of mild hypovolemia (up to a 20% decrease in estimated circulating blood volume) as the use of arterial waveform analysis in hemodynamically stable, mechanically ventilated patients undergoing autologous hemodilution.[154] On the contrary, Landsverk and colleagues found that there are larger intraindividual and interindividual variability in critically ill patients in indices derived from pulse oximeter technology than from those using arterial waveforms and that this may limit the reliability of predicting volume responsiveness using the pulse oximeter.[155]

The use of the respiratory-induced waveform variation (RIWV) in photoplethysmography may be useful in detecting hypovolemia in spontaneously breathing humans.[156,157] In a study of trauma patients in the prehospital setting, Chen and colleagues found that photoplethysmography RIWV was independently correlated with major hemorrhage and that it may enhance detection of hypovolemia beyond the use of standard vital signs.[156] In a study of volunteers, McGrath and colleagues progressively reduced central blood volume using lower body negative pressure up to −100 mm Hg and investigated the pulse shape features of the photoplethysmographic patter obtained from sensors placed on the finger, forehead, and ear to determine which might serve as indicator of hypovolemia.[157] The investigators found that reductions in pulse amplitude, width, and area under the curve of the pulse oximeter waveform from the ear and forehead were strongly correlated with reductions in stroke volume with the forehead sensor having the best performance. These changes in waveform were seen before reductions in arterial blood pressure. The increased sympathetic activity that accompanies hypovolemia and the concomitant peripheral vasoconstriction were thought by the investigators to reduce the ability of the photoplethysmogram obtained from the finger probe to function as well as the probes in other locations in detecting hypovolemia.

The Massimo Corporation developed a proprietary algorithm, the Pleth Variability Index (PVI), which allows continuous and automated calculation of respiratory-induced variations of the photoplethysmographic waveform. PVI is a dynamic measure of the changes in the perfusion index (PI) that occur over a complete respiratory cycle. The PI is the ratio of pulsatile absorption of the pulse oximeter signal (AC) to that obtained during the baseline nonpulsatile signal (DC), and it reflects the amplitude of the plethysmographic waveform.[115] To calculate PI, the pulsatile signal is indexed to the nonpulsatile blood flow and expressed as a percentage: $PI = (AC/DC) \times 100$. The PVI calculation uses the maximal (PI_{max}) and minimal (PI_{min}) PI values over the respiratory cycle: $PVI = [(PI_{max} - PI_{min})/PI_{max}] \times 100$, expressed as a percentage.[158]

Studies have investigated the usefulness of the PVI to predict fluid responsiveness in patients and guide patient management.[159-161] In patients after cardiac surgery, PVI was able to predict the reduction in cardiac output produced by the application of PEEP of 10 cm H_2O when patients were mechanically ventilated with a V_T greater than 8 mL/kg.[158] When patients were ventilated with a V_T of 6 mL/kg, the PVI and the change in respiratory variation in arterial pulse pressure (ΔPP) were unable to

accurately assess the hemodynamic effects of PEEP. In a study of goal-directed fluid management, PVI was used to assess volume responsiveness in 82 patients undergoing abdominal surgery. The use of PVI resulted in a decrease in the volume of fluid administered in the OR and reduced lactate levels in the intraoperative and postoperative periods.[160] Zimmermann and colleagues found that PVI is comparable to stroke volume variation as an indicator of volume responsiveness.[162] PVI also can predict fluid responsiveness (i.e., increase in cardiac output of ≥15%) in mechanically ventilated critically ill patients with circulatory insufficiency after a 500-mL colloid bolus.[161] In this study, a higher PVI at baseline was associated with a larger change in cardiac output after fluid administration.

The PI that is provided in some pulse oximetric monitoring systems correlates with peripheral perfusion. Lima and colleagues found that the PI correlated with changes in the core-to-toe temperature difference in critically ill patients and suggested that it might be clinically helpful to monitor changes in PI in this population of patients.[144]

In the postoperative period, continuous pulse oximetry can be a useful surveillance monitor, and it can reduce respiratory complications. One commercially available system uses a paging system to alert the nursing staff when preset physiologic alarm limits are breached. In one study that evaluated the clinical benefits of the Patient SafetyNet System (Massimo Corp.), careful selection of the alarm limits reduced the number of false alarms but provided notification to the nurse of changes in physiologic parameters, including O_2 saturation. The investigators demonstrated a decrease in ICU transfers and reduced need for rescue events (i.e., activation of rapid response team, cardiac arrest team, or stat airway team) compared with before implementation of the system.[163] Further investigation of the clinical value of these systems is needed to justify widespread implementation.

b. CAPNOGRAPHY

Capnography provides a noninvasive method to assess ventilation and ventilation-perfusion relationships.[164-166] A capnograph provides a continuous display of the CO_2 concentration of gases from the airways. The CO_2 concentration at the end of normal exhalation (Et_{CO_2}, P_{ETCO_2}) is a reflection of gas from the distal alveoli; it therefore represents an estimate of the alveolar CO_2 concentration (P_{ACO_2}). When ventilation and perfusion are well matched, the P_{ACO_2} closely approximates the Pa_{CO_2}, and $P_{ACO_2} \cong Pa_{CO_2} \cong P_{ETCO_2}$. The normal gradient between Pa_{CO_2} and P_{ETCO_2} ($P[a - ET]_{CO_2}$) is more than 6 mm Hg. The gradient between Pa_{CO_2} and P_{ETCO_2} increases when pulmonary perfusion is reduced or ventilation is maldistributed.

The capnogram is a waveform that graphically represents the CO_2 concentration over time. The capnogram provides information about adequacy of ventilation, potential airflow obstruction, and in conjunction with other monitors, $\dot{V}/\dot{Q}$ relationships. A normal capnogram has four components, the ascending limb, alveolar plateau, descending limb, and baseline (Fig. 49-5). The ascending limb represents the CO_2 concentration of the gas in rapidly emptying alveoli. The alveolar plateau occurs

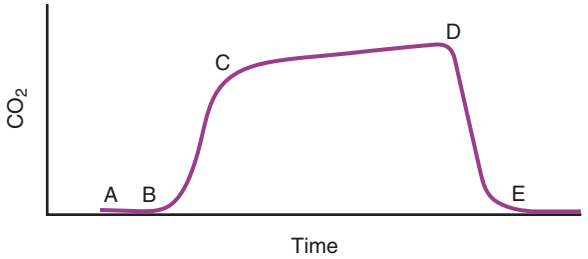

Figure 49-5 Normal capnogram. Exhalation begins at point A and continues to point *D*. Segment *C-D* is the alveolar plateau. Point *D* represents the end-tidal carbon dioxide. Inspiration is represented by rapid, descending limb of segment *D-E*, which reaches the zero baseline.

because the CO_2 concentration from uniformly ventilated alveoli is relatively constant. The P_{ETCO_2} is the point at which the CO_2 concentration is highest, representing the CO_2 concentration approximating true alveolar gas. The rapid, descending limb of the capnogram signals inspiration. The baseline represents the CO_2 concentration of inspired gas.

Various methods of gas analysis are commercially available, including mass spectrometry, Raman scattering, and infrared absorption spectrometry. The most commonly used method is infrared spectrophotometry. It is based on the principle that CO_2 absorbs infrared light. As the infrared light is passed through a sample of gas, the amount of infrared light absorbed is proportional to the concentration of CO_2 in the sample.

Two different sampling techniques are used for capnography: mainstream and sidestream devices. The mainstream (in-line) capnograph has a transducer that is connected to the patient's ETT. The transducer contains the infrared light source and a photodetector. The mainstream capnograph has a faster response time because no gas is withdrawn from the patient's airway. Secretions usually do not prevent accurate measurement because they are easily removed from the sensor site. The mainstream device does have some limitations, including the weight of the connectors, the increased equipment dead space (as much as 20 mL), and the inability to use mainstream devices in extubated patients.

The sidestream (diverting) capnograph aspirates gas from the patient's airway to the capnograph through a sampling tube. Analysis of the CO_2 concentration is performed in the monitor rather than at the airway adapter. Because the analysis is not done at the airway, the airway connector is smaller and adds no significant dead space or weight to the Y connection between the ETT and ventilator circuit. The sidestream device can also be used with a modified nasal cannula to monitor CO_2 concentrations in the airway of nonintubated patients. The response time of the sidestream capnograph is slower because it aspirates gas from the airway. The sampling can be compromised by significant water condensation in the catheter and pulmonary secretions.

Capnography has important applications during airway management and mechanical ventilatory support. It is a useful monitor during endotracheal intubation and to confirm placement of the ETT within the trachea. It can document adequacy of ventilation during mechanical

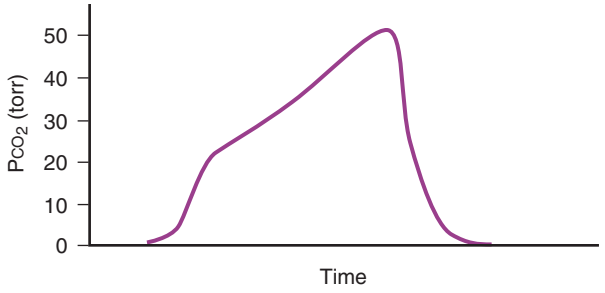

Figure 49-6 Capnograph waveform in a patient with airflow obstruction demonstrates lack of an alveolar plateau.

ventilatory support, spontaneous ventilation in intubated and nonintubated patients, and adequacy of cardiopulmonary resuscitation. Capnography can also be used to monitor the nonintubated patient using a nasal cannula that aspirates the exhaled gas and analyzes the CO_2 concentration. This technique is useful when evaluating the patient with a tenuous airway or gas exchange who may require urgent or emergent endotracheal intubation and mechanical ventilatory support.

The capnographic waveform provides a graphic display of the CO_2 concentration over time. The waveform can be used to identify significant inspiratory or expiratory airway obstruction, including intrinsic airway obstruction or a kinked ETT (Fig. 49-6). With expiratory obstruction, the waveform does not have a normal alveolar plateau. By continuously monitoring the capnographic waveform, the response to bronchodilator therapy can be visually confirmed. The capnographic waveform can also be used to diagnose rebreathing of CO_2; with rebreathing, as can occur when fresh gas flow is inadequate, the baseline (inspired) CO_2 concentration increases.

Despite its clinical utility, capnography has significant limitations as a monitor of ventilation for patients with impaired pulmonary function or hemodynamic instability. The biggest problem is that the correlation between P_{aCO_2} and P_{ETCO_2} varies and is sometimes poor in patients with low cardiac output or altered $\dot{V}/Q$ relationships. The correlation varies as the patient's clinical condition changes, making interpretations of ventilation from P_{ETCO_2} measurements alone unreliable. This has been documented in patients suffering severe traumatic injury, particularly those with traumatic brain injury for whom hypocapnia and hypercapnia should be avoided.[167,168] In a study of 180 trauma patients presenting to an ED, the correlation between P_{ETCO_2} and P_{aCO_2} was poor (R^2 = 0.277).[169] Following common recommendations for ventilation in these patients to maintain P_{ETCO_2} values between 35 and 39 mm Hg resulted in significant hypoventilation. The P_{aCO_2} was more than 40 mm Hg in 80% of cases and more than 50 mm Hg in 30% of cases. The correlation between P_{ETCO_2} and P_{aCO_2} was best for patients with only traumatic brain injury and poor for those with chest injuries or decreased perfusion. An increased difference between P_{aCO_2} and P_{ETCO_2} in patients with traumatic brain injury was observed for those with coexistent severe chest trauma, hypotension, and metabolic acidosis. For patients without significant extracranial trauma, the P_{aCO_2} and P_{ETCO_2} were 100% concordant.[170] Capnography may be used to guide ventilatory therapy in patients with traumatic brain injury, but only if there is limited injury to other organ systems. It can provide useful noninvasive information in patients undergoing apnea testing to confirm brain death,[171] although most clinicians perform confirmatory ABG analysis to document the P_{aCO_2} before declaring brain death.

IV. MONITORING RESPIRATORY FUNCTION DURING MECHANICAL VENTILATORY SUPPORT

Assessment of pulmonary mechanical function can be performed using a variety of monitoring techniques for the patient who is breathing spontaneously and for the mechanically ventilated patient.[172-175] The techniques are useful for optimizing ventilatory support in the critically ill patient, determining the extent to which the patient can initiate spontaneous ventilation, guiding the use of supportive modes of ventilation (e.g., pressure support ventilation), and determining when and how to initiate weaning from mechanical ventilatory support. With several new modes of ventilation and supportive techniques to augment patient-initiated breaths, these monitoring techniques have become an essential component of respiratory management.

A. Assessment of Pulmonary Mechanical Function

Assessment of dead space ventilation ($\dot{V}_D$) is critical to understanding the nature of a patient's respiratory dysfunction and defining the ventilatory needs of the patient. The $\dot{V}_D$ represents wasted ventilation in that it increases the work of breathing without contributing to gas exchange.

Most clinicians measure P_{aCO_2} to determine whether the patient has adequate ventilation, defined as effective removal of CO_2 by the lungs. P_{aCO_2} is an essential measure of respiratory function and cardiorespiratory relationships, although interpretation of P_{aCO_2} requires an understanding of respiratory function, acid-base status, and compensatory mechanisms by which the patient may adjust to decreased alveolar ventilation ($\dot{V}_A$). Evaluating the adequacy of ventilation requires an understanding of $\dot{V}_A$ and $\dot{V}_D$. The determinants of P_{aCO_2} are represented in Equation 5:

$$P_{aCO_2} = k\dot{V}_{CO_2}/\dot{V}_A \quad (5)$$

where
k = 0.863
$\dot{V}_{CO_2}$ = carbon dioxide production (mL/min)
$\dot{V}_A$ = alveolar ventilation (L/min)

The equation assumes that inspired CO_2 is zero. CO_2 elimination through the lung depends solely on the $\dot{V}_A$, the area within the lung where gas exchange occurs.[175] The remainder of the lung and large airways represent dead space, the volume of gas that does not participate in gas exchange; $\dot{V}_D$ has no effect on CO_2 elimination.

The required $\dot{V}_E$ to maintain CO_2 homeostasis depends on the relationship between $\dot{V}_A$ and $\dot{V}_D$. As the dead space increases, the work of breathing (respiratory rate or V_T) must increase to compensate for the wasted ventilation and maintain a normal $Paco_2$. For the clinician caring for the patient with respiratory failure, having knowledge of a patient's dead space provides important information about the $\dot{V}_E$ that is required to maintain a normal $Paco_2$ and therefore whether the patient is a candidate for weaning from mechanical ventilatory support. $\dot{V}_E$ is the sum of $\dot{V}_A$ and $\dot{V}_D$, as shown in Equation 6:

$$\dot{V}_E = \dot{V}_A + \dot{V}_D \quad (6)$$

Dead space is composed of anatomic dead space, alveolar dead space, and dead space imposed by equipment used to maintain the airway and ensure ventilation. The anatomic dead space is the volume of gas within the conducting airways; in a normal, 70-kg man, it averages about 156 mL (about 1 mL/lb).[176] The volume of the anatomic dead space increases with increases in lung volume and decreases in the supine position.[177-180] Intubation of the airway with an ETT decreases the anatomic dead space by about 50% because of the elimination of the extrathoracic airway (the nose and mouth, which do not contribute to gas exchange).[179,181] Depending on the intraluminal volume of the ETT and any additional apparatus dead space, the actual reduction of the anatomic dead space that occurs after endotracheal intubation may be inconsequential. Alveolar dead space is defined as the amount of gas that penetrates to the alveolar level but does not participate in gas exchange. In healthy individuals, this volume is minimal; however, alveolar dead space is increased in patients with $\dot{V}/\dot{Q}$ inequalities, such as those with pulmonary emboli or severe lung injury. The physiologic dead space is the sum of the anatomic and alveolar dead spaces and is represented by the total volume of gas in each breath that does not participate in gas exchange.

The portion of each breath that is dead space can be determined by calculating the ratio of dead space volume to tidal volume (V_D/V_T). The V_D/V_T is a useful clinical monitor of the overall work of breathing. It can be estimated using the Bohr equation:

$$V_D/V_T = PACO_2 - PECO_2/PACO_2 - PICO_2 \quad (7)$$

where
$PACO_2$ = alveolar carbon dioxide tension
$PECO_2$ = carbon dioxide tension in mixed expired gas
$PICO_2$ = inspired carbon dioxide tension

The V_D/V_T can be estimated more easily by assuming that $PICO_2$ is zero and estimating alveolar CO_2 as arterial CO_2. This simplified formula represents the Enghoff modification of the Bohr equation[70,72,181]:

$$V_D/V_T = PaCO_2 - PECO_2/PaCO_2 \quad (8)$$

The normal V_D/V_T is 0.3 at rest; it decreases during exercise, primarily as a result of an increase in V_T, a more efficient way to increase alveolar ventilation with increasing O_2 consumption and CO_2 production.[179,181] Patients with severe respiratory failure may have a V_D/V_T value as high as 0.75, even with an ETT in place. In this situation, the patient's work of breathing is so high that discontinuation of some level of ventilatory support is not possible,[182] although modes of ventilation that increase V_T without an accompanying increase in work of breathing, such as pressure support ventilation, may facilitate spontaneous ventilatory work.

From a measurement of $PECO_2$ and $Paco_2$, the V_D/V_T can be calculated. $PECO_2$ can be measured by collecting expired gas in a large-volume reservoir (e.g., Douglas bag, meteorologic balloon) for 3 to 5 minutes (depending on the $\dot{V}_E$) and measuring the CO_2 tension of a sample of this gas.[181,183] $Paco_2$ is measured from blood gas obtained simultaneously during the collection of the expired gas.

Some technical factors must be taken into account when measuring V_D/V_T in mechanically ventilated patients. A correction must be made for gas compression within the ventilator, connecting tubing, and any additional dead space from the apparatus.[184] If the compression volume is ignored, the true physiologic dead space is underestimated by as much as 16%. Newer ventilators adjust the V_T to take into account the compression volume of the ventilator circuit. Several ventilator parameters can influence the accuracy of the measurement of V_D. For example, physiologic dead space was found to increase markedly when the duration of inspiration during mechanical ventilation was decreased from 1 to 0.5 second in paralyzed patients.[185] A nomogram of the relationship between $\dot{V}_E$, V_D/V_T, and $Paco_2$ in mechanically ventilated patients was developed to aid in the titration of ventilatory support, assess the response to medical therapy, and increase the precision of the therapeutic management of critically ill patients.[186]

A simpler method for estimating V_D/V_T has been described. Measurement of the carbon dioxide pressure (Pco_2) in the condensate of expired gas in the collection bottle from the expiratory limb of the mechanical ventilator is equivalent to the cumbersome technique of collecting the mixed expired gas.[183] This Pco_2 value can be substituted for $PECO_2$, greatly simplifying the measurement of physiologic dead space in mechanically ventilated patients.

Another approach to the noninvasive assessment of the physiologic V_D/V_T ratio substitutes $PETCO_2$ for $Paco_2$. For normal subjects, the relationship between $PETCO_2$ and $Paco_2$ is well established.[187,188] At rest, $PETCO_2$ underestimates $Paco_2$ by 2 to 3 mm Hg. However, with exercise, $PETCO_2$ can overestimate $Paco_2$. The difference between $PETCO_2$ and $Paco_2$ varies directly with V_T and cardiac output and inversely with respiratory rate.

For patients undergoing general anesthesia or with respiratory failure, the gradient between arterial and end-tidal CO_2 ($P[a - ET]CO_2$) increases.[179,189] This increase reflects more ventilation to lung units with high $\dot{V}/\dot{Q}$ relationships. For patients with normal pulmonary function who are mechanically ventilated during general anesthesia, the $P[a - ET]CO_2$ averages 5 mm Hg; the $P[a - ET]CO_2$ can be as high as 15 mm Hg in the supine

position. The average $P[a - ET]CO_2$ increases to 8 mm Hg when these patients are placed in the lateral decubitus position.[190] In patients with respiratory failure, the $P[a - ET]CO_2$ can be even greater. In patients with respiratory failure, there is a close correlation between $P[a - ET]CO_2$ and V_D/V_T.[189] The $P[a - ET]CO_2$ can therefore be used as an indicator of the efficiency of ventilation.

In patients with acute lung injury, an increase in V_D/V_T correlates with increased mortality and with a decrease in ventilator free days. As a result, the V_D/V_T can be used as a marker of severity of disease.[191,192] Frankenfield and colleagues[193] developed and validated an equation that uses clinically available data to estimate V/V_T: $V_D/V_T = 0.32 + 0.0106 (PaCO_2 - EtCO_2) + 0.003$ (respiratory rate) + 0.0015 (age in years). The equation was constructed from data obtained from 135 patients and validated on an additional 50 patients ($R^2 = 0.67$). Volumetric capnography, also called the single-breath test for CO_2, can be used to estimate physiologic dead space.[189] Volumetric capnography enlists a plot of the expired CO_2 against the exhaled volume of a single breath. Volumetric capnography in combination with D-dimer testing has been used in the ED to help evaluate patients with suspected pulmonary emboli and to select the optimal level of PEEP in anesthetized, morbidly obese patients.[194,195]

1. Airway Resistance and Lung-Thorax Compliance

In the intubated, ventilated patient, airway resistance and lung-thorax compliance can be differentiated by evaluating peak and plateau pressures and by the difference between them (Fig. 49-7). The peak airway pressure generated by the ventilator reflects the pressure necessary to overcome airway resistance and compliance of the lung and chest wall. The peak pressure is elevated when airway resistance is increased, as may occur with increased pulmonary secretions or a kinked ETT or when lung-thorax compliance is reduced.[196] The peak pressure is influenced by other factors, including ventilator parameters, such as inspiratory flow rate and pattern, V_T, and the ETT size. The ratio of the V_T delivered divided by the pressure change, the difference between the peak inspiratory pressure and PEEP, is the dynamic compliance. Dynamic compliance is reduced when airway resistance is increased or lung-thorax compliance is reduced.

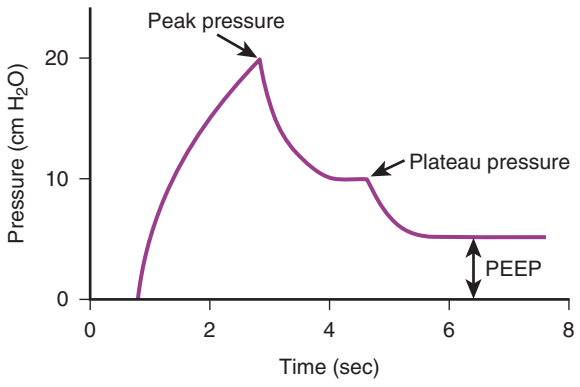

Figure 49-7 Graphic display of airway pressure in a mechanically ventilated patient. Peak inspiratory pressure is achieved during gas flow into lung. Plateau pressure is achieved by temporary occlusion of expiratory tubing. From these pressures, dynamic and static compliance can be calculated. *PEEP,* Positive end-expiratory pressure.

To differentiate the cause for reduced dynamic compliance and increased peak airway pressure, the static compliance must be calculated. Static compliance can be assessed by determining the plateau pressure, the pressure achieved in the airways when the lung is inflated to a specific V_T under conditions of zero gas flow. Static compliance is measured when inspiration is complete and the lung remains inflated with no further gas flow. Most mechanical ventilators have the capability to provide an inspiratory pause (hold) that allows measurement of the plateau pressure. The pressure generated in the lung during the inspiratory pause is the pressure required to overcome lung and chest wall compliance. Because there is no gas flow at the time of measurement, airway resistance does not contribute to the measured pressure. The static compliance can be estimated by dividing the V_T by the difference between the plateau pressure and PEEP. The normal static compliance measured using this method is 60 to 100 mL/cm H_2O. The static compliance is reduced in patients with an extensive pulmonary infiltrate, pulmonary edema, atelectasis, endobronchial intubation, pneumothorax, or any decrease in chest wall compliance, as may occur with chest wall edema or subcutaneous emphysema.

2. Intrinsic Positive End-Expiratory Pressure

Hyperinflation (overdistention) of the lung occurs in some mechanically ventilated patients because of air trapping. Gas can be trapped within the lung during the expiratory phase because of dynamic airflow limitation (e.g., associated with asthma) or inadequate expiratory time, as may occur when the inspiratory flow is so low that it causes a high inspiratory-to-expiratory (I:E) ratio. The hyperinflation that results has been called auto-PEEP, intrinsic PEEP (PEEPi), or occult PEEP.[26,197] The presence of auto-PEEP increases the risk of barotrauma, compromises hemodynamics by reducing venous return, increases the patient's work of breathing, and can result in unilateral lung hyperinflation.[26,184,197]

Identification of PEEPi is difficult. PEEPi is not reflected in the pressure measured on the manometer of the ventilator at the end of exhalation, because at end expiration, the exhalation valve is open to atmospheric pressure (PEEP = 0 cm H_2O) or reflects the level of PEEP provided by the ventilator (Fig. 49-8). PEEPi can be quantitated by occluding the expiratory port of the ventilator circuit at the end of exhalation immediately before the next breath is delivered. The pressure in the lungs and ventilator circuit equilibrates. The level of PEEPi is then displayed on the manometer. Although this approach provides an estimate of the magnitude of gas trapping, it is technically difficult and hard to reproduce. Another method to determine whether PEEPi is present, but not to quantitate it, uses evaluation of the expiratory flow waveform. If expiratory flow does not fall to zero before the next inspiration, gas is trapped within the lung, creating PEEPi (Fig. 49-9). When PEEPi is identified using this method, the flow waveform can be monitored while adjusting ventilator parameters to minimize PEEPi.

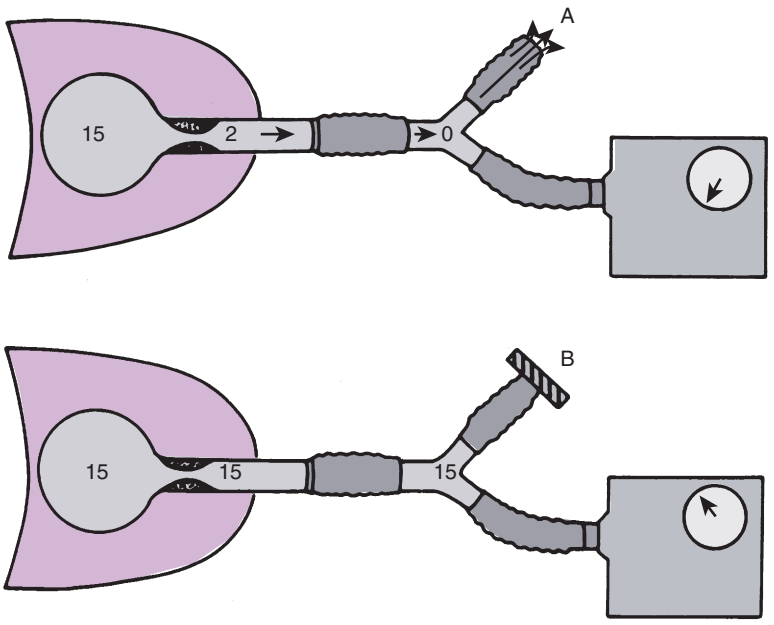

Figure 49-8 *A,* Auto–positive end-expiratory pressure (PEEP) is detected by occlusion of the end-expiratory port just before initiation of the next ventilator inflation cycle. *B,* The ventilator's manometer measures alveolar pressure (auto-PEEP) only when pressures are allowed to equilibrate by occlusion of the expiratory port and end exhalation. (From Pepe PE, Marini JJ: Occult positive end-expiratory pressure in mechanically ventilated patients with airflow obstruction: The auto-PEEP effect. *Am Rev Respir Dis* 126:166–170, 1982.)

3. Ventilatory Waveform Analysis

Ventilatory waveform analysis is a useful method to assess airway patency, pulmonary function, and the patient-ventilator interface. Most critical care ventilators have a variety of waveform monitoring capabilities; for applications in which the ventilators do not have integrated waveform monitoring capability, separate monitors are available to assess waveform, work of breathing, capnography, and other useful monitoring parameters, such as O_2 consumption, CO_2 production, and calculated energy expenditure. Although all of these measures help in the care of critically ill patients, the waveforms are particularly useful in assessing the patient's air movement, identifying the presence of gas trapping, and for many patients, providing critically important information about the adequacy of the ventilatory parameters used to optimize gas exchange. Evaluating the flow-time and pressure-time curves can provide information about whether the patient is able to trigger the ventilator to initiate spontaneously supported breaths (e.g., pressure support) and to determine whether the peak inspiratory flow and flow pattern are adequate to meet the patient's needs.[198-200] When the patient appears agitated or dyssynchronous with the ventilator, the waveforms can be useful in giving direct feedback about whether the problem is related to inappropriately low inspiratory flow or other ventilator-dependent parameters or inadequate analgesia or sedation.[201-203]

In many cases, modifications to the ventilator can improve the clinical situation and minimize the need for excessive sedation. In addition to displaying inspiratory and expiratory flow patterns, the ventilator displays pressure-volume and flow-volume loops, both of which can be useful in assessing whether the peak inspiratory flow is too high or too low or the V_T is too high, putting the patient at risk for pulmonary volutrauma.[204] For patients with adult respiratory distress syndrome, in whom we recognize the deleterious effects of high V_T and high airway pressures, analysis of the waveforms can help in adjusting ventilator parameters to optimize gas exchange without increasing the risk of lung

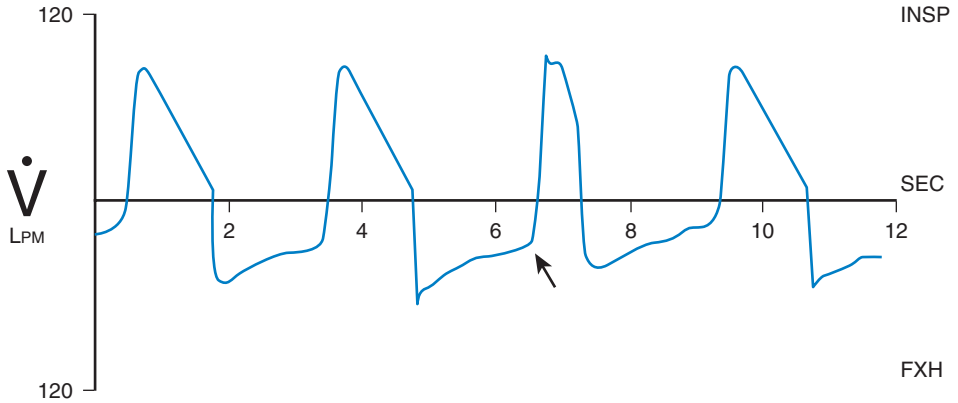

Figure 49-9 Flow-time curve demonstrates expiratory flow continuing until initiation of inspiration *(arrow)*. In a normal patient, expiratory flow falls to zero, indicating complete emptying to functional residual capacity. Continued expiratory flow indicates gas trapping.

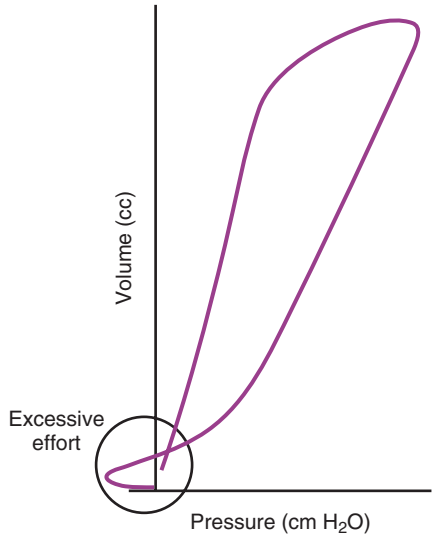

Figure 49-10 Pressure-volume curve identifies excessive effort by the patient to initiate a patient-triggered breath. Excessive effort is required to initiate a breath for assist-control ventilation or pressure-support ventilation. (From Novametrix Medical Systems: *Bedside respiratory mechanics monitoring,* Wallingford, CT, 1998, Novametrix Medical Systems.)

disruption.[205] Figure 49-10 illustrates waveforms that identify excessive work of breathing during patient-initiated breaths. While monitoring the waveforms, adjustments can be made in ventilator parameters to optimize flow patterns and minimize airway pressures, PEEPi, and work of breathing.

4. Work of Breathing

The work of breathing is another important monitor of a patient's respiratory status, respiratory reserve, and likelihood of being successfully weaned from mechanical ventilatory support. The patient's work of breathing (WOBp) can be assessed by clinical evaluation at the bedside or calculated using data obtained from an esophageal balloon and flow transducer at the airway.[177,206] The clinical evaluation of WOBp, although useful, can be misleading. Some patients who appear to have excessive WOBp indicate that they are comfortable. Others with a low $\dot{V}_E$ and slow respiratory rate are already working maximally, and although they appear comfortable at the current level of ventilatory support, they cannot tolerate any further increase in their WOBp.

To better assess the WOBp and monitor the patient's efforts more closely while adjusting the level of ventilatory support, the WOBp can be measured directly using bedside monitors. The monitors require placement of an esophageal balloon to measure esophageal pressure as an estimate of intrapleural pressure. The WOBp is calculated by integrating the area under the pressure-volume loop. With an understanding of each of the components of WOBp, flow-resistive, elastic, and apparatus-induced modifications can be made in ventilator parameters to minimize the patient's WOBp. This monitoring technique has been recommended as a way to adjust pressure support ventilation to optimize gas exchange while minimizing WOBp. Although the additional information about the patient-ventilator interface has resulted in modifications of methods of ventilating critically ill patients, no studies have documented which parameters are most useful to monitor and which modifications to ventilator management result in the best outcomes.

B. Assessment of Pulmonary Function During Weaning

Several measures of pulmonary mechanical function are used to evaluate the likelihood of weaning success in the mechanically ventilated ICU patient.[182] Vital capacity (VC) and maximum inspiratory pressure (MIP or Pimax) are commonly employed to evaluate pulmonary mechanical function. A VC of 10 mL/kg and Pimax more negative than −20 cm H_2O have been useful predictors of weaning success for some patients. Other measures of mechanical function that have been used to predict weaning success include maximum voluntary ventilation (MVV) greater than two times the resting level and $\dot{V}_E$ less than 10 L/min. A V_D/V_T greater than 0.6 has predicted weaning failure consistently. Unfortunately, although each of these parameters can be used to assess pulmonary mechanical function, several studies have demonstrated that none predicts weaning success.

Other monitoring techniques have been employed to predict weaning success, including continuous measurement of O_2 consumption.[207] Although many studies have attempted to define key factors in predicting weaning success, changes in mechanical ventilatory capabilities and our understanding of the risks and benefits of mechanical ventilatory support have had a major impact on methods for assessment and monitoring of patients. The use of pressure support ventilation and noninvasive modes of ventilatory support have made interpretation of the studies and recommendations difficult. One of the key components in the decision-making process about weaning and discontinuation of mechanical ventilatory support is related to the patient's ability to protect the airway and the need for intensive respiratory care rather than specific respiratory mechanical parameters. Many patients previously thought to be unweanable can be weaned from mandatory ventilatory support and provided with ventilatory assistance using pressure-support ventilation through an ETT or using noninvasive ventilation, BiPAP by mask, or mask CPAP. The traditional methods for assessing weaning may no longer apply. Nonetheless, an understanding of the various methods that have been used to assess weaning potential is critical to defining the most effective way to have a patient make the transition from positive-pressure ventilation to spontaneous ventilation.

1. Weaning Indices

Several indices have been developed to predict when a patient can be successfully weaned from mechanical ventilatory support. These indices combine multiple individual parameters to predict weaning success; some incorporate indices of gas exchange. One study evaluated multiparameter indices, including the rapid shallow breathing (RSB) index, the ratio of respiratory frequency divided by VT in liters, and the CROP index (i.e., thoracic *c*ompliance, *r*espiratory rate, arterial *o*xygenation, Pimax),

which incorporates measures of dynamic lung compliance, respiratory rate, gas exchange, and inspiratory pressure.[208] An RSB index of less than 105 was shown to have a high predictive value for weaning success, whereas the CROP index and more traditional indices had poor predictive values. A study could not confirm these findings and demonstrated that an RSB index of less than 105 did not predict failed weaning.[209]

2. Breathing Pattern Analysis

Respiratory impedance plethysmography (RIP) can be used to assess the breathing pattern by measuring V_T, respiratory frequency, inspiratory time, and the contribution of the rib cage and abdomen to lung volume changes.[37,38] Using RIP, the relationship between rib cage and abdominal contributions to V_T (i.e., respiratory muscle dyssynchrony) has been quantitated. RIP is useful for evaluating changes in functional residual capacity and level of PEEPi as ventilator parameters are adjusted. As a method for predicting weaning success, the technique has had variable success.

3. Airway Occlusion Pressure

The airway occlusion pressure has been used as an index of respiratory drive, although it is rarely used as a routine monitor of ventilatory drive. Airway occlusion pressure is the pressure generated 0.1 second ($P_{0.1}$) after initiating an inspiratory effort against an occluded airway. The $P_{0.1}$ in normal subjects usually is less than 2 cm H_2O. Some studies suggest that a $P_{0.1}$ value greater than 6 cm H_2O is incompatible with successful weaning for patients with COPD.[210] Few studies have confirmed the value of airway occlusion pressure as a predictor of successful weaning success,[211,212] and its clinical utility remains unclear.

V. CONCLUSIONS

Several methods are available to monitor the airway and pulmonary function in the patient who requires endotracheal intubation and mechanical ventilatory support. Monitoring techniques include clinical assessment, monitors of gas exchange, and a variety of methods to evaluate pulmonary mechanical function. Selection of the most appropriate monitors for each patient depends on an understanding of the clinical situation, the available monitoring techniques, the information each monitor provides, and the limitations of the monitors. The challenge for the physician is to identify and appropriately use techniques that optimize clinical management and reduce morbidity and mortality, rather than using any monitor simply because it is available.

VI. CLINICAL PEARLS

- The most reliable method for determining the intratracheal location of an artificial airway is direct visualization of the device passing through the vocal cords; fiberoptic assessment can define the specific location of the endotracheal tube in the airways.
- When using CO_2 detection in exhaled gas from an artificial airway to document whether the endotracheal tube is within the trachea, CO_2 should be present for four or five breaths.
- Respiratory dyssynchrony (i.e., abdominal expansion during inspiration without chest excursions) in a patient without upper airway obstruction is an early and critical indicator of respiratory muscle fatigue and impending respiratory failure.
- The accuracy of pulse oximetry is altered by several factors, including external light sources, motion, poor perfusion, and dyshemoglobinemias.
- Analysis of the plethysmographic waveform from a pulse oximeter has clinical utility in the hemodynamic assessment of patients and evaluation of intravascular volume status.
- In patients with traumatic brain injury, adjustment of ventilatory parameters based on end-tidal CO_2 values may be unreliable.
- V_D/V_T can be used as a marker of disease severity in patients with acute lung injury.

Chapter 50

Extubation and Reintubation of the Difficult Airway

RICHARD M. COOPER | SOFIA KHAN

I. Introduction

II. Extubation Failures and Challenges

III. Extubation Risk Stratification
- A. Routine Extubations
  1. Hypoventilation Syndromes
  2. Hypoxemic Respiratory Failure
  3. Inability to Protect the Airway
  4. Failure of Pulmonary Toilet
  5. Inadvertent Extubations
  6. Entrapment
  7. Hypertension and Tachycardia
  8. Intracranial Hypertension
  9. Intraocular Pressure
  10. Coughing
  11. Laryngeal Edema
  12. Laryngospasm
  13. Macroglossia
  14. Laryngeal or Tracheal Injury
  15. Airway Injury
  16. Postobstructive Pulmonary Edema
- B. Higher-Risk Extubations

IV. Clinical Settings of Complications
- A. Operative Conditions
  1. Laryngoscopic Surgery
  2. Thyroid Surgery
  3. Carotid Artery Surgery
  4. Cervical Surgery
  5. Maxillofacial Surgery and Trauma
  6. Deep Neck Infections
  7. Posterior Fossa Surgery
  8. Stereotactic Surgery and Cervical Immobilization
  9. Tracheal Resections
  10. Palatoplasty
- B. Preexisting Medical Conditions
  1. Paradoxical Vocal Cord Motion
  2. Parkinson's Disease
  3. Rheumatoid Arthritis
  4. Tracheomalacia
  5. Obstructive Sleep Apnea Syndrome
  6. Laryngeal Incompetence
  7. Pulmonary Aspiration of Gastric Contents

V. Factors Affecting Intubation and Extubation
- A. Previously Encountered Airway Difficulties
- B. Limited Access
- C. High-Risk Cases

VI. Extubation Strategies
- A. Deep versus Awake Extubation
- B. Extubation with a Laryngeal Mask or Other Supraglottic Airway
- C. Extubation or Reintubation over a Fiberoptic Bronchoscope or Laryngoscope
- D. Extubation with a Supraglottic Airway with or Without a Bronchoscope
- E. Use of a Gum Elastic Bougie or Mizus Endotracheal Tube Replacement Obturator
- F. Use of Jet Stylets
- G. Use of Commercial Tube Exchangers
  1. Tracheal Tube Exchangers
  2. Cook Airway Exchange Catheters
  3. Arndt Airway Exchange Catheter
  4. Endotracheal Ventilation Catheter
- H. Exchange of Double-Lumen Tubes
  1. Visually Assisted Tube Exchange
  2. Conversion from Nasal to Oral Intubation
  3. Conversion from Oral to Nasal Intubation
  4. Conversion from Supraglottic Airways to Endotracheal Tubes
  5. Changing Tracheostomy Tubes

VII. Jet Ventilation through Stylets
- A. In Vitro Studies
- B. In Vivo Studies

VIII. Conclusions

IX. Clinical Pearls

I. INTRODUCTION

Tracheal extubation has received relatively limited critical scrutiny compared with that accorded to intubation. Textbooks, reviews, and conferences focusing on the airway frequently ignore this aspect of management, despite the observation that airway complications are significantly more likely to be associated with extubation than intubation.[1] These complications range from the relatively minor, such as coughing and transient breath holding that have little impact on outcome, to those that are life-threatening. The American Society of Anesthesiologists (ASA) Closed Claims Project analyzed adverse respiratory events and found that 17% of brain injuries and deaths occurred after extubation in the operating room or postanesthesia care unit (PACU).[2] Complications associated with extubation in critical care areas are likely to occur more frequently and have more serious consequences.[3,4]

The ASA Task Force on Management of the Difficult Airway and the Canadian Airway Focus Group recommended a preformulated strategy for extubation of the difficult airway and an airway management plan for dealing with post-extubation hypoventilation.[5,6] This chapter classifies the complications associated with routine and more complex tracheal extubation or reintubation, proposes a risk stratification for extubation and reintubation in various clinical settings, and suggests strategies that may prove helpful in reducing serious complications or death.

Low-risk or routine extubations have been reviewed elsewhere and are not the focus of this chapter. Although they are dealt with only briefly, concerns include the adequacy of recovery from neuromuscular blockade, depressant effects of narcotics and residual volatile or intravenous sedatives, level of consciousness, hemodynamic stability, adequate ventilation and oxygenation, normothermia, freedom from noxious stimulation, and airway patency.[7-10] The controversy about deep versus awake extubation has been addressed elsewhere,[10-12] and most of the present discussion concentrates on extubation of more challenging airways and strategies that may increase the probability of success.

II. EXTUBATION FAILURES AND CHALLENGES

Extubation fails when an attempt to remove a tracheal tube is unsuccessful. Reintubation failure occurs when extubation is followed by an immediate or delayed but unsuccessful attempt to reintubate the trachea. There is no agreement about how to define failure, and because there is no consensus about the time frame, reported incidences may vary. It is reasonable to consider the failed extubation in two separate clinical settings: the intensive care unit (ICU), where such failures are relatively common, and the operating room or PACU, where they are far less common.

In the ICU, the ability to predict readiness for extubation is imprecise despite a host of predictive criteria.[13-16] To minimize the risks, discomfort, and expense of prolonged intubation, a trial of extubation is occasionally attempted, but it may be followed sometime thereafter by a need to reintubate. The incidence of required reintubation ranges from 6% to 20%, and it depends on the clinical mix of patients,[15,17,18] their critical acuity, critical care resources, and the threshold levels for extubation. Even if reintubation is successful, patients who failed their initial extubation had increased rates of ICU mortality and cost of care, prolonged ICU stay, and hospital length of stay.[19] Compared with routine postoperative patients, intensive care patients are more likely to fail extubation because neurologic obtundation may leave them unable to protect their airways. Debilitation and impaired mucociliary clearance may interfere with pulmonary toilet, and diminished strength, altered pulmonary mechanics, increased dead space, and venous admixture may result in hypercapnic or hypoxemic respiratory failure.

Although the complications associated with extubation of postoperative patients may be more common than those associated with intubation, they rarely require reintubation. Studies involving a wide case mix of postoperative patients show a high degree of concordance regarding the incidence of required reintubation. Combining the results of four large studies enrolling more than 150,000 patients, the incidence ranged from 0.09% to 0.19%.[20-23] The reintubation rate appears to be significantly higher (1% to 3%) after selected surgical procedures such as panendoscopy [20] and a variety of head and neck procedures.[24-28]

Postoperative reintubation, although uncommon, may offer some unexpected challenges, including anatomic distortion, physiologic instability, incomplete information concerning the patient, lack of essential equipment and time, and inexperienced personnel. These problems may convert a previously easily managed airway into a life-threatening disaster. A difficult airway adequately managed during a controlled intubation is completely different from the difficult airway in an agitated, hypoxemic, and hypotensive patient.

III. EXTUBATION RISK STRATIFICATION

Risks related to extubation fall into two broad categories: the risk of extubation failing and the risk of reintubation failing. Within each category, there is a continuum from low to high risk. Like the prediction of a difficult intubation, this is an inexact science; it is probably safest to err on the cautious side. Most extubations are expected and turn out to be uneventful, but even these routine extubations may be associated with complications (Box 50-1).

The causes of a failed extubation can be classified as a failure of oxygenation, failure of ventilation, inadequate clearance of pulmonary secretions, or loss of airway patency. We cannot always predict which patients will require reintubation, and if reintubation is likely to be difficult, it is prudent to employ strategies expected to maximize the likelihood of success. In this discussion, if reintubation is expected to be difficult, we regard such extubations as intermediate- or high-risk extubations, although such designations are based on probability and clinical judgment.

BOX 50-1 Complications of Routine Extubations

- Unintended extubation
- Fixation of endotracheal tube
- Hypertension, tachycardia
- Coughing, breath-holding
- Laryngeal injury
- Laryngospasm or vocal cord paralysis
- Stridor, airway obstruction
- Negative pressure pulmonary edema
- Laryngeal incompetence
- Aspiration

A. Routine Extubations

A retrospective database review from The University of Michigan analyzed 107,317 general anesthetics administered between 1994 and 1999.[23] It identified 191 required reintubations in the operating room or PACU, 112 (58.6%) of which were for respiratory reasons. The most common respiratory causes were hypercapnic or hypoxemic respiratory insufficiency (60%), respiratory obstruction (20.5%), and laryngospasm or bronchospasm (19.5%). Failed extubations from a respiratory cause occurred at a rate of 112/107,301 or 0.1%. Unintended extubation accounted for 25 of 191 reintubations, all of which occurred in the operating room. Surgical complications, including neck hematoma, pneumothorax, laryngeal nerve paralysis, and bleeding, accounted for 16 of 191 reintubations. Contrary to their expectations, the investigators found that excessive narcotics (9 cases) and prolonged neuromuscular blockade with pancuronium (2 cases) were responsible for only 11 of 191 reintubations. This self-reported information was retrospective, and sometimes required interpretation of the causes from the therapies applied (e.g., narcotic antagonists, additional doses of anticholinergics).

A prospective study from Thailand found a rate of reintubation occurring within 24 hours of 27 per 10,000 patients.[29] This was twice the rate observed in the University of Michigan study.[23] The precipitating factor in the Thai study was thought to be residual neuromuscular weakness in almost three quarters of cases requiring reintubation in the operating room or PACU. In a Taiwanese database that surveyed almost 138,000 patients undergoing general anesthesia between 2005 and 2007, 83 reintubations were performed after intended extubation.[30] Overall, this represented a rate of 6 reintubations per 10,000 patients. Comparing these patients with a matched cohort not requiring reintubation, the investigators identified the following factors as most predictive of a need for reintubation: chronic obstructive pulmonary disease (odds ratio [OR] = 7.17; 95% confidence interval [CI], 1.98 to 26.00), pneumonia (OR = 7.94; 95% CI, 1.03 to 32.78), ascites (OR = 13.86; 95% CI, 1.08 to 174.74), and systemic inflammatory response syndrome (OR = 11.90; 95% CI, 2.63 to 53.86).

1. Hypoventilation Syndromes

The ASA Closed Claims Project found that 4% of 1175 closed claims resulted from critical respiratory events in the PACU. The highest proportion was attributed to inadequate ventilation, and many of these patients died or suffered brain damage.[31]

Many clinical conditions may give rise to postoperative ventilatory failure. A multicenter, prospective survey in France that looked at almost 200,000 general anesthetics administered between 1978 and 1982 found that postoperative respiratory depression accounted for 27 of 85 respiratory complications that were life-threatening or had serious sequelae. These complications were responsible for seven deaths and five cases of hypoxic encephalopathy.[32] A respiratory rate of less than 8 breaths/min was observed by PACU nurses among 0.2% of 24,000 patients after general anesthesia.[22]

Hypoventilation may be mediated centrally at the level of the upper motor neuron, anterior horn cell, lower motor neuron, neuromuscular junction, or respiratory muscles. Clinical correlates include central sleep apnea, carotid endarterectomy,[33] medullary injuries, demyelinating disorders, direct injury to peripheral nerves, poliomyelitis, Guillain-Barré syndrome, motor neuron disease, myasthenia gravis, and botulism. Hypoventilation may result from the loss of lung or pleural elasticity, diaphragmatic splinting caused by abdominal pain or distention, thoracic deformities such as kyphoscoliosis, or multifactorial entities such as morbid obesity and severe chronic obstructive pulmonary disease. Rarely, hypercapnia results from excess carbon dioxide production or a marked increase in physiologic dead space.

The residual effects of anesthetic drugs contribute to inadequate postoperative ventilation.[34-36] It may be aggravated by incomplete reversal of neuromuscular blockers,[37] hypocalcemia or hypermagnesemia, or the administration of other drugs, including antibiotics, local anesthetics, diuretics, and calcium channel blockers, which may potentiate neuromuscular blockade.

2. Hypoxemic Respiratory Failure

A review of the many causes of postoperative hypoxemia is beyond the scope of this chapter, but it can occur because of hypoventilation, a low inspired oxygen concentration, ventilation-perfusion mismatch, right-to-left shunting, increased oxygen consumption, diminished oxygen transport, or rarely, an impairment of oxygen diffusion. These events are more likely in some clinical situations because of preexisting medical conditions or anesthetic and surgical interventions. If sufficiently severe, there may be a requirement for continuous positive airway pressure (CPAP) or reintubation and mechanical ventilation.

3. Inability to Protect the Airway

ICU or postoperative patients may be unable to protect the airway because of preexisting obtundation, neurologic injury, or the effects of residual anesthesia. In the latter case, it may be possible to temporize by turning patients on their sides, altering their positions (head up or head down) or by reversing residual medications with antagonists. These measures may not restore airway competency, and lack of resolution may necessitate reintubation.

4. Failure of Pulmonary Toilet

Inadequate clearance of pulmonary secretions may result from a depressed level of consciousness with impaired airway reflexes, overproduction of secretions, alteration of sputum consistency leading to inspissation and plugging, impaired mucociliary clearance, or inadequate neuromuscular reserve. These problems may result in atelectasis or pneumonia with attendant hypoxemic respiratory failure. Alterations in pulmonary mechanics may also lead to hypercapnia, necessitating reintubation.

5. Inadvertent Extubations

Inadvertent extubations may result from movement of or by the patient with an inadequately secured tracheal tube. Intraoperatively, this may occur in the prone position, when the airway is shared with the surgeon, when the head and neck are extended, when draping obscures the view, or when drapes adhere to the endotracheal tube (ETT) or circuit and are carelessly removed. In the ICU, extubation may occur when the patient is repositioned for a radiograph or routine nursing care. Patients insufficiently sedated are at greater risk for deliberate self-extubation,[38] but those more heavily sedated are more likely to require reintubation.[39] Fastidious attention to securing and supporting the ETT and breathing circuit is essential. Self-extubation may occur during emergence from anesthesia, when the patient is confused, agitated, and distressed, which promotes premature extubation. In the ICU, it may not be possible to know whether a self-extubation is accidental or deliberate, but many of these patients require reintubation,[40] are more likely to exhibit post-extubation stridor, and may need multiple intubation attempts, increasing the likelihood of esophageal intubation and death.[41-43]

6. Entrapment

The tracheal tube may become entrapped due to an inability to deflate the cuff,[44,45] or there may be difficulties with the pilot tube.[46,47] Difficulties include a crimped pilot tube, a defective pilot valve, and fixation of the tracheal tube by Kirschner wires,[48] screws,[49] ligatures,[50] or entanglement with other devices.[51,52] Entrapment can also occur during a percutaneous tracheostomy.[53] Mechanical obstruction of an entrapped tube is a life-threatening complication. Partial transection of the tracheal tube by an osteotome during a maxillary osteotomy has resulted in the partially cut tube forming a barb that caught on the posterior aspect of the hard palate.[54] One report of tube entrapment with fatal consequences involved a Carlens tube that was inadvertently sutured to the pulmonary artery.[55] Lang and colleagues recommended routine intraoperative testing for tracheal tube movement when fixation devices are used in proximity to the airway.[49] Uncertainty about tube movement should prompt fiberoptic examination before emergence from general anesthesia.

7. Hypertension and Tachycardia

Transient hemodynamic disturbances accompany extubation in most adults. These responses may be prevented by deep extubation,[56] insertion of a laryngeal mask airway (LMA) before emergence, or attenuated by concurrent medication.[57-59] Most healthy patients not on antihypertensive agents or other cardioactive drugs exhibit increases in heart rate and systolic blood pressure of more than 20% in association with extubation.[60] After coronary artery bypass surgery, these changes tend to be transient, lasting 5 to 10 minutes, and they usually are not associated with electrocardiographic evidence of myocardial ischemia.[61] Coronary sinus lactate extraction measurements, however, indicate that among patients with poor cardiac function, extubation may be associated with myocardial ischemia.[62] Patients with inadequately controlled hypertension, carcinoid, pheochromocytoma, hypertension associated with pregnancy, or hyperthyroidism may be expected to display even greater increases in blood pressure in response to tracheal extubation. The specific strategies needed to attenuate these usually transient changes are dictated by the clinical context. The strategies, which are not universally effective, include the use of intracuff,[63-65] intratracheal,[66] or intravenous lidocaine[61,67,68]; beta-blockers[60,69-71]; dexmedetomidine[72,73]; and nitrates.

8. Intracranial Hypertension

Tracheal intubation and suctioning are associated with a rise in intracranial pressure. Extubation probably is associated with comparable or even greater increases in intracranial pressure. There is evidence, albeit contradictory, that intravenous and endotracheal lidocaine attenuate this effect.[74,75]

9. Intraocular Pressure

Madan and colleagues compared the intraocular pressure changes of tracheal intubation and extubation in children with and without glaucoma.[76] They observed significantly greater increases 30 seconds and 2 minutes after deep extubation compared with the corresponding times after uncomplicated intubations. These differences were seen in both groups of children. It is likely that significant increases in intraocular pressure observed after deep extubation would have been even higher had extubation occurred after recovery of consciousness. Lamb and coworkers observed similar effects of extubation on intraocular pressure in adults and commented that this increase could be prevented by using an LMA rather than a tracheal tube.[77]

10. Coughing

Coughing on emergence from general anesthesia is virtually ubiquitous, particularly when an ETT is used.[78] No difference between smokers and nonsmokers is observed. Although coughing is a protective reflex, it can be particularly troublesome in the setting of ophthalmologic, neurologic, oropharyngeal, and neck surgery.

Several strategies have been proposed to minimize coughing, including deep endotracheal extubation, primary use of or conversion to an LMA,[57,79,80] use of the sedative dexmedetomidine,[73] intravenous or topical application of a local anesthetic to the vocal folds, and use of intracuff lidocaine.[63,65,67,81] However, coughing on emergence is common and relatively benign for most patients.

The emergence of severe acute respiratory syndrome (SARS) and the high prevalence of drug-resistant droplet or airborne diseases in some locales make coughing potentially hazardous to the airway manager. In 2003, Toronto was the North American epicenter for SARS, and coughing assumed life-threatening proportions for medical personnel.[82-87] Patients with cough, fever, and pulmonary infiltrates were dangerous, and coughing on emergence was not protective, but rather posed a threat by dispersing infectious respiratory droplets on those in the patient's vicinity. The strategies adopted at that time have been largely relaxed, although they may again become necessary when new risks threaten patients and care providers.

11. Laryngeal Edema

Several of the complications of endotracheal intubation do not become apparent until after extubation occurs.[88] Glottic or tracheal injury may occur despite a good laryngeal view or during awake fiberoptic intubation.[89-91] Anatomic or functional laryngeal problems are more likely to develop as a consequence of a difficult or prolonged intubation attempts.[22] Possible airway injuries include laryngeal edema, laceration, hematoma, granuloma formation, vocal fold immobility, and dislocation of the arytenoid cartilages.[92]

Glottic edema has been classified as supraglottic, retroarytenoidal, and subglottic.[93] Supraglottic edema may result in posterior displacement of the epiglottis, reducing the laryngeal inlet and causing inspiratory obstruction. Retroarytenoidal edema restricts movement of the arytenoid cartilages, limiting vocal cord abduction on inspiration. Subglottic edema, a particular problem in neonates and infants, results in swelling of the loose submucosal connective tissue that is confined by the nonexpandable cricoid cartilage. In neonates and small children, this is the narrowest part of the upper airway, and small reductions in diameter result in a significant increase in airway resistance. In children, laryngeal edema is promoted by a tight-fitting ETT, traumatic intubation, intubation longer than 1 hour, coughing on the tracheal tube, and intraoperative alterations of head position.[94] Koka and coworkers found an incidence of 1% among children younger than 17 years. Laryngeal edema should be suspected when inspiratory stridor develops within 6 hours of extubation. Management of laryngeal edema depends on its severity. Treatment options include head-up positioning, supplemental humidified oxygen, racemic epinephrine, helium-oxygen administration, reintubation, and tracheostomy.

Clinical studies of children and adults that evaluated the role of prophylactic corticosteroids in the prevention of post-extubation stridor have yielded contradictory findings.[95-98] In the setting of adult ICUs, a large, multicenter, prospective, randomized, double-blind trial of methylprednisolone (20 mg administered 12 hours before and every 4 hours until extubation) versus placebo found that steroids significantly reduced post-extubation laryngeal edema (11 of 355 versus 76 of 343, $P < 0.0001$) and required reintubation due to laryngeal edema (8% versus 54%, $P = 0.005$). Laryngeal edema was defined by any two of stridor, inspiratory prolongation, and use of accessory muscles. It was classified as severe if reintubation was required within 36 hours. Laryngoscopy was not performed unless reintubation was required. Factors associated with a greater risk of laryngeal edema included female sex, shorter height, larger-diameter ETT, admission for trauma, and shorter duration of intubation. The absence of pretreatment with methylprednisolone was associated with a hazard ratio of more than 8.[99] It is possible that the benefits of steroids are restricted to high-risk populations and require administration of multiple doses.[100, 101] Contradictory findings may relate to risk factors in the study populations and variability of dosage regimens.

An alternative classification has been proposed for laryngotracheal injury after prolonged intubation.[102-104] Immediate post-extubation airway obstruction results from glottic and subglottic granulation tissue, which may swell on removal of the ETT. Posterior glottic and subglottic stenosis due to contracting scar tissue results in increasing obstruction weeks or months after extubation. Benjamin found that fiberoptic evaluation or laryngoscopy with the tube in situ was of limited value.[102] An ETT obscures the view of the posterior glottis and subglottis. These lesions were best identified using rigid telescopes with image magnification during general anesthesia. This approach permitted anticipation of problems and development of a management strategy.

12. Laryngospasm

Laryngospasm is believed to be a common cause of post-extubation airway obstruction, particularly in children.[105] Even in adults, Rose and colleagues found that it accounted for 23.3% of critical postoperative respiratory events, although the diagnosis was presumptive.[106] Olsson and Hallen observed an increased incidence among patients presenting for emergency surgery, those requiring nasogastric tubes, and patients undergoing tonsillectomy, cervical dilation, hypospadias correction, oral endoscopy, or excision of skin lesions.[105] A variety of triggers are recognized, including vagal, trigeminal, auditory, phrenic, sciatic, and splanchnic nerve stimulation; cervical flexion or extension with an indwelling ETT; or vocal cord irritation from blood, vomitus, or oral secretions.[107] A risk assessment questionnaire was used in a study to prospectively evaluate almost 10,000 children undergoing general anesthesia. A positive history of nocturnal dry cough, exertional wheezing, or more than three wheezing episodes in the prior 12 months was associated with a fourfold increase in the risk of laryngospasm in the PACU and a 2.7-fold increased risk of airway obstruction during surgery or in the PACU.[108] Twice as many children were managed with an LMA than an ETT, and an equal number had their devices removed awake and asleep. The depth of anesthesia at the time of device removal did not influence the incidence of laryngospasm.

Laryngospasm involves bilateral adduction of the true vocal folds, vestibular folds, and aryepiglottic folds that outlasts the duration of the stimulus. This is protective to the extent that it prevents aspiration of solids and liquids. It becomes maladaptive when it restricts ventilation and oxygenation. The intrinsic laryngeal muscles are the main mediators of laryngospasm, and they include

the cricothyroids, lateral cricoarytenoids, and thyroarytenoid muscles. The cricothyroid muscles are the vocal cord tensors, an action mediated by the SLN. Management of laryngospasm consists of prevention by either extubating at a sufficiently deep plane of anesthesia or awaiting recovery of consciousness.[56] Potential airway irritants should be removed and painful stimulation should be discontinued. If laryngospasm occurs, oxygen by sustained positive pressure may be helpful, although this may push the aryepiglottic folds more tightly together.[109] Larson described a technique of applying firm digital pressure anteriorly directed to the "laryngospasm notch" between the ascending mandibular ramus and the mastoid process and observed that this technique is rapid and highly effective.[110] Very small doses of a short-acting neuromuscular blocker with or without reintubation may be necessary.[111,112]

13. Macroglossia

Massive tongue swelling may complicate prolonged posterior fossa surgery performed with the patient in the sitting, prone, or park bench position.[113-116] It is also seen with very steep or prolonged Trendelenburg positioning, hypothyroidism, acromegaly, lymphangioma, idiopathic hyperplasia, metabolic disorders, amyloidosis, cystic hygroma, neurofibromatosis, rhabdomyosarcoma, sublingual or submandibular infections, and chromosomal abnormalities such as the Beckwith-Wiedemann syndrome.[117]

The most common and dramatic presentation of macroglossia results from angioedema.[118] It can be congenital or acquired. Hereditary angioedema results from a deficiency of C1 esterase inhibitor; acquired C1 esterase deficiency is associated with histamine release, a physical stimulus, or most commonly, a reaction to angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.[118,119] Although involvement of the tongue is the most obvious manifestation, the uvula, soft tissues, and larynx may also be involved.

In the ICU setting, macroglossia may be seen as a complication of extreme volume overloading or tongue trauma, particularly when it is further complicated by a coagulopathic state. If this occurs or progresses after extubation, it can lead to partial or complete airway obstruction, making reintubation necessary but difficult or impossible.[114] Lam and Vavilala postulate that positioning in most cases results in venous compression leading to arterial insufficiency and subsequent reperfusion injury.[115] Alternatively, local compression may cause venous or lymphatic obstruction with resultant immediate and typically milder tongue swelling. The latter form is less severe but more apparent, and extubation is likely to be postponed.

14. Laryngeal or Tracheal Injury

Airway injuries, such as lacerations, edema, arytenoid dislocation, and vocal fold paralysis, may occur from the lips to the distal trachea. The lip or tongue may become entrapped between the laryngoscope blade and the mandibular teeth, resulting in swelling or bleeding, although this is unlikely to be severe enough to complicate extubation. The glottis may be injured as a result of insertion of a round tube through a triangular opening. The trachea can be lacerated or penetrated by the ETT or its introducer or by ischemic compression by the cuff on the tracheal mucosa. Palatopharyngeal injuries have been described as a consequence of blind insertion of an ETT during video laryngoscopy.[120-127] Although these injuries are not often apparent at the time of laryngoscopy, they have been managed conservatively and should not complicate extubation. The epiglottis can be downfolded during intubation, but the consequences of downfolding, even if prolonged, are unknown.[128]

Laryngeal injuries accounted for 33% of all airway injury claims and 6% of all claims in the ASA Closed Claims Project database.[129] They range from transient hoarseness to vocal fold paralysis. Even when direct laryngoscopy provides a satisfactory glottic view or intubation is facilitated by fiberoptic instrumentation,[89,91] airway injury can occur and go unsuspected until after the ETT is removed. Airway injuries are presumed to be less likely if intubation is easy, but analysis of the ASA Closed Claims Project revealed that 58% of airway trauma and 80% of laryngeal injuries were associated with intubations that were not difficult.[129,130] Judging from the findings of the Closed Claims Project, difficult intubations were more likely to result in pharyngeal and esophageal than tracheal injuries.

Vocal fold immobility may result from injury to the recurrent laryngeal nerve or the arytenoid cartilages.[92,131-139] Arytenoid immobility has resulted from seemingly uneventful Macintosh and McCoy direct laryngoscopy,[137,140] double-lumen tube insertion, and lightwand intubation.[134] The mechanism of this injury is uncertain. It may be a consequence of a subluxation or a hemarthrosis with subsequent resolution or fixation. Prolonged or stressful contact between the ETT and the posteromedial aspects of the vocal cords, arytenoids, or posterior commissure may result in ulceration of the perichondrium, which heals with fibrous adhesions that produce an immobile glottis. This complication may be more common than the literature indicates.[92,141] Persistent post-extubation hoarseness, a breathy voice, and an ineffective cough should prompt assessment by an otolaryngologist. The diagnosis is confirmed by endoscopic visualization of an immobile vocal cord associated with a rotated arytenoid cartilage.[88] If the diagnosis is made early, before the onset of ankylosis, it may be possible to manipulate the arytenoid back into position.

Vocal fold paralysis results from injury to the vagus or one of its branches (i.e., recurrent laryngeal nerve [RLN] or external division of the superior laryngeal nerve [ex-SLN]) and may resemble arytenoid dislocation or ankylosis. Differentiation may require palpation of the cricoarytenoid joints under anesthesia or laryngeal electromyography.[88] When vocal fold paralysis occurs as a surgical complication, it is usually associated with neck, thyroid, or thoracic surgery. The left RLN can also be compressed by thoracic tumors, aortic aneurysmal dilatation, left atrial enlargement, or during closure of a patent ductus arteriosus. Occasionally, a surgical cause cannot be implicated. Cavo and coworkers postulated that an overinflated ETT cuff might result in injury to the anterior divisions of the RLN.[142]

The RLN supplies all of the intrinsic laryngeal muscles except the cricothyroid, the true vocal cord tensor, which is innervated by the ex-SLNs. Unilateral ex-SLN injury results in a shortened, adducted vocal fold with a shift of the epiglottis and the anterior larynx toward the affected side. This produces a breathy voice but no obstruction and usually resolves within days to months. Bilateral ex-SLN injury causes the epiglottis to overhang, making the vocal folds difficult to visualize. If seen, they are bowed. This produces hoarseness with reduction in volume and range but no obstruction. Unilateral RLN injury causes the vocal fold to assume a fixed paramedian position and produces a hoarse voice. There may be a marginal airway with a weak cough. Bilateral RLN injury results in both vocal folds being fixed in the paramedian position and inspiratory stridor, often necessitating a surgical airway.[143]

Pharyngeal, nasopharyngeal, and esophageal injuries include perforation, lacerations, contusions, and infections. These injuries may be associated with difficult laryngoscopy or intubation, but they may also result from the blind passage of a gum elastic bougie,[144] nasogastric tube,[145] nasotracheal tube,[146] suction catheter, esophageal stethoscope transesophageal echo probe, or temperature probe.[147] Penetrating injuries can communicate with the esophagus, resulting in a tracheoesophageal fistula, or with the mediastinum, which may go unrecognized and result in mediastinitis, retropharyngeal abscess, and death.[131] After a brief intubation, soft tissue injuries resulting in airway obstruction are more likely to result from edema or hematoma than infection. Most of the described injuries do not significantly complicate extubation. Laryngeal and tracheal stenoses are serious complications, but they are rarely evident at the time of extubation.

15. Airway Injury

Burn patients can have intrinsic and extrinsic airway injuries. Circumferential neck involvement is an example of an extrinsic injury. Smoke inhalation or thermal injuries are examples of intrinsic injuries. Burn patients are at particular risk of requiring reintubation. They can have bronchorrhea, impaired mucociliary clearance and local defenses, laryngeal and supraglottic edema, increased carbon dioxide production, and progressive acute respiratory distress syndrome. Carbon monoxide may also diminish their level of consciousness and the ability to protect their airway. It may be difficult to secure the tracheal tube because of involvement of the adjacent skin, and burn victims may be agitated or uncooperative, increasing the risk of unintended extubation.[148] Kemper and coworkers reported their management of 13 burn patients younger than 15 years, 7 of whom exhibited post-extubation stridor. Patients treated with helium-oxygen mixtures had lower stridor scores than patients treated with an air-oxygen mixture.[149] They found that 11 of 30 extubated burn victims required treatment for stridor after extubation, consisting of racemic epinephrine, helium-oxygen, reintubation (n = 5), or tracheostomy (n = 1). The absence of a cuff leak was considered to be the best predictor of failure, with a sensitivity of 100% and a positive predictive value of 79%.[149]

A variety of conditions may lead to airway edema severe enough to result in post-extubation stridor. It occurred in 2% to 37% of ICU patients after "prolonged intubation."[150] A test was sought to predict patients with sufficient airway swelling to compromise safe extubation. The cuff-leak test was initially proposed for children with croup.[151] The concept is that marked airway swelling is likely if air does not escape around the deflated ETT cuff when the ETT is occluded as the patient exhales. The cuff-leak test was the best predictor of successful extubation in a pediatric burn and trauma unit, and although sensitive, it was not specific for predicting stridor, necessitating reintubation in 62 adults.[152,153]

The test has been refined by evaluating cuff-leak volume as the difference between inspiratory and expiratory tidal volumes during assist-control ventilation after cuff deflation.[41,154] Two studies found the cuff-leak volume could predict post-extubation stridor. In one study, 8 of 45 patients exhibited stridor, 4 of whom required reintubation.[154] In the other study involving 88 adult medical ICU patients, 6 patients exhibited stridor, 3 of whom required reintubation.[41] They observed a significantly smaller cuff leak in patients who subsequently developed stridor, concluding that this measurement was the best predictor of the presence or absence of stridor. However, a study of 561 consecutive cardiothoracic patients who were extubated within 24 hours (median, 12 hours) defined a the cuff leak as the difference between the inspired and expired tidal volumes during assist-controlled ventilation. None of the (20) patients with leaks <110 mL developed stridor whereas one patient with a leak of 350 mL did and required reintubation. This led the investigators to conclude that the quantitative cuff-leak test was not reliable in this patient population.[155]

In another study involving 110 trauma victims, cuff leaks of less than 10% had a 96% specificity for predicting post-extubation stridor or the need for reintubation.[156] De Bast and colleagues studied 76 adults in a combined medical-surgical ICU.[157] An equal number of patients had been intubated for more or less than 48 hours. Assist-control ventilation was reinstituted after cuff deflation, and the percentage of cuff leak was determined. Receiver operating characteristic (ROC) curves yielded a cutoff value of 15.5% cuff leak to equalize the false positives and false negatives for reintubation due to laryngeal edema, but this study was relatively small. Among patients intubated for more than 48 hours, only 2 of 22 with large-volume leaks and 6 of 16 with small-volume leaks required reintubation for laryngeal edema.

Kriner and colleagues evaluated the cuff-leak test for its ability to predict post-extubation stridor among 462 adult patients intubated for longer than 24 hours.[150] They evaluated the two thresholds previously described; a positive test was defined as a cuff-leak volume of 110 mL or less or of 15.5% or less of the exhaled tidal volume. Ten of 82 patients with leak volumes of 110 mL or less developed post-extubation stridor, and 10 of 380 with larger leaks developed post-extubation stridor, giving a positive predictive value for stridor of 0.12 and negative predictive value of 0.97. The sensitivity and specificity of the test under these conditions were 0.50 and 0.84, respectively.[150] With leak volumes of 15.5% or less, 7 of 48

patients developed post-extubation stridor, and 13 of 414 patients with volumes greater than 15.5% developed stridor, yielding positive and negative predictive values of 0.15 and 0.97, respectively. The sensitivity and specificity of this test for post-extubation stridor were 0.35 and 0.91, respectively. The prevalence of post-extubation stridor was 20 of 462. Seven of these patients required reintubation; 15 were managed with racemic epinephrine or helium-oxygen mixtures, or both, and 2 of the 15 failed, requiring intubation. The investigators concluded that neither threshold adequately predicted post-extubation stridor or could justify delaying extubation.

The reported variability of post-extubation stridor (2% to 37%) results in part from inconsistent diagnostic criteria,[150] but undoubtedly there are many other factors at play. Factors increasing the risk of post-extubation stridor include longer duration of intubation,[150] trauma and burns,[14,148,154,158] pediatric age group,[158] female gender,[95,97,150] traumatic or emergent intubations, periods of hypotension, agitation, persistent attempts at phonation, inadequate ETT fixation, aggressive tracheal suctioning, highly positive fluid balance, low plasma oncotic pressure, gastroesophageal reflux, increased ETT diameter, and the presence of a nasogastric tube.[95,97,150]

In summary, it appears that despite the intuitive appeal of the cuff-leak test, neither the qualitative nor quantitative test adequately predicts adult patients who will develop stridor after extubation.[150,155,159] It did not predict where patients were likely to require reintubation. Deem argued that absence of a cuff leak might result in an unnecessary delay of extubation, whereas a large cuff leak might produce false reassurance that there will be no difficulties.[159] At least in adults, the value of this test is uncertain.

16. Postobstructive Pulmonary Edema

Severe airway obstruction from any cause may complicate extubation and lead to postobstructive pulmonary edema, also called negative-pressure pulmonary edema.[160] This edema occurs when a forceful inspiratory effort is made against an obstructed airway (i.e., Mueller maneuver), often a closed glottis, generating large negative intrapleural pressures that promote venous return. The increase in venous pressure is aggravated by a lowered alveolar pressure, resulting in transudation of fluids into the pulmonary interstitium and alveoli. It may also result in a rightward shift of the interatrial and interventricular septa, raising left atrial and ventricular pressures. Some instances may be complicated by a permeability defect with exudative fluid and inflammatory cells.[161-166]

Postobstructive pulmonary edema usually occurs in adult patients with upper airway tumors, severe laryngospasm, or rarely, bilateral vocal cord palsy,[167] whereas in children, it occurs most commonly as a complication of croup or epiglottitis.[168] The onset may be within minutes of the development of airway obstruction. It typically resolves with relief of the obstruction and supportive treatment for pulmonary edema.[166]

B. Higher-Risk Extubations

Although the previously described complications may follow a routine extubation, two additional groups of patients may be affected: those with a higher risk for reintubation and those in whom accomplishing reintubation can be challenging or impossible. Patients at higher risk for reintubation have preexisting medical conditions that reduce their physiologic reserve, ranging from moderate disability to an extremely marginal state. The possibility of higher-risk extubations also exists for a continuum of patients, from those in whom mask ventilation and reintubation should be easily achieved to those in whom both would pose a significant challenge. They may have their jaws wired shut or have a neck that is very poorly suited for emergent surgical access.[169,170]

Chronic pulmonary or cardiac disease may compromise spontaneous ventilation and necessitate intubation. The patient with an ineffective cough or increased secretions may have a need for pulmonary toilet. An obtunded patient may be unable to protect his airway. A list of higher-risk extubations is provided in Table 50-1.

Any reintubation is fundamentally different from the original intubation, because it is likely to occur in an urgent or emergent setting with limited information, personnel, and equipment. The patient is more likely to be hypoxic, acidotic, agitated, and hemodynamically unstable, and the procedure may be done in haste by the available personnel. A preemptive strategy is appropriate to manage these patients.

IV. CLINICAL SETTINGS OF COMPLICATIONS

A. Operative Conditions

1. Laryngoscopic Surgery

Mathew and colleagues looked at 13,593 consecutive PACU admissions from 1986 through 1989.[21] Twenty-six (0.19%) of these patients required reintubation while in the PACU; seven of them had undergone ear, nose, and throat procedures. Of the seven patients, three had laryngeal edema, one was obstructed from a large thyroid, two bled at the operative site, and one developed postobstructive pulmonary edema after a tonsillectomy.

Patients undergoing laryngoscopy and panendoscopy (i.e., laryngoscopy, bronchoscopy, and esophagoscopy) are at an increased postoperative risk for airway obstruction and are approximately 20 times as likely to require reintubation as patients undergoing a wide variety of other surgical procedures.[20] Reviewing the records of 324 diagnostic laryngoscopies and 302 panendoscopies, Hill and colleagues found that patients who had undergone laryngeal biopsy were at the greatest postoperative airway risk. Thirteen (5%) of 252 patients required reintubation, most within 1 hour of extubation. Twelve of 13 had undergone laryngeal biopsy. Most of these patients had chronic obstructive pulmonary disease, and their need for reintubation was attributed largely to this.

Robinson prospectively studied 183 patients who had 204 endoscopic laryngeal procedures.[171] Seven patients had tracheostomies before or after their surgery because of high-risk airways. Two of the remaining patients developed postoperative stridor; one required reintubation, and the other required a delayed tracheostomy. Indirect

TABLE 50-1
Complications of Higher-Risk Extubations

Complication	Surgical and Medical Settings
Inability to Tolerate Extubation and Required Reintubation	
Airway obstruction	Laryngeal injury or hypopharyngeal swelling after laryngoscopy
	Paradoxical vocal cord motion
	After thyroidectomy, anterior cervical surgery, or carotid artery surgery
	Wound swelling, hematoma
	Vocal cord injury (e.g., recurrent laryngeal nerve)
	Hypoglossal nerve injury
	After palatoplasty
	Maxillofacial swelling
	Macroglossia
	Obstructive sleep apnea
	Rheumatoid arthritis
	Parkinson's disease
	Prolonged intubation
Inadequate ventilation	Central sleep apnea
	Severe chronic obstructive pulmonary disease
	Residual sedation or neuromuscular blockade
	Preexisting neuromuscular disorder
	Diaphragmatic splinting
	Relative hypoventilation (e.g., increased CO_2 production)
Inadequate oxygenation	Inadequate inspired oxygen concentration
	Ventilation-perfusion mismatch
	Right-left shunt
	Increased O_2 consumption
	Decreased O_2 delivery
	Impaired pulmonary diffusion
Failure of pulmonary toilet	Obtundation
	Pulmonary secretions
	Quantity
	Quality (inspissated)
	Impaired mucociliary clearance
	Neuromuscular impairment
Inability to protect airway	Obtundation
	Neuromuscular disorder
Difficulty Reestablishing the Airway	
Airway injury	Thermal injury, smoke inhalation
	Blood or trauma obscuring the view
	Blood or trauma obstructing the airway
Previous airway difficulties	Known prior difficulties (e.g., multiple attempts, devices, or operators)
	Cormack-Lehane class ≧3 for laryngeal view
Limited airway access	Maxillomandibular fixation
	Cervical immobilization, unstable cervical spine, or halo fixation
	Tracheal resection (e.g., guardian suture)
	Major head and neck surgery
Emergent setting	Lack of knowledge regarding prior or potential difficulties
	Lack of expertise
	Insufficient time to prepare personnel, equipment, and medications

laryngoscopy carried out 4 to 6 hours after surgery revealed mucosal hemorrhage or laryngopharyngeal swelling in 32% of cases. Because the patients undergoing tracheostomy were not described, it is possible that the low incidence of reintubation resulted from an aggressive approach to preemptive tracheostomy.

2. Thyroid Surgery

A variety of airway-related injuries can be associated with thyroidectomies, including SLN and RLN injuries, wound hematoma, and tracheomalacia. Lacoste and colleagues retrospectively reviewed the records of 3008 patients who underwent thyroidectomies between 1968 and 1988.[27] The RLN had been identified intraoperatively in 2427 of these patients. Indirect laryngoscopy was performed on the third or fifth postoperative day. The RLN was damaged in 0.5% of patients with benign goiters and 10.6% of patients with thyroid cancer. RLN injury produces hoarseness, persistent coughing with phonation, and risk of aspiration. Unilateral RLN palsy was observed in 1.1% of patients. Three patients had bilateral RLN palsy and required tracheostomy. Six of a total of 16 deaths during the first 30 postoperative days were attributed to respiratory complications. One death occurred after failed intubation due to a deviated, constricted trachea. A second death was attributed to difficulties performing a tracheostomy. Two deaths resulted from aspiration or pneumonia, possibly related to RLN dysfunction.

SLN injury is more challenging to diagnose. It produces dysphonia and vocal fatigue, particularly in the higher registers. In a 5-year, multicenter study involving 42 centers and almost 15,000 thyroid operations, the diagnosis was suspected in 3.7% and confirmed in 0.4% of patients.[172]

Local hemorrhage or hematoma occurs postoperatively in 0.1% to 1.6% of patients undergoing thyroid surgery and in 0.36% of the patients cared for by Lacoste and colleagues.[27,172-174] These complications occurred 5 minutes to 3 days postoperatively. Re-exploration within the first day was required only twice. Airway obstruction may result from significant laryngeal and pharyngeal edema, and wound evacuation may be of limited value in the relief of airway obstruction.[173,175,176] It may result from or be aggravated by ligature slippage, coughing, vomiting,[174] coagulopathies, and reoperation.[173] The prophylactic placement of surgical drains likely reduces the incidence of this complication. Wound evacuation may result in significant improvement; however this is not always the case. If time permits or intubation fails, wound evacuation should be considered.[176] Laryngeal edema may persist after the wound has been evacuated, necessitating postoperative intubation.

Tracheomalacia is rarely diagnosed after thyroidectomies, even in patients with significant retrosternal tracheal compression, although it may exist subclinically.[177-181] Although symptoms, computed tomography (CT), and pulmonary function test results make it easy to recognize airway compression preoperatively, tracheomalacia may be difficult to predict or even detect from the surgical field, and it does not become apparent until after the ETT is removed and spontaneous ventilation has resumed.[182]

3. Carotid Artery Surgery

Neck swelling or hematoma formation after carotid endarterectomy may be relatively common. The New York Carotid Artery Surgery (NYCAS) study analyzed 9308 procedures performed between 1998 and 1999 at 167 hospitals.[183] A hematoma was identified in 5% of patients, substantially increasing the risk of death (OR = 4.30; 95% CI, 2.72 to 5.00) and stroke (OR = 3.89; 95% CI, 2.82 to 5.38). Hematoma occurrence reported in the literature ranges from 1.2% to 12%, depending on the definition used.[183] The overall rate of wound hematomas in the North American Symptomatic Carotid Endarterectomy Trial (NASCET), involving 1415 patients was 7.1%, 3.9% of which cases were considered to be mild (i.e., no delay in discharge), 3.0% were moderate (i.e., delay in discharge), and 0.3% were severe (i.e., permanent functional disability or death). The moderate and severe cases required re-exploration or wound evacuation (3.3%). Hematoma contributed to the death of four patients.[184] When wound hematomas are identified by a comparison of preoperative and postoperative CT scans, it occurs far more frequently (26%).[185] The postoperative reintubation or exploration rate is 1% to 3.3%.[184,186]

Kunkel and colleagues described 15 patients who developed wound hematomas after carotid endarterectomy.[187] Eight of these were evacuated under local anesthesia. In six of seven cases in which general anesthesia was induced before opening the wound, difficulties arose with airway management, resulting in two deaths and one patient with severe neurologic impairment. O'Sullivan and coworkers reported a similar experience for six patients with airway obstruction after carotid endarterectomy.[188] Stridor was not relieved by wound evacuation. Administration of muscle relaxants made manual mask ventilation and tracheal intubation virtually impossible due to marked glottic or supraglottic edema. Cyanosis and extreme bradydysrhythmias or asystole occurred in four patients. The providers endorsed Kunkle's recommendation for wound evacuation but thought that much of the airway compromise was caused by edema from venous or lymphatic congestion. They emphasized that the outward appearance may lead to an underestimation of the situation's gravity. Voice changes are early signs of danger and may be relatively subtle. Rapid clinical deterioration can occur after stridor develops.[189]

Studies by Carmichael and colleagues provided additional evidence for the role of swelling and bleeding in a small but elegant study. They compared the CT scans of 19 patients before and after carotid endarterectomy surgery.[185] Clinically, 1 patient had severe swelling, 4 had moderate swelling, and 3 had mild swelling, but 10 were deemed normal. However, postoperative CT scans demonstrated significant swelling of the retropharyngeal space and a reduction of the anteroposterior and transverse airway diameter, particularly at the level of the hyoid. Compared with preoperative CT scans, the calculated volume reduction averaged 32% ± 7% for extubated patients. The scans revealed a wound hematoma estimated to be greater than 10 mL (range, 44 to 94 mL) in 5 of 19 patients. Patients who remained intubated postoperatively showed a significantly greater volume reduction of 62% ± 9% ($P < 0.025$). Those remaining intubated as a result of swelling had contralateral extension of the swelling. These observations may help to explain why opening the wound frequently fails to provide benefit in many patients. Nonetheless, it may be difficult to clinically differentiate bleeding from swelling. After radiologic demonstration of swelling, the same group evaluated the benefits of prophylactic dexamethasone but failed to demonstrate any clinical benefit.[190]

A 10-year, retrospective review of 3224 carotid endarterectomies performed at The Mayo Clinic revealed that 44 (1.4%) patients required wound exploration within 72 hours of surgery, despite the nonreversal of heparin.[191] In two patients, re-exploration occurred before the initial extubation. The decision to re-explore was made in the PACU for 7 patients; the remaining 35 were identified in the ICU or ward. Only one patient required a surgical airway when direct laryngoscopy failed in the ICU. Several techniques were initially employed: awake bronchoscopic intubation (15 of 20 of which were successful), direct laryngoscopy after induction (13 of 15 were successful), and awake direct laryngoscopy (5 of 7 were successful). When awake bronchoscopy failed, direct laryngoscopy was successful whether the patient was awake (3 of 3) or asleep (2 of 2). When direct laryngoscopy initially failed after induction in two patients, it succeeded after opening the incision. When awake direct laryngoscopy failed, one patient required a surgical airway; in the other, direct laryngoscopy succeeded after opening the incision. Despite the size of this series, it is not possible to draw conclusions about which techniques are most successful. Success likely depends on the skill and judgment of the airway manager. It is also possible that this study differed from the other studies in that the decision to re-explore was made earlier and patients had less airway distortion.

Several nerve injuries can result from carotid artery surgery or the anesthetic technique. The range reported in the literature is 3% to 23%, although most of these cases resolve within 4 months of surgery.[192] In the NYCAS study, cranial nerve palsies occurred in 514 (5.5%) of 9308 patients and involved, in descending order, the hypoglossal nerve (170), producing tongue deviation to the operative side; a branch of the facial nerve (126), resulting in lip or facial droop; the glossopharyngeal nerve (41); a branch of the vagus, which may involve the RLN and produce vocal cord paresis (31); the trigeminal nerve (19); a branch of the cervical plexus (10); or more than one nerve group (117).[183]

Bilateral vocal cord and bilateral hypoglossal nerve palsies have been described after staged, bilateral carotid endarterectomies.[24,25] In the latter case, the first procedure, performed under regional anesthesia, had been complicated by a wound hematoma, resulting in numbness over the anterior neck and diminished sensation in the C2 and C3 distribution. The subsequent endarterectomy, done 4 weeks later under deep cervical plexus block with subcutaneous infiltration, caused intraoperative airway obstruction and asystole. The airway was secured, but repeated attempts at extubation resulted in persistent obstruction due to bilateral hypoglossal nerve palsy. In another case, performed under cervical plexus

block, the patient developed bilateral vocal cord paralysis that required intubation and subsequent tracheotomy. It is suspected that she had a previously unrecognized contralateral vocal cord palsy from a prior thyroidectomy.[193] In this case, the vocal cord dysfunction was co-incident with retraction of the carotid sheath—although it can also be induced by a cervical plexus block—but it raises the importance of the preoperative assessment of patients who have had prior head and neck surgery.

4. Cervical Surgery

Cervical spine procedures may be followed by airway-related complications, including vocal cord paralysis and airway obstruction. Vocal cord dysfunction was seen in 5% of 411 patients undergoing anterior cervical discectomy and fusion.[194] Stridor was observed in one patient with bilateral vocal cord paralysis who required a tracheostomy. Fifteen of 17 patients had recovered by 12 months. One additional patient had recovered by 15 months, and the remaining patient was lost to follow-up.

Emery and colleagues studied the records of 133 patients who underwent cervical corpectomies with arthrodesis between 1974 and 1989.[26] The patients had undergone an anterior approach to achieve a three-level vertebral body and disc resection with bone grafting. This surgical approach requires tracheal and esophageal retraction toward the opposite side to permit exposure. Drains were placed, and all patients were immobilized by a halo vest or a rigid head-cervical-thoracic orthosis. They identified seven patients (5.3%) who required postoperative reintubation, and although they did not compare these patients with those not requiring reintubation, they attempted to identify common features that increased the risk of postoperative airway compromise. Three patients were immediately reintubated in the operating room, and four were reintubated 12 to 91 hours postoperatively. Severe hypopharyngeal swelling was observed at reintubation in four of seven patients and possibly in a fifth. Five of the seven reintubations had no serious sequelae; these patients were extubated within 2 to 8 days. One patient required a cricothyroidotomy, but delay resulted in hypoxic encephalopathy and death. Another patient was reintubated but developed and succumbed to severe adult respiratory distress syndrome. The investigators think that preexisting pulmonary disease, moderate or severe preoperative myelopathy, extensive multilevel decompression with prolonged surgery, and tissue retraction were risk factors for postoperative airway obstruction, but there were no controls.[26] They recommended 1 to 3 days of elective intubation postoperatively, a cuff-leak test, and direct laryngoscopy at extubation.

Venna and Rowbottom reviewed the records of 180 patients who had undergone a variety of cervical surgical procedures.[28] Based on the Emery study, they had made the decision to keep high-risk patients intubated until they met specified criteria, including a demonstrable cuff leak and the absence of significant airway edema on laryngoscopy. The average time to extubation was 33.5 hours. Despite the delay and the aforementioned criteria, 12 patients (6.6%) demonstrated post-extubation stridor and breathing difficulties, and 5 (2.7%) required reintubation. Two patients required tracheostomy, and two deaths were attributed to airway obstruction and unsuccessful reintubation.

Sagi and coworkers conducted a retrospective chart review of 311 anterior cervical procedures in an effort to identify the factors associated with airway complications.[195] In this series, 19 (6.1%) of patients had airway complications, but only 6 (1.9%) required reintubation. Most of these complications were attributed to pharyngeal edema. Risk factors included increased intraoperative bleeding, prolonged surgery (>5 hours), and exposure of more than three vertebral bodies, particularly when they included C2, C3, or C4. Reviewing the literature, these investigators identified an airway complication rate of 2.4% (from 1615 cases), 35 of whom required reintubation or tracheostomy. On average, those requiring reintubation did so at 24 hours.

Epstein and coworkers developed a collaborative protocol involving the neurosurgeon and anesthesiologist. Their objective was avoidance of reintubations.[196] Although their study enrolled only 58 patients, they required high-risk, lengthy procedures involving several cervical levels and significant blood loss. All patients remained electively intubated overnight and underwent fiberoptic airway examination before considering extubation. Most patients were extubated the day after surgery, but three remained intubated until day 7. Only one patient required reintubation. This reintubation rate was essentially the same as that observed by Emery and colleagues,[26] but Epstein's cohort appeared to undergo higher-risk surgery.

In an effort to better understand the mechanism of postoperative airway obstruction, Andrew and Sidhu compared the soft tissue changes on the preoperative and postoperative cervical spine radiographs of 32 consecutive patients after a one- or two-level anterior cervical discectomy and fusion.[197] They found that the swelling was maximal at the C3-C4 level, corresponding to the area where Emery observed pharyngeal edema. None of their patients experienced dyspnea despite mean differences of 9.4 mm (95% CI, 7.41 to 11.09 mm) to 10.7 mm (95% CI, 7. 8.82 to 12.58 mm) between the preoperative and postoperative radiographs at C3 and C4, respectively. It appears that this area is most vulnerable, regardless of the level operated on. Compared with Sagi's study, these patients underwent much shorter and more limited procedures.

Extubation criteria after anterior cervical spine surgery were discussed at length in the Society for Airway Management online Forum in 2011. The groups who perform this surgery frequently tend to extubate most of their patients at the conclusion of surgery, except when the blood loss is high (e.g., >500 mL), the surgery is prolonged (e.g., >5 hours), the operation involves more than three levels, the airway was difficult or expected to be difficult, or comorbidities exist, such as severe cervical myelopathy, obesity, and obstructive sleep apnea (OSA). Patients with multiple risk factors are cared for in an ICU and are extubated over an airway exchange catheter (AEC) (personal communication from C.A. Hagberg, SAM Forum, February 2011).

Patients undergoing posterior cervical surgery may face the risk of macroglossia and significant retropharyngeal and hypopharyngeal swelling, which may be aggravated by fixation of the cervical spine and make intubation more difficult.[198] There is a low probability (1.1% to 1.7%) that reintubation will be required,[196,198] but accomplishing this may be very difficult.

5. Maxillofacial Surgery and Trauma

Maxillary and mandibular surgery produces conspicuous and often worrisome swelling. Anxiety regarding postoperative care may be heightened by limited airway access, fear that airway intervention may disrupt the surgical repair, and anecdotal reports of near misses or actual fatalities. Because many of these patients are young and otherwise healthy and are undergoing elective surgery for functional or cosmetic improvement, there may be concerns about litigation. It is speculative about whether this results in more or less aggressive care.

Although these concerns demand special attention, deaths rarely occur. In a review of 461 perioperative deaths reported to the Ontario, Canada, coroner between 1986 and 1995, the investigators found only one death associated with orthognathic surgery, although they were unable to determine how many such cases had been performed (see "In Vivo Studies").[199] They were unable to identify nonlethal complications. Meisami and others performed magnetic resonance imaging (MRI) approximately 24 hours after maxillary or mandibular surgery in 40 patients.[200] Despite the significant facial swelling seen in almost all the patients, none exhibited soft tissue swelling from the base of the tongue to the glottis.

Complete airway obstruction after elective orthognathic surgery has been reported. Dark and colleagues described a case involving a young woman who underwent seemingly uneventful mandibular and maxillary osteotomies with submental liposuction.[201] Immediately after extubation, she developed airway obstruction requiring reintubation. Repeated fiberoptic examination and CT showed severe and extensive edema from the tongue to the trachea, which was maximal at the level of the hyoid. By the fourth postoperative day, a cuff leak was detected, and the patient was successfully extubated over a tube exchanger. Hogan and Argalious described a patient in whom maxillomandibular advancement was performed for OSA.[202] The procedure lasted 9 hours, during which he received 7200 mL of crystalloid and 500 mL hetastarch. He remained intubated overnight, and after demonstrating adequate spontaneous ventilation and a cuff leak, he was extubated (over a 19-F AEC). Extubation was immediately followed by clinical evidence of airway obstruction, and he was reintubated. The obstruction was attributed to fractured hardware and a hematoma in the piriform fossa that caused extrinsic compression. This could easily have resulted from periglottic edema. The investigators concluded that patients undergoing this type of surgery face a high risk of airway complications and recommended nasopharyngolaryngoscopy before extubation.

Clinical assessment of airway edema is unreliable,[200] and studies indicate that the cuff-leak test is neither sufficiently sensitive nor specific to determine when to extubate these patients. Endoscopic assessment may help to identify patients who harbor occult clots (i.e., "coroner's clot") behind the soft palate or adjacent to the glottis, but it may miss or itself give rise to troublesome bleeding.

Maxillofacial injuries often result from unrestrained occupants of motor vehicles encountering an unyielding dashboard, windshield, or steering wheel. Gunshot wounds or physical altercations also cause maxillofacial injury. Airway obstruction is a primary cause of morbidity and mortality in these patients, and many die before they reach the hospital.[203] Those with less life-threatening injuries are likely to present with a full stomach, and many have associated head and neck injuries, lacerations, loose or avulsed teeth, intraoral fractures, and fractures extending into the paranasal sinuses, into the orbit, or through the cribriform plate. They may also have an unstable cervical spine or damage to the neural axis. Injuries to the lower face raise the possibility of a laryngeal fracture. Intermaxillary fixation may be part of the surgical plan, necessitating a nasal intubation or a surgical airway. Timing of tracheal extubation is complex and must take into consideration factors such as the patient's level of consciousness, ability to maintain satisfactory gas exchange, coagulation status, and integrity of protective airway reflexes. Attention must be paid to the difficulties originally encountered in securing the airway and an evaluation of whether reintubation would be easier or more difficult after surgery and resuscitation. Most of the trauma literature about airway management addresses intubation and offers little help with extubation, making cooperation between the anesthesiologist,[204,205] surgeon, and critical care physician essential. Intermaxillary fixation requires wire cutters to be immediately available and personnel to know which wires to cut. A flexible bronchoscope, provisions for an emergency surgical airway, and the required expertise should be immediately available at the time of extubation. Alternatives include prophylactic tracheotomy, submental intubation,[206-208] nasal intubation, and bronchoscopic airway evaluation performed before extubation,[209] although assessment may be limited to supraglottic structures and exclusion of tube entrapment. Ideally, extubation should be accomplished in a reversible manner, permitting supplemental oxygenation, ventilation, and reintubation if needed (see "Extubation Strategies").

6. Deep Neck Infections

Infections involving the submandibular, sublingual, submental, prevertebral, parapharyngeal, and retropharyngeal spaces are significant airway management challenges, whether intubation is achieved for surgical drainage or for protection during medical management. In expert hands, bronchoscopy-assisted intubation can often be achieved.[210] When this is unsuccessful or constitutes a significant risk of rupturing the abscess, a surgical airway before incision and drainage may be called for.[211] Potter and colleagues retrospectively compared the outcomes of 34 patients in whom a tracheotomy was performed with 51 patients who remained intubated after surgical drainage.[212] All patients had undergone surgical drainage for impending airway compromise and required airway

support postoperatively. It was not always evident to the investigators why a particular strategy was chosen, and these groups were not likely identical. Airway loss occurred more commonly in the intubated patients, but this characteristic was not statistically significant. Two deaths occurred, one resulting from an unintended extubation and the other from post-extubation laryngeal edema and an inability to reestablish the airway. The latter patient had a cuff leak before extubation, and signs of obstruction developed 30 minutes after the ETT was removed. Surgical drainage rarely results in immediate airway improvement, and reintubation or emergent placement of a surgical airway, if required, may be complicated by edema, tissue distortion, and urgency.

7. Posterior Fossa Surgery

Posterior fossa surgery can cause injury to cranial nerves, bilateral vocal cord paralysis, brainstem or respiratory control center injury, and macroglossia.[114,115,167,213-216] Because the nerve roots may be very close to the operative site, the resultant injuries may be bilateral, extensive, and transient or permanent. Gorski and coworkers suggested that tolerance of the ETT and the absence of a gag reflex on oral suctioning should arouse suspicion of such an injury.[214] Howard and colleagues described a patient with a recurrent choroid plexus papilloma involving the fourth ventricle.[215] Preoperatively, the patient displayed bulbar dysfunction. His extubation on the first postoperative day was complicated by complete airway obstruction, hypoxia, and a seizure. Laryngoscopy performed after neuromuscular blockade revealed mildly edematous vocal cords. After reintubation and elective tracheostomy, fiberoptic examination showed the vocal folds in a neutral position. Nocturnal ventilation and tracheostomy were still required at 1 and 3 months, respectively. This patient demonstrated central apnea and bulbar dysfunction with hypoglossal paralysis and unopposed vocal fold adduction.

Artru and colleagues described a patient with a cerebellar mass, severe papilledema, and bulbar signs.[213] Despite recovery of consciousness and strength, the patient remained apneic and required ventilatory support for 7 days. The investigators cautioned that the dorsal pons and medulla are the sites of the cardiovascular and respiratory centers that control hemodynamics and ventilation. The area is also host to several cranial nerve nuclei. Damage to these areas can result from edema, disruption, ischemia, or compression and may cause a loss of respiratory drive or airway obstruction.

Dohi and coworkers described a patient who developed bulbar signs, including bilateral vocal cord paralysis after excision of a recurrent cerebellopontine angle tumor.[167] Negative-pressure pulmonary edema developed as a consequence of a bilateral, presumably central RLN injury, and a tracheostomy was required until recovery 3 months later. During the initial intubation, the glottis could not be seen by direct laryngoscopy, and blind intubation was performed. The details of three subsequent unsuccessful extubations and reintubations were not described. Trials of extubation in a patient known to be a difficult (direct) laryngoscopy case are life-threatening and cannot be justified. A tracheostomy was performed, and vocal cord function recovered after 3 months.

Early vocal cord evaluation after extubation has been advocated along with the involvement of a neurosurgeon, otolaryngologist, speech therapist, and intensivist to manage patients who have developed laryngeal dysfunction.[216] A tracheostomy and an enteral feeding tube may be needed. A more preemptive approach (described later in more detail) involves flexible laryngoscopic assessment through a supraglottic airway (SGA) after removal of the ETT.

8. Stereotactic Surgery and Cervical Immobilization

Stereotactic neurosurgical and neuroradiologic procedures are finding increasing applications. When head frames are used, they may impede access for SGA placement or laryngoscopy. Similarly, patients in cervical immobilization devices for spinal cord protection may undergo high-risk surgical procedures.[116] Careful planning for their extubation is critical because reintubation may be difficult, and rapid surgical access may be virtually impossible. Full recovery of strength and consciousness, persistence of respiratory drive, the presence of a cuff leak, preservation of protective reflexes, and absence of significant tongue swelling are the essential prerequisites for extubation. Postoperative seizures, vomiting, elevated intracranial pressure, and neurologic obtundation may make extubation particularly hazardous. Several of the strategies described subsequently should be given serious consideration in managing these patients.

9. Tracheal Resections

Patients with moderate or severe tracheal stenosis may come for surgical tracheal resection. These patients usually have tracheal stenosis or tracheomalacia, often caused by prolonged intubation or occasionally caused by a retrosternal mass. Some patients may have compromised preoperative respiratory function. After an end-to-end anastomosis, the surgeon may elect to place a "guardian suture" from the chin to the chest, maintaining the head and neck in flexion and thereby minimizing traction on the suture lines (Fig. 50-1).[217,218] The preference is for early extubation to avoid positive pressure, coughing, and presence of a foreign body in the airway.[217-221] A cough-free extubation is highly desirable, as is avoidance of a need for reintubation, which if required could prove very challenging.

10. Palatoplasty

A variety of surgical procedures have been employed to treat OSA, including uvulopalatopharyngoplasty, midline glossectomy, mandibular advancement, limited mandibular osteotomies with genioglossal advancement, and hyoid bone suspension.[222] Pepin and colleagues published a critical analysis of the literature on the risks and benefits of surgical treatment of snoring and OSA.[223] They identified "at least five deaths" after uvulopalatopharyngoplasty and found that few studies had adequate numbers to allow conclusions to be drawn regarding their outcomes. Less than one half of the studies commented on the frequency of complications. A retrospective review of 101 uvulopalatopharyngoplasties identified an early postoperative respiratory complication rate of 10%.[224] Ten of

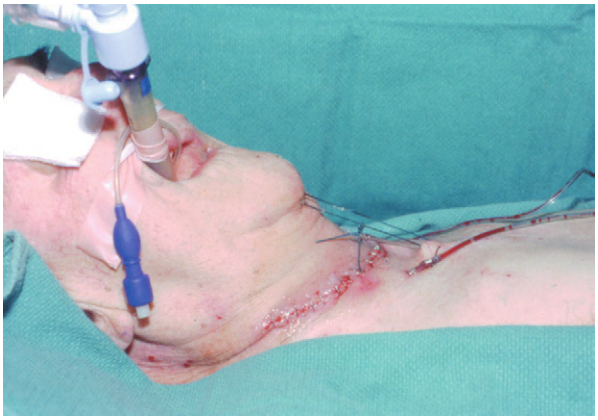

Figure 50-1 This patient has undergone a cricotracheal resection. Cervical extension is restricted by a chin-to-chest guardian suture. The patient has been extubated, and a laryngeal mask airway has been introduced before reversal of neuromuscular blockade or awakening. This reduces coughing on emergence, allowing gradual recovery and assessment of spontaneous respiratory function while minimizing the potential distraction of the surgical anastomosis. It also provides the optimal means of performing flexible laryngobronchial examination under controlled conditions. (Courtesy of Patrick Gullane, MD, University Health Network, Toronto, Ont.)

11 patients required reintubation, and 1 death resulted from airway obstruction.

Uvulopalatopharyngoplasty was introduced to deal with retropalatine collapse. However, in approximately one half of the adult patients with OSA, obstruction occurs at the retrolingual pharynx. Tongue suspension is one of several approaches introduced to manage the latter group of patients.[225] The procedure involves placement of an anchoring screw in the genial tubercle and attachment of a suture through the base of the tongue. Szokol described a morbidly obese patient with OSA in whom this procedure was performed.[222] Laryngoscopy and bag-mask ventilation had been difficult. At the conclusion of the procedure, the patient was fully awake, was able to sustain a head lift for 5 seconds, demonstrated a negative inspiratory pressure of 40 cm H_2O, and was extubated. Stridor was observed immediately, and bag-mask and laryngeal mask ventilation were ineffective. Attempts to reintubate the patient were unsuccessful, necessitating a cricothyroidotomy. Subsequent direct laryngoscopy showed a markedly swollen epiglottis and grossly edematous laryngeal and hypopharyngeal tissues. The patient developed negative-pressure pulmonary edema, and a tracheostomy was performed 2 days later because of persistent swelling. Tracheal decannulation occurred uneventfully 2 weeks later. The physicians speculated that airway manipulation during the surgery was the cause of this patient's swelling. They did not consider that the swelling might have resulted from or at least been aggravated by repeated attempts at laryngoscopy.

Palatoplasty, alone or in combination with other procedures, may be performed on patients with cleft palates or other congenital abnormalities. In one study, 14 (5.7%) of 247 patients undergoing palatoplasty had postoperative airway problems, 12 of whom required reintubation. One half of the patients experiencing complications had Pierre Robin sequence; three of the patients required reintubation 24 to 48 hours postoperatively.[226]

B. Preexisting Medical Conditions

1. Paradoxical Vocal Cord Motion

Paradoxical vocal cord motion (PVCM) is the quintessential example of a situation wherein reintubation will be required. Intubation is not more difficult; extubation is the challenge. This uncommon and poorly understood condition is frequently mistaken for refractory asthma or recurrent laryngospasm.[227-229] The diagnosis is both overlooked and overused, leading to confusion.[230] It also is called vocal cord dysfunction, Munchausen stridor, psychogenic stridor, factitious asthma, pseudoasthma, and irritable larynx syndrome.[230,231] Normal vocal cord motion involves inspiratory abduction and 10% to 40% adduction on expiration. With PVCM, adduction of the true vocal cords occurs on inspiration or expiration, or both. The false vocal cords and the posterior laryngeal wall may further contribute to the airway obstruction.[231-234] This condition may be associated with psychosocial disorders, stress, exercise, gastroesophageal reflux, irritant exposure, or airway manipulation. Pulmonary function tests show normal expiratory but flattened inspiratory flow loops. It is important to differentiate this condition from asthma, laryngospasm, anaphylaxis, angioedema, gastroesophageal reflux, and vocal cord paralysis. The incidence of PVCM is unknown.

Harbison and coworkers described two patients who had post-extubation stridor after thyroidectomies.[235] This is a particularly challenging situation with a complex differential diagnosis, especially because one of the patients had unilateral vocal cord paralysis preoperatively. In that patient, post-extubation stridor developed 24 hours postoperatively and could be observed while awake and asleep. Fiberoptic examination under sedation showed paradoxical motion of the mobile cord. She was managed successfully with speech therapy. They speculated that these cases might have resulted from surgical manipulation of the RLN during the thyroidectomies.

Hammer and colleagues described a 32-year-old woman with recurrent episodes of stridor,[236] sometimes associated with cyanosis, despite normal flow-volume loops and pulmonary function tests. The diagnosis of PVCM was made endoscopically and managed with relaxation techniques. After preoperative sedation, topical lidocaine, and bilateral SLN blocks, she underwent an awake fiberoptic intubation. At the conclusion of surgery, extubation was performed after she was fully awake, but sustained inspiratory stridor ensued, resulting in reintubation. A subsequent attempt the next day confirmed inspiratory vocal fold adduction, and a tracheostomy was required for 58 days. In the absence of features predicting a challenging intubation, there seems little justification for awake intubation, and it may contribute unnecessarily to an anxiety disorder.

PVCM imposes no special requirements for intubation. The abnormality is functional rather than anatomic. Appropriate management depends on having the correct diagnosis, which requires clinical suspicion and endoscopic confirmation of inspiratory adduction of the vocal cords. Adequate oxygenation, consideration of CPAP or helium-oxygen administration, positioning, reassurance, and support may suffice, although sedation may be

required after the diagnosis is confirmed. Speech therapy, psychotherapy, hypnosis, and reassurance may be helpful in the long-term management,[237] but such is not always the case.[227] Some reports have recommended electromyographically guided botulinum toxin injection into the thyroarytenoid muscle for recalcitrant cases. The optimal anesthetic management of these patients is unknown. Regional anesthesia avoids airway intervention, but it does not ensure that a condition that may be stress related will not occur. Familiarity with this condition, calm reassurance when there is prior suspicion, and perhaps deep extubation seem prudent.

2. Parkinson's Disease

Susceptibility to aspiration is common among patients with Parkinson's disease and is the most common cause of death. Dysphonia, most frequently hypophonia, occurs in approximately 70% to 90% of patients with Parkinson's disease.[238,239] Video stroboscopic findings include laryngeal tremor, vocal fold bowing, and abnormal glottic opening and closing.[239] Several neurodegenerative diseases, including multiple system atrophy, have some features in common with Parkinson's disease, including dysphonia, and these patients may exhibit bilateral abductor vocal fold paresis. Typically, symptoms in patients with Parkinson's disease progress insidiously, are not recognized by the patient, and may be associated with nocturnal stridor. These features resemble those of OSA identified by polysomnography. Many of these patients may benefit from nocturnal CPAP or bi-level positive airway pressure (BiPAP).[238]

Blumin and Berke described seven patients, only one of whom presented for surgery. This patient underwent a transurethral prostate resection under general anesthesia, and 2 weeks after surgery, he returned with biphasic stridor that necessitated an emergent tracheostomy. It is unclear whether there was a relationship between the surgery or anesthesia and subsequent airway obstruction.

Patients with multiple system atrophy have daytime hypoxemia associated with abnormal laryngopharyngeal movements, including obstruction at the arytenoids, epiglottis, base of the tongue, and soft palate. The significance of these problems is unclear, but they may contribute to complications after extubation.[240]

Vincken and colleagues studied 27 patients with extrapyramidal disorders.[241] Twenty-four had flow-volume loops, many of which demonstrated saw-toothed oscillations, even in the absence of respiratory symptoms. They observed oscillations with rhythmic (4 to 8 Hz) or irregular movements of the glottis and supraglottic structures. Ten patients exhibited intermittent upper airway obstruction. Four patients had stridor or dyspnea. The investigators believed that the upper airway was the primary site of involvement. In a subsequent report, they observed symptomatic improvement with levodopa despite persistence of the oscillatory pattern on flow-volume loops.[242] Inspiratory and expiratory flows after levodopa increased from 1.40 to 3.50 L/sec and 0.95 to 5.05 L/sec, respectively. Bronchodilators provided no additional benefit. This case may have important implications for the perioperative management of patients with Parkinson's disease.

Easdown and colleagues described a patient with Parkinson's disease who had a respiratory arrest 60 hours after surgery.[243] Before that event, the patient had episodic desaturation, labored breathing, and progressive hypercapnia in the absence of tremor or rigidity. Treatment with bronchodilators produced no benefit, and his condition improved immediately after intubation. With the ETT, compliance and resistance appeared normal. This patient's levodopa or carbidopa had not been resumed postoperatively, and the investigators speculated that this caused or contributed to upper airway obstruction. Because most patients with Parkinson's disease are elderly and may have comorbidities that can make the diagnosis uncertain, it is important to consider involvement of the upper airway and the dramatic effect withdrawal and reinstatement of medications can have on their clinical course. This concern is reinforced by a case report describing a patient who developed airway obstruction and acute respiratory acidosis requiring intubation preoperatively because five doses of his antiparkinsonian medications were withheld while he was being fasted.[244] Easdown and colleagues emphasized the importance of continuing these medications, and avoidance of dopamine antagonists throughout the perioperative period.[243]

Backus and colleagues described a patient with longstanding Parkinson's disease who became aphonic, developed stridor, and suffered respiratory arrest shortly after taking cough medication.[245] Complete upper airway obstruction recurred with vocal fold apposition immediately after extubation. Four days later, the patient extubated herself with no further complications. The investigators interpreted this spontaneous laryngospasm as a manifestation of Parkinson's disease. Others have observed upper airway dysfunction, airflow limitation, and bilateral abductor vocal cord paralysis in association with Parkinson's disease. The first episode might not have been spontaneous but instead a consequence of aspiration of the cough medicine. Nonetheless, there remains a possibility that these patients are more prone to laryngospasm, whether spontaneous or induced by glottic stimulation.

Liu and coworkers described airway obstruction during induction of anesthesia.[246] Despite being unable to visualize the larynx, they attributed the obstruction to laryngospasm. The obstruction resolved with awake, blind nasal intubation but recurred 24 hours later on extubation. At that point, fiberoptic examination showed inspiratory vocal fold adduction, necessitating reintubation. It is unclear whether they were observing manifestations of Parkinson's disease or PVCM, but extubation was uneventful 24 hours later after increasing the dosage of levodopa or carbidopa.

Parkinson's disease is a common disorder, but only 13 cases of stridor have been attributed to it.[239] The pathogenesis of upper airway obstruction is unknown. It may be mediated by the basal ganglia and nucleus ambiguus. A similar phenomenon involving esophageal spasm has been associated with Parkinson's disease. One theory invokes laryngeal hypertonicity, which may be triggered by copious secretions.

3. Rheumatoid Arthritis

In patients with rheumatoid arthritis, the airway manager needs to be concerned about three joint areas: the cervical spine, the temporomandibular joint (TMJ), and the cricoarytenoid joint.[247] Autopsy studies suggest that 30% to 50% of patients with rheumatoid arthritis have significant cervical spine involvement. Cervical subluxation has been identified clinically in 43% to 86% of these patients and may represent a serious neurologic risk during intubation with flexion or extension.[145,247-249] The spectrum of cervical involvement ranges from ligamentous destruction with subluxation and impaction to extreme limitations in the range of motion because of fibrosis and ankylosis. These patients may have a narrowed glottic aperture, limited mouth opening due to involvement of the TMJs, micrognathism, laryngeal deviation, and cricoarytenoid and cricothyroid involvement.[250,251] Kohjitani and colleagues retrospectively described four patients undergoing bilateral TMJ replacement; three had glottic erythema and swelling on endoscopy, three had OSA, and three experienced laryngospasm at intubation and after extubation.[251] TMJ involvement may result in loss of ramal height and micrognathia with or without ankylosis and associated OSA.

Cricoarytenoid arthritis and its consequences have long been recognized in the anesthesia and general medical literature.[252-256] Although rheumatoid arthritis is the most common cause of this condition, it also may be associated with bacterial infections, mumps, diphtheria, syphilis, tuberculosis, Reiter's syndrome, ankylosing spondylitis, systemic lupus erythematosus, gout, progressive systemic sclerosis, and other conditions.[257] The cricoarytenoid joint has a synovial lining and bursa. Its mobility is vital for speech, respiration, and protection from aspiration. Inflammatory changes may include effusion, pannus formation, joint erosion, and ankylosis, any of which may compromise the joint's functions. Its involvement may be unsuspected or mistaken for asthma until intubation or after extubation and may necessitate a surgical airway.[258,259] Dysphonia, dyspnea, or stridor should raise suspicion of this possibility. Complete airway obstruction is a well-described but uncommon complication, despite involvement of the cricoarytenoids in 26% to 86% of patients with rheumatoid arthritis.[251,259] Laryngoscopy may reveal a rough and thick mucosa with narrowing of the vocal chink. Although airway obstruction occurs most commonly in patients with long-standing rheumatoid arthritis with polyarticular and systemic involvement, laryngeal stridor has been described as the sole manifestation of this disease.[260]

Keenan and coworkers described tracheal scoliosis, which consisted of tracheal deviation, laryngeal rotation, anterior angulation, and vocal fold adduction seen fiberoptically and on CT scans.[255] It was presumed to result from the loss of vertical height and asymmetrical bony erosions.

Wattenmaker and colleagues studied patients with rheumatoid arthritis undergoing posterior cervical spine procedures.[250] Their primary objective was to compare the perioperative airway complications seen in rheumatoid arthritis patients when intubation was performed by direct laryngoscopic or flexible bronchoscopy. Retrospectively reviewing 128 consecutive posterior cervical procedures, upper airway obstruction characterized by stridor occurred in 9 of 128 patients, 1 of 70 patients intubated with bronchoscopic guidance, and 8 of 58 patients intubated otherwise (i.e., direct laryngoscopy or blind nasotracheal technique). Five patients (all in the nonbronchoscopic group) required emergency reintubation that proved to be very difficult, with two near fatalities and one death. Although the two groups were similar with regard to age, gender, American Rheumatology Association classification, ASA physical status, duration of surgery and anesthesia, fluid balance, and postoperative immobilization, there were significant differences in time to extubation. Seven of the patients could not be intubated by flexible bronchoscopy and were therefore intubated by a nonfiberoptic technique. The patients were not randomized to different methods; criteria for the method of intubation and techniques were not described; all patients were intubated awake; and the study was carried out over an 11-year period.[261] Although it is not possible to draw firm conclusions from this study, there was a high incidence (7%) of post-extubation stridor and difficult or failed reintubations, regardless of the intubation technique.

Patients with rheumatoid arthritis qualify as higher-risk extubation cases because they may have a fixed or unstable cervical spine, TMJ ankylosis, difficult intubations by direct or flexible laryngoscopy, and increased risk of post-extubation airway obstruction. Several investigators have recommended postponing extubation until the patient is wide awake. Unfortunately, this provides increased protection against nothing other than laryngospasm and aspiration. The prevailing wisdom is that patients with limited mouth opening and a potentially unstable cervical spine should be intubated with a flexible bronchoscope.[250] This method involves blind passage of the ETT through the cords, which may be traumatic,[91,261] particularly in the face of preexisting cricoarytenoid arthritis. Regional anesthesia should be considered as an alternative to general anesthesia when appropriate. When intubation cannot be avoided, proposed extubation strategies include a preemptive tracheostomy or a method that increases the reversibility of extubation. Neither strategy has been prospectively evaluated in this population.

4. Tracheomalacia

Tracheomalacia is a dynamic airway obstruction resulting from loss of the cartilaginous tracheal support. This results in the posterior membranous wall bulging anteriorly when the intratracheal pressure is reduced or the intrathoracic pressure is increased.[141] Although rare, it should be considered when the patient has dyspnea on exertion with difficulty clearing secretions and a seal-like, incessant cough.[141,262]

Patients frequently are misdiagnosed with asthma and fail to respond to escalating therapy. Pulmonary function tests (i.e., forced expiratory volume at 1 second, forced vital capacity, and peak expiratory flow) show severely diminished expiratory flow with relative preservation of the inspiratory flow. The diagnosis may be confirmed

fiberoptically during spontaneous breathing. Tracheomalacia may be congenital[263] or result from vascular compression,[264] an intrathoracic goiter,[265] chronic obstructive pulmonary disease, or prolonged intubation. The latter may be caused by ETT cuff-induced erosion of the tracheal cartilage with or without extension to the membranous trachea.

The severity of the dynamic obstruction is proportional to the expiratory force. It may be unapparent during quiet breathing but disabling in a distressed patient. Positive pressure or bypassing the lesion with a tracheal tube provides temporary relief while further management options are considered. They may include medical management, surgical resection, or placement of a stent.[262] Additional suggestions for the extubation of a patient with suspected tracheomalacia are described later.

Relapsing polychondritis is an example of extensive tracheobronchomalacia. It is a rare, multisystem disease characterized by episodic inflammation of cartilaginous structures resulting in tissue destruction.[262,266] Laryngeal and tracheal tract involvement occurs in approximately one half of patients. It usually occurs early in the course of the disease and may manifest as hoarseness, nonproductive cough, shortness of breath, and stridor. Upper airway obstruction is usually diffuse and may progress to involve the glottis, subglottic area, trachea, and bronchial cartilages. Histologically, there is evidence of perichondral inflammation and replacement of cartilage by fibrous tissue that manifests as inflammatory swelling and progressive destruction of cartilage. The clinical manifestations range from bronchorrhea and recurrent pneumonia to airway collapse. Medical management consists of steroids, nonsteroidal anti-inflammatory drugs, and immunosuppressant agents, but their benefit varies. Surgical management consists of external airway splinting or self-expanding metallic stents. These patients may present for bronchoscopy, tracheostomy, tracheal or nasal reconstruction, aortic valve replacement, or stent placement.[264,267-271] Airway collapse after extubation should be anticipated and may be temporarily dealt with by CPAP.[272,273]

5. Obstructive Sleep Apnea Syndrome

In the ASA Closed Claims Project analysis of adverse respiratory events, 65 of the 156 perioperative events involved obese patients; for the claims specifically related to extubation, 12 of the 18 were obese, and 5 of these patients had been diagnosed with OSA.[2] OSA correlates positively with age and obesity, both of which are becoming increasingly prevalent. The pathophysiology and perioperative airway management of OSA in obese patients has been comprehensively reviewed.[274-276] Many surgical patients have undiagnosed or untreated OSA. OSA syndrome is associated with an increased risk of gastroesophageal reflux, difficult mask ventilation[276-278] and laryngoscopic intubation,[279-282] and accelerated arterial oxygen desaturation.[276,283] The risk of airway obstruction after surgery is increased for patients with OSA; life-threatening post-extubation obstruction occurred in 7 (5%) of 135 patients.[279,284] Rapid desaturation, difficult mask ventilation, and difficult direct laryngoscopy make this a particularly high-risk setting.[285] The ASA practice guidelines for the management of patients with OSA provided limited guidance beyond a strong recommendation that they be fully awake and that the airway manager verify that neuromuscular blockade is completely reversed before extubation. If possible, extubation and recovery should be carried out in the lateral or semi-upright position,[286] nasal CPAP should be available or routinely implemented, and consideration should be given to extubation over a tube exchanger.[274,276,280,284,287] These strategies have been associated with better outcomes, and anecdotal comparisons are compelling, but they have not been subjected to controlled, randomized trials, and they were not addressed by the ASA Task Force.

6. Laryngeal Incompetence

Laryngeal function may be disturbed for at least 4 hours after tracheal extubation.[288] Immediately after extubation, 8 (33%) of 24 patients aspirated swallowed radiopaque dye; 5 showed radiologic evidence of massive aspiration. Four hours after extubation, 4 (20%) of 20 patients aspirated dye; 3 had massive aspirations. At 24 hours, the rate was reduced to 5%. In this study, patients had been intubated for 8 to 28 hours during and after cardiac surgery. Although the investigators did not observe a relationship between duration of intubation (8 to 28 hours) and aspiration, it is unclear whether the presumed laryngeal incompetence occurs after brief intubation or is more common and severe with prolonged intubation. The mechanism of laryngeal incompetence was postulated to be primarily sensory because patients who aspirated dye did not cough.

Residual neuromuscular paralysis is a common problem in postoperative patients and may result in hypoventilation, hypoxemia, pharyngeal and laryngeal dysfunction, or increased pulmonary aspiration.[264,289] Pharyngeal function was impaired in conscious volunteers receiving a continuous infusion of vecuronium and resulted in laryngeal penetration of contrast medium proportional to the degree of blockade.[290] Relaxation of the upper esophageal sphincter was also observed. None of the volunteers coughed or had respiratory symptoms. Berg and colleagues found a higher incidence of postoperative pulmonary complications (i.e., pulmonary infiltrate or atelectasis associated with cough, sputum, or shortness of breath) among patients randomly assigned to receive a long-acting or intermediate-acting neuromuscular blocker.[291] It is intriguing to speculate on how residual neuromuscular blockade may contribute to laryngeal incompetence.

7. Pulmonary Aspiration of Gastric Contents

Although more patients are being diagnosed with gastroesophageal reflux, the diagnosis of perioperative pulmonary aspiration has not increased.[292,293] Aspiration is estimated to complicate 1 of 2000 to 3000 general anesthetics and was responsible for only 3 of 156 perioperative events in the ASA Closed Claims Project review.[2,293,294] Nonetheless, it is the leading cause of pneumonia in the ICU and a common cause of acute respiratory distress syndrome.[295] Many of these cases are ventilator-associated pneumonia and occur with the ETT in situ. Factors predisposing a surgical patient to aspiration include

emergency surgery, pain, obesity, narcotics, nausea, ileus, bowel obstruction, pregnancy, some surgical positions, depressed level of consciousness, inadequate depth of anesthesia, postoperative drowsiness, and residual neuromuscular blockade. Despite the ubiquity of these conditions, perioperative aspiration is not commonly identified. Before intubation, difficult bag-mask ventilation may result in gastric distention, which may be further complicated if laryngoscopy proves difficult because it may delay securing the airway. Repeated laryngoscopic attempts may cause edema, thereby increasing glottic resistance. Aspiration may also result from obtundation or conditions that impair vocal cord apposition (e.g., vocal cord paralysis, laryngeal incompetence, residual neuromuscular blockade, granulomas). Aspiration can cause serious morbidity and death.[292-295]

Although most incidents of aspiration seem to occur at induction, many occur during maintenance and recovery from anesthesia.[296] Numerous strategies have been described to reduce the risk at induction, but relatively little information is available on how best to prevent this later. Premature extubation, postoperative nausea, delayed gastric emptying, residual neuromuscular blockade, relaxation of the esophageal sphincters, decreased level of consciousness, gagging on an ETT, supine recovery, and impaired laryngeal competence may make emergence from anesthesia and tracheal extubation as problematic as induction. A kinked or clamped nasogastric tube may promote regurgitation and aspiration. Evidence-based recommendations on an extubation strategy to reduce aspiration are not available. It would seem logical to minimize the contributing factors: postoperative nausea and vomiting, residual neuromuscular blockade, decreased level of consciousness and associated diminished protective airway reflexes, and gastric evacuation. We do not know whether gastric decompression reduces aspiration; a well-seated i-gel SGA[297] or ProSeal LMA may or may not offer some protection from aspiration.[298-300] With the current information, it is not appropriate to recommend the elective use of these devices in a patient at increased risk for aspiration.

V. FACTORS AFFECTING INTUBATION AND EXTUBATION

A. Previously Encountered Airway Difficulties

Multiple attempts at laryngoscopy by experienced personnel, a need for alternative airway management techniques due to failure of direct laryngoscopy, and prior difficulty prompting the primary use of alternative techniques are settings in which reintubation may be problematic. In urgent or emergent circumstances, methods that had previously been successful may not be available or appropriate. The required equipment, necessary skills, or time required to perform alternative techniques may not be available. Uncertainty regarding the ease of ventilation or intubation may correctly lead to disinclination to administer paralytic and sedating drugs. Although they may facilitate ventilation and intubation, failure will result in an apneic patient who can neither be ventilated nor intubated. Knowledge of prior difficulties may result in intubation conditions that are less favorable to success. Repeated attempts at laryngoscopy are associated with a significant increase in the risk of hypoxemia, esophageal intubation, regurgitation, aspiration, bradycardia, and cardiac arrest.[2,301] To avoid this risk, flexible bronchoscopic intubation may be considered, but in an agitated, hypoxic patient with secretions or blood in the airway, it may be difficult to achieve adequate topical anesthesia, and the procedure may be difficult or impossible.

B. Limited Access

Limited access to the airway is exemplified by intermaxillary fixation, severe cervical restriction, instability, or immobilization, and the chin-to-chest guardian suture (see Fig. 50-1) to prevent traction tracheal resection. More commonly, this situation may arise in the confining space of a PACU, ICU, or patient room where access is limited. In each case, there may be additional risks related to oxygenation, ventilation, airway obstruction, or pulmonary toilet. For example, after cervical fixation or orthognathic surgery, the patient may have macroglossia or supraglottic edema. A patient requiring tracheal resection may be unable to clear blood or secretions from the airway.

C. High-Risk Cases

A higher-risk extubation exists when there is an increased likelihood that reintubation will be necessary or an increased risk that reestablishing the airway will be difficult. The increased need to reintubate may result from failure of oxygenation, ventilation, pulmonary toilet, or loss of airway patency. These risks cannot always be anticipated, but there are often identifiable patients with less reserve. The clinical conditions previously discussed, including OSA; rheumatoid arthritis; cervical, tracheal, thyroid, or carotid surgery; and intermaxillary fixation, are higher-risk settings because reintubation may be challenging.

The clinical playing field may not be level at all hours of the day. The immediate availability of highly trained primary and support personnel, equipment, and the necessary clinical information may be problematic at night or during periods of intense activity. The ASA Task Force on Management of the Difficult Airway and the Canadian Airway Focus Group recommended a preformulated strategy for extubation of the difficult airway.[5,6] The ASA Closed Claims Project supported the need for such a strategy.[2] Patients at risk for hypoventilation, hypoxemia, and loss of airway patency have been discussed. The remainder of this chapter addresses specific extubation strategies.

VI. EXTUBATION STRATEGIES

If any of the higher-risk extubation conditions exists or is anticipated, the clinician should consider a strategy that does not cut off access to the airway. Ideally, the strategy should permit continued administration of oxygen or ventilation of a failing patient even while the airway is

being reestablished. These objectives are consistent with the ASA Task Force and Canadian Airway Focus Group recommendations.[5,6]

Extubation risk stratification is largely based on intuition, anecdotal reports, and limited clinical series. The proposed classification and strategies are becoming broader and deeper with time. Because most patients—even those at high risk—can be successfully extubated, any proposed strategy must entail less risk than removing the tracheal tube and hoping for the best. It should also involve minimal discomfort, have an acceptable cost, and facilitate oxygenation, ventilation, and reintubation.

A. Deep versus Awake Extubation

Extubations may be performed before or after recovery of consciousness. Deep extubation ordinarily occurs after full recovery of neuromuscular function and the resumption of spontaneous ventilation. Its purported advantage is avoidance of the adverse reflexes associated with extubation, such as hypertension, dysrhythmias, coughing, laryngospasm, and increased intraocular or intracranial pressures. The fundamental disadvantage of deep extubation is the patient's inability to protect his airway against obstruction and aspiration. When deep extubation is improperly executed, laryngospasm and its attendant complications are more likely to occur. Although not having to wait for the recovery of consciousness may accelerate operating room turnover, this approach is more difficult to justify when anesthetic agents having a faster elimination time are available. Delays in recovery usually are brief. Unscavenged volatile anesthetic agents may also represent an occupational health hazard. A significant proportion of American anesthesiologists practice the technique, at least some of the time, but there are few data for adults that compare the safety of deep extubation with that of awake extubation.[12] Koga and colleagues compared three small groups of adult patients who underwent deep extubation, awake extubation, or deep extubation after the insertion of an LMA.[80] Straining occurred in a high (but comparable) proportion of patients whether the ETT was removed before or after recovery of consciousness.

Current strategies include extubation on low-dose propofol or remifentanil and intracuff or intravenous lidocaine, which may reduce coughing and straining on extubation. Deep extubation followed by LMA insertion (with 2% to 3% isoflurane) is discussed later. Deep extubation is contraindicated when mask ventilation was or is likely to be difficult, the risk of aspiration is increased, endotracheal intubation was difficult, or airway edema is likely.

B. Extubation with a Laryngeal Mask or Other Supraglottic Airway

On emergence from general anesthesia, most patients tolerate an LMA with less coughing and changes in intraocular, intracranial, and arterial pressures (see Fig. 50-1).[57,77,80,302,303] Silva and Brimacombe substituted an LMA for the ETT in a small series of patients while still asleep and paralyzed after completion of neurosurgical procedures.[304] Muscle relaxation was then reversed, and the anesthetic was discontinued. The LMAs were removed when the patients resumed spontaneous ventilation and obeyed commands. None of the 10 patients coughed, and changes in the rate-pressure product (indicating cardiac oxygen requirements) were minimal. The investigators concluded that the technique might prove useful in patients undergoing other types of surgical procedures. They stressed that this substitution should be performed only by those skilled in LMA insertion. Patients must be at a sufficient depth of anesthesia or coughing, breath-holding, laryngospasm, and the very pressor responses this substitution is intended to avoid may occur. Bailey and others recommended that the LMA be inserted before removal of the ETT to prevent losing the airway after tracheal extubation.[80,305] Compared with deep tracheal extubation followed by Guedel airway insertion, there was a lower incidence of coughing and requirement for airway manipulation.[305] Koga and coworkers compared this technique with deep and awake tracheal extubation.[80] They observed no difference in recovery conditions between patients in whom the ETT was removed by deep or awake methods; however, they noticed a significant improvement in recovery conditions when the LMA substitution was performed. This technique is useful but can jeopardize a secure airway if not properly executed. It should be practiced on routine airways before use in higher-risk extubations.[306] Brimacombe suggested (personal communication, December 2010) that a ProSeal LMA or LMA Supreme with a gum elastic bougie inserted through the drainage tube could produce a more secure substitution for an ETT.[307]

Sometimes, it is desirable to perform the exchange of an ETT for an SGA in reverse. Several types of tube exchanges have been described. Asai wanted to replace a damaged ETT in a patient who had been a difficult intubation.[308] He inserted an LMA Classic behind the existing ETT. A fiberoptic bronchoscope (FOB) with a replacement 7-mm ETT was introduced through the LMA; the FOB was advanced through the vocal cords, and the original ETT was removed. The new ETT was then advanced over the FOB, which was removed. To extend the length of the ETT to enable its removal from the LMA, another ETT was inserted into the proximal end of the replacement ETT.[308] This technique was complicated and could easily have failed.

Matioc and Arndt wished to substitute an ETT for a ProSeal LMA.[309] Using an Arndt Airway Exchange Catheter Set (Cook Critical Care, Bloomington, IN) (see Fig. 50-6), they introduced an FOB through the ProSeal LMA into the trachea. The set comes with a 144-cm extrastiff Amplatz guidewire, which was passed through the FOB, and the latter was removed. An 11-F, 70-cm, Cook airway exchange catheter (CAEC) was introduced over the guidewire and the ProSeal LMA was removed. The replacement ETT was then advanced over the exchange catheter.

A simpler approach involving the Aintree intubation catheter (Cook Critical Care) has been described with a variety of SGAs, including the cuffed oropharyngeal airway (COPA),[310] the LMA Classic,[311-313] the LMA

ProSeal,[314,315] and the LMA Supreme.[316] The Aintree intubation catheter is 56 cm long and has an internal diameter (ID) of 4.7 mm; its outer diameter (OD) is 6.3 mm (19 F). A bronchoscope (<4 mm) can be inserted through the device, leaving 3 or 4 cm protruding beyond its tip. A 7-mm or larger ETT can be advanced over it. Only the distal 3 to 4 cm of the protruding bronchoscope is flexible, but it is usually sufficient to allow successful maneuvering into the trachea, after which the SGA is removed and a replacement ETT is advanced over the Aintree catheter. A Rapi-Fit adapter is provided to enable positive-pressure ventilation while the substitution is performed. The Aintree intubation catheter and FOB are inserted together through the SGA. There are several advantages of this technique.[315,317] It can be used to facilitate conversion from an unmodified LMA to an oral ETT of adequate size. Sufficient length allows the LMA to be removed with minimal risk of losing the airway. The Aintree intubation catheter fits tightly to the insertion cord of the FOB and to the ETT, thereby reducing the size discrepancy that often results in difficult glottic passage. The catheter can be used as a conduit for manual or jet ventilation during an exchange. An LMA Classic, inserted as a rescue device (for "cannot intubate, cannot ventilate" cases) can facilitate safe tube exchange without the need for an intubating LMA.

C. Extubation or Reintubation over a Fiberoptic Bronchoscope or Laryngoscope

When tube entrapment is a possibility, extubation over an FOB can avert a disastrous outcome. For a spontaneously breathing patient, extubation over an FOB provides the opportunity of visually assessing the trachea and laryngeal anatomy and function. This can help in the patient suspected of having tracheomalacia, vocal cord paresis, or PVCM. It also permits assessment of supraglottic structures.[318] These opportunities can be maximized by reassuring the patient and by providing judicious sedation, an antisialagogue, and the use of a Yankauer sucker for oral secretions. The oropharynx is suctioned, taking care to avoid inducing a gag reflex. The FOB is placed above the carina, and the cuff is slowly deflated to minimize coughing. The ETT is slowly withdrawn into the oropharynx, followed by very gradual withdrawal of the FOB to the supraglottic region. After the patient is comfortable, the FOB is further withdrawn to a position just above the vocal cords. Even with this deliberate technique, the exercise is frequently frustrated by excessive secretions, coughing, swallowing, or poor tolerance with insufficient opportunity of visualizing the structures of interest.

If the technique is successful, it may identify problems and anticipate complications. When significant abnormalities are identified, a decision must be made about whether to immediately reinsert the ETT or withdraw the FOB and manage the patient with agents such as corticosteroids, racemic epinephrine, and helium-oxygen.[149,152] This technique is not practical for performing a trial of extubation, in part because such a trial lasts only seconds or minutes.

Watson endorsed the use of an FOB to exchange ETTs, citing the advantages of minimal sedation, risk of aspiration, hemodynamic embarrassment, and uncertainty about tube placement.[319] His technique involved passing the loaded FOB alongside the existing ETT. He had used this technique successfully in 13 of 15 attempts. Dellinger suggested that use of an FOB to perform tube exchanges offered the greatest likelihood of reintubation success and recommended techniques for conversion from nasal to oral, oral to nasal, and oral to oral ETT exchange in addition to extubation.[318] We have found this method of extubation to be unreliable and one that demands immediate and often incorrect clinical judgment.

D. Extubation with a Supraglottic Airway with or Without a Bronchoscope

Extubation of a difficult airway over an FOB or SGA has the limitations previously described, but the combination of these devices offers significant advantages. Replacement of an ETT with an SGA provides an excellent means of performing a fiberoptic assessment of glottic and subglottic anatomy and function. After the substitution is performed and the patient is under anesthesia or a suitable degree of sedation, muscle relaxation can be reversed and spontaneous ventilation allowed to resume. An FOB is then passed through the SGA, and vocal fold movement and appearance can be assessed while the concentrations of oxygen and volatile agents (if necessary) can be controlled. The view is protected from oral secretions, and inadequate ventilation can be supplemented. PVCM or tracheomalacia can be visually and functionally evaluated, although both may be minimal if the patient is deeply anesthetized.

This technique is useful in patients with recurrent post-extubation stridor or those at risk for static or dynamic tracheal stenosis. We frequently employ this technique in patients undergoing thyroidectomy when tracheomalacia or vocal fold paralysis is suspected.[181]

E. Use of a Gum Elastic Bougie or Mizus Endotracheal Tube Replacement Obturator

Finucane and Kupshik described an awake, blind nasal intubation in a patient with cervical instability, but the cuff became damaged, requiring a tube exchange.[320] They used the 63-cm-long, 4-mm-OD plastic sleeve from a brachial central venous catheter as a tube exchanger. Others have used a gum elastic bougie to achieve similar objectives.[321-324]

Cook Critical Care designed the Mizus Endotracheal Tube Replacement Obturator (METTRO) for the replacement of endotracheal and tracheostomy tubes (Fig. 50-2). It is available in two sizes: 70 cm long (7.0 F, 2.3 mm) for replacement of ETTs as small as 3 mm and 80 cm long (19 F, 6.3 mm) for passing through tubes 7 mm or larger. The METTRO is a single-use, flexible, radiopaque, solid device with a tapered tip and distance markings. The package insert instructs the user to advance this device until resistance is encountered, but this recommendation can result in coughing, discomfort,

Figure 50-2 The Mizus Endotracheal Tube Replacement Obturator (METTRO) is a solid device that is tapered at the end. It is available in two diameters (7 and 19 mm) and two lengths (70 and 80 cm). The figure shows the proximal *(bottom)* and distal *(top)* ends of one of these. (Courtesy of Cook Critical Care, Bloomington, IN.)

Figure 50-3 An Endotracheal Ventilation Catheter (ETVC) properly secured tube exchanger.

hypertension, and tachycardia. Tracheal perforation has been reported using different devices but following similar recommendations.[325,326]

The smaller airway obturator has been used to maintain airway access during tracheostomies in 22 patients and for "tentative extubations" in 7 patients.[327] The smaller-caliber device was preferred by Audenaert and colleagues because patient discomfort was minimal during tube exchanges and the device was unobtrusive during surgical tracheostomies. The obturator was removed when it was apparent that the patient was unlikely to require reintubation. The 19-F obturator was not conducive to spontaneous breathing. Chipley and coworkers used a METTRO in an obese patient with a fractured occipital condyle recovering from respiratory failure.[328] They left this in place for 48 hours, removing it when extubation appeared to be successful. They also described the use of the obturator to stimulate coughing, although this might have been ill advised given the possibility of tracheal perforation. The METTRO obturator is being phased out and will soon be unavailable.

In a modification of the Eschmann gum elastic bougie (Intubation Guide, Smiths Medical, Keene, NH), both ends of the bougie were amputated, exposing a hollow core. A cannula, syringe, and ETT connector enabled this assembly to be connected to an oxygen source.[329]

F. Use of Jet Stylets

The ubiquitous nasogastric tube has been used as an exchange catheter,[330] but these devices are specifically formulated to become softer as they are warmed. This thermolability is not a desirable characteristic for a tube exchanger.

Bedger and Chang coined the term *jet stylet* to refer to a self-fashioned, 65-cm-long, plastic catheter with a removable 15-mm adapter at the proximal end. It could be connected to an anesthesia machine or jet injector.[331] They created three side ports cut into the distal 5 cm to minimize catheter whip during jet ventilation. They used the stylet for extubation or reintubation of 59 patients. It also functioned adequately in patients when it was used for jet ventilation and oxygen insufflation. Although no complications were described in this series, in an earlier report, Bedger and Chang described tension pneumothoraces in 3 of 600 patients ventilated through a 3.5-mm-OD pediatric chest tube at 15 psi.[332] This stylet had been used to provide airway access and ventilation during direct laryngoscopy. They speculated that the pneumothoraces might have resulted from endobronchial migration of the catheter. They did not consider the possibility that barotrauma occurred as a result of jet ventilation against apposed vocal cords as the patients were recovering from neuromuscular blockade.

G. Use of Commercial Tube Exchangers

Several commercial products incorporate many of the features described by Bedger and Chang.[331] They are long, hollow catheters that may include connectors for jet or manual ventilation. Most have distance and radiopaque markers. They also have end and distal side holes. They can be introduced through an existing ETT, permitting its withdrawal. Oxygen insufflation or jet ventilation can be provided through the tube exchanger. Respiratory monitoring can be achieved by connection to a capnograph. Spontaneous breathing may take place around the device. In most reports, these catheters have been tolerated well enough that they can be left in situ until it is unlikely that reintubation will be required. They must be properly secured to ensure that they do not come out prematurely (Fig. 50-3). Even with the catheter in place, most patients will be able to talk or cough.

If reintubation or a tube exchange is required, it can be facilitated with gentle laryngoscopy, not necessarily to reveal the glottis but to retract the tongue. Reintubation using a tube exchanger is similar to intubation over an FOB, and the difference of diameters between the tube exchanger and the advancing ETT may predict the relative ease of tube advancement. It is wise to delegate someone to secure the exchange catheter during reintubation. If resistance is encountered, ETT rotation may successfully release the tube from the piriform fossa, "vocal cord," or arytenoid cartilage, but it is best to

minimize the size discrepancy by choosing a larger-diameter tube exchanger or a smaller-diameter ETT.

These devices are consistent with practice guidelines from the ASA Task Force and Canadian Airway Focus Group recommendations regarding the extubation of the difficult airway.[5,6] They increase the probability that reintubation will succeed; if difficulty is encountered, the device can provide a conduit for oxygen insufflation. Jet ventilation, if necessary, can be accomplished while alternative techniques are explored. This may be thought of as a reversible or staged extubation. With the device in place, other options can be pursued, including evaluation of the benefits of helium-oxygen mixtures or inhalation of racemic epinephrine. Knowing that the patient is satisfactorily oxygenated and ventilated, the airway manager can recruit additional information, equipment, and expertise.

The differences between these commercial products are far less important than the concept of a reversible extubation. In our opinion, reintubation of the high-risk patient may be unlikely, but it must have a high probability of success.

1. Tracheal Tube Exchangers

The most basic commercial tube exchangers are the Sheridan T.T.X. (Hudson Respiratory Care Inc. [RCI], Temecula, CA) (Fig. 50-4) and the JEM Endotracheal Tube Changer (Instrumentation Industries Inc., Bethel Park, PA). The T.T.X. devices are available in four ODs (2.0-, 3.3-, 4.8-, and 5.8 mm) and two lengths (56 and 81 cm). The smallest can be inserted into tracheal tubes with IDs as small as 2.5 mm. A longer, 100-cm endobronchial exchanger (Sheridan E.T.X.) is available for exchanging double-lumen tubes. They are firm—Shore hardness of 85, the same durometer measurement as the CAEC and Cardiomed International's Endotracheal Ventilation Catheter (ETVC)—although thermolabile and therefore subject to softening with heat. They are frosted to minimize drag and have a radiopaque stripe and distance markings. They have no side holes or connectors. An alternative product, the Sheridan JETTX Exchanger, is a longer device (100 cm), but it is available in only a single OD that is suitable for ETTs greater than 6.5-mm ID. It incorporates a proximal slip-fit connector that can be connected by a Luer-Lok to a jet ventilator. As with the T.T.X., there is only a single, distal end hole.

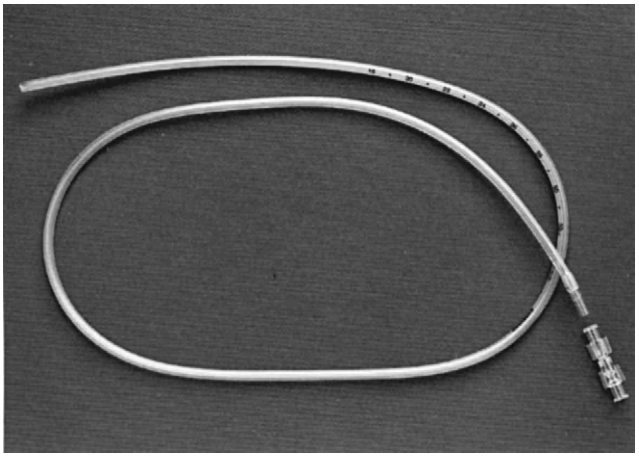

Figure 50-4 The tracheal tube exchanger (Sheridan T.T.X., Hudson RCI) is a simple catheter with no proximal or distal modifications. These devices are available in four diameters and two lengths. If the device is to be used for ventilation, it must be adapted by the user. There are no distal side ports, which makes jet injection potentially hazardous. (From Cooper RM: The difficult airway–II. *Anesthesiol Clin North Am* 13:683–707, 1995.)

The JEM devices are available in nine sizes and are compatible with ETTs from 2.5- to 7.5-mm ID (JEM 325 to 400). These are single-use, high-density, polyethylene devices without proximal connectors or distal side holes.

2. Cook Airway Exchange Catheters

Cook Critical Care has developed a family of hollow stylets known as CAECs (Fig. 50-5A). They are available in 8.0-, 11-, 14-, and 19-F sizes, corresponding to 2.7-, 3.7-, 4.7-, and 6.3-mm ODs, respectively. They can be used to exchange ETTs with IDs of 3, 4, 5, and 7 mm, respectively. The 8-F CAEC is 45 cm long, and the others are 83 cm long. The devices are radiopaque, have distance markings between 15 and 30 cm from the distal end, and have two distal side holes and an end hole. Proximally, two types of connectors are secured and released by a patented Rapi-Fit adapter (see Fig. 50-5B). They provide a 15-mm connection or a Luer-Lok jet ventilation attachment and were designed for rapid removal and reattachment while the tracheal tube is being off-loaded and replaced. The length and IDs (1.6 to 3.4 mm) make manual ventilation with a resuscitation bag possible but useful only for short periods because resistance is very high. The Luer-Lok jet Rapi-Fit connector allows jet ventilation, but the paucity of distal side holes potentially increases catheter whip and the risk of barotrauma.[333]

Atlas and Mort examined the relationship between the diameter of the two larger CAECs and tolerance, as well as the ability to phonate and cough.[334] It is unclear whether their patients were randomly assigned to specific sizes of catheters. Phonation and discomfort were similar in both groups, with only 3 of 101 patients experiencing significant discomfort. Cough effort tended to be reduced with the larger CAEC, but this did not achieve significance. Atlas and colleagues also looked at a larger tube exchanger (JEM 400 Endotracheal Tube Changer, Instrumentation Industries Inc.), which they reasoned would have a higher degree of success as a tube exchanger. This device has an OD of 6.35 mm and is said to be stiffer. They adapted the JEM 400 using the Rapi-Fit connector from the CAEC 19-83 to enable jet ventilation.[335] This device, like the Sheridan JETTX, has only a single end-hole and is not recommended for jet ventilation.

Mort evaluated the concept of reversible extubation in patients with difficult airways.[336] From an institutional database, he identified patients who were extubated in the operating room, PACU, or ICU with a CAEC. The tube exchanger was left in place until the need for reintubation was considered unlikely. Over a 9-year period, 354 patients qualified. Two groups emerged: those who required reintubation while the AEC was still in place and another group who required reintubation within 7 days but after the AEC had been removed. Airway-related complications were compared for the two groups. The AEC dwell time was a mean of 3.9 hours (range, 5

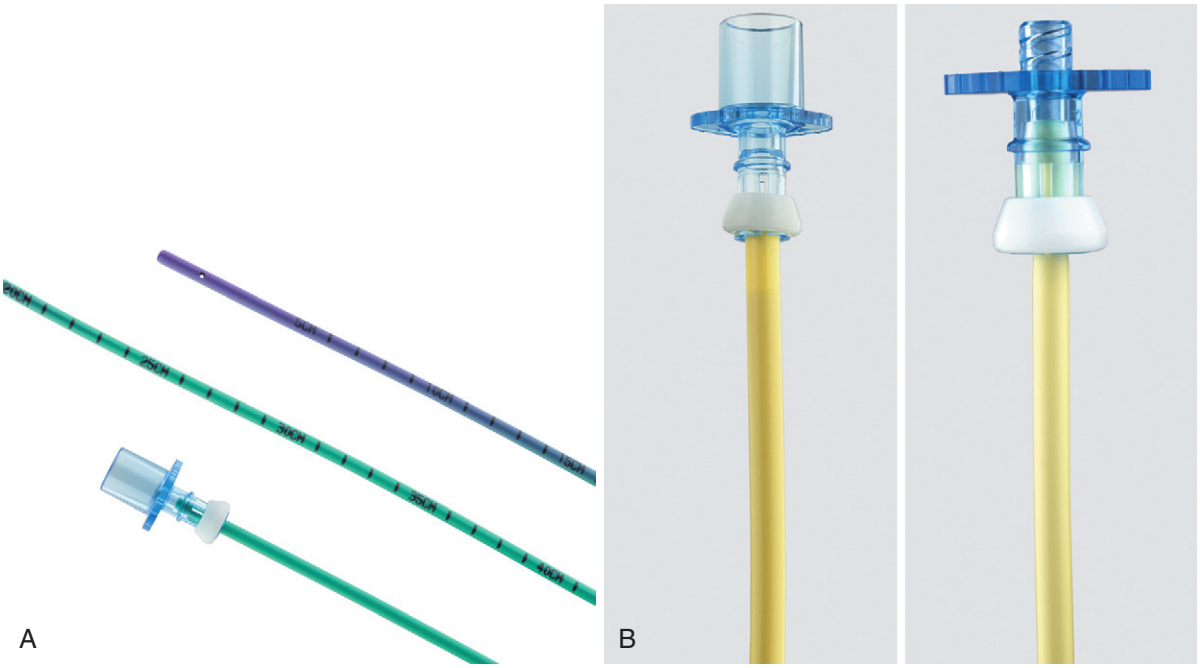

Figure 50-5 The Cook airway exchange catheters are available in four diameters and two lengths. They are radiopaque and have distance markings at each centimeter throughout the working length. **A,** The proximal Rapi-Fit adapter, the middle section, and the distal end of a flexible-tip exchange catheter (available only on the double-lumen exchange catheter). Notice that there are two distal side holes and one end hole. **B,** Two Rapi-Fit adapters: a Luer-Lok jet adapter *(right)* and a 15-mm connector *(left)*. (Courtesy of Cook Critical Care, Bloomington, IN.)

minutes to 72 hours). Of 354 patients, 288 were extubated in the ICU and had previously required three or more laryngoscopic attempts or alternative devices to achieve intubation. Comparing the overall success rate in the two groups, 47 of 51 patients in the AEC group were successfully reintubated, 87% on the first attempt. The four failures in this group resulted from inadvertent removal of the AEC in three; one patient was rescued with an intubating LMA and flexible bronchoscope. Mild (SpO_2 < 90%) and severe hypoxia (<70%) were experienced by three and four patients, respectively. Of the 37 patients requiring reintubation without an AEC, the first pass success rate was only 14%, with mild and severe hypoxia in 50% and 19%, respectively; three or more laryngoscopy attempts in 28 of 36 patients; and the need for a rescue device in 32 of 36 patients.[336] In all cases, reintubation was attempted by a member of an anesthesia airway team: an attending anesthesiologist or a resident under direct supervision. Although reintubation over an AEC does not guarantee first-pass success, this strategy was strikingly more effective (87% versus 14% first-pass success) and had far fewer life-threatening complications.

3. Arndt Airway Exchange Catheter

The Arndt Airway Exchange Catheter (Cook Critical Care), a radiopaque exchange catheter, consists of an extrastiff Amplatz guidewire with positioning marks, a Rapi-Fit adapter, a bronchoscopic port, and a distally tapered 14-F (4.7-mm-OD), 70-cm-long AEC. It was designed for the exchange of LMAs, endobronchial tubes, and ETTs (Fig. 50-6). Bronchoscopy is performed through the existing airway device. The flexible end of the Amplatz guidewire is introduced through the working channel of the bronchoscope and under visual control and is advanced to the level of the carina. The bronchoscope is removed over the wire, taking care that it is neither advanced nor withdrawn. The Arndt AEC is advanced over the guidewire to the appropriate depth, determined by aligning the distance markings on the airway device with that of the AEC. The original airway is carefully

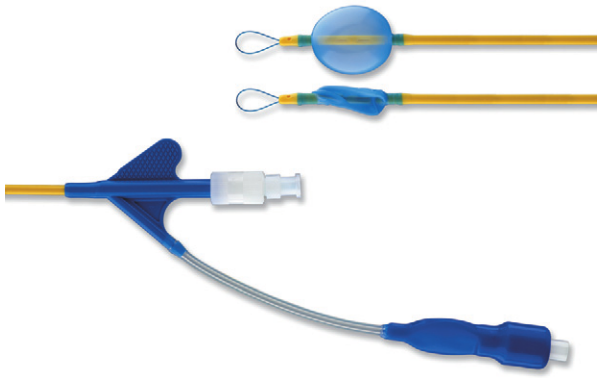

Figure 50-6 The Arndt Airway Exchange Catheter Set (Cook Critical Care, Bloomington, IN) consists of a bronchoscopic adapter, a stiff Amplatz guidewire, a tapered airway exchange catheter, and two Rapi-Fit adapters. The adapter permits continuation of positive pressure ventilation while a bronchoscope is introduced through the original endotracheal tube (ETT). The guidewire is inserted through the bronchoscope's working channel, and the original ETT and bronchoscope are withdrawn. A tapered exchange catheter is advanced over the guidewire, and it may be connected with a 15-mm or jet Rapi-Fit adapter to provide ventilation. The replacement ETT is then advanced over the exchange catheter.

removed, and its replacement is advanced over the AEC.[309]

4. Endotracheal Ventilation Catheter

Cardiomed's Endotracheal Ventilation Catheter (Lindsay, Ontario, Canada) is made of a hybrid plastic (Fig. 50-7). It is 85 cm long and has a 4-mm OD (12 F) and 3-mm ID. It has a radiopaque stripe along its entire length and distance markings at 4-cm intervals. Proximally, it has a male hose barb with a threaded adapter welded into the catheter. These attachments have been constructed to prevent restriction of the catheter's ID. The threaded adapter connects to an easily removed Luer-Lok adapter. Distally, it is blunt ended with one end hole and eight helically arranged side holes to minimize catheter whip and jet ventilation pressures. Unpublished studies by the manufacturer found no significant softening over time at body temperature. This is desirable for a product that may remain in situ and be required to serve as a stylet. A metal guidewire is available to provide additional stiffness, but we have not found this to be necessary.

The ETVC was designed to facilitate reversible extubation.[337] We have used it in at least 600 patients, the first 202 of whom has been reported.[338] Although the ETVC had been used to facilitate reintubation, this was not required in most cases. In the original series, reintubation or tube exchange was performed in 32 (16%) of 202 cases, a rate that was very similar to that reported by others.[339] In both series, the ETVC[338] and the CAEC[339] were used primarily to maintain airway access. In the original publication, the ETVC was used for oxygen insufflation (31 patients), jet ventilation (45 patients), and post-extubation capnography (54 patients).[338]

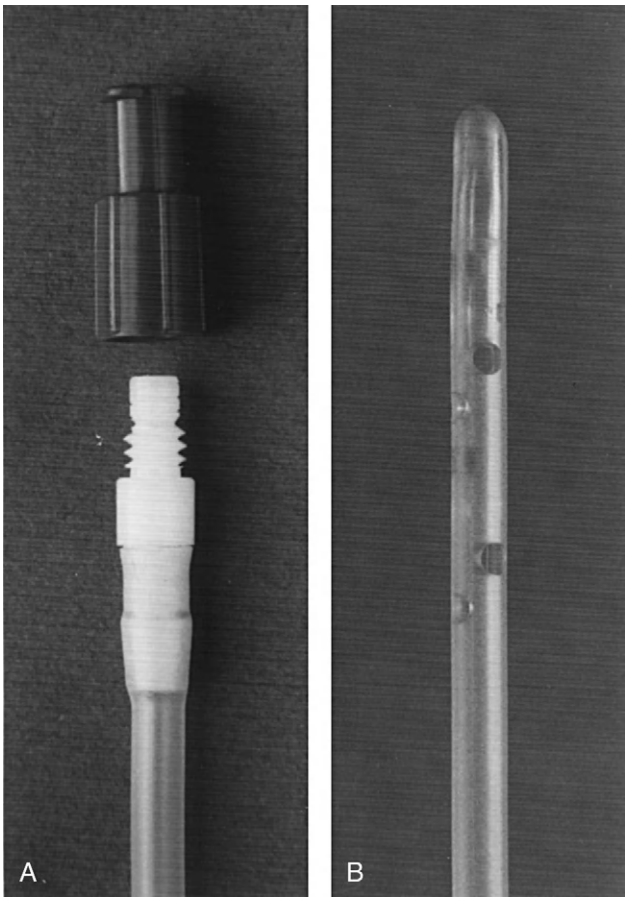

Figure 50-7 The Endotracheal Ventilation Catheter (ETVC) is available in one length (85 cm) with an outside diameter of 4 mm. It is nonthermolabile and has a radiopaque stripe along its length. There are distance markings every 4 cm. **A,** Proximally, there is a welded, barbed, plastic connector with a threaded Luer-Lok adapter for jet ventilation. **B,** Distally, there is a blunt end hole with eight helically arranged side holes, which minimize catheter whip and reduce the jet injection pressure.

Reintubation was successful in 20 (91%) of 22 attempts. One failure occurred with a softer prototype. The second failure resulted when an inexperienced and unsupervised operator attempted a tube exchange. Difficulty was occasionally encountered advancing the ETT through the glottis, similar to that experienced when using an FOB to intubate.[340] Tongue retraction with a laryngoscope blade should always be attempted when possible. ETT rotation or the use of an ETT such as the Parker Flex-Tip (Parker Medical, Boulder, CO) may prove useful. Because the ETVC has a relatively small OD, use of a smaller-diameter ETT is recommended.

Oxygen insufflation was achieved by connecting the male component of the ETVC to an oxygen flowmeter with 1 to 2 L/min flow rate, which was titrated to the arterial saturation. Jet ventilation is discussed later.

Complications included barotrauma, intolerance, unintended dislodgment, and tracheal perforation. Intolerance occurred in 2 of 202 patients (typically because of carinal irritation) and in 1 patient recently recovered from status asthmaticus. Intolerance should prompt reassessment of the depth of insertion. If the depth is clinically or radiographically appropriate, and the ETVC (or other AEC) continues to be required, tolerance usually can be achieved by instilling lidocaine through the device. Most patients, including those with reactive airways, have tolerated the ETVC without difficulty. Dislodgement occurred when the ETVC was inadequately secured or the patient "tongued" the catheter out. Proper fixation is essential (see Fig. 50-3). Tracheal or bronchial perforation with different instrumentation has been described.[325,326] In our case, it occurred in a patient with obstructing, proliferative tracheal papillomatosis and a chronic tracheostomy. A rigid prototype catheter was inserted alongside the tracheostomy, penetrating the posterior tracheal wall. Jet ventilation resulted in fatal barotrauma. Aspiration and laryngospasm have not been observed.

H. Exchange of Double-Lumen Tubes

Double-lumen tubes are selected for procedures requiring lung isolation. Although the resistance through a larger double-lumen tube does not preclude postoperative ventilation or weaning, it may be desirable to replace it with a single-lumen tube, particularly if care is to be transferred to an area where familiarity is lacking or ventilatory support may be prolonged. The double-lumen tube may have to be changed because of damage to a cuff or because the initial tube was an inappropriate size. Substitution can often be achieved by direct or indirect (e.g., video) laryngoscopy. While the larynx is in view, the double-lumen tube is withdrawn and immediately

replaced with a single-lumen tube or replacement double-lumen tube. Occasionally, this cannot be accomplished.[341] Whether the substitution is a single- to double-, double- to single-, or double- to double-lumen tube, the requirements are similar, and the previously described tube exchangers may not be sufficiently long or firm.[342,343]

The Sheridan E.T.X. Exchanger is 100 cm long and was designed for use with the Sheri-Bronch double-lumen tube (35 to 41 F). It has one distal end hole. There are distance markings and tracheal and bronchial markings to indicate when the distal tip of the E.T.X. is at the opening of the distal lumen. This device lacks a connector for manual ventilation, and the manufacturer recommends against the use of jet ventilation.

Extra Firm with Soft Tip tube exchangers (Cook Critical Care) are available in 11- and 14-F sizes. They are 100 cm long and were designed specifically for the exchange of double-lumen tracheal tubes (designations C-CAE-11.0-100-DLT-EF ST and CAE-14.0-100-DLT-EF ST). These devices have ODs of 3.7 mm and 6.3 mm, respectively. The *soft tip* refers to the distal 7-cm segment of the catheter.

1. Visually Assisted Tube Exchange

It is difficult to imagine a safer or more secure confirmation of a tube exchange than seeing one tube replace another. This is not always possible, but it sometimes may be achieved by combining techniques, such as indirect laryngoscopy (video laryngoscopy) with a tube exchanger, thereby providing security, visual verification, and a means of correcting difficulties with tube advancement.

The recently discontinued WuScope (Achi Corp., Fremont, CA, and Asahi Optical, Tokyo, Japan) has been used to exchange double-lumen tubes and conventional ETTs in patients with difficult airways.[344-346] The WuScope provided a good glottic view in a morbidly obese patient with adult respiratory distress syndrome and permitted insertion of a suction catheter anterior to the existing nasotracheal tube. The nasotracheal tube was withdrawn, and the replacement oral ETT was easily advanced over the suction catheter with minimal interruption of mechanical ventilation. We think that a visually direct tube exchange with a WuScope, Bullard Scope (Circon, Santa Barbara, CA), Upsher UltraScope (Mercury Medical, Clearwater, FL), or video laryngoscope is preferable to blind passage of an ETT over a flexible bronchoscope or tube exchanger. A hollow tube exchanger, however, would have permitted oxygen insufflation or jet ventilation had desaturation or difficulties with tube advancement occurred. A supraglottic view (in contrast to the infraglottic view provided by a flexible bronchoscope) of the exchange enables identification and correction of an ETT impingement or the outward migration of the exchange catheter.[347]

The concept of visually direct tube exchange was assessed retrospectively in a population in whom no view of the larynx could be obtained by direct laryngoscopy.[348] Using one of three indirect laryngoscopes—the Glidescope (Verathon Medical, Bothell WA), Airtraq (Prodol Meditec, Vizcaya, Spain), or McGrath Series 5 (Aircraft Medical, Edinburgh, Scotland)—in conjunction with an AEC, 51 exchanges were performed. Four of the cases involved a double-lumen tube converted to a conventional ETT or a nasal to oral conversion. Thirty-seven patients had previously difficult intubations requiring multiple attempts or a rescue technique. Most of the patients were obese or morbidly obese and had a positive fluid balance of more than 10 L over the previous 4 days. The intention of the study was not to compare the specific devices but rather to evaluate the advantages of visually directing the tube exchange. Mort reported that this was achieved on the first attempt in 47 of 49 patients.[348] In the two failures, use of the Glidescope video laryngoscope afforded an excellent view of the AEC migrating cephalad, allowing rapid reintubation with a styletted ETT. He pointed out that had the tube exchange been performed blindly, the replacement would have failed, with potentially serious consequences. Others have made similar observations.[349,350] These findings and our personal experiences are consistent with Mort's recommendations.

2. Conversion from Nasal to Oral Intubation

Blind or bronchoscopically assisted nasal intubation is sometimes performed when oral approaches are difficult or unsuccessful. The nasal tube may have to be converted to an oral one because of complications or the intended surgery. Whenever possible, this should be done under visual control, assisted by a flexible bronchoscope,[351] rigid fiberoptic device, or video or optical laryngoscope.[344,348] The more anatomically or physiologically challenging the patient, the more compelling the case for including a tube exchanger.

Gabriel and Azocar described a patient in halo fixation in whom the connector was detached and the nasotracheal tube was advanced deeper into the trachea.[352] The tube was then grasped close to the uvula with forceps and digitally extracted through the mouth. Novella used a Sheridan T.T.X. to convert a nasal to an oral tube in a patient with Klippel-Feil syndrome who first underwent orthognathic surgery and subsequent septorhinoplasty.[353] After completion of orthognathic surgery, the T.T.X. was inserted into the nasal tracheal tube, and the latter was withdrawn. The T.T.X. was then grasped with two Magill forceps; the caudal one was used to stabilize the catheter, and the cephalad one was used to withdraw the proximal end out of the mouth. An oral tube was then railroaded over the T.T.X. Cooper described a similar maneuver in a patient in whom oral fiberoptic intubation could not be accomplished, but fiberoptic nasal intubation was achieved.[354] He passed an ETVC through the existing nasal tube and removed the latter. The ETVC was then stabilized with caudal Magill forceps and withdrawn through the mouth with the cephalad forceps. Oxygen insufflation was provided through the ETVC, which was then used to thread an oral tube into the trachea. In this case, oxygen desaturation was avoided, although the procedure was easily and quickly accomplished.

3. Conversion from Oral to Nasal Intubation

During efforts to convert from an oral to a nasal tracheal tube, Sumiyoshi and coworkers used negative-pressure ventilation during the tube exchange.[355] Their patient was in a halo and chest cast due to a cervical injury, and

laryngoscopy had been unsuccessful. An attempt to introduce a 4.8-mm FOB adjacent to the existing tube (with a tube exchanger through it) was unsuccessful. A subsequent effort involved a 3.5-mm FOB and a 7-F METTRO using negative pressure to achieve ventilation. A smaller, hollow tube exchanger might have been successful and could have avoided the risk of negative-pressure pulmonary edema resulting from an ETT and FOB occupying a small glottic opening.[356] Smith and Fenner performed an oral to nasal conversion using a 4.0-mm-OD, flexible bronchoscope, which they inserted through the glottis and anterior to an oral tube.[357] The oral tube was withdrawn, and a nasal tube was advanced over the FOB. Many of the difficulties in performing a tube exchange can be avoided with the use of indirect (fiberoptic or video) laryngoscopes, ideally in combination with AECs.

4. Conversion from Supraglottic Airways to Endotracheal Tubes

A discussion of the conversion of various SGAs to ETTs is beyond the scope of this chapter, but the process is addressed elsewhere. Whenever possible, this conversion should be facilitated by visual guidance, using direct laryngoscopy or an indirect technique. These techniques include the use of a flexible bronchoscope and Aintree catheter or a video laryngoscope.[358,359]

5. Changing Tracheostomy Tubes

A tracheostomy tube may need to be replaced because of tube damage, such as cuff rupture, occlusion with secretions, or conversion to another type or size of tracheostomy tube. If the tracheostomy was recently performed, the tissue is friable. In patients in whom a false passage has been created during the original procedure, in those with poor tissue integrity, or those highly dependent on supplemental oxygen, exchanging the tracheostomy tube can be difficult and fraught with complications. The Weinmann Tracheostomy Exchange Set (Cook Critical Care) (Fig. 50-8), consists of a Ciaglia Blue Rhino tracheostomy dilator, a CAEC, Rapi-Fit adapter, and two loading dilators (26 and 28 F). The 45-cm-long exchange catheter is passed through the tracheostomy tube to be replaced; its cuff is deflated, and the tube is removed over the exchange catheter. The replacement tracheostomy tube and its loading dilator are placed over the AEC, which is connected to the Rapi-Fit adapter, permitting ventilation as required. The loading catheter and tracheostomy catheter are advanced using the AEC as a guide. If stomal dilatation is required, the set is equipped with Ciglia Blue Rhino dilators (32 to 38 F).[360] The only description of this device advocates jet ventilation and high-flow oxygen insufflation. AEC insertion must be atraumatic, confirmed with a carbon dioxide (CO_2) tracing, and the depth verified to ensure it is not beyond the carina. Only the amount of oxygen (O_2) required to prevent significant oxygen desaturation should be supplied.

VII. JET VENTILATION THROUGH STYLETS

The preceding sections stressed the importance of being able to supplement oxygenation during a tube exchange. In most circumstances, a patient's oxygen content can be adequately sustained with insufflation, obviating the need for high-pressure jet ventilation. If oxygen requirements are high before a tube exchange, the equipment should be immediately available to provide jet ventilation. This equipment consists of a manually cycled, Venturi-type jet ventilator with a Luer-Lok adapter and an in-line pressure-reducing valve (see Fig. 50-8).[361] The objective of jet ventilation is to correct life-threatening hypoxemia—not to normalize arterial blood gases. Although the achievement of normal $Paco_2$ may be attainable, the risks quite likely exceed the benefits.[343] Barotrauma has occurred through such misguided objectives, and it has been fatal in some cases.

As an example of the risks, the Chief Coroner of Ontario, Canada, investigated the death of a man who had intermaxillary fixation after orthognathic surgery. He was awake and comfortable at the conclusion of surgery. He was extubated over an AEC, through which oxygen was insufflated at 5 L/min. On arrival in the PACU, he was distressed and complained of back pain and difficulty breathing. Shortly thereafter, he had a cardiac arrest. Needle thoracentesis revealed a tension pneumothorax, and although the initial resuscitation restored a pulse, he developed hypoxic encephalopathy and died. It is unclear whether the insertion was traumatic (although the autopsy did not reveal a laceration or perforation at the distal tip location), whether the flows were at some point much higher, or whether jet ventilation had been employed at any time. The specific device, its size, and details regarding its insertion and fixation are unknown, but it is advisable to obtain a capnographic tracing before applying oxygen insufflation or jet ventilation. The lowest possible flows and driving pressures should be used.

A. In Vitro Studies

Transtracheal jet ventilation by means of an intravenous catheter or intratracheal ventilation using a stylet or tube exchanger has been advocated in the management of the "cannot intubate, cannot ventilate" patient.[5,362] The inspiratory volume depends on the driving pressure, injection

time, respiratory compliance and resistance, and resistance of the tube exchanger. The latter is determined by the catheter's ID and length. The expiratory volume depends on exhalation time, elastic recoil of the lungs, and airways resistance.[361,363] Mismatch between inspiratory and expiratory volumes can have serious consequences.

In vitro studies using jet stylets have been conducted to determine flow, pressure, and entrainment characteristics. Using an in vitro model, with three sizes of Sheridan T.T.X. catheters, Dworkin and colleagues measured the inspiratory and expiratory flows resulting from a 50-psi injection as the simulated upper airway resistance, lung compliance, gas flow rate, and injection times were varied.[363] The upper airway resistance was determined by the effective tracheal diameter, which they defined as a computed difference between the OD of the T.T.X. and the tracheal diameter. They simulated upper airway obstruction by using various sizes of ETT adapters (11- to 3.5-mm ID) in the proximal airway. The gas flows through the large, medium, and small tube exchangers, when connected to a pressure source of 50 psi, were 63, 33, and 12 L/min, respectively. In their model, if the difference between the tracheal and T.T.X. diameters resulted in an effective tracheal diameter that was greater than 4 to 4.5 mm, air trapping did not occur. Because increased upper airway resistance and reduced effective tracheal diameter resulted in larger tidal volumes, they concluded that jet ventilation through a long catheter that was positioned close to the carina caused little Venturi effect or air entrainment. Placement of the catheter close to the carina may ensure a higher oxygen concentration by reducing room air entrainment, but it also increases the risk of distal catheter migration and barotrauma.

In another in vitro model, calculations based on oxygen dilution and direct measurement using a pneumotachograph revealed that air entrainment accounted for 0% to 31% of the inspired volume.[364] The largest T.T.X. and lung compliance resulted in the greatest entrainment. Gaughan and colleagues used a high driving pressure (50 psi), long inspiratory time (1 second), and brief expiratory time (1 second).[364] Even within a low-compliance system, the large T.T.X. was associated with excessive tidal volumes.

Prolonging expiratory time reduces the minute ventilation by reducing the respiratory rate. This technique still exposes the lungs to potentially injurious tidal volumes. An alternative approach is to reduce the driving pressure. Gaughan and coworkers assessed the tidal volumes and air entrainment in a model lung with a range of compliance sets ventilated by high- and low-flow regulators through 14- and 16-gauge intravenous catheters.[365] Their high-flow regulator at steady state produced flow rates of 320 L/min at 100 psi, whereas the low-flow regulator produced flows up to 15 L/min at 9 to 5 psi. Intravenous catheters, because of their short length, offer considerably less resistance to flow. Their proximity to the upper airway also results in greater air entrainment (15% to 74%). Both high- and low-flow regulators allowed adequate minute ventilation in the setting of normal tracheal and bronchial diameters and normal compliance. The investigators recommended that during transtracheal jet ventilation, when low-flow regulators were used, an inspiratory-to-expiratory (I:E) ratio of 1:1 should be used because it yields the greatest minute ventilation. Although this observation is undoubtedly true, it remains to be determined whether such high minute volumes are clinically necessary or safe.[343,361]

B. In Vivo Studies

Chang and colleagues provided intraoperative jet ventilation using a 3.5-mm chest tube as a jet catheter.[332] They ventilated with 15 psi at 10 to 16 breaths/min and continued until spontaneous ventilation was deemed adequate. The patient recovered but had a left pneumothorax that was attributed to catheter migration and unilateral ventilation. The investigators mentioned that they had encountered three cases of pneumothoraces and one pneumoperitoneum in approximately 600 similar procedures. They drew attention to the importance of catheter placement and advised that even brief airway obstruction can result in barotrauma. However, they failed to mention that vocal fold apposition occurring during recovery might promote this complication. In a subsequent paper, the same investigators stated that the jet stylet had been used for the ventilation of six patients, resulting in normocarbia and adequate ventilation.[331] Baraka described a patient with a poor laryngeal view in whom an ETT exchange was facilitated using a CAEC.[366] This was advanced until resistance was encountered. Jet ventilation at 50 psi was commenced before withdrawal of the ETT or deflation of its cuff. The result was right-chest expansion but incomplete deflation, but within three breaths, asystole was observed. A needle thoracotomy confirmed the diagnosis of tension pneumothorax, and sinus rhythm was restored.[366]

Egol and colleagues described pneumothoraces and a pneumoperitoneum in three patients using a variety of delivery devices and driving pressures.[333] They included an 18-F suction catheter at 50 psi, a nasogastric sump tube at 20 psi (inspiratory time at 30%), and a fiberoptic laryngoscope at 40 psi. They attributed the barotrauma observed to incorrect catheter placement, ventilation during phonation, and possible direct mucosal penetration from jet injection. They examined the relationship between the number of distal side holes in the tube exchanger and the pressure at the catheter tip. At any given driving pressure, the more side holes, the lower the pressure at the catheter tip. They recommended vigilance regarding the location of the catheter tip, including avoidance of direct mucosal contact and insertion into orifices where exhalation might be restricted. They advocated securing the catheter to minimize migration, use of catheters with multiple side holes, use of small-diameter jet catheters to minimize the resistance to exhalation, and use of the minimal effective driving pressure. They encouraged the development and use of an effective pressure sensor and pressure-cutoff device.

The ETVC has an end hole and eight distal side holes (see Fig. 50-7). Its use to provide jet ventilation during general anesthesia with muscle relaxation on 45 occasions was described.[338] Its attachment to a handheld jet ventilator with a pressure-reducing valve is shown in Figure 50-9. Between 1991 and 1993, Irish and coworkers

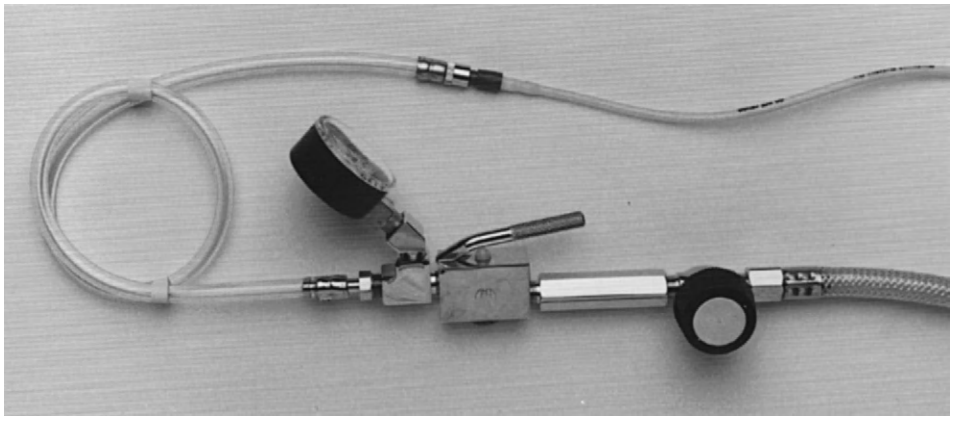

Figure 50-9 An Endotracheal Ventilation Catheter (ETVC) is connected to a handheld jet injector. The Rapi-Fit adapter or the Sheridan JETTX exchanger can be similarly attached. A pressure-reducing valve enables the operator to select a driving pressure that yields adequate chest expansion while minimizing the risk of barotrauma.

used this device with a driving pressure of 50 psi in 25 anesthetized and paralyzed patients undergoing percutaneous dilatational tracheostomies.[367] They observed barotrauma in one patient. Arterial blood gases in 12 consecutive, critically ill patients revealed a pH of 7.37 ± 0.09, $Paco_2$ of 45.5 ± 10.8, and Pao_2 of 256 ± 126 (mean ± SD). In a subsequent report, a patient ventilated for 90 minutes at only 20 psi developed a pneumothorax.[343] Chan and Manninen also described use of the ETVC to provide jet ventilation.[368] After performing a fiberoptic intubation in a patient with an unstable cervical spine, they discovered that the cuff of the ETT had been damaged. They inserted a flexible bronchoscope through the other nostril and advanced it through the vocal cords anterior to the original ETT. They then passed an ETVC through the original ETT and provided three breaths of jet ventilation at 50 psi. The patient developed a pneumothorax. Unfortunately, they used a high driving pressure through an exchange catheter that might have been too deeply inserted in the setting of near-complete glottic occlusion (i.e., partial cuff deflation, 6-mm ETT, and an FOB passing through the vocal cords).

These cases reinforce the general principles previously stated.[343,369] The need for jet ventilation should always be weighed against its possible risks. It should be immediately available and used when there is evidence of deteriorating oxygenation. If a 15-mm connector is available, capnography should be used to confirm intratracheal placement. An in-line pressure-reducing valve should be used, and ventilation should begin with the lowest pressure capable of producing adequate chest expansion. The duration of inspiration should be minimized while the duration of exhalation is determined by observing the return of the thoracic diameter to its position before inspiratory. The depth of catheter insertion should be far enough from the carina that distal migration does not occur but not so proximal that jet ventilation results in the catheter's ejection from the glottis. Multiple distal side holes can reduce catheter whip and the distal catheter pressure during jet ventilation. Every effort must be taken to minimize expiratory resistance.

VIII. CONCLUSIONS

Successful airway management does not end with tracheal intubation, any more than a safe flight is only concerned only with the take-off. Although respiratory complications are more common at extubation than during intubation, most are relatively minor and do not require reintubation. However, the need for reintubation cannot always be predicted. Reintubation may prove to be difficult and dangerous in a variety of circumstances. The ASA Task Force and the Canadian Airway Focus Group have recommended that each anesthesiologist have a preformulated strategy for extubation of the difficult airway. A risk stratification scheme can be used to identify patients for whom special extubation precautions seem to be warranted. Although many strategies are available, their benefits have not been subjected to rigorous evaluation. A reversible extubation can be performed with a tube exchanger. Use of a stylet does not guarantee that reintubation will succeed. The probability of a successful tube exchange may be enhanced if it can be performed under visual control using direct or indirect laryngoscopy. Carefully used, however, it should enhance patient safety by providing oxygen insufflation and jet ventilation while other avenues are explored.

IX. CLINICAL PEARLS

- Careful planning of tracheal extubation or tube exchange is as vital as the planning required for intubation. Airway complications are as common after tube removal as during insertion.
- Extubation carries the risk of reintubation and the risk of failed reintubation.
- Reintubation may be required because of an airway obstruction or because of failure of oxygenation, ventilation, clearance of secretions, or airway protection.
- Anticipating a successful extubation is an inexact science. Any emergent reintubation is likely to be more complex due to urgent conditions and physiologic instability.

- Reintubation may fail because of inadequate access to the airway (e.g., halo fixation, maxillomandibular fixation), preexisting anatomic features (e.g., retrognathism, prominent incisors), inadequate preparation, lack of expertise or insufficient information (e.g., emergencies), a rapidly deteriorating clinical state, or blood, secretions, or swelling obscuring the visual field.
- Many threatening circumstances can be anticipated and managed preemptively with an extubation strategy.
- Extubation strategies include deep extubation, bronchoscopic examination under anesthesia through a supraglottic airway (SGA), substitution of an endotracheal tube with an SGA, and extubation over a tube exchanger.
- The safest extubation strategy may be a surgical airway.
- A supraglottic device or tube exchanger should be left in place until it is likely that reintubation will not be required. Premature withdrawal is a common mistake.
- A reintubation strategy may include the judicious administration of oxygen by insufflation or jet ventilation; advancement of an endotracheal tube over the tube exchanger, preferably with tongue retraction; or indirect laryngoscopy.

VI. Complications with Extubation
- A. Hemodynamic Changes
- B. Laryngospasm
- C. Laryngeal Edema
- D. Laryngotracheal Trauma
- E. Bronchospasm
- F. Negative-Pressure Pulmonary Edema
- G. Aspiration
- H. Airway Compression
- I. Difficult Extubation
- J. Accidental Extubation

VII. Conclusions

VIII. Clinical Pearls

I. COMPLICATIONS IN MANAGING PATIENTS WITH DIFFICULT AIRWAYS

Difficulty in managing the airway is the most important cause of anesthesia-related morbidity and mortality. In the American Society of Anesthesiologists (ASA) Closed Claims Project, 6% of all claims concerned airway injury.[1] Difficult intubation was a factor in only 39% of airway injury claims. Eighty-seven percent of the airway injuries were temporary, and 8% resulted in death. In 21%, the standard of care was inappropriate (Table 51-1). Female patients, elective surgery, and outpatient procedures had higher rates of injury. There was no difference in ASA physical status classification and obesity among those with airway injuries during general anesthesia.

TABLE 51-1
Severity of Injury and Standard of Care

Site of Injury (*N*)	SEVERITY OF INJURY		STANDARD OF CARE	
	Nonfatal *n* (%)	Fatal *n* (%)	Standard *n* (%)	Substandard *n* (%)
Larynx (87)	86 (99)	1 (1)	74 (96)	3 (4)
Pharynx (51)	46 (90)	5 (10)	29 (71)	12 (29)
Esophagus (48)	39 (81)	9 (19)	25 (60)	17 (40)
Trachea (39)	33 (85)	6 (15)	20 (63)	12 (38)
TMJ (27)	27 (100)	0	21 (100)	0
Nose (13)	13 (100)	0	11 (85)	2 (15)

TMJ, Temporomandibular joint.
Modified from Domino KB, Posner KL, Caplan RA, Cheney FW: Airway injury during anesthesia: A closed claims analysis. *Anesthesiology* 91:1703, 1999.

International studies exploring the incidence of complications during general anesthesia have been published in the United Kingdom,[2,3] Australia,[4] and France.[5] The procedural problems and airway complications found in these studies are summarized in Table 51-2.

The inability to secure the airway and subsequent failure of oxygenation constitute a life-threatening complication. In absence of major oxygen (O_2) reserves, failure of oxygenation leads to hypoxia, followed by brain damage, cardiovascular breakdown, and death. As soon as oxygenation is no longer achievable, tissue damage is initiated, and irreversible injury occurs in a few minutes. The ultimate goal of airway management is oxygenation of the patient, not placement of an endotracheal tube (ETT).

Some complications are dramatic and immediately life-threatening (e.g., unrecognized esophageal intubation, tracheal rupture); some are severe and long-lasting (e.g., nerve injuries), and some are painful for the patient (e.g., sore throat). Good clinical practice aims to avoid all of these complications.

A. History of the Patient and Examination

Serious complications of airway management may result from not recognizing the level of airway difficulties. For example, it is impossible to clear an airway problem at the level of the vocal cords or the upper trachea when using a supralaryngeal airway device (SAD). These cases should be managed with endotracheal intubation or with a transglottic or transtracheal airway. Similarly, fiberoptically guided intubation may not prove beneficial in cases of bleeding and vomiting.

To minimize injury to the patient, the anesthesiologist should examine the airway carefully, identify potential problems, devise a plan that involves the least risk for injury, and have a backup plan that can be instituted immediately if needed. Common sense should prevail at all times. Lessons learned from difficult cases should be used to modify daily practice and minimize future problems associated with airway management.

The first step in managing patients with difficult airways is to establish a specific algorithm for the anesthesia department by accepting the existing ASA algorithm or adapting it to the requirements of the specific patient population of the department. The first step in this algorithm is identification of patients with difficult airways during the preoperative examination. Most patients have the typical physical signs or history of a difficult airway and are easily identified. Although a few patients have none of these signs, they remain at risk for a difficult airway, and we should focus on them. Unfortunately, a reliable test for detecting all patients at risk does not exist. The sensitivity and specificity of all existing tests are rather low. The anesthesiologist must be alert to all possibilities, because airway difficulties may occur at any time.

All tests should be performed in a standardized manner for every patient to prevent errors in the results. Practitioners should understand the functions and limits of each test. Combinations of simple tests or the application of more complex tests may increase the predictive value

TABLE 51-2
Procedural Problems and Airway Complications Encountered During General Anesthesia

Respiration	Equipment	Drugs	Management
Difficult intubation	Substandard monitoring	Missing drugs	Insufficient training
Difficult ventilation	Defective apparatus	Mixup of drugs	No specialist on call
Failed intubation	Equipment not available	Drug overdosage	Inadequate assistance
Aspiration		Drug hangover	Insufficient diagnostic
Laryngospasm			Nonfasted patient
Bronchospasm			
Pneumothorax			
Airway trauma			
Airway obstruction			
Respiratory depression			

Data from references 2-5.

of the preanesthesia examination findings.[6,7] In uncertain cases, the preoperative evaluation of the airway can use fiberoptic devices under local anesthesia. Test and physical examination results must be documented, especially when the examiner is not the person administering anesthesia during the procedure.

B. Omission, Commission, and Communication

In anesthesia practice, errors of omission are more common than errors of commission. Errors of omission include failure to recognize the magnitude of a problem, make appropriate observations, or act in a timely manner. Errors of commission include trauma to the lips, nose, or laryngotracheal mucosa; forcing sharp instruments into areas in which they do not belong; and introducing air or secretions into regions of the body in which further complications will ensue. The primary goal of anesthesiologists is to ensure the safety and well-being of their patients, and they are usually careful in performing the technical aspects of their jobs. The most frequent cause of fatal errors in medical practice, especially in the field of airway management, is to ignore inadequate experience and skills and not call for help.

C. Planning and Scheduling

Many complications of airway management result from insufficient communication between the members of the medical team and improper coordination of patients in the operating room schedule. A patient with known difficult airway problems should be scheduled at a time when the most experienced anesthesiologists and surgeons are available. Communication among the entire staff is paramount to create optimal conditions for the patient's safety.

Delayed recognition of complications leads to delayed therapy. Inadequate monitoring, nonfunctional equipment, and untrained staff have been linked to airway catastrophes. For optimal airway management, a difficult airway cart must be available, as recommended in the ASA guidelines. The cart should include additional devices and specialized equipment for managing all airway problems.

II. COMPLICATIONS WITH SUPRALARYNGEAL AIRWAY DEVICES

A. Mask Ventilation

The difficult mask ventilation is an underestimated aspect of managing a difficult airway. Ventilation using a bag-mask breathing system is an essential task of the trained anesthesiologist, and it may be life-saving for the patient. The "cannot intubate, cannot ventilate" (CICV) scenario represents the most extreme type of airway problem.[8] Mask ventilation is used at the beginning of most cases of general anesthesia. Although the mask and the technique may seem benign, each can cause problems.

1. The Sterilization Process

Many of the devices used to ventilate the patient and secure the airway are disposable, but some equipment is reusable. All devices should be checked before use, and reusable items should be free of residual cleaning agents. Masks may have pinhole defects in their air-filled bladders, allowing air leaks or extravasation of cleaning fluid. In one case report, the fluid caused severe burning and irritation to the patient's eyes,[9] and another patient contracted chemical conjunctivitis from residual glutaraldehyde on an anesthesia mask.[10] If ethylene oxide, a common cleaning solution, adheres to reusable surfaces, it can cause serious mucosal injury. Water added to ethylene oxide forms ethylene glycol, a known irritant. Residual glutaraldehyde on an improperly rinsed laryngoscope blade caused massive tongue swelling and life-threatening allergic glossitis.[11] Care must be taken to thoroughly rinse the suction channel of a fiberoptic bronchoscope (FOB) after cleaning. Residual agents may drip out of the FOB port into the larynx or trachea, causing severe chemical burns.

2. Mechanical Difficulties

A mask is typically applied to a patient's face *before* induction of general anesthesia. Preoxygenation of the patient is the first step in securing the airway. The mask should be applied during spontaneous breathing, before drugs are given. During placement, direct contact of the rigid parts of the mask with the bridge of the nose or mandible should be avoided because they are at particular risk for compromised blood flow.[11] Bruising and soft tissue damage may occur in these regions with excessive pressure, and pressure damage to the mental nerves as they exit from the foramina has been implicated in lower lip numbness in two patients.[12] Care must be taken to avoid contact with the eyes to prevent corneal abrasions, retinal artery occlusions, and blindness. As induction proceeds, firmer mask pressure and stronger lifting pressure on the angle of the mandible become necessary to maintain a tight mask fit and secure the airway. Pressure on the soft tissue of the submandibular region may obstruct the airway, especially in small children, or it can damage the mandibular branch of the facial nerve, resulting in transient facial nerve paralysis.[13]

Occasionally, the base of the tongue may fall back into the oral pharynx during induction and obstruct the airway. Oropharyngeal airways must be gently inserted into the mouth to avoid injury, such as broken teeth or mucosal tears. Improper placement may worsen airway obstruction by forcing the tongue backward. Equal care should be given to the placement of nasopharyngeal airways to avoid bleeding and epistaxis.

Before insertion of an oropharyngeal or nasopharyngeal airway, the oropharyngeal space should be enlarged. During conventional mask ventilation, the mandible is pressed against the maxilla, blocking condylar motion and hindering sufficient mouth opening and maximal extension of the base of the tongue. The mouth is opened and the mandible gently drawn forward and upward to displace the base of the tongue to a ventral position and increase the oropharyngeal space.

The lifting pressure applied to the angle of the mandible is sometimes sufficient to subluxate the temporomandibular joint (TMJ). Patients may experience persistent pain or bruising at these points and may have chronic dislocation of the jaw, which can cause severe discomfort.

Positive airway pressure can force air into the stomach instead of the trachea, producing gastric distention, difficult ventilation, and increased likelihood of regurgitation. Cricoid pressure can help to reduce the amount of air being forced into the stomach. The ability to achieve adequate mask ventilation should be assessed preoperatively. Independent risk factors for difficult mask ventilation are the presence of a beard, increased body mass index, lack of teeth, age older than 55 years, history of snoring or sleep apnea, limited mandibular protrusion test, male gender, Mallampati class III or IV (used to predict ease of intubation), and airway masses or tumors.[14]

Other factors may make mask ventilation difficult or impossible, such as large tongues, facial burns or deformities, stridor, or nasal polyposis. In these cases, it may be best to avoid mask ventilation and perform awake fiberoptic intubation. Patients with trauma to the pharyngeal mucosa may be at risk for subcutaneous emphysema.

Laryngoceles may manifest as or cause upper airway obstruction during induction of anesthesia. Congenital factors contribute to development of laryngoceles, and persons who play wind instruments also may be at risk because high intrapharyngeal pressures can weaken soft tissue and cause laryngoceles in the lateral pharynx.[15,16]

3. Prolonged Mask Ventilation

Because mask ventilation offers no protection against silent regurgitation, the anesthesiologist should be vigilant for questionable airway noise, coughing, or bucking. Transparent masks allow visualization of the mouth and early identification of vomitus. Extra care should be taken to avoid undue pressure on vulnerable parts of the face. When continuous positive airway pressure (CPAP) is applied to patients with basilar skull fractures, pneumocephalus may occur.[17,18] At least one case report identified positive airway pressure as the cause of bilateral otorrhagia.[19]

Mask ventilation is relatively contraindicated in nonfasting patients, intestinal obstruction, head-low position, extreme obesity, tracheoesophageal fistula, and massive naso-oropharyngeal bleeding, although it may be lifesaving when other airway devices fail. Especially in pediatric cases, it may be necessary to avoid hypoxia.[20]

Adequate monitoring during mask ventilation includes observation of chest movement, pulse oximetry, measurement of end-tidal carbon dioxide ($ETCO_2$), and breathing pressure control. In infants, a precordial placed stethoscope is recommended.

B. Laryngeal Mask Airway

The laryngeal mask airway (LMA), a device designed for upper airway management, is a cross between a face mask and an ETT. The LMA has been used in millions of patients and has been accepted as a safe technique in many types of surgical procedures. With use of the LMA, muscle relaxation is unnecessary, laryngoscopy is avoided, and hemodynamic changes are minimized during insertion. The LMA has a clear advantage when laryngeal trauma must be minimized (e.g., in operatic singers), when a standard mask fit is impossible, and when light planes of anesthesia are desired.[21] It has proved valuable in situations in which mask ventilation is unexpectedly difficult and direct laryngoscopy impossible, and it may be used as a conduit for a fiberoptic intubation with a standard ETT.[22] Use of the device is an integral part of the ASA difficult airway algorithm.[23]

Placing the LMA correctly can be difficult in some patients. The mask may fold on itself, and pressure on the epiglottis can push the device down into the glottic opening, or the epiglottis may become entrapped in the laryngeal inlet of the mask. The tip of the epiglottis may fold into the vocal cords, increasing the work of breathing and producing coughing, laryngospasm, or complete airway obstruction. Excess lubricant can leak into the trachea, promoting coughing or laryngospasm.[24] Regardless of the problems encountered in placing the LMA, airway patency is usually maintained. An inadequate mouth opening (<1.5 cm), inadequate anesthesia depth, insertion with a not fully deflated cuff, inadequate size of LMA, inadequate force during insertion, and inadequate volumes for cuff inflation can cause malpositioning of the LMA.

Numerous complications are associated with the LMA. Perhaps the greatest limitation is the inability of the LMA to protect against pulmonary aspiration and regurgitation of gastric contents. Because the LMA does not isolate the trachea from the esophagus, its use is risky when the patient has a full stomach or when high airway pressures are necessary for positive-pressure ventilation. The overall risk of aspiration and regurgitation using the LMA seems to be in the same low range as endotracheal intubation when the indications and contraindications for the LMA are respected.[25] The risk of aspiration, which is a consequence of the device's design, should be weighed against the advantages of the LMA in cases of difficult intubation and ventilation. Other complications have been reported with the use of the LMA. Their incidence and severity depend on the user's skills and experience, depth of anesthesia, and anatomic or pathologic factors.[26]

Failure to insert the LMA results from inadequate anesthesia depth, suboptimal head and neck position, incorrect mask deflation, failure to follow the palatopharyngeal curve during insertion, inadequate depth of insertion, cricoid pressure, and oral variations such as large tonsils. Laryngeal spasm and coughing result from inadequate anesthesia depth, tip impaction against the glottis, and aspiration. Mask leaks or the inability to ventilate the lungs results from inadequate anesthesia depth, malpositioned mask, inadequate size of the mask, and high airway pressure. A displacement of the LMA after insertion is caused by inadequate anesthesia depth, a pulled or twisted tube, and inadequate mask size. Problems during recovery are removal of the LMA at an inappropriate anesthesia depth, laryngospasm and coughing when oral secretions enter the larynx after cuff deflation, tube occlusion caused by biting, and regurgitation. Effects on

pharyngolaryngeal reflexes such as laryngeal spasm, coughing, gagging, bronchospasm, breath-holding, and retching may be associated with LMA use.

The incidence of sore throat with this device is between 17% and 26%.[27] The incidence of failed placement is 1% to 5%, although this rate tends to decrease with increasing operator experience.[28] The LMA cuff is permeable to nitrous oxide and carbon dioxide, which results in substantial increases in cuff pressure and volume during prolonged procedures.[29,30]

Several case reports mention edema of the epiglottis, uvula, posterior pharyngeal wall, and vocal cords; in the worst cases, these conditions have led to airway obstruction.[31-33] Nerve paralysis (i.e., lingual, recurrent, hypoglossal, and glossopharyngeal), postobstructive pulmonary edema, tongue cyanosis, and transient dysarthria have been reported. Cuff-pressure control can reduce at least some of these complications.[27,34-37] Other problems with the LMA include dislodgment, kinking, and foreign bodies in the tube, leading to airway obstruction.[38]

Newer designs of the LMA were developed to increase comfort, handling, or safety in various situations. To minimize the risk of aspiration and regurgitation, the ProSeal laryngeal mask airway (PLMA), which has an esophageal vent, was released in 2000.[39] It isolates the glottis from the upper esophagus when correctly positioned, which further protects the airway.[40,41] Some cases with gastric insufflation with a malpositioned PLMA were reported.[42,43]

The intubating laryngeal mask airway (ILMA) was designed to overcome unexpected difficult laryngoscopic intubation. Use of the ILMA has been successful in patients with difficult airways.[44,45] Tracheal intubation through the ILMA using special ETTs is easier than with the standard LMA, and the success rate for blind insertion of a tube through the ILMA is more than 90%.[46,47] Branthwaite reported a case of larynx perforation leading to mediastinitis and the patient's death.[48] Fiberoptically guided insertion of an ETT through an LMA has had the highest success rate for intubation and the lowest rate for damage of laryngeal structures.

Modifications of extraglottic airways combine features of various LMAs. For example, the LMA Supreme combines the Fastrach intubating laryngeal mask airway (ILMA-Fastrach) shape with the PLMA gastric port, resulting in a higher rate of success on first attempt at insertion and lower leak pressures, and the LMA I-Gel supraglottic airway is a single-use device without an inflatable cuff.[49,50] Other devices, such as the LMA C-Trach, use integrated fiberoptic channels to visualize the glottic region.[51] Overall rates of complications are similar to those described earlier.

Classic contraindications to using an LMA include nonfasted patients, extreme obesity, necessity of high breathing pressures (20 to 25 cm H_2O) in the presence of low pulmonary compliance or chronic obstructive pulmonary disease (COPD), acute abdomen, hiatal hernia, Zenker's diverticulum, trauma, intoxication, airway problems at the glottic or infraglottic level, and thoracic trauma. Nevertheless, the LMA's successors, particularly those with a channel for the insertion of a gastric tube, have led to more liberal use of LMA devices.[52-54]

C. Esophageal-Tracheal Combitube

The esophageal-tracheal Combitube is an esophagotracheal, double-lumen airway designed for emergency use when standard airway management measures have failed.[55,56] Use in elective surgery has been reported.[57-60]

The device is inserted blindly into the mouth and advanced to preset markings. The distal tube is usually positioned within the esophagus at this point. A distal cuff is inflated within the esophagus, and a large-volume proximal cuff is inflated inside the pharynx. Ventilation is then attempted through the esophageal tube because esophageal intubation occurs in approximately 96% of insertions. If ventilation through this lumen fails, ventilation is attempted through the tracheal lumen. The device is designed for single use, but a study of multiple uses of the Combitube found no problems with the reprocessing.[61] Another study warned against reuse because insufficient cleaning may lead to transmission of iatrogenic infections.[62]

The 37-F (small adult) Combitube is not recommended for patients shorter than 120 cm, and the 41-F Combitube is not recommended for patients shorter than 150 cm. Disregarding those recommendations may induce serious esophageal injury. Further contraindications to using a Combitube are intact gag reflexes, ingestion of caustic substances, known esophageal disease, airway problems at the glottic or infraglottic level, and latex allergy.[56]

The Combitube has major disadvantages because of its design. It can be used for a maximum of 8 hours (tracheobronchial care is difficult through the Combitube), suctioning of the trachea is not possible with the device in the esophageal position (may become problematic with copious tracheal secretions), it may injure pharyngeal and esophageal soft tissues, and no pediatric sizes are available.

Complications have been reported with use of the Combitube. In two patients, the device was inserted too far, causing the large pharyngeal cuff to lie directly over the glottis and obstruct the upper airway.[63] This was easily resolved by partially withdrawing the Combitube until breath sounds were auscultated. Tongue discoloration has been reported while the pharyngeal cuff was inflated, but it usually resolves immediately without further adverse sequelae after the cuff is deflated. The Combitube has been linked to glossopharyngeal and hypoglossal nerve dysfunction, esophageal rupture, subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, and tracheal and esophageal injury and bleeding.[64-66] Esophageal lacerations were most likely caused by incorrect use; in both cases, the distal cuff was overblocked, and the larger Combitube (41 F) was used in a small patient. Despite their disadvantages, the Combitube and the EasyTube are widely accepted as devices for managing the difficult airway.

D. Other Supraglottic Airway Devices

Many devices are available for managing the airway at the supraglottic level: cuffed oropharyngeal airway (COPA), laryngeal tube (LT), LaryVent, glottic aperture

seal airway (GO2 airway), Cobra perilaryngeal airway (CobraPLA), and King Laryngeal Tube Suction (LTS).[67-69] Overall, they seem to cause complications and physiologic alterations similar to those found with the LMA.[70,71] The devices were designed for separating the airway from the esophageus but do not efficiently protect the airway from regurgitation and aspiration. They share several advantages and disadvantages. Contraindications include nonfasted patients, gastroesophageal reflux, hiatal hernia, pregnancy, obesity, reduced pulmonary compliance, glottic and infraglottic stenosis, and a mechanical obstruction of the oropharynx. Most complications arise from dislodgment, overblocking the cuff, and insufficient depth of anesthesia. Most of the devices were developed in the past few years, and acceptance in routine practice has varied.

Another concern is the wide range of supraglottic devices. In addition to the limited storage space provided on the airway management cart, it seems impossible to maintain regular and sufficient training with all devices for all practitioners. Many complications in airway management are caused by operator inexperience and by inadequate or nonfunctional equipment. The recommendation for all anesthesiologists is to select a few devices that are used routinely or for which practitioners are well trained.

III. COMPLICATIONS WITH INTUBATION

A. Endotracheal Intubation

1. Anatomic Requirements

Successful oral intubation requires four anatomic traits: adequate mouth opening, sufficient pharyngeal space (determined by visualization of the hypopharynx), compliant submandibular tissue (determined by measuring the thyromental distance), and adequate atlanto-occipital extension.[72] If the patient's anatomy is compromised in any of these factors, intubation will be difficult. For optimal conditions, a free view to the vocal cords is necessary, and introduction of the ETT should be easily performed.

The opening to the airway may prove inadequate because of facial scars, TMJ disease, macroglossia, or dental disease. Nasal intubation techniques, such as blind or fiberoptic approaches, may overcome this problem. A fiberoptic technique is preferred because blind techniques are associated with a high incidence of complications.

The pharyngeal space may be limited by tumors, abscesses, edema, and surgical or traumatic disruption. If the anatomy is distorted, the anesthesiologist must optimize the view of the vocal cords. Awake intubation may be necessary, and it should be considered whenever the pharyngeal space is limited. If direct laryngoscopy is performed, the patient should be placed in the sniffing position, and a styletted ETT should be considered. Every effort—backward-upward-rightward pressure (BURP) or optimal external laryngeal manipulation (OELM)—should be made to optimize visualization and identification of the laryngeal and pharyngeal structures.[73,74]

Compliance of the submandibular space is essential to ensure that the tongue can be placed out of the way to view the glottis. Compliance may be decreased by scarring, changes caused by radiation, or localized infections. Extension of the atlanto-occipital region is necessary to lift the epiglottis off the posterior pharyngeal wall during direct laryngoscopy. A fused, fixed, or unstable spine may be rigid enough to impede visualization of the glottic structures. Awake intubation or fiberoptic techniques should be considered in these instances.

2. Laryngoscope Modifications and Rigid Optical Instruments

Laryngoscopes are designed for visualization of the vocal cords and for placement of the ETT into the trachea under direct vision. The two main types are the curved Macintosh blade and the straight blade (i.e., Miller with a curved tip and Wisconsin or Foregger with a straight tip). All blades are available in different sizes for every age of patients. The main injury caused by using laryngoscopes is damage to the teeth. In cases of inadequate visualization of the vocal cords, a change of the patient's head position may lead to success. In some cases, a blade of inadequate size is responsible for intubation failure. An external laryngeal manipulation (e.g., BURP, OELM) may move the vocal cords into the line of vision and facilitate intubation.

Obtaining a view of the vocal cords with a conventional laryngoscope requires optimal positioning of the patient. With a flexible fiberscope, positioning is not an issue, and damage to the teeth is less likely. Similarly, with innovations such as the Glidescope video laryngoscope, Airtraq laryngoscope, McGrath video laryngoscope, Pentax Airway Scope (Pentax AWS), and Truview video laryngoscope, a video image of the oropharynx and the laryngeal inlet is transmitted from the camera in the tip of the blade and allows laryngoscopy and intubation in positions other than the sniffing position. The advantages of these instruments help to reduce the number of difficult or failed intubations and the incidence of dental damage. In studies on mannequins or patients with normal airways, these devices have been evaluated as better than or equal to the Macintosh laryngoscope, and data demonstrate successful intubation of patients with known or suspected difficult airways.[75,76] Although visualization of the vocal cords has become easier, insertion of the intubation tube can be tricky. The monitor view reveals only the laryngeal inlet, and advancing the tube into the larynx may requires an introducer or a built-in guiding channel, which can make the instrument bulky and the technique more complicated than with a conventional laryngoscope. Several cases of pharyngeal injuries have been reported with the rigid stylet of the Glidescope .[77] Increased awareness of potential complications, better training and supervision, and appropriate equipment and patient selection can reduce the incidence of complications.

Laryngoscopy requires deep anesthesia because it causes strong stimulation of physiologic reflexes, and respiratory, cardiovascular, and neurologic adverse effects are possible.[78] Hypertensive patients, pregnant patients with hypertension, and patients with ischemic heart

disease are particularly at risk. Deep anesthesia, application of topical anesthetics, prevention of the sympathoadrenal response with drugs such as atropine or intravenous lidocaine, and minimizing mechanical stimulation can attenuate the adverse effects.

Laryngoscopes have been modified to optimize visualization of the vocal cords. The Corazelli-London and McCoy-Mirakuhr flexible-tip blades may achieve a better view of the glottis by drawing the epiglottis up.[79]

Rigid optical instruments such as the Bonfils retromolar intubation fiberscope and its modifications,[80] the Bullard laryngoscope, and the intubation tracheoscope[81] are not commonly used in anesthesiology. They require skilled handling, and experience should be gained in routine cases to apply to difficult airway situations. The rigid intubation tracheoscope, a familiar device in ear, nose, and throat surgery, has special indications and may be useful in the hands of anesthesiologists. Available in two sizes (child and adult), it consists of a battery-filled handle and a straight, rigid tube with a connection to a breathing bag or circuit. The rigid tracheoscope is useful for tumors, scars, and abscesses in the oropharynx, base of the tongue, and larynx and for aspirated foreign bodies.

The disadvantages of these instruments are a relatively closed view through the tube, a high risk of damage to the teeth and laryngeal structures, possible perforation of the hypopharynx, and risk of aspiration. High-flow oxygen insufflation through a port induced subcutaneous cervical and facial emphysema in one patient.[82]

3. Difficult Intubation

Despite optimal positioning of the head and neck, the glottis is sometimes impossible to visualize, even in patients without obvious predisposing features.[83-85] Risk factors for difficult tracheal intubation include male sex, age between 40 and 59 years, and obesity.[72] Anesthesiologists should be aware of the potential for a difficult intubation in the following circumstances:

- Posterior depth of the mandible greater than 2.7 cm (which limits submandibular displacement of the soft tissues)
- Anterior depth of the mandible greater than 4.8 cm
- Correlation between effective length of the mandible and a posterior depth less than 3.6
- Distance between the occiput and spinous process of C1 of about 2.6 mm
- Distance between the spinous processes of C1 and C2 of about 2.6 mm (which narrows the limits of head extension)
- Longer maxilla with protruding teeth
- Caudally positioned hyoid bone (increasing the mandible-hyoid distance)
- More rostrally positioned angle of the mandible (a phenotypical receding mandible)[83,86-89]

A chin-to-thyroid cartilage distance of less than three finger breadths (about 7 cm) hampers visualization of the glottis.[90] A combination of tests may increase the predictive value of the preanesthesia examination results.[6,7] Causes for difficulty in securing the airway are shown in Box 51-1.[25,91] Computerized analysis of facial structure provides an accurate approach to predicting difficult intubation.[92] Patients who proved difficult to intubate should be told about it and given written documentation so that they can notify future anesthesiologists. Patients should be registered with the MedicAlert Foundation.

Box 51-1 Miscellaneous Causes of Difficult Securing of the Airway

Symptoms

Dumpling voice
Hoarseness
Pathologic respiratory sound
Foreign body feeling
Odynophagia

Constitutional Factors

Mouth opening <3 cm
Microstomia
Dental abnormalities
Macroglossia
Receding mandible
Obesity
Buffalo neck
Moon face
Beard

Diseases

Limited temporomandibular joint mobility
Limited atlanto-occipital and atlantoaxial joint mobility
Unstable cervical spine
Limited laryngeal mobility
Postoperative or post-traumatic rigidity of the soft tissue of mouth and neck
Congenital, postoperative, post-traumatic anomalies of face and neck
Abscesses and tumors in face and neck
Paradontosis
Phlegmon of the floor of the mouth and of the neck
Epiglottitis
Mediastinitis
Stenosis of the upper airway
Enlarged goiter

Modified from Krier C, Georgi R: Airway management: Is there more than one "gold standard"? *Anasthesiol Intensivmed Notfallmed Schmerzther* 36:193–194, 2001.

4. Nasotracheal Passage

a. CRANIAL INTUBATION

Nasotracheal intubations are potentially hazardous. In patients with basilar skull fractures or certain facial fractures (e.g., LeFort II or III fractures), the ETT may be inadvertently introduced into the cranial vault (Fig. 51-1).[93] Fractures of the frontal part of the skull base with cerebrospinal rhinorrhea, intranasal abscesses or abscesses with intranasal expansion, choanal atresia, hyperplastic tonsils, tendency to uncontrollable nasal bleeding, and coagulopathies are considered contraindications to nasotracheal intubation. In a case of nasotracheal intubation, asystole occurred after the tube was introduced into the orbit.[94] However, if care is taken, the complication rates of oral and nasal intubation are not different.[95] Nasal intubation in a patient with a known or suspected skull

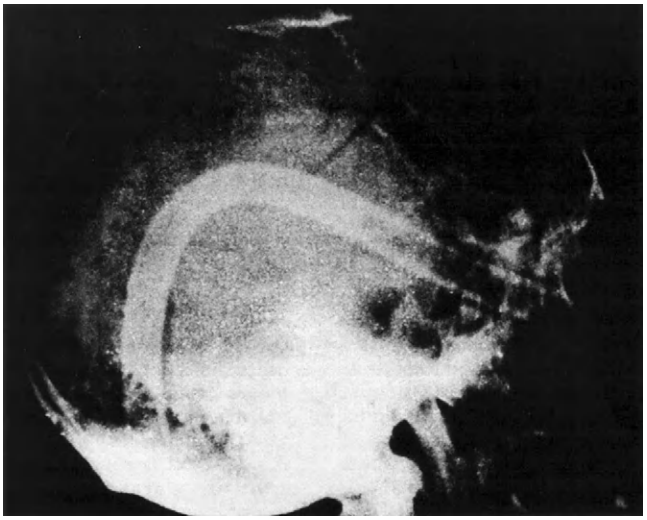

Figure 51-1 Intracranial nasotracheal tube (computer enhanced). (From Horellou MF, Mathe D, Feiss P: A hazard of naso-tracheal intubation. *Anaesthesia* 33:73, 1978.)

fracture should be performed only by using fiberoptic bronchoscopy and with extreme caution in the inferior nasal meatus. For midfacial fractures with intact dura mater, it is possible to open the dura by manipulation during nasotracheal intubation.

b. NASAL INJURY

Nasotracheal intubation may be problematic in the presence of hypertrophic turbinates, extreme deviation of the nasal septum, prominences on the nasal septum, chronic infections in the nasal cavity, and nasal polyposis. Minor bruising occurs in 54% of nasal intubations and most commonly involves the mucosa overlying the inferior turbinate and the adjacent septum.[96] If epistaxis occurs, the ETT cuff should be inflated and remain in the nostril to tamponade the bleeding.

The nasal mucosa must be vasoconstricted before instrumentation.[97] Some agents used for this purpose are 0.5% phenylephrine in 4% lidocaine or 0.1% xylometazoline. A 4% solution of cocaine may be associated with severe adverse effects and is no longer recommended for vasoconstriction. The risk of nasal injury can be minimized with the use of a small, well-lubricated ETT with a flexible tip that has been soaked in warm water.[98]

Possible complications of nasotracheal intubation are dislodgment of nasal polyps,[88] dislodgment of nasal turbinates,[99,100] adenoidectomy, injury of the nasal septum, perforation of the piriform sinus, and the epiglottic vallecula. In case of injury to the piriform sinus, the internal branch of the superior laryngeal nerve, soft tissue of the pharynx, the larynx, and the superior laryngeal vessels may be damaged. Tears in the pharyngeal mucosa can mature into retropharyngeal abscesses.[101] Nasotracheal tubes may dissect and run behind the posterior pharyngeal wall. Patients with an obstructed nasal passage due to convoluted turbinates are at increased risk for this complication. One case of external compression of the nasotracheal tube due to the displaced bony fragments of multiple Le Fort fractures was reported.[102]

Delayed complications of nasotracheal intubation include pharyngitis, rhinitis, and synechia between the nasal septum and inferior turbinate bone. After the tube is secured in the trachea, ensure that it is also secured properly at the level of the nostril. Distortion of the nares can lead to ischemia, skin necrosis, or nasal adhesions.

Even without gross trauma, mechanical damage to the superficial epithelial layers caused by nasal intubation results in mucociliary slowing in 65% of patients and bacteremia in another 5.5%.[103,104] The most common organisms introduced into the blood are nasopharyngeal commensal organisms (e.g., *Streptococcus viridans*), which can cause endocarditis and systemic infection. Even short-term intubation has caused nasal septal and retropharyngeal abscesses. Acute otitis media has occurred in 13% of nasally intubated neonates.[105] Paranasal sinusitis has been reported, most commonly occurring with nasal intubation for more than 5 days.[106,107] Infection may be related to sustained edema and occlusion of the sinus drainage pathways. Prompt diagnosis is critical, and paranasal sinusitis should be suspected in any patient with facial tenderness, pain, or purulent nasal discharge or in any nasally intubated patient who develops sepsis with no other obvious source. A careful examination of the patient is necessary, but the success of a previous cosmetic operation should not be endangered. The nasal structures must be checked again postoperatively.

c. FOREIGN BODIES

The nostrils are common sites for entry of foreign bodies. Small children, known for placing small objects into their orifices, find the nostrils one of the most accessible sites. More than 80% of patients who aspirated a foreign body are children, and most were between 1 and 3 years old.[108-110] Foreign body aspiration is the cause of death of 7% of children younger than 4 years.

Smith and colleagues reported a rhinolith that was dislodged during nasotracheal intubation.[111] The mass had formed around the rubber tire of a toy car that the patient had placed in his nose 30 years earlier. Nasotracheal intubation can dislodge similar foreign bodies that may obstruct the ETT, pharynx, or trachea. If a nasal foreign body is known or suspected, it should be gently dislodged, advanced into the oral pharynx, and retrieved before intubation. Mask ventilation may also dislodge foreign bodies to the lower parts of the airway.

5. Traumatic Intubation

Difficult intubations often are traumatic intubations. In a case of difficult intubation, the practitioner tends to increase the lifting forces of the laryngoscope blade, which may damage the intraoral tissues and osseous structures. When the operator continues to intubate the patient many times without changing his approach or technique, difficult intubation is changing to traumatic intubation. Use of increasing forces causes swelling, bleeding, or perforation, and the intubation becomes more and more difficult. It may end in a CICV situation. We recommend a maximum of three attempts to achieve intubation using a laryngoscope. If intubation fails after three attempts, another airway-securing technique should be used following the airway management algorithm.

a. LIP TRAUMA

Lip injuries, which are typically found on the right upper lip, include lacerations, hematomas, edema, and teeth marks. They are usually caused by inattentive laryngoscopy performed by inexperienced practitioners, the laryngoscope blade, and the teeth. Although these lesions are annoying to the patient, they are usually self-limited.

b. DENTAL TRAUMA

The incidence of dental injuries associated with anesthesia is greater than 1 case in 4500 procedures.[112] Maxillary central incisors are most at risk; 50% of these injuries happen during laryngoscopy, 23% after extubation, 8% during extubation, and 5% in the context of regional anesthesia. Dental injuries are also associated with the use of LMAs and oropharyngeal airways. With insufficient anesthesia, depth biting against the tube is possible. Dental injuries are most common in small children, patients with periodontal disease (in which structural support is poor) or fixed dental work (e.g., bridges, capped teeth), protrusion of the upper incisors (i.e., overbite), carious teeth, and cases of difficult intubation. Preexisting dental pathology should be explored, and all loose, diseased, chipped, or capped teeth must be documented in the chart before anesthesia induction and intubation.[113] The patient must be advised of the risk of dental damage. Tooth guards may be used, but they can be awkward and obstruct vision,[114] although the time for intubation is not significantly longer.[115]

Fragments of chipped or partially broken teeth and completely avulsed teeth should be located and retrieved. Care should be taken to ensure that no foreign bodies slip into the pharynx to later become lodged in the esophagus or the larynx. Avulsed teeth should be saved in a moist gauze or in normal saline without cleaning them. Tooth aspiration may cause serious complications requiring rigid or flexible bronchoscopy for removal. With a rapid response from an oral surgeon or a dentist, an intact tooth often can be reimplanted and saved. The optimal time is within the first hour; thereafter, reimplantation success diminishes with increasing time.[116]

c. TONGUE INJURY

Massive tongue swelling, or macroglossia, has been reported in adult and pediatric patients.[117,118] Some cases occurred while a bite block was in place, some happened with an oral airway and soft tissue compression of the chin, and some occurred with no protective device. The common denominator was that they all occurred when there was substantial neck flexion during endotracheal intubation and surgery was prolonged. Macroglossia results from obstructed venous and lymphatic drainage of the tongue, and it has been associated with angiotensin-converting enzyme inhibitors.[119] In each case, the ETT might have severely compromised the circulation on the affected side of the tongue. One report described the sudden onset of tongue swelling after prolonged surgery to repair a cleft palate,[120] during which the tongue was retracted extensively. Obstruction of the submandibular duct by an ETT may lead to massive tongue swelling.[121] Reduced sense of taste, cyanosis, or loss of tongue sensation is possible after compression of the lingual nerve or by lingual artery compression during forced intubation or associated with an oversized, malpositioned, or overinflated LMA.

d. DAMAGE TO THE UVULA

Uvula trauma is usually associated with the use of ETTs, oropharyngeal and nasopharyngeal airways, LMAs,[122] or Combitubes and with overzealous blind use of a suction catheter.[123] The results of damaging the uvula are edema and necrosis.[124] Sore throat, odynophagia, painful swallowing, coughing, foreign body sensation, and serious life-threatening airway obstruction are reported.[125]

e. PHARYNGEAL MUCOSAL DAMAGE

A postoperative sore throat (POST) likely represents a broad constellation of signs and symptoms. The incidence of POST after intubation is higher than POST after LMA use and after face mask ventilation.[126,127] The incidence of sore throat associated with the use of the Combitube was 48%.[128] Aggressive suctioning is probably a mitigating factor. The incidence is substantially higher in women and in patients undergoing thyroid surgery. No correlation was seen with factors such as age, use of muscle relaxants, type of narcotic used, number of intubation attempts, or duration of intubation. Small tube and cuff size and topical treatment and inhalation of steroids have a positive impact on POST.[129] However, pain on swallowing usually lasts no more than 24 to 48 hours and can be relieved in part by having the patient breathe humidified air.

f. LARYNGEAL TRAUMA AND DAMAGE TO THE VOCAL CORDS

Trauma to the larynx may occur after endotracheal intubation. It depends on the intubator's skill and the degree of difficulty. In one large study, 6.2% of patients sustained severe lesions, 4.5% had hematoma of the vocal cords, 1% had hematoma of the supraglottic region, and 1% sustained lacerations and scars of the vocal cord mucosa.[130] Recovery typically is prompt with conservative therapy.[131] Hoarseness may appear 2 weeks postoperatively.[132]

Granulations usually occur as a complication of long-term intubation. However, a small but significant number of patients sustain laryngeal injuries during short-term intubation.[133] Intubation can cause various degrees of laryngeal trauma, including thickening, edema, erythema, hematoma, and granuloma of the vocal folds.[134,135] Injuries of the laryngeal muscles and suspensory ligaments are possible. The larynx should be inspected for injury before insertion of the ETT to document and treat preexistent lesions. Anesthesiologists should be vigilant in all cases of hoarseness, and patients should be examined by an otorhinolaryngologist preoperatively.

Arytenoid dislocation and subluxation have been reported as a rare complication of intubation.[136] Mitigating factors include traumatic and difficult intubations, repeated attempts at intubation, and attempted intubation using blind techniques such as light-guided intubation,[137] retrograde intubation, and use of the McCoy laryngoscope.[138] Early diagnosis and conservative or operative treatment are necessary,[139] because fibrosis with subsequent malpositioning and ankylosis may occur after 48 hours.

The vocal process of the arytenoid is the most common site of injury by the ETT because it is positioned between the vocal cords. Granuloma formation most commonly occurs at this site. The degree of injury worsens with increasing tube size and duration of intubation.[140]

Many investigators have reported unilateral or bilateral vocal cord paralysis after intubation, which is usually temporary.[141-144] One report associated vocal cord paralysis with use of ethylene oxide to sterilize ETTs.[145] Hoarseness occurs with unilateral paralysis, whereas respiratory obstruction occurs with bilateral problems. The most likely source of injury is an ETT cuff malpositioned in the subglottic larynx with pressure on the recurrent laryngeal nerve.[142,143] Permanent voice change after intubation because of external laryngeal nerve trauma has been reported in up to 3% of patients undergoing surgery at sites other than the head or neck. The incidence may be decreased by avoiding overinflation of the ETT cuff and by placing the ETT at least 15 mm below the vocal cords.[142] Eroded vocal cords may adhere to one another, eventually forming synechiae. This is a potential problem when airflow between the vocal cords has been compromised as a result of tracheostomy.[146] Surgical correction is usually necessary.

g. TRACHEOBRONCHIAL TRAUMA

Tracheal trauma has many causes.[147] Injury may result from an overinflated ETT cuff, inadequate tube size, or malpositioned tube tip, laryngoscope, stylet, tube exchanger, or related equipment. Predisposing factors include anatomic difficulties; blind or hurried intubation; inadequate positioning; poor visualization; and most commonly, inexperience of the intubator. The presence of an ETT may lead to edema, desquamation, inflammation, and ulceration of the airway.[148] The severity of the injury may be related to the duration of intubation, although this relationship is not well established.[149] Any irritating stimulus, such as pressure from an oversized ETT, dry inhaled gases, allergic reactions to inhaled sprays, or chemical irritation from residual cleaning solutions, can initiate an inflammatory response and cause mucosal edema in the larynx or trachea. Edema after extubation limits the lumen diameter and increases airway resistance. Small children are most susceptible to this problem, in which a sudden increase in airway resistance results from laryngotracheobronchitis or croup. Almost 4% of children 1 to 3 years old develop croup after tracheal intubation.[150,151] Mechanical trauma may result from sharp objects within the trachea, such as a stylet tip that extends beyond the length of the ETT. Tracheal ruptures, especially after emergency intubation, were reported.[152] One case of a bronchial rupture caused by an ETT exchanger was reported.[153]

ETT cuffs inflated to a pressure greater than that of the capillary perfusion may devitalize the tracheal mucosa, leading to ulceration, necrosis, and loss of structural integrity.[154] Ulceration can occur at even lower pressures in hypotensive patients. The need for increasing cuff volumes to maintain a seal is an ominous sign that heralds tracheomalacia.[155] Massive gastric distention in an intubated patient may signal the presence of a tracheoesophageal fistula as the cuff progressively erodes into the esophagus.[156] Any patient with more than 10 mL of blood in the ETT without a known cause should be assessed for a tracheocarotid fistula.[157] The various nerves in this region of the neck are also at risk. Erosion of the ETT into the paratracheal nerves may result in dysphonia, hoarseness, and laryngeal incompetence. Tracheomalacia results from erosion confined to the tracheal cartilages. The anesthesiologist must inflate the ETT cuff only as much as necessary to ensure an adequate airway seal. When nitrous oxide is used during a lengthy surgical procedure, the pressure in the cuff should be checked by a cuff pressure control device. In the presence of 70% nitrous oxide, intracuff pressures take an average of 12 minutes to increase to levels that are potentially high enough to cause tracheal ischemia.[154] The cuff pressure should not exceed 25 cm H_2O. Increasing cuff pressure caused by surgical manipulations can be observed and prevented by using a cuff pressure control device.

Tracheal intubation may erode the tracheal mucosa, leading to scar tissue, which ultimately retracts and leads to stenoses of the trachea, larynx, or nares. The reported incidence of granulomas is 1 case in every 800 to 20,000 intubations.[158,159] They are more common in women than in men and occur rarely in children. The most common site of erosion is along the posterior laryngeal wall, where granulation tissue easily overgrows. Side effects of granulomas include cough, hoarseness, and throat pain. The growths may be prevented by minimizing the trauma associated with laryngoscopy and intubation. When granulomas occur, surgical excision is usually required.

Membranes and webs may eventually replace tracheal and laryngeal ulcers. These growths are commonly thick and gray. Care should be taken while intubating patients with these lesions because inadvertent detachment may result in respiratory obstruction or bleeding into the airway. With time, the inflammatory process associated with laryngeal ulcers may extend to the laryngeal cartilage. If this occurs, the cartilage may become inflamed (i.e., chondritis) or softened (i.e., chondromalacia).

Several months after prolonged tracheal intubation, tracheal stenosis and fibrosis may occur. This usually represents the end stage of a progression from tracheal wall erosion to cartilaginous weakening to healing with fibrosis.[147] Stenoses typically occur at the site of an inflated cuff, although they may occur at the ETT tip. Symptoms include a nonproductive cough, dyspnea, and signs of respiratory obstruction. Dilation of the stenosis is curative in its early stages. However, surgical correction may be necessary after the tracheal lumen has been reduced to 4 to 5 mm.[160,161]

Supraglottic complications induced by long-term intubation may be prevented by early tracheostomy. There is no evidence supporting an ideal time for tracheostomy in long-term ventilated patients.

h. BAROTRAUMA

Barotrauma results from high-pressure distention of intrapulmonary structures. High-flow insufflation techniques in which small catheters are used distal to the larynx are most often associated with barotrauma. These problems are common in microlaryngeal surgery when jet ventilation is used.[162-166] Direct impingement of the catheter tip

on the tracheal mucosa may also cause barotrauma.[164] Edema or hematoma may occur if the jet of air strikes the mucosa of the larynx or the vocal cords, leading to laryngospasm. When air leaks into the peribronchial tissues, it can traverse into the subcutaneous space, the lung interstitium, or the pleural and pericardial cavities. Pneumomediastinum or tension pneumothorax and possibly tamponade are the results, and chest tubes may be necessary. Progressive accumulation of air may cause loss of pulmonary compliance, loss of ventilatory volume, or if the accumulation is large enough, overdistension of lung tissue with cardiopulmonary compromise and, finally, impossible ventilation. Safety mechanisms should be in place to prevent high-pressure airflow in the event that intrapulmonary pressures become excessive. For diseased pulmonary tissue, the least possible airway pressure should be used to prevent parenchymal blowout. This advice also applies to patients with blunt thoracic trauma who have subcutaneous emphysema. They should be presumed to have a bronchial leak unless proved otherwise. Barotrauma may also result from upper airway obstruction during jet ventilation.[167]

i. NERVE INJURIES

Laryngoscopy and cuffed supraglottic airway devices may cause periodic or permanent nerve injury. Lingual, recurrent, hypoglossal, and glossopharyngeal nerve paralysis have been described for LMA devices, and neuropraxia with weakness, numbness, or paralysis of the tongue can occur after laryngoscopy.[34] After damage to the internal branch of the superior laryngeal nerve during a difficult intubation, two patients had signs of aspiration.[168]

Malposition of the cuff or tube may be one reason for this rare damage. Ahmad and Yentis postulated that lingual nerve injury may occur where the nerve distal to its gingival branch is compressed by the LMA tubing against the side of the tongue.[169] In addition to the cases previously described, we observed one case of permanent anosmia after nasotracheal intubation with no pathologic findings.

j. SPINAL CORD AND VERTEBRAL COLUMN INJURY

Airway managing techniques such as chin lift, jaw thrust, and direct laryngoscopy transmit movement to the cervical spine. When a patient's neck is fused, adequate neck extension may be impossible to obtain. Attempting to hyperextend the necks of these patients may result in cervical fractures and quadriplegia.[170] A head that is fixated in a cervical collar or halo does not allow neck extension and limits the successful use of direct laryngoscopy. Using a fiberoptic device to assist intubation should be considered in these cases. If immediate intubation is necessary, patients with an acute fracture of the back and neck may be supported by in-line cervical stabilization during careful intubation while protecting the head against excessive movement and fixing it in a safe position by a second person.[171] C1 and C2 fractures seem to be particularly vulnerable because any degree of extension may compromise spinal cord function. Between 10% and 25% of spinal cord injuries occur because of improper immobilization of the vertebral column after trauma, and neurologic deterioration was associated with direct laryngoscopy in a patient with a cervical spine injury.[172-175]

Several conditions, such as Down syndrome and rheumatoid arthritis, are associated with atlantoaxial instability.[176,177] Excessive neck extension in a patient with an undiagnosed Arnold-Chiari malformation may cause worsening of cerebellar tonsil herniation.[178] Patients with underlying diseases such as connective tissue disorders, lytic bone tumors, and osteoporosis should be intubated carefully, and extreme neck extension should be avoided in every patient because of loss of muscle tone by curarizing drugs. A range-of-motion test and an assessment of neck extension should be performed before inducing anesthesia. A case of quadriplegia after bag-ventilation, direct laryngoscopy, and cricothyrotomy in a patient with an unrecognized cervical spine injury was reported.[175] Hastings found in a review of records of 150 patients with unstable cervical spine injury a 1.3% incidence of neurologic deterioration after elective surgery with tracheal intubation. Inadequate airway management may result in disaster of permanent spinal cord injury. Awake fiberoptic intubation should be considered when neck extension cannot be achieved without the risk of damage and time is not crucial. It is considered the safest method for airway management in patients with cervical spine injury, followed by LMA and the Combitube.[171]

k. EYE INJURIES

The ASA Closed Claims Project reported that the eye injuries were responsible for 3% of all claims; of these, 35% were related to corneal injuries, with corneal abrasions being the most common eye complication.[179] They are primarily caused by a face mask being placed on an open eye or by the eyelids not being completely closed during anesthesia.[180,181] Jewelry, identification cards, and loose-fitting watch bands have been implicated in scratching the eyeball.[182] A stethoscope hanging from the neck of a clinician can fall forward and strike the patient's eyes or forehead. Prevention consists of vigilance on the part of the anesthesiologist and application of adhesive tape over the closed eyelids. Especially during head and neck surgery, the eyelids should be taped closed, and the eyes should be covered carefully with soft eyepads.[183] Some clinicians routinely apply lubricating ointment to the inside of the eyelids, although this has not been proved to increase efficacy.

Although these injuries typically heal within 24 hours, they are usually painful and can lead to corneal ulceration. An immediate ophthalmologic consultation is recommended. Local anesthetics should not be applied because they can delay regeneration of the epithelium and may promote keratitis. Treatment consists of allowing the injured eye to rest by use of an eye patch and applying an antibiotic ointment.

l. TEMPOROMANDIBULAR JOINT INJURIES

TMJ anatomy is special in that one side cannot be moved without the other side. Both joints represent a functional unit, and injuries to one TMJ affect the other side. Opening the mouth is a combination of rotary and translational movement in the joint. The rotary movement allows only a mouth opening of about 25 mm; the

Figure 51-2 Necrosis of right nasal wing after 3 days of intubation with an anatomic, preformed tube.

maximal opening is achieved by the translational movement. Pathologic changes such as bone cysts, rheumatid arthritis, and atrophy of the mandible due to age can reduce the joint mobility and may lead to fractures. Rupture of the lateral ligament is possible. TMJ injuries are caused by increasing forces during laryngoscopy to optimize the view of the vocal cords. Limited mouth opening, pain in the joint, lateral deviation of the mandible (e.g., unilateral luxation), protrusion of the mandible (e.g., bilateral luxation), and lockjaw (e.g., fixation after joint luxation) may occur. Most reported cases of TMJ injury were not associated with difficult airway.[184]

m. DAMAGE TO THE NOSE

Some injuries to the nose and endonasal structures were described previously. Using anatomically preformed tubes for head and neck surgery or compression of the nasal wing may lead to necrosis in the worse cases (Fig. 51-2). Wrapping the tube with foam material at the nasal wing level and careful nursing in cases of long-term intubation may reduce or avoid this complication.

6. Esophageal Intubation

a. ENDOTRACHEAL TUBE PLACEMENT

When visualization of the glottis is difficult, the ETT may inadvertently be introduced into the esophagus. Esophageal intubation is more common among inexperienced practitioners, but it may also occur in the hands of experienced stuff members. Intubating the esophagus is not disastrous, but failing to detect and correct the condition is. Recognition of this error must be rapid to avoid the adverse effects of prolonged hypoxia. A closed claims analysis of adverse anesthesia events reported that 18% of respiratory-related claims involved esophageal intubation.[185] Preoxygenation can help alleviate this problem by allowing a longer apneic period for tracheal intubation and by delaying the onset of hypoxemia. End-tidal CO_2 capnography is essential in confirming endotracheal placement of the tube. Capnography should be available wherever intubation is performed. In out-of-hospital practice and emergency medicine, where capnography may not be available, calorimetric single-use CO_2 detectors or an esophageal detector device can help to identify failed intubation in 94.6%.[186] Esophageal intubation can briefly produce an end-tidal CO_2 capnogram (e.g., in presence of CO_2-containing drinks in the stomach), but the waveform diminishes rapidly after three to five breaths.[187,188] Fiberoptic control is another safe way to confirm the correct position of the tube. Other signs, such as equal bilateral breath sounds, symmetrical bilateral chest wall movement, epigastric auscultation and observation, and tube condensation, are potentially misleading.[189] A misplaced tube should remain in place while the trachea is correctly intubated. This helps to identify the correct orifice for intubation and protects the trachea from invasion by regurgitated stomach contents. Once proper endotracheal intubation is achieved after an esophageal intubation, the stomach should be suctioned to minimize vomiting, gastric perforation, or compromise of ventilation.

b. ESOPHAGEAL PERFORATION AND RETROPHARYNGEAL ABSCESS

Perforation of the esophagus has been reported on several occasions.[190-198] It seems most likely to occur when inexperienced clinicians handle emergency situations, when intubation is difficult, or in presence of esophageal pathology. Perforation occurs most commonly over the cricopharyngeus muscle on the posterior esophageal wall, where the esophagus is narrow and thin. Subcutaneous emphysema, pneumothorax, fever, cellulitis, cyanosis, throat pain, mediastinitis, empyema, pericarditis, and death can occur. Early detection and treatment of the condition are critical because the mortality rate of mediastinitis is more than 50%. An esophageal perforation should be suspected in any patient with a fever, sore throat, and subcutaneous emphysema after a difficult intubation.

A case report identified a traumatic tracheal perforation through the esophagus in a patient with a difficult intubation.[199] Cases of esophageal perforation have been associated with the use of an esophageal-tracheal Combitube.[65,66]

7. Bronchial Intubation

a. USE OF AN ENDOTRACHEAL TUBE

Bronchial intubation is common and sometimes difficult to identify. Asymmetrical chest expansion, unilateral absence of breath sounds (especially on the left side), and eventual arterial blood gas abnormalities are diagnostic features. Bronchial intubation (preferentially right-sided) is more common in newborns and children, because of the small distance between the carina and the glottis. The position of the tip of the tube should be carefully

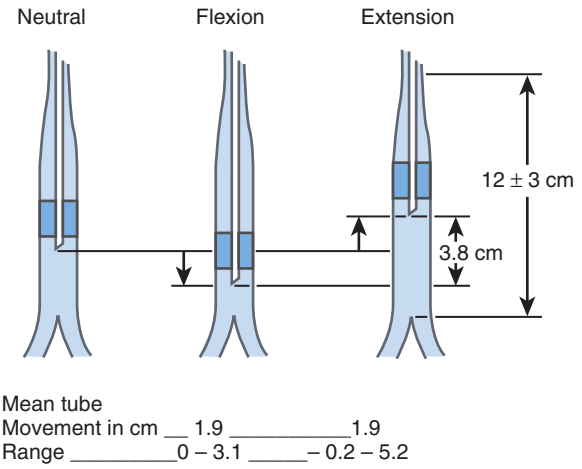

Figure 51-3 The mean movement of an endotracheal tube with flexion and extension of the neck from a neutral position. The mean tube movement between flexion and extension is one third to one fourth of the length of a normal adult trachea (12 ± 3 cm). (From Conrardy PA, Goodman LR, Lainge F, et al: Alteration of endotracheal tube position: Flexion and extension of the neck. *Crit Care Med* 4:8, 1976.)

monitored in children. If bronchial intubation goes undetected, it may lead to atelectasis, hypoxia, and pulmonary edema.[200] Transillumination of the neck with a lightwand can assist in tube location,[201] although not in cases of obesity and large goiter. Fiberoptic control is the best tool to detect proper position of the tube. The ETT may be deliberately advanced into a main stem bronchus and withdrawn until bilateral breath sounds are auscultated.

The tip of the ETT may move between 3.8 and 6.4 cm during flexion or extension of the patient's head as the patient is positioned for surgery (Fig. 51-3).[202] It is easy to remember that the tip of the ETT moves in the same direction as the patient's nose. If the patient's neck is flexed, the nose is pointed downward, and the ETT advances farther into the trachea. The tube moves away from the carina an average of 0.7 cm during lateral rotation of the head. Care should be taken in case of cleft palate surgery or tonsillectomy. Special blades used by the surgeon to achieve a direct view may move the ETT forward during positioning the blade. A stethoscope placed on the left chest helps to identify an endobronchial tube that is being displaced.

When inadvertent bronchial intubation is discovered, the tube should be withdrawn several centimeters and the lungs inflated sufficiently to expand any atelectatic areas. In cases of chronic atelectasis, bronchoscopy may be required to remove mucous plugs. This problem can be avoided by measuring the length of the ETT alongside the patient before intubation. The tip of the tube should ideally be at least 2 cm above the carina, which may be approximated at the sternal angle (of Louis) adjacent to the junction of the sternum with the second rib. Appropriate orotracheal tube depths are 21 cm from the teeth in adult women and 23 cm in adult men, and nasotracheal tube depths are 25 cm in women and 27 cm in men from the nares.[203]

b. USE OF A DOUBLE-LUMEN TUBE

Safe limits for the placement of double-lumen tubes have been outlined by Benumof and colleagues.[204] Modern FOBs have removed the guesswork surrounding endotracheal-bronchial tube tip location. The double-lumen tube may be inserted blindly into the appropriate bronchus, followed by bronchoscopic confirmation of its position, or the bronchoscope may be inserted initially and used as a stylet over which the double-lumen tube is advanced. Fiberoptic bronchoscopy significantly reduces malposition of the double-lumen tube, and its routine use is recommended after intubation, changing patient's position, increasing ventilation pressure, and irregular auscultation sounds. However, even in the best of hands, tracheobronchial injuries occur.[205] Bronchial rupture is a serious complication that requires immediate attention. Using double-lumen tubes that are too large may be the cause of bronchial trauma.[206] The 37- to 39-F double-lumen tubes are recommended for women, and the 39- to 41-F tubes are recommended for men.

B. Maintenance of the Endotracheal Tube

1. Airway Obstruction

A patent airway is an absolute requirement for safe anesthesia. Airway obstruction can occur at any time during administration of general anesthesia, particularly in prolonged operations or in patients with predisposing anatomic abnormalities. Airway obstruction should be considered when an intubated patient has diminished breath sounds associated with increasing peak inspiratory pressures. Obstruction can result from diverse factors,[207] including a sharp bend or kink in the ETT, a tube that has been bitten closed, or a tube that is obstructed with mucus, blood, foreign bodies, or lubricant.[208,209] The ETT may become warm with continued use during prolonged procedures; under these circumstances, the tube may kink and become obstructed. Many clinicians mistakenly treat the patient for bronchospasm when the turbulent air movement comes from the ETT, not from the patient. At least two cases have been reported in which the plastic coating on a stylet sheared off and occluded the lumen of an ETT.[210,211] In another case, a tube was obstructed by the prominent knuckle of an aortic arch.[212] Nitrous oxide can cause expansion of gas bubbles trapped in the walls of an ETT, leading to airway obstruction.[213]

The cuff of an ETT can cause airway obstruction. An overinflated cuff may compress the bevel of the ETT against the tracheal wall, occluding its tip.[214] The cuff may also herniate over the tip of the tube and cause an obstruction.[215] When faced with any of these problems, the best solution is to pass a suction catheter or an FOB down the lumen of the ETT and attempt to clear it. If the tube is totally obstructed, passage of a stylet may be tried. Total obstruction that cannot be remedied quickly requires removal of the tube, and the patient should be reintubated as rapidly as possible. The ETT and connecting hoses should be supported and, if necessary, taped to prevent kinking caused by their own weight. Inspiratory gases should be humidified during long anesthesia to prevent tube obstruction from dried secretions.

Unusual causes of airway obstruction have been reported. In two patients, complete airway obstruction occurred secondary to achalasia and esophageal dilation.[216,217] Two cases of tension hydrothorax that caused airway obstruction during laparoscopic surgery have been reported. The first patient had malignant ascites that, when combined with a pneumoperitoneum, led to a rapid accumulation of pleural fluid with respiratory and cardiovascular compromise.[218] The second case occurred during operative hysteroscopy when a large volume of glycine was absorbed through opened myometrial vessels under high intraabdominal pressure.[219] In each case, more than 1.5 L of clear fluid was drained once chest tubes were placed.

2. Disconnection and Dislodgment

A common and serious complication of tracheal intubation is disconnection of the ETT from the remainder of the anesthesia circuit. This was identified as the most common critical incident in a study of anesthesia-related human errors and equipment failures.[220] A trained anesthesiologist usually identifies this problem immediately. The low-pressure alarm sounds first, and the patient's breath sounds become absent. However, if the ventilator continues to function normally, the physician may be unaware of the nature of the problem. Disconnections are most likely to occur if the connections are made of dissimilar materials, if the patient's head is turned away from the anesthesiologist, or if the airway connections are hidden beneath the surgical drapes. Alarms to signal airway disconnection are included on all modern anesthesia machines, and their signals should be taken seriously.

Connections between the ETT and the breathing circuit should be checked and reinforced at the outset, before the anesthesiologist loses visual control of the airway. There should be no tension on the connections from the weight of the corrugated tubing or the drapes on the tubing. Members of the surgical team should be discouraged from inadvertently leaning on any portion of the breathing circuit. The exact site of disconnection should be ascertained rapidly by checking each connection, beginning at the patient's airway and moving proximally back to the machine.[221] Nonetheless, the anesthesiologist must have a prearranged plan in mind in the event that an airway is inadvertently disconnected or dislodged during surgery.

3. Circuit Leaks

Leaks in an air delivery circuit can cause hypoventilation and dilution of the inspired gases by entry of room air into the system. With an ascending bellows system, such as that found in newer models of anesthesia machines, the bellows do not rise completely during exhalation if there is a leak. This situation indicates that the circuit leak exceeds the inflow of fresh gas. Older machines with a descending bellows system do not provide such a visual clue and appear to function normally. The anesthesiologist should be vigilant at all times for signs of a circuit leak. The inspired oxygen concentration measured at the gas sampling port is reduced because of dilution with room air, and the partial pressure of end-tidal CO_2 increases. Cyanosis, decreased oxygen saturation (Spo_2), or hypertension and tachycardia associated with hypercapnia may be the presenting signs, although each of these is typically a late finding.

Mnemonics such as COVER ABCD–A SWIFT CHECK may help to diagnose and treat the conditions[222]:

C Circulation, capnograph, and color (saturation)
O Oxygen supply and oxygen analyzer
V Ventilation of intubated patient and vaporizers (include analyzers)
E Endotracheal tube (position, orientation, and patency) and eliminate machine problems
R Review monitors and equipment
A Airway (with face or laryngeal mask)
B Breathing (with spontaneous ventilation)
C Circulation (in detail)
D Drugs (consider all given or not given)
A Awareness of air and allergy
SWIFT CHECK of patient, surgeon, process, and responses

4. Laser Fires

Lasers are frequently used in the operating room to ablate benign and neoplastic tissues in the airway. The use of special laser-guarded or metal tubes is recommended, and all inflammatory materials such as prosthetic teeth and nasogastric tubes should be removed. One of the most catastrophic events associated with their use is an airway fire, which occurs when the laser ignites the ETT.[223-225] The risk that a laser beam will contact the wall of an ETT is 1 : 2.[226] Perforation of the tube may occur and produce a blowtorch-like flame. Oxygen-rich inspired gas concentrations fuel brisk ignition of the plastic in the ETT and can fuel a fire in both directions. The ETT acts as a blowtorch; the fire is fed by the combustible walls of the tube and is intensified by the high rate of oxygen flow. The heat and fumes of the burning plastic may cause severe damage to the airway. Treatment consists of immediately disconnecting the circuit from the ETT and removing the burning tube from the airway. If the tube is not burning or if complete loss of the airway may occur with removal of the tube, leaving the tube in situ should be considered. The fire should be extinguished with saline, and the patient should be supported by face mask ventilation. The airway should be evaluated for damage with bronchoscopy, and the appropriate supportive respiratory care should be given.

Many precautions can reduce the risk for an airway fire. If possible, placement of an ETT may be avoided altogether if air can be delivered through a ventilating laryngoscope, a jet ventilation system, or by intermittent apneic ventilation.[227] If a tracheostomy tube is in place, ventilation may occur distal to the site of laser surgery. The choice of laser tubes should be consistent with the type of laser used. Blocking cuffs are particularly vulnerable to the laser beam. Covering the tube with saline-soaked gauze or noncombustible tape, using a positive end-expiratory pressure (PEEP) of 5 to 10 cm H_2O to prevent aspiration of material in case of cuff puncture, and filling the cuff with saline to act as extinguisher in the event of puncture are measures that can protect the

patient's airway.[228,229] Placing a dye, such as methylene blue, in the saline can further alert the anesthesiologist, because in the event of a fire, a stream that is the color of the dye will be emitted.

Nitrous oxide should be avoided because it supports combustion. Oxygen concentrations should never exceed 40% for the same reason.[230,231]

C. Special Techniques

1. Fiberoptic Intubation

Fiberoptic intubation is the method of choice in all cases of anticipated difficult airway. It combines direct vision with flexibility to view the pharynx when direct laryngoscopy is considered difficult or impossible. Use of the FOB is not a quick technique, and it probably should not be considered when speed is required. Although the device can be used in many different situations involving airway management and preoperative evaluation of critical patients, it also has several limitations and potential complications.

Intubation with an FOB should not be attempted when the pharynx is filled with blood or saliva, when inadequate space exists within the oral cavity to identify pharyngeal structures, or when time is critical and creating a surgical airway is the priority. Relative contraindications include marked tissue edema, distortion of the oropharyngeal anatomy, narrowed nasal passages, soft tissue traction, and a severe cervical flexion deformity. Operator experience with the technique and proper preparation are essential. Connecting the device to a video system can help with guidance by a more experienced bystander particularly in training situations.[232]

Potential complications associated with the FOB include bleeding, epistaxis (especially if a nasal airway is attempted), laryngotracheal trauma, laryngospasm, bronchospasm, and aspiration of blood, saliva, or gastric contents. Another possible hazard is associated with the practice of insufflating oxygen through the suction channel. Although this technique can help to keep the tip of the bronchoscope clean and provide for a high volume of forced inspiratory oxygen, it can also cause high-pressure submucosal injection of oxygen if the tip cuts into the pharyngeal mucosa. If this sequence occurs, the result may be pronounced subcutaneous emphysema of the pharynx, face, and periorbital regions.[233]

2. Lighted Stylets

The lighted stylet may be used to facilitate intubation under local and general anesthesia. A light at the tip of a flexible stylet is used to transilluminate the soft tissues of the pharynx. The device can be used blindly or as an aid when direct laryngoscopy is difficult. It may also confirm that the tip of an ETT is still within the cervical trachea and establish that the tube has not been advanced too far.[234]

Because use of the lighted stylet is a blind technique, the pharyngeal pathologic condition cannot be visualized or avoided. This method should not be used in patients with suspected abnormalities of the upper airway, such as tumors, polyps, infections (e.g., epiglottitis, retropharyngeal abscess), trauma, or foreign bodies. The lighted stylet should be used with caution in patients in whom transillumination of the anterior neck is limited, such those with dark skin pigmentation, morbid obesity, limited neck mobility, a large tongue, and a long epiglottis. If placement of the stylet is difficult, the anesthesiologist should consider abandoning the technique for fear of worsening a pathologic process.

Several real and potential complications have been reported with the use of this device. Sore throat, hoarseness, mucosal damage, and arytenoid subluxation are possible. Several cases have been reported in which the light fell off of the end of the stylet. In another instance, the protective tubing was not removed from the stylet and had the potential to become dislodged within the trachea. Heat damage to the tracheal mucosa in prolonged intubation is a potential risk with inappropriate handling. To avoid heat damage, the Trachlight's bulb flashes on and off after 30 seconds.[235]

Recommendation for use in emergency cases cannot be given because the risk of regurgitation is high, cricoid pressure may affect the ease of intubation, and in some cases, more than one attempt is necessary. The transillumination technique is not suitable for verification of the ETT's position because of misinterpretations.

3. Submandibular and Submental Approach for Tracheal Intubation

The oral route for tracheal intubation can interfere with some maxillofacial surgical procedures, and the nasal route can be contraindicated or impossible. Nasotracheal intubation is contraindicated in patients with fractures in the cribriform plate of the ethmoid, which frequently accompany Le Fort II and III maxillary fractures, because of the potential complications of infection and the possibility of cranial intubation. Tracheostomy is the usual solution in these circumstances, but it also carries complications. An alternative method is to introduce the tracheal tube through a submental or a submandibular incision, bypassing the surgical area and avoiding the complications of tracheostomy. Damage to adjacent structures with bleeding, tube displacement, aspiration, and hypoxia when passing the tube through a submental excision and infections have been reported.[236,237]

IV. COMPLICATIONS WITH INFRAGLOTTIC PROCEDURES

Infraglottic airway access is the last step in the ASA airway management algorithm. When tracheal intubation is impossible, a patient's airway is compromised, and the patient's condition deteriorates into a CICV situation threatening brain damage or death, life-saving steps must be undertaken immediately. There are no contraindications for infraglottic procedures in these critical situations. The most severe complication is failure to establish an airway before damage or death occurs. Complications arise because the decision to progress to a surgical airway is not made soon enough or because the procedure is performed too slowly. In all cases of difficult airway, the practitioner should evaluate the possibility of an infraglottic airway access. Difficult anatomic situations,

marked scars, abscesses, and morbid obesity may limit infraglottic access techniques.

Infraglottic airway techniques are suitable for emergency situations, and they are indicated for oxygenation and ventilation of anesthetized patients. Surgical procedures of the upper airway, laryngeal surgery, and diagnostic procedures have been successfully managed with this technique.

A. Translaryngeal Airway

1. Retrograde Wire Intubation

Retrograde wire intubation is an excellent technique for securing a difficult airway. It can be used when anatomic limitations obscure the glottic opening. Because the technique is blind, it is important to exercise caution and not worsen any preexisting conditions. The technique has variations, such as using the FOB by passing the wire through the suction channel or through a tube exchanger.[238]

Although simple in concept, the basic technique has numerous problems and potential complications. The procedure takes some time to perform and should not be considered under emergency circumstances unless the practitioner is very experienced. The tip of the ETT has been known to get caught on the glottic structures. The problem may be alleviated somewhat by using a tapered dilator inside the ETT or by using an epidural catheter as the wire to assist with passing the ETT through the glottis. Bleeding may occur at the site of the tracheal puncture in quantities sufficient to cause a tracheal clot or airway obstruction. Cases of severe hemoptysis with resultant hypoxia, cardiopulmonary arrest, arrhythmias, and death after retrograde wire intubation have been reported.[239-242] Subcutaneous emphysema localized to the area of the transtracheal needle puncture is common but usually self-limited. In severe cases, the air may track back through the fascial planes of the neck, leading to tracheal compression with resultant airway compromise, pneumomediastinum, and pneumothorax.[243,244] Laryngospasm may result from irritation by the retrograde wire unless the vocal cords are anesthetized or relaxed. Other, less common complications include esophageal perforations, tracheal hematoma, laryngeal edema, infections, tracheitis, tracheal fistulas, trigeminal nerve injury, and vocal cord damage.[245,246] The complications reported with retrograde wire intubation were most often associated with multiple attempts, large-gauge needles, and untrained staff members in emergency settings.[247]

2. Cricothyrotomy

Two methods are described: the surgical cricothyrotomy (using a scalpel) and the needle cricothyrotomy (using a needle set). In both procedures, the cricothyroid membrane must be perforated. Acute complications include bleeding (especially during surgical cricothyrotomy), misplacement of the tube (especially after needle cricothyrotomy), failure of airway access, wound infection, displaced cartilage fractures, and laryngotracheal separation.[248] Other complications include breaking and bending of the needle, subcutaneous emphysema, pneumothorax, pneumomediastinum, and pneumopericardium. When cricothyrotomy is performed in the case of total upper airway obstruction, barotrauma may occur because of expiratory blockade.

Granulation tissue around the tracheostomy site, subglottic stenosis, massive laryngeal mucosa trauma, endolaryngeal hematoma and laceration, vocal cord paralysis, hoarseness, and thyroid cartilage fracture with dysphasia are direct long-term complications. Indirect long-term complications include brain damage or mental impairment due to hypoxia when the cricothyrotomy takes more than 2 to 3 minutes.

Every emergency translaryngeal airway should be changed to a formal tracheostomy as soon as possible. Subglottic stenosis is a delayed complication, especially in children.

B. Transtracheal Airway

1. Transtracheal Jet Ventilation

One emergency method is transtracheal jet ventilation (TTJV), which is accomplished by introducing a small, percutaneous catheter into the trachea and insufflating the respiratory tract with high-pressure oxygen over a jet ventilator or a hand jet device (e.g., VBM Manujet). Although this technique may be helpful in critical situations, life-threatening problems are associated with it.

To accomplish TTJV, a long, large-bore catheter is advanced through the cricothyroid membrane into the trachea. If this catheter is displaced from the trachea, subcutaneous emphysema, hypoventilation, pneumomediastinum, pneumothorax, severe abdominal distention, or death may result.[164] On the basis of normal skin compliance, a 4-inch catheter may be pulled into the subcutaneous space by applying traction to its proximal end. The hub of the TTJV catheter must be continuously pressed firmly against the skin.

Barotrauma is a potential complication of TTJV.[249,250] Oxygen delivered through a transtracheal catheter must be able to escape the lungs freely, or overdistention and pulmonary rupture may occur.[251,252] Any changes in breath sounds, chest wall expansion, or hemodynamics should be considered to result from pneumothorax. In cases of total airway obstruction, the risk for pneumothorax is greatly increased because gas cannot escape from the lungs in a normal manner. Strong consideration should be given to placing a second transtracheal egress catheter in these circumstances. Laryngospasm can impede the outward flow of oxygen from the trachea. It should be prevented by providing adequate local anesthesia to the neighboring structures or by relaxing the patient.[250] If the larynx is obstructed by a foreign body, only low-flow oxygen should be delivered until safe egress of gas is established. Inadvertent placement of a gas delivery line into the gastrointestinal tract may result in complications and may cause gastric rupture, esophageal perforation, bleeding, hematoma, and hemoptysis.[253,254]

Damage to the tracheal mucosa may occur in patients who are managed with long-term TTJV, especially if the gas is not humidified.[255] The possibility of tracheal mucosal ulceration should be considered in any patient if nonhumidified TTJV is attempted through single-orifice catheters for a prolonged period.

2. Percutaneous Dilatational Tracheostomy

Percutaneous dilatational tracheostomy is not primarily recommended for emergency use. With further development, these insertion techniques became faster and appeared to be suitable for emergency situations in skilled hands.[256-260] Different sets are available.

Bleeding, subcutaneous and mediastinal emphysema, pneumothorax, airway obstruction, aspiration, infection, and death are early complications. Accidental extubation is a serious complication, because replacement of the cannula may be impossible. In this situation, orotracheal intubation or a translaryngeal oxygenation is required.[261] Bacteremia also has been reported.[262]

Delayed complications include tracheal stenosis, scars, hoarseness, and tracheoesophageal and tracheocutaneous fistulas. The incidence of injury for percutaneous dilatational tracheostomy is 2%, which is lower than for formal tracheostomy.

3. Formal Tracheostomy

A formal tracheostomy is rarely recommended in emergency situations. Various types of instruments, assistance, and sterile conditions are required, and the tracheostomy should be performed only by a trained surgeon.

Bleeding is a complication of all surgical procedures, including airway access procedures. Minitracheostomy occasionally results in excessive bleeding into the airway, necessitating progression to full surgical tracheostomy.[263] The inflated cuff used in formal tracheostomy prevents pulmonary aspiration of blood. In rare cases, the innominate artery can rupture into the trachea because of excessive pressure from the tracheostomy tube, with resultant massive hemorrhage into the airway. Air embolism during operative procedure is possible.

If an air leak occurs and the cervical skin has healed around the tracheostomy tube, air can escape into the subcutaneous spaces of the neck, resulting in subcutaneous emphysema. If the condition goes unrecognized and the patient is maintained on high-pressure mechanical ventilation, the air may track to other locations. Air escaping into the paratracheal spaces can result in a pneumomediastinum. Air released into the pleural cavity can result in a tension pneumothorax.

Tracheal stenosis is a complication of long-term tracheostomy. A tracheostomy tube can cause tracheal erosion, particularly into the esophagus (i.e., tracheoesophageal fistula) or the brachiocephalic artery. These tubes typically sit low in the trachea and are designed with a fixed curve. Tube pressure can damage the skin at the insertion site.

Accidental extubation and dislodgment of the cannula occurs occasionally, most often in the early postoperative period. If the cannula is inadvertently removed from a fresh tracheostomy, it should be replaced as quickly as possible. Infection, mediastinal sepsis, tracheal stenosis, and tracheomalacia are rare late complications.

V. PHYSIOLOGIC RESPONSES

The larynx has the greatest afferent nerve supply of the airway. Airway reflexes are important in protection of the airway. They must be suppressed for stress-free airway management, especially for endotracheal intubation. Intensive autonomic response may occur during placement, maintenance, and removal of all airway management devices.

A. Hemodynamic Changes

Direct laryngoscopy and tracheal intubation are potent stimuli that may instigate an intense autonomic response.[264,265] Tachycardia, hypertension, arrhythmias, bronchospasm, and bronchorrhea are common; hypotension and bradycardia occur less often. Patients with preexisting hypertension are even more at risk when they are under stress.

Oczenski and colleagues showed that the insertion of a Combitube was associated with a significantly higher and longer-lasting increase in systolic, diastolic, and mean arterial pressure; heart rate; and plasma catecholamine concentration compared with insertion of a LMA and laryngoscopic endotracheal intubation (Fig. 51-4).[266] Hemodynamic and catecholamine responses to insertion of an LMA are minimal.[267,268] The apparently sympathetically mediated responses to mechanical stimulation of larynx, trachea-carina, and bronchi may be completely or partially blocked by topical or intravenous lidocaine.[269] The magnitude of stimuli to the upper airway depends on the number of attempts and the duration of intubation. In cases of difficult airway situations a higher increase of hemodynamic responses is anticipated. The hemodynamic response may also be blunted by giving opioids or short-acting selective β_1-blockers before laryngoscopy and intubation.[270] Because many patients have coexisting cardiovascular disease and cannot meet increased myocardial oxygen demands, large hemodynamic responses must be prevented. More than 11% of patients with myocardial disease develop some degree of myocardial ischemia during intubation.[271] The key is to provide an adequate depth of anesthesia with intravenous or inhalational agents before instrumentation of the airway.

Fiberoptic intubation performed under sufficient local anesthesia and conscious sedation is an appropriate technique to prevent major hemodynamic changes during intubation. Minor hemodynamic changes and minor increases of plasma catecholamine concentration are nevertheless apparent in this technique. Fiberoptic intubation using a special mask adapter shows fewer hemodynamic changes than those caused by laryngoscopy after induction of anesthesia. The lowest cardiovascular responses were documented in patients after insertion of an LMA.[272]

B. Laryngospasm

Laryngospasm is a protective reflex mediated by the vagus nerve. This reflex is an attempt to prevent aspiration of foreign bodies into the trachea. It may be provoked by movement of the cervical spine, pain, vocal cord irritation by secretions, or sudden stimulation while the patient is still in a light plane of anesthesia.[273]

In some cases of laryngospasm, the patient makes respiratory efforts but cannot move air in or out of the

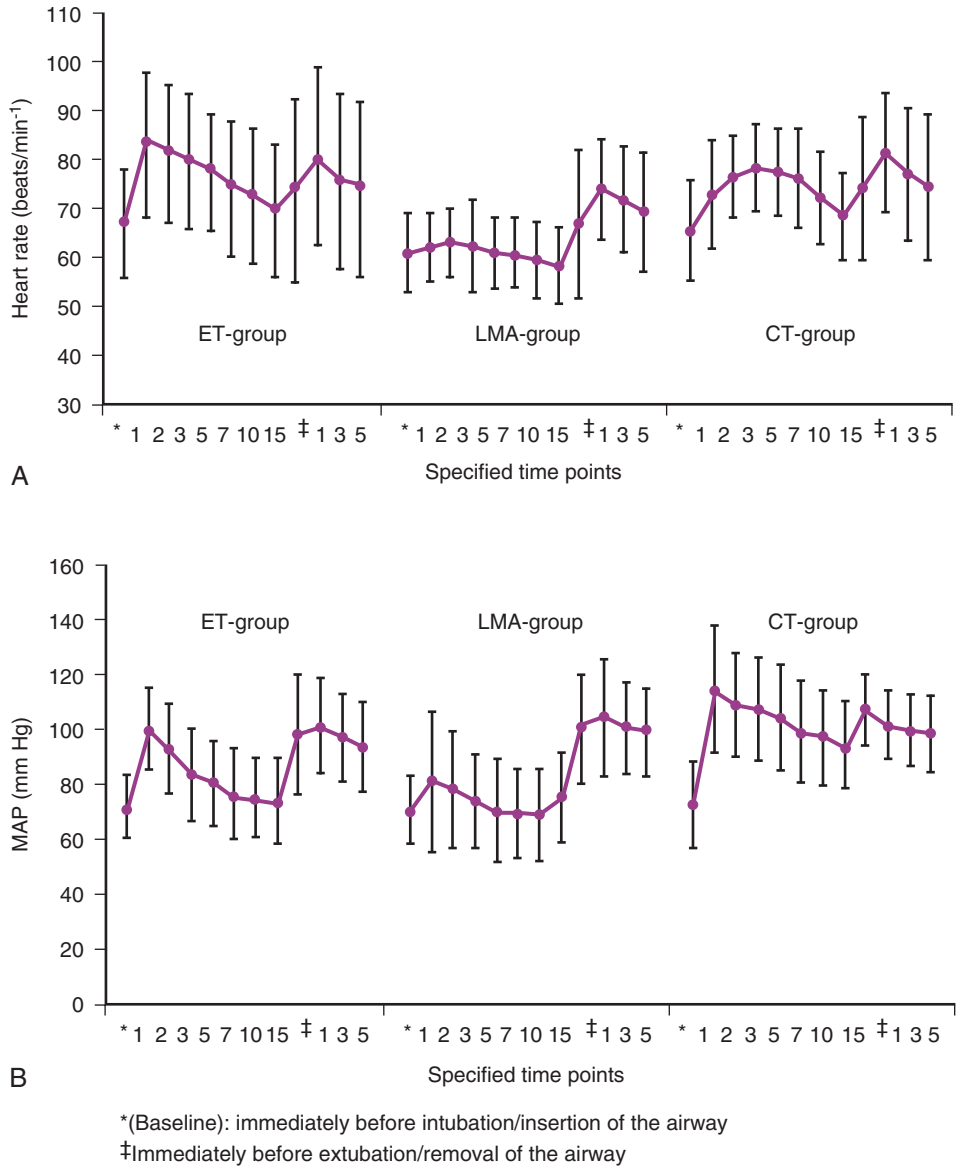

Figure 51-4 **A** and **B,** Heart rate and mean arterial blood pressure *(MAP)* at specified times (mean ± SD, *n* = 73) during insertion of the endotracheal tube *(ET),* laryngeal mask airway *(LMA),* and Combitube *(CT).* (From Oczenski W, Krenn H, Dahaba AA, et al: Hemodynamic and catecholamine stress responses to insertion of the Combitube, laryngeal mask airway or tracheal intubation. *Anesth Analg* 88:1389, 1999.)

lungs. If direct laryngoscopy was performed, the vocal cords would be completely adducted. However, laryngospasm involves more than spastic closure of the vocal cords. An infolding of the arytenoids and the aryepiglottic folds occurs; these structures are subsequently covered by the epiglottis.[274] Malpositioning, incorrect insertion of an LMA, secretions or blood in the airway, and inadequate depth of anesthesia during intubation or extubation of the LMA or tracheal tube may induce laryngospasm. It may also occur during fiberoptic intubation performed in unanesthetized or subanesthetized laryngeal structures. A firm jaw thrust can sometimes break the spasm—the hyoid is elevated, thereby stretching the epiglottis and aryepiglottic folds to open the forced closure.

The stimulus should be removed, a change of airway should be considered, and secretions should be suctioned away. Positive mask pressure with 100% oxygen may help by distending the pharynx or vocal cords, but this technique is not always adequate. Gentle chest compression in children may also help.[275] Deepening the anesthesia with small doses of propofol (0.25 to 0.8 mg/kg given intravenously can treat laryngospasm in 76.9%) or treatment with a short-acting muscle relaxant (0.1 to 3 mg/kg of succinylcholine) are the most promising ways to break the spasm.[276]

C. Bronchospasm

Tracheal irritation from the ETT can cause bronchospasm that is sufficiently severe to prevent air movement throughout the lungs.[277] Approximately 80% of the measurable resistance to airflow occurs in the large central airways; the remaining 20% occurs in the smaller peripheral bronchioles.[278] The incidence of intraoperative

bronchospasm is almost 9% with endotracheal intubation, 0,13% with an LMA, but almost 0% with mask ventilation.[279,280] Poor correlation is seen with age, sex, duration or severity of reactive airway disease, duration of anesthesia, or the forced expiratory volume in 1 second.[279] Other factors that may contribute to bronchospasm include inhaled stimulants, release of allergic mediators, viral infections, exercise, or pharmacologic factors (including beta-blockers, prostaglandin inhibitors, and anticholinesterases). Bronchospasm may occur during fiberoptic intubation if parts of subglottic airway are insufficiently anesthetized. The spasm can be treated with inhalation of epinephrine or isoproterenol or a β_2-agonist (e.g., albuterol, metaproterenol, or terbutaline) or by deepening the level of a volatile anesthetic.

D. Coughing and Bucking

Two additional adverse responses to intubation are coughing and bucking on the ETT.[281] These responses are potentially hazardous in cases of increased intracranial pressure,[282] intracranial vascular anomalies, open-globe injuries, or ophthalmologic surgery or in cases in which increased intra-abdominal pressure may rupture an abdominal incision.[283] Intubating a patient only when an adequate depth of anesthesia has been achieved helps to prevent this reflex.

Coughing and bucking occur less frequently with the LMA. However, in the case of lubricant globules on the anterior surface of the cuff, light anesthesia, and malpositioning, they may be observed.

E. Vomiting, Regurgitation, and Aspiration

The overall incidence of aspiration during general anesthesia has been reported as 1 in 2131 procedures (in Sweden) to 1 in 14,150 procedures (in France). The incidence in the United States was 1 in 3216 procedures. The associated mortality rate was 1 in 71,829 cases in the United States.[284] A meta-analysis of 547 publications concerning use of the LMA suggested that the overall incidence of pulmonary aspiration was about 2 in 10,000 cases.[285]

The ETT and Combitube are most effective in preventing pulmonary aspiration. To reduce the risk of pulmonary aspiration, some airway management devices, such as the ProSeal-LMA and the Laryngeal Tube S, were redesigned.

In any patient considered to have a full stomach, the likelihood of vomiting in response to irritation of the airway is increased, and aspiration of stomach contents is a constant concern. Aspiration leads to coughing, laryngospasm, and bronchospasm, assuming that protective reflexes are intact. Hypertonia, bradycardia, asystole, and hypoxia may occur. The magnitude of pulmonary reactions depends on the type and quantity of the aspirated material.[286]

The Sellick maneuver, or cricoid pressure (CP), is controversial. Although some strongly endorse the technique and trust its effectiveness, others think that CP should be abandoned because it adds to patients' risks with no evidence of gained benefit. Other practitioners apply CP because they think it is a low-risk technique that may work in some patients. The future of CP use lies in the answer to the question of whether it is effective in preventing regurgitation or an unnecessary hazard. Because aspiration is a rare event, a study to confirm the preventive effect of CP may not be feasible.

It is possible to completely obstruct the airway with CP. CP has resulted in airway obstruction in patients with lingual tonsils, lingual thyroid glands,[287] and undiagnosed laryngeal trauma.[288] If any doubt exists about the success of an oral intubation, awake techniques should be considered under these circumstances.[289]

F. Intraocular Pressure Changes

Intraocular pressure increases during direct laryngoscopy and extubation, but not during LMA insertion.[290,291] Decreased intraocular pressure was observed under tracheal intubation during general anesthesia with propofol and with sevoflurane, both combined with remifentanil.[292]

Sufentanil is effective in preventing intraocular pressure increases caused by rapid-sequence induction with succinylcholine; alternatively rocuronium can be used.[293] Increased intraocular pressure should be strictly avoided in patients with penetrating eye injuries.

G. Intracranial Pressure Changes

Intracranial pressure markedly and transiently rises during laryngoscopy and endotracheal intubation. Patients with head injury are at risk from this increase because it reduces cerebral perfusion and may increase the likelihood of secondary brain damage.[294] Fiberoptic bronchoscopy produces a substantial but transient increase of intracranial pressure.[295] Deep anesthesia during induction can prevent these adverse effects.

H. Apnea

Apnea may be a reflex response to tracheal irritation from the ETT or other airway techniques. Extraneous reasons for the apnea—for example, if the patient is a premature or term neonate,[296] has had induction drugs or excessive narcotics, or has a reflux response to light levels of anesthesia—should be ruled out initially. If no clear reason exists for the patient's lack of respiratory effort, mechanical ventilation can be initiated, and spontaneous ventilation can be attempted later.

I. Latex Allergy

Of anaphylaxis episodes occurring during surgical procedures, 16.6% are related to latex allergies.[297] To prevent anaphylaxis during anesthesia and surgery, the patient's history should be evaluated preoperatively. There is no therapy for latex allergy, and avoidance of latex-containing products is mandatory for predisposed individuals.[298] Latex allergy affects 8% of the U.S. general population and has a prevalence of 30% among health care workers.[299,300] There has been an increase in the incidence of type I and IV latex sensitivity in the general population, from 1% in 1980 to 8% in 1996.[301] The prevalence

Secondary Effects

Central Nervous System
- Increased intracranial pressure

Eyes
- Increased intraocular pressure

Modified from Hartley M: Difficulties in tracheal extubation. In Latto IP, Vaughan RS, editors: *Difficulties in tracheal intubation,* London, 1997, Saunders.

of latex sensitivity among anesthesiologists is about 12.5%, and the prevalence of allergy is 2.4%.[302]

Patients with spina bifida, rubber industry workers, atopic patients, and patients with a history of many operations are most at risk.[303] Patients with certain exotic food allergies may also have a coexisting latex allergy[304]; in one study, the rate was 86%.[305]

Patients with type I hypersensitivity are at risk for anaphylaxis with hypotension, rash, and bronchospasm. Type I hypersensitivity symptoms are localized contact urticaria with pruritus and edema. Generalized reactions are rash or hives, tearing, rhinitis, hoarseness, dyspnea, nausea, vomiting, bronchospasm, abdominal cramping, and diarrhea.

Contamination with latex during anesthesia is possible through direct contact by face mask, endotracheal and gastric tubes, gloves, syringes, and electrodes; through inhalation from contaminated circuits and room air; and through the parenteral path with latex-containing intravenous administration sets.

Most airway management devices are available as latex-free products. The oropharyngeal cuff of the Combitube contains latex; therefore, it is contraindicated in patients with known latex allergy. All anesthesiology departments should have a special latex-safe cart with all medical supplies and devices.

VI. COMPLICATIONS WITH EXTUBATION

Primary and secondary responses to extubation are possible. The primary effects are local and systemic responses (Box 51-2). The same responses after intubation may be observed at extubation. During intubation, the patient is more protected by anesthesia induction than during extubation, and the cardiovascular responses may be even more exaggerated. The most serious complication after extubation is acute airway obstruction. Decreased consciousness with central respiratory depression, decreased muscle tone, and tongue retraction to the postpharyngeal wall may lead to inspiratory or expiratory stridor, dyspnea, cyanosis, tachycardia, hypertension, agitation, and sweating. Laryngospasm is also possible, and urgent treatment is necessary to prevent hypoxia, brain damage, and death. Other complications after extubation are not caused by the removal of the tube itself; they are consequences of the previous intubation and the duration of tube placement, such as laryngitis, edema, ulcerations, granuloma, or synechia of the vocal cords. The quality of tracheal intubation contributes to laryngeal morbidity, and excellent conditions are less frequently associated with postoperative hoarseness and vocal cord sequelae.

A. Hemodynamic Changes

Hemodynamic changes, including a 20% increase in heart rate and blood pressure, occur in most patients at the time of extubation,[306,307] and symptoms that are associated with sympathoadrenal activity should be expected. These changes are usually transient and rarely require treatment. Although most patients tolerate these hemodynamic responses well, patients with cardiac disease,[271] pregnancy-induced hypertension,[308] and increased intracranial pressure may be at particular risk for life-threatening ischemic myocardial episodes.[309] Patients with cardiac disease have had decreased ejection fractions at the time of extubation.[310] Management consists of extubation under deep anesthesia or pharmacologic therapy. Deep extubation is inappropriate for patients with a difficult airway, those at high risk for aspiration, and those with compromised airway access. Pharmacologic strategies emphasize the importance of decreasing the heart rate, such as with short-acting beta-blockers.[311] Cerebral hemorrhage is possible. Using an LMA may significantly reduce local and cardiovascular responses at removal if the cuff pressure is minimized to avoid overstimulation of the patient.[26]

B. Laryngospasm

In a computer-aided study of 136,929 patients, the incidence of laryngospasm was 50 cases per 1000 children with bronchial asthma or airway infection and 25 cases per 1000 in children 1 to 3 months old after tracheal intubation had been performed.[312]

The optimal course for treating laryngospasm is to avoid it in the first place. Treatment was described earlier. When laryngospasm is anticipated, the patient may undergo a deep extubation. A patient undergoing deep extubation should be placed in the lateral position with the head down to keep the vocal cords clear of secretions during emergence. It is best to extubate patients during a positive-pressure breath to remove residual secretions. Extubation during positive-pressure breath is the procedure of choice in children. A study showed that children could be safely extubated in deep anesthesia from a 1.5 minimum effective alveolar anesthetic concentration of sevoflurane or desflurane.[313] The study of Koga and

colleagues showed that the rate of airway obstruction in patients extubated during deep anesthesia (17 of 20) was not higher than in patients extubated after regained consciousness (18 of 20).[314]

C. Laryngeal Edema

Laryngeal edema is an important cause of post-extubation obstruction, especially in neonates and infants. This condition has various causes and is classified as supraglottic, retroarytenoidal, or subglottic.[315] Supraglottic edema most commonly results from surgical manipulation, positioning, hematoma formation, overaggressive fluid management, impaired venous drainage, or coexisting conditions (e.g., preeclampsia, angioneurotic edema). Retroarytenoidal edema typically results from local trauma or irritation. Subglottic edema occurs most often in children, particularly neonates and infants. Factors associated with development of subglottic edema include traumatic intubation, intubation lasting longer than 1 hour, bucking on the ETT, changes in head position, or tight-fitting tubes. Laryngeal edema usually manifests as stridor within 30 to 60 minutes after extubation, although it may start as late as 6 hours after extubation. Regardless of the cause of laryngeal edema, management depends on the severity of the condition. Therapy consists of humidified oxygen, nebulized epinephrine, head-up positioning, and occasionally reintubation with a smaller ETT. The practice of administering parenteral steroids with the goal of preventing or reducing edema after long-term (>36 hours) ventilation may prove beneficial for adult patients, but routine administration for anesthesia is controversial.[316]

D. Laryngotracheal Trauma

Unlike trauma during intubation, airway trauma at the time of extubation is not well described. Arytenoid cartilage dislocation has been reported after difficult and routine intubations.[122,317] Symptoms become apparent soon after extubation and may be mild (e.g., difficulty swallowing, voice changes) or major (e.g., complete airway obstruction). Management depends on the severity of the condition. Options include reintubation, arytenoid reduction, and tracheostomy. If laryngotracheal trauma is suspected, an otolaryngology consultation is warranted.

E. Bronchospasm

In patients at risk for bronchospasm, the timing of extubation is important. These patients may be extubated during deep anesthesia (if this approach can be used safely) or when they are fully awake and their own airway reflexes are present. Although the degree of spasm in this condition may be severe, it is usually self-limited and short-lived.

F. Negative-Pressure Pulmonary Edema

When airway obstruction occurs after extubation in the case of laryngospasm, negative-pressure pulmonary edema may occur in a spontaneously breathing patient. As a result of inspiratory effort against the closed glottis, these patients generate negative intrapleural pressure of more than 100 cm H_2O. Rib retraction with poor air movement, laryngospasm, and stridor may lead to the rare diagnosis. Increased left ventricular preload and afterload, altered pulmonary vascular resistance, increased adrenergic state, right ventricle dilation, intraventricular septum shift to the left, left ventricular diastolic dysfunction, increased left heart loading conditions, enhanced microvascular intramural hydrostatic pressure, negative pleural pressure, and transmission to the lung interstitium may result in a marked increase in transmural pressure, fluid filtration into the lung, and development of pulmonary edema.[318]

Negative-pressure pulmonary edema is seen within minutes after extubation. Hemoptysis and alveolar hemorrhage are rare symptoms. Management involves removing the obstruction, supporting the patient with oxygen, monitoring the patient closely, and reducing the afterload. CPAP therapy is useful, and reintubation is rarely necessary. Most cases resolve spontaneously without further complications.

G. Aspiration

Pulmonary aspiration of gastric contents is a constant threat for any patient who has a full stomach or is at risk for postoperative vomiting. Laryngeal function is altered for at least 4 hours after tracheal extubation.[319] Coughing is a physiologic response to protect the airway from aspiration. Depression of reflexes, along with the presence of residual anesthetic agents, places most recently extubated patients at risk. Aspiration is probably more prevalent than is currently thought. Most cases are so minor that they do not affect the patient's postoperative course. Reducing gastric contents by suctioning through a gastric tube and extubation with the patient placed in the lateral position with a head-down tilt is the safest protection against aspiration. Perioperative problems, if they do occur, are usually attributed to factors such as atelectasis. Management consists of supportive measures. Depending on the extent of aspiration, measures include supportive care, ranging from administration of oxygen through a nasal cannula to reintubation with mechanical ventilation, and PEEP.

H. Airway Compression

External compression of the airway after extubation may lead to obstruction. An excessively tight postoperative neck dressing is a cause of external compression that is easily resolved. A more ominous situation is a rapidly expanding hematoma close to the airway. This may occur after certain operations, such as carotid endarterectomy, and must be quickly diagnosed and treated before total airway obstruction occurs.[320] Immediate surgical re-exploration is indicated, although the airway concerns for these patients should be approached with extreme caution. To minimize airway distortion, general anesthesia should be avoided until the wound is evacuated under local anesthesia. However, even after surgical

drainage, airway obstruction may occur as the result of venous or lymphatic congestion. Any use of muscle relaxants during anesthesia induction in these patients may result in catastrophe, regardless of whether the wound was previously drained. Conservative options for managing the airway in this situation include awake fiberoptic intubation, surgical airways, or inhalation induction. Muscle relaxants should be avoided until the airway is secured.

External compression of the neck, such as chronic compression of a goiter, may also result from tracheomalacia.[321] This condition is usually seen after the goiter has been removed, although cases were reported in which the airway collapsed with induction or after extubation.[322,323] Airway obstruction in these patients becomes apparent soon after extubation. Management includes reintubation, surgical tracheal support (i.e., stenting), or tracheostomy below the level of obstruction.

I. Difficult Extubation

Occasionally, ETTs are difficult to remove. Possible causes are failure to deflate the cuff, use of an oversized tube,[324] adhesion of the tube to the tracheal wall,[325] or transfixation of the tube by an inadvertent suture to a nearby organ, a wire, a screw placed in an oromaxillofacial operation, or a broken drill.[326-329,340] Possible sequelae of these complications include airway leak, aspiration, tube obstruction, and trauma from attempts at forceful extubation. One case was reported in which a nasogastric tube made a loop around the ETT.[330] In most cases, the problem arises from an inability to deflate the cuff, commonly as a result of failure in the cuff-deflating mechanism. If this problem occurs, the cuff should be punctured with a transtracheal needle. If tube fixation is suspected, the passage of the tube should be checked with a suction catheter or a fiberscope. Forceful removal of an ETT with the cuff inflated may result in damage to the vocal cords and arytenoid dislocation.

J. Accidental Extubation

Accidental extubation during anesthesia has been reported with disposable tonsillectomy instruments,[331] change of the patient's head position, and in neurosurgery with the patient in the knee-elbow position.[332] Most accidental extubations were reported from intensive care unit patients, for whom self-extubation was the most common incident (77% to 85%).[333-335] The rate of reintubation was 37% to 57%.[333-335] The requirement for reintubation is higher for patients with full ventilatory support than those during the weaning phase.

Patients at risk for accidental extubation are characterized by the absence of physical restraints, a high nurse-to-patient ratio, trips out of the intensive care unit (59%), light sedation (43%), use of bedside portable radiography, accidental removal of the nasogastric tube or tugging on the ETT, oral intubation, and insufficient sedation.[336] Complications after accidental extubation may be hypoxia, hypercarbic respiratory failure, aspiration, retention of pulmonary secretion, arrhythmia, and tachycardia. To avoid unplanned extubation, tubes can be secured with special tube holders,[337] with waterproof tape, and with fixation using a knot or a bow.[338,339]

Reintubation may be very difficult, especially after a difficult intubation. The use of a Combitube or an LMA is required in some cases of inadequate access to the patient's head in the intensive care setting.[340]

VII. CONCLUSIONS

Anesthesiologists face many challenges and complications when managing airways. Errors may be technical or judgmental. By learning from the mistakes of the past, we can avoid or minimize them by anticipating problems, devising safe primary and backup plans for every patient, maintaining vigilance throughout all operative procedures, and using common sense at all times.

VIII. CLINICAL PEARLS

- The final goal of airway management is oxygenation of the patient, not placement of an endotracheal tube (ETT).
- Serious complications of airway management result from not recognizing the level of airway difficulties.
- To minimize injury to the patient, the anesthesiologist should examine the patient's airway carefully, identify potential problems, devise a plan that involves the least risk for injury, and have a backup plan immediately available. Common sense should prevail at all times.
- In daily anesthesia practice, errors of omission are more common than errors of commission. Errors of omission include failure to recognize the magnitude of a problem, failure to make appropriate observations, and failure to act in a timely manner. Errors of commission include actions such as trauma to the lips, nose, or laryngotracheal mucosa; forcing sharp instruments into areas in which they do not belong; or introducing air or secretions into regions of the body in which further complications will ensue.
- Many complications in airway management result from insufficient communication between the members of the medical team and improper coordination of the patients in the daily operating room schedule. A patient with known difficult airway problems should be scheduled at a time when the most experienced anesthesiologists and surgeons are available.
- Delayed recognition of complications leads to delayed therapy. Inadequate monitoring, nonfunctional equipment, and an untrained staff can contribute to airway catastrophes.
- The overall risk of aspiration and regurgitation using the laryngeal mask airway (LMA) is about that for endotracheal intubation when the indications and contraindications for the LMA are respected. The risk of aspiration, which is a consequence of the airway device's design, should be weighed against the advantages of the LMA in cases of difficult intubation and ventilation.

- Because of the increased risk associated with multiple attempts of any airway technique, a maximum of three attempts is recommended to minimize trauma to the airway.
- Any airway device technique may cause movement and subsequent injury to the patient with an injured cervical spine.
- A patent airway is an absolute requirement for safe anesthesia. Airway obstruction can occur at any time during administration of general anesthesia, particularly in prolonged operations or in patients with predisposing anatomic abnormalities. The most serious complication after extubation is the occurrence of acute airway obstruction.

VIII. Clinical Pearls

I. BACKGROUND

Management of the airway is the most important and potentially the most life-saving (or life-threatening) task that an anesthesiologist, emergency department (ED) physician, or intensivist performs. Missteps in airway management can result in mortality or significant morbidity. In 1985, the American Society of Anesthesiologists (ASA) Committee on Professional Liability began to analyze closed-claim malpractice cases to objectively assess adverse outcomes from anesthesia. The initial analysis of the data, published in 1990, revealed that respiratory events accounted for 34% of the claims (522/1541 cases) and that 85% of the respiratory events resulted in permanent neurologic injury or death.[1] Three mechanisms of adverse outcome from respiratory events accounted for 73% of the events: inadequate ventilation (38%), esophageal intubation (18%), and difficult endotracheal intubation (DI; 17%).

The reviewers concluded that 90% of the cases of inadequate ventilation and esophageal intubation could have been prevented if monitoring with capnography and pulse oximetry had been employed. It was also concluded that only 36% of the cases of DI were easily preventable. In response to this finding, the Task Force on Management of the Difficult Airway (DA) was formed by the ASA. After an exhaustive search and evaluation of the medical literature concerning airway management published between 1973 and 1991, the task force published *Practice Guidelines for Management of the Difficult Airway* in March, 1993.[2] These guidelines included recommendations for evaluation of the airway, basic preparation for DA management, strategy for intubation of the DA, and postoperative care. The Task Force also developed an algorithm for management of the DA. Updated guidelines, based on information accrued since 1993, were published in 2003.[3] It can be anticipated that future updates based on experience with new airway devices will occur.[4] Other organizations with interest in airway management have also published airway management guidelines.[5]

A. Is There Evidence That the Difficult Airway Guidelines Have Been Effective in Reducing Adverse Airway Events?

A review of the closed claims database in 1999 revealed a decline in claims for adverse respiratory events, primarily related to a reduction in claims for inadequate ventilation and esophageal intubation.[6] Claims for adverse events secondary to DI remained relatively constant, and claims for trauma to the upper airway increased. The claims for pharyngeal and esophageal trauma were frequently associated with DI. Another study, published in 2005, compared claims for DA management during two time periods: 1985–1992 (before DA guidelines) and 1993–1999 (after DA guidelines). Claims for adverse respiratory outcomes (death or brain death) during induction of anesthesia decreased by 67% during the

latter period compared with the former. However, claims for similar adverse respiratory outcomes occurring during the maintenance phase of anesthesia, at extubation, or during recovery did not change.[7]

Although respiratory events are more likely to result in an adverse outcome, the incidence of patients with a DA in clinical anesthesia practice is actually quite low. The incidence of *failure to intubate the trachea* in a large series of surgical patients was only 0.3%.[8] Although the most comprehensive published data have concerned perioperative airway management, airway management in the prehospital setting, in the ED, and in the intensive care unit (ICU) is no less important and must be included in any airway education program.[9] Airway management is not an easy skill to learn, and educators must give careful consideration to the complexity of airway management and the ability of different types of health care providers to manage ventilation and endotracheal intubation.

Objectives for education in airway management include the theoretical and practical aspects of airway devices and techniques and a time-based environment that mimics actual clinical situations. The student must also gain an appreciation of the relationship between the practitioner and the patient and the effects that clinical decisions may have on outcome.[10] The teaching program must allow the learner in a nonclinical environment to make choices that may result in an adverse outcome.

II. MILLER'S LEARNING PYRAMID

An airway teaching program must teach simple maneuvers (e.g., performing a jaw thrust) as well as complex skills such as awake fiberoptic intubation (FOI). The design of a successful education program begins with the development of clear objectives. What has to be taught, to whom, and how? The program must also address different knowledge and skill levels. Miller's learning pyramid for assessment of clinical skills has four stages of ability: *Knows, Knows How, Shows How,* and *Does* (Fig. 52-1).[11]

An example of this pyramid can be applied to use of the laryngeal mask airway (LMA). The first level, *Knows,* is the knowledge that there is a need for airway management and that the LMA can be used for that purpose. *Knows How* is the knowledge of how to prepare and insert the LMA. At the next competence level, the learner *Shows* that he or she is capable of inserting the LMA. The highest competence level, *Does,* reflects transfer of the new skill (LMA use) to the clinical situation. The first three levels of the learning pyramid can be achieved with didactic lectures, video observation, computer programs, and skill-training with mannequins, animal models, or cadavers.

Because skills and scientific information gained during simulator training may not be easy to transfer directly to clinical practice, the clinical environment is the best environment for developing airway management skills.[12] Practicing techniques such as airway assessment, bag-mask ventilation (BMV), supralaryngeal airway (SLA) insertion, direct laryngoscopy, and FOI in actual patients would be ideal. The highest competence level (*Does*) in airway management ultimately requires practice in the clinical environment. There are, however, a number of barriers to training exclusively in the clinical arena (Box 52-1). Training outside the operating room (OR) or ICU is done to minimize the risk to patients and promote efficient clinical learning.

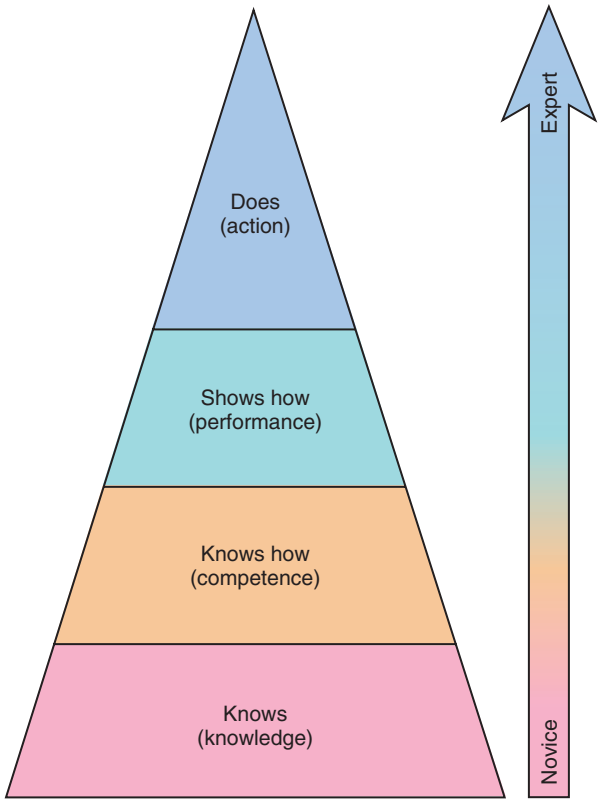

Figure 52-1 Level of competence based on clinical assessment. The highest level of competence, *Does,* is ultimately achieved with clinical performance. (Adapted from Miller GE: The assessment of clinical skills/competence/performance. *Academic Medicine* 65, S63–S67, 1990.)

III. COMPUTER-BASED LEARNING

The pace of development of interactive computer-assisted instructional programs has surpassed simulation development over the past 10 years. Computer-assisted

BOX 52-1 Barriers to Teaching Difficult Airway Management in the Clinical Environment

Infrequent opportunities for certain skills
- Retrograde intubation
- Transtracheal jet ventilation
- Percutaneous tracheostomy

Time pressure in the clinical setting

Difficulty in matching knowledgeable teachers and the right patient with the trainee

Perceived risks of practicing on patients when the technique is not indicated

Ethical considerations
- High risk and high cost of management failure by an inexperienced trainee
- Use of new methods before adequate experience with the method is obtained

instruction can facilitate the organization and linkage of information directly applicable to clinical situations.[13] A major advantage of computer-based instruction is the low cost after development and the lack of need for a human instructor. The learner can use the program at his or her own pace and as many times as necessary to achieve mastery of the subject. The increased power of laptop computers has reduced the need for computer centers and provides the learner with exceptional mobility. Computer-assisted instruction can also provide alternative learning methods for students who do not learn well with traditional teaching methods.

A clinical department can develop its own instructional programs or access existing programs via the Internet. The number of Web sites relevant to anesthesia continues to grow, and the Internet provides rapid access for users in remote locations.[14] However, Internet programs are not peer-reviewed, and quality can be variable.[15] The transition from Web 1.0 to Web 2.0 has encouraged more interactivity and improved the quality of Web-based education.[16] The disadvantages of Web-based education, such as insufficient feedback and instructional ambiguity, can be overcome by providing local faculty input to supplement the Web-based program.

Technical assistance may be required for the clinical faculty to facilitate in-house program development. The potentially daunting task of program assembly and maintenance must not be an obstacle to the faculty.

There are several objectives of an interactive airway management program (Box 52-2). One is to familiarize the learner with the anatomy and physiology of the upper airway. The complexity of the upper airway is often overlooked, and understanding of upper airway function can provide an early warning of impending respiratory difficulty. The structure and function of various airway devices can be displayed with diagrams, photographs, and videotapes. Computer-based multimedia programs can demonstrate device function and technique with a much more effective presentation than a traditional lecture format.

After the basic principles of airway management have been presented, interactive programs can be directed to elucidate the intricacies of the DA algorithm so that the learner understands the critical decision points during the course of airway management. A library of actual airway abnormalities can be loaded onto the computer as an additional teaching tool. Most modern video laryngoscopes (VLs) and flexible fiberoptic bronchoscopes (FFBs) can record airway examinations and airway device insertion. The combination of text material and narration with imported diagrams, photographs, and videotapes can be used to explain concepts and airway management techniques in considerable detail. More advanced interactive programs can simulate the clinical environment and present actual clinical scenarios in a real-time environment that permits the student to halt the program and access information that may affect the decision process. Such scenario-based learning is becoming increasingly important in medical education.

BOX 52-2 Instructional Components of an Airway Management Educational Program

Upper airway anatomy and physiology
Principles of the airway examination
- Recognition of the abnormal airway

Structure and function of airway devices
- Bag-mask ventilation (BMV)
- Pharyngeal airways
- Supralaryngeal airways (SLAs)
- Conventional direct laryngoscopes
- Video laryngoscopes (VLs)
- Flexible fiberoptic bronchoscopes (FFBs)
- Emergent invasive techniques

Static simulation practice (e.g., mannequin)
Examples of upper airway pathology
Critical decision points in the difficult airway algorithm
- Indications for awake intubation
- Cannot intubate, can ventilate
- Cannot intubate, cannot ventilate

Real-time clinical simulation

IV. EFFICACY OF SIMULATION IN EDUCATION

Simulation has been used for decades to address training problems in high-risk disciplines such as military science and aviation. Medical simulation began in the mid-1990s and has grown rapidly.[17] Simulator training programs incorporate psychomotor and decision-making skills that address the highest level of competence in Miller's pyramid: *Does*. When the programs are appropriately designed, simulation can close the gap between acquisition of skills and meaningful use of the acquired skills (Fig. 52-2). This may be especially true for rare situations. Because the incidence of the DA is low in clinical practice, two questions must be addressed: How can an anesthesiologist in clinical practice learn new airway skills? and How can the ramifications of critical decision points in airway management be learned?

The inherent nature of airway management includes uncertainty, complexity, time pressure, and high costs for failure. Simulation provides the ideal method for closely replicating the clinical situation and may help to scientifically evaluate strategies, decision points, and algorithm adherence.[18,19] The efficacy of education with medical simulation is well established, but its effect on reducing the incidence of adverse patient outcomes is more controversial.[18,20-24] It is easy to prove the effect of a theoretical lecture or workshop with a pretest and post-test. It is not easy to prove the effect of simulation on patient outcome in rare but life-threatening situations such as the DA. Nevertheless, there is evidence in the literature that simulator- and scenario-based training improves patient care.

V. TYPES OF SIMULATORS

Simulators can be classified as low-fidelity (static) or high-fidelity (dynamic).

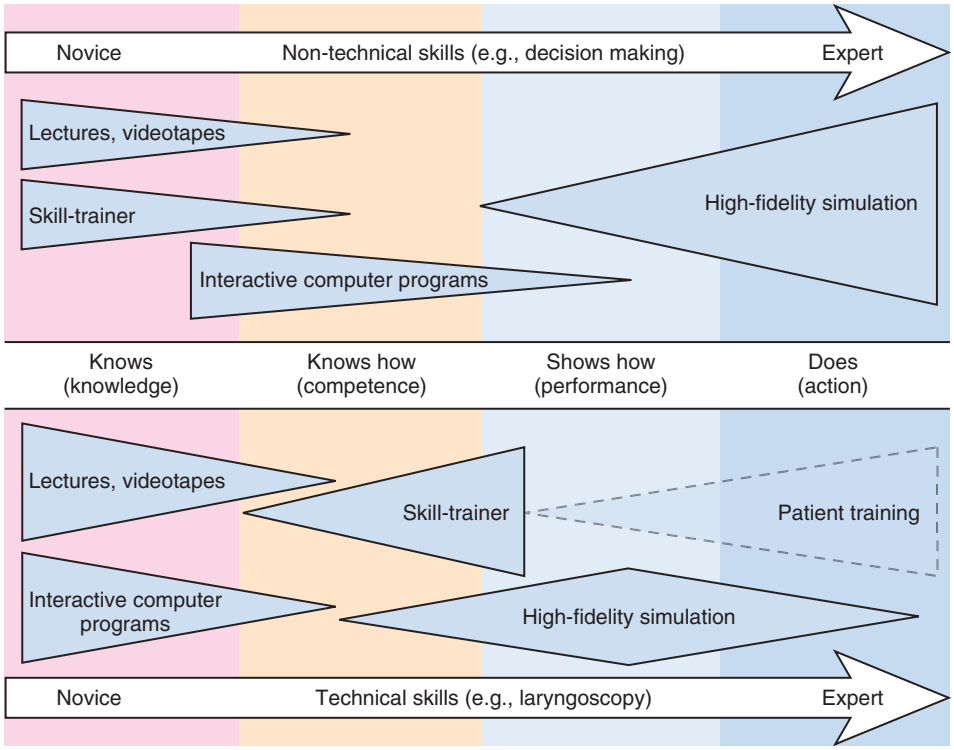

Figure 52-2 Indications for use of different training tools in the acquisition of technical and nontechnical skills based on Miller's learning pyramid. The width of the pyramid should reflect the benefit of the distinct training tool on the indicated level of competency.

A. Low-Fidelity Simulators

Skill-trainers or mannequins are available for most airway devices, such as conventional laryngoscopes, SLAs, and FFBs. Skill-trainers are designed to teach specific motor skills, such as direct laryngoscopy, the fundamentals of FFB guidance, or SLA insertion.

Mannequins do not always accurately replicate human anatomy and cannot be altered to represent abnormal anatomy. Such low-fidelity simulators provide neither physiologic data nor clinical feedback for the learner. Despite these shortcomings, however, effective skill transference to clinical use may be facilitated.[25]

B. High-Fidelity Simulators

High-fidelity simulators, more commonly referred to as human patient simulators, offer many advantages over low-fidelity simulators. Physiologic parameters such as blood pressure, heart rate, pulse oximetry, capnography, breath sounds, peripheral pulses, and temperature can be programmed into the simulator. High-fidelity simulators cannot accommodate the variations in human anatomy.[26] This is especially true for DI scenarios in which insertion of an SLA may be clinically effective. The reason is that the DI scenario in the simulator is created by supraglottic obstruction rather than laryngeal displacement.

Current simulators have pre-programmed clinical scenarios that require no program assembly and minimal technical expertise on the part of the instructor. The teaching programs present time-based physiologic changes in the simulator that accurately reflect actual clinical events. The programs allow the learner many different management choices, and the instructor can vary the simulator's physiologic responses based on the learner's selection of techniques. Human performance deteriorates during periods of stress, and there is a tendency to revert to old behavior patterns. Translated to airway management, this may result in repetitive attempts to use airway techniques that have previously failed (e.g., rigid direct laryngoscopy) while the patient's condition continues to worsen. Simulation can be used to teach new management techniques, and permits the learner to apply those techniques in a simulated environment in which the adverse effects of a poor choice will be evident. Repetitive simulated encounters can then be employed until the new technique becomes part of the learner's management armamentarium. High-fidelity medical simulation can create a learning environment that supports experiential and reflective learning. For this purpose, a realistic scenario based on a real-life situation is introduced into an authentic environment, followed by a structured debriefing about strategies the learner chose. Appropriate simulation teaching programs help the student develop integrated emotional, cognitive, and psychomotor abilities that effect a change in behavior and performance in the clinical setting. These advantages offset the initial capital investment, need for training space, and operational costs.

Many medical institutions and health care consortiums have invested in multipurpose simulation centers to provide training for different types of health care providers. These centers replicate ORs, ICU beds, ward beds, examination rooms, and ambulance bays to provide a realistic setting for trainees (Fig. 52-3). Simulation centers

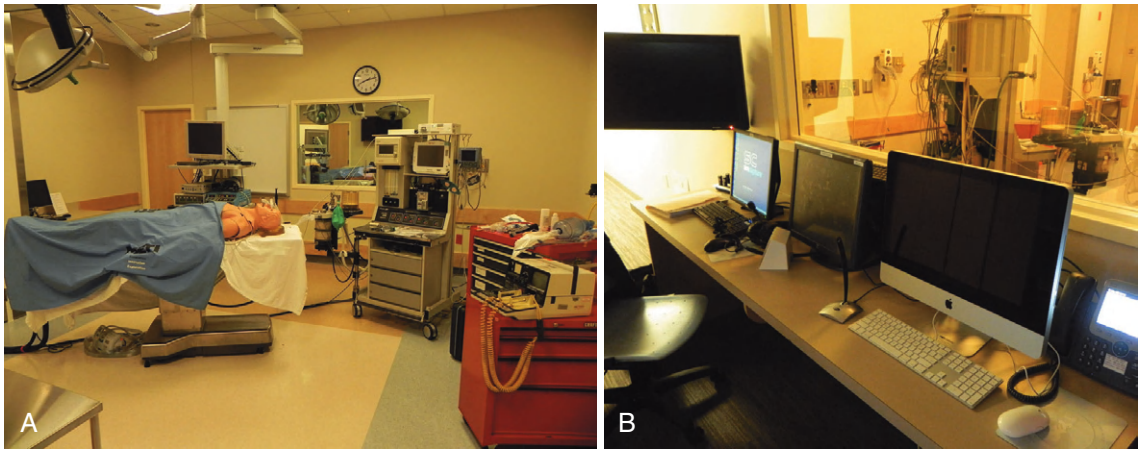

Figure 52-3 **A,** A simulated operating room (OR) equipped with a high-fidelity human patient simulator. **B,** The control room of the simulated OR. The trainer can orchestrate the simulator session from the control room while observing the trainee's performance through the one-way mirror.

can employ full-time technicians to manage the technical aspects of simulation. This allows the teaching faculty to concentrate their efforts on curriculum development and the direction of simulation sessions.

Trainees from many disciplines need experience with simulation education. Licensure and board accreditation examination systems are rapidly incorporating an evaluation of performance with high-fidelity simulation.[27-29]

VI. AIRWAY MANAGEMENT SKILLS

There are several skills that the experienced airway provider must acquire in order to provide comprehensive airway management. Airway management skills are not easy to learn, the time to apply those skills to the apneic patient is short, and the risks of failure include death or permanent neurologic injury.[30] Traditional educational programs depend on the accumulation of clinical experience, which may take years. Structured simulation-based teaching should provide a broader experience in a shorter period of time, thereby improving the airway management skills of a greater number of providers.

The instructor must determine what level of skill a particular provider must possess to meet his or her expected need. A gastroenterologist administering or supervising the administration of medications for conscious sedation does not require the same level of airway management expertise as the ED physician or the anesthesiologist. There is considerable variation in the airway skills of first responders, and the rescue airway techniques that are to be applied by first responders must be determined in the early planning phase of the teaching program. The instructor must design an educational program that meets the objectives for each type of student. The program will consist of the didactic material that explains the theory of the skill and describes how the technique is employed. After the theory is understood, the student can learn and demonstrate proficiency with static simulators (mannequins). For some skills, proficiency with a static mannequin is all that is required; other skills may require additional simulation experience before clinical application.

One of the challenges in designing a course for airway instruction is the myriad of devices and techniques that are commercially available. It is not possible for an institution to have all devices available, nor is it possible for an individual to be proficient with every device. Practitioners need to be selective in choice of airway devices based on the patient population served and the resources available from the institution. Proficiency with one type of device from each category is satisfactory for most situations.

A. Bag-Mask Ventilation

BMV is an important airway management technique that does not receive as much attention as it deserves. A major determinant of successful resuscitation of an apneic patient is the rapidity with which the first responder can establish effective ventilation. The student should know the effect of the unconscious state (whether drug or disease induced) on the upper airway and how this produces airway obstruction. Relaxation of the pharyngeal muscles and tongue obstructs the hypopharynx and allows the epiglottis to obstruct the glottic inlet. Elevation of the mandible lifts the tongue off the posterior pharyngeal wall and moves the epiglottis away from the glottic inlet, thereby opening the airway. Compression of the face mask against the face to produce an airtight seal permits positive-pressure ventilation (PPV) via the unobstructed airway. After the student understands these basic principles, instruction with a static mannequin demonstrates the actual technique of BMV. When the learner can demonstrate proficiency with the mannequin, he or she is ready to apply the skill to patients.

Since the LMA entered clinical practice, there has been concern about loss of BMV skills. Practice of this technique can occur in the OR while neuromuscular blockade takes effect. Also, very short procedures could continue to be performed with mask ventilation rather than light ventilation.

An additional exercise that is highly instructive is teaching the students to use BMV on each other. Augmented ventilation of the conscious patient allows the

student to learn how to synchronize gentle PPV with the subject's inherent inspiration. After a short period of supplemental hyperventilation, the learner can completely control the conscious subject's ventilation.

B. Pharyngeal Airways

Pharyngeal airways, including oropharyngeal and nasopharyngeal airways, are designed to provide a patent passage through the mouth and hypopharynx by elevating the tongue and epiglottis. Pharyngeal airways are simple in design but extremely effective for alleviating upper airway obstruction. Insertion of a pharyngeal airway and two-person ventilation can provide effective ventilation in some of the most challenging DA cases. The use of pharyngeal airways can be easily integrated into the instructional program for BMV. Any medical provider who may encounter upper airway obstruction should be proficient with the use of pharyngeal airways.

C. Supralaryngeal Airways

Effective use of SLAs requires a higher level of expertise than the use of pharyngeal airways. There are many manufacturers that supply SLAs, and insertion techniques vary. All SLAs are purported to provide a secure airway with a seal adequate for PPV. However, many SLAs have not undergone rigorous investigation before market release. Such devices may not survive the rigors of clinical practice and may be withdrawn from the market subsequently. Course design should focus on the concepts that are central to all SLA devices. Didactic material presented to the learner should explain the rationale for the device's design and provide complete description of the insertion technique and correct positioning of the SLA in the upper airway. The learner must also understand the procedures for confirmation of correct placement and potential complications before clinical application of the technique. Users with an incomplete knowledge of potential difficulties are likely to encounter some complications. Despite the risk of complications, SLAs have a high success rate for establishing effective ventilation during resuscitation.

The LMA has been shown to be an effective device for emergency ventilation when used by relatively inexperienced providers. First responders should be trained in use of the LMA as an early intervention. The medical literature concerning effectiveness of the LMA during resuscitation is extensive. Whether such effectiveness can be achieved with other SLA devices has not yet been proven, but the supposition seems likely.

Information that the learner should acquire during the initial phase of the training program includes the structural function of the device and correct insertion and positioning. Common to all SLA devices is their insertion over the tongue, into the hypopharynx, and above the glottic inlet. Although the type of SLA employed varies from institution to institution, it is beneficial to provide training with different SLA devices. There are several mannequins available for SLA insertion training, but performance varies, and the instructor must select one that is suitable for the particular device used.[31]

The depth and intensity of SLA training depends on the level of performance that is desired, and the goals for each type of medical provider must be clearly delineated. Anesthesiologists, who require the highest level of performance, must invest considerable time in mastering the use of the LMA. There are two learning curves: an initial learning phase consisting of 50 to 75 insertions, and a slower learning phase encompassing hundreds of insertions.[32-34]

D. Conventional Direct Laryngoscopy

Conventional direct laryngoscopy has been a mainstay for airway management for decades and is considered by many to be the gold standard for emergency airway management. Skill development for direct laryngoscopy is difficult and requires more experience than previously thought.[35] Numerous studies have demonstrated that alternative airway techniques, such as placement of an SLA, actually result in more rapid and effective ventilation than endotracheal intubation with conventional direct laryngoscopy. Such observations have caused many airway educators to change how they teach emergency airway management.[36]

The rigid, direct laryngoscope is designed to align the three axes—oral cavity, hypopharynx, and larynx—so as to establish a line of sight for passage of an endotracheal tube. Line of sight is achieved by depressing the tongue and sublingual tissue with the rigid laryngoscope blade into the submandibular space. Anatomic variations such as abnormal or carious dentition, a small mandible, lingual tonsillar hyperplasia, reduced cervical mobility, and obesity may reduce the effectiveness of the rigid laryngoscope in developing a line of sight. The application of excessive force to the upper airway can cause significant injury. Insertion of the laryngoscope blade and points of force application require subtle skills that are not easily appreciated by the novice with mere observation. A methodical instruction program that includes guided clinical experience is necessary. It is no longer acceptable for learners to begin direct laryngoscopy by intubating patients.

A training course for providers who have little or no experience with conventional direct laryngoscopy should begin with lecture material that includes upper airway anatomy and physiology, the mechanics of direct laryngoscopy, and sequential instruction on the intubation process. Models have been developed that can be adjusted to reflect anatomic variants so that the student can see the effects of these variants on intubation technique.[37] Mannequin practice with a VL has been shown to improve the success rate for intubation of patients.[38] A clinical instructor should expect all novices to have extensive simulated experience before patient exposure. Selection of appropriate patients (such as lean, edentulous patients followed by patients with normal dentition) enhances the experience while reducing the likelihood of patient injury. Endotracheal intubation of patients who are likely to have rapid arterial oxygen desaturation, such as obese patients or children, should be done only after the learner has accumulated significant experience.

E. Video Laryngoscopy

Advances in imaging technology have spawned a new class of intubation devices, the VLs.[39] VLs continue to be refined and may in the future become the instrument of choice for all endotracheal intubations. The Bullard laryngoscope was introduced many years ago and was perhaps the first VL to have significant clinical application. The refinement of other imaging techniques has generated an increase in the number of different VLs now available. The basic components of all VLs are a rigid, anatomic blade and an imaging device that provides a view of the larynx without requiring line of sight. The important advantage of such a design is that it permits a reduction in the force that must be exerted by the laryngoscope blade on the patient's upper airway in order to see the glottic inlet.

Although the blade of the VL resembles the blade of a conventional direct laryngoscope, the insertion techniques for the two devices are different. A conventional direct laryngoscope blade is inserted in the right side of the mouth with the tip of the blade directed toward the right tonsil bed. The blade is then redirected toward the midline and advanced until the epiglottis is seen. Once the epiglottis is visualized, the blade can be advanced into the vallecula or underneath the epiglottis to expose the glottis. The VL, on the other hand, should be passed over the tongue in the midline and advanced until the epiglottis appears. The blade is then advanced into the vallecula and rotated slightly anterior, which elevates the epiglottis and permits a good view of the glottis.

Even experienced laryngoscopists do not appreciate the differences in technique when they first use a VL. Comparative studies of various laryngoscopes provide information about performance in different scenarios, and students should be exposed to several VLs so they can determine which one is best for them.[40,41] Once the technique of video laryngoscopy has been mastered, many prefer it to conventional direct laryngoscopy for even routine endotracheal intubations.

F. Fiberoptic-Assisted Endotracheal Intubation

Fiberoptic-assisted endotracheal intubation (FOI) has revolutionized management of the DA. FFBs for airway management began to be used in anesthesia practice in the 1970s but initially did not gain widespread acceptance. The problem was a lack of effective training of anesthesiologists. In most cases, the FFB was used only when a DA was anticipated and the plan was for an awake intubation. The clinical situation, consequently, was an inexperienced endoscopist, an abnormal airway, and an awake, uncomfortable patient. The outcome was not likely to be pleasant or successful. It was not until creative airway management teachers developed effective teaching programs that FOI became a routine part of resident education.[42,43] Although much progress has been made with resident education, there is still inconsistency among residency programs with respect to FOI.[44]

Performance of FOI is a skill that every advanced airway management provider should master. Although the process by which providers are taught this skill has not been standardized, there is sufficient evidence in the medical literature to provide guidance for instructional development. A department's or institution's ultimate training system may be influenced by financial and manpower resources. There are low-tech and high-tech models and simulators that can be used. Do skills learned with models and simulators transfer to clinical performance? Resolution of this question is central to the efficacy of medical simulation education and remains controversial.[45] The preponderance of evidence concerning FOI affirms the theory that there is significant skill retention and transference.[46-48]

The course for FOI should begin with didactic material that describes upper airway anatomy, FFB construction and operation, and the fundamentals of FFB manipulation. This material may be presented in a traditional lecture format or via a computer program. The next phase of the program must permit the learner to practice FOI. This can be accomplished with static mannequins of the head and neck or with simple, nonanatomic models that require the learner to recognize objects or numbers after FFB manipulation. These models can be constructed with boxes or tubes that require the learner to visualize the images through the FFB during the process of FOI (Fig. 52-4). More realistic static mannequins are also available (Fig. 52-5). The video bronchoscope is a very useful device because the instructor can observe the intubation process on the monitor and offer suggestions to the learner as the intubation progresses (Fig. 52-6). Modern video bronchoscopes produce a high-resolution, wide-angle image of the airway. Teaching with a video bronchoscope improves the rapidity and success of endotracheal intubation by anesthesiology residents.[49]

There are high-fidelity simulators specifically designed for FFB training. These simulators accurately reproduce the responses to the user's manipulations, including mucosal bleeding, coughing, and laryngeal motion with respiration. Goldman and associates demonstrated that virtual reality–trained novices quickly learned FFB manipulation, and after a short training period, they performed as well as experienced attending anesthesiologists.[50] A high-fidelity simulator can replace the need for practice with animal and cadaver models. High-fidelity

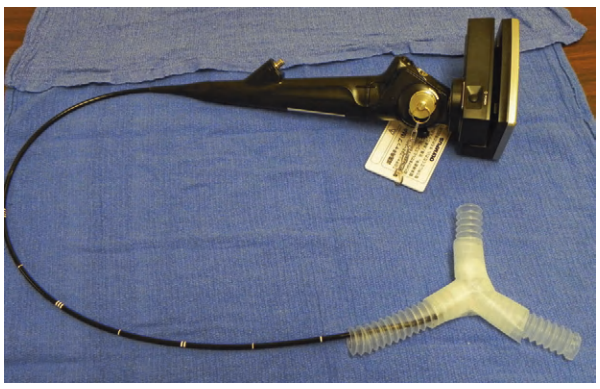

Figure 52-4 An inexpensive and easily constructed model of a tracheobronchial tree made from anesthesia circuit tubing.

Figure 52-5 An anesthesiology resident practicing fiberoptic intubation with a static mannequin.

simulators are expensive and may not offer significant advantages over less expensive models. Virtual reality computer programs may provide the same benefits as high-tech bronchoscopic simulators.[51]

After the student has mastered the extraoperative phases of the training program, he or she is ready to begin clinical training with oral FOI of lean patients with normal airways receiving general anesthesia.[52,53] This part of the training emphasizes FFB navigation, management of secretions in the airway, and passage of an endotracheal tube over the FFB. This teaching program works just as well for pediatric patients.[54] The time required to become competent with FOI varies from resident to resident. Some may be very capable after 10 to 15 successful intubations, whereas others may require 25 to 50 intubations.[55] After a resident is competent with FOI of normal patients, he or she can progress to patients that can be easily ventilated after induction of anesthesia but in whom laryngoscopy is difficult.

After proficiency with FOI of anesthetized patients can be demonstrated, the learner is ready to progress to awake intubation. The entire educational process can be completed in 4 to 6 weeks by most anesthesiology residents—a relatively short time to acquire such a valuable skill (Box 52-3). The challenge for residents from other specialties is having enough clinical opportunities after completing simulator training. Collaborative efforts among anesthesiologists; intensivists; ED physicians; ear, nose, and throat surgeons; and pulmonologists are required to meet the educational needs of all the appropriate disciplines.

Education of practicing clinicians who did not have formal training in FOI remains a significant challenge, because the pressures of clinical practice may not allow time for graded patient experience. Many attendees of educational fiberoptic workshops report an extremely low rate of clinical application after the workshop. The ultimate solution for this group of clinicians may be high-fidelity simulation training at a simulation center followed by experience with more recently trained clinicians as they join the practice group.

BOX 52-3 Instructional Program for Fiberoptic-Assisted Endotracheal Intubation

Informational
- Upper airway anatomy
- Fiberscope structure
- Fiberoptic function
- Fundamentals of fiberoptic intubation

Simulation
- Static mannequins
- Virtual reality computer
- Virtual reality simulator

Graded clinical experience
- Normal airway patients (general anesthesia)
- Easy ventilation, difficult intubation patients (general anesthesia)
- Awake intubation

Figure 52-6 A resident practicing guidance with a flexible fiberoptic video bronchoscope on a mannequin under faculty supervision.

G. Invasive Airway Techniques

Invasive airway techniques are difficult to practice because of limited clinical opportunities. Although mannequins do not accurately replicate the clinical scenario for most invasive airway techniques, mannequin practice does allow the learner to practice the sequence of steps for emergency invasive airway management. Some institutions employ fresh cadavers, isolated animal tracheas,

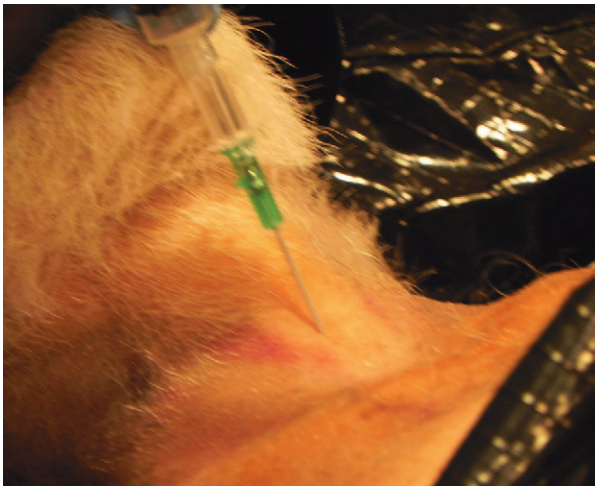

Figure 52-7 Percutaneous identification of the trachea with needle aspiration through the cricothyroid membrane of a human cadaver. This is the initial step in emergency cricothyrotomy.

or anesthetized animals as models for invasive airway insertion (Fig. 52-7).[56,57]

The necessity for emergency invasive airway procedures has undoubtedly been diminished by the development of SLAs and VLs.[58] This is fortunate in that providers with minimal invasive experience do not have a high success rate with invasive airway techniques and can encounter significant complications when performing them.[59] However, there are still situations in which all noninvasive methods have failed and an emergent, invasive airway technique is required.

H. Comprehensive Airway Management

The final step for educating individual medical providers who need broad airway skills, such as anesthesiologists, ED physicians, and critical care physicians, is a clinical rotation focused on airway management problems. The traditional approach to clinical airway training was based on the concept that each resident would acquire sufficient exposure to airway cases during residency (apprenticeship model). This teaching model promotes inconsistency among programs and individual inconsistencies within programs. Professional anesthesiology organizations have failed to provide specific guidelines for training in airway management. More progressive educators have instituted airway rotations in their residency programs to expose all residents to a wide variety of airway devices and techniques.[60] As more clinicians who have had comprehensive airway training enter clinical practice, their training should provide a springboard for further professional development.[61]

Simulation can be employed to evaluate team performance and institutional protocols.[62,63] This methodology will assume increasing importance as health care institutions merge into larger organizations and become more process oriented. For many processes it is yet unknown whether patient outcome is significantly improved, therefore a validation of their merit is required. Multidisciplinary simulated exercises may expose deficiencies in institutional procedures for management of high-risk patient events.

VII. CONCLUSIONS

Clinical teaching of airway management on actual patients is irreplaceable. However, the risk of complications is increased when novices are being taught airway management methods. Learning the fundamentals of airway management outside the OR, ED, or ICU better prepares the learner for clinical experience. The educator will find that outside instruction renders the clinical teaching experience more efficient with reduced patient risk. The development of powerful personal computers and high-fidelity simulators permits the construction of interactive programs with realistic clinical scenarios that mimic actual patient experiences. These tools allow the learner to participate in simulated airway events and to practice repeatedly until the management concepts and airway techniques are mastered.

It is imperative that instructional courses be tailored to the skill level of the learner and that clear objectives be elucidated during the process of course design. Extraoperative instruction can occur with an integration of traditional teaching methods, computer programs, low-fidelity and high-fidelity simulators, and animal models. The development of virtual reality computer programs and simulators is progressing at a rapid pace. Some airway management skills are difficult to learn, and robust instructional programs must become an integral part of residency training. Coordination of nonclinical and clinical instructional programs will ensure effective acquisition of airway management skills with minimal risk to patients.

Training programs should develop simulation-based education curricula.[64] Instruction in airway management is well suited for simulation. An alternative to developing an in-house simulation center is to use established simulation centers. The ASA has developed a process for simulation center endorsement, and the network of endorsed simulation centers continues to expand. There is little doubt that medical simulation at all levels of complexity has become an integral part of medical education.

VIII. CLINICAL PEARLS

- The first step in developing a simulation program is construction of a curriculum with clear educational objectives.
- The technology of the simulator should not interfere with teaching objectives.
- The type of simulator (low-fidelity or high-fidelity) should be matched to the educational plan.
- Simulation should replicate the clinical environment as closely as possible.
- Licensure and accreditation may in the future require measurement of performance on simulators.

VII. Clinical Pearls

I. INTRODUCTION

Airway management of either the routine or the difficult airway remains a critical aspect of both anesthesiology training and lifelong anesthetic practice. Anesthesiologists remain the most recognized "airway management specialists" and are routinely involved in elective and emergency procedures involving securing the airway throughout the hospital. Anesthesiologists may be asked to provide a secure airway as an application of advanced cardiac life support during cardiorespiratory arrest, as part of an elective or emergency surgical or radiologic procedure, or in the intensive care unit (ICU).

The American Society of Anesthesiologists (ASA) closed-claims analyses are a series of publications that review closed malpractice claims against anesthesiologists gleaned from the databases of 35 medical liability insurance carriers. The initial 1990 report reviewed adverse respiratory events associated with anesthesia care during the 1970s and 1980s.[1] In the 1970s, 55% of all claims of death or brain damage were caused by anesthetic-associated adverse respiratory events. Respiratory events during anesthetic care leading to adverse outcomes were the largest group of injuries resulting in malpractice litigation. This landmark study highlighted the three mechanisms associated with adverse outcomes: inadequate ventilation, unrecognized esophageal intubation, and difficult endotracheal intubation. Other events noted in a subsequent study included airway trauma, pneumothorax, aspiration of orogastric contents, and bronchospasm. These less common adverse respiratory events can be associated with anesthetic care as well.[2]

In 1998, a follow-up study noted a significant change in airway-related closed claims during the 1990s.[3] During this decade, a 10% decrease in the incidence of anesthetic-related adverse respiratory events was noted. This dramatic decline can be attributed to the routine use of pulse oximetry, use of capnography, and the advent and widespread use of the ASA Difficult Airway Algorithm in continuing education.[4,5] Additional factors that play vital roles include residency training specifically focused on airway management, continuing education in airway management, and scientific literature on management of the difficult airway.[6]

II. IMPORTANCE OF LIFELONG LEARNING IN AIRWAY MANAGEMENT

The importance of clinical education in airway management during residency training and in the postgraduate setting can be underscored by a brief review of airway management in the ICU. Anesthesiologists are often consulted for airway management in the ICU during both residency training and postgraduate practice.[7] Nayyar and Lisbon[8] surveyed anesthesiology residency training programs with regard to emergency airway management practices outside the operating room (OR). In the vast majority of programs surveyed, anesthesiologists performed most of the intubations on the hospital ward, including the ICU. This study supports the importance of tailoring airway practice to the patient environment, as supported by the scientific literature.

Mort[9] reviewed the incidence of hemodynamic and airway complications associated with tracheal reintubation after unplanned extubation in the ICU. The 57 patients reintubated after self-extubation were examined over a 27-month period; 93% of reintubations occurred within 2 hours of self-extubation. Of these patients, 72% had hemodynamic compromise or airway-related complications such as hypotension (35%), tachycardia (30%), hypertension (14%), multiple laryngoscopic attempts (22%), difficult laryngoscopy (16%), difficult intubation (14%), hypoxemia (14%), and esophageal intubation (14%). One patient required a surgical airway. One case of "cannot ventilate, cannot intubate" leading to cardiac arrest and death occurred. Less than one third of the patients studied had a "mishap-free" reintubation in the ICU.[9] Thus, it was recommended that individual ICUs develop strategies to decrease the rate of self-extubation based on patient safety and the impact of emergency airway management.

Mort[10,11] reported two additional studies of airway management in remote settings pertinent to clinical practice. The first study used an emergency intubation database from 1990 to 2002 in support of the ASA guidelines for difficult airway management, concluding that when conventional intubation techniques fail after three attempts, advanced airway devices should be used and immediately available.[10] The database was divided into two periods. Period A (1990-1995) included 340 intubations in which accessory airway devices, such as the laryngeal mask airway (LMA), bougie, Combitube, or fiberoptic bronchoscope, were not routinely available. Period B (1995-2002) included 437 patients for whom these devices were readily available. The relationship between the use of any accessory airway devices and airway and hemodynamic complications, including number of intubation attempts, hypoxemia, regurgitation, aspiration, bradycardia, and dysrhythmia, was determined. Intubations were performed in the surgical ICU, medical ICU, hospital ward, neurosurgical or trauma ICU, coronary care ICU, emergency department, and postanesthetic care unit. The study found a 33% reduction in hypoxemic episodes (oxygen saturation [Spo_2] <90%) and a 50% reduction in severe hypoxemic episodes (Spo_2 <70%) in group B patients, for whom accessory airway devices were readily available. Regurgitation was reduced from 4% to 1.7%, aspiration from 2.1% to 0.2%, bradycardia from 5% to 2%, dysrhythmia from 9.1% to 3.7%, and multiple intubation attempts from 30% to 15% in group A and B patients, respectively. The use of accessory airway devices increased from 5% in Group A patients to 42% in Group B patients. Notably, LMA use increased 21-fold. The aggressive approach of incorporating the ASA difficult airway management guidelines by early intervention with accessory airway devices led to a remarkable reduction in multiple attempts at laryngoscopy and a decreased incidence of airway and hemodynamic complications. This study confirms the importance of application of the ASA algorithm outside the OR setting and also justifies the immediate availability of a well-stocked difficult airway cart in all hospital locations where emergency airway management is performed, especially the ICU setting. It also illustrates the importance of familiarity with and experience in the use of accessory airway devices as a mandatory part of the standard of care in routine anesthetic practice.

In the second study, Mort[11] reviewed the utility of exchanging an endotracheal tube (ETT) in the ICU by two methods: direct laryngoscopy (DL) or airway exchange catheters (AECs). ETT exchanges from an 8-year quality improvement database were reviewed. Patients with an uncompromised glottic view (Cormack-Lehane views 1 and 2) were divided by method of exchange: DL ($n = 99$) versus AEC, Cook 14 or 19 French ($n = 34$). Hypoxemia, intubation attempts, esophageal intubation, bradycardia, cardiac arrest, and the need for a surgical airway were compared. Successful ETT exchange on the first attempt was higher with use of an AEC (95% AEC vs. 62% DL). The need for multiple attempts at laryngoscopy was higher in the DL group (26% DL vs. 2.9% AEC). In addition, rescue airway techniques were used more frequently in the DL group (16 of 99 cases; a surgical airway was necessary in 5 of the 16 DL-rescued airways). No rescue maneuvers were necessary in the AEC group. Hypoxemia and severe hypoxemia, esophageal intubation, bradyarrhythmias, and cardiac arrest during DL for ETT exchange were also more frequent in the DL group. It was determined that use of an AEC during ETT exchange in the ICU lowered the risk of complications considerably, even in the presence of a previously uncompromised view of the glottic inlet. This study also highlights the importance of familiarity with alternative techniques to DL as part of safe airway management and anesthetic practice.

Mort[12] also studied the hazards of repeated attempts at laryngoscopy in critically ill patients, with 2833 critically ill patients entered in an emergency intubation quality improvement database. Patients had cardiovascular, pulmonary, metabolic, neurologic, or traumatic injuries. In this retrospective review, the practice analysis documented in the database was evaluated for both airway and hemodynamic complications. These variables were correlated with the number of laryngoscopic attempts required for successful intubation. All the patients required emergency intubation outside the OR setting. A statistically significant increase was seen in airway-related complications when the number of laryngoscopic attempts increased to two or more intubation attempts. The incidences of hypoxemia, regurgitation of gastric contents, aspiration of gastric contents, bradycardia, and cardiac arrest were significantly higher when the number of attempts at conventional laryngoscopy increased. This study supports the recommendation of the ASA Task Force on Management of the Difficult Airway guidelines to limit the number of laryngoscopy attempts and to be facile and familiar with alternative techniques of difficult airway management.[12]

These studies highlight the importance of committed, lifelong learning in the variety of techniques in advanced airway management available to the anesthesiologist. This chapter focuses on the means available to accomplish this goal by review of pertinent supporting literature.

III. TEACHING AIRWAY MANAGEMENT—THE COMPONENTS

The topic of teaching airway management skills can be divided into several components, including anatomy, evaluation of the airway, and teaching materials, such as airway simulators (see Chapter 52). In addition, the scientific literature supports teaching techniques in mask airway management, direct laryngoscopy, fiberoptic intubation, supraglottic airway ventilation or assisted intubation, video laryngoscopy, and surgical airway management. The scientific literature also highlights the utility of instruction in airway management during anesthesiology residency training and postgraduate courses.

Several authors advocate review of basic anatomy as essential groundwork for mastery of difficult airway management. Gaiser[6] published a review of teaching airway management skills, advocating use of an anatomy textbook as a valuable teaching tool. Review of basic airway anatomy can be achieved in lecture format or self-study.[6,13,14] Katz and colleagues[15] used videotapes to review basic airway anatomy as a part of their learning module in fiberoptic intubation (FOI). Haponik and associates[16] used a computer software program to teach tracheobronchial anatomy as a preparation for a virtual training course on FOI. Evaluation of the airway for potential difficulty is an integral part of difficult airway management. The second iteration of the ASA practice guidelines stresses the importance of a thorough history and physical examination of each patient for anticipated difficulty.[5] This evidence-based guideline incorporates 11 physical examination points related to the airway that provide a succinct set of predictors of potential airway difficulty (see Chapter 10). The current guidelines for management of the difficult airway may also be found at the ASA website, www.asahq.org.

Although practicing anesthesiologists and anesthesiology residents have unlimited access to techniques for evaluation of potential difficulty in airway management, other physicians do not. The American College of Obstetricians and Gynecologists (ACOG) emphasizes the importance of identifying parturients at risk for possible difficult intubation (DI) during emergency delivery: "The obstetric care team should be alert to the presence of risk factors that place the parturient at risk for complications from general anesthesia."[17] At the Hospital of the University of Pennsylvania, Gaiser and associates[18] studied the ability of obstetricians to recognize parturients at risk for DI in light of the ACOG policy statement. The 160 parturients had an airway examination conducted by four separate physicians, an attending and resident obstetrician, as well as an attending and resident anesthesiologist. The physicians were asked to complete a questionnaire about DI, use of antepartum consultation, and the choice of labor analgesia after each patient's examination. During the first 80 airway examinations, the obstetricians did not receive any guidance or education on recognition of the difficult airway and complications associated with it. For the following 80 airway examinations, the obstetricians received a 30-minute tutorial on methods to examine the airway for potential difficulty, as well as the complications of DI. The anesthesiologists' responses were used as the standard. The sensitivity, specificity, and positive and negative predictive values were calculated for the responses of the other physicians. Unfortunately, brief, 30-minute tutorials did not affect the results of the obstetricians' ability to assess the airway. Instruction did not affect the number of consultations requested by either resident or attending obstetricians for possible DI. However, attending obstetricians were significantly more likely to utilize epidural analgesia for 2 cm of cervical dilation in women with a possible difficult airway.[18] This study highlights the importance of discussing airway management and its potential complications with surgical colleagues because it can affect clinical judgment, in this case, a change in the choice and timing of labor analgesia in parturients with a suspected difficult airway.

IV. INSTRUCTION IN SPECIFIC TECHNIQUES OR DEVICES

The scientific literature is replete with studies pertaining to mastery of specific devices and techniques of airway management, and a brief review of supraglottic airways, fiberoptic intubation, and the surgical airway is warranted.

A. Laryngeal Mask Airway

The past 30 years has seen a proliferation of supraglottic airway devices. Starting with the laryngeal mask airway described in 1983 by Brain,[19] 14 different supraglottic devices were listed by Cook[20] in 2003. Recommended training for the use of these devices varies according to idiosyncrasies of the individual device. The LMA remains the prototypical supraglottic airway.

Brimacombe[21] provides an excellent review of educational considerations with the LMA, summarizing the myriad sources detailing skills acquisition using the various versions of the LMA. Gurman and coauthors[22] compared retention of airway management skills in 47 medical students instructed in the use of direct laryngoscopy, LMA, and Combitube placement during a 2-week rotation in anesthesiology. Mannequins were used for teaching and testing. The authors noted no diminution in skill with any device over a 6-month period following training.

Dickinson and Curry[23] studied the efficacy of mannequin training for proper LMA insertion in paramedics attending an Advanced Cardiac Life Support (ACLS) training course.[23] A high success rate in the use of the LMA led to the conclusion that this was a suitable alternative to live training in patients. Ferson and coworkers[24] studied 20 anesthesiologists over 2 months, examining the efficacy of instruction in the use of the LMA by comparing manual or videotape training with hands-on training by an experienced anesthesiologist using a mannequin. More than 90% of participants in the hands-on training group achieved passing scores for LMA insertion technique after 17 insertions. Less than 30% of the group using manual videotape training achieved this score.

Brimacombe[21] suggests that four phases of education are required to incorporate the LMA into clinical practice (Box 53-1). Phases 2 to 4 are enhanced when a mentor

Box 53-1 Phases of Education for Incorporation of Laryngeal Mask Airway (LMA) into Clinical Practice

Phase 1: Reading and viewing instructional material to gain an understanding of basic concepts on LMA use.
Phase 2: Mannequin or cadaver training to develop basic motor skills for LMA use.
Phase 3: Use of LMA clinically in simple, elective cases to acquire basic clinical skills.
Phase 4: Use of LMA in more complex cases to acquire advanced clinical skills.

(e.g., experienced LMA user) is available to the novice for individualized training. Coulson and coauthors[25] showed that digital insertion of the ProSeal LMA (pLMA) using inexperienced personnel after mannequin-only training was as successful as in anesthetized adults. Success rates of approximately 90% after 2 minutes were found in each group.

The I-gel (Intersurgical, Workingham, UK) is another supraglottic airway device (SAD) with demonstrated promise. Wharton and associates[26] demonstrated an 82.5% success rate in mannequins and 80% success rate in anesthetized patients on the first attempt by novice users (medical students, non-anesthesia physicians, allied health professionals). Roberts[27] concluded that mannequin-only training in the emergency technique for LMA insertion is as effective as live patient training. However, Rai and Popat[28] note the limitations of mannequin-only studies and training, emphasizing that even advanced, high-fidelity simulation mannequins are unable to recreate the "feel" and finer aspects of human airway anatomy.

B. Fiberoptic Intubation

In an early study of clinical competence in the performance of fiberoptic laryngoscopy and endotracheal intubation, Johnson and Roberts[29] hypothesized that an acceptable level of technical expertise in fiberoptic intubation could be acquired within 10 intubations while maintaining patient safety. The learning objectives included an intubation time of 2 minutes or less and greater than 90% success on the first intubation attempt. Ninety-one ASA class I or II patients with normal laryngeal anatomy undergoing general anesthesia were intubated orally with an Olympus LF-1 fiberoptic scope after induction of general anesthesia. The mean time for intubation was 1.92 (±1.45) minutes. Four anesthesiology residents without prior fiberoptic experience intubated at least 15 patients each. A learning curve was generated using logarithmic analysis of the mean (±SD) time for intubation of patients 1 to 15 for all residents combined. The learning curve noted that the mean intubation time decreased from 4.00 (±2.91) minutes to 1.52 (±0.76) minutes within the first 10 intubations. After the tenth asleep FOI, the mean intubation time was 1.53 minutes, with greater than 95% success rate for the first attempt. No clinically significant changes in oxygen saturation (S_{O_2}), mean arterial pressure, or heart rate were noted during asleep FOI in this study. An acceptable level of technical expertise in FOI can be achieved safely by performing at least 10 elective asleep FOIs by novice anesthesiologists.[29]

Erb[30] evaluated teaching orotracheal FOI in 100 anesthetized, spontaneously breathing patients. Five anesthesia residents without prior experience in FOI participated in this study. Each resident randomly intubated 10 spontaneously breathing patients (group A) and 10 paralyzed patients (group B) tracheally. An overall success rate of 96% was defined as successful endotracheal intubation in two attempts or less. No difference was found between the two groups. During FOI, S_{O_2} remained over 95% in group A, whereas 2 of 10 patients in group B had S_{O_2} fall below 95% during fiberoptic attempts. The authors noted that FOI under conditions of spontaneous respiration is a well-established, standard-of-care technique of difficult airway management. This study demonstrated a feasible and safe method to train novices in the skill of FOI under conditions of general anesthesia and spontaneous ventilation.[30]

At the Children's Memorial Hospital at Northwestern University, Wheeler and colleagues[31] performed a study teaching residents pediatric FOI. Twenty clinical anesthesia second-year (CA-2) residents were randomly assigned to the traditional teaching group (FOI with standard eyepiece) or the video-assisted group (FOI using integrated camera and video screen). All residents were novices in pediatric FOI. One of two attending anesthesiologists supervised each resident during the elective FOI of 15 healthy children ages 1 to 6 years. Variables included time from mask removal to confirmation of successful endotracheal intubation by end-tidal carbon dioxide detection and FOI attempts up to 3 minutes or three attempts. The primary outcome of time to success or failure was compared between the two groups. Failure rates, as well as the number of attempts, were also compared. Of 300 intubations attempted; eight failed. On average, the group using video-assisted FOI as a training tool was faster and three times more likely to achieve successful FOI. The video-assisted group also had significantly fewer attempts at intubation than the residents in the traditional group. The authors concluded that a video-assisted system, where the attending anesthesiologist is able to provide real-time feedback during FOI of pediatric patients, was superior as a teaching method to the traditional teaching model.[31] The newer generations of video FOI equipment are especially useful in such teaching situations. This type of equipment allows for viewing by multiple persons, as well as capture of still images and videos for later review (Olympus MAF-Type GM, TM, LF-V).

Ovassapian[32] provides a succinct review of learning fiberoptic intubation techniques, emphasizing the following points to encourage more frequent use of the fiberscope in anesthesia and critical care practice[8] (Boxes 53-2 and 53-3:

1. The techniques of FOI are not difficult to learn. Mastery of the art of fiberoptic airway management readily develops with time and experience.
2. The technique of FOI is different from rigid laryngoscopy. Without formal training, the anesthesiologist

Box 53-2 Guidelines for Successful Fiberoptic Intubation

1. Organize a functional fiberoptic cart.
2. Maintain a functional fiberscope.
3. Follow a checklist prior to each use.
4. Skillfully manipulate the fiberscope.
5. Follow approaches and steps of fiberoptic intubation.

should not expect immediate and successful use of the fiberscope for endotracheal intubation.

3. No anesthesiologist should perform a new technical task without studying and developing the required base of knowledge involved in its performance.
4. The fiberscope is a simple but sophisticated airway management tool. It should be utilized to its full diagnostic and therapeutic potential in airway management. The greater the experience of the anesthesiologist in using the fiberscope under a variety of clinical circumstances, the greater is the degree of skill that develops with time.
5. The essential steps for successful use of the fiberscope include organizing and maintaining a functional fiberoptic cart, setting up an instrument and intubation checklist, and practicing on models to develop the skills necessary for fiberoptic maneuvering.

Naik and coauthors[33] attempted to determine if FOI skills learned outside the OR on a simple model could be transferred to the clinical setting. Twenty-four first-year anesthesiology and second-year internal medicine residents were recruited for this study. Residents were randomly allocated to a didactic teaching group ($n = 12$) or a model-training group ($n = 12$). The didactic teaching group received a detailed lecture from an expert in FOI. The model-training group was expertly guided through the tasks performed on a simple model designed to refine fiberoptic manipulation skills. After the training session, residents performed a fiberoptic orotracheal intubation on healthy, consenting, anesthetized, paralyzed female patients who were undergoing elective surgery. Patients were predicted to be easy laryngoscopic intubations. Two "blinded" anesthesiologists evaluated each patient. The authors found that the model-training group outperformed the didactic group in the OR when evaluated with a global rating scale, as well as a preparatory checklist. The model-trained residents completed fiberoptic orotracheal intubation significantly faster and more often than didactic-trained residents. The authors concluded that training fiberoptic orotracheal intubation skills using a simple model is more effective than conventional didactic instruction, when incorporating skills in the clinical setting. They suggested that incorporation of model-based training in FOI may greatly reduce the time accompanying subsequent training in the OR.[33]

Box 53-3 Knowledge Base for Performing Fiberoptic Intubation (FOI)

- How the fiberscope functions
- How to avoid damaging the fiberscope
- Indications for FOI
- Limitations of FOI
- How to recognize abnormal airway anatomy
- Appropriate preparation of the patient
- How to provide safe conscious sedation
- How to provide good topical anesthesia of the airway
- How to monitor the patient adequately
- Causes of failure of FOI
- Complications of fiberoptic airway endoscopy

In a study of an educational resource specific to the acquisition and maintenance of endoscopic skills, Marsland and colleagues[34] describe the use of DEXTER. This nonanatomic, endoscopic dexterity–training system is designed to encourage practice in fiberoptic endoscopy as well as establish and maintain a state of procedural readiness. Educational training systems such as DEXTER help to maintain these skills even if the anesthesiologist's clinical exposure to difficult airway management is sporadic.

The pulmonary literature also addresses the issue of training in fiberoptic bronchoscopy. In a study of "virtual reality" bronchoscopic training, Colt and colleagues[13] hypothesized that novice trainees in the procedure of flexible fiberoptic bronchoscopy could rapidly acquire basic skills using a virtual-reality skill center. Furthermore, these trainees would compare favorably with senior colleagues who had been conventionally trained on live patients. Five novice bronchoscopists entering a pulmonary–critical care training program were studied prospectively. Flexible fiberoptic bronchoscopic inspection of the tracheobronchial tree was taught using a virtual-reality bronchoscopic skill center, including a proxy flexible bronchoscope, robotic interface device, and personal computer with monitor and simulation software (PreOp Endoscopy Simulator; Immersion Medical, Gaithersburg, Md). The proxy bronchoscope, modeled after a conventional fiberoptic bronchoscope, provides realistic images to the users as they navigate through virtual tracheobronchial anatomy.[13] The authors measured dexterity, speed, and accuracy using the skill center as well as an inanimate airway model before and after 4 hours of group instruction and 4 hours of individual unsupervised practice. The results of this group were compared with those of a control group of four skilled physicians. Each of these pulmonologists had performed at least 200 bronchoscopies during 2 years of training. They found that novice bronchoscopists significantly improved dexterity and accuracy using either the virtual or inanimate airway model. After training, fewer bronchial segments were missed, and fewer contacts with the tracheobronchial wall occurred. Speed and total time spent with unvisualized bronchial anatomy did not change. After training, novice performance equaled or surpassed that of skilled physicians. Novices tended to perform more thorough examinations of the tracheobronchial tree. They missed significantly fewer bronchial segments in both the inanimate and virtual simulation models. The authors concluded that a short, focused course of instruction and unsupervised practice using a virtual bronchoscopy simulator enabled novices to achieve a level of technical skill similar to that of

colleagues with several years of experience.[13] These skills were reproduced in an inanimate airway training model that mimics direct care of patients.

Conversely, Crabtree and associates[35] showed that simulator performance may not be a good indicator of FOI performance in the clinical setting. Chandra and colleagues[36] concluded that there was no added benefit from training on costly virtual-reality models compared with low-fidelity, nonanatomic models designed to refine FOI skills with respect to transfer of skills to actual patient care.

C. Surgical Airway

Lack of experience is the main source of procedural failure with cricothyrotomy, although hands-on training is also lacking. A study evaluating difficult airway instruction found that although 80% of American anesthesiology residency training programs taught cricothyrotomy, 60% of these courses consisted of only lectures.[37] As a result, many physicians lack the necessary skills to perform a cricothyrotomy correctly or expeditiously.

Correct and safe performance of cricothyrotomy is life-saving in patients who cannot be ventilated or intubated successfully. Eisenburger and coworkers[38] compared conventional surgical technique (group 1) versus Seldinger technique (group 2) emergency cricothyrotomy performed by inexperienced clinicians in adult human cadavers. The ease of use and times to locate the cricothyroid membrane, to tracheal puncture, and to first lung ventilation were compared. Participants were allowed a single attempt at the procedure. A pathologist dissected the neck of each cadaver to assess the correct position of the tube and any injury to the airway. Subjective assessment of the technique on a visual analog scale (1 = easiest to 5 = most difficult) was conducted. The age, height, and weight of the cadavers used in this study were uniform. Subjective assessment of each method as well as anatomy of the cadavers was not statistically different between the two groups. Correct tracheal placement of the tube was achieved in 70% of surgical cricothyrotomies (n = 14) and 60% of Seldinger cricothyrotomy (n = 12). Five attempts in group 2 (Seldinger) were aborted because of kinking of the guidewire. Time intervals between start of the procedure and location of the cricothyroid membrane, tracheal puncture, and first ventilation were not statistically different. Thus, in this limited study, each method showed equally poor performance and suggested that further study be undertaken to define the learning curve of this life-saving procedure.[38]

McCarthy and colleagues[39] attempted to define the accuracy of cricothyrotomy performed in canine versus human cadaver models during surgical skills training. Thirty-three advanced trauma life support (ATLS) physician students performed cricothyrotomy in canine models. Ten flight nurses performed a bimonthly surgical skills practicum on similarly prepared animals. Neck specimens of the euthanized animals were excised, fixed, and mapped by the authors. Subsequent courses in ATLS used human cadavers and similarly prepared trainees. In these models, cricothyrotomy sites were mapped in situ. In canine models, 47 neck specimens of 52 attempted cricothyrotomies were inspected and mapped. Four specimens were excluded from the final analysis because of multiple attempts at cricothyrotomy. Thirteen of the 43 analyzed canine models had a misplaced cricothyrotomy (30.2%). Cricothyrotomy attempts were correct 27 of 28 times in the human cadaver model (96.4%). The authors concluded that placement accuracy in the canine model was low, and that human cadaver models were superior for realistic training.[39]

Wong and associates[40] attempted to determine the minimum training experience required to perform surgical cricothyroidotomy in 40 seconds or less in mannequins. The 102 anesthesiologists participating in this study were shown a video demonstrating the Seldinger technique of cricothyrotomy. They then performed 10 consecutive cricothyrotomy procedures on a mannequin using a preassembled percutaneous dilatational cricothyrotomy set (Melker Emergency Percutaneous Dilatational Set; Cook Critical Care, Bloomington, Ind). Each attempted procedure was timed from initial palpation of the skin to successful lung insufflation. Cricothyrotomy was considered successful if performed in 40 seconds or less. Cricothyrotomy time was considered to have reached a plateau when there was no significant reduction in time in three consecutive attempts. A significant reduction in time for successful cricothyrotomy was found over the 10 attempts. The cricothyrotomy time reached a plateau by the fourth attempt. Success rate reached a plateau by the fifth attempt. The authors concluded that mannequin practice for percutaneous dilational cricothyrotomy led to a reduction in cricothyrotomy time and improved success rates of this procedure. By the fifth attempt, 96% of participants were able to perform a cricothyrotomy successfully in 40 seconds or less. The authors recommended that clinicians providing emergency airway management should be trained on mannequins for at least five attempts or until performance times of 40 seconds or less are achieved. Clinical correlation and optimal retraining intervals for this procedure have yet to be determined.[40]

Friedman and colleagues[37] compared cricothyrotomy skills acquired in a simple inexpensive model to those learned on a high-fidelity simulator using valid evaluation instruments and testing on cadavers. First-year and second-year anesthesia residents were recruited. All performed a pretest videotaped cricothyrotomy on cadavers. Subjects were then randomized into two groups. The high-fidelity group (n = 11) performed two cricothyrotomies on a full-scale simulator with anatomically accurate larynx. The low-fidelity group (n = 11) performed two cricothyrotomies on a low-fidelity model constructed from corrugated tubing. Within 2 weeks, all subjects performed a post-test. Two blinded examiners graded and timed the performances using a checklist and global rating scale. The results showed no significant difference between the two groups. The authors concluded that skills acquired using the simple model were not significantly different from those acquired using the expensive simulator.[37] Skills acquired from both models transferred effectively to cadaver performance.

V. RESIDENT TRAINING IN ADVANCED AIRWAY MANAGEMENT

Anesthesiologists are physicians specialized in advanced airway management, including ventilation and endotracheal intubation. Despite extensive exposure to advanced airway management, challenges to intubation and ventilation may be encountered in daily practice. It is vital to provide trainees experience in the recognition and management of the difficult airway. Formal, organized rotations in advanced airway management better prepare future physicians in management of a difficult airway. Training programs with a comprehensive difficult airway rotation are associated with decreased respiratory morbidity and less need for emergency surgical airways.[41]

Since the introduction of the ASA Practice Guidelines for Management of the Difficult Airway in 1993, surveys have assessed if training programs are incorporating a difficult airway module in their core curriculum. A recent survey, conducted by a Society of Airway Management (SAM) task force, showed that 43 of 88 ACGME- and ACUDA-approved residency programs offered a formal airway rotation, a significant increase from 33% of residency training programs in 2003.[42,43]

Despite an improved emphasis on teaching trainees the recognition and management of the difficult airway, there remains a lack of uniformity with regard to minimum requirements for competencies with a variety of airway devices or techniques. As a result, a trainee's experience in advanced airway management may vary dramatically from one training program to another. The following reviews discuss factors that are important considerations in the development of a useful and successful difficult airway management curriculum.

In 1995, a survey on formal training in advanced airway management techniques was sent to the program directors of 169 anesthesiology residency training programs in the United States; 143 directors responded.[44] Formal rotations in advanced airway management were brief and often limited to didactic lectures. Only 27% of responding programs had a formal advanced airway management course in their curriculum, and 60% of these courses were less than 2 weeks in duration.

Subsequently, a number of academic anesthesiology departments published their specific rotations in advanced airway management. Cooper and Benumof[45] described the University of California–San Diego Department of Anesthesiology's advanced airway rotation. The goal of this rotation was to create nonurgent, nonstressful learning situations where a number of airway management techniques can be mastered in patients. The rotation includes the administrative responsibilities of starting an airway rotation. Administrative aspects include (1) approval of the residency program director, the departmental education committee, or both; (2) selecting experienced faculty to serve as instructors; (3) careful scheduling; (4) formulating the didactic program; and (5) having the appropriate equipment available (e.g., a dedicated difficult airway cart). Residents receive a syllabus containing classic and current articles on both airway management devices and techniques before the rotation. The syllabus is the foundation for both formal didactic teaching and informal teaching in the OR.[45] Before use in any patient, any new or unfamiliar airway device or technique is discussed thoroughly with regard to theory, description, insertion technique, and current clinical practice. Subsequently, the individual device is used in models, mannequins, or both. When invasive techniques are introduced (e.g., retrograde intubation, transtracheal jet ventilation, or percutaneous cricothyrotomy), a special workshop is held at the anatomy laboratory of the medical school. Human cadavers serve as models for instruction in the necessary technical skills involved in the procedure.

Patient selection is critical during this rotation. According to the authors, straightforward patients are ideal, including ASA class I or II patients undergoing elective general anesthesia without the need for extensive monitoring or setup. These patients undergo surgery in the supine position, with ready access to the airway throughout the procedure. Patients with head or neck injury, in whom there is competition for the airway, are generally avoided unless the patient requires an awake intubation technique. Patients with a known or suspected difficult airway are prioritized to the resident on the airway management rotation. A goal of this rotation is to perform advanced airway management techniques for 40 to 50 patients during the 1-month rotation.[45] Didactic teaching includes performance of a thorough evaluation of the airway based on the current ASA recommendations on difficult airway management.[5] The findings of every airway examination are discussed with the supervising faculty. Residents are instructed in proper preparation of the patient for awake intubation techniques. In addition, they garner experience in devices such as the LMA, Combitube, lighted stylets, and advanced rigid fiberoptic laryngoscopes. The adjunct use of the fiberoptic bronchoscope (FOB) is encouraged. Once a patent airway is established, the resident is encouraged to identify all pertinent tracheobronchial anatomy by inserting an FOB through a bronchoscope adapter.[45]

Dunn and colleagues[46] at Baystate Medical Center in Springfield, Massachusetts, described their resident training in advanced airway management. They developed a formal advanced airway management program consisting of two separate 1-month rotations. Each rotation has a separate focus. One month occurs during the later half of the CA-1 year. The second month occurs during the CA-2 year. Residents are given a set of objectives, a required reading list, and a required number of procedures unique to advanced airway management. These procedures must be performed during the course of the rotation. This rotation consists of a core faculty group with expertise in airway management. According to the authors, five issues must be addressed in order to implement an airway rotation: (1) equipment, (2) core faculty, (3) curriculum, (4) time commitment, and (5) faculty development.[46]

The Baystate Medical Center rotation uses seven difficult airway (DA) carts distributed in five anesthetizing locations. The carts are uniformly set up and stocked. The authors believe that uniformity of *equipment* enhances physician performance of emergent airway management. Each cart and its contents cost approximately $30,000.[46]

Contents of the DA carts include a variety of face masks, different sizes of the LMA, Combitube, and transtracheal puncture equipment. Each DA cart is equipped with the three modalities of difficult airway management thought to be the most helpful: flexible FOB, intubating LMA (Fastrach; LMA North America, San Diego), and a variety of rigid fiberoptic laryngoscopes. Each cart incorporates a video system, which improves teaching and is an integral part of the program.

Core faculty members are proficient in all modalities of airway management. The size of the core faculty group is sufficient to ensure coverage during vacations, other clinical commitments, and so forth. At least one faculty member is available each day of the rotation. Contact with a core group of faculty ensures that residents master each technique in an adequately supervised fashion.[46]

The *curriculum* for this rotation includes a required reading list. Each of these publications requires discussion with a core faculty member to demonstrate adequate knowledge of the contents. The first month's rotation for CA-1 residents focuses on the ASA airway management algorithm, as well as techniques of FOB. The second month's rotation for CA-2 residents has a separate reading list and focuses on alternative techniques of advanced airway management as well as complications.[46] Requirements for successful completion of the first month of the rotation include no fewer than 10 fiberoptic intubations, 10 Bullard Scope intubations, and six LMA Fastrach intubations. In the second month of the airway rotation, the resident is required to perform at least 10 additional fiberoptic intubations (at least two pediatric fiberoptic intubations), 10 Bullard intubations, and six LMA Fastrach intubations. Residents in both months of the rotation are encouraged to seek out "known difficult airway" cases on the elective schedule, as well as participate in the preoperative consultation of these patients. A worksheet detailing each difficult airway case is kept by the resident and "signed off" by the core faculty. The authors detail the importance of departmental commitment to advanced airway management training, as well as the development of faculty interested in advanced airway management.[46]

Hagberg and colleagues[43] at the University of Texas Medical School at Houston reviewed the instruction of airway management skills during anesthesiology residency training. This study, a follow-up to Koppel and Reed's study,[44] was conducted 3 years after the mandate of the Accreditation Council for Graduate Medical Education (ACGME) requiring that residents have significant experience in specialized techniques of airway management, such as fiberoptic intubation, double-lumen tube placement, and LMA use.[43] A survey of all directors of anesthesiology residency programs listed in the Graduate Medical Education Directory for the years 1998 and 1999 was conducted. The survey was sent by both e-mail and fax to each program director. A second copy was sent to non-responders 4 weeks after the initial mailing. Of the 132 program directors surveyed, 79 (60%) replied. Of the 79 respondents, 26 reported programs (33%) that had a difficult airway rotation. Interestingly, this number had increased only slightly since prior publications and the ACGME mandate.[43] An advanced airway management rotation was offered throughout the clinical base years of training in 13 (49%) programs of respondents. The rotation was 1 week in duration in 16 (61%) of the cases offering a program. Formal instruction was given before the start of the rotation in 18 (69%) programs. Instruction usually occurred using surgical patients (in 22 or 85% of programs), using ASA I or II patients (in 20 or 77% of programs), and was conducted by select faculty (in 20 or 78% of programs).

The most frequently taught airway management modalities included the flexible FOB and the LMA. Invasive techniques such as percutaneous cricothyrotomy or tracheostomy were taught infrequently. There was a time limitation of 2 to 5 minutes or a maximum number of attempts in device-specific airway management in five programs (19%). A required case number for each device was found in five of the programs surveyed (19%). In this survey, instruction in advanced techniques of airway management occurred most often in the form of video, written instruction, and practice on actual patients undergoing surgical procedures. Nontraditional methods of instruction, such as computer-assisted instruction or patient simulators, were used infrequently. Residents received both skills and written evaluation in 63% of the programs with a specific rotation in advanced airway management.[43]

This study raised several questions about the instruction of advanced airway management, suggesting further study on the efficacy of different training techniques. The authors are proponents of a future clinical certification process for training in advanced airway management for all anesthesiologists. They suggest that the residency review committees for anesthesiology and the ACGME should establish number requirements for specific airway-related procedures to ensure standardization of resident training. Follow-up studies are warranted when such mandates are established, because standardization of training in these techniques may further decrease airway-related morbidity and mortality.[43]

Allen and Murray[47] addressed the issue of *patient consent* when teaching airway management skills, suggesting that any procedure that deviates significantly from the standard of care should invoke patient consent. In the authors' practice, substitution of laryngoscope blades or use of the LMA or lightwand does not require specific patient consent. However, use of the Combitube, FOI, any retrograde technique, or elective repeated instrumentation with several different devices requires patient consent. Most important, the authors stress that constant supervision of residents by experienced faculty is of paramount importance to minimize patient risk. Initial experience in advanced airway management in a simulated environment may further reduce patient risk.[47]

Benumof and Cooper's reply[48] to Allen and Murray[47] stated that special consent was not necessary for well-established and accepted airway management techniques, especially in the presence of experienced faculty. Constant supervision by experienced faculty ensures against undue force or rough handling of the airway and offers the ability to abort or change an initial airway management technique as needed. In Benumof and Cooper's published experience of approximately 1000

faculty–airway rotation resident cases, only three adverse outcomes occurred. In two cases, intubation through the self-sealing FOB adapter on an intubating anesthesia mask resulted in a piece of the blue diaphragm being inadvertently carried into the trachea; thus, these adapters were no longer used. In each case, the complication was recognized immediately by the supervising faculty. Bronchoscopy forceps were used in both cases through the FOB's working channel to retrieve the piece of plastic, without incident. The third event occurred when an improperly sterilized LMA was used. The LMA was inadvertently cleaned in Cidex, and perilaryngeal edema ensued in the patient. The patient was tracheally intubated and experienced no long-term morbidity. The cleaning impropriety was corrected. The authors stress that careful use of accepted methods under strict and expert supervision does not mandate patient consent.[48]

Learning in the OR or emergency room environment is not ideal, because it imposes stressors on both the patient and the student. Possible dental trauma, aspiration, and bruised or lacerated soft tissue can occur, even under close patient supervision. Factors that may hinder the learning process for the resident include concerns of harming the patient and increased performance pressure with watchful OR staff (nurses, surgeons). In addition, time constraints, such as impending oxygen desaturation, delay of the start of surgical case, and increased pressure to maintain the OR schedule, can interfere with the airway management learning process and limits opportunity for instruction and criticism.[49] Furthermore, students are rarely given a second chance if they fail the first time, especially if the patient is a difficult intubation. This further hinders the learning process for the student. Conversely, other procedures are simply not reasonable to practice on healthy patients, such as cricothyrotomy. Despite these limitations, the performance of various airway management skills in the elective patient or simulated setting are vitally important to the success in more urgent or unanticipated settings.

In a 2007 *Chest* article, Kory and associates[50] evaluated the teaching of airway management in medicine residents, challenging the traditional belief of "learning by doing" for resident training. The authors hypothesized that the "see one, do one, teach one" method is not appropriate in high-risk, low-frequency events such as respiratory arrest and difficult intubation patients. Although most programs offer simulation technology, it is not yet a standard component of residency training programs. Studying scenario-based training (SBT) and computerized patient simulator (CPS) versus traditionally trained (TT), the authors found that SBT-trained and CPS-trained internal medicine residents performed better than TT internal medicine residents in airway management skills.[50] This study focused on internal medicine residents, but its basic principles can theoretically be extrapolated to the training of any medical specialty in difficult airway management.

Training using simulators can be helpful for more advanced airway skills such as FOI and the intubating laryngeal mask airway (ILMA). Simulation facilitates the learning process in airway management and also offers other advantages, such as no risk of patient injury. Simulation allows for the performance of multiple attempts and types of interventions, allowing for errors because patient harm is avoided. Interventions can be stopped for feedback from trainers, uncommon scenarios can be created for serial practice, and interventions can be repeated after feedback for reinforced teaching. Simulator training decreases the amount of time performing the actual task on patients. This is useful for new trainees, whose skills are generally limited, and reduces the potential for patient injury. Naik and associates[33] show that acquired skills from a simple training model are transferable to the clinical environment. Compared with basic didactic training, those who trained with a basic model for FOI demonstrated a faster intubation time, improved intubation success rate, and better technique. Further discussion of the role of simulation in advanced airway management is discussed in Chapter 52.

Model trainings can also be beneficial for tasks that are infrequently encountered on actual patients. Kory and others[50] studied the progression of two groups: medical students trained by the traditional method of experience as clinical opportunities arose vs. students trained through patient simulator and SBT. The simulator group outperformed the TT group.

Another option for practice in infrequently performed airway management techniques involves the use of recently deceased individuals. Advantages include the ability to practice invasive procedures such as cricothyrotomy in a realistic setting. Consent from family members is obtained for this practice. Olsen and colleagues[51] found that obtaining consent from family to perform postmortem procedures is a valid option. The most common reason for refusal is personal and religious beliefs. After consent in this study, a cricothyrotomy was performed by emergency medicine resident physicians, supervised by an attending physician.

To develop successful skills in airway management, anesthesia residents should use mannequins and simulators suitable for the intricacy of the training objective. Simple models are sufficient in gaining basic skills and knowledge. Once a trainee becomes more comfortable with the device or technique, more detailed models and simulators may be helpful in conveying more complex goals and objectives. At Penn State's training program, anesthesia residents use mannequins for practice in cricothyrotomy. However, mannequin training alone is not sufficient for developing intubation skills or management of a difficult airway with most devices. One study showed that only 53 of 103 intubations by emergency medical technicians (EMTs), solely using mannequin practice, were successful, with many requiring more than one attempt.[52]

Laryngoscopy and intubation are fundamental skills of all anesthesiologists. However, it is necessary to be proficient with other adjunctive airway management skills to have a variety of methods to secure a difficult airway successfully. Connelly and associates[53] conducted a retrospective study of unanticipated difficult airways and found higher success rates with LMA and FOI, when compared to repeated direct laryngoscopy. National surveys of anesthesia programs find that more than one skill set is needed to be effective in managing a difficult

airway. This is partly the result of the variation in accessibility of certain equipment from place to place.[43] In addition to basic laryngoscopy and mask ventilation, proficiency with FOI and ILMA use are both deemed essential in training.[49]

Skill in providing ventilation through basic face mask skills is often overlooked during residency training. Effective mask airway can salvage a difficult intubation in emergency settings, but it is also used for adequate preoxygenation and to control ventilation as part of initial resuscitation. Areas of focus include proper mask selection, proper mask placement to provide a good seal, and proper neck extension and jaw thrust, to facilitate mask ventilation and prevent associated complications, such as gastric distention or aspiration, soft tissue injury, and corneal abrasions.[54] Equally important is the recognition of patient characteristics associated with difficult mask ventilation and use of an oral/nasal airway, when needed.

Laryngoscopy is a basic skill all anesthesia residents must acquire during their residency. A study of first-year anesthesia residents by Konrad and colleagues[55] found that successful intubation increased rapidly during the first 20 attempts, and the learning curve reached 90% success rate after a mean of 57 attempts. However, even after 80 intubations, 18% of residents still required assistance. Mulcaster and associates[56] investigated skill with direct laryngoscopy by nonanesthesia individuals and found similar results, with an average of 47 intubation attempts needed to reach a 90% success rate. Mannequin training alone was not sufficient to adequately prepare nonanesthesia individuals for successful direct laryngoscopy. A majority of the individuals studied had difficulties with direct laryngoscopy performed on patients despite 20 successful intubations on mannequins. Hirsch-Allen and coworkers[57] found that the year of training and type of residency were associated with multiple tracheal intubation attempts. Anesthesia residents had the lowest reintubation rate, regardless of their year of training. This important study emphasizes that a higher number of intubations is needed to obtain a 90% successful rate for nonanesthesia physicians who desire to master the technique of direct laryngoscopy and endotracheal intubation.

In a study of LMAs placed by EMTs, insertion was 100% successful in mannequins but only 64% successful in the field.[58] This emphasizes the performance of LMA insertion on live patients and deemphasizes the importance of mannequin training as a sole teaching tool.

Video-enabled technology is another tool in the airway management armamentarium[59] and another vital skill that residents should acquire during residency training. Video-enabled airway technology includes the integration of existing intubation equipment (laryngoscope, fiberscope) with a video system, allowing the image to be projected onto a monitor. Recording the resident's attempt at intubation enables supervising faculty to provide insight on the performance, allows for review and correction of technical inadequacies by guiding the resident's hand during the attempt, and allows for feedback afterward. Instructors are able to visualize what the trainee sees during laryngoscopy or FOI. By doing so, the video system allows both mentor and student to share the same view of anatomy and to follow the progress of the airway management technique employed.[60]

Video-enabled systems may be superior in the successful intubation of some difficult airway patients compared with conventional direct laryngoscopy.[59] Jungbauer and colleagues[61] prospectively studied tracheal intubation of 200 patients with Mallampati scores of 3 or 4 using the Berci-Kaplan video laryngoscopy (Storz) system, versus direct laryngoscopy. The video system provided a superior view of the cords, had a higher success rate, had faster time to intubation, and required fewer optimizing maneuvers than direct laryngoscopy.[61] Marrel and associates[62] studied video laryngoscopy and direct laryngoscopy in 80 morbidly obese patients. They found that the view achieved with the video system was significantly better in 28 patients and duration of intubation shorter.

Numerous studies support the routine use of alternatives to direct laryngoscopy in the setting of failed and known difficult intubation. Studies support the use of salvage interventions in the setting of an unanticipated difficult intubation with a practiced alternative, because these are likely to be associated with better outcomes compared with persistent direct laryngoscopy. Video laryngoscopy is emerging as a vital tool in both anticipated and unanticipated difficult intubation.[59] Residents should be familiar and trained to use one or more of the commercially available video laryngoscopes during their training. Video laryngoscopes are necessary tools for difficult airway management when direct laryngoscopy fails and also serve as invaluable tools in teaching advanced airway management.

VI. CONCLUSIONS

Anesthesiologists are recognized as airway management specialists in most aspects of modern medical practice. With this recognition comes responsibility. Anesthesiologists should make a career-long commitment to foster expertise in the recognition and management of the difficult airway through proficient examination of the patient, communication and documentation of airway management concerns with physician colleagues, and appropriate application of specialized techniques of advanced airway management, when applicable. Fortunately, a variety of different methods are available for training and experience in advanced airway management. The key to learning and skill acquisition remains the interest and commitment of the individual.

VII. CLINICAL PEARLS

- Hands-on training with laryngeal mask airway insertion is associated with higher success rates than manual or videotape training. However, even the most advanced mannequins are unable to recreate human airway anatomy.
- Novice anesthesiologists can safely achieve an acceptable level of technical expertise in fiberoptic intubation by performing at least 10 elective, asleep fiberoptic intubations.

- The main cause of failure with cricothyrotomy is lack of experience and hands-on training. Ten attempts on a manikin decreases time and improves success in percutaneous dilatational cricothyrotomy.
- Establishment of an airway rotation requires proper equipment, core faculty, curriculum, time commitment, and faculty development.
- Constant faculty supervision provides patient safety and the ability to abort or change airway management.
- Learning in the OR is not ideal. Training using simulators can be helpful with more advanced airway skills, such as fiberoptic intubation and intubating LMA. Skills achieved with simple training models are transferable to the clinical environment.
- Laryngoscopy is a basic skill all anesthesia residents should master during training.
- Video-enabled technology can be beneficial in the training of residents in difficult airway management.
- Residents should be familiar with various intubating devices during training. Salvage interventions for unanticipated difficult intubation are associated with better outcomes than persistent direct laryngoscopy.
- Use of airway exchange catheters during endotracheal tube exchange in the ICU lowers the risk of complications, even with a previously uncompromised view of the glottic inlet.

Appendix A

Appendix B

I. OVERVIEW

Dissemination of critical airway information traditionally has been accomplished by documentation in the medical record, by verbal communication to patients and physicians, by letter, or by a combination of these. Significant shortcomings of these types of communication include questionable understanding by the patient or future care provider of the significance of the airway difficulty, nonuniformity of documentation, and an inability to access the information at a later date, particularly during an emergency. Even the emergence of the electronic health record (EHR) has not yet provided an answer to the need for universal access to emergency medical information. However, a solution that is already in place is the nonprofit MedicAlert Foundation, the oldest and foremost national and international emergency medical information and identification service. Founded in 1956, MedicAlert Foundation International, headquartered in Turlock, California, relays critical, life-saving medical

*The MedicAlert® Foundation is a 501(c)(3) nonprofit organization. ©2011 All Rights Reserved. MedicAlert® is a U.S. registered trademark and service mark.

information through a live 24/7 service for its 4 million members.

In 1992, the MedicAlert Foundation National Difficult Airway/Intubation Registry was begun to facilitate uniform documentation and effective dissemination of standardized critical information related to complex airway management. The Registry was created by the Anesthesia Advisory Council of the MedicAlert Foundation, a volunteer multidisciplinary team of anesthesiologists, otolaryngologists, and experts in quality assurance and risk management. According to Andrew Wigglesworth, President and CEO of MedicAlert Foundation International, Registry contained almost 11,700 patients with identified difficult airway or difficult intubation in 2010 (personal communication, May 14, 2010).

This chapter focuses on how critical airway information can be effectively disseminated to future care providers through the MedicAlert Foundation and the National Difficult Airway/Intubation Registry. The components and benefits of the MedicAlert Foundation and this Registry are compared with those of in-house anesthesia documentation, letters to the patient, airway registries, commercially available for-profit medical alert information systems, and the yet-to-be realized universal EHR. Information on how patients can join the MedicAlert Foundation and enroll in the National Difficult Airway/Intubation Registry can be found in Appendix A.

II. DIFFICULT AIRWAY/INTUBATION: A MULTIFACETED PROBLEM

Complex airway management is a multifaceted problem involving practitioners in a variety of clinical settings. The consequences of failed airway management can be devastating to the patient, the practitioner, and the health care system. Critical issues include (1) identification of patients with difficult airway/intubation, (2) use of practice guidelines and a difficult airway/intubation algorithm for airway management, (3) use of a difficult airway/intubation team, and (4) the consequences of difficult airway/intubation.

A. Identification of Patients

Controversies regarding predictors and definitions of "difficult" cases exist both within and among medical specialties that deal with difficult airway/intubation. This is a consequence of the complex interactions among patient variables, the clinical setting, and the skills of the practitioner.[21] Historically, the anesthesiology literature has cited an incidence of 1% to 3% unanticipated difficult airway/intubation in patients undergoing general endotracheal anesthesia in the operating room.[2-5] More recently, incidences up to 18% have been reported.[6,7] In non–operating room emergent intubations, the reported incidence of difficult intubation has ranged from 6% to 10%.[8,9]

At a local level, if a 1% to 3% incidence is applied, then an institution in which 25,000 general endotracheal anesthetic procedures are performed annually could have 250 to 750 unanticipated difficult airway/intubations per year. On a national level, based on an American Society of Anesthesiologists (ASA) membership of 44,000 and assuming that a full-time practicing anesthesiologist is likely to encounter at least one unanticipated difficult intubation per year,[10] there could be 44,000 unanticipated difficult airway/intubations annually in the United States. These numbers do not take into account intubations that occur in clinical settings other than the operating room or are performed by anesthesia care providers who are not members of the ASA. Consideration of the possible number of unanticipated difficult airway/intubations on an international level further shows that the scope of this problem and its impact on patients and the health care system warrants vigorous efforts to identify solutions.

B. Multidisciplinary Practice Guidelines and Difficult Airway/Intubation Algorithms

The ASA first developed and published practice guidelines for management of the difficult airway in 1993.[2] These guidelines heightened practitioners' awareness of the scope and magnitude of problems related to complex airway management and encouraged familiarity with a standardized clinical airway algorithm. At that same time, the Johns Hopkins Department of Anesthesiology and Critical Medicine initiated a collaborative effort with the Department of Otolaryngology—Head and Neck Surgery to develop and modify airway management techniques and clinical algorithms.[11]

More recently, other organizations and countries have proposed and tested their own strategies and algorithms for managing difficult airway/intubation cases.[12-15] Some algorithms incorporate the use of new airway devices,[16] whereas others are designed for use in settings other than the operating room.[8,17] A text on emergency department airway management has recommended a universal algorithm in addition to algorithms for specific circumstances.[18,19] Guidelines developed for anesthesiologists in the operating room cannot reasonably be applied to emergent intubation in the field, and the most successful algorithms have been developed at a local level by a multidisciplinary team.[20]

The creation of these various algorithms is still in harmony with the purpose of the ASA practice guidelines: (1) the practice guidelines are not intended as standards or absolute requirements; (2) they are subject to revision as warranted by the evolution of medical knowledge, technology, and practice; and (3) their recommendations may be adopted, modified, or rejected according to clinical needs and constraints.[1] Considering all of these variables tends to move airway management farther away from one standardized difficult airway/intubation algorithm. This leads to the inevitable conclusion, as noted in an ASA editorial, that optimal or preferred tracheal intubation techniques and devices will be different for each individual patient and depend on the skill and experience of the practitioner in that particular clinical setting.[21]

C. A Difficult Airway/Intubation Team

Strategies for improving the response to difficult airway/intubation during an emergency code situation can

include the use of a difficult airway response team (DART) and a DART equipment cart such as the one developed in 2008 at the Johns Hopkins Medical Institutions. This multidepartmental educational and operational program involved anesthesiology, otolaryngology, trauma surgery, and the emergency department; clarified unclear roles of the various providers; and initiated facility-wide quality improvement of problems such as difficulty accessing specific equipment.[22] A retrospective review at this institution of cases from 1992 through 2006 demonstrated an annual frequency of approximately 6.5 emergency surgical airways (cricothyrotomy or tracheostomy). Two years after initiation of a comprehensive DART program, the annual frequency was approximately 2.2, despite an increase in the number of patients reported to have difficult airway/intubation.[23] Implementation of the DART program also reduced the number of airway sentinel events from several in the preceding 2 years to none in the first 2 years of the DART program. In addition, no claims related to airway events were paid during this time.[24]

D. Consequences of Difficult Airway Management

The consequences of a difficult airway or difficult intubation can include minor or major adverse medical events or death, professional liability to the practitioner, and direct and indirect costs to the patient and the health care system. In 1988, the ASA Committee on Professional Liability closed claims study found that respiratory events were the most common cause of brain damage and death during anesthesia, with difficult intubation being the likeliest category for risk reduction. The median payment for respiratory claims was $200,000.[25] In a 1992 loss analysis study conducted by the Physicians Insurers Association of America, files from 43 physician-owned malpractice insurance companies (representing approximately 2000 anesthesiologists nationally) ranked "intubation problems" as the third most prevalent misadventure. The average paid indemnity for 175 of 339 files was $196,958.[26] In an analysis of approximately 5000 claims filed in Maryland over a 15-year period that named an anesthesiologist as a defendant, insertion of an endotracheal tube was the sixth most common medical procedure leading to a liability claim. One malpractice claim was filed for every 7.5 patient injuries that occurred from difficult airway events and adverse outcomes, and a single claim in 1994 resulted in a jury award of $5 million (Laura Morlick, Johns Hopkins Medical Institutions, Baltimore, MD, personal communication, July 17, 1994). A study of the ASA closed claims database from 1985 to 1999 revealed that 67% of claims of difficult airway liability were associated with intubation.[27]

During airway management, repeated intubation attempts cause swelling and bleeding, with each attempt creating a greater likelihood of failed intubation and ventilation leading to potentially disastrous consequences, even brain damage or death.[18,27,28] Prolongation of the airway management process has been shown to increase the rate complications up to 70% with multiple tracheal intubation attempts.[8,29]

Most complaints initiated against physicians are unrelated to the physician's technical skill but arise because of inadequate records or poor communication. More complete documentation and communication may be the practitioner's best defense.[30] A 1994 survey of patients who were enrolled by Johns Hopkins in the MedicAlert National Difficult Airway/Intubation Registry found that, despite experiencing adverse outcomes (cancellation of surgery, dental trauma, soft tissue trauma, desaturation, cardiovascular compromise, and cricothyrotomy or tracheostomy), 100% felt that the enrollment gave them a sense of comfort in that future care providers would understand the significance of their difficult airway/intubation. Enrollment in the Registry and documentation of enrollment in the patient's medical record is a positive reflection of the provider's concern for the patient's future safety.[31] In a fall 2010 survey conducted by the MedicAlert Foundation of more than 700 members already enrolled in the National Difficult Airway/Intubation Registry, 69.6% of respondents said that a physician had recommended that they enroll, and 92.7% said that what they expected to gain from enrolling was peace of mind knowing that their difficult airway/intubation information would be available in an emergency (A. Wigglesworth, personal communication, September 23, 2010).

III. DIFFICULT AIRWAY/INTUBATION: DOCUMENTATION OF CRITICAL INFORMATION

The communication of successful and unsuccessful airway management techniques consists of two parts: (1) documentation at the time of the event (preanesthesia, anesthesia, postanesthesia) for concurrent care providers during that episode of care, and (2) dissemination of that information to future care providers during subsequent episodes of care. This section deals with documentation to concurrent care providers during an episode of care.

A. Documentation in Medical Records

In the past, no standardized, uniform, readily available document existed to precisely record airway events. Traditionally, difficult airway/intubation information was recorded in the paper anesthesia record as a nonstandardized, handwritten, free text entry. This information was not included in the operative report or on the face sheet of the medical record; it was hidden and seldom accessed by physicians and nurses caring for the patient in the intensive care unit or nursing unit. In addition, this information was department specific in that it was not shared with other departments (emergency; ear, nose, and throat) within the institution that also encountered patients with difficult airway or difficult intubation.

In 1987, Martin L. Norton and colleagues at the University of Michigan pioneered efforts to more fully evaluate patients with complex airway problems by establishing the University of Michigan Airway Clinic.

This is believed to be the first formally established clinic specifically for patients with difficult airway/intubation. Clinical documentation consisted of a handwritten airway clinic record sheet and photodocumentation.[32] Since that time, the standard of care for documentation of difficult airway/intubation information has been steadily evolving. In 1992, Lynette Mark and colleagues in the Johns Hopkins Anesthesiology and Critical Care Medicine Department developed the Anesthesiology Consultant Report. This two-page report fully described the preoperative evaluation of a difficult airway/intubation, including intraoperative airway techniques and management and a narrative description of the events. The Anesthesiology Consultant Report raised the standard of documentation during a patient's initial episode of care in that its detailed airway management documentation was a more accessible part of the patient's medical record. Care providers were also alerted by a highly visible wristband.[11]

In 1993 and 2003, the ASA practice guidelines recommended that anesthesiologists document more fully in the medical record and include a description of the nature of the airway difficulties, the various airway management techniques that were employed, and the extent to which each of these techniques was beneficial or detrimental in managing the difficult airway.[1,2]

B. Documentation in In-House Electronic Medical Records

At the Johns Hopkins Medical Institutions, the 1992 Anesthesia Consultant Report evolved into an Anesthesia Consult form that contained a template and free-text entry as part of the in-house Johns Hopkins computerized medical record. In 1995, at Beth Israel Deaconess Medical Center in Boston, patients' difficult airway/intubation information was entered into the nurse's assessment section, and a "difficult airway/intubation" notice was placed in the computerized patient record.[33]

At present, the electronic medical record (EMR) is, by definition, limited to a single health system. The University of Michigan Department of Anesthesiology and many other facilities use a perioperative clinical information software system such as Centricity (General Electric Healthcare, Waukesha, WI) to collect difficult airway/intubation information in an airway management record that contains required fields, a drop-down menu, and a comment section for free text. This information is available at bedside workstations throughout the facility, including the floor and intensive care units, as part of the EMR.[9] Other institutions have developed their own EMR systems for in-house use, with multiple terminals that allow access throughout the hospital.

Recording in the EMR that the patient has a difficult airway or difficult intubation triggers the use of a difficult airway/intubation wristband and an alert on the facesheet similar to that for allergies. A commercially developed or in-house EMR system can ensure that a patient with difficult airway/intubation is recognized as such during the remainder of the hospital stay and subsequent hospital stays.

IV. DIFFICULT AIRWAY/INTUBATION: DISSEMINATION OF CRITICAL INFORMATION

The communication of successful and unsuccessful airway management techniques consists of documentation at the time of the event and dissemination of that information to future care providers. This section deals with dissemination of that critical information.

A. ASA Recommendations for Dissemination of Information

Before the creation of the ASA practice guidelines, there was little or no literature discussing the benefits of patient notification of difficult airway management.[7] The 1993 ASA practice guidelines recommended that the anesthesiologist inform the patient (or responsible person) of the airway difficulty that was encountered and that notification systems, such as a written report or letter to the patient or communication with the patient's surgeon or primary caregiver, could be considered.[2] The 2003 ASA practice guidelines added a recommendation for a bracelet or equivalent identification device that could be kept with the patient at all times.[1]

B. Dissemination of Information via Paper Medical Records

Traditionally, difficult airway/intubation information was housed in the patient's paper medical record. Even when this written documentation was adequate, it usually could not be disseminated to care providers during subsequent episodes of care because it was difficult or impossible to retrieve paper-based records from storage, particularly in the event of an emergency.

C. Verbal Dissemination of Information

Most anesthesiologists inform the patient of a difficult airway/intubation in the postanesthesia care unit. However, this verbal communication of difficult airway information to the patient is unreliable. Communication can be hindered by the patient's intubation or by postoperative pain or sedation. Family members present are usually more concerned about the patient's surgical findings and recovery from anesthesia and surgery.[7] One study found that 50% of patients informed verbally did not recall or were unsure about ever having had a postoperative conversation with their anesthesiologist.[34]

Difficult airway/intubation information relayed verbally can be miscommunicated because of patients' lack of understanding of medical words or because anxiety related to their medical condition prevents them from assimilating this information. In addition, providers may underrepresent the severity of the difficult airway/intubation to allay patients' anxiety or because of fear of liability exposure. When these patients reenter the health care system, the previous verbal communication about difficult airway/intubation may not be remembered, and they may deny any difficult airway history or relate a

vague history. In an emergency situation, patients who are unconscious cannot relate any difficult airway/intubation information they may have been told.

D. Dissemination of Information via Letters

Beginning in 1992, the Johns Hopkins Anesthesia Consultant Report (described previously) was distributed by letter to the patient's surgeon and referring physician.[11] In 2000, the Department of Anesthesiology at Mayo Clinic Scottsdale began providing written notification to patients about their difficult airway in the form of letters mailed 1 week postoperatively. However, in a follow-up survey 2 years later, 20% of patients could not recall receiving the letter. To improve communication, the Clinic followed up with a telephone call to confirm receipt of the letter and to emphasize the importance of the difficult airway/intubation. A MedicAlert Foundation brochure was also included in the letter. The survey found that of those patients who remembered receiving a difficult airway/intubation letter, 41% had informed their primary care physician of their difficult airway, and 95% who subsequently had surgery had informed their surgeons or anesthesiologist or both. The survey concluded that the patients were able to inform subsequent care providers that they had a difficult airway even though most of them did not understand how "difficult airway" affected their subsequent anesthesia and airway management.[34]

More recently, various publications have reiterated the need for some type of standard written notification or airway alert form to be distributed to the patient, the primary care provider, and the surgeon.[7,35]

E. Dissemination of Information via Difficult Airway/Intubation Registries

In some facilities, after a patient has been identified as having a difficult airway or difficult intubation and the airway management information has been entered in a hospital-wide information system, the patient's name is entered into an in-house difficult airway/intubation registry.

In 1987, the Norton and colleagues at the University of Michigan established a permanent in-house Airway Clinic (described previously) linked to an Airway Registry and an information response center for dissemination of critical airway information. As the Registry grew in size, it became increasingly apparent that the response center could not accommodate 24-hour emergency requests for difficult airway/intubation information, so Registry patients were enrolled in the MedicAlert Foundation registry.[36] In 1992, Mark and colleagues at the Johns Hopkins Medical Institutions established a permanent in-house Difficult Airway/Intubation Registry.[11] This registry still exists, and all patients who are identified as having difficult airway/intubation are entered into this in-house database; a note or flag is placed in their electronic record, and they receive a follow-up letter that includes a brochure and recommendation that they enroll in the MedicAlert Foundation. In 1995, in response to the ASA Difficult Airway Task Force practice guidelines and the Anesthesia Advisory Counsel of the MedicAlert Foundation, an in-house computerized Difficult Airway Registry was initiated at Beth Israel Deaconess Medical Center.[36]

The purpose of an in-house registry is to disseminate critical airway information during subsequent episodes of care at that facility. A review of 119 patients in the Beth Israel Deaconess Medical Center difficult airway registry from 1995 to 1997 found that 31 (26%) had returned for surgery one or more times and that the registry provided valuable information for subsequent airway management.[37] However, in-house difficult airway/intubation registries are not common, even at tertiary-level institutions, and the information they contain is available only within that institution.

F. Dissemination of Information via Electronic Medical Records and Electronic Health Records Systems

In 1991, the Institute of Medicine set a goal of 10 years for widespread use of computerized patient records. In 1994, the Computer-Based Patient Record Institute announced that it would seek major funding to finalize the development of standards for health care informatics. Since then, the EMR has been implemented in some places; however, its scope is limited to a single health system.

More recently, there has been a push to implement an EHR system in American health care, with an increase in motivation provided by funding from the American Recovery and Reinvestment Act of 2009 (ARRA) directed at supporting such implementation. In an EHR system, the patient's complete health record would be captured across all health care institutions. This is the focus of the ARRA funding, as reinforced by Meaningful Use requirements (explicit criteria for receiving Medicare payments for provision of medical care). In 2011, Beth Israel Deaconess Medical Center became the first hospital to have its in-house–developed EHR system certified as meeting Meaningful Use requirements.[38] Part of the certification involved having the capacity to provide patients with an electronic copy of their health information within 3 business days (if they request it). The goal is to provide patients access to information that is important to them, when they need it, and to allow patients to be treated holistically through coordination with other providers.[39] However, an electronic copy of the record provided 3 business days after discharge may not provide access to critical information when patients need it and does not automatically ensure coordination of care with other providers.

A survey found that only 1 in 7 consumers could access their medical records electronically; even when access was possible, 40% were unable to see certain documents (e.g., laboratory reports, prescription history, immunization records).[40] In 2009, the Health Information Technology for Economic and Clinical Health (HITECH) Act was passed in an effort to improve the health of Americans and the performance of the health care system. Some of its programs included support for state initiatives for health information exchange and

creation of a common platform for health information exchange across the country: the National Health Information Network (NHIN).[41]

One state program is the Chesapeake Regional Information System for Our Patients (CRISP) in Maryland. Its goal is to deliver the right health information to the right place at the right time. However, not all Maryland hospitals are included in the CRISP program, and the program does not access medical information on a national level, does not provide emergency information to Maryland residents who travel outside of the state or internationally, and does not cover new residents who have moved into the state and whose medical information is housed elsewhere.[42] Over time, it is hoped that this and other state programs can be expanded to form the envisioned (NHIN). The emergence and encouraged development of an EHR system in the United States cannot, at present, provide an answer to the need for immediate national or international access to emergency medical information. However, a solution that is already in place and fully operational can be found with the MedicAlert Foundation.

V. THE MEDICALERT FOUNDATION

The MedicAlert Foundation pioneered and maintains the foremost national and international emergency medical information and identification services system that provides immediate access to critical medical information.

A. History of the MedicAlert Foundation

The MedicAlert Foundation is a 501(c)3 nonprofit organization that was founded in 1956 by Dr. Marion C. Collins, a physician, and his family because of his daughter's life-threatening allergy. The MedicAlert Foundation has been endorsed by more than 50 organizations, including the ASA in 1979, the World Federation of Societies of Anaesthesiologists (WFSA) in 1992, and the American Academy of Otolaryngology–Head and Neck Surgery Foundation (AAO-HNS) in 1993. Many of the founding members of the Society for Airway Management (SAM) in 1995 were already members of the MedicAlert Foundation's Anesthesia Advisory Council. In 1996, on the occasion of the MedicAlert Foundation's 40th anniversary, the wife of its founding physician, Chrissie Collins, was awarded the American Medical Association's highest honor, the Citation for Distinguished Service.

The MedicAlert Foundation has nine international affiliates providing services in 25 countries and in 140 different languages. The MedicAlert Foundation, headquartered in the United States, has been in operation since 1956 and is still the only nonprofit agency providing emergency medical information and identification services. Its mission is to protect and save lives by disseminating critical patient information immediately and accurately, when needed, for its 4 million members (2.3 million in the United States and 1.7 million worldwide).

Figure 54-1 MedicAlert medical IDs. The MedicAlert medical ID as a necklace and a bracelet. The reverse side of the medical ID shows the MedicAlert Foundation's telephone numbers (toll-free nationally and internationally without charge to the caller), the Difficult Airway/Intubation designation, and the patient's unique MedicAlert Foundation identification number. (Courtesy of the MedicAlert Foundation, Turlock, CA.)

B. Services Provided by the MedicAlert Foundation

The MedicAlert Foundation's core services comprise a four-part system: a personalized and custom-made MedicAlert medical ID worn as a bracelet or necklace (Fig. 54-1), a personalized MedicAlert wallet card (Fig. 54-2), an Emergency Medical Information Record (EMIR), and the MedicAlert live 24/7 Emergency Response Service Center. The MedicAlert medical ID and MedicAlert wallet card immediately alert a care provider that the patient has a specific medical condition, such as an allergy, autism, asthma, diabetes, or difficult airway/intubation. Engraved on the medical ID and printed on the wallet card is the toll-free emergency phone number, 1-800-607-2565. For members who travel internationally, MedicAlert recommends that they also have engraved on the medical ID and printed on the wallet card the International Call Collect number, 209-634-4917. The Emergency Response Center accepts all international collect calls and is staffed by a team of medically trained personnel who respond to calls 24 hours a day, 7 days a week, in more than 140 languages.

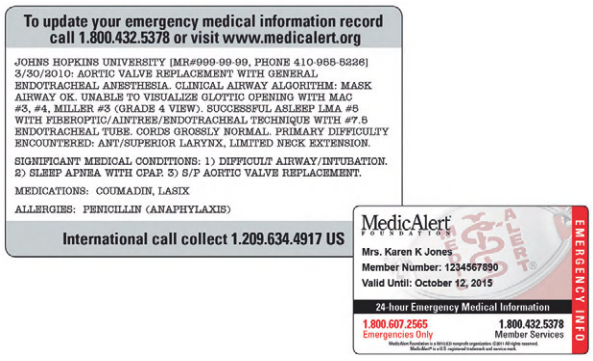

Figure 54-2 The MedicAlert Wallet Card. This card contains a narrative of the patient's medical diagnoses and specific successful and unsuccessful airway techniques that have been used. (Courtesy of the MedicAlert Foundation, Turlock, CA.)

In 1990, the MedicAlert Foundation expanded member information to include Advance Directives and information about medical devices. The Foundation has partnered with the Alzheimer's Association since 2007 and with the Autism Society of America since 2009 to provide life-saving services to high-risk patients.

The MedicAlert Foundation has always been on the cutting edge of information-providing services. In the 1970s, it computerized all of its members' records and was the first registry to use a scan form system to reduce the costs of data entry.[43] Since 1990, the MedicAlert Foundation has offered members their own personal EMIR). Looking to the future, the EHR system envisions seamless, immediate, and simultaneous access by more than one health care provider to all parts of a patient's record regardless of where those parts were created or stored. Far from competing with the envisioned EHR system, the MedicAlert Foundation has anticipated it and embraced the goal of enabling the dissemination of information to any EHR system. This could be as simple as an HL7 text message or as complicated as a set of discrete data detailing specific medical information. By serving as a central repository in a web of interconnected EHR systems, the MedicAlert Foundation could play a key role in providing critical life-saving information to the clinical systems directly involved in a patient's care. Finally, as patients continue to become more engaged in managing their own health care through the use of personal health records (PHRs)—as provided by Microsoft, Google, and other vendors—the MedicAlert Foundation will be able to keep patients' PHRs updated with the latest medical information.

The MedicAlert Foundation maintains the privacy and confidentiality of member's information. All electronic data are securely encrypted and backed up in earthquake-, fire-, and flood-proof locations. Overall security is reviewed by a third party. Financial information is used only for MedicAlert billing and is never shared with any other person or organization for other purposes.

At the time of member enrollment, the MedicAlert Foundation obtains prior approval for storage and transfer of members' information to emergency responders. Personal and medical information remains secure and confidential and is used solely for its authorized and intended purpose. The MedicAlert Foundation may release de-identified member information for valid medical research. The release of identifiable member information for medical research or clinical trials requires the member's informed consent in accordance with applicable laws and regulations for human subject trials. For more than 50 years, there have been no claims against the MedicAlert Foundation for breach of confidentiality or dissemination of incorrect medical information. Although the MedicAlert Foundation is not defined as a "covered entity" under the Health Insurance Portability and Accountability Act (HIPAA) of 1996, the organization's information privacy and security standards complement the HIPAA provisions and are fully compliant with the requirements of the Federal Trade Commission and those of the European Union SafeHarbor framework.

C. Membership in the MedicAlert Foundation

MedicAlert Foundation membership is $35/year for adults. This allows members to manage their own personal EMIR, with no limit on the number of updates per year. Members can update their information 24 hours a day by logging on to their own personal secure online account. An annual membership for children is $20/year. A MedicAlert Gold membership is available for $9.95/month; members with this status can consolidate all of their paper records (e.g., laboratory reports, immunization records, radiology reports, electrocardiography results) in an electronic format. Members each have a unique Document Center that can receive faxed medical records from their physicians. The faxed documents are then converted into a PDF file and are available 24 hours a day from any Internet-connected computer. Information on how patients can enroll in the MedicAlert Foundation is presented in Appendix A.

VI. THE MEDICALERT FOUNDATION NATIONAL DIFFICULT AIRWAY/INTUBATION REGISTRY

For years, anesthesiologists have recognized the value of the MedicAlert Foundation's emergency response system for patients with malignant hyperthermia (Index Zero hotline). They have also encouraged patients to enroll in the MedicAlert Foundation under a general designation of "difficult airway."

A. History of the Registry

In 1992, the ASA and others recommended the creation of a national difficult airway registry for the United States.[1] At that time, the Anesthesia Advisory Council, a volunteer, multidisciplinary team of anesthesiologists, otolaryngologists, and experts in quality assurance and risk management (see Appendix B), joined together to address the following questions: (1) When an airway event happens, is there consistency in documentation? and (2) Is there a central, accessible database for dissemination of critical airway information? The Council identified only two existing airway databases, those at the University of Michigan Airway Clinic and the MedicAlert Foundation. The Anesthesia Advisory Council recommended the creation of the National Difficult Airway/Intubation Registry within the MedicAlert Foundation to facilitate uniform documentation and effective dissemination of standardized critical information related to complex airway management. The Council selected the category "difficult airway/intubation" as a standard nomenclature to be engraved on the MedicAlert medical ID.

In 1995, the SAM was founded, and the Anesthesia Advisory Council passed the torch to the SAM to take the MedicAlert National Difficult Airway/Intubation Registry into the next millennium.[44] Today, it is the only difficult airway/intubation registry that exists at a national level in the United States.

On an international level, Austria established the Austrian Difficult Airway/Intubation Registry (ADAIR) in 1999,[45] and Denmark established the Danish Difficult Airway Registry in 2005.[46] These registries are not international in scope. Only the MedicAlert Foundation National Difficult Airway/Intubation Registry is truly international, because it is able to disseminate critical information to care providers anywhere in the world 24 hours a day, 7 days a week, in 140 different languages.

B. Objectives of the Registry

The major objectives of the Anesthesia Advisory Council for the National Difficult Airway/Intubation Registry were (1) to develop and implement mechanisms for uniform documentation and dissemination of critical information, (2) to establish a central database of airway management information for research purposes, (3) to conduct long-term tracking of patients to assess implications of adverse outcomes for future management, and (4) to determine whether rapid and economical dissemination of critical airway information could have a positive impact on the future care of patients and overall costs to the health care system.

C. Components of the Registry

The components of the National Difficult Airway/Intubation Registry include information for health care providers and patients, a specialized enrollment form, a secure database, the supporting services of the MedicAlert Foundation (i.e., medical ID, wallet card, EMIR, and 24/7 Emergency Response Service Center), and a follow-up letter sent to the primary care physician or specialist (as indicated by the patient on the enrollment form). In 2003, the ASA practice guidelines recommended that a notification bracelet or equivalent identification device be included as part of a notification system for difficult airway/intubation patients.[1] This has always been a part of the MedicAlert system since its beginning in 1956.

The National Difficult Airway/Intubation Registry specialized enrollment form is in a PDF format. The anesthesiologist downloads the form from the website (www.medicalert.org [accessed April 2012]) and prints it out, or the MedicAlert Foundation can send it to the anesthesiologist as a PDF attachment to an e-mail. The anesthesiologist completes and signs the airway database section (Fig. 54-3) of the enrollment form. This section includes the hospital name, patient's medical record number, surgical procedure, date of procedure, clinical anesthesia profile, nature of difficulty encountered, reasons for difficulty, successful and unsuccessful techniques, best visualization of airway anatomy, clinically applied algorithm, and clinical outcome. With the exception of specific airway requirements (related to tracheal surgery, stenosis, or other conditions requiring specific sizes of endotracheal tubes), recommendations for future airway management are not included, so as to avoid conflict with future practitioners' choices of airway management techniques. The form is then given to the patient to complete (including the name of the primary care physician), sign, and mail in (or fax to) the MedicAlert Foundation along with a check or credit card information for the enrollment fee. The amount of the enrollment fee depends on which type of membership the patient selects. For patients who are unable to pay for membership, the MedicAlert Foundation will enroll them for free if the completed enrollment form is accompanied by a statement of financial need that is written on official letterhead paper and signed by the anesthesiologist or other provider.

D. Characteristics of Registry Patients

Between 1992 and 1994, more than 250 adult and pediatric patients throughout the United States were enrolled in the MedicAlert Foundation National Difficult Airway/Intubation Registry. Their characteristics were as follows: ASA classes I and II, 54%; ASA classes III and IV, 46%; ASA class V, 0%. For airway management in these patients, conventional laryngoscopy was successful only about 20% of the time. These patients had 39 reported adverse outcomes: cancellations, 9 (23%); dental trauma, 3 (8%); desaturation, 7 (18%); soft tissue trauma, 11 (28%); cardiovascular compromise, 2 (5%); and other, 7 (18%). Patients were enrolled from private and academic institutions, from outpatient surgical centers, and by self-referral.[47] By 2003, there were approximately 7020 patients enrolled in the MedicAlert National Difficult Airway/Intubation Registry.[34]

As of 2010, there were almost 11,700 patients enrolled in the MedicAlert National Difficult Airway/Intubation Registry (A. Wigglesworth, personal communication, May 14, 2011). The MedicAlert Foundation, the Anesthesia Advisory Council, and SAM are in the process of analyzing this registry, and efforts are underway to expand the enrollment form in the future to an international query.

E. Benefits of the Registry

Benefits of the National Difficult Airway/Intubation Registry include patient safety, practitioner security, and cost savings. With enrollment, the patient's primary care physician and specialists are notified of the patient's difficult airway/intubation status to facilitate local continuity of care. The patient is also protected during subsequent episodes of care. A 2010 survey of more than 700 members in the MedicAlert Foundation National Difficult Airway/Intubation Registry found that 11.2% had had another episode of care in which difficult airway/intubation was a factor (A. Wigglesworth, personal communication, October 2010).

The Registry provides a chronology of the patient's airway events over time, reflecting changes in pathophysiology and airway management. This chronology assists future care providers in their decision-making process and allays any concerns about mistakenly labeling a patient as having a difficult airway or difficult intubation. The patient's MedicAlert medical ID or wallet card provides a visible or easily accessible reminder of the difficult airway/intubation status, and the MedicAlert Foundation's toll-free phone number provides access to the

5. TO BE FILLED OUT BY PRACTITIONER (Patient should proceed to question 6): Not placed on Medic Alert computer record until validated by physician.

1. _____ _____/____/_____
HOSPITAL NAME **MEDICAL RECORD #** (Very important) **PROCEDURE** Mo Day Year

2. Clinical profile: ❑ Anesthesiologist ❑ CRNA ❑ Otolaryngologist ❑ ED
Other _____
ASA classification ❑ I ❑ II ❑ III ❑ IV ❑ V ❑ E
HT _____ Wt/kg _____
Site: ❑ OR ❑ Non-OR ❑ Ward ❑ ED Other _____
Monitors utilized: ❑ Capnography ❑ Oximetry Other _____

3. The difficult airway was: ❑ Anticipated ❑ Unanticipated

4. If anticipated, how was the difficulty discovered?
❑ Airway history by patient/family interview ❑ Physical exam
❑ Documentation in medical record ❑ Diagnostic tests/consultations
Specify _____

5. What type of difficult airway was encountered?
❑ Mask/ventilation ❑ Intubation ❑ Extubation Other _____

6. The difficulty encountered was primarily:
❑ Small mouth ❑ Tongue ❑ Dentition ❑ Ant/superior larynx
❑ Limited jaw opening/mobility ❑ Limited neck extention ❑ C-spine stability
❑ Distorted anatomy ❑ Infection ❑ Pregnancy Other _____

7. Visualization (check all that apply)
❑ Complete glottic opening ❑ Partial glottic opening ❑ Arytenoids
❑ Tip of epiglottis

8. What equipment/techniques were successful in airway management?
(Circle all that apply)
Awake • Asleep • Nasal • Oral • Blind nasal • Laryngeal mask • MAC #1 2 3 4 •
MILLER #1 2 3 4 • Fiberoptic • Intubation guide • Retrograde • Lightwand •
Jet ventilation • Cricothyrotomy • Existing trach/surgical airway •
Percutaneous crico/trach • Bougie • Combitube • Tracheotomy •
Specialized laryngoscope, blade and size (specify) _____
Endotracheal tube and size (specify) _____
Other and size (specify) _____

9. What equipment/techniques were unsuccessful in airway management?
(Circle all that apply)
Awake • Asleep • Nasal • Oral • Blind nasal • Laryngeal mask • MAC #1 2 3 4 •
MILLER #1 2 3 4 • Fiberoptic • Intubation guide • Retrograde • Lightwand •
Jet ventilation • Cricothyrotomy • Existing trach/surgical airway •
Percutaneous crico/trach • Bougie • Combitube • Tracheotomy •
Specialized laryngoscope, blade and size (specify) _____
Endotracheal tube and size (specify) _____
Other and size (specify) _____

10 . What was the outcome? ❑ No adverse outcomes ❑ Cancel procedure
❑ Dental trauma ❑ Soft tissue/nasal trauma ❑ Laryngeal trauma ❑ Desaturation
❑ Vocal chord trauma ❑ Tracheal trauma ❑ Cardiovascular compromise ❑ Aspiration
Other: _____

Specify clinically applied algorithm, number of attempts and pertinent findings. _____
_____
_____
Recommendations for colleagues: _____
Physician or anesthetist's signature _____ Print name/phone # _____
Include on wallet card? ❑ Yes ❑ No

6. SELECT YOUR EMBLEM: Indicate style and metal type desired.

STYLE	METAL	FEE**:
❑ Small bracelet	❑ Stainless steel	$35
❑ Standard bracelet	❑ Sterling silver	$50
❑ Necklace	❑ Gold filled	$75
	❑ Designer silver	$115

(Fees and terms subject to change without notice)

7. BRACELET SIZE: ❑ 6" ❑ 6 1/2" ❑ 7" ❑ 7 1/2" ❑ 8" ❑ 8 1/2" ❑ 9"

8. PAYMENT CALCULATION

** REGISTRATION FEE: $ _____
(Tax deductible medical expense.)
Includes issuance of ID number, wallet card and one custom engraved emblem with chain.
ANNUAL MEMBERSHIP FEE: $15 $ Ø
(First year free.) *Includes 24-hour, year-round emergency hot line service and free updating of your computer record.*
CONTRIBUTION: (Tax deductible) $ _____
MedicAlert, a nonprofit foundation, is partially supported by contibutions for professional and public education programs.
TOTAL AMOUNT ENCLOSED: $ _____

9. METHOD OF PAYMENT
❑ Check ❑ Mastercard ❑ Visa ❑ Discover ❑ Money order *(No other cards accepted.)*
No CODs. Payment must accompany order.
Send to: **Medic Alert, 2323 Colorado Ave., Turlock, CA 95382**

Card number: _____

Expiration date: _____
Note: Your signature and payment or card information must be indicated to enroll by mail.

Figure 54-3 The MedicAlert Foundation National Difficult Airway/Intubation Registry Enrollment Form, showing the airway database section from the original (1994) Registry enrollment form. In 2011, the Society for Airway Management (SAM) began revising this section, and the updated version will be available in the near future on the MedicAlert Foundation's Web site and possibly on the SAM Web site. (Courtesy of Lynette J. Mark, MD.)

details of the patient's airway management information 24/7, no matter where the patient travels in the world.

The Registry increases practitioner protection from liability by improving provider-patient communication. Enrollment gives providers an opportunity to inform patients of their airway difficulties and adverse events while offering a way to protect them during subsequent events, and this is perceived as a positive reflection of the provider's concern. As described previously, a 1994 survey of Johns Hopkins patients found that, despite experiencing adverse outcomes, 100% of patients felt that enrollment in the Registry gave them a sense of comfort that future care providers would understand their condition.[31] In the operating room, this difficult

airway/intubation knowledge may help avoid adverse outcomes and malpractice suits.

The cost of initial enrollment in the Registry may be justified by future cost savings realized by the patient and the provider or institution. Knowing that a patient was previously identified as having a difficult airway or difficult intubation and what techniques were used could promote the cost-effective use of equipment and operating room time and decrease the incidence of cancellations. A 10-month study of 690 patients undergoing coronary artery bypass surgery at the Johns Hopkins Medical Institutions as the first procedure of the day looked at charges for anesthesia preparation time (i.e., anesthesiologist's professional fee, anesthesia resident's charge, drug and supply charges, and operating room time charges). Of these patients, 684 had no airway difficulty (control group) and 6 had difficult airway/intubation and were subsequently enrolled in the National Difficult Airway/Intubation Registry. There was a mean charge of $990.71 for the control group patients and a mean charge of $1578.24 for the difficult airway/intubation patients, representing a 59% increase over the control group.[48]

VII. OTHER EMERGENCY MEDICAL RESPONSE SYSTEMS

There are currently more than 600 commercial, for-profit emergency response systems that are available to consumers. Of these, some offer a visible medical ID in the form of a necklace or bracelet or a separate wallet card, but none offers that final link of a live 24/7, toll-free national and international hotline to disseminate critical medical information in an emergency situation. The MedicAlert Foundation is the only nonprofit organization that offers this comprehensive program of services and the only organization that has an ongoing Difficult Airway/Intubation Registry (A. Wigglesworth, personal communication, May 14, 2011).

VIII. CONCLUSIONS

Information is the lifeblood of modern medicine, and health information technology is its circulatory system.[49] Quality improvements in the process of managing difficult airway/intubation situations (methods to identify patients, algorithms, equipment, airway teams) should be vigorous and ongoing but should be accompanied by improvements in how airway information is documented and disseminated. Once a patient with a difficult airway/intubation is identified, documentation of the airway management is critical and should include the specifics of successful and unsuccessful techniques, the skill level of the practitioner, and the clinical setting where the event occurred. The patient's in-house EMR, which can be accessed by multiple care providers and is linked to a difficult airway/intubation patient wristband and an alert on the facesheet, ensures that the patient is recognized as such throughout the initial episode of care.

After a difficult airway/intubation event has occurred, a critical issue is how this patient-specific information can be disseminated to future care providers in a timely manner during a subsequent episode of care. This is important because the availability of documentation of successful and unsuccessful airway management techniques can decrease the number of intubation attempts that are associated with complications (including death and brain damage), thereby improving patient safety and decreasing practitioner liability. ASA recommendations for dissemination of this information include informing the patient (or responsible person) of the presence of a difficult airway and the reasons for difficulty with (1) a written report or letter to the patient, (2) a report in the medical record, (3) a chart flag, (4) communication with the patient's surgeon or primary caregiver, and (5) a notification bracelet or equivalent identification device.

Informing the patient via verbal communication of difficult airway/intubation information should always be done, but this should not be regarded as a reliable way to disseminate critical information. Even when patients relay the fact of difficult airway/intubation to the next anesthesiologist, the details of successful and unsuccessful airway management techniques may not be included. Written communication of difficult airway information in the form of a letter to the patient is an effective strategy, but some patients will not remember receiving the letter, and others will lose or misplace the letter over time. In the event of an emergency, it is highly unlikely that patients would have those letters in their possession or that their primary care providers could access those letters in a timely way in their medical records. In-house difficult airway/intubation registries can successfully provide critical airway management information but only for a select group of patients who return to the same facility. It is evident that even with implementation of each of the first four ASA recommendations and other strategies, the patient's critical airway information may not be readily available outside the immediate scope of the hospital or primary caregiver.

Although an EHR system is under development and much progress has been made, the complexity and scope of issues to be addressed makes the time frame for accomplishing this goal uncertain. At present, difficult airway/intubation information in a patient's EMR record may be available at some hospitals or through a small network of related facilities but not comprehensively throughout a region or state and not nationally or internationally. At present, none of these methods of dissemination of information can fulfill the need for immediate access to emergency medical information whenever and wherever it is needed.

It is only by implementing the fifth ASA recommendation for a notification bracelet or equivalent identification device—a visible medical ID that speaks for itself—that the presence of the patient's difficult airway/intubation can be made known to any future care provider in any setting. And to be most effective, this medical ID must be linked to a database that provides patient-specific difficult airway/intubation information on demand at any time, anywhere in the world.

Fortunately, this solution is already in place and fully operational in the MedicAlert Foundation. Only the MedicAlert Foundation fulfills the need for immediate access to and dissemination of emergency medical information, nationally or internationally. The visible

MedicAlert difficult airway/intubation medical ID speaks for itself and is recognized by care providers around the world. The medical ID is linked to an Emergency Response Center that is staffed by a team of medically trained personnel who respond to calls from care providers 24 hours a day, 7 days a week, in more than 140 languages, and the MedicAlert Foundation National Difficult Airway/Intubation Registry provides the critical details of a patient's prior airway management to future care providers anywhere and at any time they are needed.

IX. CLINICAL PEARLS

- The MedicAlert Foundation, founded in 1965 and endorsed by the American Society of Anesthesiologists (ASA) in 1979, is the only 501(c)(3) nonprofit organization that provides a comprehensive medical service to members, in the form of visible medical ID, a separate wallet card, a Web-accessible personal health record, and a 24/7 live emergency response service.
- In 1992, the MedicAlert Foundation National Difficult Airway/Intubation Registry was created to facilitate uniform documentation and effective dissemination of standardized critical information related to complex airway management.
- The ASA Practice Guidelines for the Difficult Airway recommend the following components for dissemination of critical airway information: (1) a written report or letter to the patient, (2) a report in the medical record, (3) a chart flag, (4) communication with the patient's surgeon or primary caregiver, and (5) a notification bracelet or equivalent identification device. MedicAlert is currently the only organization that can readily provide this service.
- The consequences of a difficult airway/intubation may include minor or major adverse medical events or death, professional liability to the practitioner, and direct and indirect costs to the patient and health care system. Difficult airway/intubation still accounts for the highest percentage of closed claims in anesthesia.
- By 2010, the MedicAlert National Difficult Airway/Intubation Registry included more than 11,000 active members with the condition of "difficult airway."
- Individuals can become members of the MedicAlert Foundation by calling 1-800-ID-ALERT or by visiting the Web site (www.medicalert.org [accessed April 2012]). There is an annual enrollment fee, but if a person cannot afford the fee, a health care provider may contact MedicAlert and request that the fee be waived.
- The Foundation plans to have an updated National Difficult Airway/Intubation Registry form available on both their Web site and that of the Society for Airway Management (www.samhq.com [accessed April 2012]) by the summer of 2012.

IV. Clinical Pearls

I. HISTORICAL PERSPECTIVE

Anesthesiologists have a long-standing appreciation for risks associated with airway management. During the past 60 years, a variety of studies have demonstrated that events involving the respiratory system are a prominent cause of adverse outcomes in anesthesia practice.[1-8] A few examples help illustrate this point. The Anesthesia Study Commission, which investigated anesthesia-related fatalities in metropolitan Philadelphia during the period 1935–1944, identified respiratory factors such as airway obstruction, hypoxia, and aspiration as the probable cause of death in approximately 19% of cases.[7] A large, multicenter study by Beecher and Todd, conducted about a decade later when curare and other muscle relaxants were first entering clinical practice, led to the recognition of excess mortality associated with perioperative respiratory depression.[1] In the 1970s, Utting and colleagues analyzed a 7-year series of anesthesia accidents reported to the Medical Defence Union of the United Kingdom (UK).[8] Of 227 cases resulting in death or brain damage, 36% involved adverse respiratory events such as esophageal intubation, ventilator misuse, and aspiration.

Critical-incident studies have offered a similar picture. A landmark study in the late 1970s by Cooper and colleagues revealed that 29% of reported incidents were related to respiratory events such as airway mismanagement or failure and misuse of ventilators and breathing circuits.[2] A decade later, the Australian Incident Monitoring Study provided a detailed analysis of the first 2000 cases voluntarily submitted since the late 1980s.[6] In their collection of critical incidents, problems with ventilation accounted for 16% of reports from anesthesiologists in Australia and New Zealand.

II. THE CLOSED CLAIMS PERSPECTIVE

Closed medical malpractice claims represent an important resource for the study of professional liability associated with airway management. To better appreciate this resource, it is helpful to describe some basic features of claims data.

A medical malpractice claim is a demand for financial compensation by an individual who has sustained injury in connection with medical care. Resolution of a claim usually occurs by an out-of-court process or by litigation. Once a claim is resolved, its file is closed. A closed claim file typically contains a broad assortment of documents related to the adverse outcome. These documents may include medical records, narrative statements by the involved health care personnel, expert and peer reviews, deposition summaries, outcome and follow-up reports, and the cost of settlement or jury award.

Claims represent only a small fraction of all adverse outcomes arising from medical care. The Harvard Medical Practice Study of patients in New York State in 1984 reported that approximately 4% of patients sustained an iatrogenic injury during hospitalization,[9] but only 1 of every 8 injured patients filed a malpractice claim. Similar

Data from ASA Closed Claims Database, 2008.

findings were described 10 years earlier by the Medical Insurance Feasibility Study in California.[10] These small fractions make it unlikely that claims can be regarded as representing a cross section of all adverse outcomes.

Although claims may not serve as a representative sample of the entire population of adverse outcomes, these cases have a direct and important implication for the study of professional liability: the cost of claims plays an important role in determining the cost of medical malpractice premiums. By studying a large collection of claims, it may be possible to identify types of adverse events that consistently make a large contribution to insurance costs. This information helps focus research and risk management strategies on areas of clinical practice associated with the greatest losses. Successfully reducing losses may lead to lower premiums, with accompanying savings for physicians, patients, and associated third-party participants. Because many types of adverse outcomes are relatively rare, claims files also represent an enriched environment for collecting information about infrequent but catastrophic events. Examination of a large set of rare or unusual adverse outcomes with a common theme provides an opportunity to generate hypotheses of causation and remedy that may not be evident to anesthesiologists who experience such cases as isolated events.

Since 1985, the Committee on Professional Liability of the American Society of Anesthesiologists (ASA) has engaged in a structured analysis of closed anesthesia claims in the United States, known as the ASA Closed Claims Project. Cases involving adverse anesthetic outcomes are retrieved from the closed claims files of U.S. medical-liability insurance carriers who voluntarily participate in the project. Claims for dental injury are not included in the ASA Closed Claims Project, and the data reported in this chapter also exclude claims associated with chronic pain management. In aggregate, the participating carriers provide coverage for approximately 36% of U.S. anesthesiologists. Because several years often elapse between the occurrence of an adverse event and the closure of its associated claim, the majority of cases span an interval from the 1980s to the early 2000s. The database now contains more than 8000 cases.

A detailed description of data collection procedures for the Closed Claims Project has been reported previously.[11,12] In brief, each claim file is reviewed by a practicing anesthesiologist, and a standardized form is used to record detailed information on characteristics of patients, surgical procedures, anesthetic agents and techniques, involved personnel, sequence of events, standard of care, critical incidents, clinical manifestations, responsibility, and outcome. Standard of care is rated on the basis of reasonable and prudent practices at the time of the event. Practice patterns that may have evolved at a later date are not retrospectively applied when the standard of care is rated. An adverse outcome is deemed preventable with better monitoring if the reviewer finds that the use—or better use—of any monitor would probably have prevented the outcome, whether or not such a monitor was available at the time of the event. An acceptable level of interrater reliability has been established for reviewer judgments on the standard of care and preventability of adverse outcomes with better monitoring.[13]

A. Principal Features of Adverse Respiratory Outcomes and High-Frequency Adverse Respiratory Events

1. Basic Features

Adverse respiratory events constitute the single largest source of injury in the Closed Claims Project (Table 55-1). A detailed analysis of these events was initiated when the database reached a total of 1541 claims.[14] The contrast between adverse respiratory events and other claims was particularly unfavorable. Respiratory event–related claims were (and still are) characterized by a high frequency of devastating outcomes and costly payments (Table 55-2).

Just three mechanisms of injury accounted for almost two thirds of all claims for adverse respiratory events (Table 55-3). These mechanisms were inadequate ventilation (24% of cases), esophageal intubation (12%), and difficult intubation (DI; 24%). In the 1990s, after the adoption of pulse oximetry and end-tidal CO_2 (Et_{CO_2}) as monitoring standards, DI (28%) and inadequate ventilation (18%) remained the most common adverse respiratory events, but esophageal intubation (5%) had decreased greatly compared with earlier decades (see Table 55-3). Evaluation of claims from the early 2000s suggests that this profile of adverse respiratory events is staying the same.

Aspiration was the third most common adverse respiratory event in the 1990s and 2000s. The remaining adverse respiratory events were produced by a variety of low-frequency mechanisms including airway obstruction, bronchospasm, premature and unintentional extubation, endobronchial intubation, inadequate inspired oxygen delivery, and equipment failure. Special features of low-frequency events are discussed later in this chapter.

TABLE 55-2
Comparison of Respiratory and Nonrespiratory Events*

*Total anesthesia claims = 8954. Claims for chronic pain management are excluded. Claims with unknown year of event are not shown.
†$P < 0.05$ for respiratory compared with nonrespiratory events in all time periods and overall (chi square for proportions and Kolmogorov-Smirnov test for payments).
Data from ASA Closed Claims Database, 2008.

A detailed display of outcome and payment data for the three most common types of adverse respiratory events since 1990 (inadequate ventilation, DI, and aspiration) is shown in Table 55-4. Death and permanent brain damage were more frequent in claims for respiratory events compared with nonrespiratory events ($P < 0.05$). Claims for inadequate ventilation exhibited the highest proportion of death and brain damage (89%, see Table 55-4). Overall, payment for respiratory-related claims ranged from $1260 to $11 million (in 2008$). Most claims (61%) resulted in payment. Claims for adverse respiratory events typically involved healthy adults undergoing nonemergency surgery with general anesthesia (GA) (Table 55-5).

The reviewers judged that better monitoring would have prevented the adverse outcome in 20% of the 867 claims for adverse respiratory events since 1990. In contrast, only 7% of nonrespiratory claims were judged preventable with better monitoring ($P < 0.01$). Half (54%) of all claims for inadequate ventilation were considered preventable with better monitoring, as opposed to 5% of claims for DI and only 1% of claims for aspiration.

For the claims considered preventable with better monitoring, the reviewers pointed to pulse oximetry, capnometry, or both in most cases. Data on the role of better monitoring in the prevention of adverse outcomes must be interpreted with particular care, because the reviewers were not asked to consider confounding factors such as equipment malfunction, diversion of attention, or the impact of false-positive and false-negative results. Therefore, the reviewers' judgments should be regarded as a near-maximum (and probably unattainable) estimate of the efficacy of better monitoring. It should also be noted that this analysis is based on claims for events that occurred after the adoption of pulse oximetry and Et_{CO_2} as ASA standards.

2. Inadequate Ventilation

The largest class of adverse respiratory events was inadequate ventilation. The distinguishing feature in this group of claims was the reviewer's inability to identify a specific mechanism of injury. In part, the inability to assign a mechanism of injury may reflect uncertainty on the part of the original health care providers. Because

TABLE 55-3
Most Common Adverse Respiratory Events as Proportion of All Respiratory Events in Decade*

Respiratory Event	Total (*n* = 1928)	1970s (*n* = 232)	1980s (*n* = 811)	1990s (*n* = 597)	2000s (*n* = 267)
Inadequate ventilation and/or oxygenation	24%	37%	24%	18%	25%
Difficult intubation	24%	15%	24%	28%	22%

Payment frequency	63%	64%	55%	61%	45%

*Total anesthesia claims = 8954. Claims for chronic pain management and all claims for events prior to 1990 are excluded.
†$P < 0.05$ compared with nonrespiratory events in all outcome and payment categories.
Data from ASA Closed Claims Database, 2008.

most adverse events occurred before the widespread use of pulse oximetry and capnometry, the uncertainty may be due to the limitations of traditional clinical signs, such as chest excursion, reservoir bag motion, and breath sounds. With increasing use of quantitative measures of ventilation, fewer cases have been assigned to the category of inadequate ventilation. These events have declined in occurrence from 37% of all respiratory events in the 1970s to 25% in the 2000s (see Table 55-3). It is also possible that a delayed rather than contemporaneous approach to the investigation of adverse outcomes is not powerful enough to provide an understanding of many events.

3. Esophageal Intubation

Prompt detection of esophageal intubation is a key concern in anesthesia practice. At present, anesthesiologists rely primarily on capnometry to confirm endotracheal intubation. The ASA Closed Claims Project database provides an important lesson about the pitfalls of less quantitative methods.

In 1990, we performed an in-depth analysis of 94 closed claims for esophageal intubation.[14] Almost all (92%) of these claims occurred during the period 1975–1985, before routine use of intraoperative capnometry. The single most striking finding was that detection of esophageal intubation required at least 5 minutes in most cases (97%). Our immediate reaction was simply, "What took so long?" We wondered whether such delays in detection were caused by incompetence or negligence (e.g., intubation performed by a legally blind physician, minimal attention to the patient during the procedure), but we found only eight claims (9%) that could be explained in such a way.

A closer look at the esophageal intubation claims suggested that reliance on indirect tests of ventilation may have been an important factor contributing to delay. For example, auscultation is a test that is traditionally used during the first few minutes after intubation. In our set of claims, auscultation of breath sounds was documented in 62 of the 94 claims for esophageal intubation (63%). In 3 (5%) of these cases, breath sound auscultation led to a correct diagnosis of esophageal intubation. In 30 cases (48%), auscultation led to the erroneous conclusion that the endotracheal tube (ETT) was located in the trachea when it was actually in the esophagus. This result was termed a misdiagnosis of endotracheal intubation.

The diagnostic error in such cases was recognized in a variety of ways, including later reexamination with direct laryngoscopy, absence of any object in the trachea at the time of an emergency tracheostomy (despite ongoing "ventilation" through an ETT), resolution of cyanosis after reintubation (often by a second participant), and discovery of esophageal intubation at autopsy. In 29 (47%) of the 62 claims in which auscultation was documented, the records did not contain sufficient information to determine how the auscultatory findings were interpreted. In another 32 cases (34%), there was no information about the use of auscultation.

Using this information, we constructed a best-case scenario by assuming that auscultation led to a correct diagnosis in the 3 cases in which it actually did so, as well as in the 61 cases in which there was no information

TABLE 55-5

Basic Clinical Features of Cases Involving Adverse Respiratory Events Occurring in 1990 or Later*

Feature	Respiratory Events (*n* = 867)	All Others (*n* = 3681)
Age in years (mean ± SD)	47.2 ± 19.8	45.5 ± 18.7

Data from ASA Closed Claims Database, 2008.

about its role or the information was unclear. Using this approach of constructing a hypothetical situation to demonstrate the greatest possible benefit, auscultation is still associated with a misdiagnosis rate of 32% (30 of 94 cases). Although the limitations of auscultation are well known,[15] we think these claims emphasize the importance of confirming intubation with the quantitative and ongoing information provided by capnometry.

Another indirect test of ventilation is cyanosis. Almost all of the esophageal intubation claims that we studied took place before pulse oximetry became part of the ASA Standards for Basic Anesthetic Monitoring. The human eye is relatively insensitive to the changes in skin color that occur during arterial desaturation,[16,17] so it is not surprising that cyanosis preceded the recognition of esophageal intubation in only 34% of cases. One might also expect cardiovascular clues to accompany hypoxemia or hypercarbia and that these clues might alert the anesthesiologist to the possibility of esophageal intubation. Indeed, at least one major hemodynamic derangement was recorded in 79 (84%) of the 94 claims for esophageal intubation, and this knowledge preceded the recognition of esophageal intubation in 60 claims (65%). In order of frequency, the abnormalities included bradycardia, asystole, hypotension, unspecified dysrhythmia, tachycardia, and ventricular fibrillation (Table 55-6). Such changes certainly have the potential to serve as cues, but when they are extremely severe (e.g., ventricular fibrillation, asystole) they draw attention away from the underlying problem and leave very little time for effective remedies. These features point to the importance of confirmatory tests that provide early, direct, and ongoing confirmation of ventilation through the ETT.

Is injury from undetected esophageal intubation no longer a concern? As shown in Table 55-3, claims for esophageal intubation decreased considerably in the 1990s and later compared with the prior two decades. A few claims for esophageal intubation still enter the database, but they usually involve cases in which capnometry was unavailable or not used or the procedure took place in a remote location.[18]

4. Difficult Intubation

Claims for DI in the ASA Closed Claims Project were distinguished by a relatively small percentage of cases in which care was considered less than appropriate (46%, compared with more than 80% for inadequate ventilation and esophageal intubation) and by a similarly small percentage of cases in which better monitoring would have prevented the complication (19%, again compared with more than 80% for inadequate ventilation and esophageal intubation). Although these findings seem outwardly favorable, the comparisons are not so attractive from the perspective of risk reduction. If most cases of DI cannot be linked to obvious inadequacies in care or deficiencies in monitoring, it is unlikely that claims analysis alone can point to effective or broad-based remedies. Simulators, algorithms, and drill routines have generated considerable interest in recent years. These newer educational tools and management strategies may provide an important opportunity for clinicians to gain concentrated exposure to relatively infrequent events.

An evidence-based guideline for management of the difficult airway (DA) has been developed by the ASA.[19] Key features of this guideline are discussed in Chapter 10. The impact of this set of guidelines on claims involving DA management was studied in the ASA Closed Claims Project.[20] DA problems were encountered during all phases of anesthesia management, including preinduction, induction, maintenance, emergence, postanesthesia care unit (PACU) care, and intensive care unit settings. Death and brain damage were more common in DA claims arising from procedures performed outside the operating room (OR) or the PACU and in the settings of difficult mask ventilation (DMV); "cannot intubate, cannot ventilate" (CICV) emergencies; or persistent intubation attempts.[20]

TABLE 55-6

Major Hemodynamic Derangements Accompanying Esophageal Intubation Claims*

Hemodynamic Derangement	Percent of Claims (n = 94)
Bradycardia	57
Asystole	55
Hypotension	49
Unspecified dysrhythmia	10
Tachycardia	5
Ventricular fibrillation	1

*Percentages sum to more than 100 because of multiple derangements. Total anesthesia claims = 1541.
Data from ASA Closed Claims Database, 1990. Table adapted from Caplan RA, Posner KL, Cheney FW, et al: Adverse respiratory events in anesthesia: A closed claims analysis. *Anesthesiology* 72:828, 1990.

5. Aspiration

An in-depth analysis of claims for pulmonary aspiration was conducted in 1991, when such claims accounted for 3% of the database (56 cases).[21] Almost all cases (95%) occurred in patients who received GA. The aspirated material was gastric contents in 88% of these cases; other cases involved aspiration of blood, pus, or teeth. Approximately one third (34%) of aspirations took place during anesthetic induction just before endotracheal intubation. In 6 of these cases, aspiration occurred during a rapid-sequence induction; in another 6, the aspiration occurred under circumstances in which the reviewer believed that rapid-sequence induction was indicated but in which it was not used. Another one third of aspiration cases (36%) took place during the maintenance phase of mask GA. Only 2 cases (4%) occurred during the maintenance phase of endotracheal GA. Aspiration occurred in one of these cases when the ETT was removed to facilitate the passage of a nasogastric tube. In the other instance, aspiration occurred while an ETT with a leaking cuff was being replaced with a new tube. The remaining cases (18%) took place during emergence from anesthesia.

Two clinical factors—pregnancy and emergency surgical status—were particularly prevalent in claims for aspiration. Obstetric patients accounted for 12% of the overall database but represented 29% of all aspiration claims ($P < 0.05$) in the 1991 study.[21] This trend changed dramatically in subsequent years, with aspiration occurring in fewer than 1% of obstetric claims from 1990 or

TABLE 55-7
Low-Frequency Adverse Respiratory Events

	n (% of Total)	Death (%)	Brain Damage (%)	Payment Frequency (%)	Payment Median ($)
Type of Claim					
Airway trauma	97 (4.7)	12	0	60	22,000

Other respiratory events	462 (22.6)	70	23	75	233,000
All nonrespiratory events	1284 (63.7)	22	9	59	40,000

*Because >1 adverse respiratory event occurred in 16 claims, the total number of claims for 316 events is 300. Total no. of claims = 2046.
†$P < 0.01$ compared with other respiratory claims.
‡$P < 0.01$ compared with nonrespiratory claims.
Data from ASA Closed Claims Database, 1991. Table adapted from Cheney FW, Posner KL, Caplan RA, et al: Adverse respiratory events infrequently leading to malpractice suits: A closed claims analysis. *Anesthesiology* 75:932, 1991.

later.[22] Emergency surgery patients accounted for 19% of the database in 1991 but represented 45% of all aspiration claims ($P < 0.01$). It is also noteworthy that 23% of aspiration claims involved a problem with airway management, such as DI (9 cases) or esophageal intubation (4 cases). This relationship was previously reported by Olsson and colleagues.[23]

Overall, aspiration accounted for only 3% of claims in the database. This is consistent with the observation by Warner and colleagues that the incidence of aspiration in more than 200,000 patients who underwent elective or emergency surgery during 1985–1991 was very low (1 in 3216).[24] These observations suggest that current strategies used to prevent aspiration in the United States are generally successful, particularly in obstetric patients.

B. Low-Frequency Adverse Respiratory Events

1. Basic Features

The foregoing discussion focused on the most common mechanisms of respiratory injury in the closed claims database. A formal study of low-frequency adverse respiratory events was conducted in 1991, when the ASA Closed Claims Project database had reached 2046 cases.[21] Although these events were much less common (each category representing no more than 5% of the overall database), sufficient claims were collected to permit the identification of recurrent themes that might contribute to liability. Five categories of events have been studied in depth, each category containing at least 40 claims and together encompassing 300 claims, or about 15% of the overall database. These categories are airway trauma, pneumothorax, airway obstruction, aspiration, and bronchospasm. Death or brain damage occurred in almost half (47%) of these cases, and the median payment was $60,000 (Table 55-7). Airway trauma was reanalyzed in detail in 1999.[25] Aspiration now represents one of the most common adverse respiratory events.

2. Airway Trauma

Airway trauma was the most common type of low-frequency airway event, accounting for 266 of 4460 claims, or 6% of the overall database, in the 1999 study.[25] DI was associated with 103 (39%) of these claims. The most frequent sites of injury were the larynx, pharynx, and esophagus (Table 55-8), which together accounted for 70% of injuries associated with airway trauma claims. Esophageal and tracheal injuries were more likely than other airway trauma claims to be associated with DI. In contrast, laryngeal and temporomandibular joint (TMJ) injuries were rarely associated with DI. Pharyngeal and

*$P < 0.05$ compared with other sites combined. Total anesthesia claims = 4460.
Data from ASA Closed Claims Database, 1999. Table adapted from Domino KB, Posner KL, Caplan RA, et al: Airway injury during anesthesia: A closed claims analysis. *Anesthesiology* 91:1703, 1999.

esophageal injuries most commonly consisted of lacerations or perforations leading to mediastinitis or mediastinal abscess. The most common laryngeal injuries were vocal cord paralysis (30 cases), granuloma (15 cases), and arytenoid dislocation (7 cases). None of the 27 TMJ injuries was associated with DI.

These claims provide several useful insights. Circumstances surrounding DI clearly put the tissues of the pharynx and esophagus at risk. The clinical implication is that patients in whom endotracheal intubation has been difficult should be observed for, or told to watch for, the development of signs and symptoms of pharyngeal abscess or mediastinitis. Because soft tissue infections may develop slowly over a period of days, an apparent lack of complications in the first few hours after surgery should not be regarded as a definitive outcome in patients who have experienced DI. This is especially important to remember in the ambulatory surgery setting.

Although it is easy to understand how DI may lead to trauma of the larynx, it is less apparent why laryngeal injuries appeared to be so infrequently associated with DI. The reasons for vocal cord paralysis, granuloma, and arytenoid dislocation with routine intubation were not apparent from the data available in the claim file. Similarly, it is curious that TMJ injury was present only with routine intubation. One might expect that TMJ injury would be more commonly associated with DI, in which forces applied to the jaw during airway manipulation and laryngoscopy might be more intense or prolonged than those encountered during routine intubation. These observations suggest that many injuries to the larynx and TMJ may be related to predisposing factors or underlying characteristics of patients that we do not yet understand. A similar phenomenon was observed in the review of closed claims for peripheral nerve injuries.[26,27]

3. Pneumothorax

Pneumothorax was the second most common type of low-frequency airway event.[21] Clinical activities that were not directly or clearly related to airway management were associated with 43 (64%) of the 67 claims for pneumothorax (Table 55-9). In particular, five types of nerve blocks (supraclavicular, intercostal, stellate ganglion, interscalene, and suprascapular) were responsible for 40% of pneumothorax claims. Airway instrumentation was associated with pneumothorax in 19% of cases. The actual mechanism of pneumothorax was not anatomically proved in most cases but was usually attributed to laryngoscopy, ETT placement, or bronchoscopy on the basis of clinical events and reviewer judgments. Barotrauma was the cause of pneumothorax in 11 claims (16%), mostly arising from obstruction of the expiratory limb of a mechanical ventilator or the use of excessive tidal volumes (7 cases).

TABLE 55-9

Clinical Factors Associated with Pneumothorax Claims*

Clinical Factor	Claims	Total (%)
Airway Related		
Airway instrumentation	13	19
Barotrauma	11	16
Non-airway Related		
Regional block	27	40
Central line	5	7
Spontaneous or unknown	5	7
Other	6	9
Total	67	100

*Total anesthesia claims = 2046.
Data from ASA Closed Claims Database, 1991. Table adapted from Cheney FW, Posner KL, Caplan RA, et al: Adverse respiratory events infrequently leading to malpractice suit: A closed claims analysis. *Anesthesiology* 75:932, 1991.

A notable feature of pneumothorax claims was the marked disparity in outcome between events associated with airway instrumentation and events arising from nerve blocks or central-line placement. In the subset of 24 claims involving airway instrumentation, the outcome in 16 cases (67%) was death or permanent brain damage. In contrast, there were no instances of death or brain damage in the 16 cases of pneumothorax that arose after nerve blocks or central-line placement. We speculate that this difference may be due at least in part to the more rapid compromise of respiratory and circulatory function that occurs under conditions of mechanical ventilation and positive-pressure gas delivery. Not surprisingly, the median payment for pneumothorax associated with nerve block or central-line placement was only $6000, whereas that for cases associated with airway instrumentation was $75,000.

4. Airway Obstruction

Airway obstruction accounted for 56 claims, or approximately 3% of the database.[21] Most cases (89%) occurred during GA. Obstruction was attributed to an upper airway site in 39 claims (70%), although an exact cause or site was identifiable in only half of these claims. Laryngospasm was the most common cause of upper airway obstruction, accounting for 11 (28%) of 39 cases. Other causes of upper airway obstruction included foreign body (4 cases), laryngeal polyps (2 cases), laryngeal edema (1 case), and pharyngeal hematoma (1 case). In 10 cases of upper airway obstruction, emergency tracheostomy was performed.

Causes of lower airway obstruction (21% of claims) included blood clots or mucus plugs in the tracheal lumen and external compression related to mediastinal tumor masses or blood. ETT obstruction accounted for 9% of cases and was attributed to blood clots in the lumen of the ETT or to kinking of the tube itself. Other factors associated with claims for airway obstruction included concurrent DI (17 cases, 30%), operation on the airway (13 cases, 23%), and pediatric age group (10 cases, 18%). The outcome in almost all claims for airway obstruction (87%) was death or brain damage.

5. Bronchospasm

Adverse outcomes arising from bronchospasm accounted for 40 claims, or almost 2% of the database.[21] Most of these claims (80%) occurred during the administration of GA as the primary anesthetic technique. Almost half (48%) of the patients had a medical history that included asthma, chronic obstructive pulmonary disease, smoking, or some combination of these. In cases involving the

administration of GA, the first occurrence of bronchospasm was more often at the time of intubation (69%) than during maintenance (25%) or emergence (6%).

Twenty percent of claims for bronchospasm were associated with the conduct of regional anesthesia. In most of these cases, bronchospasm occurred during cesarean section when endotracheal intubation was required for management of a failed block or a high block in a patient with a history of asthma. These cases illustrate the concept that regional anesthesia does not, in itself, obviate the risk associated with intraoperative management of reactive airway disease. In particular, the risk of bronchospasm may be especially pronounced in this setting, because relatively modest doses of intravenous agents are often used in an effort to minimize anesthetic effects on the fetus.

Bronchospasm claims were also notable in cases that involved a difficult differential diagnosis. The claims files in the 1991 study indicated that clinicians had difficulty distinguishing between bronchospasm and the presence of esophageal intubation (6 cases) or pneumothorax (4 cases). Et_{CO_2} monitoring was not used in any of the 6 cases in which the failure to make a correct and timely differential diagnosis between esophageal intubation and bronchospasm led to an adverse outcome. Et_{CO_2} is now an ASA standard for verification and monitoring of ETT placement, and bronchospasm appears to be on a steadily declining trend (see Table 55-3). However, it is important to recognize that failure to differentiate between bronchospasm and esophageal intubation may still occur in cases in which bronchospasm is so severe that ventilation is impossible and CO_2 cannot reach the detector in clinically useful amounts. In this circumstance, fiberoptic bronchoscopy can be helpful.

C. Emerging Trends from the ASA Closed Claims Project

The database of the Closed Claims Project is now sufficiently large that it can be studied for evidence of changing trends in the overall distribution of adverse events and outcomes. In doing so, two key limitations must be emphasized. First, these data cannot be used to generate any general estimates of risk. This limitation arises from a lack of denominator data, a probable bias toward severe outcomes, and partial reliance on the observations of direct participants. Second, the resolution of a claim is a lengthy process. Typically, this leads to a delay of approximately 5 years between the occurrence of a claim and its entry into the database. Therefore, the most recent trends (which are usually of greatest interest) must be viewed as especially tentative because they may change considerably as additional claims are resolved and processed.

In 1999, an examination of trends was conducted.[11] At that point, the database consisted of more than 4000 claims drawn from 35 U.S. insurance organizations. Two major trends were evident. First, there was a general decrease in the severity of injury that was specifically characterized by a declining incidence of claims for death and brain damage. For example, 56% of claims between 1970 and 1979 involved death or brain damage, compared with only 31% of those between 1990 and 1994. Second, the contribution of adverse respiratory events to death and brain damage declined. During the earliest interval, 1970–1979, 56% of claims for death and brain damage arose from respiratory system events. This percentage decreased to 49% in 1980–1989 and to 38% from 1990 onward.

Some tentative associations can be postulated. In the 1990s, there were several changes in monitoring and clinical practice that may have had an impact on adverse respiratory events. Pulse oximetry and end-tidal capnometry have been widely available since the mid-1980s. Moreover, the ASA Standards for Basic Intraoperative Monitoring specified the use of pulse oximetry for basic intraoperative monitoring beginning in 1990 and Et_{CO_2} for verification of endotracheal intubation beginning in 1991.

Is the presence of these monitors reflected in the pattern of liability for closed claims? This question was explored in 2006, when the overall database contained 6894 cases.[28] Claims for death and brain damage between 1975 and 2000 were analyzed. Respiratory events declined from approximately 50% of death and brain damage claims before 1986 to 28% by 1992. A downward trend in claims for death and brain damage and a similar downward trend in the proportion of respiratory events leading to these claims preceded the introduction of pulse oximetry and Et_{CO_2} monitoring into anesthetic practice. These decreases seemed to be unrelated to the increase in the proportion of claims in which these monitors were used.[28]

New trends in adverse respiratory events are now emerging outside the traditional arena of GA in the OR. An analysis of closed claims from 1990 or later that were associated with monitored anesthesia care (MAC) revealed that respiratory depression after an absolute or relative overdose of sedative or opioid drugs was the most common specific mechanism leading to claims (21%).[29] Most of these claims involved death or brain damage. Improved respiratory monitoring (capnography, improved vigilance, audible alarms) might have prevented almost half of these claims. One quarter of these claims arose from procedures performed in the endoscopy suite.

Analysis of claims from 1990 or later associated with procedures outside the OR found that adverse respiratory events were more common in remote locations and were often judged as preventable by better respiratory monitoring.[18] A 2009 ASA Statement on Respiratory Monitoring During Endoscopic Procedures provided guidance on CO_2 monitoring and airway management during endoscopic procedures.[30] Since July 2011, the ASA Standards for Basic Anesthetic Monitoring have provided additional specificity about the use of CO_2 monitoring: "During moderate or deep sedation the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled CO_2 unless precluded or invalidated by the nature of the patient, procedure, or equipment.[31]

As mentioned previously, evidence-based guidelines for management of the DA have been developed by the ASA.[19] Clinicians often worry that the proliferation of practice guidelines will lead to a general increase in

liability. It is important to remember that modern, evidence-based guidelines have a relatively flexible place in medical practice that differs from that of standards. Standards are typically used for straightforward aspects of care that command high levels of agreement and acceptance. Noncompliance implies an action that is outside a clearly recognized norm; in some instances, such actions may be accompanied by sanctions. Guidelines are employed for more complex aspects of care that cannot be precisely codified and accepted in a near-uniform fashion. Guidelines are intended as recommendations that can assist the anesthesiologist and the patient in making decisions about health care. Guidelines may be accepted, modified, or even rejected according to specific clinical needs and constraints. This means that not following a guideline, under some clinical conditions, can still be a decision that is consistent with reasonable and prudent practice. In DA malpractice claims, the ASA guideline for management of the DA has rarely been an issue in litigation. In the few claims in which the guideline was a factor, it was used for the defense more often than for the plaintiff.[20]

III. CONCLUSIONS

The database of the ASA Closed Claims Project indicates that adverse events involving the respiratory system continue to constitute an important source of liability in anesthetic practice. These events represent a particularly urgent target for research and preventive strategies because they are characterized by a high frequency of severe outcomes and costly payments.

Inadequate ventilation and DI account for almost one half of all adverse respiratory events. The occurrence of injuries related to inadequate ventilation has been decreasing, but DI remains a recurring problem. The use of capnography to confirm ETT placement seems to have reduced the severity of outcomes associated with delayed recognition of esophageal intubation. Aspiration is emerging as the third most common adverse respiratory event leading to malpractice claims.

The in-depth analysis of low-frequency respiratory events also provides valuable lessons. Complications associated with airway trauma may not manifest in the immediate postoperative period. This suggests that explicit follow-up plans and communication are particularly important for outpatients who have experienced airway management difficulties.

Overall, reviewers have found that a large proportion of claims involving adverse respiratory events might have been prevented by the use of pulse oximetry and capnography (either alone or in combination). Even after the widespread adoption of these two modalities, however, 19% to 24% of adverse respiratory events were considered preventable by better monitoring. It is difficult to know whether this perception is accurate in its own right or whether it reflects wishful hindsight and unrealistic expectations. However, recent studies of claims arising during MAC and in locations outside of the OR underscore the preventive potential of respiratory system monitoring.

IV. CLINICAL PEARLS

- Anesthesiologists have a long-standing appreciation for risks associated with airway management.
- Adverse respiratory events constitute the single largest source of injury in the ASA Closed Claims Project database.
- Claims for adverse respiratory events are characterized by devastating patient injuries and high liability payments.
- The most common adverse respiratory events in claims since 1990 are difficult intubation (DI), inadequate ventilation, and aspiration
- The occurrence of injuries related to inadequate ventilation has been decreasing, but DI remains a recurring problem.
- Adverse respiratory events are emerging as a source of patient injury during monitored anesthesia care (MAC), especially in remote locations outside the operating room (OR).

Acknowledgments

The ASA Closed Claims Project is supported by funds from the American Society of Anesthesiologists. The Project committee gratefully acknowledges the contributions of insurance companies who have granted access to closed claims files and of those members of the American Society of Anesthesiologists who have served as reviewers of closed claims and as participants in studies of peer review.
