Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Foreword

The development of airway management as a subspecialty was spurred by the findings from the American Society of Anesthesiologists (ASA) closed claims project in the early 1980s that adverse outcomes resulting from airway management were the single largest cause of malpractice lawsuits against anesthesiologists. When the first edition of *Airway Management* appeared in 1996, airway management was beginning to become a recognizable subspecialty, and the book gave the new subspecialty an intellectual spine. At the same time, the Society for Airway Management had just come into being and gave the subspecialty an administrative and educational spine. Also, the second iteration of the ASA Difficult Airway algorithm became known throughout the world at about this time, and was either practiced as published or in a slightly modified version. Research in airway management has since accelerated tremendously. Today, the large majority of training centers in the United States have a formalized teaching program (required resident rotation) in airway management. In addition, today, one just needs to walk up and down the aisles of the exhibit hall at any annual ASA meeting to find that airway management is an extremely robust and growing subspecialty, in all dimensions, throughout the world.

However, the bedrock of safe airway management, in my opinion, has not changed over the past 20 years. Safe airway management consists of the following: proper preairway management evaluation; securing the airway with the patient awake and spontaneously ventilating when difficulty with the airway is recognized (awake intubation); having plan B (and C, etc.) immediately available in case plan A does not work; allowing the patient to awaken and resume spontaneous ventilation in a timely fashion when various airway management plans are not successful; insisting on unequivocal confirmation of tracheal intubation; and finally, in this day and age of increasing incidence of morbid obesity and obstructive sleep apnea, placing the patient in the proper monitoring environment postextubation.

On top of this bedrock of safe airway management practice, new management techniques and insights make the successful application of the bedrock ever easier to apply to ever more challenging cases. The purpose and rationale of continuing a book like *Airway Management* are to keep pace with these new developments and bring the airway management community as close as possible to the advancing frontier.

The editor of the third edition of *Airway Management*, Dr. Carin Hagberg, is perfectly positioned to lead the anesthesia community as close as is realistically possible to the frontier of airway management. She is an experienced and mature practitioner of airway management and knows the bedrock. She has been a very significant person in the development of the Society of Airway Management, having held virtually every important position in the organization, and as such has great perspective on the educational and administrative needs of the airway community. She has performed research and knows what the questions are. In short, a "triple threat" leads the charge. Given the history of this subspecialty, this book, and the editor, if you want to be good at airway management today, then read and consult this book.

Jonathan L. Benumof, MD

Preface

There have been many advances in airway management over the past two decades and since the publication of the second edition of *Airway Management*. It is essential that clinicians become familiar with the most recent developments in equipment and scientific knowledge to allow the safe practice of airway management. In the third edition of this book, three new chapters (Ultrasonography of the Airway; Video Laryngoscopes; and Disaster Preparedness, Cardiopulmonary Resuscitation, and Airway Management) have been added. The remaining chapters have been substantially updated to address current thinking and practice, and the book is in full color for the first time. Also, at the end of each chapter, there are a summary, up to a dozen bulleted, concise Clinical Pearls, and selected references.

The basic structure and philosophy of the book have not changed. It is divided into seven parts. Part 1 provides basic clinical science considerations of airway management. Part 2 presents difficult airway terminology and recognition, as well as a thorough analysis of the American Society of Anesthesiologists Difficult Airway Algorithm. Part 3 emphasizes patient preparation and preintubation ventilation procedures. Part 4 covers specific methods and problems in securing an airway. Many new airway devices and techniques are reviewed, and the indications for and confirmation of tracheal intubation are provided. Part 5 covers management of difficult airway situations, such as in pediatric patients and the intensive care unit. Part 6 emphasizes postintubation procedures and discusses such issues as monitoring the airway and extubation. Part 7 presents societal considerations of airway management, including instruction and learning of airway management skills both in and out of the operating room, as well as effective dissemination of critical airway information and medical-legal considerations.

Competent and safe airway management is an essential component of anesthetic practice worldwide. The consequences of failure to adequately oxygenate and ventilate a patient's lungs can be catastrophic to both the patient and the practitioner. It is generally known that management improvements have led to a documented decline in the incidence of airway-related perioperative morbidity. Both the dissemination of information and the development of new techniques and devices have contributed to this. The modern-day anesthesia practitioner needs to learn not only the techniques of using a variety of airway devices, but also when use of each would be most appropriate in a given situation.

We are most fortunate to live in today's world of anesthesia practice. I look forward to future advances and what research will unfold in our specialty. This book will not provide competence in airway management but does offer a firm foundation upon which further training and education can be based. Effective airway management requires commitment to a process of ongoing learning, skill maintenance, and self-assessment that should last throughout the practitioner's professional career. This book should serve this commitment well.

Carin A. Hagberg, MD

Acknowledgments

The preparation of the third edition of *Airway Management* has required the help and cooperation of many. To each individual, I acknowledge my debt of gratitude. It has been both an honor and a privilege to have worked with all of the authors, including expert anesthesiologists, emergency room specialists, surgeons, radiologists, and basic scientists from across the world.

The staff at Elsevier has contributed in countless ways, with competence, patience, and hard work, particularly Julie Mirra and Sarah Wunderly, who kept me on task and played a vital role in the quality of the final written text. I would also like to thank Anne Starr for her fantastic organizational and secretarial assistance.

I especially wish to express my deep appreciation to Jon Benumof, MD, without whose mentorship I would not have become the editor of this book, and my heartfelt thanks to my family, especially my husband, Steven Roberts, without whose understanding, forbearance, and support this textbook would not have been possible.

Chapter 1

Functional Anatomy of the Airway

LEE COLEMAN | MARK ZAKOWSKI | JULIAN A. GOLD | SIVAM RAMANATHAN

I. Introduction

II. Upper Airway
- A. Nose
- B. Pharynx
  - 1. Defense Against Pathogens
  - 2. Upper Airway Obstruction
- C. Larynx
  - 1. Bones of the Larynx
  - 2. Cartilages of the Larynx
  - 3. Muscles, Innervation, and Blood Supply of the Larynx

III. Lower Airway
- A. Gross Structure of the Trachea and Bronchi
- B. Airway Epithelium and Airway Defense Mechanisms
- C. Blood Supply
- D. Function of the Lower Airway
  - 1. Forces Acting on the Airway
  - 2. Relationship Between Structure and Function

IV. Conclusions

V. Clinical Pearls

I. INTRODUCTION

The air passages starting from the nose and ending at the bronchioles are necessary for the delivery of respiratory gas to and from the alveoli. During clinical anesthesia, the anesthesiologist uses these air passages to deliver the anesthetic gases to the alveoli while, at the same time, maintaining vital respiratory gas transport. To accomplish proper airway management, anesthesiologists often gain access to the airways by means of an endotracheal tube (ETT) or other devices that are directly introduced into the patient's upper or lower air passages. In addition, anesthesiologists are called upon to establish access to the airways in certain dire emergencies. A general understanding of the airway structures is critical for establishing and maintaining the airway. For the purpose of description, the airway is divided into the *upper airway*, which extends from the nose to the glottis or thoracic inlet, and the *lower airway*, which includes the trachea, the bronchi, and the subdivisions of the bronchi. The airways also serve other important functions, such as olfaction, deglutition, and phonation. A detailed anatomic description of these structures is beyond the scope of this chapter. Structural details as they relate to function in health and disease and some important anesthetic implications are explained here. In addition, some advances in imaging techniques that give insight to functional anatomy are described.

II. UPPER AIRWAY

A. Nose

The airway functionally begins at the nares and the mouth, where air first enters the body. Phylogenetically, breathing was intended to occur through the nose. This arrangement not only enables the animal to smell danger but also permits uninterrupted conditioning of the inspired air while feeding. Resistance to airflow through the nasal passages is twice the resistance that occurs through the mouth. Therefore, during exercise or respiratory distress, mouth breathing occurs to facilitate a reduction in airway resistance and increased airflow.

The nose serves a number of functions: respiration, olfaction, humidification, filtration, and phonation. In the adult human, the two nasal fossae extend 10 to 14 cm from the nostrils to the nasopharynx. The two fossae are divided mainly by a midline quadrilateral cartilaginous septum together with the two extreme medial portions of the lateral cartilages. The nasal septum is composed mainly of the perpendicular plate of the ethmoid bone descending from the cribriform plate, the septal cartilage, and the vomer (Fig. 1-1). It is normally a midline structure but can be deviated to one side.[1] Disruption of the cribriform plate secondary to facial trauma or head injury may allow direct communication with the anterior cranial fossa. The use of positive-pressure mask ventilation in this scenario may lead to the entry of bacteria or foreign material, resulting in meningitis or sepsis. In addition, nasal airways, nasotracheal tubes, and nasogastric tubes may be inadvertently introduced into the subarachnoid space. The posterior portion of the septum is usually midline, but trauma-associated septal deviations and congenital choanal atresia can cause posterior obstruction (Fig. 1-2).

Each nasal fossa is convoluted and provides approximately 60 cm^2 surface area per side for warming and humidifying the inspired air.[2] The nose is also able to prewarm inspired air to a temperature of 32° C to 34° C, over a wide range of ambient temperatures from 8° C to

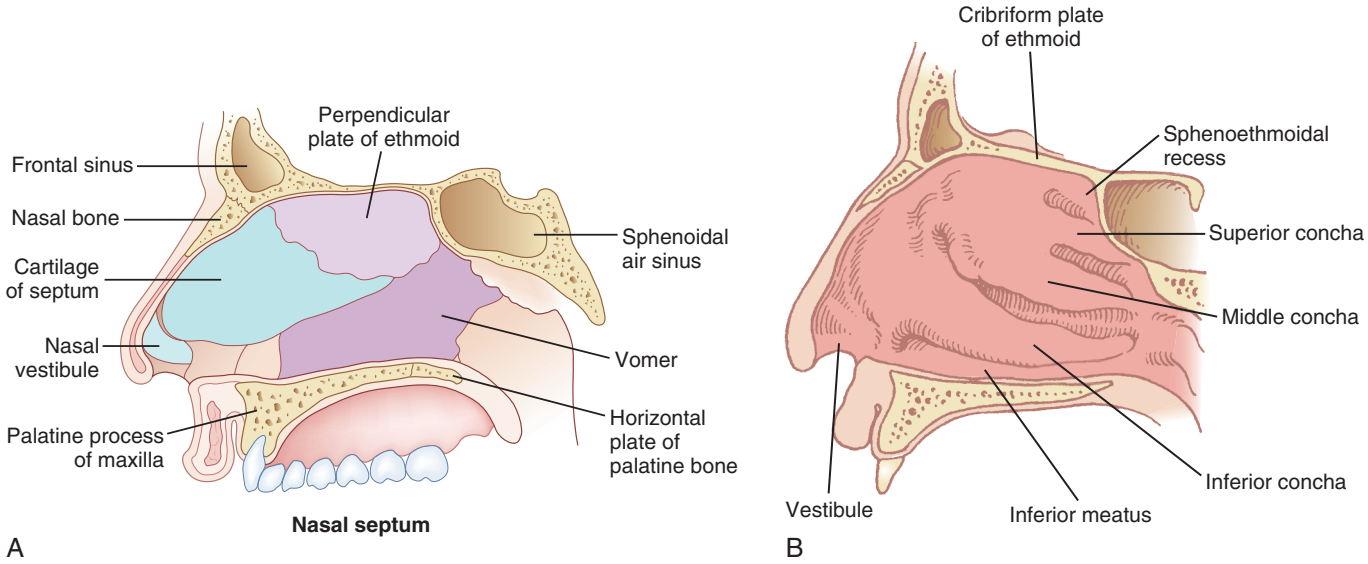

Figure 1-1 **A,** Medial wall (septum) of the nasal cavity. The sphenoid sinus opens into the sphenoethmoidal recess. The frontal, maxillary, and ethmoidal sinuses open into meatuses of the nose. Notice that the nasal septum contains cartilage in front and bone in the back. **B,** Lateral wall of the nasal cavity. Conchae are also known as turbinate bones. 40° C.[3] The nasal fossa is bounded laterally by inferior, middle, and superior turbinate bones (conchae),[4] which divide the fossa into scroll-like spaces called the inferior, middle, and superior meatuses (see Fig. 1-1).[2,5,6] The inferior turbinate usually limits the size of the nasotracheal tube that can be passed through the nose, and damage to the lateral wall may occur as a result of vigorous attempts during nasotracheal intubation. The arterial supply to the nasal cavity is mainly from the ethmoid branches of the ophthalmic artery, the sphenopalatine and greater palatine branches of the maxillary artery, and the superior labial and lateral nasal branches of the facial artery. Kiesselbach's plexus, where these vessels anastomose, is situated in Little's area on the anterior-inferior portion of the nasal septum. This is a common source of clinically significant epistaxis. The turbinates have a rich vascular supply that affords the nasal airway the ability to expand or contract according to the degree of vascular engorgement. The vascular mucous membrane overlying the turbinates can be damaged easily, leading to profuse hemorrhage. The paired paranasal sinuses—sphenoid, ethmoid, maxillary, and frontal—drain through apertures into the lateral wall of the nose. Prolonged nasotracheal intubation may lead to infection of the maxillary sinus due to obstruction of the ostia.[7]

The olfactory area is located in the upper third of the nasal fossa and consists of the middle and upper septum and the superior turbinate bone. The respiratory portion is located in the lower third of the nasal fossa.[6] The respiratory mucous membrane consists of ciliated columnar cells containing goblet cells and nonciliated columnar cells with microvilli and basal cells. The olfactory cells have specialized hairlike processes, called the olfactory hair, which are innervated by the olfactory nerve.[6]

The nonolfactory sensory nerve supply to the nasal mucosa is derived from the first two divisions of the

trigeminal nerve, the anterior ethmoidal and maxillary nerves. Airborne chemical irritants cause firing of the trigeminal nerves, which presumably are responsible for reflexes such as sneezing and apnea.[8] The afferent pathway for the sneezing reflex originates at the histamine-activated type C neurons of the trigeminal nerve, and the efferent pathway consists of several somatic motor nerves. The act of sneezing is associated with an increased intrathoracic air pressure of up to 100 mm Hg and may produce airflow up to 100 mph.[8]

The parasympathetic autonomic nerves reach the mucosa from the facial nerve after relay through the sphenopalatine ganglion, and sympathetic fibers are derived from the plexus surrounding the internal carotid artery through the vidian nerve.[9] Approximately 10,000 L of ambient air passes through the nasal airway per day, and 1 L of moisture is added to this air in the process.[10] The moisture is derived partly from transudation of fluid through the mucosal epithelium and partly from secretions produced by glands and goblet cells. These secretions have significant bactericidal properties. Foreign body invasion is further minimized by the stiff hairs (vibrissae), the ciliated epithelium, and the extensive lymphatic drainage of the area.

A series of complex autonomic reflexes controls the blood supply to the nasal mucosa and allows it to shrink and swell quickly. Reflex arcs also connect this area with other parts of the body. For example, the Kratschmer reflex leads to bronchiolar constriction on stimulation of the anterior nasal septum in animals. A demonstration of this reflex may be seen in the postoperative period as a patient becomes agitated when the nasal passage is packed.[9]

B. Pharynx

The pharynx, 12 to 15 cm long, extends from the base of the skull to the level of the cricoid cartilage anteriorly and the inferior border of the sixth cervical vertebra posteriorly.[11] It is widest at the level of the hyoid bone (5 cm) and narrowest at the level of the esophagus (1.5 cm), which is the most common site for obstruction after foreign body aspiration. It is further subdivided into the nasopharynx, oropharynx, and laryngopharynx. The nasopharynx, which primarily has a respiratory function, lies posterior to the termination of the turbinates and nasal septum and extends to the soft palate. The oropharynx has primarily a digestive function, starts below the soft palate, and extends to the superior edge of the epiglottis. The laryngopharynx (hypopharynx) lies between the fourth and sixth cervical vertebrae, starts at the superior border of the epiglottis, and extends to the inferior border of the cricoid cartilage, where it narrows and becomes continuous with the esophagus (Fig. 1-3). The eustachian tubes open into the lateral walls of the nasopharynx.

In the lateral walls of the oropharynx are situated the tonsillar pillars of the fauces. The anterior pillar contains the glossopharyngeus muscle, and the posterior pillar contains the palatoglossus muscle.[12] The wall of the pharynx consists of two layers of muscles, an external circular layer and an internal longitudinal layer. Each layer is composed of three paired muscles. The stylopharyngeus, salpingopharyngeus, and palatopharyngeus muscles form the internal layer. They elevate the pharynx and shorten the larynx during deglutition. The superior, middle, and inferior constrictors form the external layer; they advance the food in a coordinated fashion from the oropharynx into the esophagus.

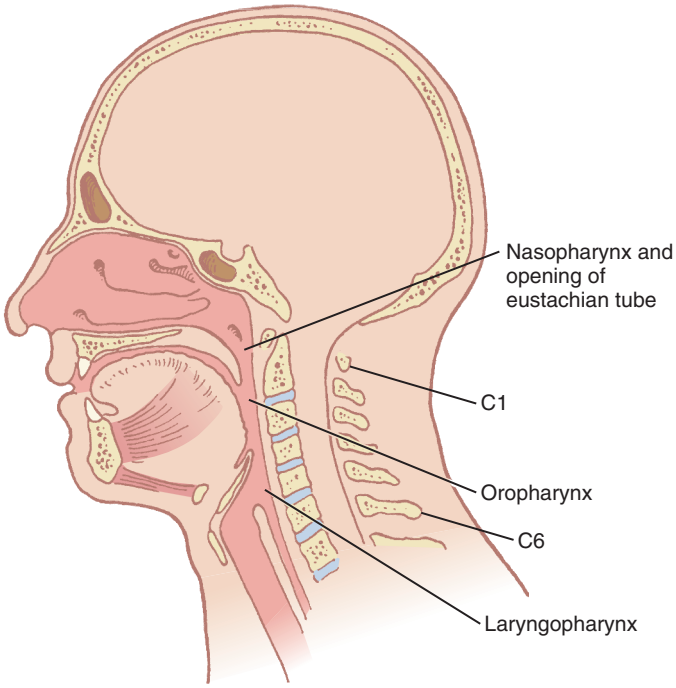

Figure 1-3 Diagrammatic representation of a sagittal section through head and neck to show divisions of the pharynx. Laryngopharynx is also known as the hypopharynx. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

The constrictors are innervated by filaments arising out of the pharyngeal plexus (formed by motor and sensory branches from the vagus, the glossopharyngeal, and the external branch of the superior laryngeal nerve). The inferior constrictor is additionally innervated by branches from the recurrent laryngeal and external laryngeal nerves. The internal layer is innervated by the glossopharyngeal nerve.

1. Defense Against Pathogens

Inhaled particles of size greater than 10 µm are removed by inertial impaction on the posterior nasopharynx. In addition, the inhaled airstream changes direction sharply (90 degrees) at the nasopharynx, resulting in some loss of momentum of the suspended particles. Being unable to remain suspended, the particles are trapped by the pharyngeal walls. The impacted particles are trapped by the circularly arrayed lymphoid tissue located at the entrance to the respiratory and alimentary tracts, known as the ring of Waldeyer (Fig. 1-4). The ring includes masses of lymphoid tissue or tonsils, including the two large palatine, lingual, eustachian tubal, and nasopharyngeal tonsils.

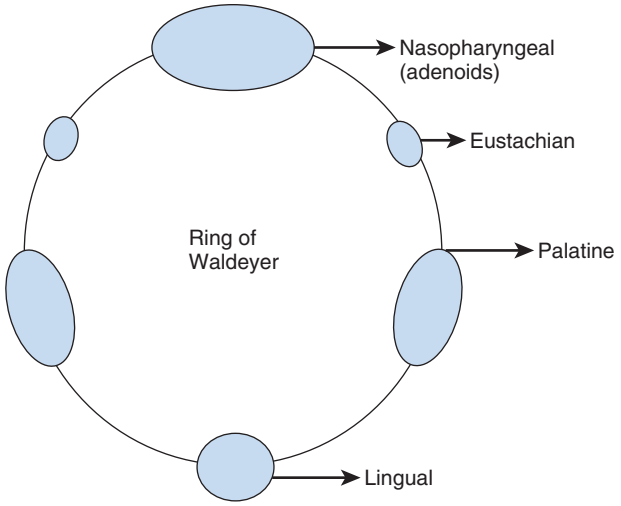

Figure 1-4 The ring of Waldeyer, a collection of lymphoid (tonsillar) tissue that guards against pathogen invasion. (Modified from Hodder Headline PLC, London.)

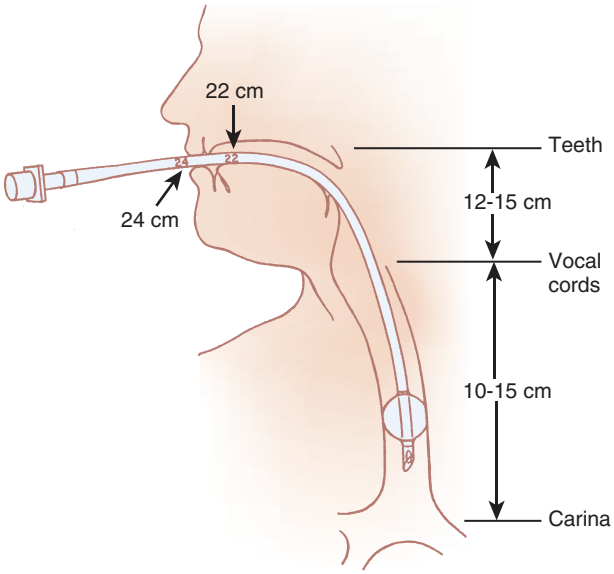

Figure 1-5 Important distances for proper endotracheal tube placement. (From Stone DJ, Bogdonoff DL: Airway considerations in the management of patients requiring long-term endotracheal intubation. *Anesth Analg* 74:276, 1992.)

The nasopharyngeal tonsils are also called adenoids.[13,14] These structures occasionally impede the passage of ETTs, especially if they are infected and enlarged. Specifically, enlarged adenoid tissue may impede passage of a nasotracheal tube or nasal airway or may simply obstruct the nasal airway passages. The lingual tonsils are located between the base of the tongue and the epiglottis. During routine anesthetic evaluation of the oropharynx, the lingual tonsils are typically not visible. Lingual tonsillar hypertrophy, which is usually asymptomatic, has been reported as a cause of unanticipated difficult intubation and fatal upper airway obstruction.[15] In addition, sepsis originating from one of the numerous lymphoid aggregates may lead to a retropharyngeal or peritonsillar abscess, which poses anesthetic challenges.[7]

Ciliary activity also works to clear trapped nonsoluble particles that are held in an outer mucus layer within the nares. This function is influenced by temperature, viscosity of the mucus, and the osmotic properties of the discharge. The ciliary movement can be negatively affected by many factors, such as viral infections or environmental agents, including air pollution and cigarette smoke. The loss of ciliary function leads to chronic and recurrent infections and can gradually severely injure the respiratory tract, leading to conditions such as chronic bronchitis, sinusitis, and otitis.[3]

2. Upper Airway Obstruction

a. SEDATION AND ANESTHESIA

The pharynx is the common pathway for food and the respiratory gases. Patency of the pharynx is vital to the patency of the airway and proper gas exchange in unintubated patients. Proper placement of an ETT requires an understanding of the distance relationships from the oropharynx to the vocal cords and carina. Complications such as a cuff leak at the level of the vocal cords and endobronchial intubation may thus be avoided (Fig. 1-5). Traditionally, it has been taught that upper airway obstruction in patients who are sedated or anesthetized (without an ETT), or who have altered levels of consciousness for other reasons, occurs as a result of the tongue's falling back onto the posterior pharyngeal wall. Specifically, it is thought that a reduction in genioglossus muscle activity leads to posterior displacement of the tongue with subsequent obstruction.[16] However, a number of publications offer a different explanation. The velopharyngeal segment of the upper airway adjacent to the soft palate has recently become the primary focus. This area is particularly prone to collapse and has been found to be the predominant flow-limiting site during sedation and anesthesia,[17] speech disorders, and obstructive sleep apnea (OSA) (Fig. 1-6).

Nandi and colleagues, using lateral radiographs in patients under general inhalational anesthesia, showed that obstructive changes in the airway occurred at the level of the soft palate and epiglottis.[18] Shorten and coworkers, using magnetic resonance imaging (MRI), found that patients receiving intravenous sedation for anxiolysis with midazolam had anterior-posterior dimensional changes in the upper airway also at the level of the soft palate and epiglottis while sparing the tongue (see Fig. 1-6).[19] In addition, Mathru and coauthors, using MRI to evaluate volunteers receiving propofol anesthesia, found that obstruction occurs at the level of the soft palate and not the tongue.[20] Therefore, it appears that the soft palate and epiglottis may play a more significant role than the tongue in pharyngeal upper airway obstruction.

b. OBSTRUCTIVE SLEEP APNEA

Reduction in the size of the pharynx is also a factor in the development of respiratory obstruction in patients with OSA.[21] This problem has been studied with the use of imaging techniques including computed tomography (CT) and MRI, nasopharyngoscopy, fluoroscopy, and

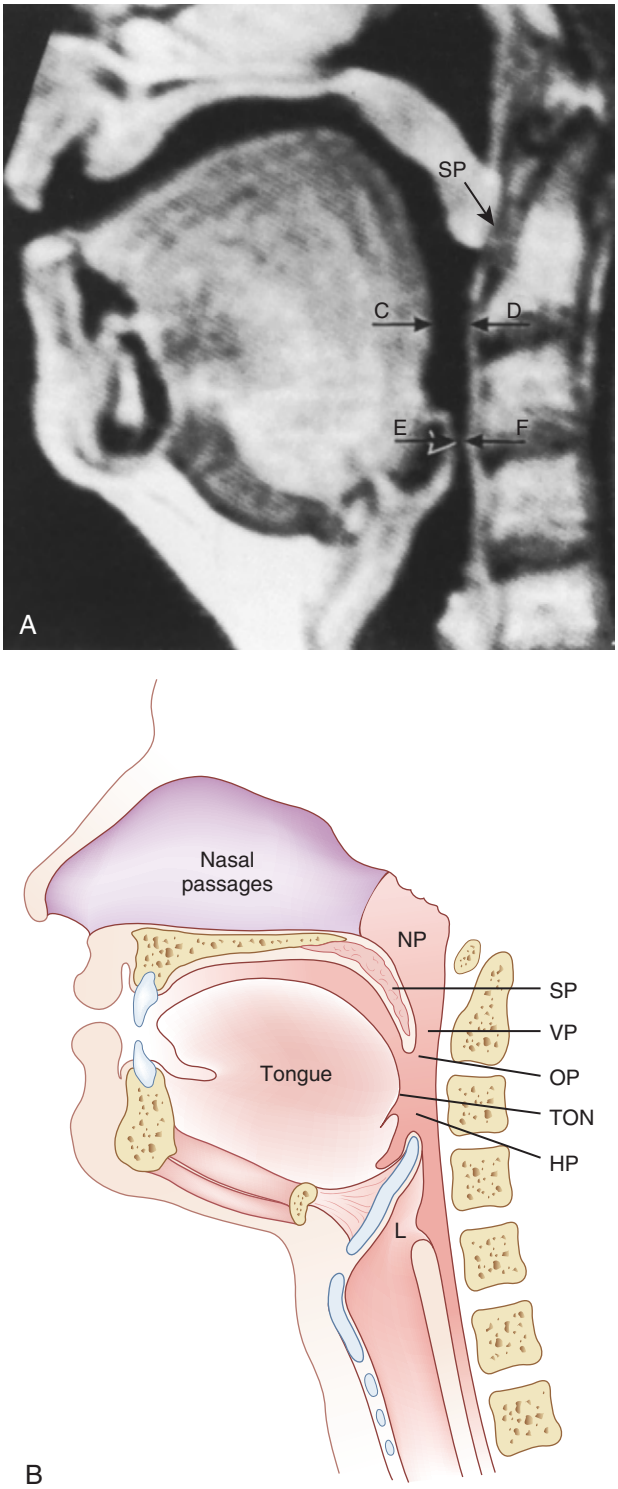

Figure 1-6 **A,** Medial sagittal view of upper airway showing site of airway obstruction in sedated patients. In the obstructed state, the soft palate is in contact with the posterior pharyngeal wall. CD, Minimum anteroposterior diameter at level of tongue; EF, minimum anteroposterior diameter at level of epiglottis. **B,** The velopharynx *(VP)* and its relation to the soft palate *(SP),* nasopharynx *(NP),* oropharynx *(OP),* tonsil *(TON),* hypopharynx *(HP),* and larynx *(L).* (From Shorten GD, Opie NJ, Graziotti P, et al: Assessment of upper airway anatomy in awake, sedated and anaesthetized patients using magnetic resonance imaging. *Anaesth Intensive Care* 22:165, 1994.)

acoustic reflection.[22] Structural changes that include tonsillar hypertrophy, retrognathia, and variations in craniofacial structures have been linked to sleep apnea risk, presumably by increasing upper airway collapsibility. CT and MRI studies in awake subjects have shown increased fatty tissue deposition and submucosal edema in the lateral walls of the pharynx, both of which can narrow the pharyngeal lumen and predispose to obstruction during sleep, when protective neuromuscular mechanisms wane.[23] Obesity, the major risk factor for OSA, has been shown to increase pharyngeal collapsibility through reductions in lung volumes, especially decreases in functional residual capacity (FRC), which are accentuated with the onset of sleep. This decrease in FRC may increase pharyngeal collapsibility through reductions in tracheal traction on the pharyngeal segment.[23,24] In awake male patients with OSA, CT has revealed a reduced airway caliber at all levels of the pharynx when compared with normal patients, with the narrowest portion posterior to the soft palate.[25]

The subatmospheric intra-airway pressure created by contraction of the diaphragm against the resistance of the nose can lead to a reduction in size of the pharyngeal airway. The collapsible segments of the pharynx are divided into three areas: retropalatal, retroglossal, and retroepiglottic. Patency depends on the contractile function of pharyngeal dilator muscles in these segments. The muscles involved are the tensor palatini, which retracts the soft palate away from the posterior pharyngeal wall; the genioglossus, which moves the tongue anteriorly; and the muscles that move the hyoid bone forward, including the geniohyoid, sternohyoid, and thyrohyoid muscles.[23,26] In patients with OSA, elevated genioglossal and tensor palatini muscle activity has been observed in the awake state. In contrast, normal subjects have lower activity in these muscles. Observations like these suggest that increased upper airway dilator muscle activity compensates for a more anatomically narrow upper airway in OSA. The reduction in upper airway muscle activity during sleep has been implicated in leading to increased likelihood of upper airway obstruction in patients with OSA compared with healthy subjects.[23,24] Studies also show that the configuration of the airway may differ in patients with OSA. Normally, the longer axis of the pharyngeal airway is transverse; however, in OSA patients the anterior-posterior axis is predominant. It is believed that this orientation is less efficient and may affect upper airway muscle function. Continuous positive airway pressure (CPAP) has been found to be effective in treating airway obstruction in these patients. The application of CPAP appears to increase the volume and cross-sectional area of the oropharynx, especially in the lateral axis.[27]

Clinical problems can arise from both the exaggeration and the depression of upper airway reflexes. A heightened reflex response can lead to laryngospasm and prolonged paroxysm of cough, whereas depressed reflexes can increase the risk of aspiration and compromised airway.[28]

The velopharynx, an area of the pharynx adjacent to the soft palate, is assuming increased importance in the understanding of OSA, speech disorders, and airway obstruction under anesthesia (see Fig. 1-6 B).[29] Fiberoptic

nasendoscopy and MRI are recommended for studying velopharyngeal dysfunction.[29-31] Six skeletal muscles—the tensor veli palatini, levator veli palatini, musculus uvulae, palatoglossus, palatopharyngeus, and superior constrictor—help form the so-called velopharyngeal sphincter. The proper function of the sphincter is vital to opening and closing of the nasal passages to airflow during deglutition and normal breathing.

C. Larynx

The larynx, which lies in the adult neck opposite the third through sixth cervical vertebrae,[12] is situated at the crossroads between the food and air passages (or conduits). It is made up of cartilages forming the skeletal framework, ligaments, membranes, and muscles. Its primary function is to serve as the "watchdog" of the respiratory tract, allowing passage only to air and preventing secretions, food, and foreign bodies from entering the trachea. In addition, it functions as the organ of phonation. The larynx may be located somewhat higher in females and children. Until puberty, no differences in laryngeal size exist between males and females. At puberty, the larynx develops more rapidly in males than in females, almost doubling in the anteroposterior diameter. The female larynx is smaller and more cephalad.[12] The measurements of the length, transverse diameter, and sagittal diameter of the adult larynx are 44, 36, and 43 mm, respectively, in the male and 41, 36, and 26 mm, respectively, in the female.[32] Most larynxes develop somewhat asymmetrically.[33] The inlet to the larynx is bounded anteriorly by the upper edge of the epiglottis, posteriorly by a fold of mucous membrane stretched between the two arytenoid cartilages, and laterally by the aryepiglottic folds.[9]

1. Bones of the Larynx

The hyoid bone (Fig. 1-7) suspends and anchors the larynx during respiratory and phonatory movement. It is U shaped, and its name is derived from the Greek word *hyoeides*, meaning shaped like the letter upsilon. It has a body, which is 2.5 cm wide by 1 cm thick, and greater and lesser horns (cornu). The hyoid does not articulate with any other bone. It is attached to the styloid processes of the temporal bones by the stylohyoid ligament and to the thyroid cartilage by the thyrohyoid membrane and muscle. Intrinsic tongue muscles originate on the hyoid, and the pharyngeal constrictors are also attached there.[4,12,34]

2. Cartilages of the Larynx

Nine cartilages provide the framework of the larynx (Fig. 1-8; see also Fig. 1-7). These are the unpaired thyroid, cricoid, and epiglottis and the paired arytenoids, corniculates, and cuneiforms. They are connected and supported by membranes, synovial joints, and ligaments. The ligaments, when covered by mucous membranes, are called folds. The thyroid, cricoid, and arytenoid cartilages consist of hyaline cartilage, whereas the other cartilages are elastic cartilage. Hyaline cartilage tends to ossify in the adult, and this occurs earlier in men than in women.[3]

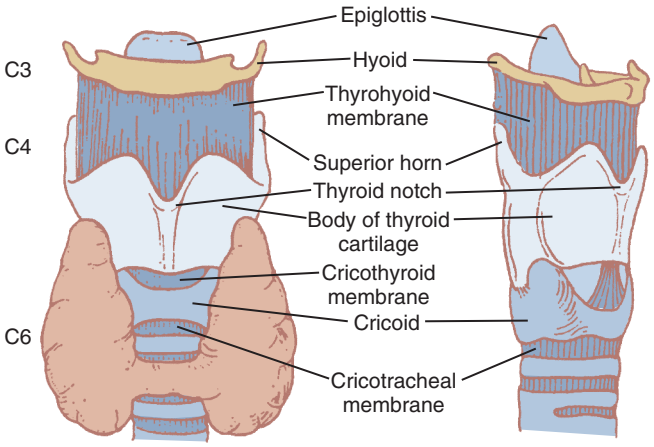

Figure 1-7 External frontal *(left)* and anterolateral *(right)* views of the larynx. Notice the location of cricothyroid membrane and thyroid gland in relation to thyroid and cricoid cartilage in the frontal view. The horn of the thyroid cartilage is also known as the cornu. In the anterolateral view, the shape of the cricoid cartilage and its relation to thyroid cartilage are shown. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

a. THYROID CARTILAGE

The thyroid cartilage, the longest laryngeal cartilage and the largest structure in the larynx, acquires its shieldlike shape from the embryologic midline fusion of the two distinct quadrilateral laminae.[35] In females, the sides join at an angle of approximately 120 degrees; in males, the angle is closer to 90 degrees. This smaller thyroid angle explains the greater laryngeal prominence ("Adam's apple"), longer vocal cords, and lower-pitched voice in

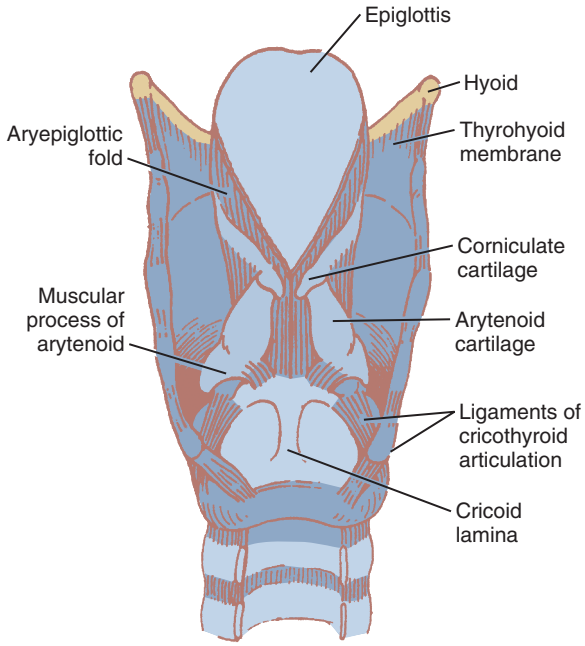

Figure 1-8 Cartilages and ligaments of the larynx seen posteriorly. Notice the location of the corniculate cartilage within the aryepiglottic fold. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

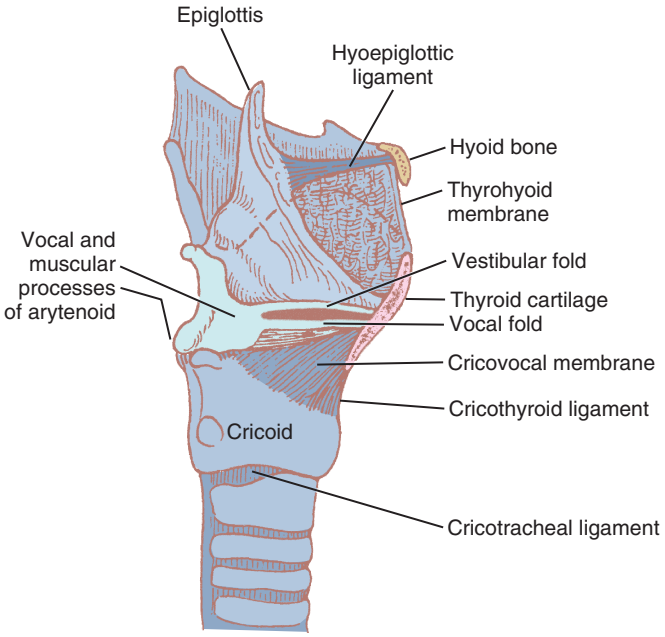

Figure 1-9 Sagittal (lateral) view of the larynx. The vocal and vestibular folds and the thyroepiglottic ligament attach to the midline of the inner surface of the thyroid cartilage. Also notice the relationship between the cricovocal membrane and the vocal folds. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

males.[36] The thyroid notch lies in the midline at the top of the fusion site of the two laminae.[37] On the inner side of this fusion line are attached the vestibular ligaments and, below them, the vocal ligaments (Fig. 1-9). The superior (greater) and inferior (lesser) cornua of the thyroid are slender, posteriorly directed extensions of the edges of the lamina. The lateral thyrohyoid ligament attaches the superior cornu to the hyoid bone, and the cricoid cartilage articulates with the inferior cornu at the cricothyroid joint. The movements of this joint are rotatory and gliding and result in changes in the length of the vocal folds.

b. CRICOID CARTILAGE

The cricoid cartilage (see Fig. 1-9) represents the anatomic lower limit of the larynx and helps support it.[35] The name *cricoid* is derived from the Greek words *krikos* and *eidos*, meaning shaped like a ring, and it is frequently said to have a signet-ring shape. It is thicker and stronger than the thyroid cartilage and represents the only complete cartilaginous ring in the airway. For this reason, cautious downward pressure on the cricoid cartilage to prevent passive regurgitation is possible without subsequent airway obstruction. Traditionally, it was thought that the pediatric airway was narrowest at the level of the cricoid, and recommendations for ETT size were made based on the size of the cricoid ring. However, studies done with video bronchoscopes on anesthetized and paralyzed children have shown that the glottic opening may be narrower than the cricoid region.[38] Therefore, an ETT tube may cause more damage to the vocal cords than to the subglottic area.

The bulky portion or lamina is located posteriorly. The tracheal rings are connected to the cricoid by ligaments and muscles. The cricoid lamina forms ball-and-socket synovial articulations with the arytenoids posterosuperiorly and with the thyroid cartilage inferolaterally and anteriorly.[35] It also attaches to the thyroid cartilage by means of the cricothyroid membrane (CTM), a relatively avascular and easily palpated landmark in most adults (see Figs. 1-8 and 1-9).

The inner diameters of the cricoid cartilage have been measured in cadavers, with great variability noted. Randestad and colleagues reported that the smallest diameter is in the frontal plane, which in females ranged from 8.9 to 17.0 mm (mean, 11.6 mm) and in males from 11.0 to 21.5 mm (mean, 15.0 mm).[39] They pointed out that placement of a standard size ETT (7 mm inner diameter for females, 8 mm for males) through the cricoid cartilage while preventing mucosal necrosis may be difficult in certain individuals.[39] The CTM represents an important identifiable landmark, providing access to the airway by percutaneous or surgical cricothyroidotomy.

The dimensions of the CTM have been identified in cadaveric specimens.[40-42] However, the actual methods of obtaining the anatomic measurements varied, making comparisons difficult to interpret. Caparosa and Zavatsky described the CTM as a trapezoid with a width ranging from 27 to 32 mm, representing the actual anatomic limit of the membrane, and a height of 5 to 12 mm.[41] Bennett and coauthors[40] reported the width as 9 to 19 mm and the height as 8 to 19 mm, whereas Dover and coworkers[42] reported a width of 6.0 to 11.0 mm and a height of 7.5 to 13.0 mm, using the distance between the cricothyroid muscles as their horizontal limit. The width and height of the membrane are reported to be smaller in females than in males.[10,42]

Anteriorly, vascular structures overlie the membrane and pose a risk of hemorrhage.[40,42-44] Cadaveric studies have reported the presence of a transverse cricothyroid artery, a branch of the superior thyroid artery, traversing the upper half of the membrane. Therefore, a transverse incision in the lower third of the membrane is recommended. The superior thyroid artery courses along the lateral edge of the membrane, and various branches of the superior and inferior thyroid veins and the jugular veins are also reported to traverse the membrane.

c. ARYTENOIDS

The two light arytenoid cartilages (see Fig. 1-8) are shaped like three-sided pyramids, and they lie in the posterior aspect of the larynx.[45] The arytenoid's medial surface is flat and is covered with only a firm, tight layer of mucoperichondrium.[45,46] The base of the arytenoid is concave and articulates by a true diarthrodial joint with the superior lateral aspect of the posterior lamina of the cricoid cartilage. It is described as a ball and socket with three movements—rocking or rotating, gliding, and pivoting—that control adduction and abduction of the vocal cords. All such synovial joints can be affected by rheumatoid arthritis. Cricoarytenoid arthritis is present in a majority of patients with rheumatoid arthritis and has been identified as a cause of life-threatening upper airway obstruction.[47] Cricoarytenoid arthropathy has also

been reported as a rare but potentially fatal cause of acute upper airway obstruction in patients with systemic lupus erythematosus.[48]

The lateral extension of the arytenoid base is called the muscular process. Important intrinsic laryngeal muscles, the lateral and posterior cricoarytenoids, originate here. The medial extension of the arytenoid base is called the vocal process. Vocal ligaments, the bases of the true vocal folds, extend from the vocal process to the midline of the inner surface of the thyroid lamina (see Fig. 1-9). The fibrous membrane that connects the vocal ligament to the thyroid cartilage actually penetrates the body of the thyroid. This membrane is called Broyles' ligament. This ligament contains lymphatics and blood vessels and therefore can act as an avenue for extension of laryngeal cancer outside the larynx.[35,49] The relationship between the anterior commissure of the larynx and the inner aspect of the thyroid cartilage is important to otolaryngologists, who perform thyroplasties and supraglottic laryngectomies on the basis of its location. A study of cadavers reported that the anterior commissure of the larynx can usually be found above the midpoint of the vertical midline fusion of the thyroid cartilage ala.[46,50]

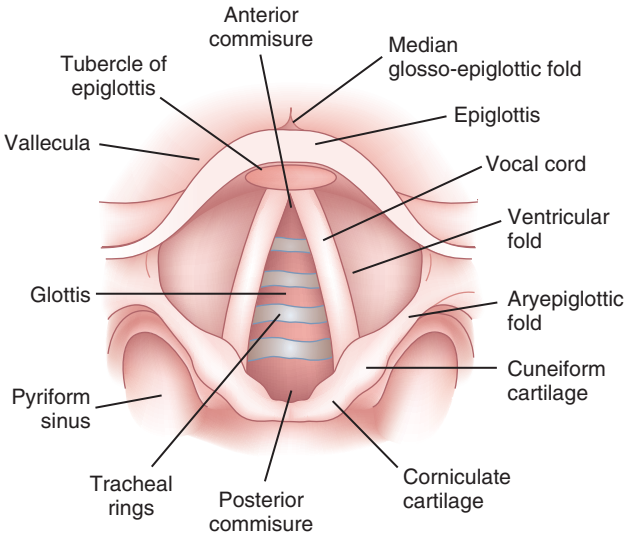

Figure 1-10 Larynx viewed from above with a laryngeal mirror. Notice the location of the anterior and posterior commissures of the larynx and the aryepiglottic fold. Elevations in the aryepiglottic folds are the cuneiform cartilages. (Modified from Tucker HM: Anatomy of the larynx. In Tucker HM, editor: *The larynx,* ed 2, New York, 1993, Thieme Medical, p 9.)

d. EPIGLOTTIS

The epiglottis is considered to be vestigial by many authorities.[51] Composed primarily of fibroelastic cartilage, the epiglottis does not ossify and maintains some flexibility throughout life.[35,45,52] It is shaped like a leaf and is found between the larynx and the base of the tongue (see Figs. 1-8 and 1-9).[34,46] The anterior surface of the epiglottis is concave, and this, in combination with laryngeal elevation, aids in airway protection during deglutition.[1] In approximately 1% of the population, the tip and posterior aspect of the epiglottis are visible during a pharyngoscopic view with the mouth opened and tongue protruded. Contrary to reports, this does not always predict ease of intubation.[53] The upper border of the epiglottis is attached by its narrow tip or petiole to the midline of the thyroid cartilage by the thyroepiglottic ligament (see Fig. 1-9). The hyoepiglottic ligament connects the epiglottis to the back of the body of the hyoid bone.[34,54] The mucous membrane that covers the anterior aspect of the epiglottis sweeps forward to the tongue as the median glossoepiglottic fold and to the pharynx as the paired lateral pharyngoepiglottic folds.[35] The pouch-like areas found between the median and lateral folds are the valleculae (Fig. 1-10). The tip of a properly placed Macintosh laryngoscope blade rests in this area. The vallecula is a common site of impaction of foreign bodies, such as fish bones, in the upper airway.

The introduction of advanced scanning techniques using contrast-enhanced multidetector computed tomography (MDCT) has enabled three-dimensional (3-D) and four-dimensional visualization of larger airways. Images of normal and diseased structures can be generated by using special postprocedure CT virtual endoscopy computer software. The presence of air-filled lumens of the upper airways makes it possible for the technical staff to build high-quality endoscopy-like images. Similar techniques have been applied to lower airways also. A virtual endoscopic picture of acute epiglottitis can be seen in Fig. 1-11.[55]

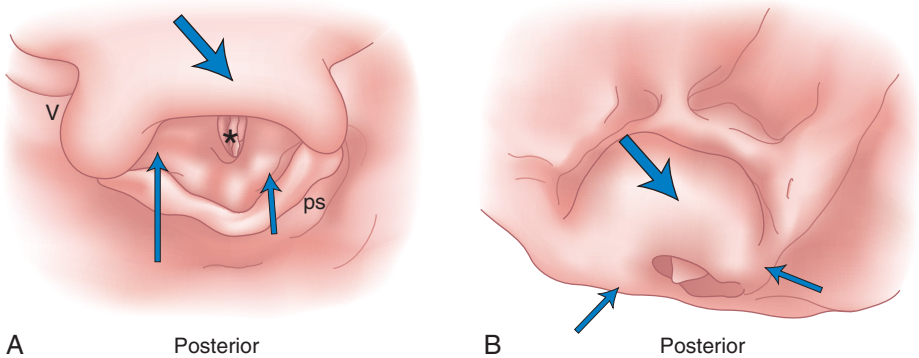

Figure 1-11 Acute epiglottitis. **A,** Virtual endoscopy showing normal appearance of the epiglottis *(large arrow),* aryepiglottic fold *(long thin arrow),* arytenoid prominence *(short thin arrow),* and glottis *(astersisk).* **B,** The appearance in acute epiglottitis. (From Thomas BP: CT virtual endoscopy in the evaluation of large airway disease: review. *AJR Integrative Imaging,* 2008.)

e. CUNEIFORM AND CORNICULATE CARTILAGES

The epiglottis is connected to the arytenoid cartilages by the laterally placed aryepiglottic ligaments and folds (see Figs. 1-8 and 1-10)). Two sets of paired fibroelastic cartilages are embedded in each aryepiglottic fold.[45] The sesamoid cuneiform cartilage is roughly cylindrical and lies anterosuperior to the corniculate in the fold. The cuneiform may be seen laryngoscopically as a whitish elevation through the mucosa (see Fig. 1-10). The corniculate is a small, triangular object visible directly over the arytenoid cartilage. The cuneiform and corniculate cartilages reinforce and support the aryepiglottic folds[35,46] and may help the arytenoids move.[12,52]

f. FALSE AND TRUE VOCAL CORDS

The thyrohyoid membrane (see Figs. 1-7 through 1-9), attaching the superior edge of the thyroid cartilage to the hyoid bone, provides cranial support and suspension.[12] It is separated from the hyoid body by a bursa that facilitates movement of the larynx during deglutition.[46] The thicker median section of the thyrohyoid membrane is the thyrohyoid ligament, and its thinner lateral edges are pierced by the internal branches of the superior laryngeal nerves.

Beneath the laryngeal mucosa is a fibrous sheet containing many elastic fibers, known as the fibroelastic membrane of the larynx. Its upper area, the quadrangular membrane, extends in the aryepiglottic fold between the arytenoids and the epiglottis. The lower free border of the membrane is called the vestibular ligament; it forms the vestibular folds, or false cords (see Figs. 1-9 and 1-10).[34,36,47]

The CTM joins the cricoid and thyroid cartilages. The thickened median area of this fibrous tissue, the "conus elasticus," extends up inside the thyroid lamina to the anterior commissure and continues and blends with the vocal ligament. The cricothyroid ligament thus connects the cricoid, thyroid, and arytenoid cartilages.[36,47] The thickened inner edges of the cricothyroid ligament, called the vocal ligament, form the base of the vocal folds (see Fig. 1-10).[12,46]

g. LARYNGEAL CAVITY

The laryngeal cavity (Fig. 1-12) extends from the laryngeal inlet to the lower border of the cricoid cartilage. When it is viewed laryngoscopically from above, two paired inward projections of tissue are visible in the laryngeal cavity: the superiorly placed vestibular folds, or false cords, and the more inferiorly placed vocal folds, or true vocal cords (see Fig. 1-10). The space between the true cords is called the rima glottidis, or the glottis (see Fig. 1-12). The glottis is divided into two parts. The anterior intermembranous section is situated between the two vocal folds. The two vocal folds meet at the anterior commissure of the larynx (see Fig. 1-10). The posterior intercartilaginous part passes between the two arytenoid cartilages and the mucosa, stretching between them in the midline posteriorly, forming the posterior commissure of the larynx (see Fig. 1-10).[36] At rest, the vocal processes are approximately 8 mm apart. The area extending from the laryngeal inlet to the vestibular folds

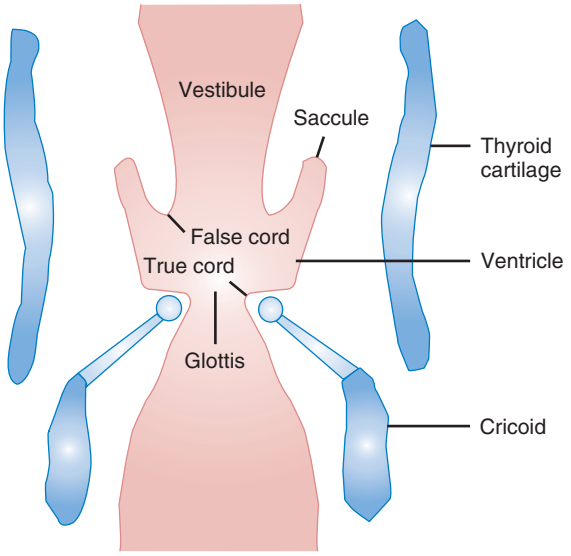

Figure 1-12 Diagrammatic representation of the laryngeal cavity. Notice the location of the false and true cords and laryngeal saccule. (Modified from Pectu LP, Sasaki CT: Laryngeal anatomy and physiology. *Clin Chest Med* 12:415, 1991.)

is known as the vestibule or supraglottic larynx (see Fig. 1-12). The laryngeal space from the free border of the cords to the cricoid cartilage is called the subglottic or infraglottic larynx.

On the basis of cadaver studies, the measurements of the subglottis have been identified.[41,56,57] Understanding the anatomic relationships between the cricothyroid space and the vocal folds is important to minimize complications after cricothyrotomy (Fig. 1-13).[58] Bennett and colleagues[40] reported this distance to be 9.78 mm. The region between the vestibular folds and the glottis is termed the ventricle or the sinus (see Fig. 1-12). The ventricle may expand anterolaterally to a pouchlike area with many lubricating mucous glands, called the laryngeal saccule (see Fig. 1-12).[35] The saccule is believed to help in voice resonance in apes.[46,51] The pyriform sinus lies laterally to the aryepiglottic fold within the inner surface of the thyroid cartilage (see Fig. 1-10).[46]

The epithelium of the vestibular folds is of the ciliated pseudostratified variety (respiratory), whereas the epithelium of the vocal folds is of the nonkeratinized squamous type.[37] Therefore, the entire interior of the larynx is covered with respiratory epithelium except for the vocal folds.[9]

Airway protection is enhanced by the orientation of the cords. The false cords are directed inferiorly at their free border. This position can help to stop egress of air during a Valsalva maneuver. The true cords are oriented slightly superiorly. This prevents air or matter from entering the lungs. Great pressure is required to separate adducted true cords.[52] Air trapped in the ventricle during closure pushes the false cords and the true cords more tightly together.[15,37,52]

3. Muscles, Innervation, and Blood Supply of the Larynx

The complex and delicate functions of the larynx are made possible by an intricate group of small muscles.

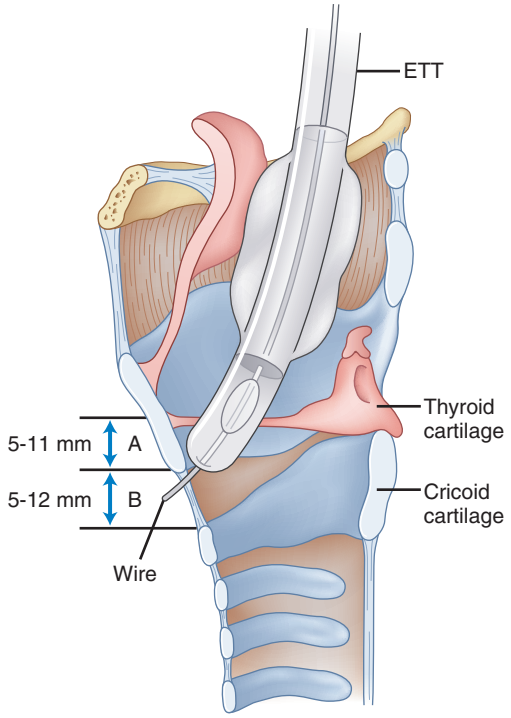

Figure 1-13 Schematic illustration showing the relationships of the larynx, thyroid, and cricoid cartilages, including the distance (range) from the vocal cords to the anteroinferior edge of the thyroid cartilage *(A)* and the distance (range) from the anteroinferior edge of the thyroid cartilage to the anterosuperior edge of the cricoid cartilage *(B)*. Also shown is the wire penetrating the cricothyroid membrane for retrograde intubation. *ETT,* Endotracheal tube. (From Kuriloff DB, Setzen M, Portnoy W: Laryngotracheal injury following cricothyroidotomy. *Laryngoscope* 99:125, 1989.)

These muscles can be divided into extrinsic and intrinsic groups.[51,54] The extrinsic group connects the larynx with its anatomic neighbors, such as the hyoid bone, and modifies the position and movement of the larynx. The intrinsic group facilitates the movements of the laryngeal cartilages against one another and directly affects glottic movement.

a. EXTRINSIC MUSCLES OF THE LARYNX

The suprahyoid muscles attach the larynx to the hyoid bone and elevate the larynx. These muscles are the stylohyoid, geniohyoid, mylohyoid, thyrohyoid, digastric, and stylopharyngeus muscles. In the infrahyoid muscle group are the omohyoid, sternothyroid, thyrohyoid, and sternohyoid muscles. These "strap" muscles, in addition to lowering the larynx, can modify the internal relationship of laryngeal cartilages and folds to one another. The inferior constrictor of the pharynx primarily assists in deglutition (Table 1-1).[12,35-37]

b. INTRINSIC MUSCLES OF THE LARYNX

The function of the intrinsic musculature is threefold: (1) to open the vocal cords during inspiration, (2) to close the cords and the laryngeal inlet during deglutition, and (3) to alter the tension of the cords during phonation.[12,35,59] The larynx can close at three levels: the aryepiglottic folds close by contraction of the aryepiglottic and oblique arytenoid muscles, the false vocal cords close by action of the lateral thyroarytenoids, and the true vocal cords by contraction of the interarytenoids, the lateral cricoarytenoids, and the cricothyroid.[12] The intrinsic muscles include the aryepiglottic and thyroepiglottic, thyroarytenoid and vocalis, oblique and transverse arytenoids, lateral and posterior cricoarytenoids, and cricothyroids (Fig. 1-14). All but the transverse arytenoid are paired.

Some authors consider the cricothyroid muscle to be both an extrinsic and an intrinsic muscle of the larynx because its actions affect both laryngeal movement and the glottic structures. It is the only intrinsic muscle found external to the larynx itself. The paired cricothyroid muscles join the cricoid cartilage and the thyroid cartilage (Fig. 1-15). The muscle has two parts. A larger, ventral section runs vertically between the cricoid and the inferior thyroid border. The smaller, oblique segment attaches to the posterior inner thyroid border and the lesser cornu of the thyroid. During swallowing, the muscle contracts and the ventral head draws the anterior part of the cricoid cartilage toward the relatively fixed lower border of the thyroid cartilage. The oblique head of the muscle rocks the cricoid lamina posteriorly. Because the arytenoids do not move, the vocal ligaments are tensed and the glottic length is increased 30%.[46,60]

The thick, posterior cricoarytenoid muscle originates near the entire posterior midline of the cricoid cartilage. Muscle fibers run superiorly and laterally to the posterior area of the muscular process of the arytenoid cartilage.[20]

TABLE 1-1
Extrinsic Muscles of the Larynx

Muscle	Function	Innervation
Sternohyoid	Indirect depressor of the larynx	Cervical plexus Ansa hypoglossi C1, C2, C3
Sternothyroid	Depresses the larynx Modifies the thyrohyoid and aryepiglottic folds	Same as above
Thyrohyoid	Same as above	Cervical plexus Hypoglossal nerve C1, C2
Thyroepiglottic	Mucosal inversion of aryepiglottic fold	Recurrent laryngeal nerve
Stylopharyngeus	Assists folding of thyroid cartilage	Glossopharyngeal
Inferior pharyngeal constrictor	Assists in swallowing	Vagus (pharyngeal plexus)

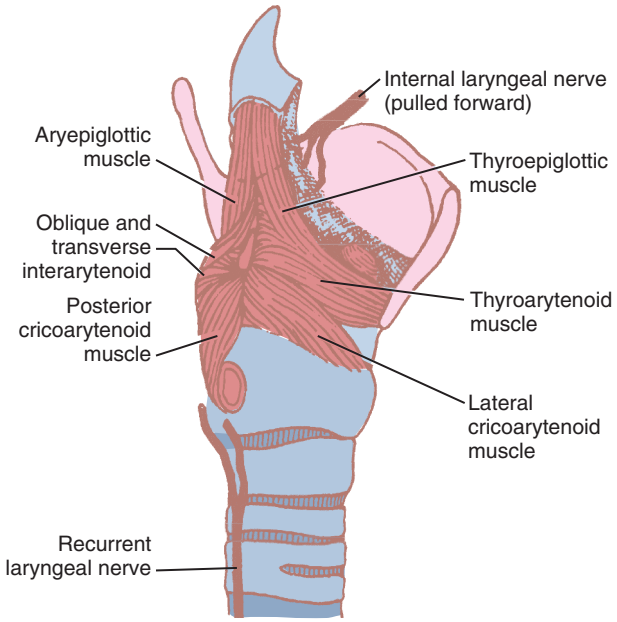

Figure 1-14 Intrinsic muscles of the larynx and their nerve supply. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

On contraction, the posterior cricoarytenoid rotates the arytenoids and moves the vocal folds laterally. The posterior cricoarytenoid is the only true abductor of the vocal folds.[36,45,46,52]

The lateral cricoarytenoid muscle joins the superior border of the lateral cricoid cartilage and the muscular process of the arytenoid. This muscle rotates the arytenoids medially, adducting the true vocal folds.[35] The unpaired transverse arytenoid muscle joins the posterolateral aspects of the arytenoids. This muscle, which is covered anteriorly by a mucous membrane, forms the posterior commissure of the larynx. Its contraction brings the arytenoids together and ensures posterior adduction of the glottis.[35,36,45]

The oblique arytenoids (see Fig. 1-14) ascend diagonally from the muscular processes posteriorly across the cartilage to the opposite superior arytenoid and help close the glottis. Fibers of the oblique arytenoid may continue from the apex through the aryepiglottic fold as the aryepiglottic muscle, which attaches itself to the lateral aspect of the epiglottis. The aryepiglottic muscle and the oblique arytenoid act as a purse-string sphincter during deglutition.[46]

The thyroarytenoid muscle (see Fig. 1-14) is broad and sometimes is divided into three parts. It is among the fastest-contracting striated muscles.[52] The muscle arises along the entire lower border of the thyroid cartilage. It passes posteriorly, superiorly, and laterally to attach to the anterolateral surface and the vocal process of the arytenoid.

The segment of thyroarytenoid muscle that lies adjacent to the vocal ligament (and frequently surrounds it) is called the vocalis muscle. The vocalis is the major tensor of vocal fold and can "thin" the fold to achieve a high pitch. Beneath the mucosa of the fold, extending from the anterior commissure back to the vocal process, is a potential space called Reinke's space. This area can become edematous if traumatized. The more laterally attached fibers of the thyroarytenoid function as the prime adductor of the vocal folds.[46]

The most lateral section of the muscle, sometimes called the thyroepiglottic muscle, attaches to the lateral aspects of arytenoids, the aryepiglottic fold, and even the epiglottis. When it contracts, the arytenoids are pulled medially, down, and forward.[35,46] This shortens and relaxes the vocal ligament. The function and innervation of the extrinsic muscles are summarized in Table 1-1. Table 1-2 describes the intrinsic musculature of the larynx.

c. INNERVATION OF THE LARYNX

The main nerves of the larynx are the recurrent laryngeal nerves and the internal and external branches of the

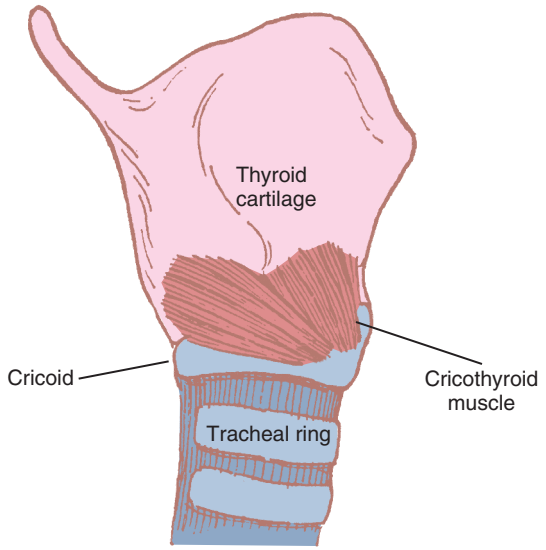

Figure 1-15 The cricothyroid muscle and its attachments. (Modified from Ellis H, Feldman S: *Anatomy for anaesthetists*, ed 6, Oxford, 1993, Blackwell Scientific.)

TABLE 1-2
Intrinsic Muscles of the Larynx

Muscle	Function	Innervation
Posterior cricoarytenoid	Abductor of vocal cords	Recurrent laryngeal
Lateral cricoarytenoid	Adducts arytenoids, closing glottis	Recurrent laryngeal
Transverse arytenoid	Adducts arytenoids	Recurrent laryngeal
Oblique arytenoid	Closes glottis	Recurrent laryngeal
Aryepiglottic	Closes glottis	Recurrent laryngeal
Vocalis	Relaxes the cords	Recurrent laryngeal
Thyroarytenoid	Relaxes tension cords	Recurrent laryngeal
Cricothyroid	Tensor of the cords	Superior laryngeal (external branch)

superior laryngeal nerves. The external branch of the superior laryngeal nerve supplies motor innervation to the cricothyroid muscle. All other motor supply to the laryngeal musculature is provided by the recurrent laryngeal nerve (see Fig. 1-14). The superior laryngeal and recurrent laryngeal nerves are derivatives of the vagus nerve.

The superior laryngeal nerve usually separates from the main trunk, off the inferior vagal ganglion, just outside the jugular foramen. At approximately the level of the hyoid bone, it divides into the smaller external and larger internal branches. The external branch travels below the superior thyroid artery to the cricothyroid muscle, giving off a branch to the inferior constrictor of the pharynx along the way. The internal branch travels along with the superior laryngeal artery and passes through the thyrohyoid membrane laterally between the greater cornu of the thyroid and the hyoid. The nerve and artery together pass through the pyriform recess, where the nerve may be anesthetized intraorally. The nerve divides almost immediately into a series of sensory branches and provides sensory innervation from the posterior aspect of the tongue base to as far down as the vocal cords. Sensory innervation of the epiglottis is dense, and the true vocal folds are more heavily innervated posteriorly than anteriorly.[52]

The left recurrent laryngeal nerve branches from the vagus in the thorax and courses cephalad after hooking around the arch of the aorta in close relation to the ligamentum arteriosum, at approximately the level of the fourth and fifth thoracic vertebrae. On the right, the nerve loops posteriorly beneath the subclavian artery, at approximately the first and second thoracic vertebrae, before following a cephalad course to the larynx. Both nerves ascend the neck in the tracheoesophageal groove before they reach the larynx. The nerves enter the larynx just posterior to, or sometimes anterior to, the cricothyroid articulation. The recurrent laryngeal nerve supplies all the intrinsic muscles of the larynx except the cricothyroid. The recurrent laryngeal nerve also provides sensory innervation to the larynx below the vocal cords. Parasympathetic fibers to the larynx travel along the laryngeal nerves, and the sympathetics from the superior cervical ganglion travel to the larynx with blood vessels. Tables 1-1 and 1-2 summarize the innervation of the laryngeal musculature.

GLOTTIC CLOSURE AND LARYNGEAL SPASM. Stimulation of the superior laryngeal nerve endings in the supraglottic region can induce protective closure of the glottis. This short-lived phenomenon is a polysynaptic involuntary reflex.[52] Triggering of other nerves, notably cranial nerves such as the trigeminal and glossopharyngeal, can produce a lesser degree of reflex glottic closure.[61,62] The nerve endings in the mammalian supraglottic area are highly sensitive to touch, heat, and chemical stimuli.[63] This sensitivity is especially intense in the posterior commissure of the larynx, close to where the pyriform recesses blend with the hypopharynx.[63,64] Complex sensory receptors, similar in structure to lingual taste buds, have been demonstrated here.[65] Instillation of water, saline, bases, or acids has been demonstrated to cause glottic closure in vitro and in vivo.[66] Infants also respond to stimulation with prolonged apnea, although this response disappears later in life.[4]

The term *episodic paroxysmal laryngospasm* has been coined to describe laryngeal dysfunction that may or may not arise as a true episode of respiratory distress.[66,67] Postoperative superior laryngeal nerve injury has been reported to cause paroxysmal laryngospasm arising with stridor and acute airway obstruction. Superior laryngeal nerve blockade may be temporarily effective in some patients.[68]

Laryngospasm occurs when glottic closure persists long after removal of the stimulus.[62,64] This has led to speculation that laryngospasm represents a focal seizure of the adductors innervated by the recurrent laryngeal nerve.[69] This state is initiated by repeated superior laryngeal nerve stimulation.[62] It has been reported that the recurrent laryngeal nerve may also be responsible for laryngospasm.[70] Symptoms abate, perhaps through a central mechanism, as hypoxia and hypercarbia worsen.[71]

VOCAL CORD PALSIES. The recurrent laryngeal nerve may be traumatized during surgery on the thyroid and parathyroid glands.[14,72] Malignancy or benign processes of the neck, trauma, pressure from an ETT or a laryngeal mask airway, and stretching of the neck may also affect the nerve.[9,54,58,73] The left recurrent laryngeal nerve may be compressed by neoplasms in the thorax, aneurysm of the aortic arch, or an enlarged left atrium (mitral stenosis).[34] It may occasionally be injured during ligation of a patent ductus arteriosus. The left nerve is likely to be paralyzed twice as frequently as the right one because of its close relationship to many intrathoracic structures. Damage to the superior laryngeal nerve (external branch) during thyroidectomy is the most common cause of voice change.[74]

Under normal circumstances, the vocal cords meet in the midline during phonation (Fig. 1-16). On inspiration, they move away from each other. They return toward the midline on expiration, leaving a small opening between them. When laryngeal spasm occurs, both true and false vocal cords lie tightly in the midline opposite each other. To arrive at a clinical diagnosis, the position of the cords must be examined laryngoscopically during phonation and inspiration (Fig. 1-17; see Fig. 1-16).

The recurrent laryngeal nerve carries both abductor and adductor fibers to the vocal cords. The abductor fibers are more vulnerable, and moderate trauma causes

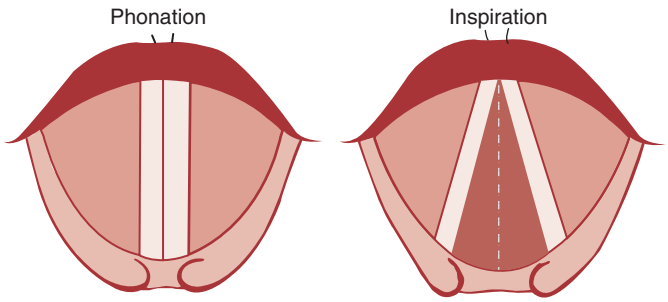

Figure 1-16 Position of vocal cords during phonation and inspiration. (From Hodder Headline PLC, London.)

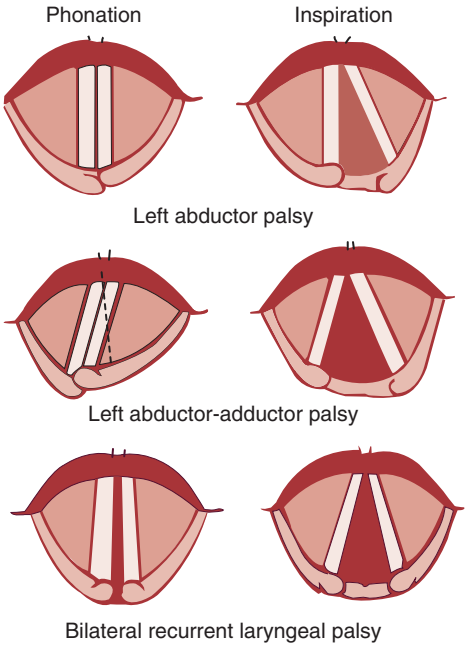

Figure 1-17 Diagrammatic representation of different types of vocal cord palsies. Notice that in complete bilateral recurrent laryngeal palsy (*bottom*), the vocal cords remain in the abducted position and the glottic opening is preserved. For details see text. (From Hodder Headline PLC, London.)

a pure abductor paralysis (Selmon's law).[75] Severe trauma causes both abductor and adductor fibers to be affected.[9] Pure adductor paralysis does not occur as a clinical entity. In the case of pure unilateral abductor palsy, both cords meet in the midline on phonation (because adduction is still possible on the affected side). However, only the normal cord abducts during inspiration (see Fig. 1-17). In the case of complete unilateral palsy of the recurrent laryngeal nerve, both abductors and adductors are affected. On phonation, the unaffected cord crosses the midline to meet its paralyzed counterpart, appearing to lie in front of the affected cord (see Fig. 1-17).[9] On inspiration, the unaffected cord moves to full abduction. When abductor fibers are damaged bilaterally (incomplete bilateral damage to the recurrent laryngeal nerve), the adductor fibers draw the cords toward each other, and the glottic opening is reduced to a slit, resulting in severe respiratory distress (see Fig. 1-17).[51,54] However, with a complete palsy, each vocal cord lies midway between abduction and adduction, and a reasonable glottic opening exists. Thus, bilateral incomplete palsy is more dangerous than the complete variety.

Damage to the external branch of the superior laryngeal nerve or to the superior laryngeal nerve trunk causes paralysis of the cricothyroid muscle (the tuning fork of the larynx), resulting in hoarseness that improves with time because of increased compensatory action of the opposite muscle. The glottic chink appears oblique during phonation. The aryepiglottic fold on the affected side appears shortened, and the one on the normal side is lengthened. The cords may appear wavy. The symptoms include frequent throat clearing and difficulty in raising the vocal pitch.[60] A total bilateral paralysis of vagus

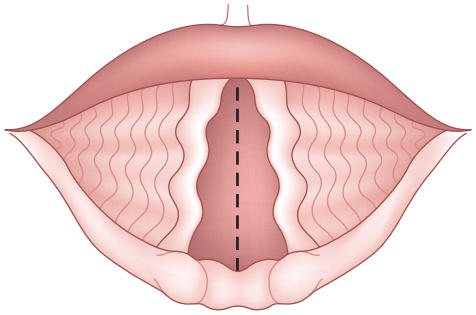

Figure 1-18 Cadaveric position of vocal cords. Notice the wavy appearance of the vocal cords, For details see text. (From Hodder Headline PLC, London.)

nerves affects the recurrent laryngeal nerves and the superior laryngeal nerves. In this condition, the cords assume the abducted, cadaveric position.[5,9] The vocal cords are relaxed and appear wavy (Fig. 1-18).[9,60] A similar picture may be seen after the use of muscle relaxants.

Topical anesthesia of the larynx may affect the fibers of the external branch of the superior laryngeal nerve and paralyze the cricothyroid muscle, signified by a "gruff" voice. Similarly, a superior laryngeal nerve block may affect the cricothyroid muscle in the same manner as surgical trauma does. These factors must be taken into consideration when evaluating post-thyroidectomy vocal cord dysfunction after surgery.

d. BLOOD SUPPLY OF THE LARYNX

Blood supply to the larynx is derived from the external carotid and subclavian arteries. The external carotid gives rise to the superior thyroid artery, which bifurcates, forming the superior laryngeal artery. This artery courses with the superior laryngeal nerve through the thyrohyoid membrane to supply the supraglottic region. The inferior thyroid artery, derived from the thyrocervical trunk, terminates as the inferior laryngeal artery. This vessel travels in the tracheoesophageal groove with the recurrent laryngeal nerve and supplies the infraglottic larynx. There are extensive connections with the ipsilateral superior laryngeal artery and across the midline. A small cricothyroid artery may branch from the superior thyroid and cross the CTM. It most commonly travels near the inferior border of the thyroid cartilage.[46]

III. LOWER AIRWAY

A. Gross Structure of the Trachea and Bronchi

The adult trachea begins at the cricoid cartilage, opposite the sixth cervical vertebra (see Figs. 1-7 and 1-8). It is 10 to 20 cm long and 12 mm in diameter. It is flattened posteriorly and contains 16 to 20 horseshoe-shaped cartilaginous rings. At the sixth ring, the trachea becomes intrathoracic. The first and last rings are broader than the rest. The lower borders of the last ring split and curve interiorly between the two bronchi to form the carina at the level of the fifth thoracic vertebra (angle of Louis, second intercostal space). The posterior part of the

trachea, void of cartilage, consists of a membrane of smooth muscle and fibroelastic tissue joining the ends of the cartilages. The muscle of the trachea is stratified with an inner circular and an outer longitudinal layer. The longitudinal bundles predominate in children but are virtually absent in adults.[45,51] Both the trachea and the proximal airways have extensive submucosal glands beneath the epithelium.[76]

It has been determined that the lengthening of the trachea during neck extension occurs mainly between the vocal cords and the sternal notch. This explains why ETTs fixed at the mouth ascend on average 2 cm in the trachea with neck extension.[77]

The tip of the tracheal tube moves toward the vocal cords, increasing the chance of accidental extubation. During flexion, the tube moves toward the carina or even the bronchus, depending on the original tube position and the extent of flexion. This is true in both adults and children.[77-79] It is therefore necessary to exercise constant vigil when the neck is moved in any direction to rule out displacement of the tube tip.

In the adult, the right main stem bronchus is wider and shorter and takes off at a steeper angle than the left main stem bronchus. Therefore, ETTs, suction catheters, and foreign bodies more readily enter the right bronchial lumen. However, the angulations of the two bronchi are almost equal in children younger than 3 years of age. The right main stem bronchus gives rise to three lobar bronchi, and the left to two. Both the main bronchi and the lower lobe bronchi are situated outside the lung substance. The large main bronchi are 7 to 12 mm in diameter; they divide into 20 bronchopulmonary divisions supplying each respective lobule's medium bronchi (4 to 7 mm) and small bronchi (0.8 to 4 mm). Bronchioles are bronchi that are smaller than 0.8 mm in diameter. Bronchioles do not have any cartilage in their walls.[46] The tracheobronchial airways occupy 1% of the lung volume, with the remaining 99% composed of large vessels and lung parenchyma.[76]

Bronchioles are of two types, terminal and respiratory. The terminal bronchioles do not bear any alveoli; they lead into the alveoli-bearing respiratory bronchioles. Each terminal bronchiole leads to three respiratory bronchioles, and each respiratory bronchiole leads to four generations of alveolar ducts (Fig. 1-19).[46] Although the diameter of each new generation of airway decreases progressively, the aggregate cross-sectional area increases. This is especially true for airways 2 mm or less in diameter, because further branching is not accompanied by concomitant decreases in caliber. The failure of the airway diameter to decrease with subsequent divisions produces the "inverted thumbtack" appearance on a graph depicting increasing surface area as a function of distance from the mouth (Fig. 1-20).[7]

The bronchi are surrounded by irregular cartilaginous rings that are similar in structure to the trachea except that the attachment of the posterior membrane is more anterior (Fig. 1-21).[47] The rings give way to discrete, cartilaginous plates as the bronchi become intrapulmonary at the lung roots (Fig. 1-22). Eventually, even these plates disappear, usually at airway diameters of approximately 0.6 mm.[47]

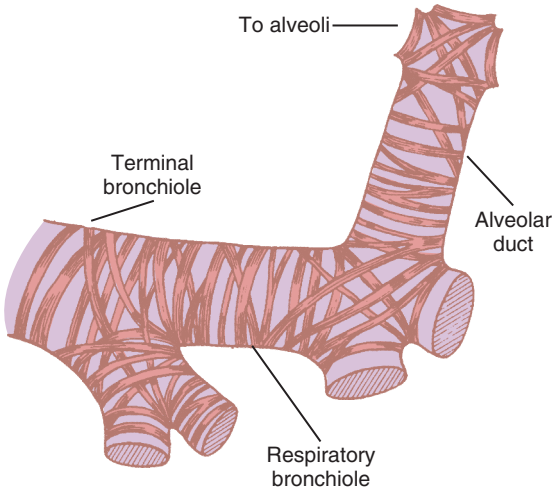

Figure 1-19 Bronchiolar division and geodesic network of muscle layer surrounding the airway. Two smooth muscle spirals run in opposite directions. This arrangement enables the muscles to constrict and shorten the airways at the same time. (Modified from Hodder Headline PLC, London.)

The rings or plates of the bronchi are interconnected by a strong fibroelastic sheath within which a myoelastic layer consisting of smooth muscle and elastic tissue is arrayed.[7] The myoelastic band is arranged in a special pattern called a geodesic network, representing the shortest distance between two points on a curved surface (see Fig. 1-19). This architectural design serves as the strongest and most effective mechanism for withstanding or generating pressures within a tube without fiber slippage along the length of the outer surface of the tube. The

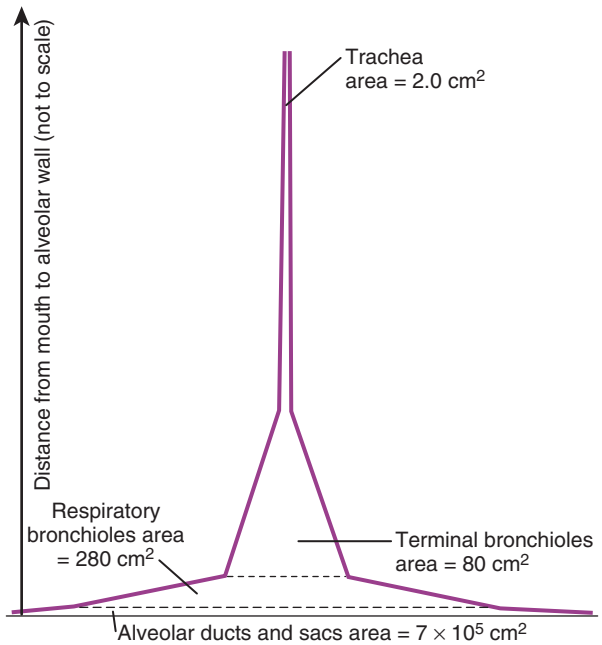

Figure 1-20 Relationship between cross-sectional area and generation of the airway. Notice the abrupt increase in cross section when the respiratory bronchiole is reached (inverted thumbtack arrangement). For details see text. (From Hodder Headline PLC, London.)

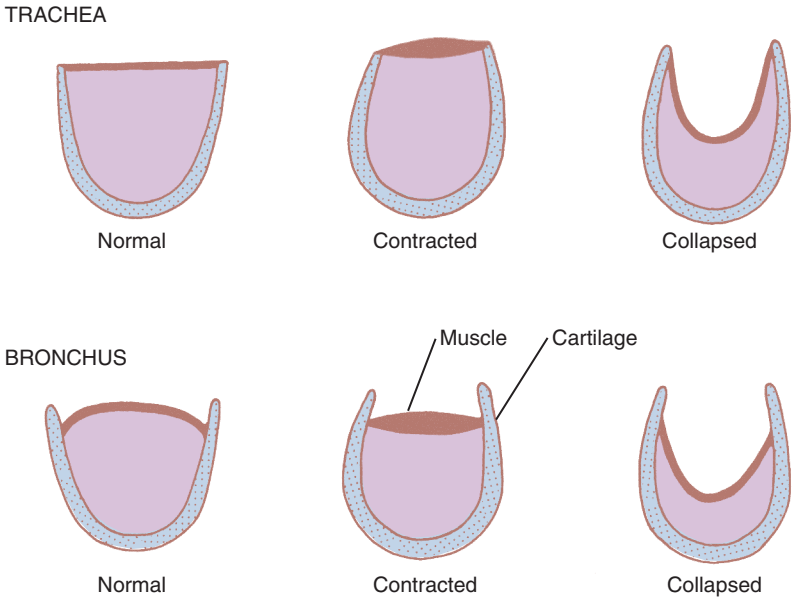

Figure 1-21 Cross-sectional view of trachea and bronchus. Notice the different sites of attachment of the posterior membrane in the tracheal and bronchial sections. Also notice the invagination of posterior membrane into the lumen in the collapsed state. (From Horsfield K: The relation between structure and function of the airways of the lung. *Br J Dis Chest* 68:145, 1974.)

network of smooth muscle runs around the airway in two opposing spirals. This arrangement helps in not only constricting the airway but shortening it.[80] The primary function of the muscular component is to change the size of the airway according to the respiratory phase. The smooth muscle tone (bronchomotor tone) is predominantly under the influence of the vagus nerve. The elastic layer runs longitudinally but encircles the bronchus at the points of division.[7]

The muscular layer becomes progressively thinner distally, but its thickness relative to the bronchial wall increases. Therefore, the terminal bronchiole with the narrowest lumen has perhaps the thickest muscle, almost 20% of the total thickness of the wall that lacks cartilaginous support.[46,47] For this reason, smaller bronchioles may be readily closed off by action of the musculature during prolonged bronchial spasm. Such an arrangement may facilitate closure of unperfused portions of the lung when a ventilation-perfusion mismatch occurs (e.g., pulmonary embolism). The smooth muscles and the glands of the cartilaginous airways are innervated by the autonomic nervous system. They are stimulated by the vagus and inhibited by sympathetic impulses derived from the upper thoracic ganglia. This smooth muscle mass can increase twofold to threefold in patients with severe asthma.[80]

B. Airway Epithelium and Airway Defense Mechanisms

The cartilaginous airways are lined by a tall, columnar, pseudostratified epithelium containing at least 13 cell types.[32] An important function of this lining is the production of mucus, a part of the respiratory defense mechanism. The mucus is steadily propelled to the outside by a conveyer belt mechanism. The large airways have a mucous secretory apparatus that consists of serous and goblet cells and submucous glands. The submucous glands empty into secretory tubules, which in turn connect with the larger connecting ducts. Several connecting ducts unite and form the ciliated duct that opens into the airway lumen. No mucous glands are present in the bronchioles.

The most numerous cells of the large airways are the ciliated epithelial cells, which bear 250 cilia per cell.[9,32] The length of the cilia decreases progressively in the smaller airways. On the surface of the cell are found small claws and microvilli. The microvilli probably regulate the volume of secretions through reabsorption, a function that may be shared with the brush cells scattered along the airways. The basal cell, more numerous in the large airways, imparts to the epithelium the pseudostratified appearance. The other cell types, except for the K cell,

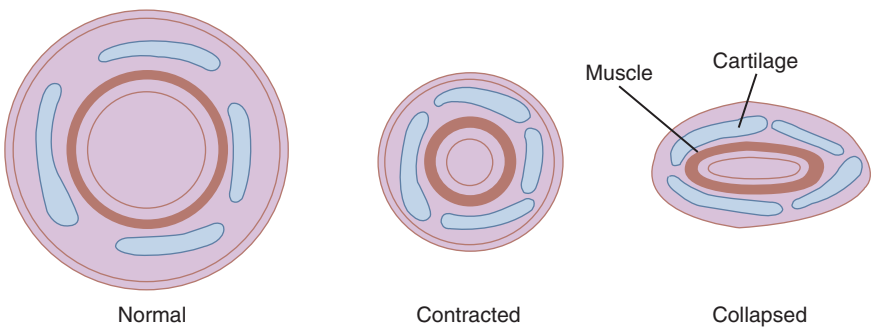

Figure 1-22 Cross-sectional views of medium bronchi (4 to 8 mm diameter) with peribronchial space. (From Horsfield K: The relation between structure and function of the airways of the lung. *Br J Dis Chest* 68:145, 1974.)

TABLE 1-3
Types of Tracheobronchial Cell

Cell	Probable Function
Epithelial	
Goblet	Mucous secretion
Serous	Mucous secretion
Ciliated	Mucous propulsion-resorption, supportive
Brush	Mucous resorption
Basal	Supportive, parent
Intermediate	Parent
Clara	Supportive, parent
Kulchitsky	Neuroendocrine; possible mechanoreceptor, chemoreceptor
Mesenchymal	
"Globule" leukocyte	Immunologic defense
Lymphocyte	Defense

Modified from Jeffrey PK, Reid L: New features of the rat airway epithelium: A quantitative and electron microscopic study. *J Anat* 120:295, 1975.

develop from the basal cell through the intermediate cell. This cell lies in the layer above the basal cell and differentiates into cells with secretory or ciliary function.[9,32,48] The K cell, or Kulchitsky-like cell, resembles the Kulchitsky cells of the gastrointestinal tract. These cells take up, decarboxylate, and store amine precursors, such as levodopa (L-dopa) and therefore are known as amine precursor uptake and decarboxylation (APUD) cells. The functions of the K cells are not definitely known, but proposed roles include mechanoreception (stretch) or chemoreception (carbon dioxide). Globule leukocytes are derived from subepithelial mast cells and interact with them to transfer immunoglobulin E to the secretions and to alter membrane permeability to locally produced or circulating antibodies. The ubiquitous lymphocytes and plasma cells defend against pathogens. Table 1-3 lists important cell types that constitute the airway epithelium.

The nonciliated bronchiolar epithelial cell, or Clara cell, largely makes up the cuboidal epithelium of the bronchioles. The Clara cells assume the role of basal cells as a stem cell in the bronchiole. Only six cell types have been recorded in the human bronchiole: the ciliated, brush, basal, K, and Clara cells and the globular leukocyte. These cells form a single-layered simple cuboidal epithelium.

C. Blood Supply

Bronchial arteries supply the bronchi and the bronchioles. Arterial supply extends into the respiratory bronchiole. Arterial anastomoses occur in the adventitia of the bronchiole. The branches enter the submucosa after piercing the muscle layer to form the submucosal capillary plexus. The venous radices arising from the capillary plexus reach the venous plexus in the adventitia by penetrating the muscle layer. When the muscle layer contracts, the arteries can maintain forward flow to the capillary plexus. However, the capillaries cannot force the blood back into the venous plexus. Therefore, prolonged bronchial spasm can lead to mucous membrane swelling in the small airways.[7] The venous drainage of the bronchi occurs through the bronchial, azygous, hemiazygos, and intercostal veins. There is some communication between the pulmonary artery and the bronchiolar capillary plexus leading to normally occurring "anatomic shunting."

D. Function of the Lower Airway

1. Forces Acting on the Airway

Different forces act on the airway to alter its morphology continuously. These forces are modified by (1) the location of a given airway segment (intrathoracic or extrathoracic), (2) the phases of respiration, (3) lung volume, (4) gravity, (5) age, and (6) disease.[47,48]

Intrathoracic, intrapulmonary airways such as the distal bronchi and bronchioles are surrounded by a potential space, the peribronchial space (Fig. 1-23). The bronchi are untethered and therefore move longitudinally within this sheath. However, the bronchiolar adventitia is attached by an elastic tissue matrix to the adjoining elastic framework of the surrounding alveoli and parenchyma. Consequently, the bronchioles are subject to transmitted tissue forces.[9,43]

Many forces act in concert to modify the airway lumen (Fig. 1-24). The forces that tend to expand the lumen include the pressure of the gas in the bronchi bronchioles and the elastic tissue forces of the alveoli. Forces that tend to close the airway include the elasticity of the bronchial wall, which increases as the lumen expands; the forces related to bronchial muscle contraction; and the pressure of the gas in the surrounding alveoli. The

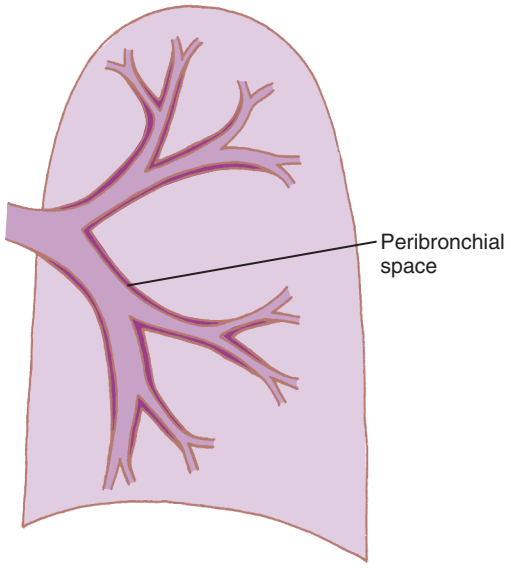

Figure 1-23 Diagram showing formation of peribronchial space by invagination of the visceral pleura. (From Horsfield K: The relation between structure and function of the airways of the lung. *Br J Dis Chest* 68:145, 1974.)

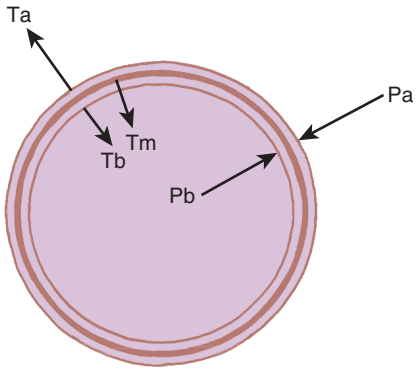

Figure 1-24 Vector diagram showing transmural forces influencing airway caliber: *Pa,* Alveolar gas pressure; *Pb,* barometric pressure; *Ta,* alveolar elastic forces; *Tb,* bronchial elastic forces; *Tm,* bronchial muscular forces. Arrow direction indicates the direction of the force. The algebraic sum of these forces determines the size of the airway lumen at any given time. (From Horsfield K: The relation between structure and function of the airways of the lung. *Br J Dis Chest* 68:145, 1974.)

algebraic sum of these forces at any given time determines the diameter of the airway.[46,47]

The lower part of the trachea and proximal bronchi are intrathoracic but extrapulmonary. Consequently, they are subject to the regular intrathoracic pressures (intrapleural pressure) but not to the tissue elastic recoil forces. The upper trachea is both extrathoracic and extrapulmonary. Although it is unaffected by the elastic recoil of the lung, it is subject to the effects of ambient pressure and cervical tissue forces.[43,47]

During spontaneous inspiration, the lung expands, which lowers the alveolar pressure more than it does the bronchial pressure, creating a pressure gradient that induces airflow. This increases the elastic retractive forces of the connective tissue and opens the intrathoracic airways. However, extrathoracic intraluminal pressure decreases relative to atmospheric pressure, with the result that the diameter of the upper trachea decreases. During expiration, alveolar pressure rises and exceeds the tissue retractive forces, thus decreasing the intrathoracic airway diameter. In this case, the extrathoracic intraluminal pressure rises above the atmospheric pressure, and the upper trachea expands. On forced expiration, alveolar pressure is greatly elevated, further reducing the diameter of the smaller airways.

The dynamic forces are altered by gravity such that the forces tending to expand the lung are greater at the top than at the bottom of the lung regardless of whether the patient is prone, supine, or erect.[49] The diameter and length of the airways of all sizes vary directly as the cube root of the lung volume varies when the lung expands.[50] On expiration below FRC, the retractive forces gradually decrease the airway size toward the point of closing volume. Because of the effect of gravity, the basal airways close first. The retractive forces of the elastic tissues decrease with aging, which explains why closing volume increases with age. This effect is exaggerated in diseases involving elastic tissue damage (e.g., pulmonary emphysema).

2. Relationship Between Structure and Function

The extent to which the retractive forces affect the airway morphology is related to the specific structure of the airway segment in question. When the fibromuscular membrane of the trachea contracts, the ends of the cartilages are approximated, and the lumen narrows in both the intrathoracic and the extrathoracic trachea. When the radial forces decrease airway diameter, the posterior membrane invaginates into the lumen (see Fig. 1-21). However, the rigid cartilaginous hoops prevent luminal occlusion. Extrapulmonary bronchi behave in a similar fashion.

The medium intrapulmonary bronchi within the peribronchial sheath are surrounded by cartilaginous plates. Although these plates add some rigidity to the wall, they do not prevent collapse, so these airways are dependent on the elastic retractive forces of the surrounding tissue (see Fig. 1-24).[47] Therefore, forced expiration can collapse many bronchioles in emphysema.

The miniature carinas at small airway bifurcations maintain airway lumens. Intrinsic bronchial muscles reduce the lumen and increase the mean velocity of the airflow during forced expiratory maneuvers, particularly in the peripheral airways with small flow rates. Here, two additional anatomic adaptations contribute to increasing flow rates. First, as the muscular ring contracts, the mucous lining is thrown into accordion-type folds that project into the lumen, further narrowing it (Fig. 1-25).[47] Second, the venous plexus situated between the muscle and the cartilage fills and invaginates into the lumen during muscle contraction. These mechanisms permit bronchoconstriction without distorting the surrounding tissues and minimize the muscular effort required to reduce the airway lumen. The drawback of such an arrangement is that even a small amount of fluid or sputum can result in complete occlusion of the small airways.[47] Therefore, it is not surprising that airway resistance is increased tremendously during an asthmatic attack that is characterized by both bronchospasm and increased secretions.[51,52,81] The small airways can also be affected by interstitial pulmonary edema, a condition in which the peribronchial space can accumulate fluid and isolate the bronchus from the surrounding retractive forces (see Fig. 1-25).

In severe asthma, thickening of the airway walls occurs due to increases in smooth muscle mass, infiltration with inflammatory cells, deposition of connective tissue, vascular changes, and mucous gland hyperplasia. Such a thickening is called *airway remodeling*. Airway remodeling occurs in milder and even asymptomatic cases of asthma. In the past, airway thickening was confirmed with the use of invasive techniques such as biopsy. More recently, scanning techniques have been used to study airway remodeling.[82] MDCT has been used to objectively assess airway remodeling in patients with severe asthma. MDCT used in conjunction with special software can yield reproducible results concerning airway remodeling, and the 3-D airway images allow for correlation of airway function with structural changes.[82] The indices of airway wall thickness measured by MDCT are inversely correlated

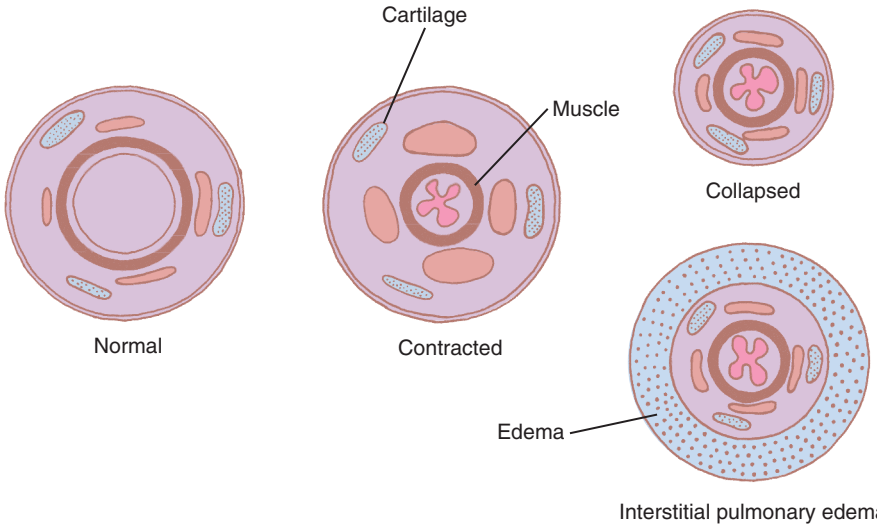

Figure 1-25 Structure of small bronchi (0.8 to 4 mm in diameter). Notice that the mucous membrane is thrown into folds in contracted and collapsed states, reducing the airway lumen. Also shown is the accumulation of interstitial edema in the peribronchial space. (From Horsfield K: The relation between structure and function of the airways of the lung. *Br J Dis Chest* 68:145, 1974.)

with changes in the 1-second forced expiratory volume (FEV_1). Noninvasive measurements of airway thickness over a period of time has the ability to show responses to treatment with corticosteroids and bronchodilators.[82,83]

IV. CONCLUSIONS

This chapter describes certain salient features of the human respiratory passages as they relate to their functional anatomy in health and disease from the anesthesiologist's point of view. It also pointed out some recent advances in scanning technology that can shed light on changes in functional anatomy of the lower airway in disease states such as asthma. It is necessary for students of anesthesia to possess some knowledge of the structures that they will most frequently use as a passageway to care of patients in their professional career.

V. CLINICAL PEARLS

- Cricoarytenoid arthritis can lead to airway difficulties in patients with rheumatoid arthritis or systemic lupus erythematosus.
- To diagnose vocal cord dysfunction, it is necessary to examine the position of the vocal cords during inspiration and phonation.
- The recurrent laryngeal and superior laryngeal nerves may be injured during thyroid surgery, leading to severe vocal cord dysfunction.
- A bilateral partial recurrent nerve palsy is more dangerous than complete palsy.
- Neck movement during anesthesia can result in movement of the tip of the endotracheal tube (ETT).
- New imaging techniques such as virtual endoscopy and multidetector computed tomography (MDCT) are providing added insight into the structure and function of the airways in health and disease.
- Upper airway obstruction in sedated patients occurs at the level of soft palate and not at the level of the tongue.

V. Conclusions

VI. Clinical Pearls

I. INTRODUCTION

Interpretation of radiologic studies is not usually in the domain of anesthesiologists. However, imaging studies can provide a wealth of information regarding the airway. This information can be aptly used for formulating an anesthetic plan. Currently, radiology is not part of the curriculum of any anesthesia residency training program; for this reason, most anesthesiologists have only rudimentary skills in the interpretation of radiologic studies. The main goal of this chapter is to introduce anesthesiologists to normal airway anatomy as visualized on conventional radiography (plain x-ray films) and on cross-sectional imaging such as computed tomography (CT) and magnetic resonance imaging (MRI) and to illustrate the anatomic variants and pathologic processes that can compromise the airway. The technical aspects of each imaging modality are reviewed briefly. Emphasis is placed on evaluation of the airway using available radiologic studies, which are most often performed for non-airway issues. Relevant information regarding the airway is readily available and ranges from conventional chest radiographs to high-resolution cross-sectional imaging of the neck or chest by CT or MRI. The clinical examples in this chapter focus on the pathologic processes involving the airway that are most relevant to anesthesiologists and include short discussions of some of the more common abnormalities.

Simplistically, the airway can be regarded as a tubular conduit for air inhaled from the nares to the tracheobronchial tree. The soft tissue structures bordering the airway have warranted more of the radiologist's attention. The integrity of the airway with its natural contrast is usually referenced with respect to extrinsic impression,

compression, encroachment, or displacement. Segmentation of the airway into compartments (i.e., head and neck, chest) is artificial and is usually done only for the ease of discussion. However, imaging of this airspace as a unique entity is gaining popularity. Knowledge of the technical differences among imaging modalities can aid in ordering and interpreting the imaging study. This is especially important when selecting a study that will best depict the anatomic structures and pathologic processes of the airway.

II. IMAGING MODALITIES

A. Conventional Radiography (Plain Film)

Wilhelm Conrad Roentgen, a German physicist, discovered x-rays on November 8, 1895, while studying the behavior of cathode rays (electrons) in high-energy cathode ray tubes. By serendipity, he noticed that a mysterious ray that escaped the cathode tube penetrated objects differently, and he named this the *x-ray*. For his work, he was awarded the first Nobel Prize for Physics in 1901.[1]

X-rays are a type of electromagnetic radiation; as the name implies, they transport energy through space as a combination of electric and magnetic fields. Other types of electromagnetic radiation include radio waves, radiant heat, and visible light. In diagnostic radiology, the predominant energy source used for imaging is ionizing radiation (i.e., alpha, beta, gamma, and x-rays). The science of electromagnetic waves and x-ray generation is very complex and exceeds the scope of this text. In principle, x-rays are produced by energy conversion as a fast stream of electrons is suddenly decelerated in an x-ray tube.[2] The localized x-ray beam that is produced passes through the part of the body being studied. The final image is dependent on the degree of attenuation of the beam by matter.

Attenuation is the reduction in the intensity of the beam as it traverses matter of different constituents. It is caused by absorption or deflection of photons from the beam. The transmitted beam determines the final image, which is represented in shades of gray.[3–5] The lightest or brightest area on the film or image represents the greatest attenuation of the beam by tissue and the least amount of beam transmitted to film. For example, bone is a high-density material that attenuates much of the x-ray beam; images of bone on x-ray films are very bright or white. A plain film image is a one-dimensional collapsed or compressed view of the body part being imaged. This information can also be presented in a digital format without the use of traditional x-ray films.

Compared with other, more sophisticated imaging modalities, conventional radiography has limited range in the display of tissues of different density and spatial resolution. Its advantages are lower cost of the examination, overall lower radiation exposure compared with a more comprehensive CT examination, and presentation of anatomy with a larger field of view. The head, chest, abdomen, or extremity can be visualized on a single film or digitized image, and therefore the image appears more familiar to nonradiologists. Also, the plain x-ray film can be obtained quickly at the patient's bedside in any location in the hospital. The combination of x-radiography with cine mode allows radiologists to obtain dynamic images, which are used to evaluate organ function (e.g., barium swallow to evaluate deglutition, intravenous pyelogram to assess renal function, vascular studies).

B. Computed Tomography

After the discovery of x-rays, it became apparent that images of the internal structures of the human body could yield important diagnostic information. However, the usefulness of x-ray studies is limited because they project a three-dimensional (3-D) object onto a two-dimensional display. With x-rays, the details of internal objects are masked by the shadows of overlying and underlying structures. The goal of diagnostic imaging is to bring forth the organ or area of interest in detail while eliminating unwanted information. Various film-based traditional tomographic techniques were developed, culminating in the creation of computerized axial tomography or computed tomography (CT).[6] The first clinically viable CT scanner was developed by Hounsfield and commercially marketed by EMI Limited (Middlesex, England) for brain imaging in the early 1970s.[7] Since then, several generations of CT scanners have been developed.

As with conventional plain film radiography, CT technology requires x-rays as the energy source. Whereas conventional radiography employs a single beam of x-rays from a single direction and yields a static image, CT images are obtained with the use of multiple collimated x-ray beams from multiple angles, and the transmitted radiation is counted by a row or rows of detectors. The patient is enclosed in a gantry, and a fan-shaped x-ray source rotates around the patient. The radiation counted by the detectors is analyzed with the use of mathematical equations to localize and characterize tissues by density and attenuation measurements. A single cross-sectional image is produced with one rotation of the gantry.[6] The gantry must then "unwind" to prepare for the next slice while the table carrying the patient moves forward or backward by a distance that is predetermined by slice thickness. An intrinsic limitation of this technique is the time required for moving the mechanical parts.

The introduction of slip-ring technology in the 1990s and the development of faster computers, high-energy x-ray tubes, and multidetectors enabled continuous activation of the x-ray source without having to unwind the gantry and also allowed continuous movement of the tabletop. This process, known as *helical CT*, is used in the latest generation of CT scanners. Because the information acquired using helical CT is volumetric, in contrast to the single slice obtained with conventional CT, the entire thorax or abdomen can be scanned in a single breath-hold. Volumetric information makes it possible to identify small lesions more accurately and allows better 3-D reformation. Because of the higher speed of data acquisition, misregistration and image degradation caused by patient motion are no longer significant concerns. This

is especially important when scanning uncooperative patients and trauma victims. The absorbed radiation dose used in multidetector helical CT (as compared with conventional single-detector row CT) is dependent on the scanning protocol and varies with the desired high-speed or high-quality study.[8]

Practically speaking, CT examinations have become routine. The spatial resolution of CT is the best of all the imaging modalities currently available. The advantage of CT technology is that it can depict accurately any pathology involving bones. Data acquisition is very quick. CT can be used to produce images in all three planes and to provide information for surface rendering and 3-D reformation, which allows the display of organs in an anatomic format that can be easily recognized by clinicians.

C. Magnetic Resonance Imaging

MRI has become one of the most widely used imaging modalities in diagnostic radiology. In contrast to conventional radiography and CT, MRI uses no ionizing radiation. Instead, imaging is based on the resonance of the atomic nuclei of certain elements such as sodium, phosphorus, and hydrogen in response to radio waves of the same frequency produced in a static magnetic field environment. Current clinical MRI units use protons from the nuclei of hydrogen atoms to generate images because hydrogen is the most abundant element in the body. Every water molecule contains two hydrogen atoms, and larger molecules, such as lipids and proteins, contain many hydrogen atoms. Powerful electromagnets are used to create a magnetic field, which influences the alignment of protons in hydrogen atoms in the body. When radio waves are applied, protons are knocked out of natural alignment, and when the radio wave is stopped, the protons return to their original state of equilibrium, realigning to the steady magnetic field and emitting energy, which is translated into weak radio signals. The time it takes for the protons to realign, referred to as a *relaxation time*, is dependent on the tissue composition and cellular environment.[9] The different relaxation times and signal strengths of the protons are processed by a computer, generating diagnostic images. With MRI, the chemical and physical properties of matter are examined at the molecular level. The relaxation times for each tissue type, designated T1 and T2, are expressed as constants at a given magnetic field strength. Imaging that optimizes T1 or T2 characteristics is referred to as T1-weighted or T2-weighted imaging, respectively. Tissue response to pathologic processes usually includes an increase in bound water (edema), which lengthens the T2 relaxation time and appears as a bright focus on T2-weighted images.[9]

MRI is more sensitive, but not necessarily more specific, in detecting pathology than CT, which depicts anatomy with unparalleled clarity. Imaging with MRI provides metabolic information at the cellular level, allowing one to link organ function and physiology to anatomic information. MRI and CT technologies also have other differences: (1) MRI shows poor bony detail, whereas CT provides excellent images of bony structures; (2) hemorrhage, especially if acute, is clearly visible on CT scans but may be difficult to diagnose with MRI because the appearance of blood varies temporally to the evolution of the breakdown products of hemoglobin; and (3) MRI is very susceptible to all types of motion artifacts, ranging from a patient's movement, breathing, swallowing, and phonation to vascular and cerebral spinal fluid pulsation and flow.

MRI scanners operate in a strong magnetic field environment, and strict precautions must be observed. Any item containing ferromagnetic substances that is introduced into the magnetic field environment can become a projectile and result in deleterious consequences for patients, personnel, and the MRI scanner itself. Therefore, no metal objects should be brought into the MRI suite if one is not absolutely certain about their composition. Only specially designed nonferromagnetic equipment is used in the MRI suite, including anesthesia machines, monitoring equipment, oxygen tanks, poles for intravenous equipment, infusion pumps, and stretchers. Pagers, telephones, handheld organizers and computers, credit cards, and analog watches must also be removed, because the strong magnetic field can cause malfunction or permanent damage to them. Patients must be carefully screened for implantable pacemakers, intracranial aneurysm clips, cochlear implants, and other metallic foreign objects before entering the MRI environment.

III. BASICS OF PLAIN FILM INTERPRETATION

To illustrate the usefulness of conventional radiography in evaluating the airway, this discussion focuses on the interpretation of plain films of the cervical spine, chest, and neck. Before the CT era, these were probably the most frequently ordered x-ray studies in the hospital setting, and they are ubiquitous in patients' film jackets and on picture archiving communication systems (PACS). As a composite, these studies provide a picture of the entire airway. Although these radiologic studies are usually obtained for reasons other than airway evaluation, it is actually in the group of patients who are "normal" or "cleared for surgery" that one may glean important observations about the airway. The anatomy and pathology displayed by plain film radiographs may alert the anesthesiologist to potential difficulties in securing the patient's airway and help him or her to develop an alternative anesthetic plan. In this sense, the information about the airway that is inherent to these x-ray examinations is gratuitous. The following sections address the basics of plain film interpretation with respect to imaging of the airway anatomy and pathology.

A. Cervical Spine Radiography

1. General Technique, Anatomy, and Basic Interpretation

The cervical spine connects the skull to the trunk; it articulates with the occiput above and the thoracic vertebrae below. The bony elements, muscles, ligaments, and intervertebral discs support and provide protection to the

spinal cord. On plain films, one can appreciate the bony morphology of the vertebrae and the disc spaces and assess the alignment of the vertebral column very quickly. This indirectly provides information regarding the integrity of the ligaments, which are crucial in maintaining alignment of the cervical spine. However, individual ligaments and muscle groups all have the same or similar attenuation and cannot be differentiated from one another on plain film. A systematic approach is recommended to evaluate the spine for bony integrity, alignment, cartilage, joint space, and soft tissue abnormalities. The disadvantages of cervical spine radiography are the limited range of tissue attenuation and the loss of spatial resolution caused by overlapping bone structures.

The most common indications for obtaining cervical spine radiographs in today's medical practice are for the evaluation of trauma, spinal stability, and cervical spondylosis and in the search for radiopaque foreign bodies. Different views of the cervical spine are tailored to each clinical need. The most common views are the lateral, anteroposterior (AP), open-mouth odontoid, oblique, and pillar views (Fig. 2-1). In acute cervical spine injury, cross-table lateral, AP, and open-mouth odontoid views are recommended. A lateral view reveals the majority of injuries (Fig. 2-2); however, patients who are rendered quadriplegic by severe ligamentous injuries may demonstrate a normal lateral cervical spine radiograph. When the AP and then the open-mouth odontoid views are added to the cross-table lateral view of the cervical spine, the sensitivity of detecting significant injury is increased from 74% to 82% and then to 93%.[10] In today's practice, cross-sectional imaging (i.e., CT of the spine) has become a mainstay in the evaluation of the cervical spine, especially in the setting of acute trauma. MRI is particularly useful in evaluating the spinal cord.

In brief, a normal lateral cervical radiograph should demonstrate seven intact vertebrae and normal alignment of the anterior and posterior aspects of the vertebral bodies. This is especially important for trauma victims, because 7% to 14% of fractures are known to occur at the C7 or C7-T1 level.[11] The posterior vertebral body line is more reliable and must be intact. The anterior vertebral line is often encumbered by the presence of anterior osteophytes. Normal facet joints overlap in an orderly fashion, similar to shingles on a rooftop. The spinolaminar line, which is the dense cortical line representing the junction of the posterior laminae and the posterior spinous process, is uninterrupted. Relative uniformity of the interlaminar (interspinous) distances should be observed. The posterior spinal line (i.e., posterior cervical line), an imaginary line extending from the spinolaminar line of the atlas to C3 (Fig. 2-3), should demonstrate a continuous curve in parallel to the posterior vertebral body line; the distance between the two correlates with the spinal canal diameter.[12]

The anatomy and integrity of the craniocervical junction are crucial to the anesthesiologist. To achieve successful and safe endotracheal intubation, the anterior atlantodental interval (AADI), the vertical and anteroposterior position of the dens, and the degree of extension of the head on the neck must be considered. The anterior arch of C1 bears a constant relationship to the dens; this is the AADI or predental space. It is defined as the space between the posterior surface of the anterior arch of C1 and the anterior surface of the dens. In flexion, because of the physiologic laxity of the cervicocranial ligaments, the anterior tubercle of the atlas assumes a more normal-appearing relationship to the dens, and the AADI increases in width, greater rostrally than caudally. In children and with flexion in adults, the AADI is normally about 5 mm. In adults, it is generally accepted that the AADI is 3 mm or less (Fig. 2-4).[12]

The bony structures of the atlantoaxial joint provide mobility (e.g., rotational movement) rather than stability. Therefore, the ligaments play a significant role in stability. The most important ligaments in the upper cervical spine are the transverse ligament, the alar ligaments, and the tectorial membrane. If the transverse ligament is disrupted and the alar and apical ligaments remain intact, up to 5 mm of movement at the atlantoaxial joint can be seen.[13] If all the ligaments have been disrupted, the AADI can measure 10 mm or larger. In atlantoaxial subluxation, the dens is invariably displaced posteriorly, which causes narrowing of the spinal canal and potential impingement of the spinal cord. The space available for the spinal cord is defined as the diameter of the spinal canal as measured in the AP plane, at the C1 level, that is not occupied by the odontoid process. In the normal spine, this space is approximately 20 mm.[13]

2. Pertinent Findings and Pathology

a. PSEUDOSUBLUXATION AND PSEUDODISLOCATION

Pseudosubluxation and *pseudodislocation* are terms applied to the physiologic anterior displacement of C2 on C3 that is frequently seen in infants and young children (Fig. 2-5). Physiologic anterior displacement of C2 on C3 and of C3 on C4 occurs in 24% and 14%, respectively, of children up to 8 years of age.[14]

In pediatric trauma cases, if C2 is anteriorly displaced and there are no other signs of trauma such as posterior arch fracture or prevertebral soft tissue hematoma, the spinolaminar lines of C1 through C3 should have a normal anatomic relationship. In a neutral position, the spinolaminar line of C2 lies on or up to 1 mm anterior or posterior to the imaginary posterior spinal line. If the C2 vertebra is intact, as the C2 body glides forward with respect to C3 during flexion, the spinolaminar line of C2 moves 1 to 2 mm anterior to the posterior spinal line. Similarly, with extension, the posterior translation of the C2 body is mirrored by similar posterior displacement of the spinolaminar line of C2 with respect to the posterior spinal line.

In traumatic spondylolisthesis, which is rare in children but more common in adults, the C2 body would translate anteriorly in flexion and posteriorly in extension, and the posterior spinal line would be maintained because of intact ligaments. However, flexion and extension films are not advisable if traumatic spondylolisthesis is suspected.

b. CONGENITAL AND DEVELOPMENTAL ANOMALIES

OCCIPITAL FUSION OF C1. Important to rigid laryngoscopy and endotracheal intubation is the distance between the

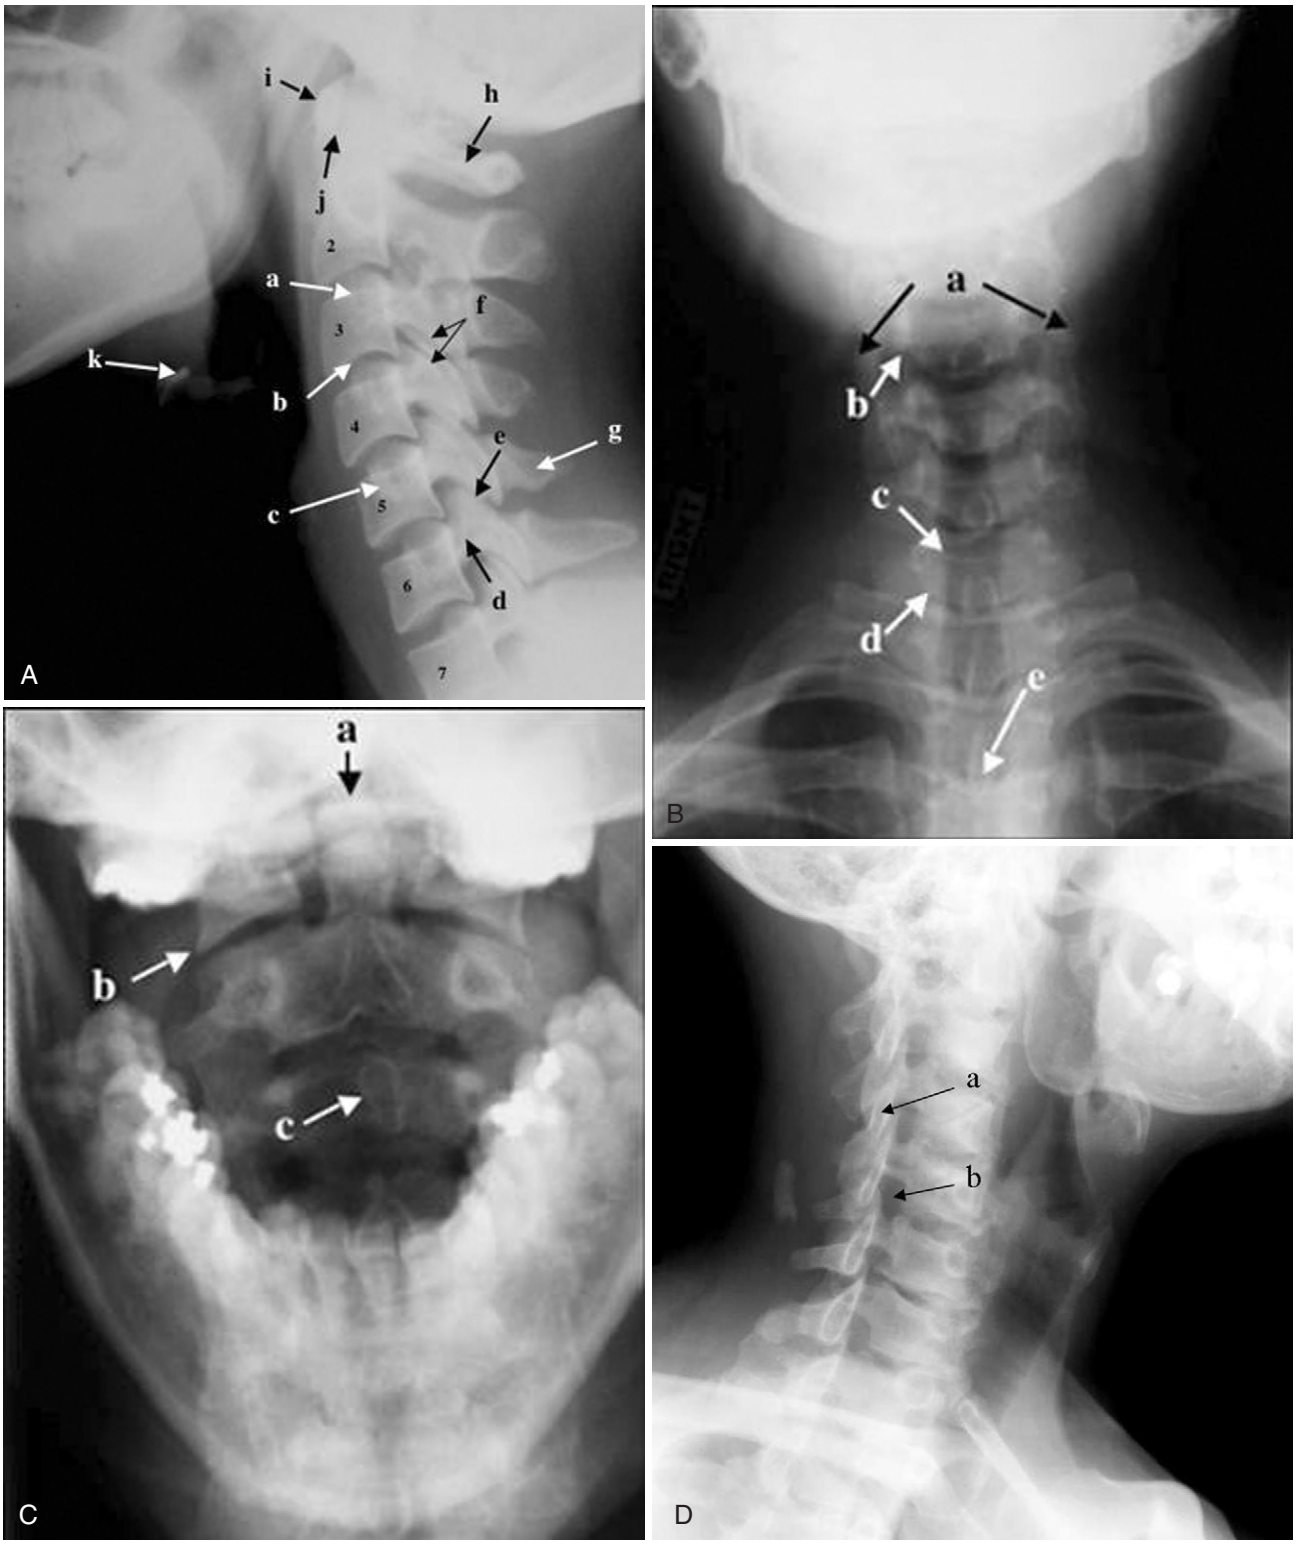

Figure 2-1 Normal cervical spine series. **A,** Lateral view shows upper (*a*) and lower (*b*) end plates of the third cervical vertebra (C3), transverse process (*c*), pedicle (*d*), facet joint (*e*), articulating facets (*f*), posterior spinous process (*g*), posterior arch of C1 (*h*), anterior arch of C1 (*i*), atlantoaxial distance (*j*), and hyoid bone (*k*). **B,** Anteroposterior view shows smoothly undulating cortical margins of the lateral masses (*a*), joint of Luschka (b), superior (*c*) and inferior (*d*) end plates, and a midline posterior spinous process (*e*). **C,** Open-mouth odontoid view shows the odontoid tip (*a*), centered between the lateral masses of the axis; symmetrical lateral margins of the lateral atlantoaxial joints (*b*); and a spinous process (*c*). **D,** Oblique view shows laminae of the articular masses (*a*), reflecting the shingling effect, and an intervertebral (neural) foramen (*b*).

Figure 2-2 Cervical spine fracture. Lateral radiograph of the cervical spine demonstrates a compression fracture of the C5 vertebra (*arrow*). A retropulsed fragment impinges on the spinal canal.

occiput and the posterior tubercle of C1, known as the atlanto-occipital distance (Fig. 2-6), which is quite variable from individual to individual. Head extension is limited by the abutment of the occiput to the posterior tubercle of C1. It has been proposed that a shorter atlanto-occipital distance decreases the effectiveness of head extension and contributes to difficult intubation.[13,15] Occipitalization of C1 with the occiput (atlanto-occipital fusion) not only limits head extension but also adds stress to the atlantoaxial joint. Although the majority of head extension occurs at the atlanto-occipital joint, some extension can also occur at C1-C2.[15] Nichol and Zuck observed that in patients with limited or no extension possible at the atlanto-occipital joint, general extension of the head actually brings the larynx "anterior," thus limiting the visibility of the larynx on laryngoscopy.[15]

NONFUSION OF ANTERIOR AND POSTERIOR ARCHES OF C1. Ossification of the atlas begins with the lateral masses during intrauterine life. At birth, neither the anterior nor the posterior arches are fused. Fusion of the anterior arch is complete between 7 and 10 years of age. During the second year, the center of the posterior tubercle appears, and by the end of the fourth year, the posterior arch becomes complete.[12] Nonfusion of the anterior or the posterior arch, or both, exists as a normal variant in adults and should not be mistaken for fracture (Fig. 2-7).

PSEUDOFRACTURES OF C2 AND DENS. The second cervical vertebra, the axis (C2), is the largest and heaviest cervical segment. The C2 vertebra arises from five or six separate ossification centers, depending on whether the centrum has one or two centers. The vertebral body is ossified at birth, and the posterior arch is partially ossified. They fuse posteriorly by the second or third year of life and unite with the body of the vertebra by the seventh year.

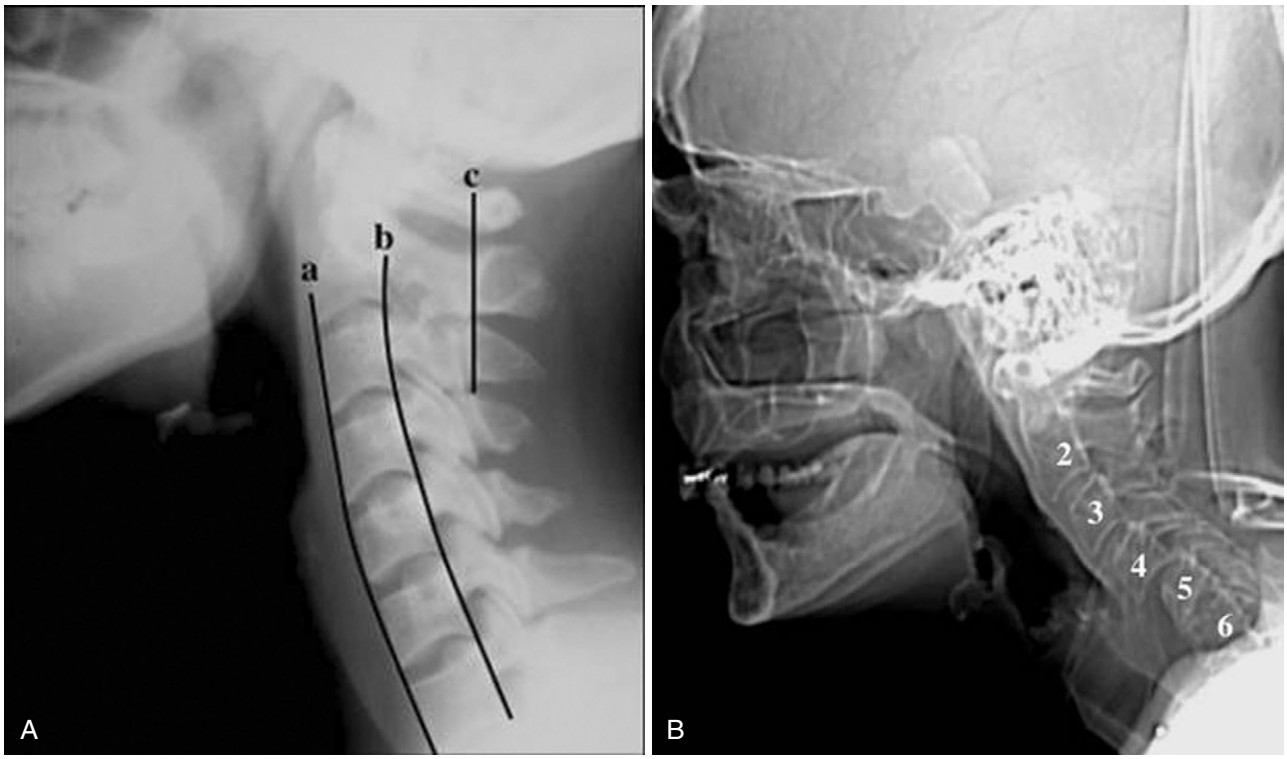

Figure 2-3 Normal lateral cervical spine radiograph **(A)** demonstrates normal alignment. *a,* Anterior spinal line; *b,* posterior vertebral line; *c,* posterior spinal line. **B,** Lateral scout view of a computed tomography scan demonstrates anterior subluxation of C4 on C5.

Figure 2-4 Anterior atlantodental interval (AADI). **A,** Lateral radiograph of the cervical spine in an adult patient. The AADI or predental space *(arrows)* is normally less than 3 mm. **B,** Lateral radiograph of the cervical spine in a pediatric patient. An AADI of up to 5 mm *(curved arrow)* can be normal in a child. The basion, the midpoint of the anterior border of the foramen magnum, is indicated by the *straight* arrow. The *dotted line* is an imaginary line indicating the inferior extension from the basion, and the posterior axial line is indicated by the *solid line*. The distance between the dotted line and the solid line is the basion-axial interval (BAI); it should be 12 mm or less for a normal occipitovertebral relationship in a child.

The odontoid process (dens) serves as the conceptual body of C1, around which the atlas rotates and bends laterally. In contrast to the other cervical vertebrae, C2 does not have a discrete pedicle. The dens is situated between the lateral masses of the atlas and is maintained in its normal sagittal relationship to the anterior arch of C1 by several ligaments, the most important of which is the transverse atlantal ligament. Superiorly, the dentate (apical) ligament extends from the clivus to the tip of the dens. Alar ligaments secure the tip of the dens to the occipital condyles and to the lateral masses of the atlas. They are the second line of defense in maintaining the proper position of the dens. The tectorial membrane is a continuum of the posterior longitudinal ligament from the body of C2 to the upper surface of the occipital bone anterior to the foramen magnum.

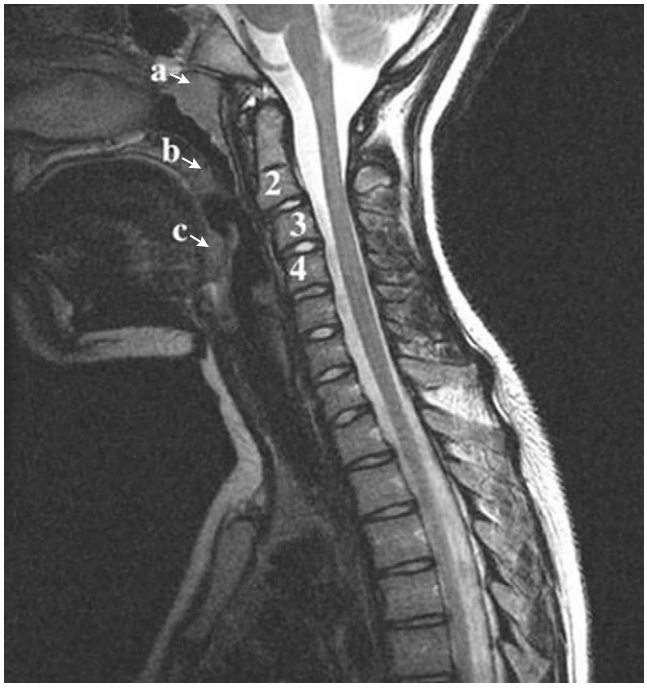

Figure 2-5 Pseudosubluxation at C2-C3. T2-weighted sagittal magnetic resonance cervical spine study demonstrates physiologic anterior displacement of C2 on C3 in a child. Also seen are normal soft tissue masses encroaching on the airway from adenoids (*a*), palatine tonsils (*b*), and lingual tonsils at the base of the tongue (*c*).

The dens ossifies from two vertically oriented centers that fuse by the seventh fetal month. Cranially, a central cleft separates the tips of these ossification centers (Fig. 2-8), and it can mimic a fracture if ossification is incomplete. The ossiculum terminale, the ossification center for the tip of the dens, may be visible on plain films, conventional tomograms, or CT scans and unites with the body by age 11 or 12 years. Failure of the ossiculum terminale to develop or failure to unite with the dens may result in a bulbous cleft dens tip. A nonunited terminal dental ossification center, called the *os terminale*, may be mistaken for a fracture of the odontoid tip.

HYPOPLASIA OF C2. The position and anatomy of the dens with respect to the anterior arch of C1 and the foramen magnum are worthy of attention. Congenital anomalies of the odontoid process, such as hypoplasia, can result in a loss of the buttressing action of the dens during extension and subsequent compression of neural elements. Examples of conditions that are associated with odontoid hypoplasia are the Morquio, Klippel-Feil, and Down syndromes; neurofibromatosis; dwarfism; spondyloepiphyseal dysplasia; osteogenesis imperfecta; and congenital scoliosis.[13,16] Patients with these conditions are

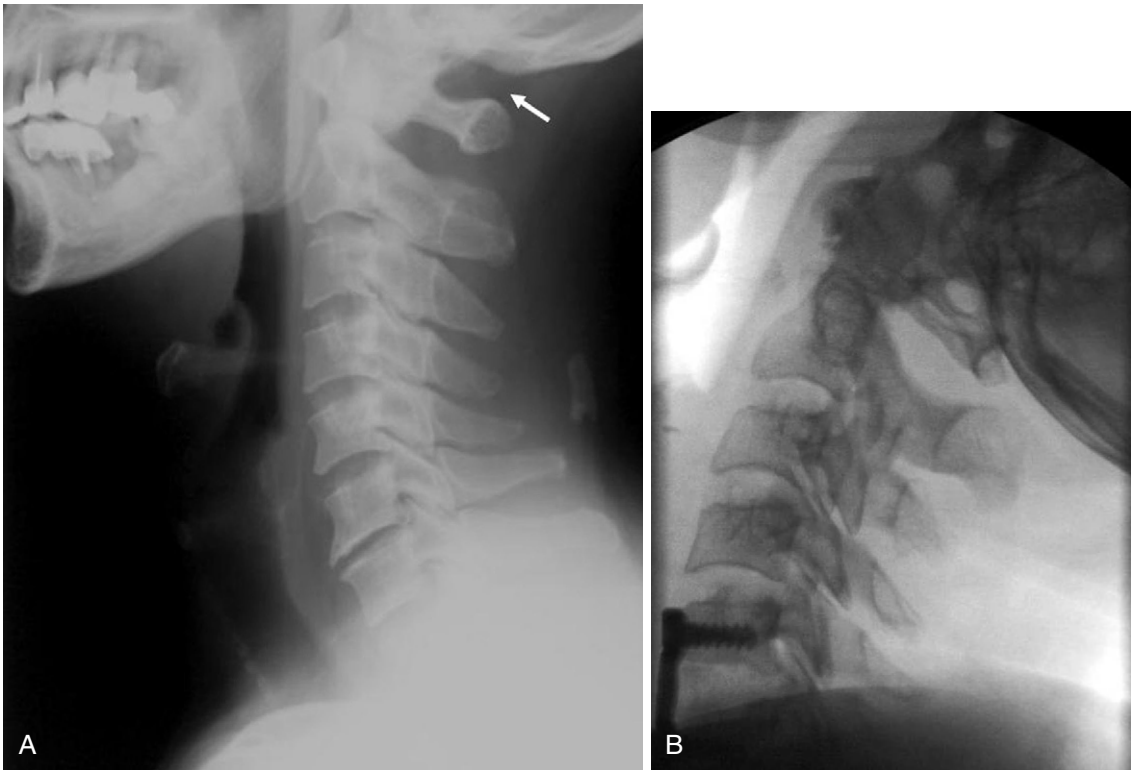

Figure 2-6 Atlanto-occipital distance. **A,** Lateral radiograph of the cervical spine in neutral position; the *arrow* indicates the atlanto-occipital distance. **B,** Lateral radiograph of the cervical spine in hyperextension. Head extension is limited by the abutment of the occiput to the posterior tubercle of C1.

predisposed to atlantoaxial subluxation and craniocervical instability, and hyperextension of the head for intubation should be avoided. In addition, congenital fusion of C2 and C3 (Fig. 2-9), whether occurring as an isolated anomaly or as part of Klippel-Feil syndrome, places added stress at the C1-C2 junction.

c. ACQUIRED PATHOLOGY

CERVICAL SPONDYLOSIS. Cervical spine radiographs are obtained for the evaluation of cervical spondylosis (Fig. 2-10). The hypertrophic bone changes associated with this condition are well depicted on radiographic studies. Large anterior osteophytes that project forward may cause dysphagia and difficult intubation. The bone canal and neural foramina are assessed for stenosis; if stenosis is present, precautions can be taken when hyperextending

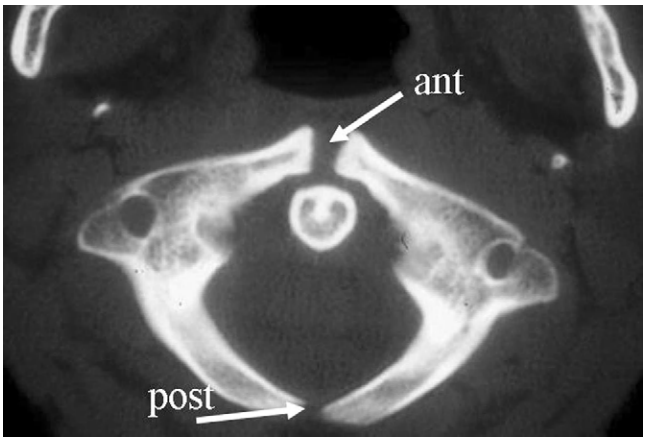

Figure 2-7 Nonfused anterior (*ant*) and posterior (*post*) arches of C1, normal variant (axial computed tomogram with bone algorithm).

Figure 2-8 Cleft dens, normal variant (*arrow*) (axial computed tomogram with bone algorithm).

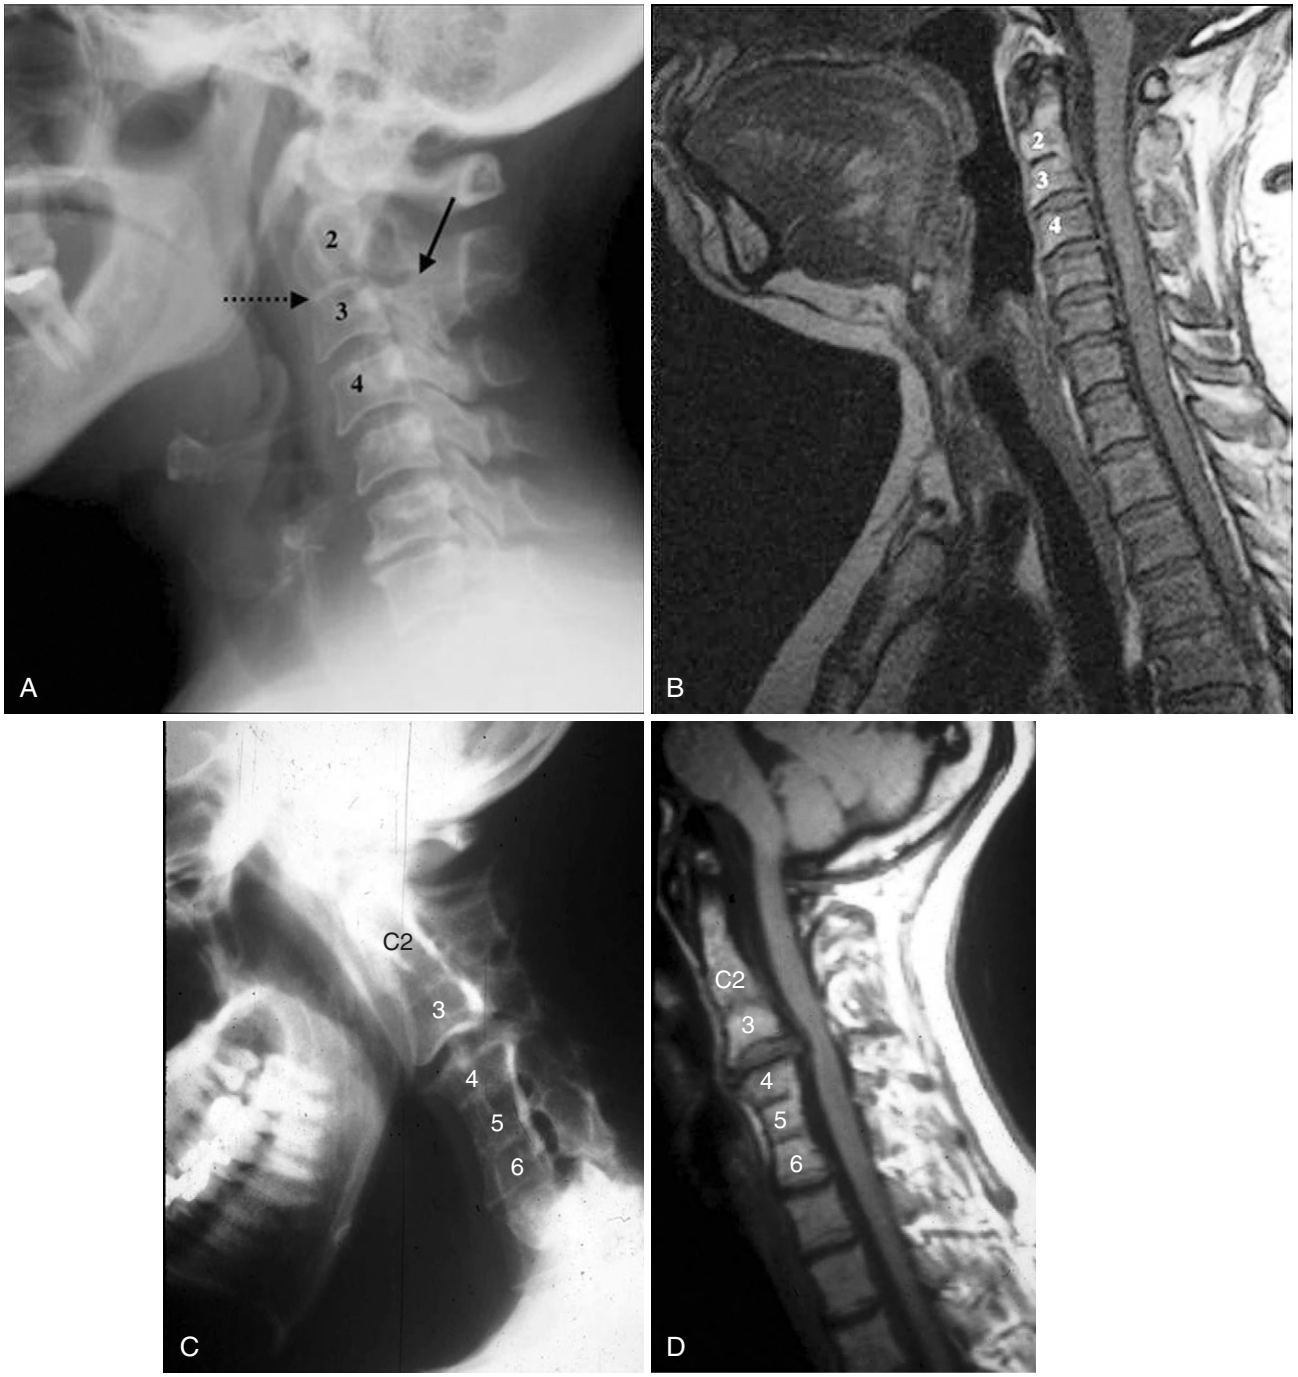

Figure 2-9 Congenital fusion of C2 and C3. Lateral cervical spine radiograph **(A)** and sagittal T1-weighted magnetic resonance (MR) study **(B)** demonstrate fusion of the C2 and C3 vertebral bodies *(dotted arrow)* and their lateral and posterior elements *(solid arrow)*. Lateral radiograph **(C)** and T1-weighted MR cervical spine study **(D)** of a patient with Klippel-Feil syndrome demonstrate fusion of C2 to C3 and fusion of C4 to C6. Not surprisingly, a disc herniation is present at the point of greatest mobility at C3-C4.

the neck and positioning the patient to avoid exacerbation of baseline neurologic symptomatology. Calcification and ossification are well depicted on radiographic studies.

Ossification of the anterior longitudinal ligament and diffuse idiopathic skeletal hyperostosis have been reported as causes of difficult intubation.[17] This can be readily appreciated on plain films. Another condition that may signal difficult intubation is calcification of the stylohyoid ligament (Fig. 2-11).[18]

INFLAMMATORY ARTHROPATHIES. Inflammatory arthropathies involving the atlantoaxial joint with subluxation are classically seen in patients with rheumatoid arthritis or ankylosing spondylitis. However, the underlying causes of atlantoaxial subluxation are quite different in these two entities. Ankylosing spondylitis is characterized by progressive fibrosis and ossification of ligaments and joint capsules. In rheumatoid arthritis, bone erosion, synovial overgrowth, and destruction of the ligaments occur.

Figure 2-10 Cervical spondylosis. Lateral cervical spine radiograph demonstrates large anterior osteophytes *(arrow)* that indent the airway and oropharynx.

Patients with rheumatoid arthritis are not only susceptible to AP subluxation at the C1-C2 junction but also at risk for vertical subluxation of the dens. Whether this condition is referred to as "cranial settling," superior migration of the odontoid process, or basilar invagination, the end result is the same.[12] The odontoid process protrudes above the foramen magnum, narrowing the available space for the spinal cord and potentially leading to cord compression with the slightest head extension (Fig. 2-12).[13]

In response to the effective foreshortening of the spine that occurs secondary to the superior migration of the odontoid process from inflammatory or degenerative disease, there is acquired rotational malalignment between the spine and larynx.[19] The larynx and the trachea, because they are semirigid structures and as a result of the tethering effect of the arch of the aorta as it passes posteriorly over the left main bronchus, are predictably displaced caudally, deviated laterally to the left, rotated to the right, and anteriorly angulated. The effective neck length can be affected by superior migration of the dens, severe spondylosis with loss of disc space, or iatrogenic causes secondary to surgery. The soft tissues of the pharynx become more redundant owing to the relative shortening of the neck, which further obscures the view of the larynx. On laryngoscopy, the vocal cords are rotated clockwise. A rotated airway is suspected when the frontal view of the cervical spine demonstrates a deviated tracheal air column.

d. ANTHROPOLOGIC MEASUREMENTS

Historically, bony landmarks other than the spine that can be appreciated on a lateral cervical spine radiograph have been used in the anesthesia arena to preoperatively predict difficult laryngoscopy and endotracheal intubation on the basis of anatomic factors. Mandibular size, the ratios of the various measurements, and their relationship to the hyoid bone have been proposed as predictors of difficult laryngoscopy (Fig. 2-13).[20] These measurements are meant to reflect the oral capacity, the degree of mouth opening, and the level of larynx.[21,22] It is apparent that the causes of difficult laryngoscopy and endotracheal intubation are multifactorial. Combined with the clinical examination, anatomic measurements and findings assessed by x-ray studies can help alert the anesthesiologist to a potentially difficult airway. In this way, difficult laryngoscopy and endotracheal intubation can be anticipated and not unexpected.

B. Soft Tissue Neck Radiography

1. General Technique, Anatomy, and Basic Interpretation

The lateral cervical spine study with bone and soft tissue technique allows an incidental view of the aerodigestive tract and a gross assessment of the overall patency of the airway. Useful ossified cartilage or bony landmarks of the pharynx and larynx that can be appreciated on the lateral neck radiograph are the hard palate, hyoid bone, thyroid, and cricoid cartilages (Fig. 2-14). The hard palate is a bony landmark used to separate the nasopharynx from the oropharynx. The larynx can be thought of as being suspended from the hyoid bone. Muscles acting on the hyoid bone elevate the larynx and provide the primary protection from aspiration. The largest cartilage in the neck is the thyroid cartilage, which along with the cricoid cartilage acts as a protective shield for the inner larynx. The cricoid cartilage is the only complete cartilaginous ring in the respiratory system. It is located at the level where the larynx ends and the trachea begins.

Normal air-filled structures seen on lateral plain films are the nasopharynx, oropharynx, and hypopharynx. Air in the pharynx outlines the soft palate, uvula, base of the tongue, and nasopharyngeal airway (Fig. 2-15). Any sizable soft tissue pathology results in deviation or effacement of the airway. The tongue constitutes the bulk of the soft tissues at the level of the oropharynx. In children, and sometimes in adults, prominent lymphatic tissues such as adenoids and palatine tonsils may encroach on the nasopharyngeal and oral airways. Lingual tonsils are located at the base of the tongue above the valleculae, which are air-filled pouches between the tongue base and the free margin of the epiglottis.

The epiglottis is an elastic fibrocartilage shaped like a flattened teardrop or leaf that tapers inferiorly and attaches to the thyroid cartilage. The epiglottis tends to be more angular in infants than in adults. During the first several years of life, the larynx changes its position in the neck.[23,24] The free edge of the epiglottis in neonates is found at or near the C1 level, and the cricoid cartilage, representing the most caudal portion of the larynx, is at

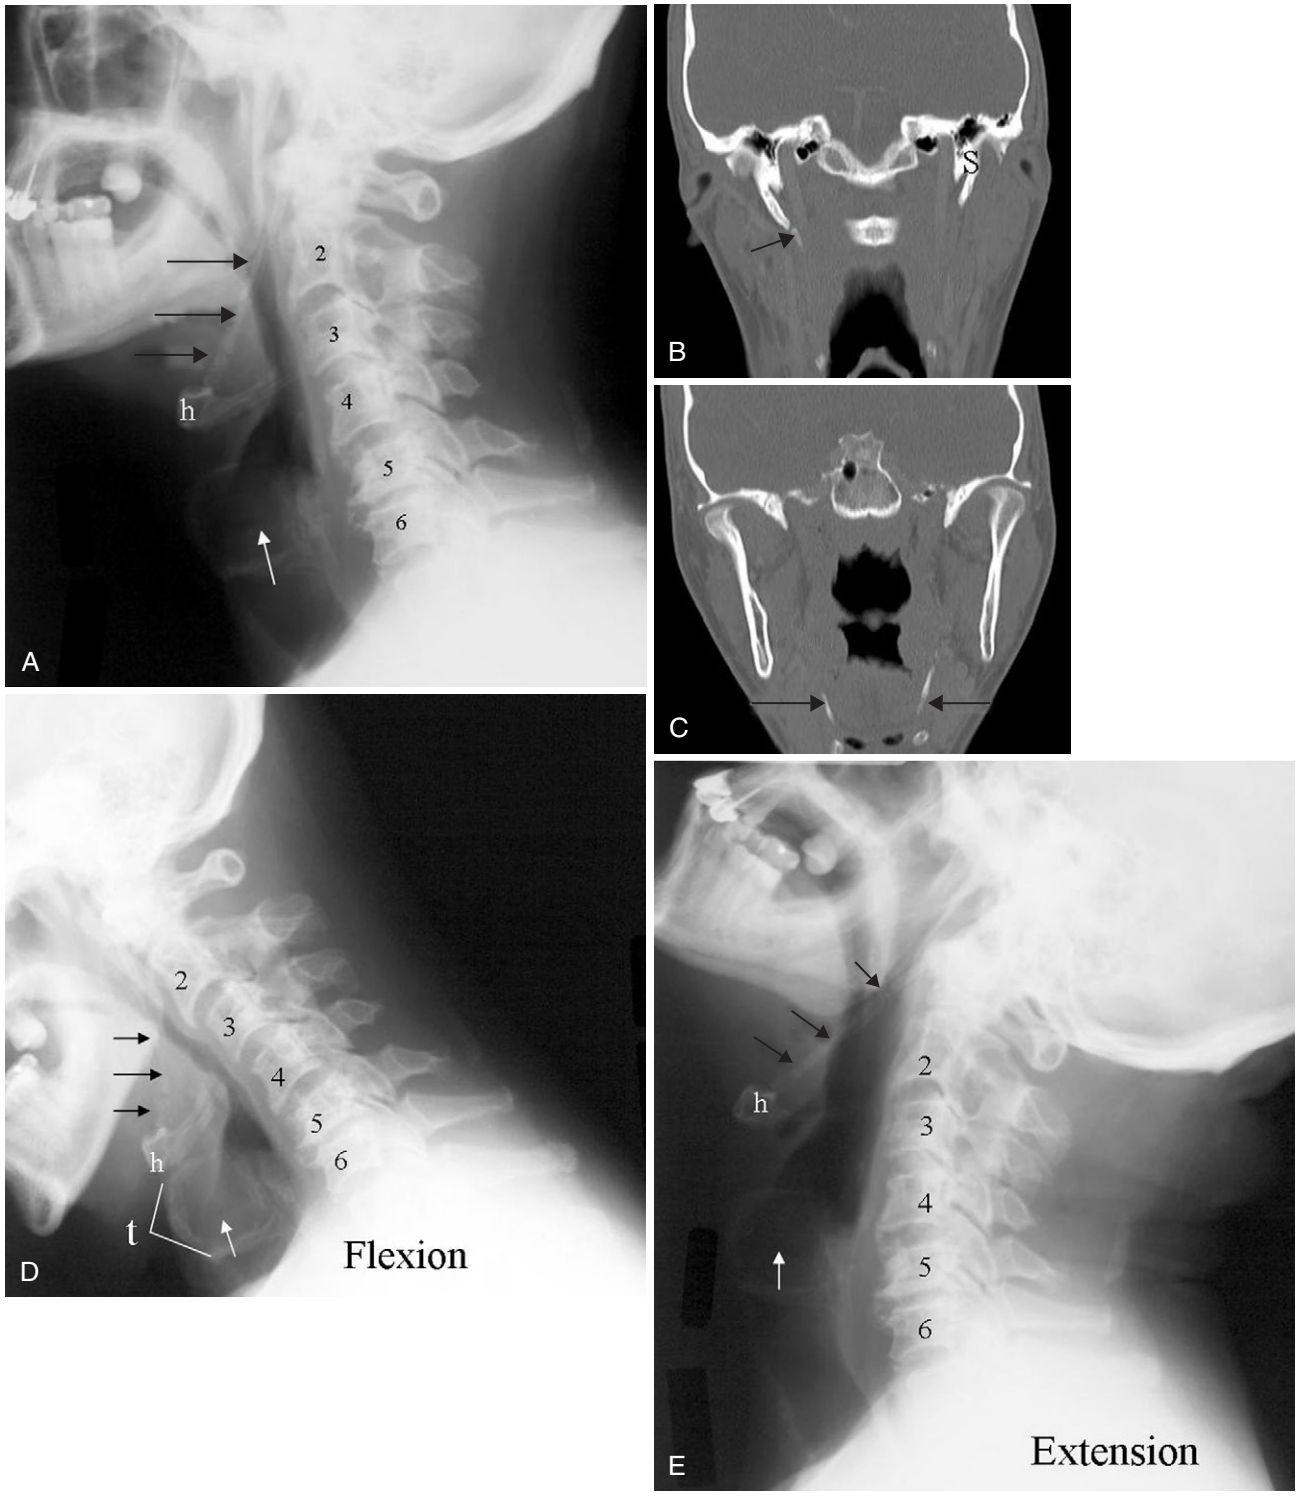

Figure 2-11 Calcified stylohyoid ligament. **A,** Lateral cervical spine radiograph. **B** and **C,** Coronal computed tomograms with bone algorithm. Lateral cervical spine flexion **(D)** and extension **(E)** views are also shown. *Black arrows* indicate calcified stylohyoid ligaments, and *white arrows* indicate the laryngeal ventricle (at the level of the vocal cords). Notice the change in the level of the hyoid bone and vocal cords with flexion and extension of the neck. *h,* Hyoid bone; *s,* styloid process; *t,* calcified thyroid cartilage.

the C4-C5 level. By adolescence, the epiglottis is found at the C2-C3 level and the cricoid is at the C6 level. The adult epiglottis is usually seen at the C3 level, with the cricoid at C6-C7. However, the position of these structures in the normal population varies by at least one vertebral body level.

Sometimes visualized by a cervical spine radiographic study with soft tissue neck technique or on the CT scout view or the MR sagittal view of the neck is a transversely oriented, air-containing lucent stripe, located just below the base of the aryepiglottic folds, which indicates the position of the air-filled laryngeal ventricle

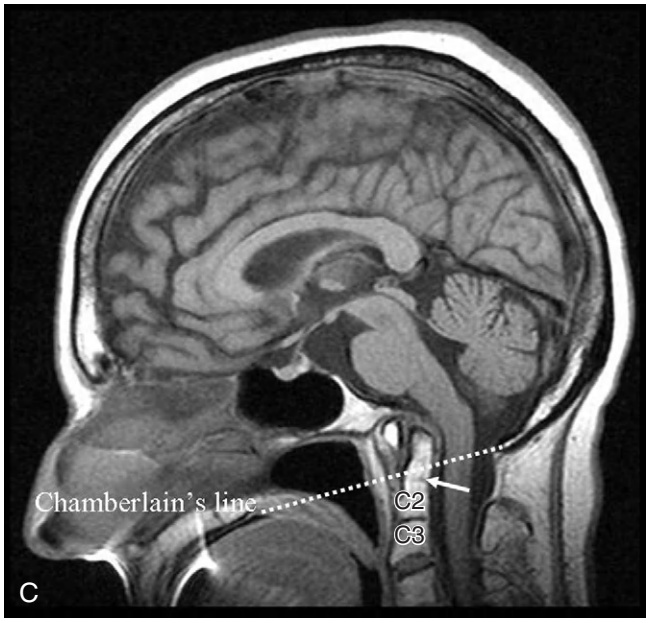

Figure 2-12 Position of the dens in a normal patient **(A),** in a rheumatoid patient **(B),** and in a nonrheumatoid patient with basilar invagination and platybasia **(C). A,** Postmyelography computed tomogram with sagittal reformation demonstrates normal relationship of the dens with respect to the foramen magnum, brainstem, and anterior arch of C1. A normal atlantoaxial distance (AADI) is seen (*arrow*). **B,** T1-weighted sagittal magnetic resonance (MR) study of the cervical spine in a rheumatoid patient with erosion and pannus formation at the atlantoaxial joint resulting in increased AADI (*arrow*), posterior subluxation of the dens, and brainstem compression. **C,** Sagittal MR study of the brain in a nonrheumatoid patient shows normal AADI, but basilar invagination and platybasia have resulted in vertical subluxation of the dens and brainstem compression. The line drawn from the hard palate to the posterior lip of the foramen magnum is Chamberlain's line (*dotted line*); basilar invagination is defined as extension of the odontoid tip 5 mm or more above this line. Also notice the fusion of the C2 and C3 vertebrae. The small, linear, dark line at the mid-C2 level is the subdental synchondrosis (*white arrow*).

(Fig. 2-16). This marks the position of the true vocal cords, which are just below this lucent stripe. Lateral to the aryepiglottic fold is the pyriform sinus of the pharynx. This anterior mucosal recess lies between the posterior third of the thyroid cartilage and the aryepiglottic fold. The extreme lower aspect of the pyriform sinus is situated between the mucosa-covered arytenoids and the mucosa-covered thyroid cartilage, at the level of the true vocal cords. The air column caudally represents the cervical trachea. On the AP view, the false and true vocal cords above and below the laryngeal ventricles may be identified, as well as the subglottic region and the trachea.

The landmarks dorsal to the airway are shadows representing the normal soft tissue structures of the posterior wall of the nasopharynx, which is closely adherent to the anterior surface of the atlas and the axis and extends superiorly to the clivus and inferiorly to become continuous with the soft tissues of the posterior wall of the hypopharynx. The ligaments of the cervicocranium are critical to maintaining stability throughout this region; they are directly involved in the range of motion of the cervicocranium and anteriorly contribute to the prevertebral soft tissue shadow. Superimposed on these deep structures are the constrictor muscles and the mucosa of the posterior pharyngeal wall. The cervicocranial prevertebral soft tissue contour should normally be slightly posteriorly concave rostral to the anterior tubercle of C1, anteriorly convex in front of the anterior tubercle, and

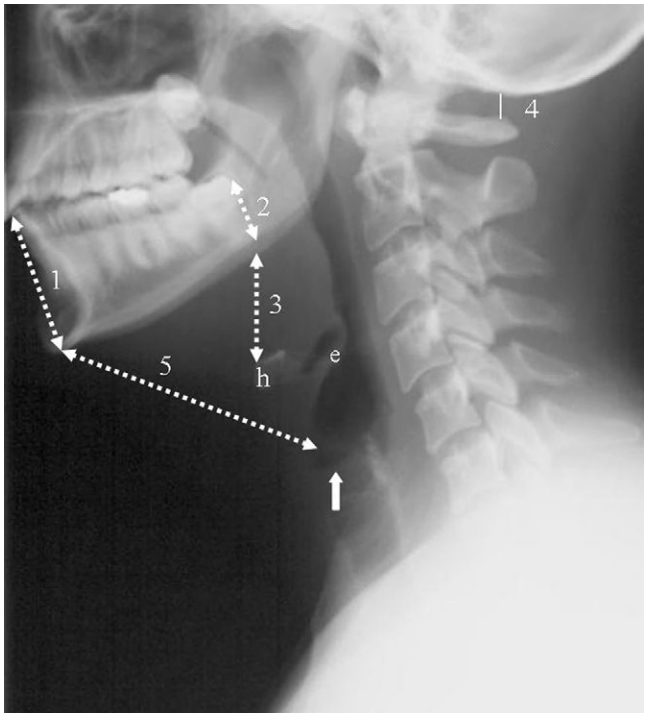

Figure 2-13 Mandibular and hyoid measurements proposed as predictors of difficult laryngoscopy: *1,* Anterior depth of mandible; *2,* posterior depth of mandible; *3,* mandibulohyoid distance; *4,* atlantooccipital distance; *5,* thyromental distance. Laryngeal ventricle (*solid arrow*) demarcates the level of the larynx. The true vocal cords are just below the level of the laryngeal ventricle. *e,* Epiglottis; *h,* hyoid bone.

Figure 2-14 Normal bony landmarks on a lateral cervical spine radiograph: *1,* Hard palate; *2,* hyoid bone; *3,* calcified thyroid cartilage; *4,* calcified cricoid cartilage; *e,* epiglottis.

posteriorly concave caudal to the anterior tubercle, depending on the amount of adenoidal tissue and on the amount of air in the pharynx.

Adenoidal tissue appears as a homogeneous, smoothly lobulated mass of varying size and configuration. The anterior surface of the adenoid is demarcated by air anteriorly and inferiorly. The air inferior to the adenoids allows differentiation between adenoids and the presence of a nasopharyngeal hematoma, which is commonly associated with major midface fractures. In infants and young children, the soft tissues of the cervicocranium are lax and redundant. Depending on the phase of respiration and position, the thickness of the prevertebral soft tissues may appear to increase and may simulate a retropharyngeal hematoma. This finding may extend to the lower cervical spine. This anomaly becomes normal if imaging is repeated with the neck extended and during inspiration. By 8 years of age, the contour of the soft tissues should resemble that seen in adults. Of note, in pediatric patients, sedation may result in a decrease in AP diameter of the pharynx at the level of the palatine tonsils, in the soft palate, and at the level of the epiglottis.

In the lower neck (C3 to C7), the prevertebral soft tissue shadow differs from that in the cervicocranium because of the presence of the beginning of the esophagus and the prevertebral fascial space, which are recognized on the lateral radiograph as a fat stripe. By standard anatomic description, the esophagus begins at the level of C4; however, in vivo, the esophageal ostium may normally be found as high as C3 or as low as C6 and varies with the phase of swallowing and the flexion and extension of the cervical spine.[25] The prevertebral soft tissue thickness, the distance between the posterior pharyngeal

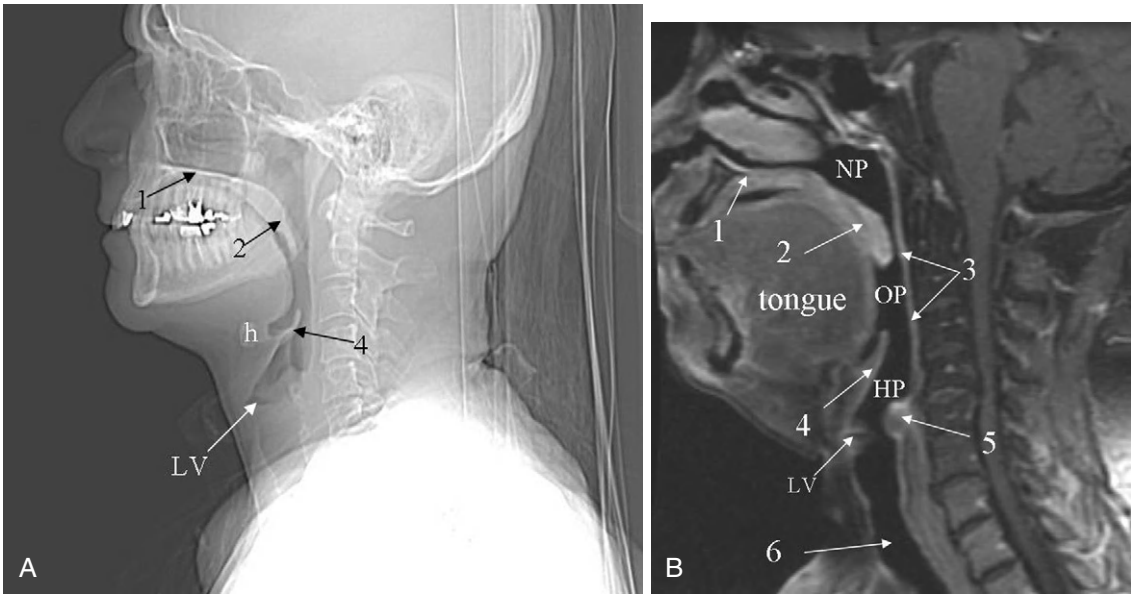

Figure 2-16 Normal airway structures seen on a computed tomographic lateral scout view **(A)** and on a T1-weighted, fat-suppressed post-contrast sagittal magnetic resonance cervical spine study **(B):** *1,* Hard palate; *2,* soft palate and uvula; *3,* retropharyngeal or prevertebral soft tissue; *4,* epiglottis; *5,* arytenoid prominence; *6,* trachea air column; *h,* hyoid bone; *HP,* hypopharynx; *LV,* laryngeal ventricle; *NP,* nasopharynx; *OP,* oropharynx.

air column and the anterior portion of the third or fourth vertebra, should not exceed one half to three quarters of the diameter of the vertebral body. In the opinion of Harris and Mirvis, only the measurement at C3 is valid, and it should not exceed 4 mm (Fig. 2-17).[12]

More caudally, at the cervicothoracic junction, assessment of the prevertebral soft tissues is based on contour rather than actual measurement. This contour should parallel the arch formed by the anterior cortices of the lower cervical and upper thoracic vertebral bodies.

In truth, plain film diagnosis of upper airway diseases has been supplanted by cross-sectional imaging, except in a few situations in which plain radiographic findings are pathognomonic of the disease. Two classic examples of plain film radiologic diagnosis are acute epiglottitis and croup.

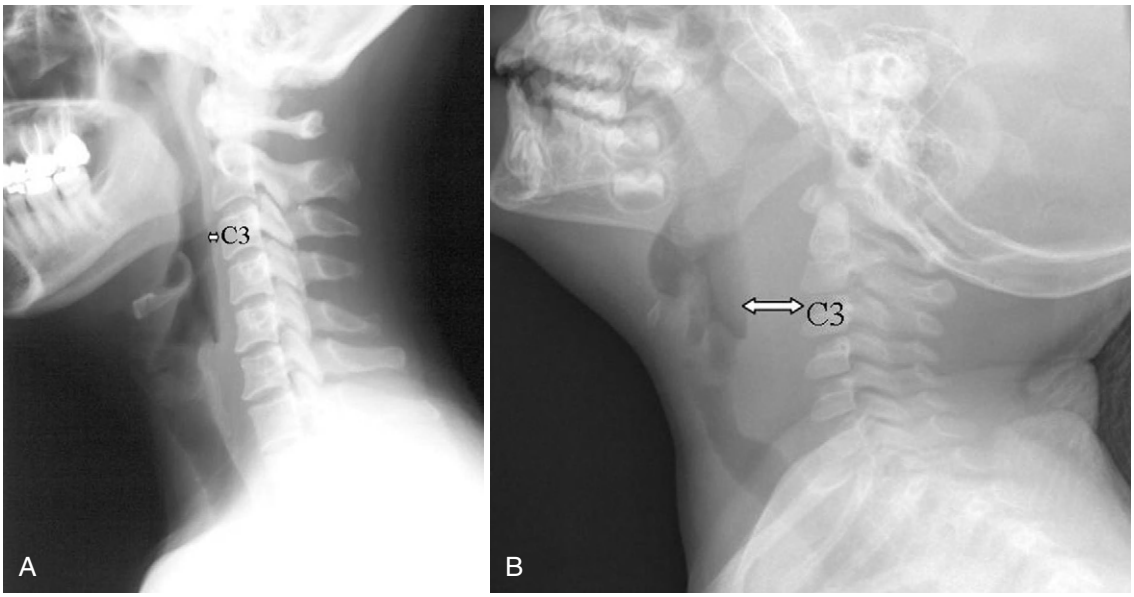

Figure 2-17 Prevertebral soft tissues seen on lateral cervical spine radiographic studies. **A,** Normal adult. **B,** Retropharyngeal abscess in a child. The arrow points to the anteriorly displace airway and increase in the prevertebral space between the vertebral column and the airway. (Courtesy of Dr. Alan Schlesinger, Texas Children's Hospital, Houston, TX.)

2. Classic Plain Film Diagnosis

a. ACUTE EPIGLOTTITIS

In acute epiglottitis (or supraglottitis, a more encompassing term), there is edema and swelling of the epiglottis with or without involvement of the aryepiglottic folds and arytenoids. The offending organism is usually *Haemophilus influenzae*. Airway compromise with a rapidly progressive course requiring emergency tracheostomy is a possibility if the entity goes unrecognized and untreated. In general, the infection is milder in adults than in children. This entity, usually a more indolent form, is making a comeback among patients with acquired immunodeficiency syndrome (AIDS).

The findings on plain film are swelling or enlargement of the epiglottis. On the conventional lateral radiograph of the neck, thickening of the free edge of the epiglottis can be appreciated and is referred to as the "thumb sign" (Fig. 2-18). The width of the adult epiglottis should be less than one third of the AP width of the C4 body. Cross-sectional imaging is superfluous. However, the degree of airway compromise can theoretically be quantified by 3-D reformation.

b. LARYNGOTRACHEOBRONCHITIS OR CROUP

In laryngotracheobronchitis or croup, the subglottic larynx is involved. This condition affects younger children and has a less fulminant course than acute epiglottitis. The swelling of the soft tissues in the subglottic neck can be appreciated on an AP view of the neck (Fig. 2-19). There is usually a long segment narrowing of the glottis and subglottic airway with loss of the normal angle between the vocal cords and the subglottic airway. This has been referred to as the "steeple sign." The hypopharynx is usually dilated because of the airway obstruction distally.

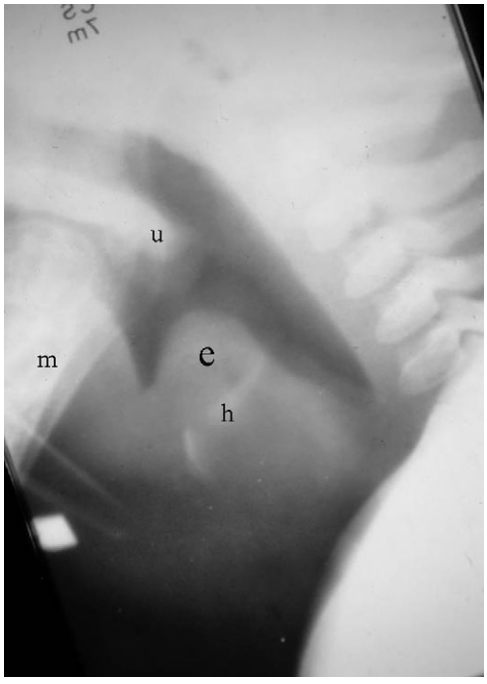

Figure 2-18 Epiglottitis. Lateral soft tissue examination of the neck during flexion in a child demonstrates an enlarged and swollen epiglottis ("thumb sign"). *e,* Epiglottis; *h,* hyoid; *m,* mandible; *u,* uvula. (Courtesy of Dr. Alan Schlesinger, Texas Children's Hospital, Houston.)

Figure 2-19 Croup. Anteroposterior soft tissue neck radiograph in an infant. Long segment narrowing of the subglottic airway is present *(arrow)* with loss of the normal angle between the vocal cords and the subglottic airway ("steeple sign"). (Courtesy of Dr. Alan Schlesinger, Texas Children Hospital, Houston.)

c. FOREIGN BODY

Plain films are usually obtained in the initial assessment of suspected foreign body ingestion. In children, up to 50% of witnessed foreign body ingestions are asymptomatic.[26] Most foreign bodies are radiopaque, but wood and plastic usually are not visible on plain films. The radiopacity of ingested fishbone varies with the type of fish.[27] In the neck, ingested foreign bodies most often lodge at the level of the pyriform sinus (Fig. 2-20).

C. Chest Radiography

1. General Technique

Before the advent of CT, chest radiography was routinely ordered to assess pulmonary and cardiovascular status, and it is still a cost-efficient examination that yields a great deal of general information. The most common views of the chest are the posteroanterior (PA), anteroposterior (AP), and lateral projections (Fig. 2-21). The PA chest view is obtained with the patient's anterior chest closest to the film cassette and the x-ray beam directed from a posterior to an anterior direction. Alternatively, the AP chest view is done with the patient's back closest to the film cassette and the x-ray beam directed in the anterior to posterior direction. The part of the chest closest to the film cassette is the least magnified; therefore, the cardiac silhouette is larger on the AP projection.

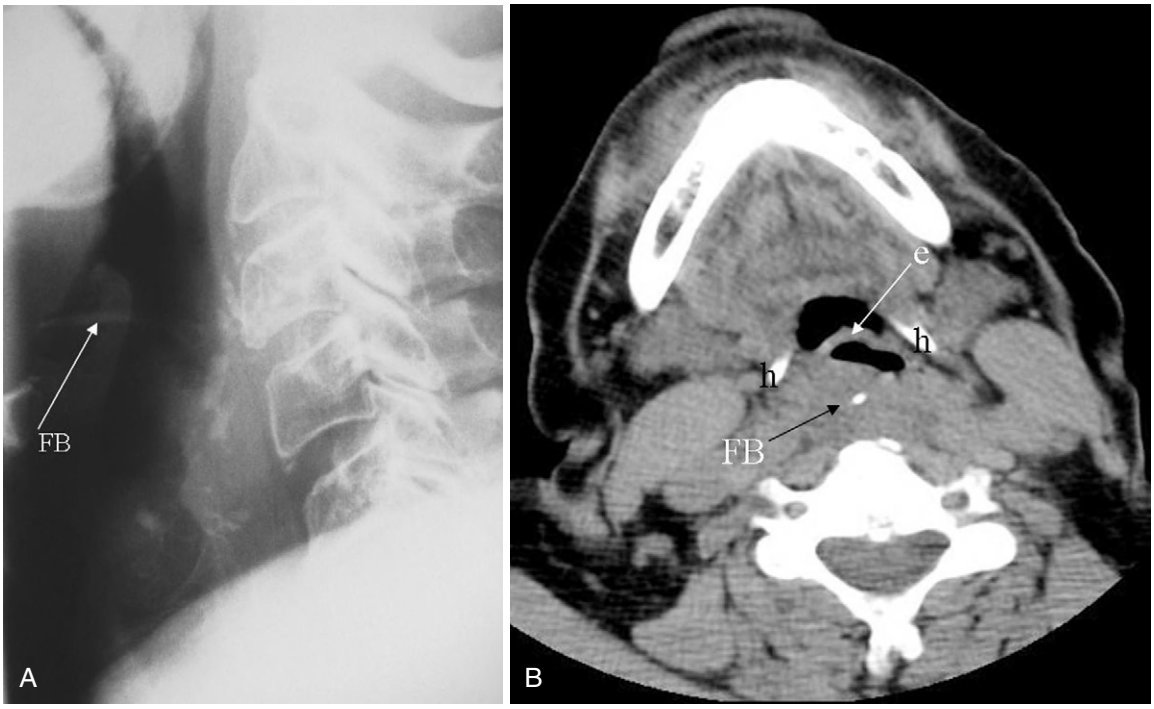

Figure 2-20 Foreign body, fishbone. **A,** Lateral radiograph of the cervical spine. **B,** Axial computed tomogram of the neck in a different patient. *e,* Tip of the epiglottis; *FB,* fishbone; *h,* hyoid.

The lateral projection is most often performed with the patient's left chest closest to the film cassette for better delineation of the structures in the left hemithorax, which is more obscured by the heart on a PA projection.

Other common projections include the oblique, decubitus, and lordotic views. The oblique view is useful for assessing a lesion with respect to other structures in the chest. The decubitus view is helpful to assess whether an apparent elevated hemidiaphragm is being caused by a large subpulmonic pleural effusion. The lordotic view is helpful to look for a suspected small apical pneumothorax, which can also be accentuated on an expiratory-phase examination.

It is useful to train one's eyes to analyze the chest radiograph systematically to cover the details of the chest wall, including the ribs, lungs (field and expansion), and mediastinal structures such as the heart and the outline of the tracheal-bronchial tree. On an adequate inspiratory film, the hemidiaphragms are below the anterior end of the sixth rib, or at least below the 10th posterior rib, and the lung expansion should be symmetrical. The right hemidiaphragm is usually half an interspace higher than the left, which is depressed by the heart (see Fig. 2-21A). Without doubt, the art of chest radiograph interpretation has diminished since the advent of CT, which demonstrates chest pathology with unparalleled clarity. However, chest radiography can still provide a composite survey of the chest at one quick glance. One can easily compare the lung volumes, identify the position of the mediastinum, determine the presence or absence of major airspace disease, and make a gross assessment of the cardiac status.

2. Interpretation of Pertinent Findings

a. LEVEL OF DIAPHRAGM

A high hemidiaphragm implies reduced lung volume, which can result from phrenic nerve paralysis, thoracic conditions causing chest pain that leads to splinting, or extrapulmonic processes such as an enlarged spleen or liver, pancreatitis, or subphrenic abscess. The presumed level of the hemidiaphragm is seen as an edge or transition between the aerated lungs and the opacity of the organs in the abdomen. If the thin leaves of the hemidiaphragm are outlined by air, a pneumoperitoneum should be considered (Fig. 2-22).

b. LUNG AERATION

A well-expanded lung should appear radiographically lucent but be traversed by "lung markings," thin threads of interstitium consisting of septa and arterial, venous, and lymphatic vessels. In most normal individuals, the lungs appear more lucent at the top owing to the distribution of the pulmonary vasculature, the effect of gravity, and overlying soft tissues such as breast tissues. In patients with congestive heart failure or pulmonary venous hypertension, this pattern is reversed, with "cephalization" and engorgement of the pulmonary veins in the upper lung zones (Fig. 2-23; also see Fig. 2-21D). In general, any process such as fluid, pus, or cells that replaces the airspaces of the lungs causes the x-ray beam to be more attenuated, allowing less of the beam to be transmitted through the patient to the film. This causes the affected areas to appear less dark or more opaque (white) on the film. A whole host of diseases could be responsible, depending on the clinical picture, including

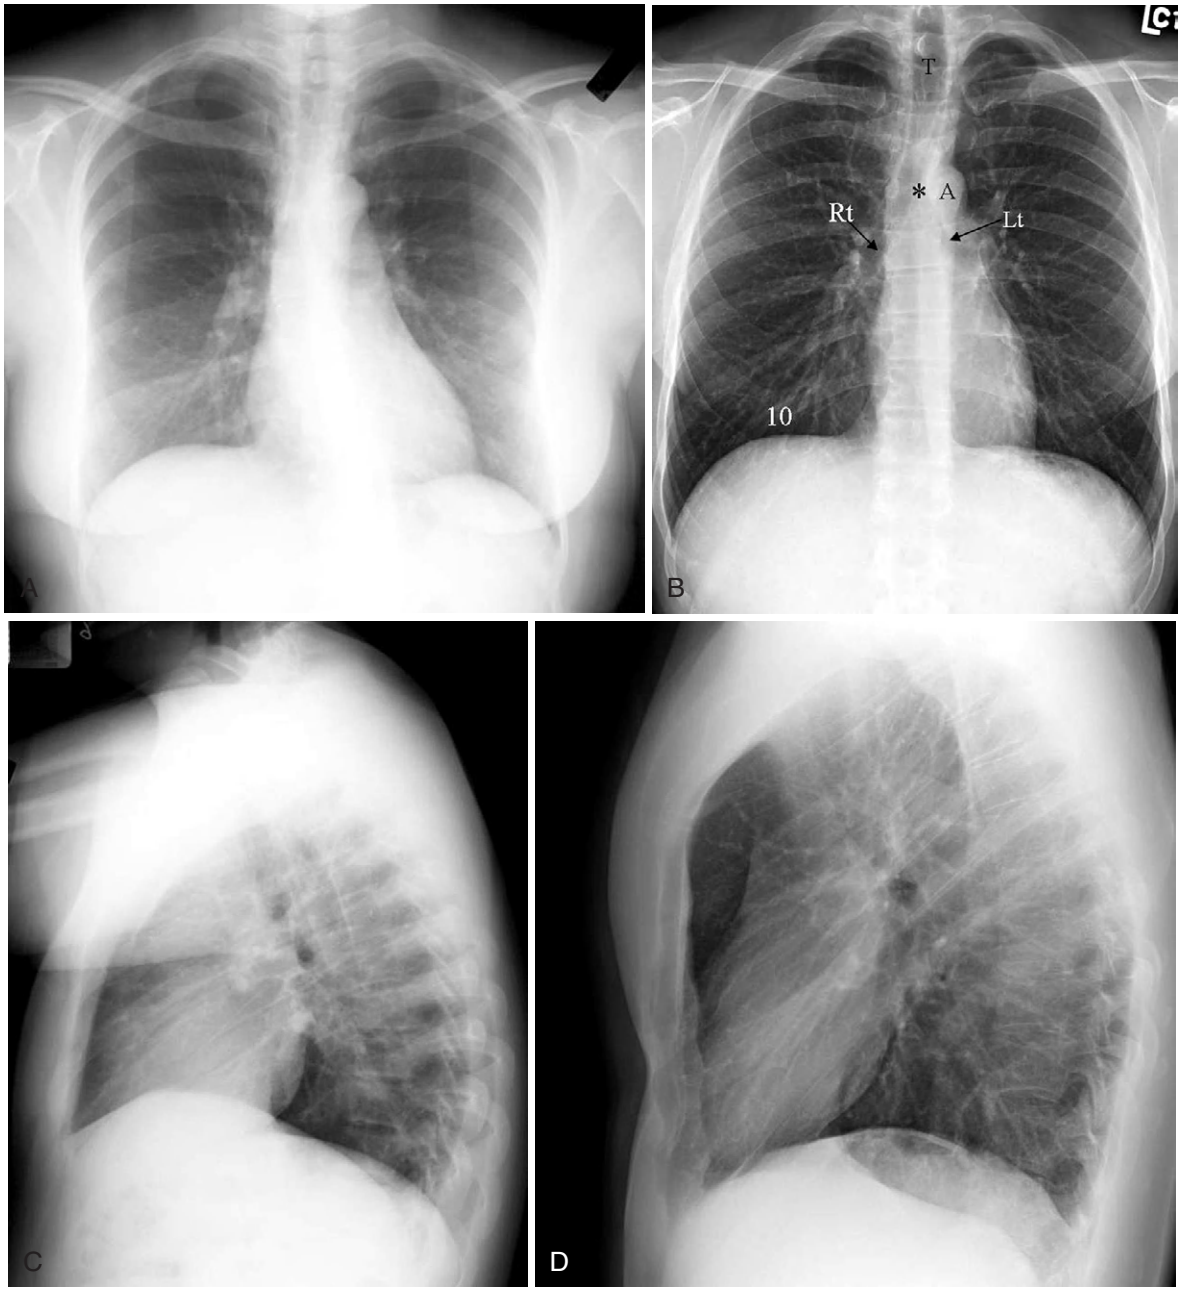

Figure 2-21 Normal posteroanterior (PA) and lateral radiographic studies of the chest. **A,** Normal PA view of a woman with increased density at the lung bases related to overlying breast tissues. **B,** PA view of a man with lucent lungs. **C,** Normal lateral chest view. **D,** Lateral view of a patient with chronic obstructive pulmonary disease showing barrel-shaped chest with increased retrosternal air; notice that the lung base appears progressively more lucent overlying the dorsal spine. The carina is indicated by an *asterisk*. *10,* 10th posterior rib; *A,* aorta; *Lt,* left bronchus; *Rt,* right bronchus; *T,* trachea.

pleural effusion, pulmonary edema, pneumonia, lung mass, lung collapse or atelectasis, lung infarct or contusion, and metastatic disease (Fig. 2-24). The key from an anesthesiologist's point of view is not to make the correct pathologic diagnosis but to note the abnormality, which may affect ventilation, and adjust the anesthetic practice accordingly.

In contrast to the increased opacity of the lung caused by the preceding conditions is a hemithorax, which appears too lucent and devoid of the expected lung markings. Two entities should be considered. Foremost is a *pneumothorax* (Fig. 2-25); if the pneumothorax is large, the collapsed lung will be medially applied against the mediastinum. If the mediastinum is shifted away from the midline, a *tension pneumothorax* may be present, and emergent management is required. More often than not, the cause is the presence in patients with chronic obstructive pulmonary disease of large emphysematous blebs, which are sometimes difficult to differentiate from a moderate to large pneumothorax.

More rare causes of a unilateral lucent lung are pulmonary oligemia with decreased pulmonary flow from a

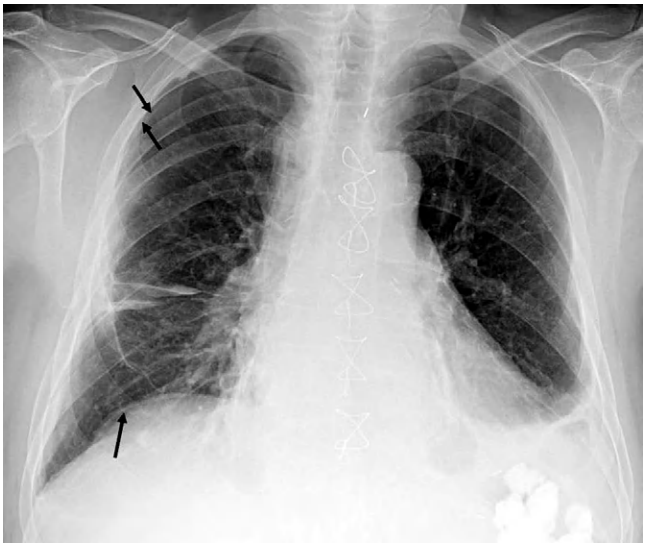

Figure 2-22 Pneumoperitoneum. Postoperative anteroposterior chest radiograph after thoracotomy. *Arrows* in right upper chest demarcate the thin pleural line defining a tiny pneumothorax. *Arrow* in right lower chest indicates the right hemidiaphragm outlined by a small pneumoperitoneum. This patient also has cardiomegaly and right midlung and left basilar atelectasis.

thromboembolism of the right or left pulmonary artery, pulmonary neoplasm, and obstructive hyperinflation. Bilateral lucent lungs are harder to appreciate. These are usually seen in patients with pulmonary stenosis secondary to cyanotic heart disease and right-to-left shunts. A discussion of the pediatric chest and congenital heart and lung diseases is beyond the scope of this chapter.

c. MEDIASTINUM AND HEART

The mediastinum lies centrally in the chest and contains the hila, tracheobronchial tree, heart and great vessels, lymph nodes, esophagus, and thymus. The mediastinum is extrapleural and is outlined by air in the adjacent lungs. Except for the air within the trachea and the main stem bronchi, the remainder of the mediastinal structures are soft tissues or of water density (including the fat) on conventional chest radiographs. Therefore, it is extremely difficult to localize a mediastinal lesion. Traditional pleural reflections or vertical lines have been described for a frontal chest radiograph that, if deviated, would suggest the presence of mediastinal pathology.

Felson proposed a radiologic approach to subdividing the mediastinum on a lateral radiograph into three compartments: anterior, middle, and posterior.[28] The anterior and middle mediastinum are divided by an imaginary line that extends along the back of the heart and front of the trachea. The middle and posterior mediastinal compartments are separated by a similar line that connects a point on each thoracic vertebra about 1 cm behind its anterior margin (Fig. 2-26).[28] Conditions that can be found in each of the compartments of the mediastinum are logically based on the anatomic structures found within the compartment. For example, tracheal, esophageal, and thyroid lesions would lie in the middle mediastinum. Neurogenic tumors and spinal problems would be in the posterior mediastinum. Cardiac and thymic lesions would occupy the anterior mediastinum. Certain diseases such as lymph node disorders, lymphoma, and aortic aneurysms may arise in any or all three compartments. Many modifications to the divisions of the mediastinum have been proposed.[29]

The great vessels and the heart should be centrally located on the AP view of the mediastinum. The aortic knob is usually on the left, and the cardiothoracic ratio on the AP view is roughly less than 50%. The hila are composed of the pulmonary arteries and their main branches, the upper lobe pulmonary veins, the major bronchi, and the lymph glands (Fig. 2-27).

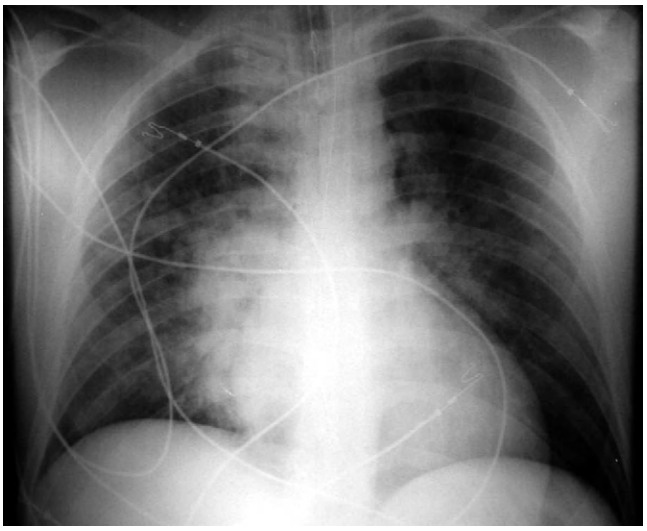

Figure 2-23 Congestive heart failure. Anteroposterior chest radiograph demonstrates engorgement of the perihilar vasculature. An endotracheal tube and a nasogastric tube are in place.

d. TRACHEOBRONCHIAL TREE

The positions of the trachea, carina, and main stem bronchi are outlined by air. The carinal bifurcation angle is typically 60 to 75 degrees.[29] The right main stem bronchus has a steeper angle than the left (see Fig. 2-21); it usually branches off the trachea at an angle of 25 to 30 degrees, whereas the left main stem bronchus leaves the trachea at a 45- to 50-degree angle. The trachea is a tubular structure that extends from the cricoid cartilage to the carina, which is located approximately at the T5 level. C-shaped hyaline cartilage rings, which can calcify with age, outline the trachea anteriorly. The posterior trachea is membranous. The mean transverse diameter of the trachea is approximately 15 mm for women and 18 mm for men.[29] The trachea in the cervical region is midline, but it is deviated to the right in the thorax.

ENDOTRACHEAL TUBE POSITIONING. Adequate positioning of an endotracheal tube (ETT) in an intubated patient is usually documented by obtaining a chest radiograph. The tip should be intrathoracic and at a distance above the carina that ensures equal ventilation to both lungs. One should evaluate the position of the ETT with the patient's head and neck in a neutral position; however, this may not be possible in an intensive care unit setting. The tip

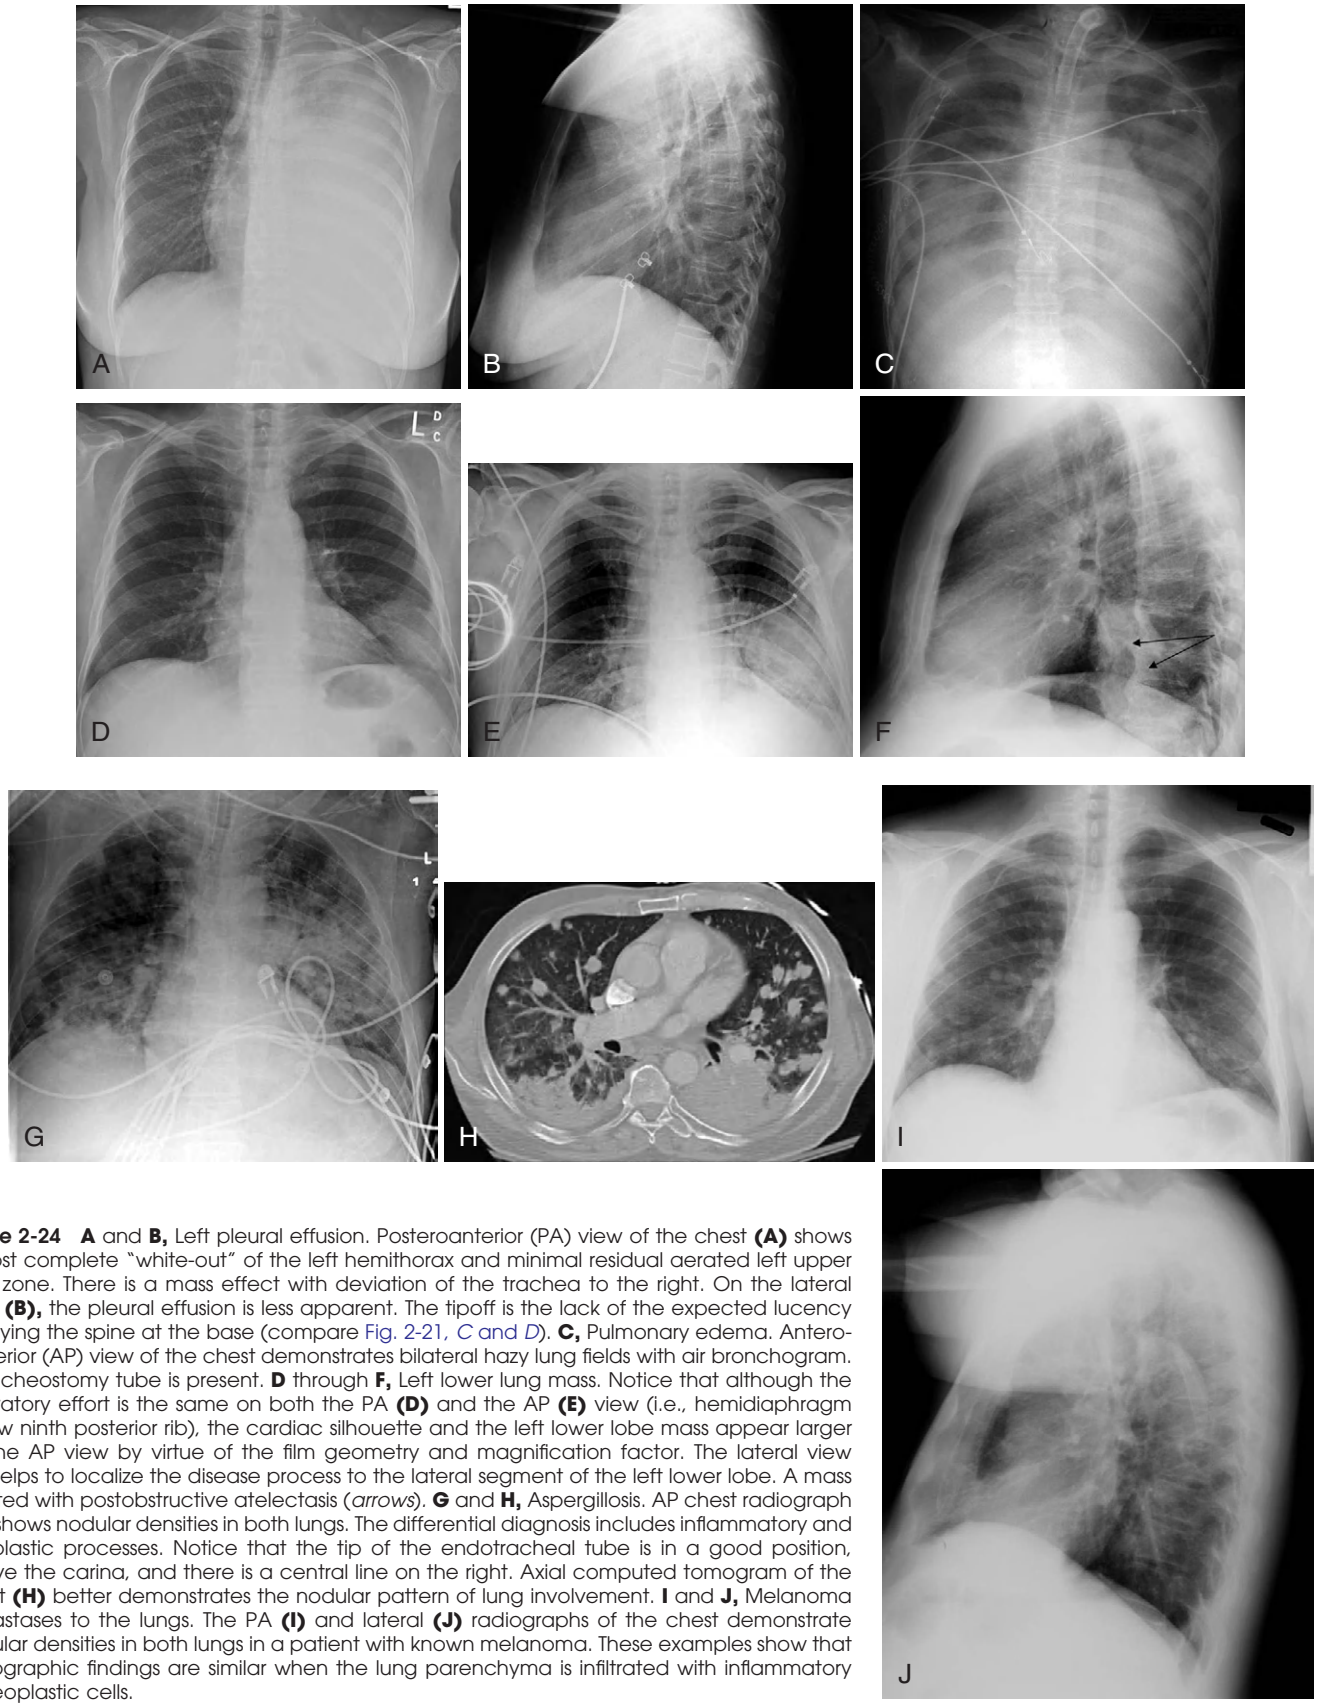

Figure 2-24 **A** and **B,** Left pleural effusion. Posteroanterior (PA) view of the chest **(A)** shows almost complete "white-out" of the left hemithorax and minimal residual aerated left upper lung zone. There is a mass effect with deviation of the trachea to the right. On the lateral view **(B),** the pleural effusion is less apparent. The tipoff is the lack of the expected lucency overlying the spine at the base (compare Fig. 2-21, *C* and *D*). **C,** Pulmonary edema. Antero-posterior (AP) view of the chest demonstrates bilateral hazy lung fields with air bronchogram. A tracheostomy tube is present. **D** through **F,** Left lower lung mass. Notice that although the inspiratory effort is the same on both the PA **(D)** and the AP **(E)** view (i.e., hemidiaphragm below ninth posterior rib), the cardiac silhouette and the left lower lobe mass appear larger on the AP view by virtue of the film geometry and magnification factor. The lateral view **(F)** helps to localize the disease process to the lateral segment of the left lower lobe. A mass is noted with postobstructive atelectasis (*arrows*). **G** and **H,** Aspergillosis. AP chest radiograph **(G)** shows nodular densities in both lungs. The differential diagnosis includes inflammatory and neoplastic processes. Notice that the tip of the endotracheal tube is in a good position, above the carina, and there is a central line on the right. Axial computed tomogram of the chest **(H)** better demonstrates the nodular pattern of lung involvement. **I** and **J,** Melanoma metastases to the lungs. The PA **(I)** and lateral **(J)** radiographs of the chest demonstrate nodular densities in both lungs in a patient with known melanoma. These examples show that radiographic findings are similar when the lung parenchyma is infiltrated with inflammatory or neoplastic cells.

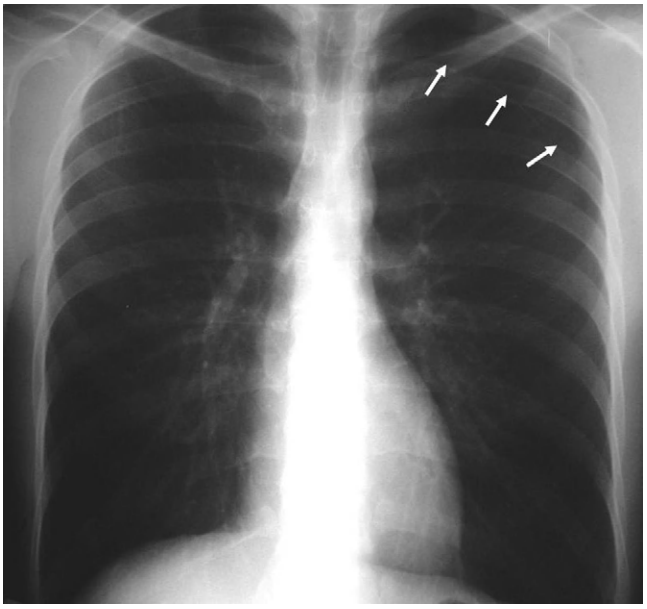

Figure 2-25 Pneumothorax. Posteroanterior chest radiograph in a young man with spontaneous pneumothorax *(arrows)*. (Courtesy of Dr. John Pagani, IRPA, Houston.)

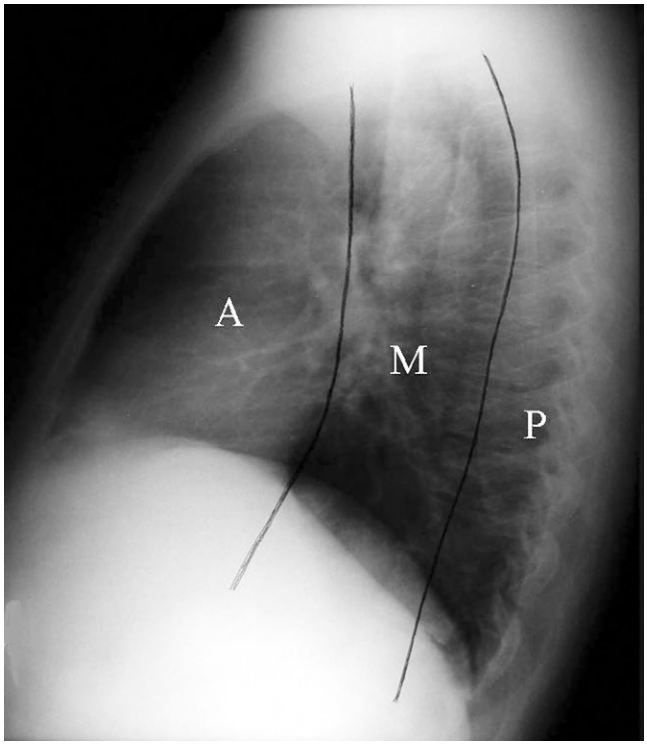

Figure 2-26 Mediastinal compartments. Lateral chest radiograph with imaginary lines drawn on the film to demonstrate the three mediastinal compartments. The anterior (*A*) and middle (*M*) mediastinal compartments are divided by a line extending along the back of the heart and front of the trachea. A line connecting each thoracic vertebra about 1 cm behind its anterior margin separates the middle from the posterior (*P*) mediastinal compartment.

of the ETT may move up or down by 1 to 2 cm with flexion or extension of the head. Rotation of the head and neck usually results in ascent of the tip.[29] The optimal position of the tip of the ETT is 3 to 5 cm above the carina, to allow enough latitude in movement of the tube with turning of the patient's head, and the inflated cuff should be below the vocal cords (Fig. 2-28).[30] Malpositioning of the cuff at the level of the vocal cords or pharynx increases the risk of aspiration. Overinflation of the cuff at the level of the vocal cords may lead to necrosis.[31] The inflated cuff of the ETT should fill the tracheal air column without changing its contour. Overall, the ETT size should be about two thirds of the diameter of the tracheal lumen. At times, the tip of the ETT extends beyond the carina, resulting in intubation of the right main bronchus, which can be detected by asymmetrical breath sounds or on chest radiographs. If this condition goes unrecognized, atelectasis in the underaerated lung may result (Fig. 2-29).

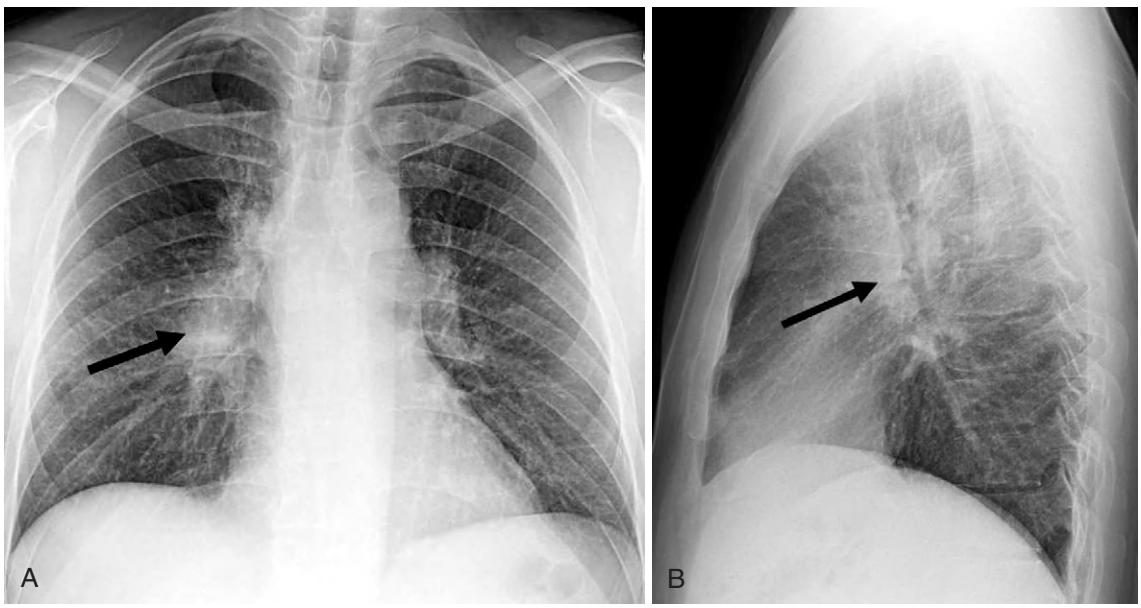

Figure 2-27 Right hilar mass and nodes *(arrows)*. Posteroanterior **(A)** and lateral **(B)** chest radiographs.

Figure 2-28 Anteroposterior (AP) portable chest radiograph. Most chest examinations in the intensive care unit are obtained with a portable x-ray machine in the AP projection. Notice the acceptable position of the ETT above the carina. A right subclavian central venous line is present with the tip in the superior vena cava. Multiple cables attached to monitors are crossing the chest.

NASOGASTRIC TUBE POSITIONING. If a nasogastric or orogastric tube is in place, it should more or less course inferiorly and to the left, toward the fundus of the stomach in the left upper quadrant, except for the unusual case of situs inversus. If the gastric tube has inadvertently intubated the bronchus, the errant course of the tube will be evident on the plain film.

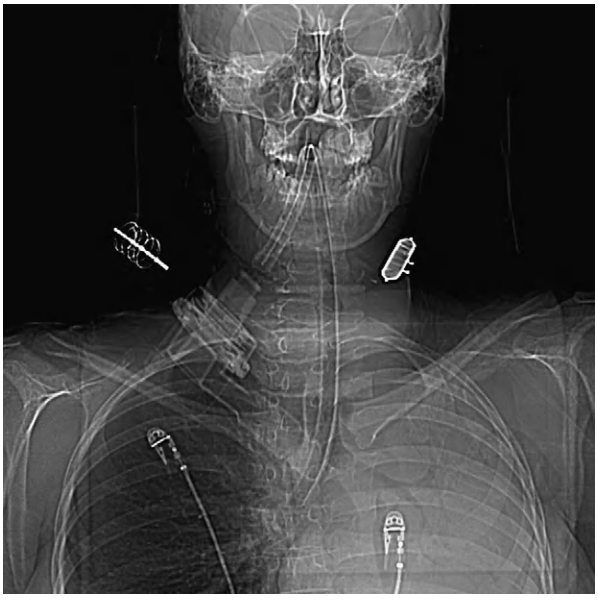

Figure 2-29 Endotracheal tube (ETT) in right main bronchus. Anteroposterior (AP) computed tomographic (CT) scout view obtained for CT soft tissue neck study reveals errant ETT in right main bronchus resulting in nonaeration of the left lung (white lung).

IV. CROSS-SECTIONAL ANATOMY AND PATHOLOGY: COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

The anatomy of the airway from the nasal cavity to the lungs is exceptionally well depicted by CT, and MRI can be a useful complement in the evaluation of these regions. MRI is superior to CT in the evaluation of tumor infiltration of soft tissues but lacks the ability to depict bone erosions secondary to tumor because cortical bone gives no MRI signal. Infiltration of the bone marrow and gross destruction of bone are appreciable on MRI. MRI takes longer to perform and therefore is susceptible to motion artifacts, including breathing and vascular pulsation artifacts, whereas spiral CT technology allows the entire neck or thorax to be scanned in a single breath-hold. Both techniques allow either direct scanning or 3-D volume acquisition with multiplanar postprocessing and reformation capabilities.

A. Midface

The development of the face, nose, and sinuses is complex but systematic. Therefore, the occurrence of congenital lesions and malformations in these areas is quite logical and predictable, depending on the time of prenatal insult. Face, nose, and sinus development is temporally and spatially related to the development of the optic nerve, globe, and corpus callosum, and this accounts for the frequency of concurrent anomalies in these regions.

The major features of the face develop during the fourth to eighth week of gestation as a result of the growth, migration, and merging of a number of processes bordering on the stomodeum, which is a slitlike invagination of the ectoderm that marks the location of the mouth. At the fourth gestational week, one unpaired and two paired prominences, derivatives of the first branchial arch, can be identified bordering the stomodeum. The unpaired median frontonasal prominence is located superiorly, the paired maxillary processes are lateral, and the paired mandibular processes are inferior.[32] The various cleft lip and palate and cleft face syndromes can be explained by the failure of these different processes to grow, migrate, and merge properly.[32]

Relevant to anesthetic practice is an awareness that midline craniofacial dysraphism can be categorized into two groups: an inferior group, in which the clefting primarily affects the upper lip, with or without the nose, and a superior group, in which the clefting primarily affects the nose, with or without involvement of the forehead and the upper lip. It is the inferior group that is associated with basal encephalocele (i.e., sphenoidal, sphenoethmoid, and ethmoid encephaloceles), callosal agenesis, and optic nerve dysplasias. The superior group is characterized by hypertelorism, a broad nasal root, and a median cleft nose, with or without a median cleft upper lip. The superior group is also associated with an increased incidence of frontonasal and intraorbital encephaloceles (Fig. 2-30).[32] The presence of these phenotypic features should alert the anesthesiologist to the possibility of an encephalocele intruding into the nasal cavity, and caution

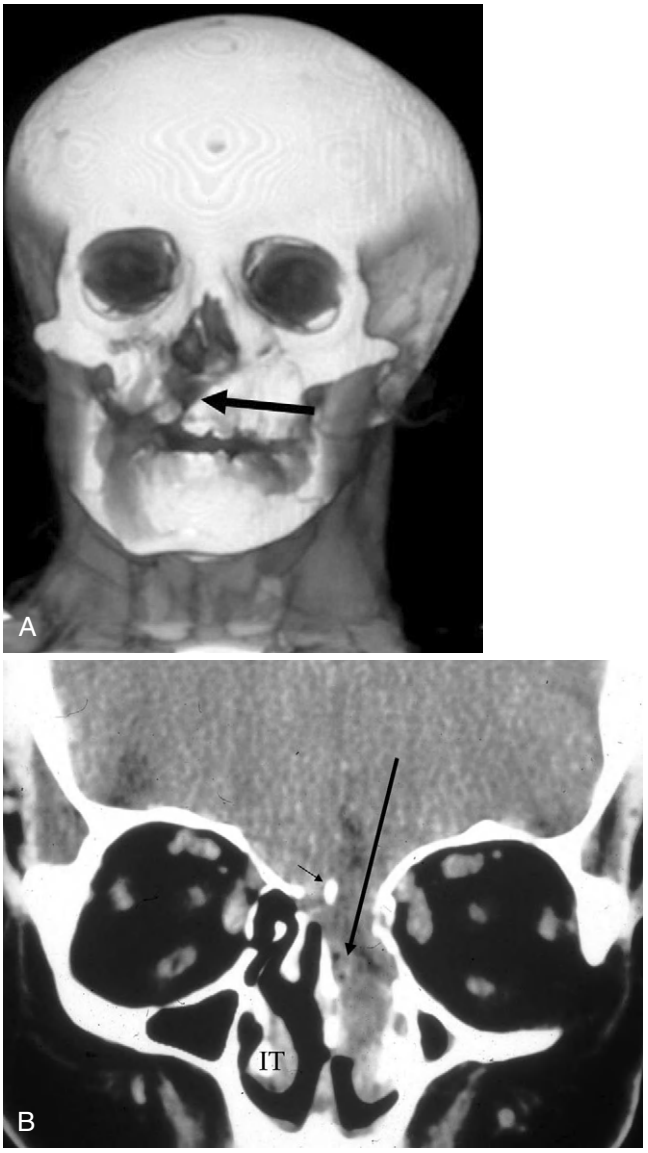

Figure 2-30 **A,** Cleft lip. Three-dimensional computed tomographic (CT) reconstruction demonstrates a bone cleft of the maxilla (*arrow*) resulting in communication between the nasal and oral cavities. **B,** Frontonasal encephalocele. Coronal CT demonstrates dehiscent left cribriform plate with soft tissue extending into the nasal cavity. The *long arrow* indicates the frontonasal encephalocele, and the *short arrow* indicates the crista galli. *IT,* Inferior turbinate.

can then be exercised when inserting a nasogastric tube (NGT) or nasal airway.

B. Nose and Nasal Cavity

The nose is pyramidal in shape and includes both the external apparatus and the nasal cavity. It is one of the two gateways to the aerodigestive tract. Most of the airflow to the lungs occurs through the nasal cavity. Mouth breathing is not physiologic; it is a learned action. The three physiologic functions of the nose are respiration, defense, and olfaction.[33] In respiration, airflow is modified by nasal resistance at the level of the nares and the nasal valves to allow efficient pulmonary ventilation. A major portion of the nasal airflow passes through the middle meatus. The passage of inspired air through the nasal cavity allows humidification and warming.[33]

1. Imaging Anatomy Overview

Cross-sectional imaging of the nose and paranasal sinuses allows one to examine the air passage from the nares to the nasopharynx. A dedicated examination of the nose and sinuses yields detailed information about this region (Fig. 2-31). Incidental imaging of the sinuses and airway on a routine brain or spine study often allows general assessment of the airway that might be useful in the overall preoperative assessment of a patient (Fig. 2-32).

The bony housing of the nose and the nasal cavities is well depicted by CT. By changing the viewing windows and level, one can delineate the soft tissue component to better advantage. The nasal cavity is divided into two cavities separated by the nasal septum. The roof of the nasal cavity is formed by the cribriform plate of the ethmoid. The hard palate serves as the floor. Protruding into the nasal cavities along the lateral walls are mucosa-covered, scroll-like projections of bone called the inferior, middle, superior, and supreme turbinates or conchae. The supreme turbinates are seen in only 60% of people.[33] The air space beneath and lateral to each turbinate, into which the paranasal sinuses drain, is referred to as the meatus.

In addition to clearly defining the anatomy, cross-sectional imaging can also be a window to viewing physiologic function, in particular the nasal cycle (the cyclic variation in the thickness of the mucosa of the nasal cavity), which repeats every 20 minutes to 6 hours.[33,34] This physiologic change is manifested as alternating side-to-side swelling of the turbinates.

2. Pertinent Imaging Pathology

a. CONGENITAL AND DEVELOPMENTAL ABNORMALITIES

CONGENITAL CHOANAL STENOSIS AND ATRESIA. The development of the nasal cavity is complete by the second month of fetal life. From the second to the sixth month of prenatal life, the nostrils are closed by epithelial plugs that later recanalize to establish a patent nasal cavity. Failure of this process could account for the congenital stenoses and atresias that cause nasal airway obstruction and are often seen in conjunction with craniofacial anomalies.[32]

Congenital nasal airway obstruction most commonly occurs in the posterior nasal cavity secondary to choanal atresia (Fig. 2-33). The atresias may be bony, membranous, or both. At birth, severe respiratory difficulty and inability to insert an NGT more than 3 to 4 cm into the nose despite the presence of air in the trachea and lungs suggests the diagnosis of atresia. However, most atresias are unilateral, and may remain undetected until late in life.

Stenosis of the posterior nasal cavity (choanae) is probably more common than true atresia. About 75% of children with bilateral choanal stenosis or atresia have other congenital abnormalities such as Apert's syndrome, Treacher Collins syndrome, or fetal alcohol syndrome. Because the pathology is usually manifested as bony overgrowth, CT is the imaging modality of choice. The major feature of atresia is an abnormal widening of the vomer

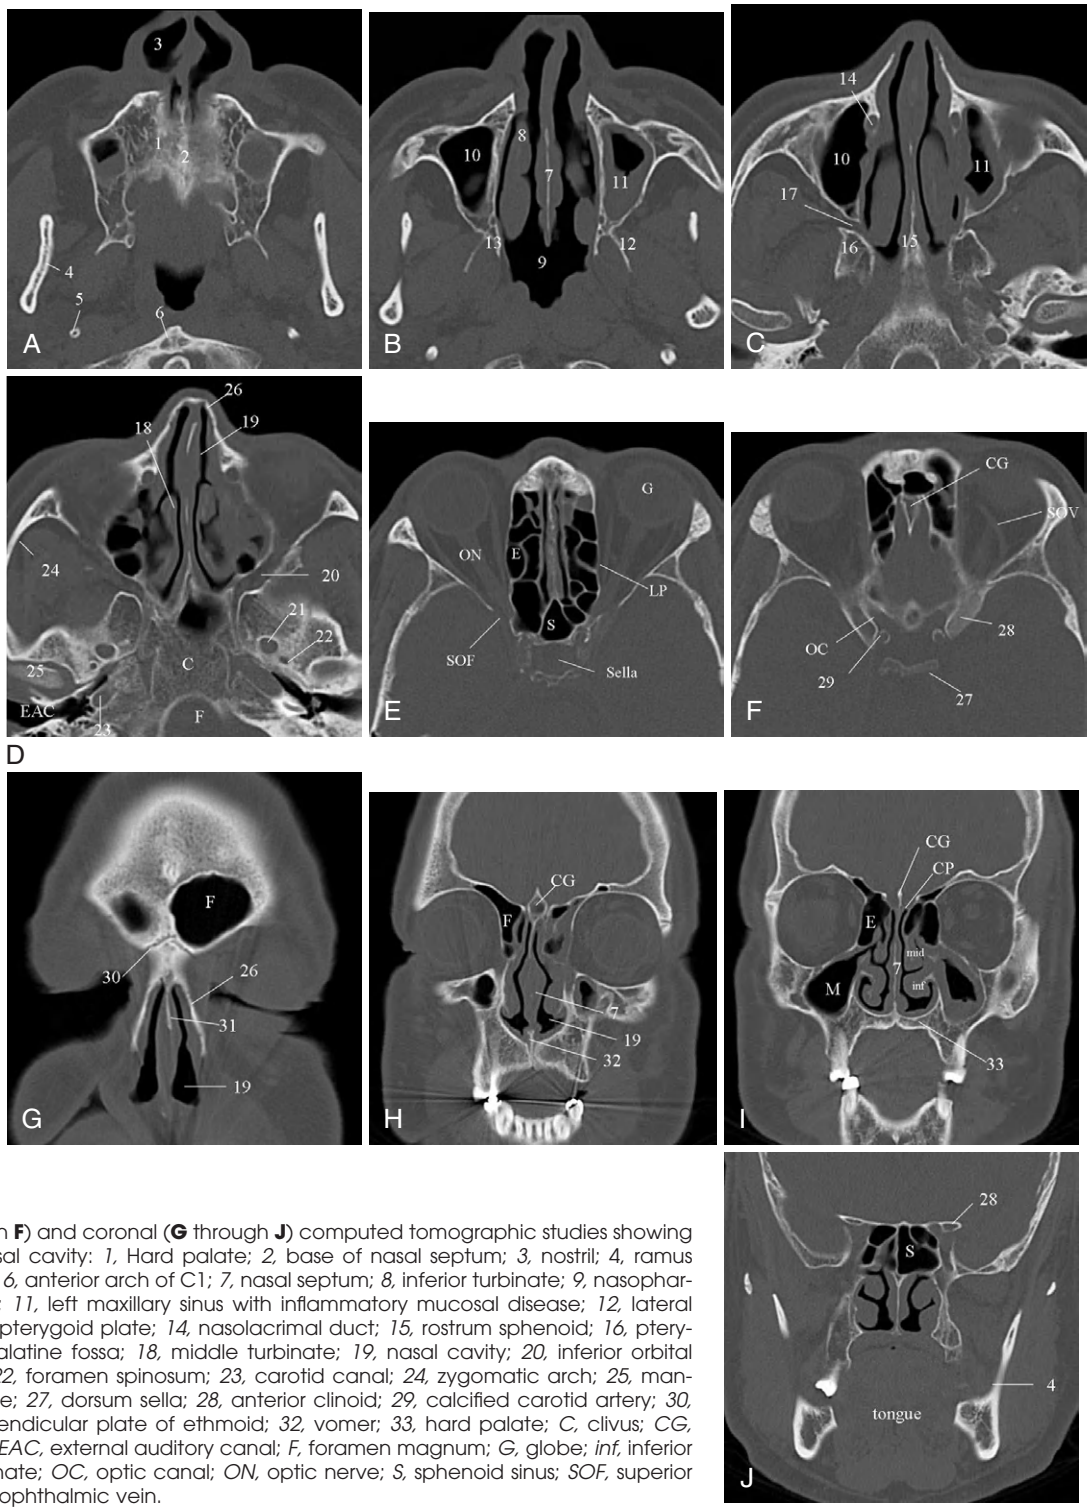

Figure 2-31 Axial (**A** through **F**) and coronal (**G** through **J**) computed tomographic studies showing the anatomy of the sinonasal cavity: *1,* Hard palate; *2,* base of nasal septum; *3,* nostril; *4,* ramus mandible; *5,* styloid process; *6,* anterior arch of C1; *7,* nasal septum; *8,* inferior turbinate; *9,* nasopharynx; *10,* right maxillary sinus; *11,* left maxillary sinus with inflammatory mucosal disease; *12,* lateral pterygoid plate; *13,* medial pterygoid plate; *14,* nasolacrimal duct; *15,* rostrum sphenoid; *16,* pterygoid process; *17,* pterygopalatine fossa; *18,* middle turbinate; *19,* nasal cavity; *20,* inferior orbital fissure; *21,* foramen ovale; *22,* foramen spinosum; *23,* carotid canal; *24,* zygomatic arch; *25,* mandibular head; *26,* nasal bone; *27,* dorsum sella; *28,* anterior clinoid; *29,* calcified carotid artery; *30,* nasofrontal suture; *31,* perpendicular plate of ethmoid; *32,* vomer; *33,* hard palate; *C,* clivus; *CG,* crista galli; *E,* ethmoid sinus; *EAC,* external auditory canal; *F,* foramen magnum; *G,* globe; *inf,* inferior turbinate; *mid,* middle turbinate; *OC,* optic canal; *ON,* optic nerve; *S,* sphenoid sinus; *SOF,* superior orbital fissure; *SOV,* superior ophthalmic vein.

(Fig. 2-34). Nasal airway obstruction may also result from rhinitis or turbinate hypertrophy.

DEVIATED SEPTUM. The cartilage of the nasal capsule, which is the foundation of the upper part of the face, eventually becomes ossified or atrophied with age. All that remains of the cartilage of the nasal capsule in adults is the anterior part of the nasal septum and the alar cartilages that surround the nostrils. The midline septal cartilage is continuous with the cartilaginous skull base. At birth, the lateral masses of the ethmoid are ossified, but the septal cartilage and the cribriform plates are still cartilaginous. Another ossification center appears in the septal cartilage anterior to the cranial base and becomes the perpendicular plate of the ethmoid. In about the third to sixth year of life, the lateral masses of the ethmoid

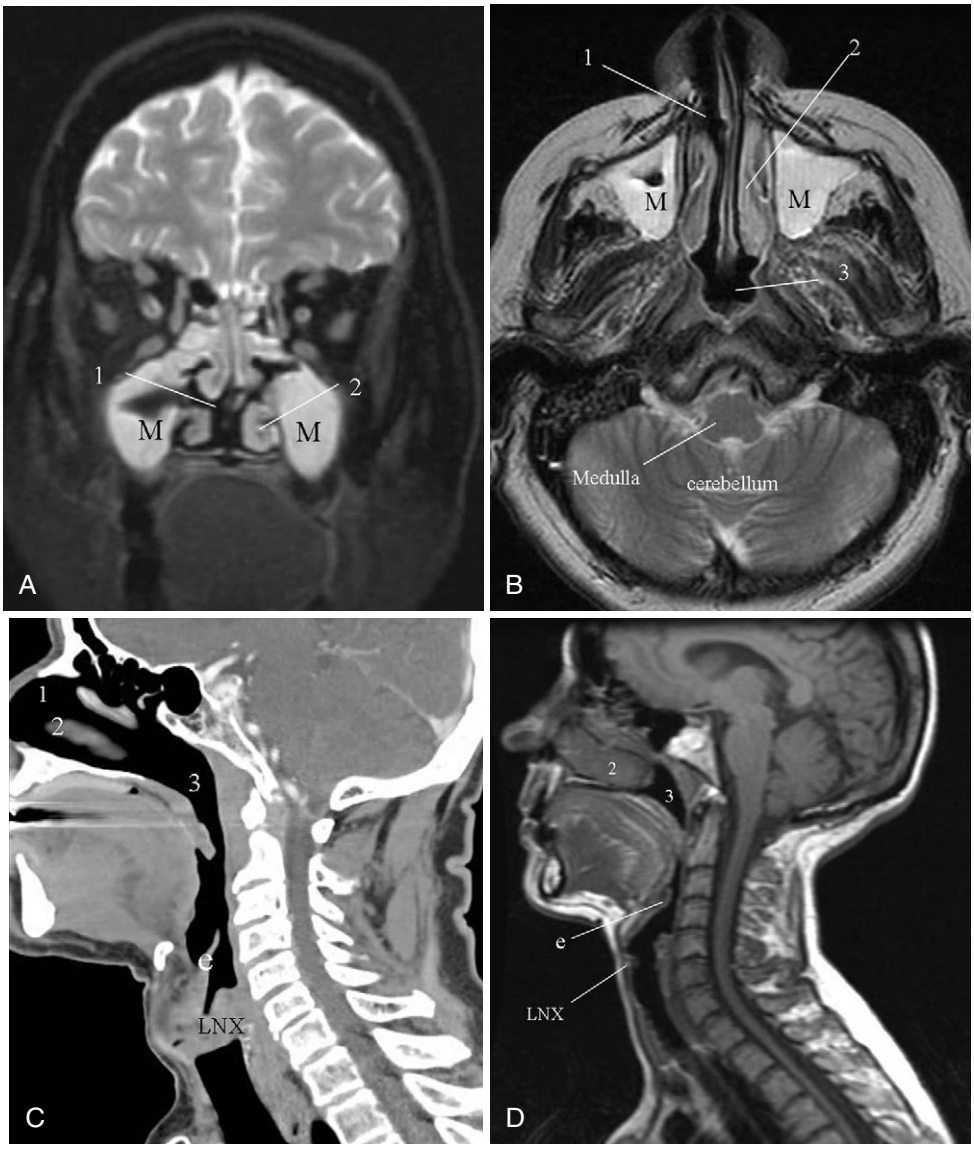

Figure 2-32 Airway as seen on routine studies. **A,** T2-weighted coronal magnetic resonance (MR) image of the brain demonstrates hyperintense, inflamed, thickened mucosa of the maxillary sinuses. **B,** T2-weighted axial MR image of the brain demonstrates sinus disease with a clear nasal cavity and nasopharynx. **C,** Sagittal reformation from computed tomographic neck examination demonstrates a clear airway from nose to trachea. **D,** T1-weighted sagittal MR cervical spine examination demonstrates signal void (black) of the air column of the airway. *1,* Nasal cavity; *2,* inferior turbinate; *3,* nasopharynx; *e,* epiglottis; *LNX,* larynx; *M,* maxillary sinus with thickened mucosa.

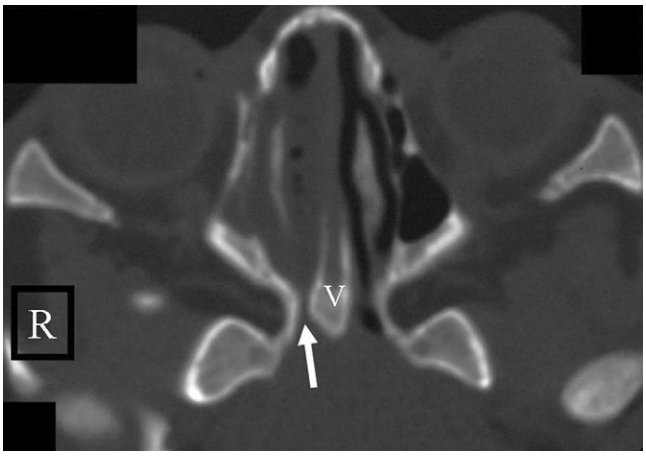

Figure 2-33 Choanal atresia. Axial computed tomographic scan demonstrates posterior aperture stenosis on the right (*arrow*). The vomer (*V*) is enlarged.

and the perpendicular plate become united across the roof of the nasal cavity by ossification of the cribriform plate, which unites with the vomer below somewhat later. Growth of the septal cartilage continues for a short time after craniofacial union is complete, and this probably accounts for what is commonly seen as deviated nasal septum.[32]

Acquired bases of deviated septum also exist (e.g., trauma), and there is a varying degree of septal deviation, which can be associated with a prominent bony beak. In most cases, septal deviation is not problematic for NGT or nasal airway insertion, but having prior knowledge of the anatomy of the nasal cavity allows one to choose the path of least resistance.

CONCHA BULLOSA. The term *concha bullosa* refers to an aerated turbinate, most often the middle turbinate, either unilateral or bilateral. In most cases it an incidental

Figure 2-34 Congenital nasal deformity. Axial computed tomographic scans demonstrate abnormal nasal bone architecture with soft tissue cleft and the impact on nasal airways.

finding. However, it can be quite large and narrows the nasal air passage. Knowing which nasal cavity is narrowed by the presence of a concha bullosa helps guide the selection of which nasal cavity to cannulate (Fig. 2-35).

b. INFLAMMATORY CONDITIONS

RHINOSINUSITIS. In general, no imaging is required for work-up of uncomplicated rhinosinusitis. Views of the sinus are included in a routine CT brain study. The air within the sinuses abuts the bony sinus wall and appears black on both CT and MRI. To assess the bony structures, CT is preferred. However, MRI is extremely useful to differentiate inflammatory disease from tumor. Inflammatory sinus disease is characterized by increased water content; therefore, an increased T2 signal (i.e., bright signal) is produced on T2-weighted imaging. Common inflammatory sinus disease is most often seen as T2-hyperintense lining of the walls of the sinus, representing thickened mucosa. In contrast, with increased cellularity, tumor masses typically exhibit an isointense signal on T2-weighted imaging. The most common local complications of inflammatory sinusitis are swollen turbinates, polyps, and retention cysts.

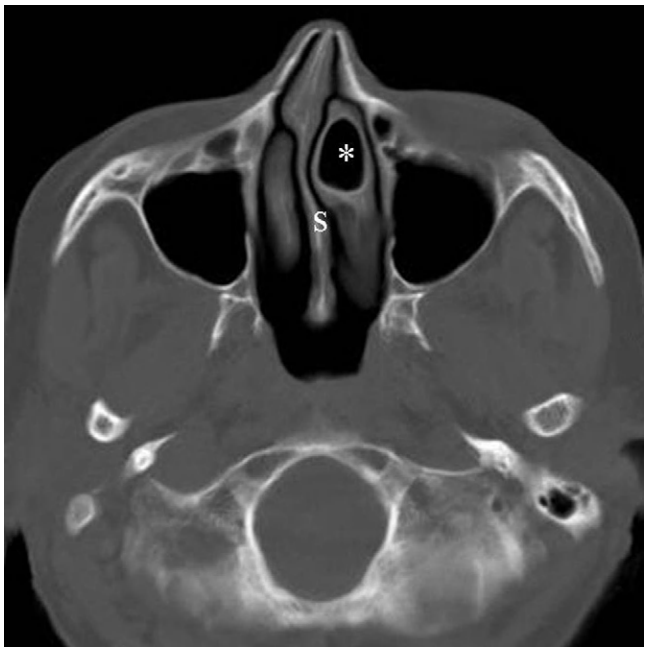

Figure 2-35 Concha bullosa. Axial computed tomographic scan demonstrates pneumatization (*asterisk*) of the left middle turbinate and deviated septum (*S*).

POLYPOSIS. Nasal airway obstruction may result from rhinitis, polyposis, or turbinate hypertrophy. These entities affecting the airway are easily recognizable on cross-sectional imaging. Sensibly, the presence of polyposis may discourage an anesthesiologist from attempting nasal intubation (Figs. 2-36 and 2-37).

c. TRAUMA

Facial fractures are often classified using the Le Fort system and its variants. This system is based on experiments predicting the course of fractures on the basis of lines of weakness in the facial skeleton. Nasal fractures are the most common facial fractures and may involve the nasal bones or the cartilaginous structures. If the nasal septum is fractured and a hematoma results, the vascular supply to the cartilage may be compromised, leading to cartilage necrosis. If the septal hematoma is not recognized and treated, it becomes an organized hematoma, which causes thickening of the septum and can result in impaired breathing (Fig. 2-38). Without doubt, CT is the modality of choice for evaluating trauma to the facial structures. Three-dimensional reconstruction and surface rendering can also be performed to better highlight fracture deformities. Even if all the details of a complex facial fracture are not known, an oral airway is preferable to a nasal airway, except in the case of mandibular fracture (Fig. 2-39), for which the nasal approach to intubation is preferred.

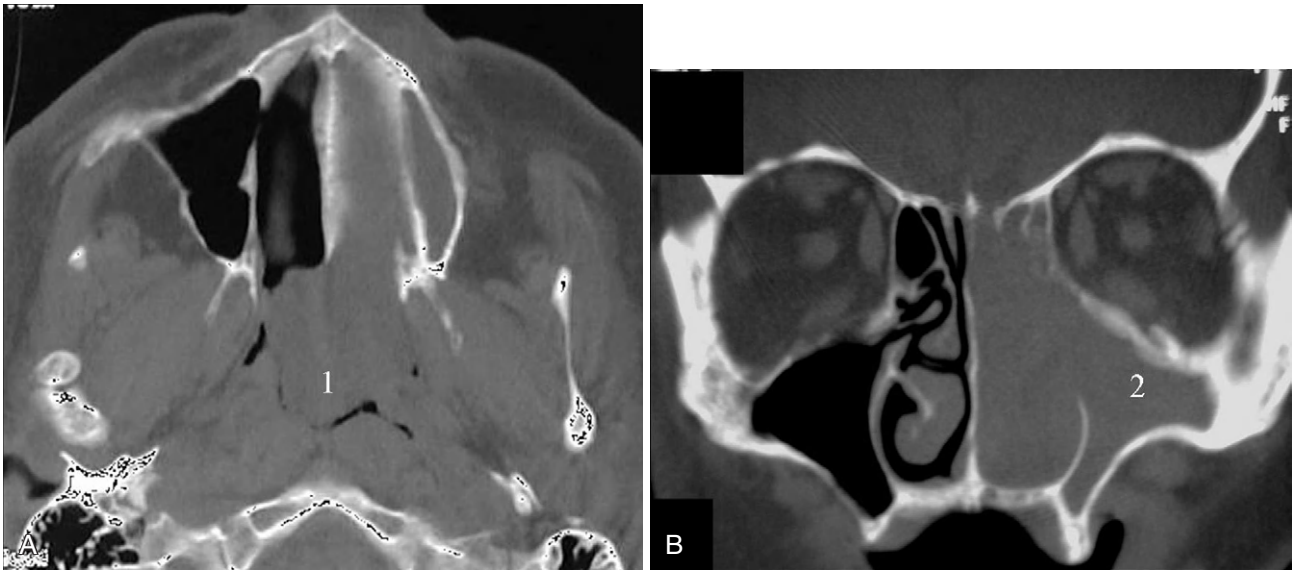

Figure 2-36 Antrochoanal polyp. Axial **(A)** and coronal **(B)** computed tomography scans demonstrate soft tissue obliterating the left nasal cavity and extending posteriorly into the nasopharynx (*1*) and laterally into the left maxillary sinus (*2*).

d. TUMORS AND OTHER CONDITIONS

MALIGNANT TUMORS. Malignant tumors of the nasal cavity and the paranasal sinuses are rare and have a poor prognosis because they are frequently diagnosed in an advanced stage. They are often accompanied by inflammatory disease. MRI is superior to CT in differentiating tumor from inflammatory disease and therefore is useful in delineating the tumor boundary from the often-associated inflammatory component. Inflammatory diseases involve a high water content; therefore, they have high T2-weighted intensity and appear bright on MRI. Nasal and paranasal tumors are usually cellular and have an intermediate-intensity signal on T2-weighted imaging (Fig. 2-40).[35,36] CT is useful for assessing bone involvement. The histology of the tumor can sometimes be suggested by the way in which the bone is affected: aggressive bone destruction is usually seen in squamous cell carcinomas (SCCs), metastatic lung and breast cancers, a few sarcomas, and rare fibrous histiocytomas (Fig. 2-41).

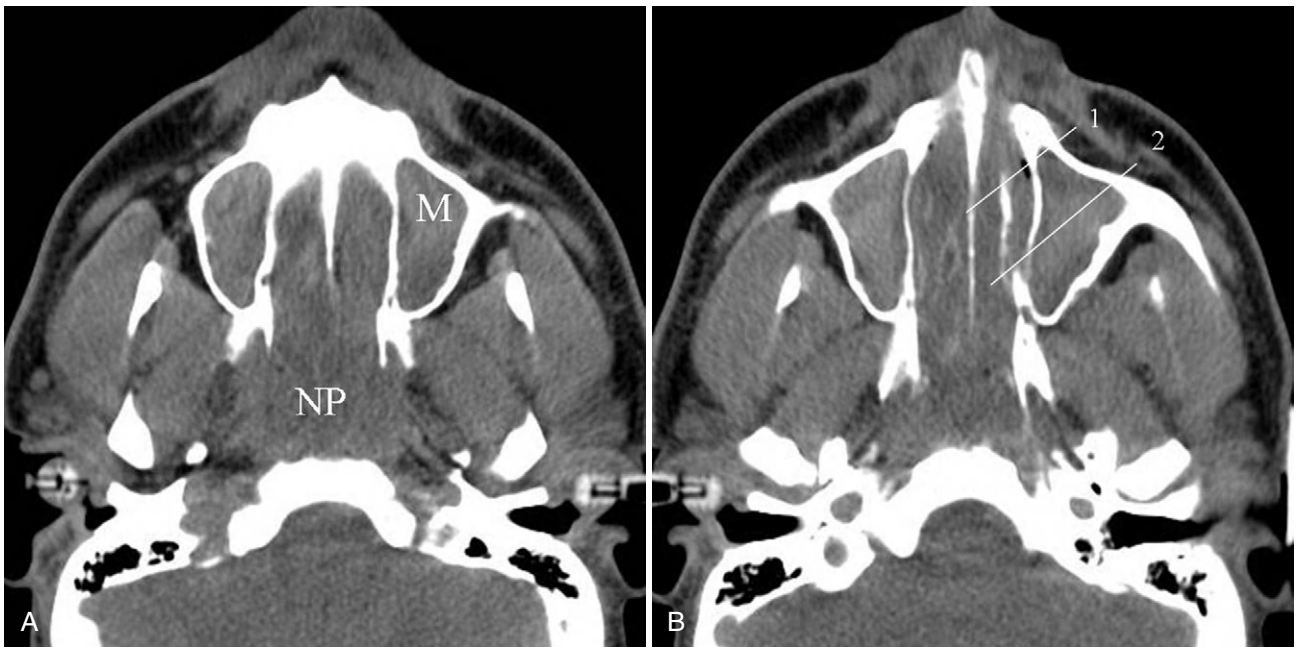

Figure 2-37 Nasal polyps. Axial computed tomography scans (**A** and **B**) demonstrate complete obliteration of the nasal passageways and pharynx by soft tissue polyps, resulting in chronic maxillary sinus inflammatory changes. *1,* Nasal septum; *2,* nasal cavity; *NP,* nasopharynx; *M,* maxillary sinus.

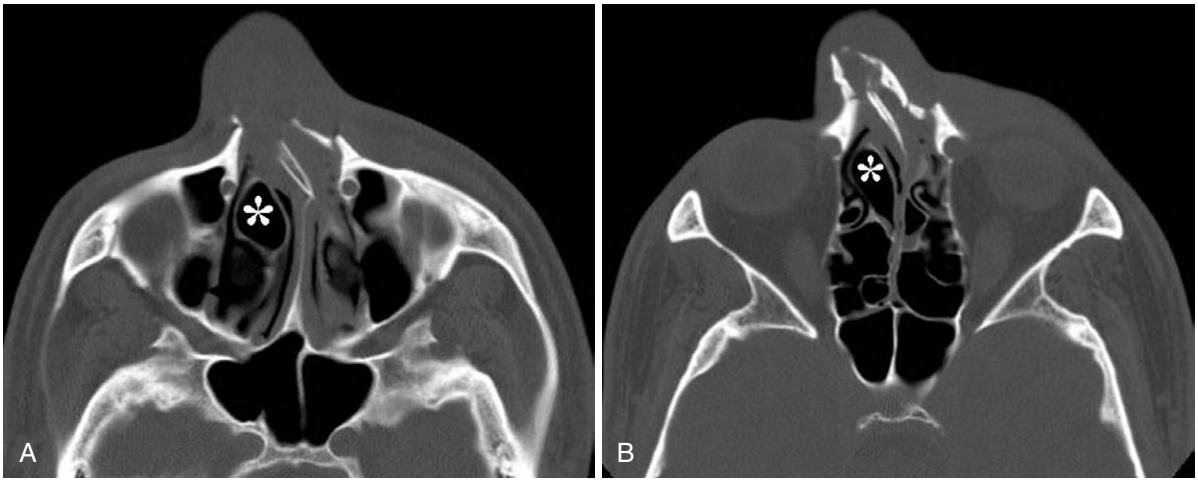

Figure 2-38 Nasal and septal fracture. Axial computed tomography scans (**A** and **B**) demonstrate comminuted fractures of the nasal bones bilaterally as well as a septal fracture. The nasal passages are further compromised by the incidental right concha bullosa (*asterisk*).

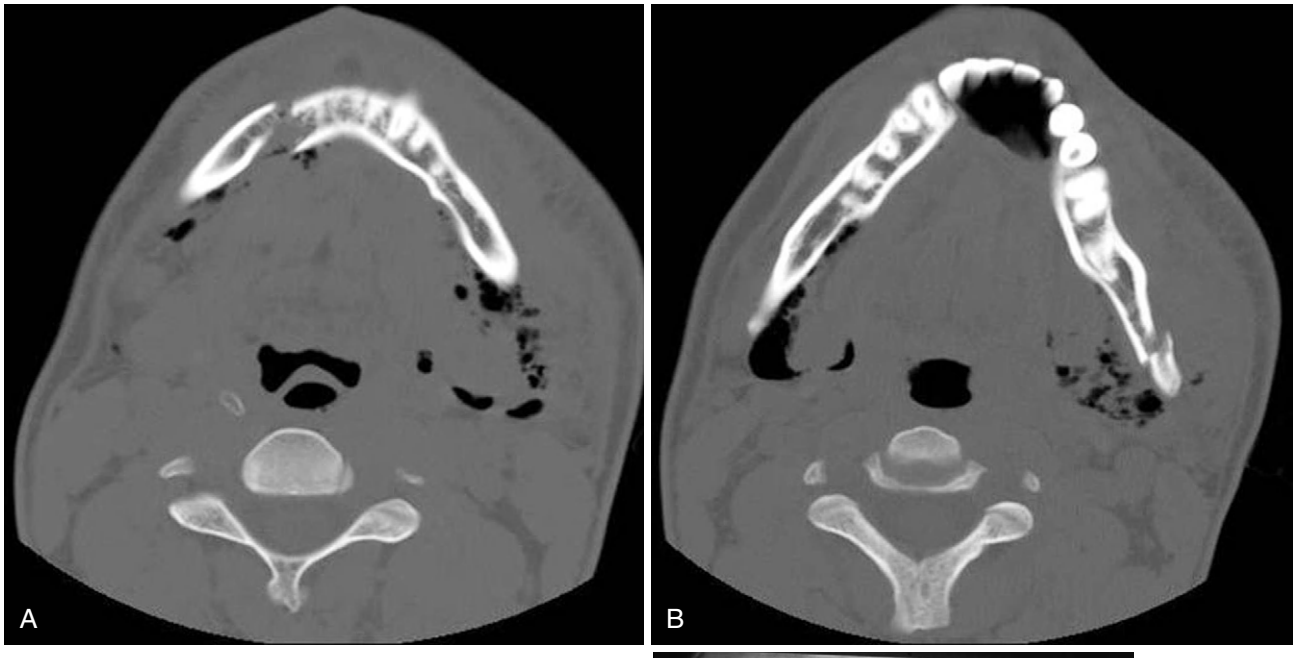

Figure 2-39 Mandibular fracture. Axial computed tomographic (CT) scans demonstrate typically paired fractures involving the right parasymphyseal body **(A)** and the left angle of the mandible **(B).** Notice the extensive air within the soft tissues. **C,** In another patient, three-dimensional surface rendering demonstrates a midline fracture of the mandible at the symphysis (*arrows*).

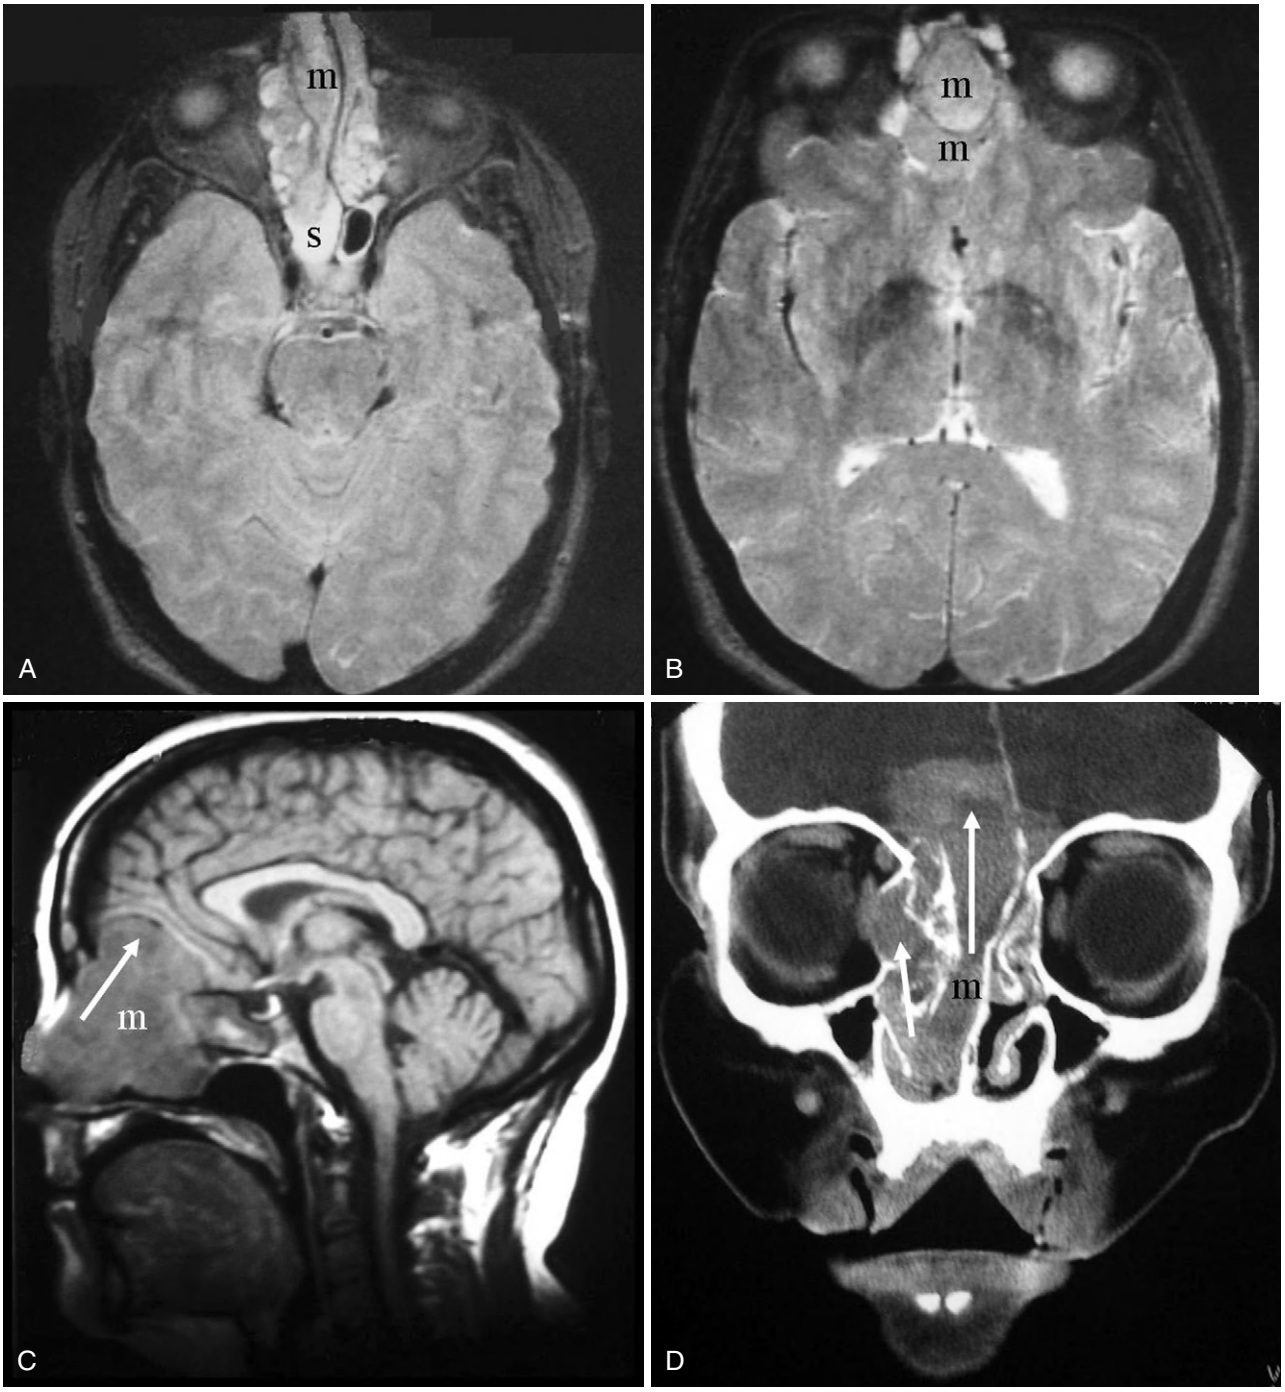

Figure 2-40 Esthesioneuroblastoma. **A** and **B,** T2-weighted axial magnetic resonance (MR) studies of the brain. Notice the large isointense soft tissue mass *(m)* in the nasal cavity, which is accompanied by obstructive inflammatory sinus disease of high T2 signal *(s)*. The extension of the mass intracranially, indicated by the *arrows,* is better appreciated on the sagittal T1-weighted MR image of the brain **(C)** and on the coronal computed tomogram (CT) with contrast **(D).** Coronal CT better demonstrates bone destruction and also extension of the tumor to the right orbit.

NONMALIGNANT DESTRUCTIVE TUMORS

Juvenile Nasopharyngeal Angiofibroma. Juvenile nasopharyngeal angiofibroma is a benign hypervascular tumor found almost exclusively in young adolescent men. It is a nonmalignant, locally destructive tumor of the sinonasal cavity. The most common presenting signs are unilateral nasal obstruction and spontaneous epistaxis. The tumor usually arises at the sphenopalatine foramen at the lateral nasopharyngeal wall and is locally destructive over time.[35] The imaging characteristics consist of a nasal cavity and nasopharyngeal mass, a widened pterygopalatine fossa, anterior displacement of the posterior wall of the maxillary sinus, and erosion of the medial pterygoid plate (Fig. 2-42). Treatment is surgical resection, often with preoperative embolization to decrease the blood supply.

Wegener's Granulomatosis. Wegener's granulomatosis, a necrotizing vasculitis, usually affects the upper and lower

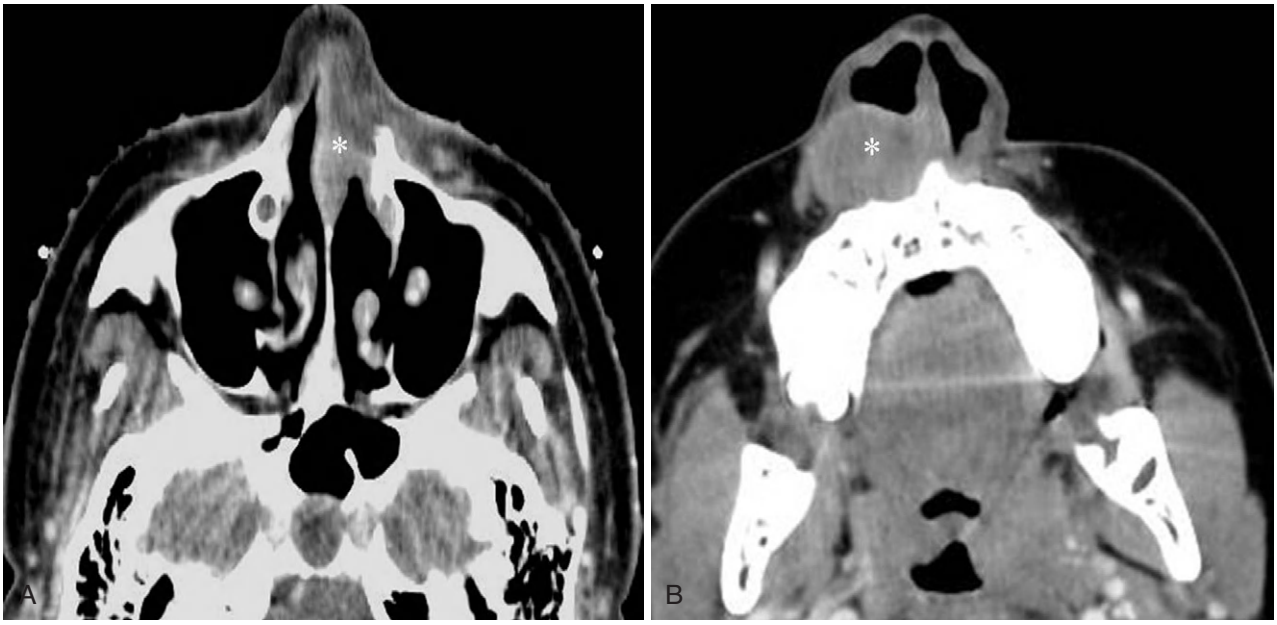

Figure 2-41 **A,** Lymphoma of the nasal septum. Axial computed tomographic (CT) scan shows an infiltrating lesion of the anterior nasal septum (*asterisk*) that extends into the left maxillary soft tissues. **B,** Rhabdomyosarcoma of the right nasal cavity and nasal ala. Axial CT scan demonstrates a soft tissue mass (*asterisk*) effacing the right nostril.

respiratory tracts and causes a renal glomerulonephritis. It is probably autoimmune in origin. It most often involves the nasal septum first and may arise as a chronic nonspecific inflammatory process. This process becomes diffuse, and septal ulcerations and perforations occur. Secondary bacterial infection often complicates the clinical and imaging picture (Fig. 2-43).[35]

Fibrous Dysplasia. Fibrous dysplasia, an idiopathic bone disorder, is not a tumor but can encroach on the airway and sinuses. Most patients are young at the time of diagnosis. There are monostotic and polyostotic forms. Craniofacial bones are more often involved in the polyostotic form (Fig. 2-44).[35]

C. Oral Cavity

The oral cavity, contiguous with the oropharynx, is the primary conduit to the gastrointestinal tract. The development of the mouth and that of the face are centered on a surface depression, the stomodeum, just below the developing brain. The ectoderm covering the forebrain extends into the stomodeum, where it lies adjacent to the foregut. The junctional zone between the ectoderm and the endoderm is the oropharyngeal membrane, which corresponds to Waldeyer's ring. Dissolution of the oropharyngeal membrane in the fourth gestational week results in establishing patency between the mouth and the foregut.[37]

The oral cavity is separated from the oropharynx by the circumvallate papillae, anterior tonsillar pillars, and soft palate. The anterior two thirds of the tongue (oral tongue), floor of the mouth, gingivobuccal and buccomasseteric regions, maxilla, and mandible are considered oral cavity structures. The anatomic distinction between the oral cavity and the oropharynx has clinical importance. Malignancies, especially SCCs, in these two regions are different in their presentation and prognosis.

1. Imaging Anatomy Overview

CT and MRI are used extensively for evaluation of the oral cavity. The advantages of CT are the speed of data acquisition and the ability to detect calcifications pertinent in the evaluation of inflammatory diseases affecting the salivary glands. For evaluating the extent of tumor infiltration of the soft tissues, MRI is superior to CT; however, it is easily degraded by motion artifacts (Fig. 2-45).

The tongue consists of two symmetrical halves separated by a midline lingual septum. Each half of the tongue is composed of muscular fibers, which are divided into extrinsic and intrinsic muscles. There are four intrinsic tongue muscles: the superior longitudinal muscle, inferior longitudinal muscle, transverse muscles, and vertical muscles. The intrinsic muscles receive motor innervation from the hypoglossal nerve (cranial nerve [CN] XII) and participate in the enunciation of various consonants. The intrinsic muscles are difficult to distinguish on CT, but they are well visualized on MRI, because each muscle bundle is surrounded by high-intensity fibrofatty tissues.

The muscles that originate externally to the tongue but have distal muscle fibers that interdigitate within the substance of the tongue are considered to be extrinsic muscles of the tongue. The main extrinsic muscles are the genioglossus, hyoglossus, and styloglossus muscles. Sometimes the superior constrictors and the palatoglossus muscles are discussed with the extrinsic muscles of the tongue. The extrinsic muscles attach the tongue to the hyoid, mandible, and styloid process.

Motor innervation comes from the hypoglossal nerve, which courses between the mylohyoid and hyoglossus muscles. The sensory input from the anterior tongue is from the lingual nerve, which is a branch of the trigeminal nerve (CN V). Special sensory taste fibers from the

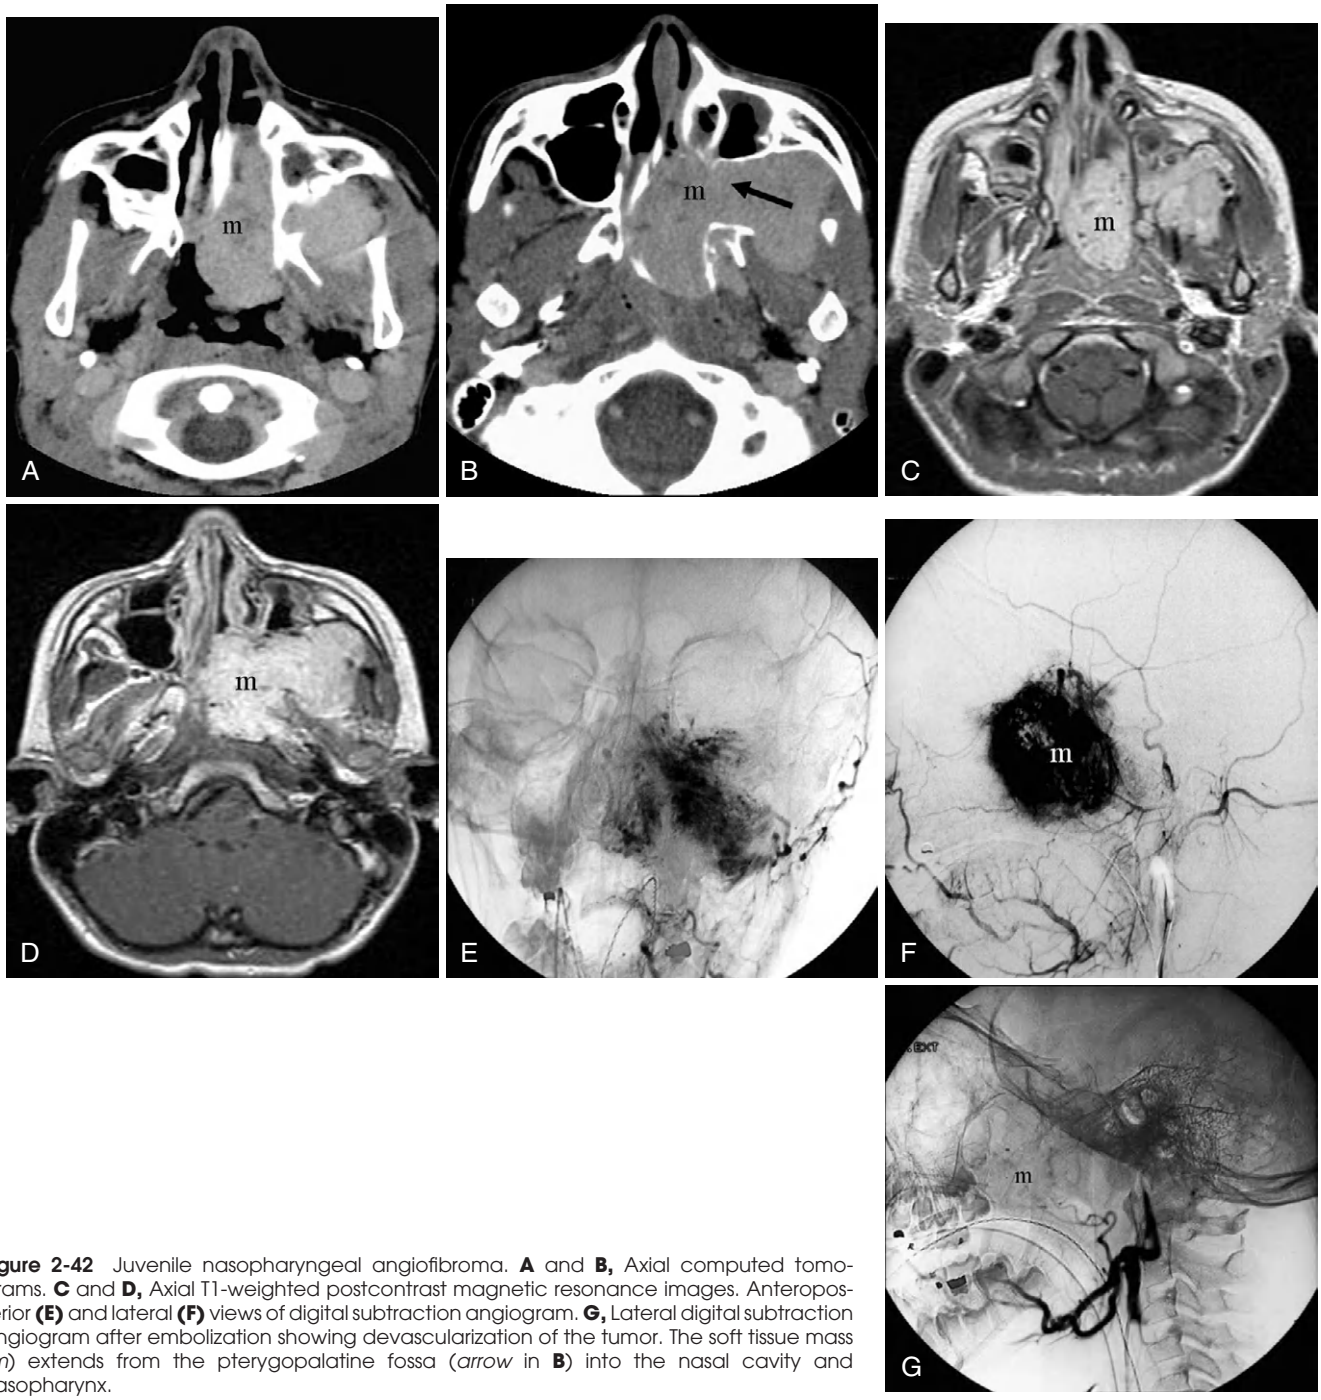

Figure 2-42 Juvenile nasopharyngeal angiofibroma. **A** and **B,** Axial computed tomograms. **C** and **D,** Axial T1-weighted postcontrast magnetic resonance images. Anteroposterior **(E)** and lateral **(F)** views of digital subtraction angiogram. **G,** Lateral digital subtraction angiogram after embolization showing devascularization of the tumor. The soft tissue mass (*m*) extends from the pterygopalatine fossa (*arrow* in **B**) into the nasal cavity and nasopharynx.

anterior two thirds of the tongue course with the lingual nerve before forming the chorda tympani nerve, which subsequently joins the facial nerve (CN VII). The special sensory fibers from the posterior one third of the tongue (tongue base) are supplied by the glossopharyngeal nerve (CN IX). The arterial blood supply to the tongue is from branches of the lingual artery, which itself is a branch of the external carotid artery. Venous drainage is to the internal jugular vein.[25,38]

The floor of the mouth is mainly composed of the mylohyoid muscles, the paired anterior bellies of the digastrics muscles, and the geniohyoid muscles. The space caudal to the mylohyoid muscle and above the hyoid bone is considered to be the suprahyoid neck. Through a gap between the free posterior border of the mylohyoid muscle and the hyoglossus muscle, the submandibular gland wraps around the dorsal aspect of the mylohyoid muscle.

Several named spaces and regions in the oral cavity are mentioned in brief because of their anatomic importance with respect to the structures contained within them. The *sublingual region* is below the mucosa of the floor of

Figure 2-43 Septal pathologies narrowing the anterior nasal cavity are shown on axial computed tomography scans. **A,** A soft tissue mass is invading the right nasal cavity and orbit; it was diagnosed as Wegener's granuloma. **B,** A septal granuloma is noted in association with focal bone destruction. **C,** A ring-enhancing lesion of the anterior septum is seen, consistent with a septal abscess.

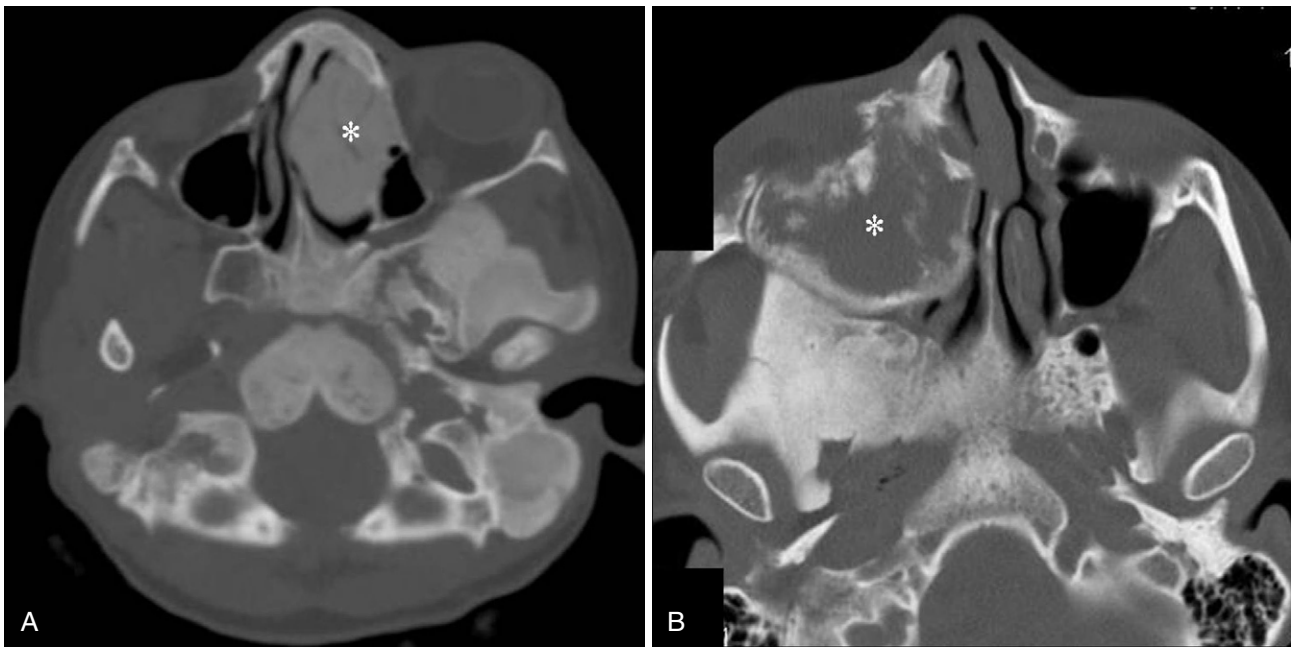

Figure 2-44 Fibrous dysplasia. **A,** Axial computed tomogram (CT) demonstrates a mass obliterating the left nasal cavity (*asterisk*) with the typical "ground glass" appearance of fibrous dysplasia involving the left skull base. **B,** Axial CT scan from a different patient demonstrates fibrous dysplasia with malignant degeneration to osteosarcoma invading the right nasal cavity and orbit (*asterisk*).

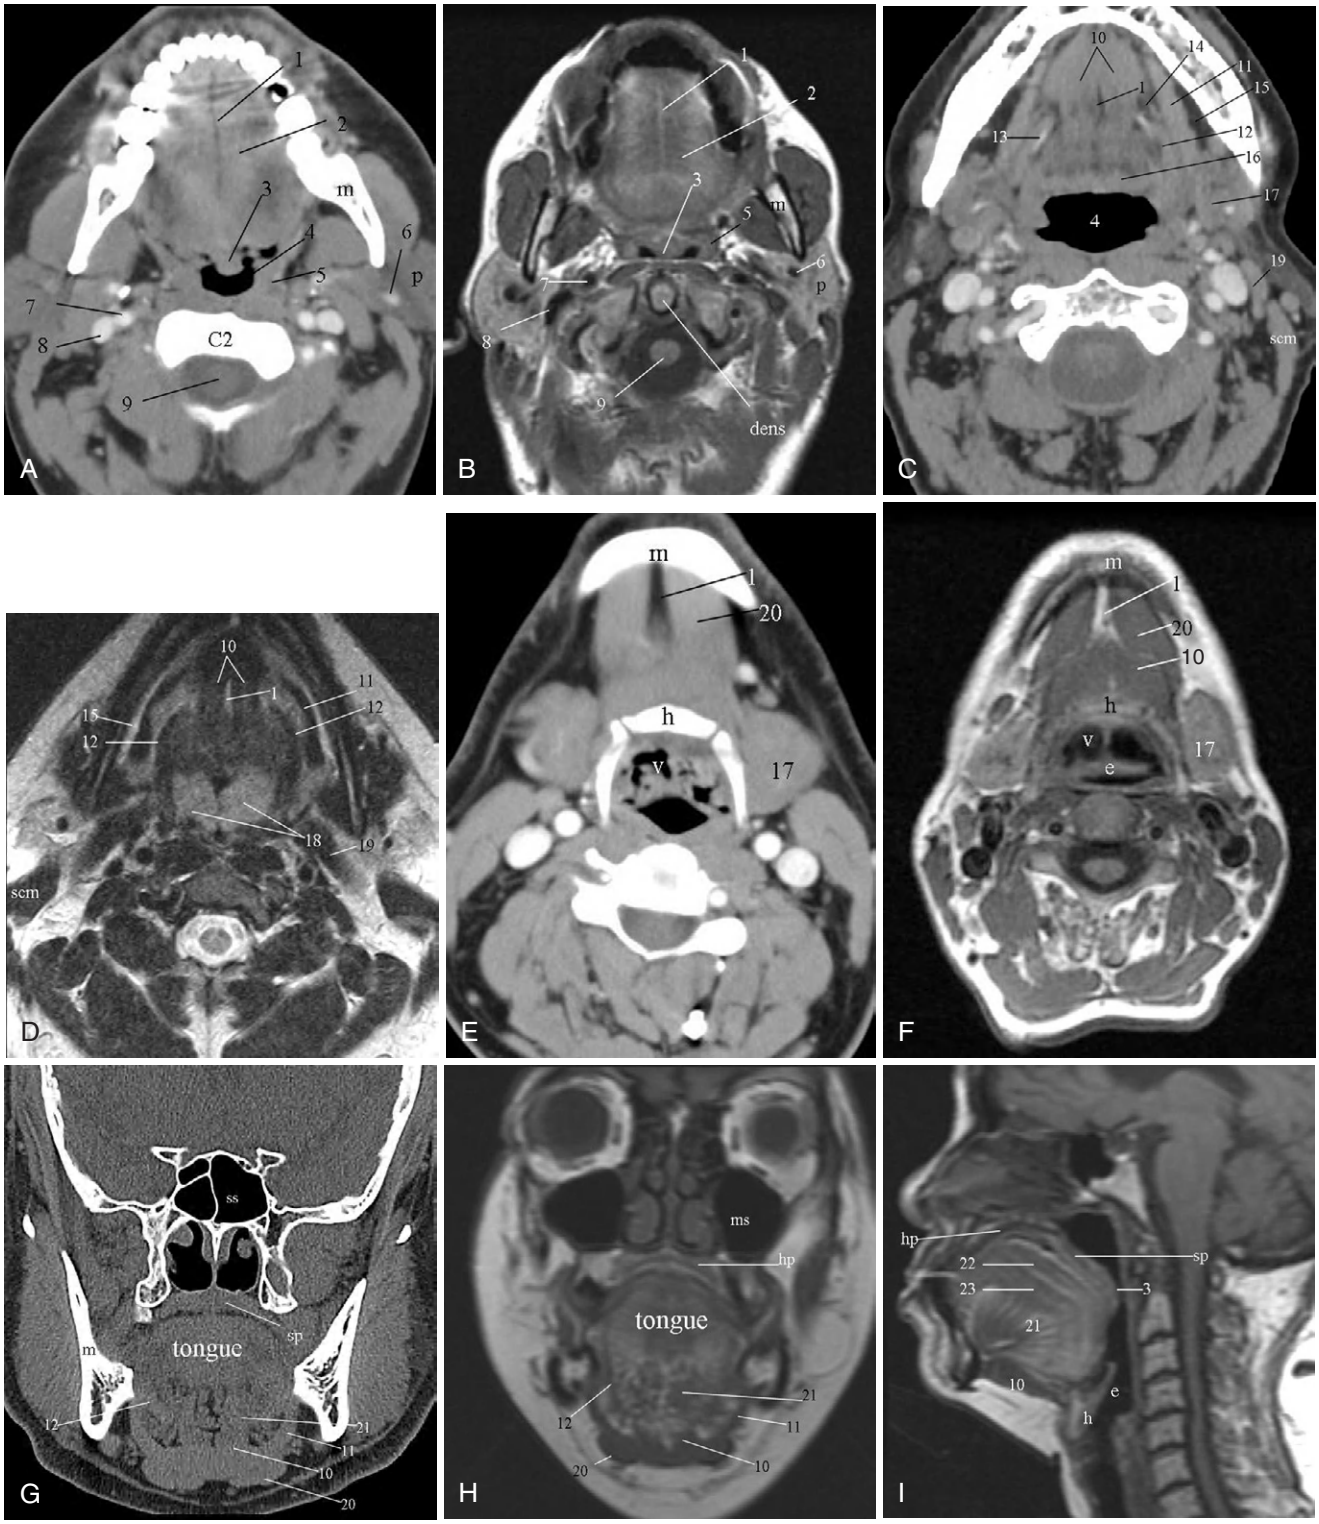

Figure 2-45 Normal anatomy of the oral cavity is demonstrated on axial computed tomographic (CT) images (**A, C,** and **E**) with corresponding axial magnetic resonance (MR) scans (**B, D,** and **F**), on coronal CT **(G)** and coronal T1-weighted MR **(H)** scans, and on a sagittal T1-weighted MR image **(I)**: *1,* Median raphe of tongue (fat is low density on CT and bright on T1-weighted MR images); *2,* tongue (transverse fibers are seen better on MR imaging); *3,* uvula; *4,* oropharynx; *5,* pharyngeal constrictor muscle; *6,* retromandibular vein; *7,* internal carotid artery; *8,* internal jugular vein; *9,* cervical cord; *10,* paired geniohyoid muscles; *11,* mylohyoid muscle; *12,* hyoglossus muscle; *13,* lingual artery and vein medial to hyoglossus muscle; *14,* Wharton's duct, hypoglossal nerve, and lingual nerve lateral to hyoglossus muscle; *15,* fat in sublingual space; *16,* tongue base; *17,* submandibular gland; *18,* palatine tonsils narrowing oropharynx; *19,* posterior belly of digastric muscle; *20,* paired anterior belly of digastric muscle; *21,* genioglossus muscle; *22,* superior longitudinal muscle; *23,* transverse muscle; *e,* epiglottis; *h,* body of hyoid bone; *hp,* hard palate; *m,* mandible; *ms,* maxillary sinus; *p,* parotid gland; *scm,* sternocleidomastoid muscle; *sp,* soft palate; *ss,* sphenoid sinus; *v,* vallecula.

the mouth, superomedial to the mylohyoid muscle and lateral to the genioglossus-geniohyoid muscles. It is primarily fat filled and is continuous with the submandibular region at the posterior margin of the mylohyoid muscle. The contents of this space include the sublingual gland and ducts, the submandibular gland duct (Wharton's duct) and sometimes a portion of the hilum of the submandibular gland, anterior fibers of the hyoglossus muscle, and the lingual artery and vein. The hyoglossus muscle is an important surgical landmark (see Fig. 2-45C). Lateral to this muscle, one can identify Wharton's duct, the hypoglossal nerve, and the lingual nerve; the lingual artery and vein lie medially. Wharton's duct runs anteriorly from the gland, traveling with the hypoglossal nerve and the lingual nerve (mandibular branch of the trigeminal nerve). Initially, it lies between the hyoglossus muscle and the mylohyoid muscle. More anteriorly, it lies between the genioglossus and mylohyoid muscles. The duct drains into the floor of the mouth, just lateral to the frenulum of the tongue.[39]

The *submandibular space* or fossa is defined as the space inferior to the mylohyoid muscle, between the mandible and the hyoid bone. At the posterior margin of the mylohyoid muscle, the submandibular space is continuous with the sublingual space and the anterior aspect of the parapharyngeal space. This communication allows the spread of pathology. The submandibular space is primarily fat filled and contains the superficial portion of the submandibular gland and lymph nodes, lymphatic vessels, and blood vessels. The anterior bellies of the digastric muscle lie in the paramedian location in this space. Branches of the facial artery and vein course lateral to the anterior digastric muscle in the fat surrounding the submandibular gland. The artery lies deep to the gland, and the anterior facial vein is superficial.[38] One important anatomic point is that pathology intrinsic to the submandibular gland displaces the facial vein laterally. Other masses lateral to the gland, including nodes, can be identified with the vein interposed between the gland and the mass.[40]

The lips are composed of orbicularis muscle, which comprises muscle fibers from multiple facial muscles that insert into the lips and additional fibers proper to the lips. The innervation to the lips is from branches of the facial nerve (CN VII). The vestibule of the mouth, or the *gingivobuccal region*, is the potential space separating the lips and cheeks from the gums and teeth. The parotid gland ducts and mucous gland ducts of the lips and cheek drain into this space, which is contiguous posteriorly with the oral cavity through the space between the last molar tooth and the ramus of the mandible.[38]

2. Pertinent Imaging Pathology

a. MACROGLOSSIA

The tongue makes up the bulk of soft tissues in the oral cavity. Enlargement of the tongue, which is defined clinically as protrusion of the tongue beyond the teeth or alveolar ridge in the resting position, compromises the oral airway and makes the insertion of airway devices challenging. Larsson and colleagues defined the appearance of macroglossia on CT imaging as (1) base of the tongue more than 50 mm in the transverse dimension, (2) genioglossus muscle more than 11 mm in the transverse dimension, (3) midline cleft on the tongue surface, and (4) submandibular glands normal in size but bulging out of the platysma muscle owing to tongue enlargement.[41]

There are congenital and noncongenital causes of macroglossia. The congenital syndromes in which macroglossia can be seen are trisomy 21, Beckwith-Wiedemann syndrome, hypothyroidism, and mucopolysaccharidoses. The more common noncongenital causes are tumor of the tongue, lymphangioma, hemangioma, acromegaly, and amyloid (Figs. 2-46 and 2-47). Rarely, infection

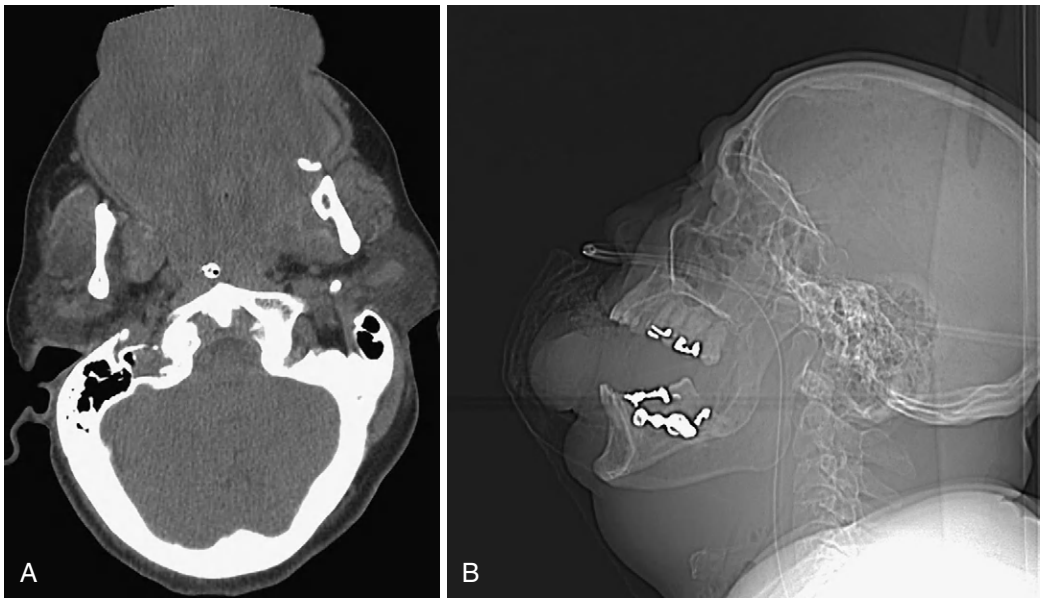

Figure 2-46 Macroglossia in a patient with a diagnosis of multiple myeloma and amyloid who developed an allergic reaction to amoxicillin clavulanate potassium (Augmentin). **A,** Axial computed tomographic (CT) image demonstrates the enlarged tongue occupying and extending beyond the oral cavity. There is no apparent oropharyngeal airway. A nasogastric tube is in place. **B,** Lateral CT scout view demonstrates the protrusion of the tongue beyond the confines of the oral cavity and diffuse soft tissue swelling on the neck.

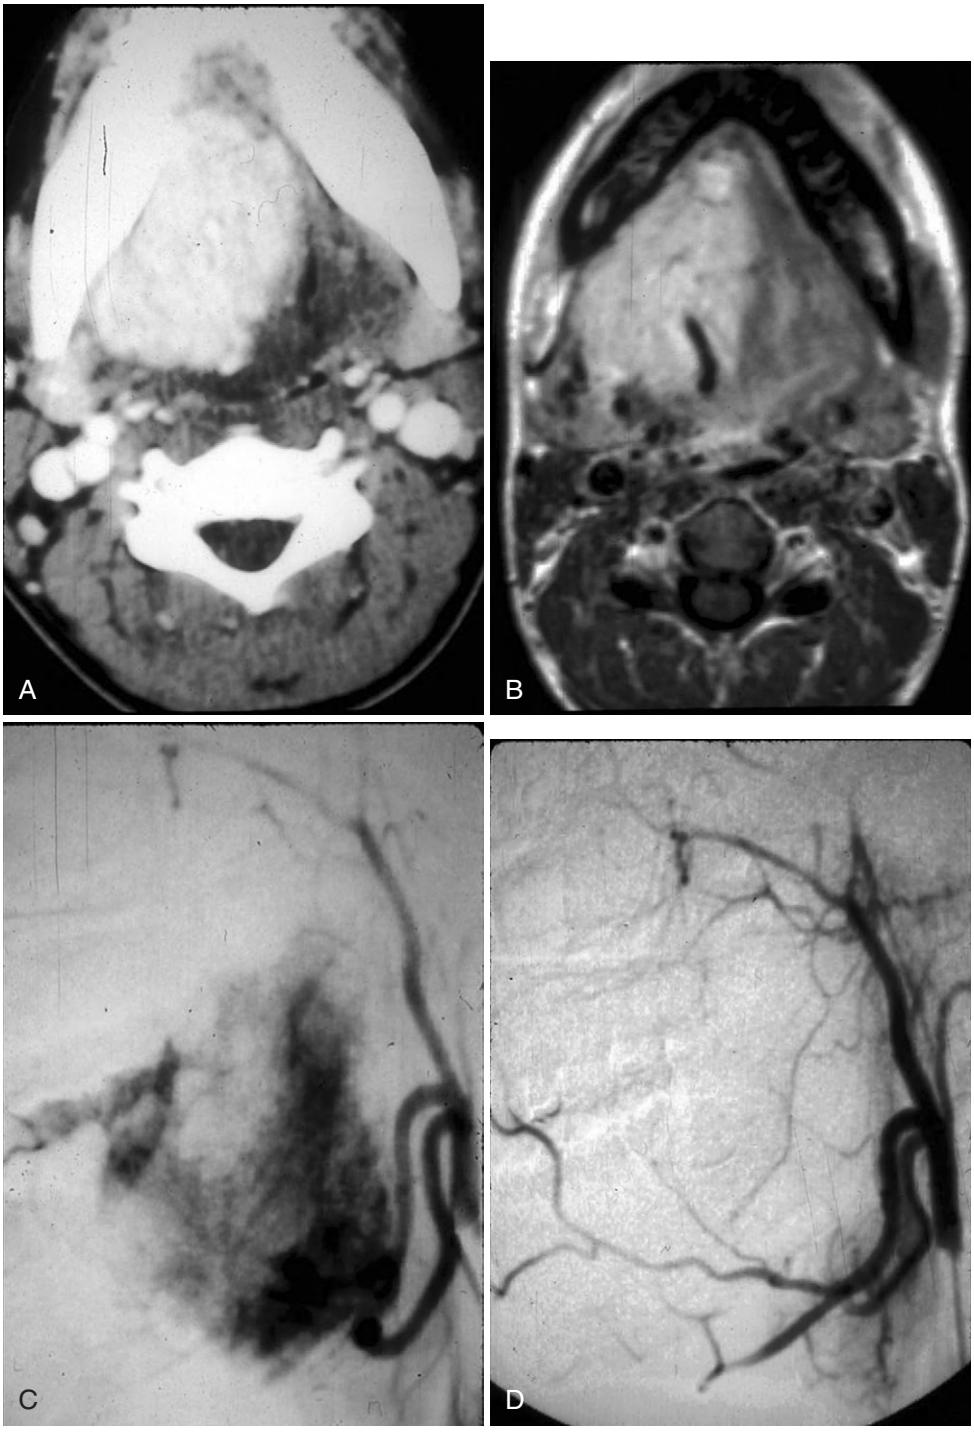

Figure 2-47 Tongue hemangioma. Contrast-enhanced computed tomography **(A)** and magnetic resonance imaging **(B)** demonstrate an enhancing right tongue lesion that almost fills the oral cavity. **C,** The vascularity of the lesion is further demonstrated in the lateral view of the right external carotid angiogram. **D,** Angiogram after embolization shows devascularization of the tumor.

can result in macroglossia, especially in an immune-compromised host (Fig. 2-48).

Posterior displacement of the tongue, or glossoptosis, may be observed with macroglossia, micrognathia or retrognathia, and neuromuscular disorders, including unilateral tongue paralysis secondary to hypoglossal nerve (CN XII) denervation. It can also occur in normal patients in some cases. The obvious complication is relative airway obstruction, which, if chronic, results in a myriad of systemic complications.

b. MICROGNATHIA AND RETROGNATHIA

Micrognathia is a term used to describe an abnormally small mandible. *Retrognathia* is defined as abnormal

Figure 2-48 *Mycobacterium avium-intracellulare* infection in an immune-compromised patient. Axial computed tomogram with contrast demonstrates an irregular enhancement of lymph nodes and lymphoid tissue at the tongue base. The fungating tongue lesion (*asterisk*) compromises the oropharyngeal airway.

posterior placement of the mandible. These two findings often coexist. Abnormal growth or placement of the mandible can be caused by malformation, deformation, or connective tissue dysplasia.[42] The most familiar syndromic form featuring an abnormal mandible is in the Pierre Robin sequence. Other clinical entities include the Treacher Collins, Stickler, and DiGeorge syndromes. Thin-section CT with 2-D or 3-D reformation provides information regarding the size and proportions of the maxilla, nose, mandible, and airway. Micrognathia and retrognathia not only contribute to airway obstruction but also are possible indicators of difficult direct laryngoscopy and endotracheal intubation that can lead to life-threatening complications (Figs. 2-49 and 2-50).[42]

c. EXOSTOSIS

Hyperostosis of the hard palate or mandible is a benign disease that is usually of no clinical significance. Most often these are small exostoses. They may arise from the oral surface of the hard palate (torus palatinus), from the alveolar portion of the maxilla in the molar region along the lingual surface of the dental arch (torus maxillaris), or along the lingual surface of the mandible (torus mandibularis) (Fig. 2-51). Large lesions may restrict tongue motion and distort the airway, leading to speech disturbance.

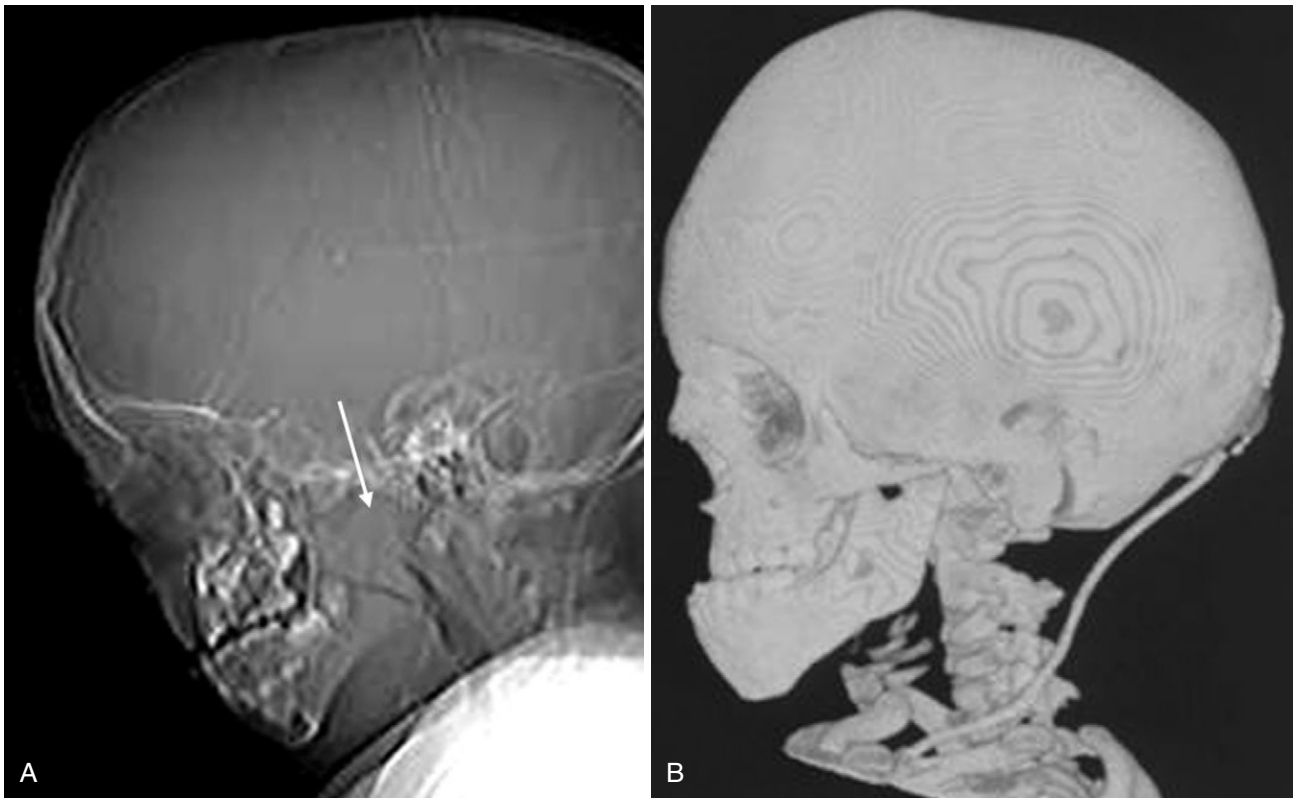

Figure 2-49 Midface regression syndrome in two patients with Jackson-Weiss syndrome and maxillary regression: computed tomographic scout view **(A)** and three-dimensional surface rendering **(B).** Notice the presence of a ventriculoperitoneal shunt; hydrocephalus may result from the craniosynostosis associated with this syndrome. The mandible is hypoplastic, and there is soft tissue obscuring the nasopharynx (*arrow*).

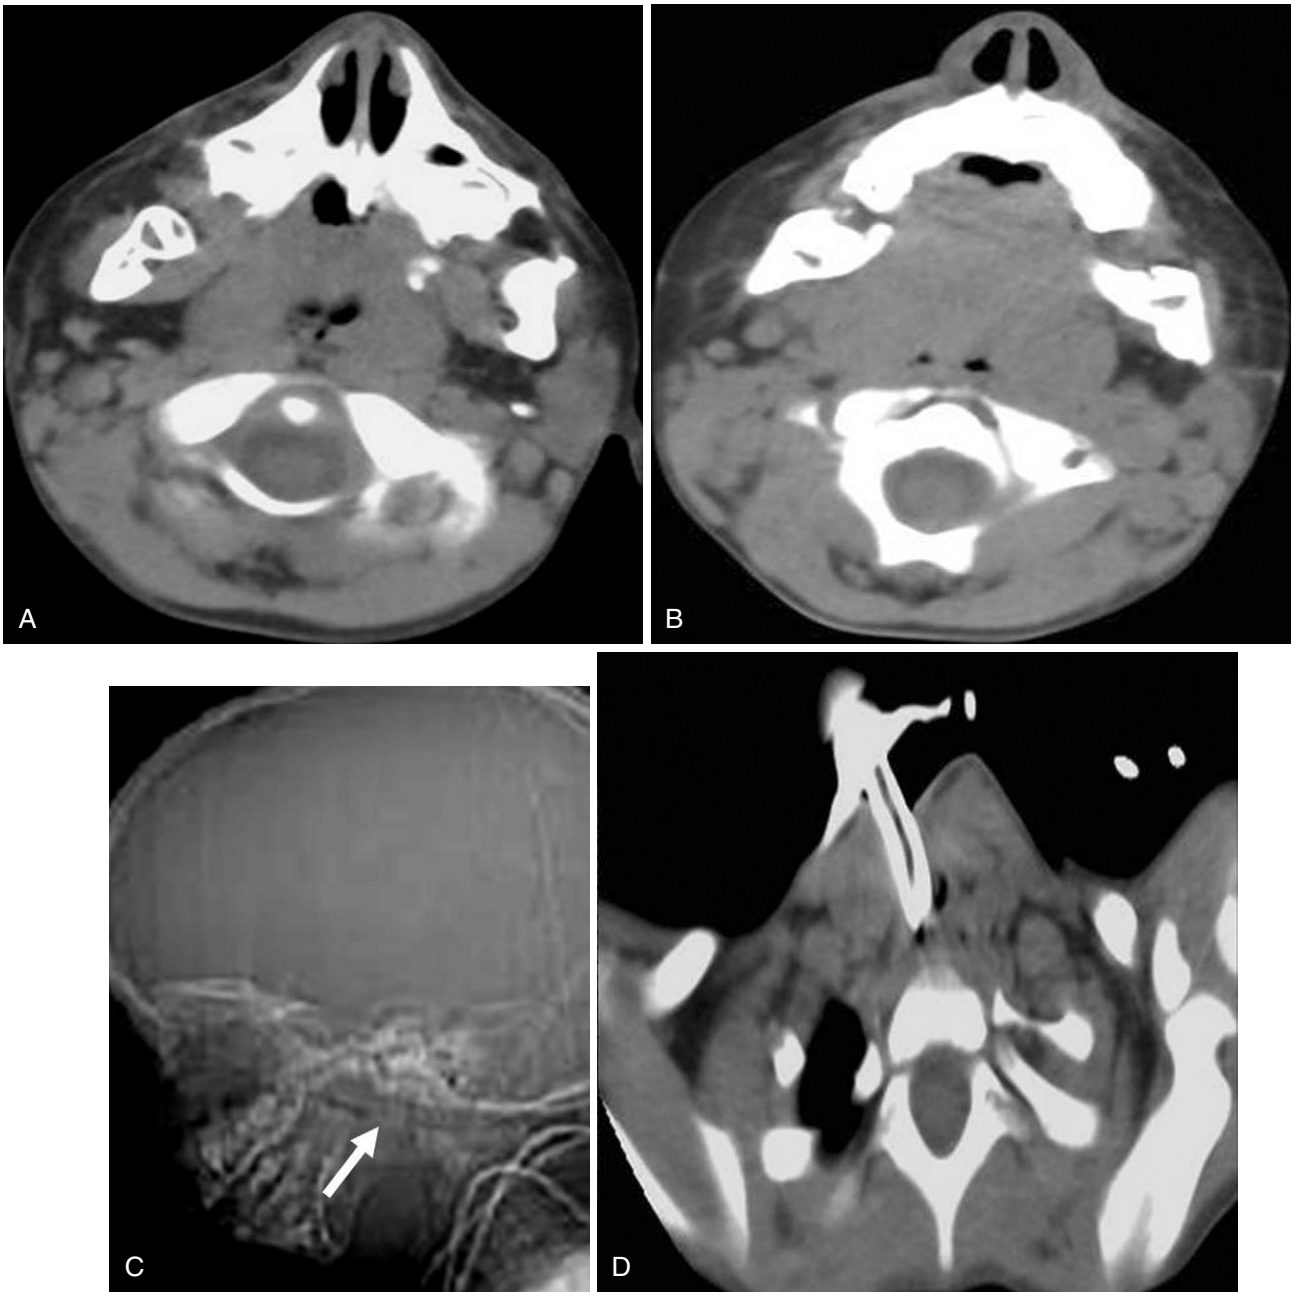

Figure 2-50 Treacher Collins syndrome. Axial computed tomographic (CT) scans at the level of the nasopharynx **(A)** and oropharynx **(B)** demonstrate almost complete obliteration of the airway by soft tissue, secondary to the facial microsomia. **C,** Lateral CT scout view demonstrates marked narrowing of the airway (*arrow*). **D,** Axial CT scan at the thoracic inlet demonstrates the tracheostomy necessitated by this condition.

d. TUMORS

Only 7% of oral cavity lesions are malignant; however, most of these malignant tumors are SCCs. Other neoplasms include minor salivary gland tumors, lymphomas, and sarcomas. Risk factors for SCC of the oral cavity include a long history of tobacco and alcohol use. SCC can arise anywhere in the oral cavity, but it has a predilection for the floor of the mouth, the ventrolateral tongue, and the soft palate complex including the retromolar trigone area and the anterior tonsillar pillar. Most lesions are moderately advanced at the time of presentation; 30% to 65% of patients with SCC of the oral cavity have nodal involvement at the time of diagnosis. The tumors of the oral cavity are usually less aggressive than SCCs arising from the oropharynx. Both CT and MRI are useful for assessing tumor extent and nodal involvement.[39]

D. Pharynx

The pharynx is a mucosa-lined tubular structure and is the portion of the aerodigestive tract extending from the skull base to the cervical esophagus. By convention and for ease of discussion, it is divided into three parts: nasopharynx, oropharynx, and hypopharynx. Anatomically,

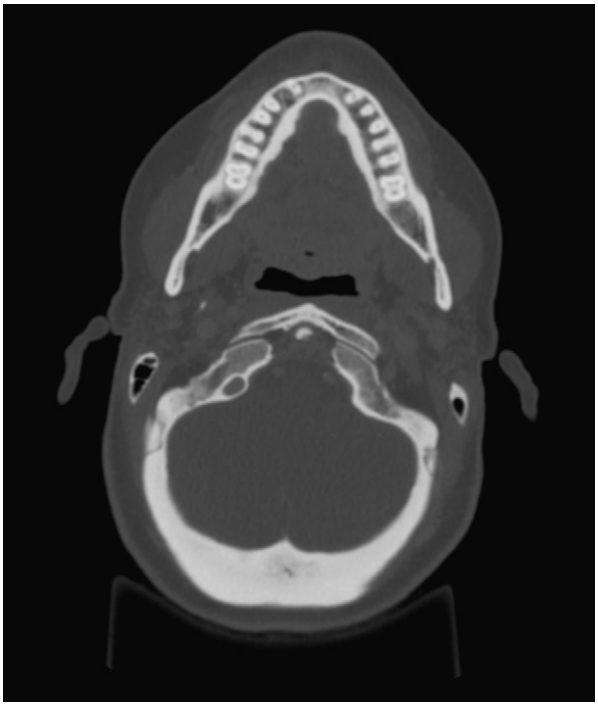

Figure 2-51 Torus mandibularis. Axial computed tomogram at the level of the mandible demonstrates cortical widening of the lingual surface of the mandible.

the nasopharynx is defined as extending from the skull base to the hard palate, the oropharynx from the hard palate to the hyoid bone, and the hypopharynx from the hyoid bone to the caudal margin of the cricoid cartilage. Below the level of the cricoid cartilage, the cervical esophagus begins. The hypopharynx can be further subdivided into the pyriform sinus region, the posterior wall, the postcricoid region, and the lateral surface of the aryepiglottic folds.[25,38]

The pharyngeal musculature includes the three overlapping constrictor muscles (the superior, middle, and inferior pharyngeal constrictors) and the cricopharyngeus, salpingopharyngeus, stylopharyngeus, palatopharyngeus, tensor veli palatini, and levator veli palatini muscles. Innervation is primarily from the pharyngeal plexus of nerves, to which the vagus (CN X) and glossopharyngeal nerve contribute. The vagus nerve primarily supplies motor innervation to the constrictors. The mandibular branch of the trigeminal nerve innervates the tensor veli palatini muscle. Sensory information travels along the glossopharyngeal nerve and the internal laryngeal branch of the superior laryngeal nerve, which arises from the vagus nerve.

The arterial supply to the pharynx is from branches of the external carotid artery, including the ascending pharyngeal artery, tonsillar branches of the facial artery, and the palatine branches of the maxillary artery. Superior and inferior thyroid arteries supply most of the lower pharynx. The primary venous drainage is through the superior and inferior thyroid veins and the pharyngeal veins into the internal jugular veins. The lymphatic drainage is complex and extensive to the jugular, retropharyngeal, posterior cervical, and paratracheal nodes.[25,43,44]

Imaging studies of the pharynx most commonly include plain radiographic films, barium studies, CT, and MRI. In contrast to CT and MRI, a barium study is a dynamic imaging technique that can demonstrate the sequential contractions of the pharyngeal musculature during deglutition. It can show whether the pharyngeal wall is fixed or pliable and may detect mucosal lesions not apparent on CT or MRI. CT and MRI are most commonly done with the patient in the supine position and the neck in the neutral position. Intravenous contrast is recommended with CT for evaluation of lymphadenopathy. The inherent differences in signal intensity between tumor, fat, and muscle on MRI often allow accurate delineation of the tumor extent without gadolinium, which is the contrast agent commonly used in clinical practice.[44] Because of the clinical concern for perineural spread of tumor in the head and neck region, MRI is usually performed with contrast.

1. Nasopharynx

a. IMAGING ANATOMY OVERVIEW

The nasopharynx is an air-containing cavity that occupies the uppermost extent of the aerodigestive tract. The roof and posterior wall of the nasopharynx are formed by the sphenoid sinus, the clivus, and anterior aspect of the first two cervical vertebrae. The inferior aspect of the nasopharynx is formed by the hard palate, the soft palate, and the ridge of pharyngeal musculature that opposes the soft palate when it is elevated (Passavant's ridge). The lateral nasopharyngeal walls are formed by the margins of the superior constrictor muscle. Anteriorly, the nasopharynx is in direct continuity with the nasal cavity through the posterior choanae. The nasopharynx is in direct communication with the middle ear cavity through the eustachian tubes (Fig. 2-52).[44]

b. PERTINENT IMAGING PATHOLOGY

ADENOIDAL HYPERTROPHY. The adenoids are lymphatic tissues that are located in the upper posterior aspect of the nasopharynx. Prominent adenoids are typical in children; by the age of 2 to 3 years, the adenoids can fill the entire nasopharynx and extend posteriorly into the posterior choanae. Regression of the lymphoid tissue starts during adolescence and continues into later life. By the age of 30 to 40 years, adenoidal tissue is minimal, although normal adenoidal tissue may occasionally be seen in adults in the fourth and fifth decades of life. Adenoid tissues appear isodense to muscle on CT imaging (see Fig. 2-52D). On MRI, the adenoids are isointense to muscle on T1-weighted imaging and hyperintense on T2-weighted imaging. If prominent adenoidal tissue is seen in an adult, human immunodeficiency virus (HIV) infection should be suspected.[44] Differentiation between lymphomatous involvement and hypertrophy of the adenoids is not possible on imaging, because both entities are hyperintense on T2-weighted imaging. Enlargement of the adenoids can cause partial obstruction of the nasopharyngeal airway and make insertion of an NGT difficult. They may also contribute to the symptom complex of obstructive sleep apnea.

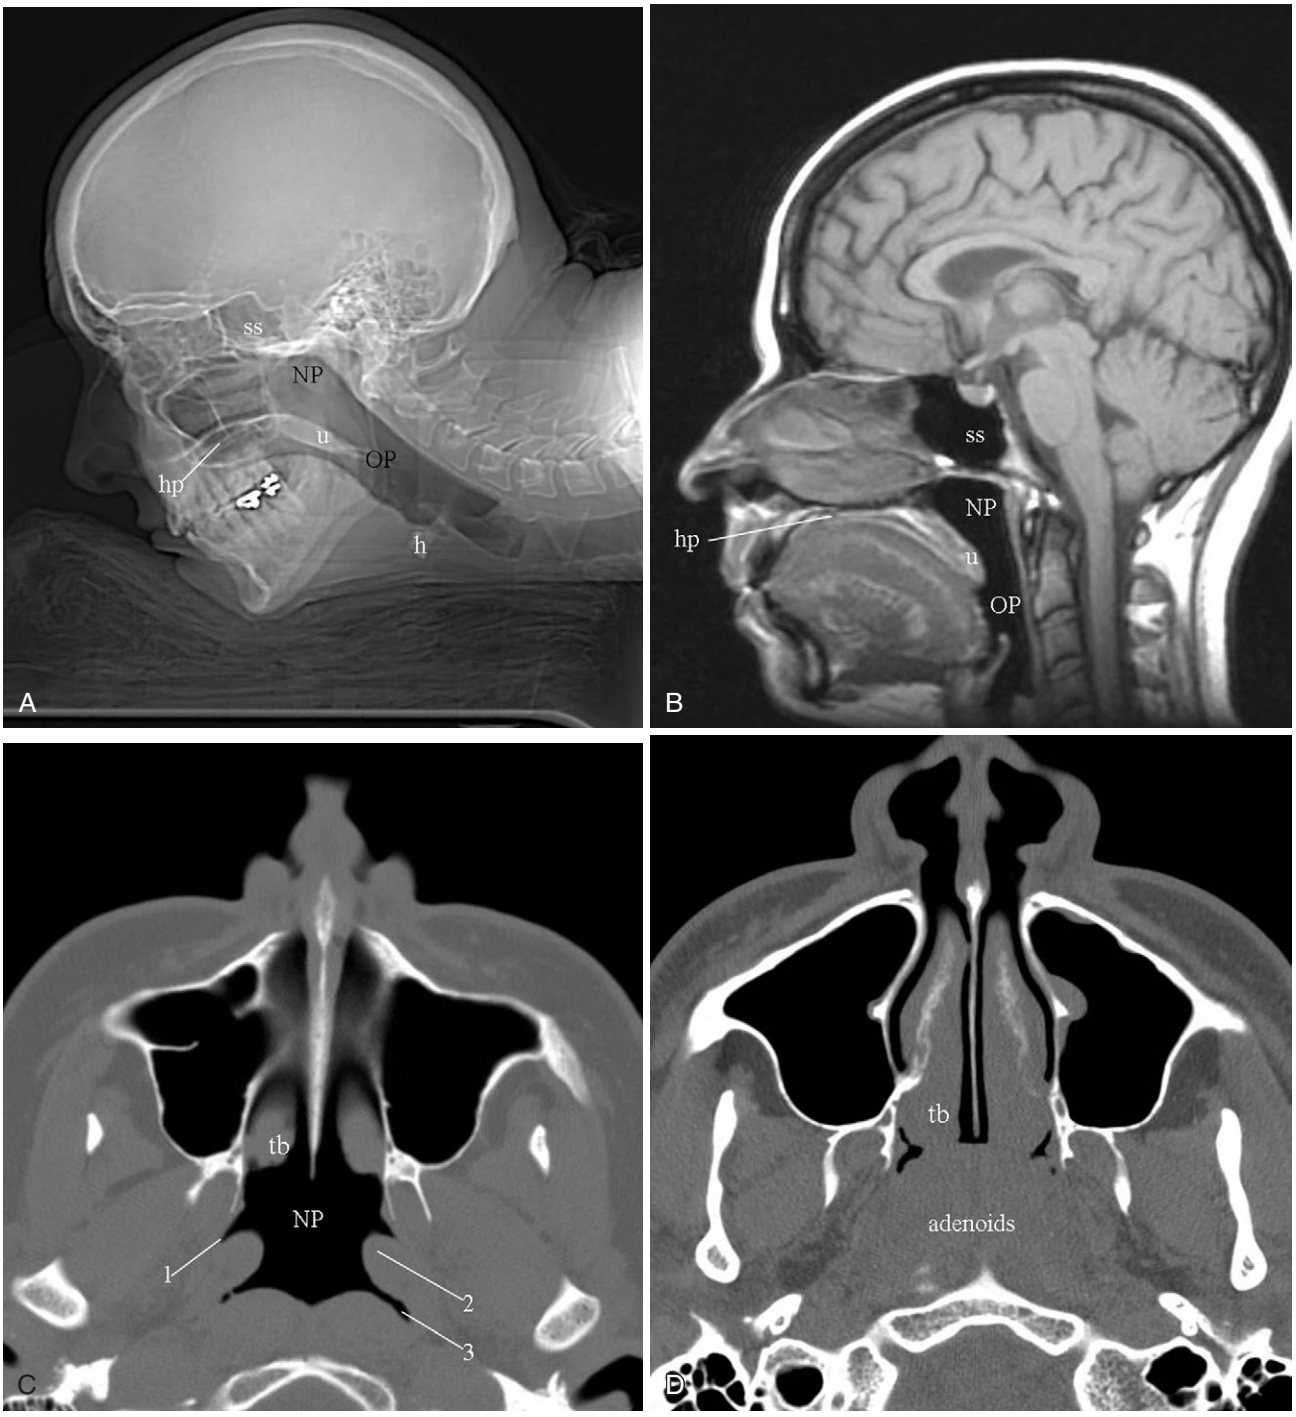

Figure 2-52 Normal anatomy of the nasopharynx. **A,** Computed tomographic (CT) scout view in prone position. **B,** T1-weighted sagittal brain magnetic resonance image. **C,** Normal nasopharynx on axial CT scan. **D,** Prominent adenoids effacing the nasopharyngeal airway. *1,* Opening of the eustachian tube; *2,* torus tubarius; *3,* fossa of Rosenmüller; *h,* hyoid; *hp,* hard palate; *NP,* nasopharynx; *OP,* oropharynx; *ss,* sphenoid sinus; *tb,* turbinate, *u,* uvula.

TORNWALDT'S CYST. Tornwaldt's cyst is a not uncommon incidental finding on MRI. It is usually midline and located between the longus capitis muscles in the posterior nasopharynx. It is a developmental anomaly in which the ascension of the notochord back into the skull base pulls a small tag of the developing nasopharyngeal mucosa with it, creating a midline pit or tract that closes over and results in a midline cyst, usually after pharyngitis. These lesions usually have a high signal intensity on T1- and T2-weighted imaging, probably because of the high protein content of the cyst fluid. Tornwaldt's cyst is usually infected by anaerobic bacteria, which may empty

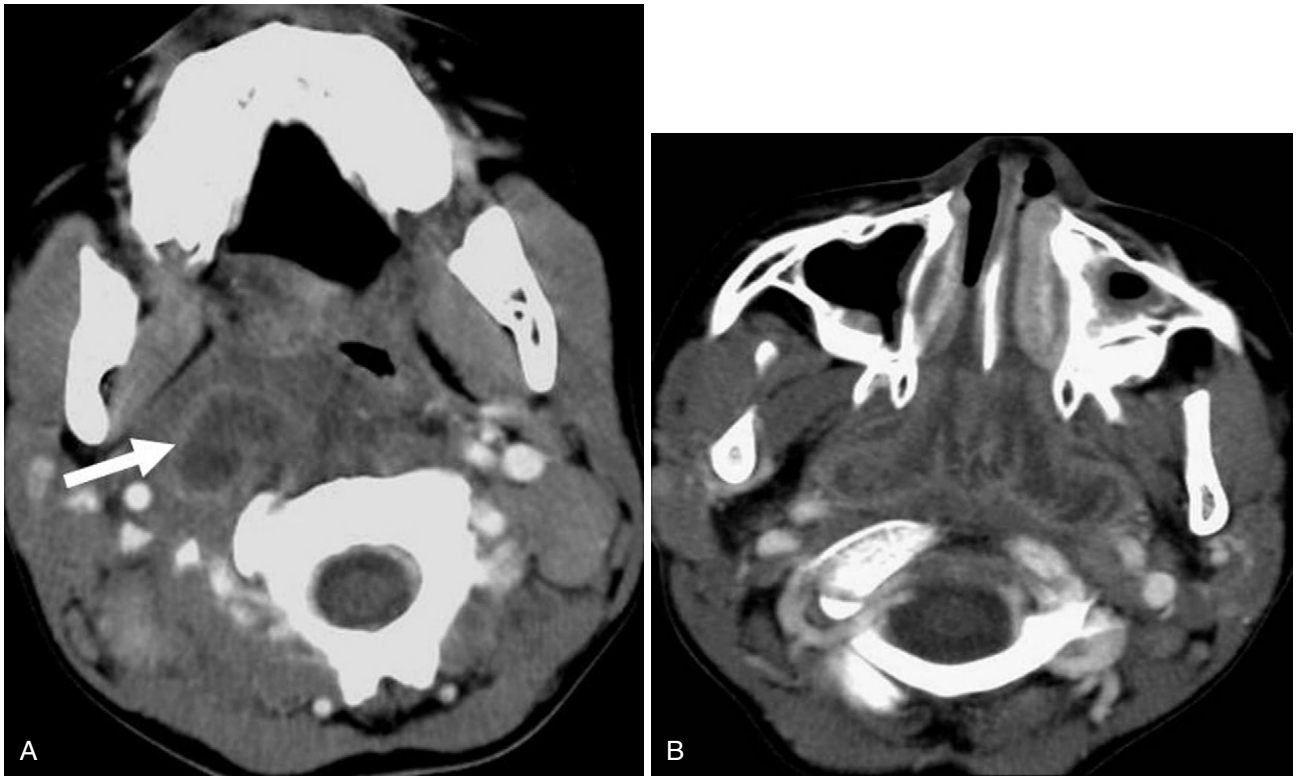

Figure 2-53 Suppurative adenitis seen on axial computed tomography scans. **A,** A ring-enhancing mass (*arrow*) in the right parapharyngeal space is deviating the oropharynx. **B,** Bilateral bulky adenopathy is present with abscess formation obliterating the nasopharynx.

into the nasopharynx and cause intermittent halitosis. The CT density of the cyst is similar to that of surrounding muscle and lymphoid tissue.

INFECTION AND ABSCESS. Abscess in the parapharyngeal space may result from tonsillar infection or from iatrogenic or traumatic perforation of the pharynx. The infection may extend from the skull base to the submandibular region and can be difficult to differentiate from a neoplastic process. If large enough, it may compromise the airway. Infection spreading to retropharyngeal nodes (suppurative adenitis) can also obliterate the nasopharynx airway (Fig. 2-53).

TUMORS AND OTHER CONDITIONS. SCC of the nasopharynx is a relatively rare cancer that accounts for only 0.25% of all malignancies in North America. It has a high rate of incidence in Asia, however, where it is the most common tumor in men, accounting for 18% of cancers in China.[43] SCC accounts for 70% or more of the malignancies arising in the nasopharynx, and lymphomas account for about 20%. The remaining 10% are a variety of lesions, including adenocarcinoma, adenoid cystic carcinoma, rhabdomyosarcoma, melanoma, extramedullary plasmacytoma, fibrosarcoma, and carcinosarcoma. Risk factors for SCC in the nasopharynx include the presence of immunoglobulin A antibodies against Epstein-Barr virus, human leukocyte antigens HLA-A2 and HLA-B-Sin histocompatibility loci, nitrosamines, polycyclic hydrocarbons, poor living conditions, and chronic sinonasal infections.[44] The most common presentation is nodal disease. There is no correlation between primary tumor size and the presence of nodal disease. Imaging with CT and MRI is performed to map accurately the extent of the disease, not for histologic diagnosis (Fig. 2-54).

2. Oropharynx

a. IMAGING ANATOMY OVERVIEW

The oropharynx is the region posterior to the oral cavity that includes the posterior one third of the tongue (tongue base), the palatine tonsils, the soft palate, and the oropharyngeal mucosa and constrictor muscles. The posterior pharyngeal wall is at the level of the second and third cervical vertebrae. Laterally, there are two mucosa-lined faucial arches; the anterior arch is formed by the mucosa of the palatoglossus muscle, and the posterior arch is formed by the palatopharyngeus muscle. The palatine tonsils are located between the two faucial arches, and the lingual tonsils reside at the base of the tongue. Both sets of tonsils vary in size and can encroach on the airway.

The arterial supply to the oropharynx is mainly from branches of the external carotid artery: the tonsillar branch of the facial artery, the ascending pharyngeal artery, the dorsal lingual arteries, and the internal maxillary and facial arteries. The venous drainage is primarily through the peritonsillar veins, which pierce the constrictor musculature and drain into the common facial vein and the pharyngeal plexus. Lymphatic drainage is mainly to the jugulodigastric chain from the skull base to the cricoid cartilage, the retropharyngeal nodes, the posterior

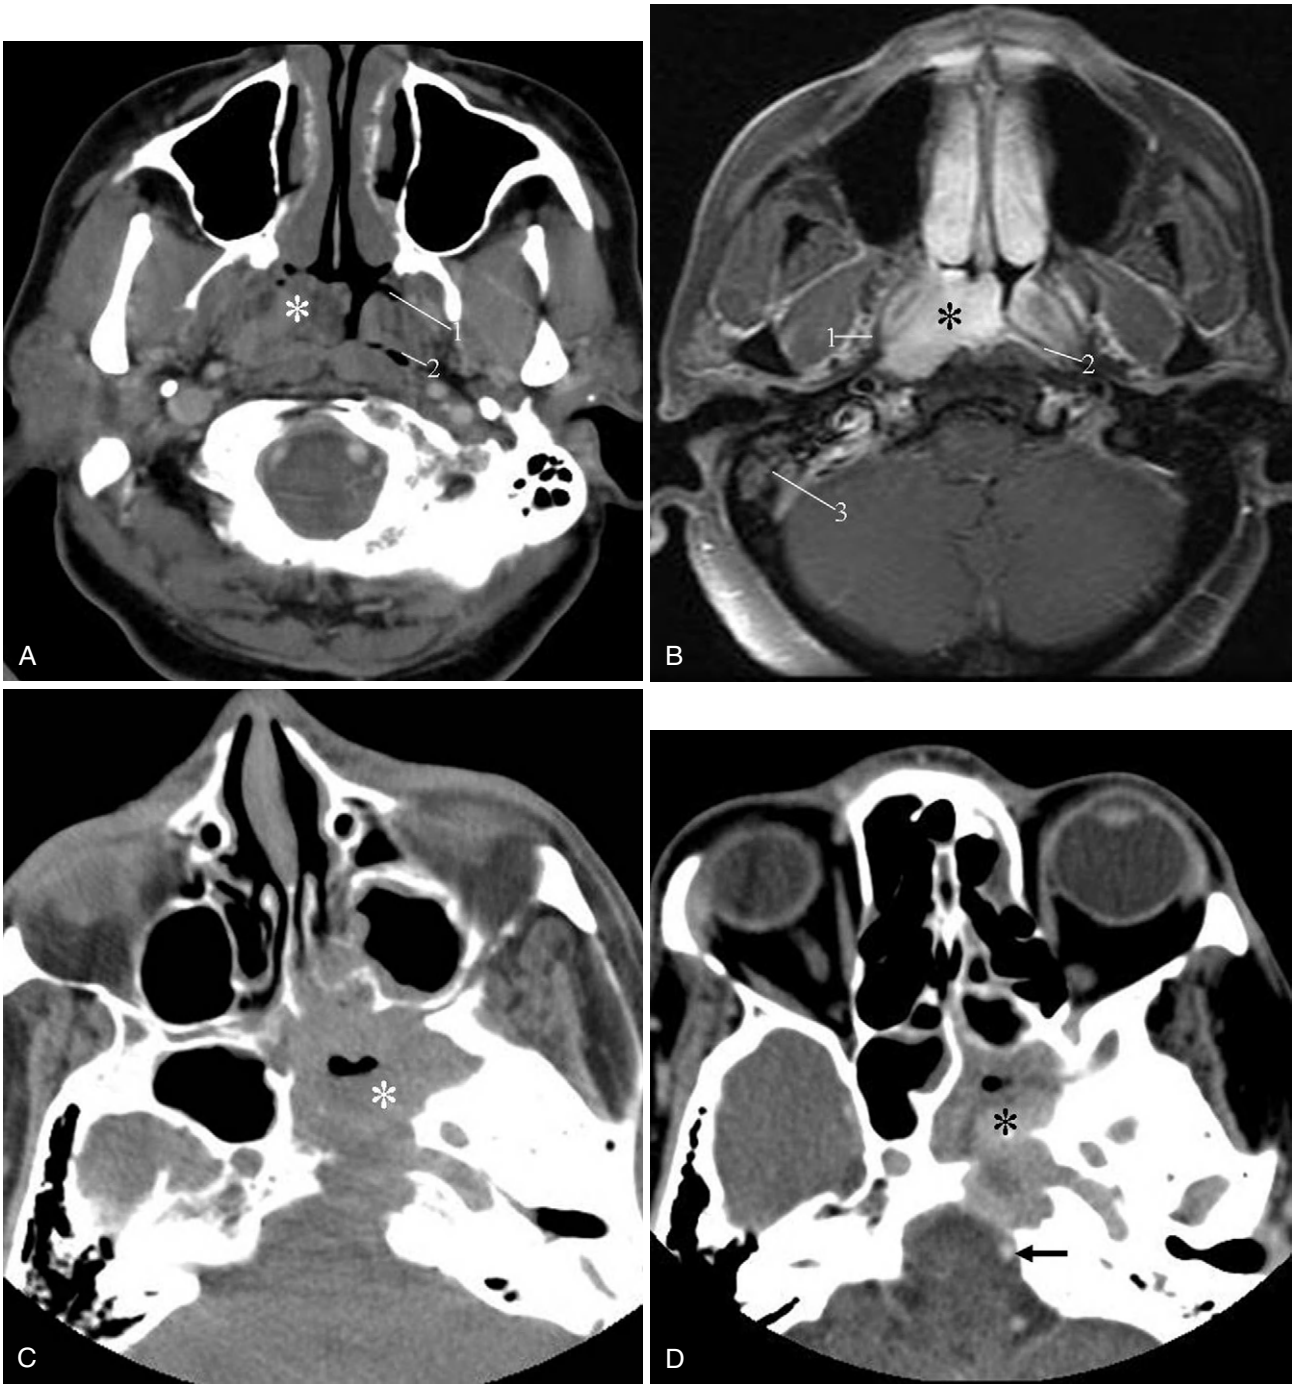

Figure 2-54 Squamous cell carcinoma (SCC) of the right nasopharynx. **A,** Axial computed tomogram (CT) with contrast demonstrates bulky soft tissue asymmetry in the nasopharynx with abnormal enhancement on the right. **B,** T1-weighted magnetic resonance image with gadolinium contrast confirms a right nasopharyngeal mass obstructing the eustachian canal and consequent opacification of the right mastoid air cells. **C,** Axial CT demonstrates SCC extending from the soft tissues of the left nasopharynx to the posterior fossa of the brain with bone destruction of the skull base. **D,** Axial CT after contrast enhancement. Notice the proximity of this invasive lesion to the vertebral artery (*arrow*) at the foramen magnum. If these findings are not appreciated at the time of surgery, an errant nasogastric tube can easily enter the cranium, damage the brainstem, and injure the vertebral artery. In each image, the mass is indicated by an *asterisk*. *1,* Eustachian tube; *2,* fossa of Rosenmüller; *3,* opacified mastoid air cells.

triangle nodes from the level of the skull base to the cricoid cartilage, and sometimes the parotid nodes.[44]

b. PERTINENT IMAGING PATHOLOGY

TONSILLAR HYPERTROPHY. During the third and fourth fetal months, lymphoid tissues invade the pharyngeal region of the adenoid tonsils, the palatine region (palatine tonsils), and the root of the tongue (lingual tonsils).[37] The adenoids are located in the roof of the nasopharynx. As mentioned previously, enlargement of the palatine and lingual tonsils may compromise the airway (Fig. 2-55).

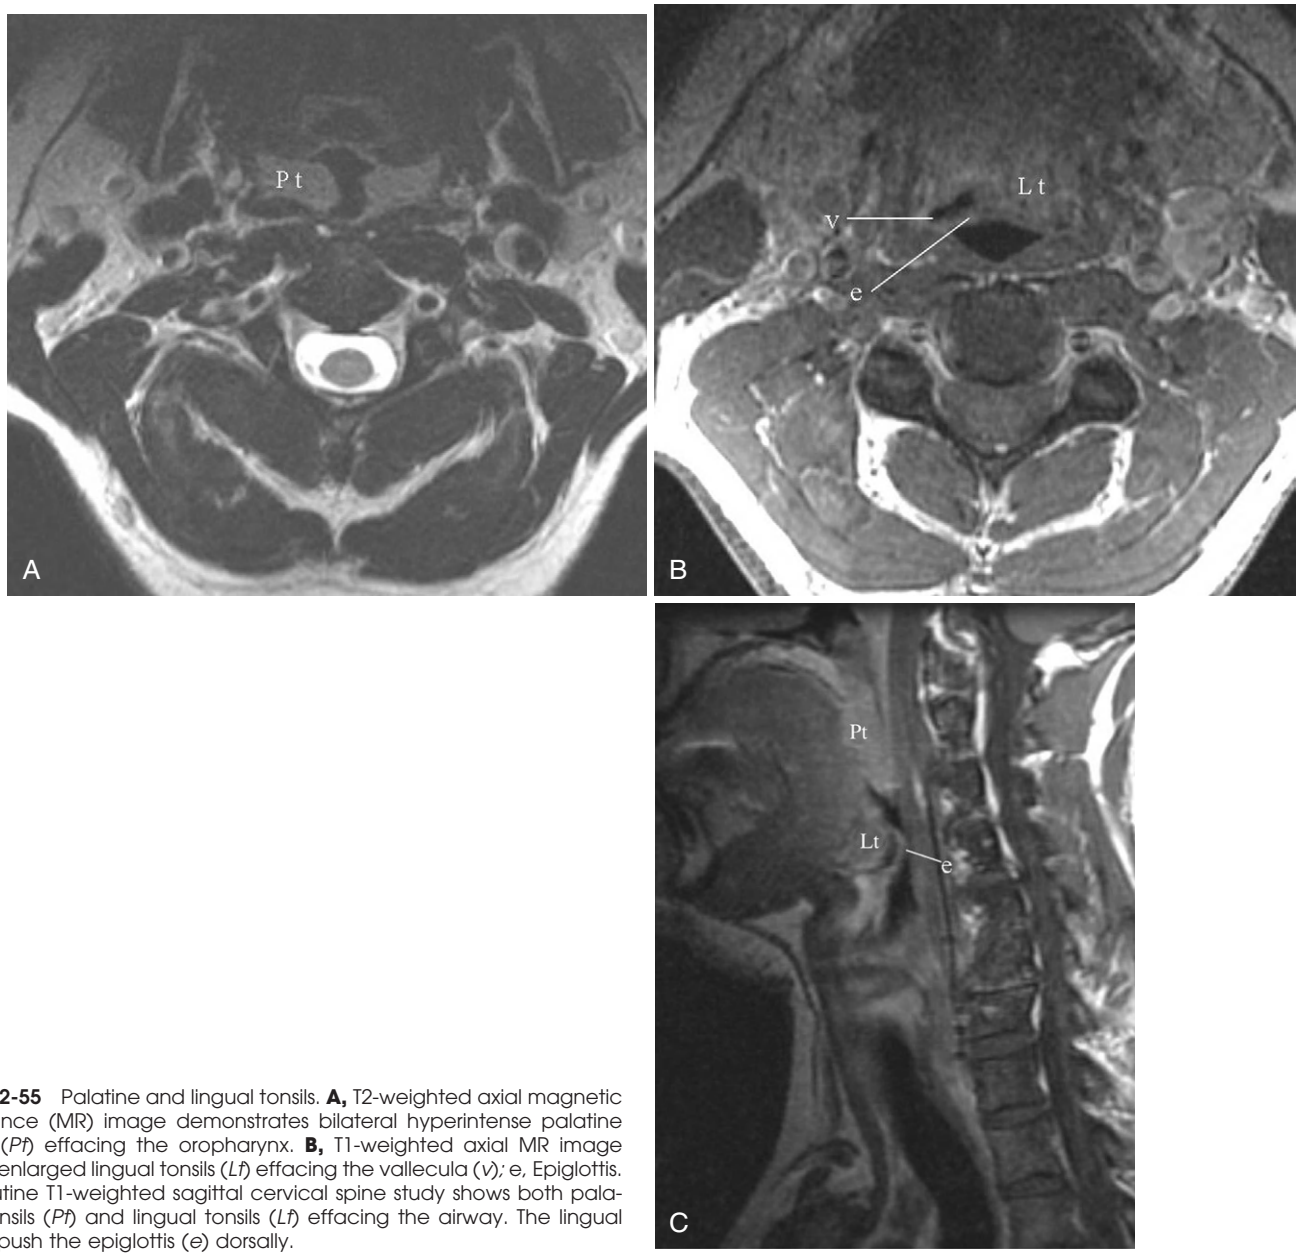

Figure 2-55 Palatine and lingual tonsils. **A,** T2-weighted axial magnetic resonance (MR) image demonstrates bilateral hyperintense palatine tonsils (*Pt*) effacing the oropharynx. **B,** T1-weighted axial MR image shows enlarged lingual tonsils (*Lt*) effacing the vallecula (*v*); e, Epiglottis. **C,** Routine T1-weighted sagittal cervical spine study shows both palatine tonsils (*Pt*) and lingual tonsils (*Lt*) effacing the airway. The lingual tonsils push the epiglottis (*e*) dorsally.

TONSILLITIS AND PERITONSILLAR ABSCESS. Acute bacterial tonsillitis is most commonly caused by β-hemolytic streptococcus, staphylococcus, pneumococcus, or *Haemophilus* species. It is usually a self-limited disease; however, uncontrolled infection of the tonsils may result in a peritonsillar abscess or, rarely, a tonsillar abscess. On CT imaging, the findings of acute or chronic tonsillitis are nonspecific. Focal homogeneous swelling of the palatine tonsils can be present and is difficult to differentiate from tumor. The imaging features of abscess formation are a low-density center and an enhancing rim of soft tissue (Fig. 2-56). Peritonsillar abscess is the accumulation of pus around the tonsils. The infection may extend to the retropharyngeal, parapharyngeal, or submandibular spaces.

RETROPHARYNGEAL PROCESS. Infection of the retropharyngeal space usually results from an infection at a site whose primary drainage is to the retropharyngeal lymph nodes, such as the nose, sinuses, throat, tonsils, oral cavity, or middle ear. The lymph nodes enlarge and undergo suppuration and eventually rupture into the retropharyngeal space, creating an abscess. It can be caused by a penetrating injury or by cervical spine osteomyelitis or diskitis. Before the advent of antibiotics, retropharyngeal infection was potentially life-threatening. A retropharyngeal space infection can extend from the skull base to the carina. On imaging, a retropharyngeal abscess expands the prevertebral space, with enhancement along its margins.

Included in the differential diagnosis of a retropharyngeal abscess is tendinitis of the longus colli, which is characterized by inflammation of the tendinous insertion of the longus colli muscle with deposition of calcium hydroxyapatite crystals. An effusion may extend from the

Figure 2-56 Tonsillar abscess. Axial computed tomogram with contrast demonstrates a left tonsillar fluid collection compressing the oropharynx.

prevertebral space into the retropharyngeal space and mimic a retropharyngeal abscess. Post-traumatic hematoma may also increase the width of the prevertebral space. In addition, cervical spine pathology can extend and enlarge the prevertebral space and cause the airway to deviate anteriorly.

TORTUOUS INTERNAL OR COMMON CAROTID ARTERY. If the course of either the common carotid artery or the internal carotid artery is directed medially, bulging of the submucosa of the oropharynx or hypopharynx may result. In this less protected location, the artery is more vulnerable to trauma. Imaging is useful to prevent unnecessary biopsy of this pseudosubmucosal mass (Fig. 2-57).

TUMORS AND OTHER CONDITIONS. SCC is the most common neoplasm of the oropharynx, and its predisposing factors include alcohol and tobacco use. Most recently, epidemiologic and molecular data have shown a strong association between human papillomavirus (HPV) infection—in particular, exposure to or infection with high-risk HPV-16—and the development of oropharyngeal cancer, especially tonsillar cancer. This subset of patients with oropharyngeal cancers present at a younger age and have distinct molecular and pathologic differences, with an as yet unexplained improved prognosis.[45] There is also a proven causal relationship between HPV-16 and the development of cervical cancer, and for this reason HPV infection is considered a sexually transmitted disease.

The site of origin determines the spread of the tumor; the most common locations are the anterior and posterior tonsillar pillars, tonsillar fossa, soft palate, and base of the tongue (Fig. 2-58). Staging of tumor in the oropharynx depends on the size of the tumor and whether it has invaded adjacent structures. Other neoplasms include lymphoma, minor salivary gland tumors, and mesenchymal tumors.

Figure 2-57 Anomalous course of carotids. **A,** Axial computed tomogram (CT) with contrast shows bilateral carotid aneurysms (*an*) effacing the oropharynx. Notice the presence of thrombus in the lumen of the aneurysm on the left. **B,** Axial CT with contrast demonstrates medially deviated carotids assuming a retropharyngeal location (*arrows*). *IJ,* Internal jugular vein.

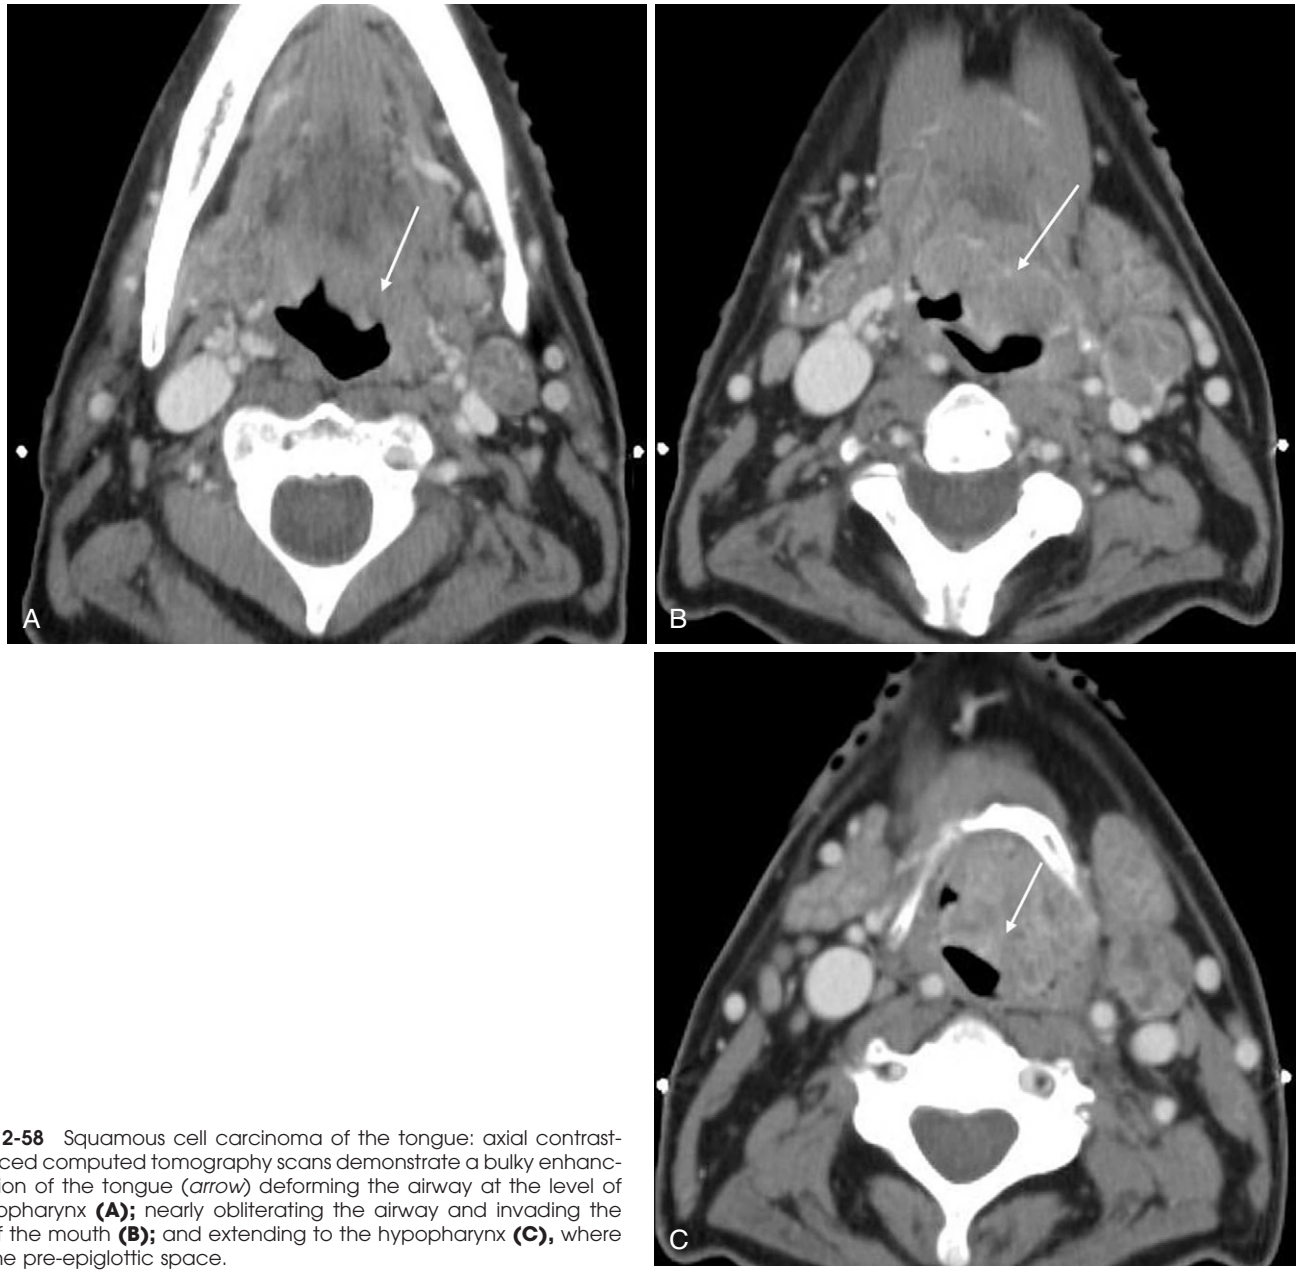

Figure 2-58 Squamous cell carcinoma of the tongue: axial contrast-enhanced computed tomography scans demonstrate a bulky enhancing lesion of the tongue (*arrow*) deforming the airway at the level of the oropharynx **(A);** nearly obliterating the airway and invading the floor of the mouth **(B);** and extending to the hypopharynx **(C),** where it fills the pre-epiglottic space.

3. Hypopharynx

The boundary of the hypopharynx is classically defined as the segment of the pharynx that extends from the level of the hyoid bone and the valleculae to the cricopharyngeus or the lower level of the cricoid cartilage. By definition, the cervical esophagus starts at the caudal end of the cricoid cartilage. The cricopharyngeus muscle acts as the superior esophageal sphincter. It arises from the lower aspect of the inferior constrictor muscle attached to the cricoid. The upper esophageal sphincter is normally closed until a specific volume and pressure in the hypopharynx trigger relaxation of the cricopharyngeus muscle to allow a bolus of food to pass into the cervical esophagus. The cricopharyngeus muscle then closes to prevent reflux.[43]

a. IMAGING ANATOMY OVERVIEW

The hypopharynx can be divided into four regions: the pyriform sinuses, the posterior wall of the hypopharynx, the postcricoid region, and the lateral surface of the aryepiglottic folds. The pyriform sinus is the anterolateral recess of the hypopharynx. The anterior pyriform sinus mucosa abuts on the posterior paraglottic space. The most caudal portion of the pyriform sinus lies at the level of the true vocal cords. The lateral aspect of the aryepiglottic folds forms the medial wall of the pyriform sinus (Fig. 2-59). This is considered a marginal zone because the aryepiglottic folds are part of both the hypopharynx and the supraglottic larynx. Tumors involving the medial surface of the aryepiglottic folds behave like laryngeal tumors. The biologic behavior of tumors arising from the

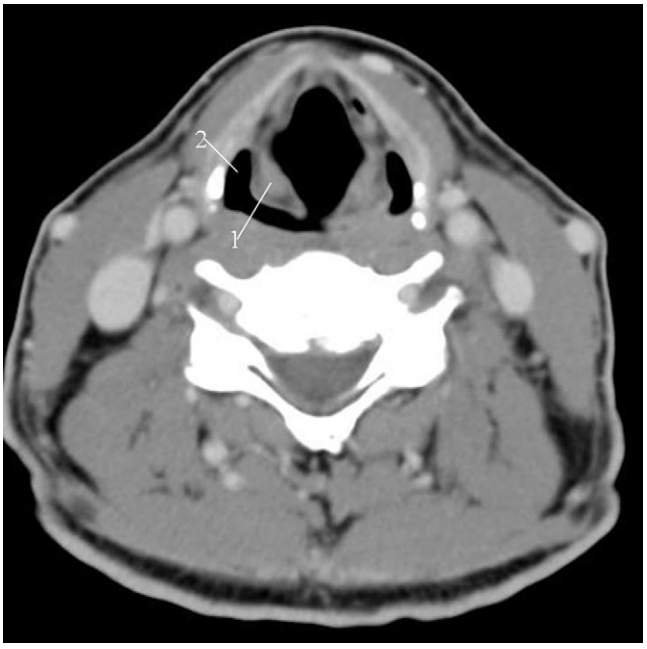

Figure 2-59 Aryepiglottic fold and pyriform sinus. Axial computed tomogram at the level of hypopharynx. *1,* Aryepiglottic fold; *2,* air-containing pyriform sinus.

lateral surface of the aryepiglottic folds is similar to that of the more aggressive pharyngeal tumors. The lateral wall of the pyriform sinus is formed by the thyroid membrane and cartilage.[44]

The posterior hypopharyngeal wall is continuous with the posterior wall of the oropharynx and begins at the level of the valleculae. It continues caudally as the posterior wall of the cricopharyngeus and the cervical esophagus. The retropharyngeal space lies behind the posterior pharyngeal wall. The anterior wall of the lower hypopharynx is referred to as the *postcricoid hypopharynx*: the larynx is anterior and the hypopharynx is posterior to this soft tissue boundary. It extends from the level of the arytenoid cartilages to the lower cricoid cartilage. On imaging, the transition from the hypopharynx to the cervical esophagus is denoted by a change in the shape of the aerodigestive tract, from crescentic or ovoid to round.

The arterial supply to the lower pharynx is mainly from the superior and inferior thyroid arteries. Venous drainage is through the superior and inferior thyroid veins and individual pharyngeal veins to the internal jugular vein.

b. PERTINENT IMAGING PATHOLOGY

PHARYNGITIS. In immunocompetent patients, imaging is usually not required for the diagnosis or management of pharyngitis. In AIDS patients, imaging may be helpful to evaluate the extent of disease. Bacterial etiology is not the only concern; opportunistic infection with *Candida* or cytomegalovirus may involve the hypopharynx. These entities do not compromise the airway, but the mucosa is friable and is susceptible to injuries from instrumentation.

PHARYNGOCELE. A pharyngocele is a broad-based outpouching of the pharyngeal mucosa of the upper pyriform sinus, which distends with phonation or during the Valsalva maneuver. These lesions are visible as air-filled structures on CT or as barium-filled areas on a barium swallow test.

ZENKER'S DIVERTICULUM. It is postulated that dyssynergy of the cricopharyngeus muscle plays a role in the formation of this pulsion diverticulum of the hypopharynx. The diverticulum typically extends posteriorly and laterally, usually to the left, and may appear as an incidental, air-filled structure in the hypopharynx on CT and MRI. If alerted to the presence of a diverticulum, one should take more caution during blind advancement of an NGT, which may take an errant course (Fig. 2-60).

TRAUMA

Hematomas. Direct trauma or iatrogenic trauma caused by instrumentation, surgery, or a foreign body may result in retropharyngeal hematoma. Hemophiliacs may be more susceptible to hematomas with minor trauma. The imaging finding is retropharyngeal or prevertebral soft tissue swelling.

Postradiation Changes. The edema that occurs after radiation therapy may persist for many months or years and reflects a radiation-induced obliterative endarteritis. In cases of edema, the pharyngeal and supraglottic mucosa appears swollen, bulging, and hypodense on CT, and the submucosa fat is thickened and streaky. The platysma muscle and skin are also thickened. The end result is fibrosis and loss of elasticity of the soft tissues. This increased rigidity of the soft tissues should be taken into account during laryngoscopy for endotracheal intubation and in selecting the correct size of a laryngeal mask airway (LMA). Specifically, the LMA needs to be one or even two sizes smaller than predicted by the patient's weight.

TUMORS AND OTHER CONDITIONS

Squamous Cell Carcinoma. The hypopharynx is lined by stratified squamous epithelium, and most tumors of the hypopharynx are SCCs (Fig. 2-61). The risk factors for SCC of the hypopharynx include alcohol abuse, smoking, and previous radiation therapy. Patients with Plummer-Vinson syndrome have a higher incidence of postcricoid carcinoma. Extensive submucosal growth is common and can be appreciated only on imaging. The airway may be effaced and displaced. Most patients have metastases to the cervical nodes at presentation. Between 4% and 15% of patients with SCC of the hypopharynx have a synchronous or metachronous second primary tumor.[44,46]

Lymphomas. Hodgkin's lymphoma predominantly affects adolescents and young adults, whereas non-Hodgkin's lymphoma is a disease of older patients. In contrast to patients with Hodgkin's disease, patients with non-Hodgkin's lymphoma present with disease in extranodal sites, such as Waldeyer's ring. The imaging features of extranodal head and neck lymphoma can be difficult to differentiate from those of SCC. Lymphadenopathy in Hodgkin's disease can be quite large without affecting the airways.

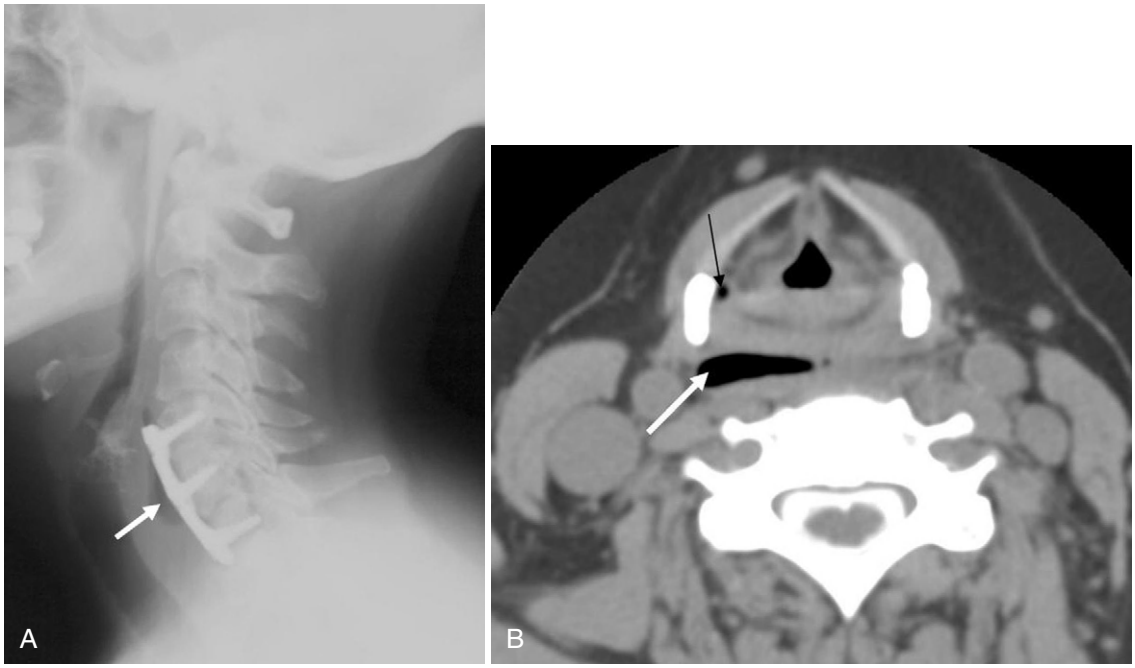

Figure 2-60 Zenker's diverticulum. **A,** Lateral cervical spine computed tomogram (CT) with soft tissue technique demonstrates an air-filled structure in the hypopharynx (*white arrow*) after anterior fusion. **B,** Axial CT at the level of the larynx shows the air-filled Zenker diverticulum to the right of midline (*white arrow*) and the tip of the right pyriform sinus (*black arrow*).

Other Malignancies. Less common primary cancers in the pharynx include minor salivary gland tumors (most often involving the soft palate), rhabdomyosarcomas, granular cell tumors, schwannomas and neurofibromas, hemangiomas, lipomas, amyloids, and metastases.[43,44]

Notice the effacement of the right pyriform sinus. *1,* Aryepiglottic fold; *2,* pyriform sinus.

E. Larynx

1. Imaging Anatomy Overview

Before the advent of CT and MRI, examination of the larynx consisted of plain radiographic films, multidirectional tomography, barium swallow, and laryngography. On a sagittal view, one can easily identify the hyoid bone, epiglottis, aryepiglottic folds, and vestibule, which is the space extending from the epiglottis to the level of the false vocal cords. At the level of the thyroid cartilage, a tiny slit of air is seen directed in the anterior-posterior direction. This is the laryngeal ventricle, which separates the false vocal cords from the true vocal cords (see Fig. 2-15).

Barium swallow, which is still used today, provides dynamic information about the swallowing mechanism and any dysfunction or incoordination of the muscles of swallowing and respiration. CT and MRI allow visualization of structures deep to the mucosa (Fig. 2-62); however, breathing and swallowing movements make imaging of the larynx difficult. The faster CT scanning technology available today allows the entire neck to be scanned in a single breath-hold. Helical technology allows reformation of the airway in multiple planes with one acquisition. MRI examination of the larynx continues to be problematic because of motion artifacts intrinsic and extrinsic to the larynx and longer acquisition time compared with CT. The advantage of MRI over CT is its ability to distinguish greater soft tissue contrast. The multiplanar capability of both CT and MRI is helpful in the evaluation of the mucosal folds and spaces in the neck.

In brief, the larynx can be considered as a conduit to the lungs. It also provides airway protection against aspiration and allows vocalization. It has an outer supporting

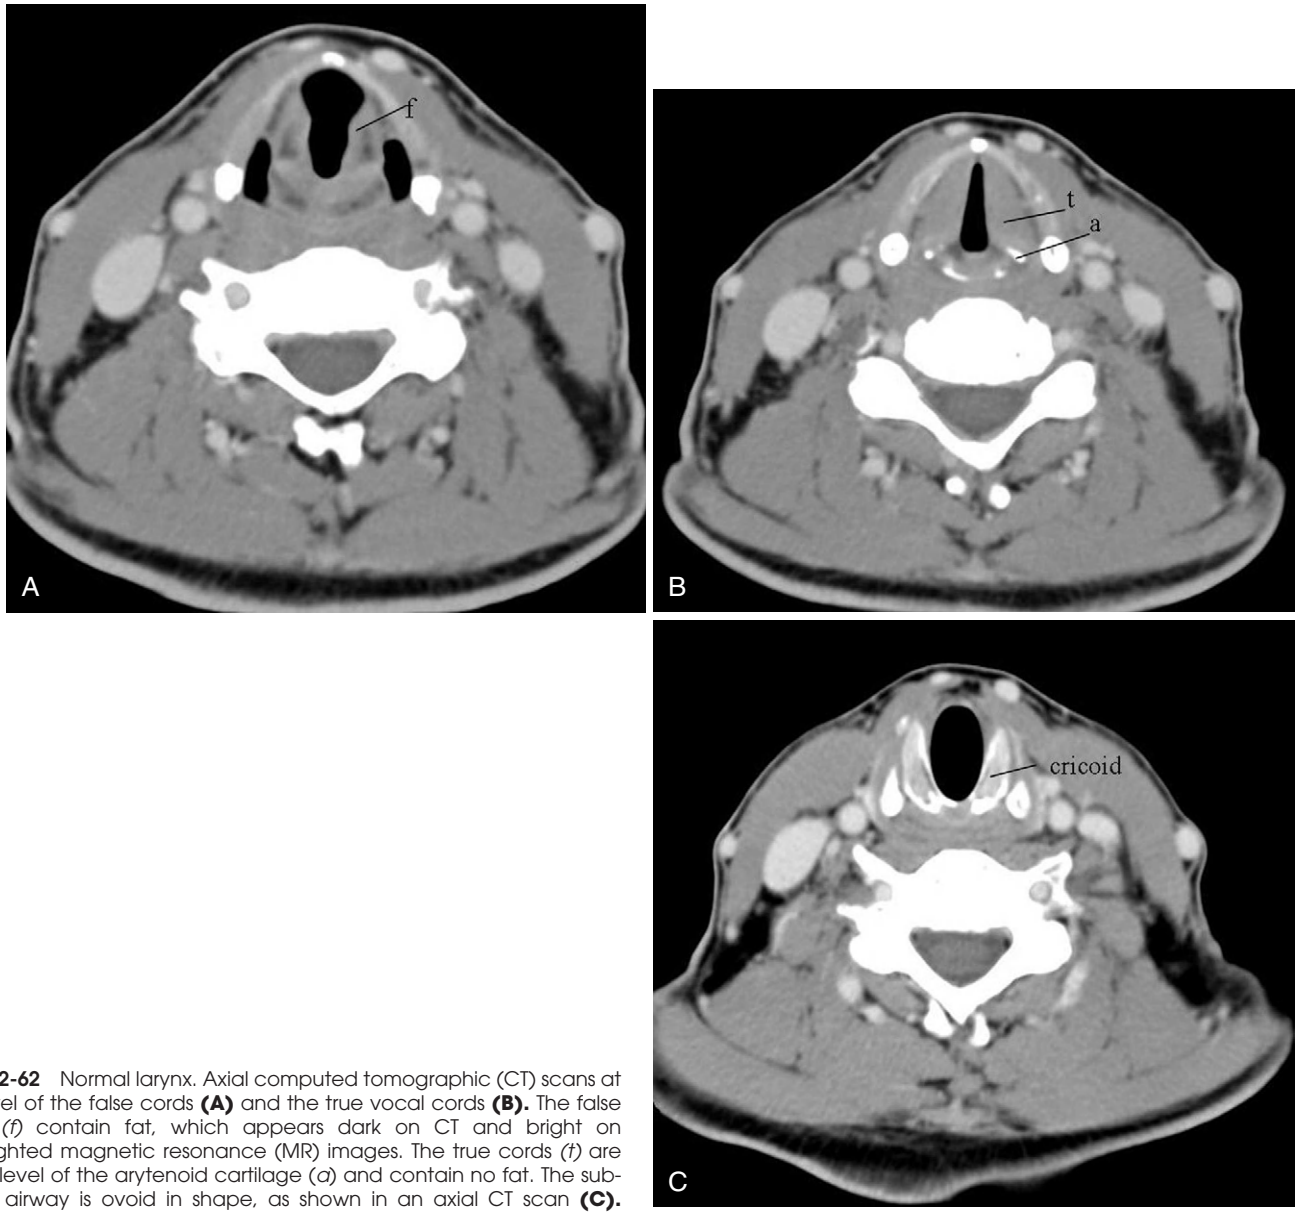

Figure 2-62 Normal larynx. Axial computed tomographic (CT) scans at the level of the false cords **(A)** and the true vocal cords **(B).** The false cords (*f*) contain fat, which appears dark on CT and bright on T1-weighted magnetic resonance (MR) images. The true cords (*t*) are at the level of the arytenoid cartilage (*a*) and contain no fat. The subglottic airway is ovoid in shape, as shown in an axial CT scan **(C).**

skeleton comprising a series of cartilages, fibrous sheets, muscles, and ligaments that provides structure and protection for the inner mucosal tube, the endolarynx. Between the cartilages and the mucosal surface lie the paraglottic and pre-epiglottic spaces, which contain loose areolar tissues, lymphatics, and muscles. Superiorly, the larynx is suspended from the hyoid bone, which is attached to the styloid process at the base of the skull by the stylohyoid ligament. Calcification of the stylohyoid ligament (see Fig. 2-11) has been proposed as a cause of difficult intubation.[18] Contraction of the muscles attached to the hyoid bone move it anterior and superior with consequent similar movements of the larynx. This sequence of movements also pulls the epiglottis to the horizontal plane, eventually inverting and closing the glottis and contributing to protection from aspiration.[47,48]

The parts of the exoskeleton of the larynx that are visible on plain radiography include the arytenoid cartilage, the cricoid cartilage, and the thyroid cartilage, which is the largest cartilage of the larynx. The thyroid cartilage is made up of two shieldlike laminae that fuse anteriorly to form the laryngeal prominence (Adam's apple). The angle of the fusion is usually more acute and more prominent in men. Paired superior and inferior cornua project from the posterior margin of the thyroid cartilage. The superior thyroid cornu is connected with the dorsal tip of the greater cornu of the hyoid bone by the thyrohyoid membrane. The inferior cornu articulates medially with the lateral wall of the cricoid cartilage to form the cricothyroid joint, where the thyroid cartilage rocks back and forth. Radiographically, this is an important landmark; it marks the entry of the recurrent laryngeal nerve to the larynx.[38] Muscles that attach to the external surface of the thyroid cartilage include the sternothyroid and thyrohyoid muscles and the inferior pharyngeal constrictors. The thyrohyoid membrane bridges

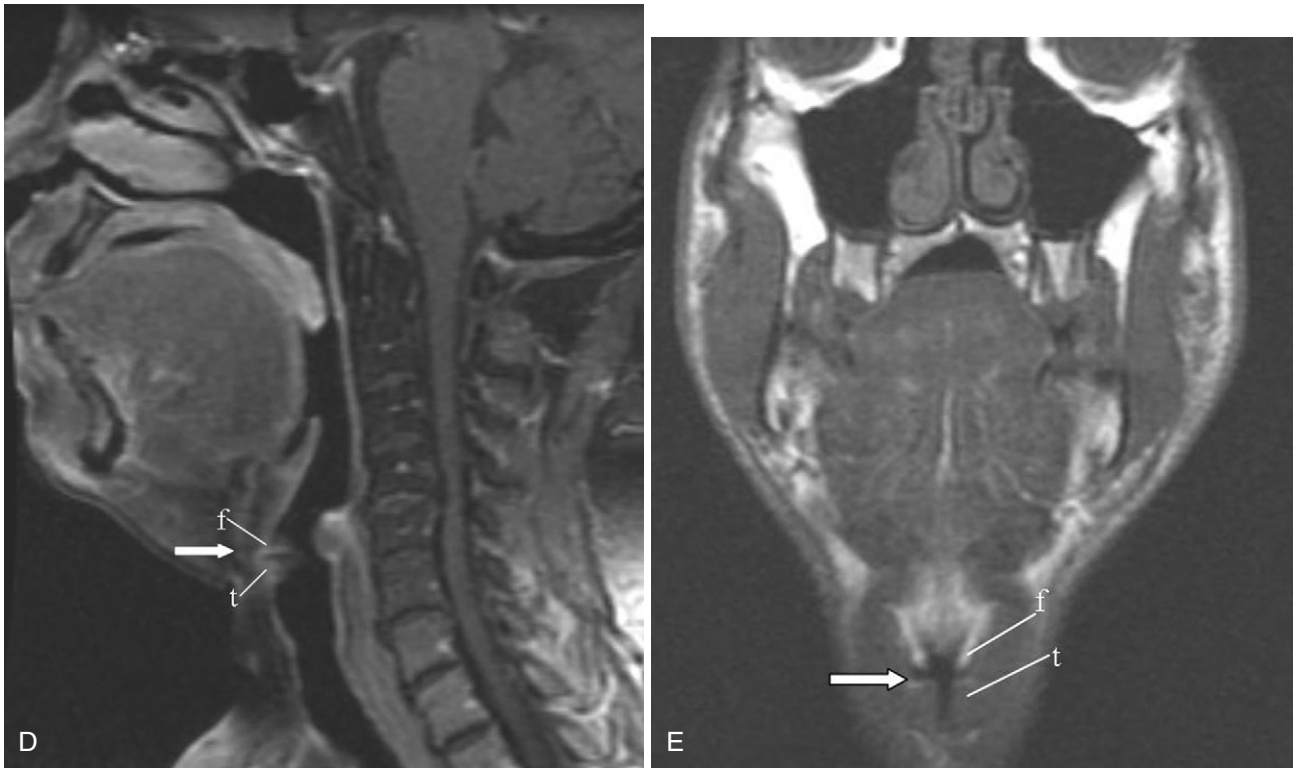

Figure 2-62, cont'd T-1 weighted sagittal **(D)** and coronal **(E)** MR images demonstrate the false cords *(f)* separated from the true cords *(f)* by the laryngeal ventricle (*arrow*).

the gap between the upper surface of the thyroid cartilage and the hyoid bone. Likewise, the cricothyroid membrane spans the distance between the lower margin of the thyroid cartilage and the cricoid cartilage.[47]

The cricoid cartilage, which is shaped like a signet ring with the larger part facing posteriorly, is the base of the larynx. On the upper surface of the cricoid lamina are two paired articular facets, on which are situated the arytenoid cartilages. The arytenoid cartilages are important surgical and imaging landmarks.[25] Each cartilage is pyramidal in shape. The base is formed by two projections: the muscular process situated on the posterolateral margin and the vocal process located anteriorly. The muscular and vocal processes are at the level of the true vocal cords.

The corniculate cartilage sits at the apex of the pyramid and is located above the level of the laryngeal ventricle, at the level of the false vocal cords. The arytenoid cartilages are important in maintaining airway patency and participate in vocalization by altering the opening of the glottis and the tension of the vocal cords. This is achieved by movements between the arytenoid and cricoid cartilages: adduction, abduction, anterior-posterior sliding, and medial-lateral sliding.[25]

For surgical planning purposes, the endolarynx can be divided into three compartments: the supraglottic larynx, the glottic larynx (glottis), and the subglottic larynx. The supraglottic airway can be defined as extending from the tip of the epiglottis to the laryngeal ventricles; it includes the false vocal cords, epiglottis, aryepiglottic folds, and arytenoids. The glottis is defined by the mucosal coverings of the true vocal cords and the anterior and posterior commissures. The subglottic larynx includes the undersurface of the true vocal cords and extends to the lower border of the cricoid cartilage.[38,47] The laryngeal ventricle demarcates two embryologically distinct laryngeal components: the supraglottic larynx and the subglottic larynx. The supraglottic larynx forms from primitive anlage and has richer lymphatics compared with the tracheobronchial buds. This embryologic and histologic difference accounts for the higher incidence of nodal metastasis at presentation of squamous cell cancer of the supraglottic larynx as compared to that of the glottic or subglottic primary.[47]

Several structures in the endoskeleton of the larynx are worth describing. The *epiglottis* is a yellow elastic fibrocartilage; its tip defines the cephalad margin of the supraglottic larynx. It has a flattened teardrop or leaf shape that tapers to an inferior point called the petiole of the epiglottis, where it attaches to the thyroid cartilage through the thyroepiglottic ligament. The superior and lateral edges are free. Most of the epiglottis extends behind the thyroid cartilage; the tip may be above the hyoid bone and sometimes can be seen through the oral cavity. It is held in place and stabilized by the hyoepiglottic and thyroepiglottic ligaments. The hyoepiglottic ligament is a tough, fibrous, fanlike ligament that extends from the ventral midline of the epiglottis to the dorsal margin of the hyoid cartilage. Immediately above the ligament are the pharyngeal recesses, the valleculae, which are situated just caudal to the tongue base. The epiglottis helps to guard against aspiration; during swallowing, the

aryepiglottic folds pull the sides of the epiglottis down, thereby narrowing the entrance to the larynx.[25,48]

The *quadrangular membrane* stretches anteriorly from the upper arytenoid and corniculate cartilages to the lateral margin of the epiglottis and contributes to the support of the epiglottis.[47] The superior free margin of this membrane forms the support for the aryepiglottic fold, which stretches from the upper margin of the arytenoids to the lateral margin of the epiglottis. The corniculate and cuneiform cartilages within the aryepiglottic fold help support the edge of each fold. These small, mucosa-covered cartilages are visualized on laryngoscopy as two small protuberances at the posterolateral border of the rima glottidis.[25] The aryepiglottic folds form the lateral margin of the vestibule of the supraglottic airway. The upper part of the aryepiglottic fold is the aryepiglottic muscle, which functions like a purse string to close the opening of the larynx during swallowing. Lateral to the aryepiglottic folds are the pyriform sinuses. The apex, the most inferior aspect of the pyriform sinus, is at the level of the true vocal cords.

The inferior free margin of the quadrangular membrane forms the *ventricular ligament*, which extends anteriorly from the superior arytenoid cartilage to the inner lamina of the thyroid cartilage and supports the free edge of the false vocal cords. The false vocal cords are superior to the true vocal cords and are separated by a lateral pouching of the airway, the laryngeal ventricle.[47] A second set of ligaments, the vocal ligaments, lies parallel and inferior to the ventricular ligament. It also extends from the vocal process of the arytenoid cartilage to the inner lamina of the thyroid just above the anterior commissure. The vocal ligament provides medial support for the true vocal cords. The space between the left and right vocal cords is referred to as the rima glottis, through which air passes to allow breathing and vocalization. Extending from the vocal ligament is another fibrous membrane, the conus elasticus, which attaches inferiorly to the upper inner margin of the cricoid cartilage. The conus spans part of the gap between the thyroid and cricoid cartilages.[25,47]

The muscles of the larynx are categorized as intrinsic and extrinsic muscles. The intrinsic muscles regulate the aperture of the rima glottis: (1) the thyroarytenoid makes up the bulk of the true vocal cord and has a lateral and a medial belly; (2) the lateral cricoarytenoids extend from the muscular process of the arytenoid cartilage to the upper lateral cricoid cartilage and function to adduct the cords; (3) the posterior cricoarytenoids extend from the muscular process of the arytenoid cartilage to the posterior surface of the cricoid cartilage and abduct the cords laterally; and (4) the intra-arytenoid muscle stretches from one arytenoid to the other and functions to adduct the vocal cords.[25,47] The extrinsic muscle is the cricothyroid muscle, which extends from the lower thyroid cartilage anteriorly to the upper cricoid cartilage. The contraction of this muscle pivots the thyroid cartilage forward around an axis through the cricothyroid joint, which stretches and tenses the vocal cords, thus affecting pitch in vocalization.[25,47]

Because the vocal cords are not static structures, they are difficult to image. During normal respiration, the vocal cords are slightly abducted. During deep inspiration, the true vocal cords fully abduct against the lateral wall of the glottic airway. The airway opening becomes narrowed with medialization of the true cords during breath-holding with or without a Valsalva maneuver, expiration, and phonation. Extending below the true vocal cords to the cricoid cartilage is the infraglottic cavity. The trachea begins below the level of the cricoid cartilage.[47]

The larynx is innervated primarily by branches of the vagus nerve.[25] The recurrent laryngeal nerve innervates all the intrinsic muscles of the larynx. If vocal cord paralysis is present and nerve damage is suspected, imaging should be tailored to follow the course of the recurrent laryngeal nerve in the neck and upper chest. The vagus nerve, after exiting the jugular foramen, passes vertically down the neck within the carotid sheath, between the internal jugular vein and the internal carotid artery (which becomes the common carotid artery) to the root of the neck. In front of the right subclavian artery, the recurrent laryngeal nerve branches from the vagus nerve, loops around the right subclavian artery, and ascends to the side of the trachea behind the common carotid artery, in the tracheoesophageal groove. On the left side, the recurrent laryngeal nerve arises at the level of the aortic arch. It loops around the arch at the point where ligamentum arteriosum is attached and ascends to the side of the trachea in the tracheoesophageal groove. The recurrent laryngeal nerve enters the larynx behind the cricothyroid joint and innervates all the muscles of the larynx except the cricothyroid muscle, which is an extrinsic muscle of the anterior larynx that is innervated by the external laryngeal branch of the superior laryngeal nerve, a branch of the vagus nerve in the neck. Sensory input from the laryngeal mucosa is by the internal laryngeal branch of the superior laryngeal nerve, which perforates the posterior lateral portion of the thyrohyoid membrane.[25]

The blood supply to the larynx is from two branches of the external carotid artery: the superior and inferior laryngeal arteries. The superior laryngeal artery, a branch of the superior thyroid artery, travels with the internal branch of the superior laryngeal nerve. The inferior laryngeal artery, a branch of the inferior thyroid artery, which is a branch of the thyrocervical trunk, accompanies the recurrent laryngeal nerve into the larynx.[25]

2. Pertinent Imaging Pathology

a. TRAUMA

Fracture of the larynx, which usually occurs as a result of a vehicular accident, can involve the thyroid cartilage, the cricoid cartilage, or both. Laryngotracheal separation is usually fatal. Dislocation of the arytenoids relative to the cricoid cartilage may be encountered. Malalignment of the thyroid and cricoid cartilages results in dislocation of the cricothyroid joint. On imaging, the presence of air in the paraglottic soft tissues is an indication of laryngeal trauma (Fig. 2-63).

Foreign bodies may be present due to trauma but are more commonly the result of ingestion or aspiration. The pyriform sinus is a common location for a foreign body.

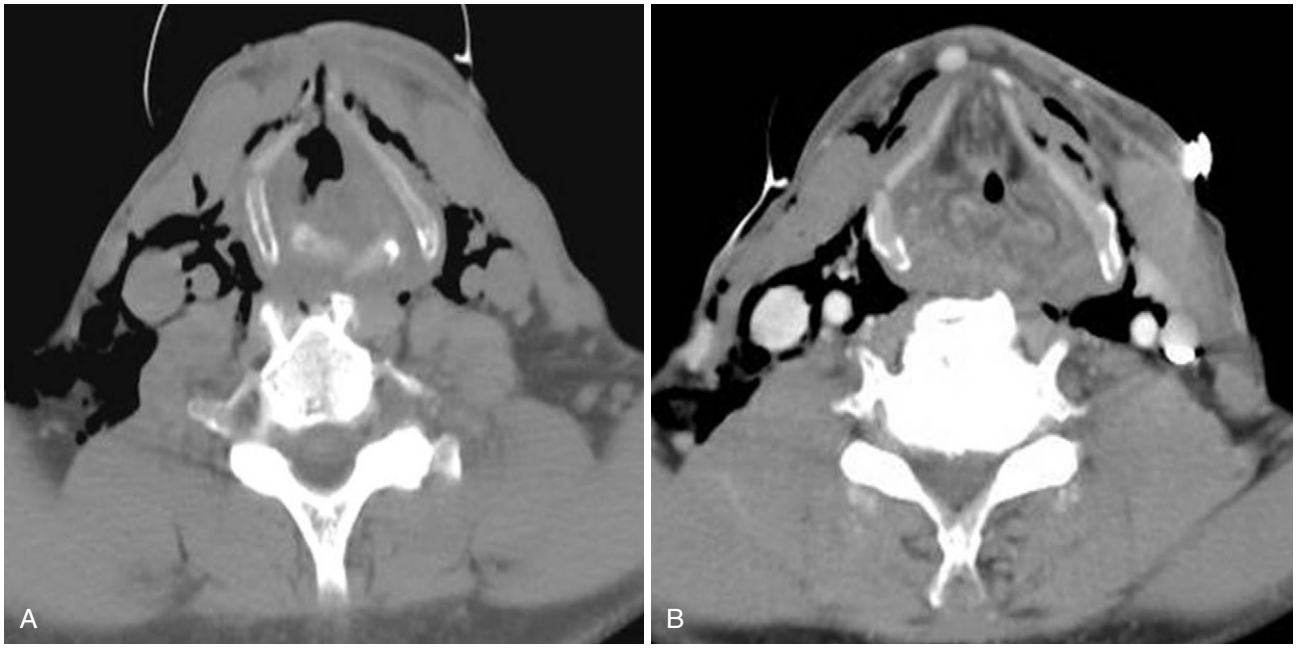

Figure 2-63 Laryngeal fracture. Precontrast **(A)** and postcontrast **(B)** axial computed tomography scans show extensive deep fascial emphysema as well as multiple fractures of the thyroid and cricoid cartilages.

If the foreign body enters the larynx, it usually passes through to the trachea or a bronchus. Burn injury to the larynx can be caused by inhalation or ingestion of hot material. The supraglottic larynx is most likely to be involved, and generalized edema can occur.

b. VOCAL CORD PARALYSIS

Vocal cord paralysis may be characterized as either a superior laryngeal nerve deficit, a recurrent laryngeal nerve deficit, or a total vagus nerve deficit. The entire course of the vagus nerve and the recurrent laryngeal nerve should be imaged when assessing vocal cord paralysis (Fig. 2-64).

The superior laryngeal nerve, through the external laryngeal branch, innervates only one muscle of the larynx—an extrinsic muscle, the cricothyroid muscle. This muscle extends between the thyroid and cricoid cartilages. As the muscle contracts, the anterior cricoid ring is pulled up toward the lower margin of the thyroid cartilage. This action rotates the upper cricoid lamina (and thus the arytenoids) posteriorly and puts tension on the true vocal cords. If one side is paralyzed, contraction of one muscle rotates the posterior cricoid to the contralateral paralyzed side.

More commonly, vocal cord paralysis is caused by recurrent laryngeal nerve pathology. All of the laryngeal muscles, except for the cricothyroid muscle, are innervated by this nerve. Most findings are secondary to atrophy of the thyroarytenoid muscle, the muscle that contributes to the bulk of the true vocal cords. The vocal cords become thinner and more pointed. Compensatory enlargement of the ventricle and the pyriform sinus is seen.[47] In the more acute phase, the paralyzed cord appears flaccid, prolapses medially because of the lack of muscular tone in the thyroarytenoid muscle, and demonstrates a lack of movement during breathing maneuvers and phonation.

c. CONGENITAL LESIONS

The respiratory system is formed from an outpouching of the primitive pharynx.[42,47] A tracheoesophageal septum is formed and separates the trachea from the primitive foregut. The laryngeal lumen is initially occluded and later recanalizes. Congenital lesions are related to delays in the development and maturation of the respiratory system.[42,47]

LARYNGOMALACIA. Laryngomalacia represents a delay in the development of the laryngeal support system. The structures of the larynx are present but are not mature enough to keep the larynx open. Primarily, the supraglottic larynx is affected to a varying degree. The presentation in the infant may vary from a floppy epiglottis only to collapse of the entire supraglottic larynx on inspiration. This abnormality is self-limited, and the problem resolves with maturation.[42,47]

WEBS AND ATRESIAS. Webs can be seen at any level of the larynx, but they are usually at the level of the true vocal cords. Subglottic webs are sometimes associated with cricoid abnormalities. Atresia of the larynx results from incomplete recanalization. Although the trachea is formed, there is no air passage to it.[42,47]

STENOSIS. Stenosis of the larynx or the upper trachea may be caused by a congenital anomaly or by iatrogenic or therapeutic trauma. Congenital subglottic stenosis is secondary to soft tissue stenosis from the true cord down to the cricoid. The infant usually outgrows this problem.

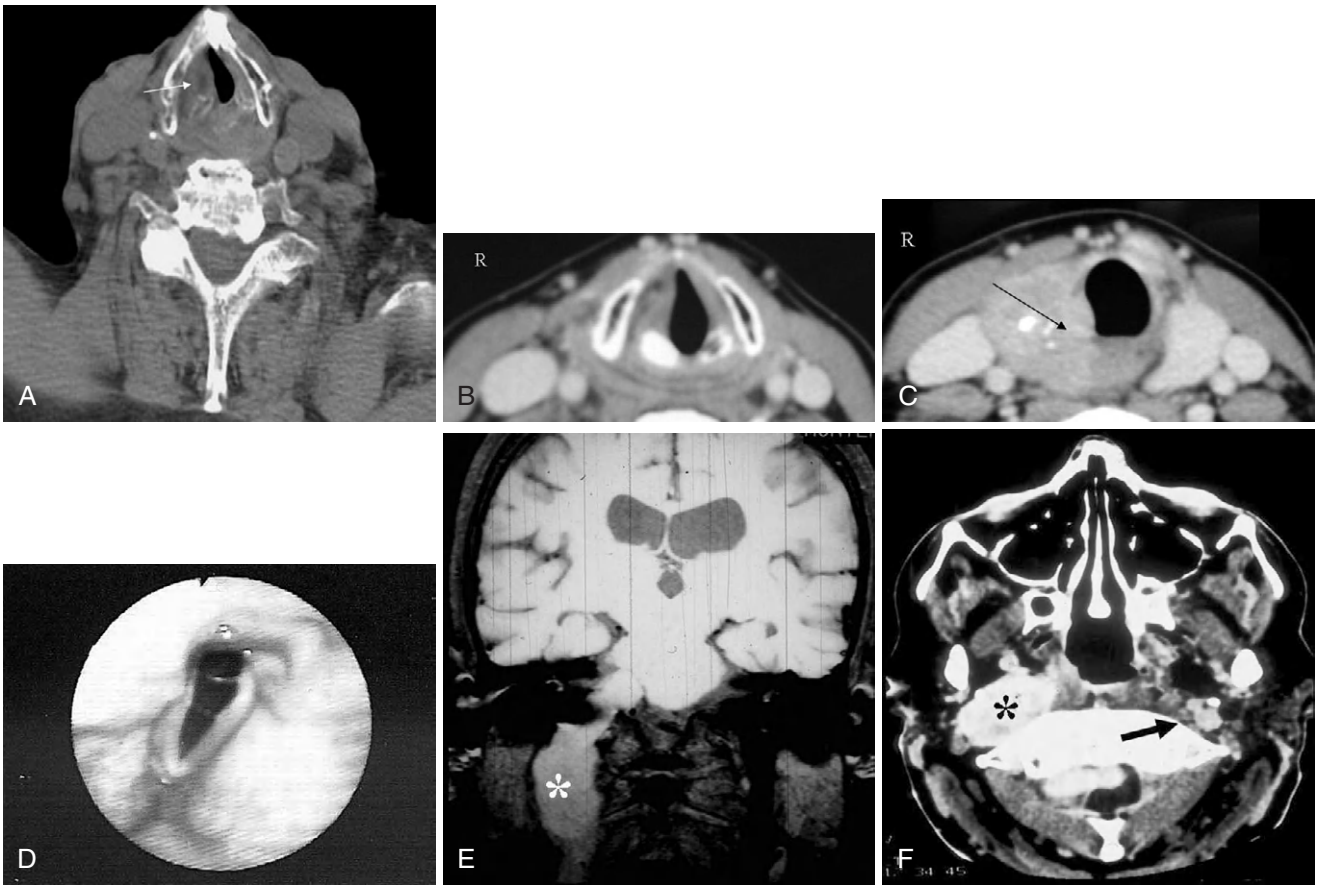

Figure 2-64 Causes of vocal cord paralysis in three different patients. In patient 1, there is right vocal cord paralysis secondary to tumor invasion. An axial computed tomographic (CT) scan **(A)** demonstrates squamous cell carcinoma invading the right vocal cord, which is medially deviated. In patient 2, there is right vocal cord paralysis secondary to tumor in the tracheoesophageal groove involving the recurrent laryngeal nerve. An axial contrast-enhanced CT scan **(B)** demonstrates a paralyzed right true vocal cord. In this case, denervation results from neural compromise in the tracheoesophageal groove due to papillary carcinoma of the right thyroid tumor **(C).** The paralyzed right cord is visualized endoscopically in **D.** In patient 3, a contrast-enhanced coronal T1-weighted magnetic resonance image **(E)** and an axial CT scan **(F)** demonstrate an enhancing vagus nerve schwannoma (*asterisk*) in a patient with known neurofibromatosis. Notice the normal vagus nerve (*arrow*), which is located within the contralateral carotid sheath, together with the carotid artery and jugular vein. This patient presented with right vocal cord paralysis.

The most common cause of stenosis is prolonged tracheal intubation or tracheostomy. Typically, the pattern of involvement starts anteriorly and laterally before eventually circumferentially involving the membranous portion. Trauma-related stenosis has a more variable pattern. Ingestion of caustic material usually results in strictures along the posterior supraglottic airway and larynx.[42,47] Both plain radiographic studies and CT are good at assessing the extent and length of the stenotic segment.

d. TUMORS AND OTHER CONDITIONS

BENIGN TUMORS. Benign masses encountered in the larynx include vocal cord nodules, juvenile papillomatosis, and other nonepithelial tumors such as hemangiomas, lipomas, leiomyomas, rhabdomyomas, chondromas, neural tumors, paragangliomas, schwannomas, and granular cell tumors.[42]

CYSTS AND LARYNGOCELES. Mucus-retention cysts can occur along any mucosal surface, but they are most common in the supraglottic larynx. Laryngoceles may be internal, external, or both. The common finding in a supraglottic mass is its connection with the laryngeal ventricle (Fig. 2-65).[42,47]

MALIGNANT NEOPLASMS. Most laryngeal tumors are malignant, and SCC is the most common type. These cancers arise on the mucosal surface and can be readily visualized by direct endoscopy. Imaging with CT and MRI is used to define the extent of the disease. Cross-sectional imaging is useful to assess the degree and direction of airway compromise (Fig. 2-66). Other cell types found are adenocarcinoma, verrucous carcinoma, and anaplastic carcinoma. More rare tumors are sarcoma, melanoma, lymphoma, leukemia, plasmacytoma, fibrous histiocytoma, and metastatic disease.[47]

F. Trachea

The trachea is a tubular structure that extends from the cricoid cartilage, at approximately the C6 level, to the carina, usually at the T5 or T6 level. It is a conduit between the larynx and the lungs and is composed of 16 to 20 incomplete hyaline cartilaginous rings bound in a

Figure 2-65 Laryngocele. Axial contrast-enhanced computed tomographic scan demonstrates a fluid-filled internal laryngocele on the left (*arrow*).

tight elastic connective tissue that is oriented longitudinally. The cartilage forms about two thirds of the circumference of the trachea; the posterior border is formed by a fibromuscular membrane. The trachea is approximately 10 to 13 cm long (average length, 11 cm). The diameter of the tracheal lumen depends on the height, age, and gender of the subject. In men, the tracheal diameter ranges from 13 to 25 mm in the coronal imaging plane and from 13 to 27 mm in the sagittal imaging plane. In women, the dimensions are 10 to 21 mm in the coronal plane and 10 to 23 mm in the sagittal plane.[49,50] Cross-sectional area correlates best with height in children.

The axial sections of the tracheal lumen assume the following successive shapes: round, lunate, flattened, and elliptical. The luminal shape is also affected by the respiratory cycle, maneuvers, and body position. During rapid and deep inspiration, the thoracic portion of the trachea widens and the cervical portion narrows; the opposite occurs with expiration. The innervation of the trachea is from the parasympathetic tracheal branches of the vagus nerve, the recurrent laryngeal nerve, and the sympathetic nerves. The trachea has a segmental blood supply from multiple branches of the inferior thyroidal arteries and bronchial arteries.[25]

1. Imaging Anatomy Overview

Radiologic evaluation of the trachea includes plain films of the neck and chest, CT, and MRI. A lateral view of the neck provides a good screening examination for the cervical trachea. Chest radiography allows an initial assessment of the thoracic trachea and mediastinal structures. CT, and especially helical CT, is superior for evaluation of the tracheal anatomy and pathology because it allows direct visualization of the cross-sectional trachea. With multiplanar reconstruction, the degree and length of stenosis can be fully assessed. Virtual bronchoscopy, which is a 3-D reconstruction of helical CT data, allows simulated navigation through the tracheobronchial tree. MRI so far has limited use owing to its longer scanning time, intrinsic artifacts from breathing motion, and limited resolution.

2. Pertinent Imaging Pathology

Early detection of tracheal pathology is unusual because significant compromise of the airway can be present before symptoms manifest. More than 75% occlusion of the luminal diameter at rest, and more than 50% occlusion during exertion, must be present before symptoms of airway obstruction are manifested.[50] If symptoms are present, a superior mediastinal mass is often found on PA chest radiography. Also, the tracheal air column may be deviated or narrowed. Rarely, tracheal enlargement occurs as a result of tracheomalacia in patients with cystic fibrosis or Ehlers-Danlos complex. Pathology affecting the trachea can largely be classified as extrinsic or intrinsic diseases.

a. EXTRINSIC TRACHEAL PATHOLOGY

THYROID GOITER. One of the more common extrinsic pathologies affecting the cervical and substernal trachea is a goiter of the thyroid gland. The trachea is usually displaced laterally, and luminal compression is evident. Vocal cord paralysis, hoarseness, dyspnea, and dysphagia may be the presenting symptoms. These symptoms are all predictable and are predicated on the location of the goiter with respect to the trachea, the esophagus, and the recurrent laryngeal nerve. The lateral and posterior extension of abnormal soft tissue with respect to the larynx displaces the airway anteriorly and laterally and may be a cause of difficult intubation (Fig. 2-67).

THYROID CARCINOMA AND NODES. As in the case of thyroid goiter, any mass involving or enlarging the thyroid gland can result in airway displacement and compression (Fig. 2-68). Enlarged lymph nodes secondary to lymphoma or metastatic disease can also cause extrinsic compression of the trachea.

VASCULAR RINGS AND SLINGS. Vascular rings encircle both the trachea and the esophagus with airway compression. The most common example is the double aortic arch. Vascular slings are noncircumferential vascular anomalies that may cause airway compromise. The trachea may be compressed posteriorly from a pulmonary artery sling, in which the left pulmonary artery arises from the right pulmonary artery. It can also be compressed from the front by the innominate artery or an aberrant left subclavian artery.

b. INTRINSIC TRACHEAL PATHOLOGY

TRAUMA. External injury to the trachea more frequently results from blunt trauma than from penetrating trauma, and it is often associated with other significant injuries to the chest, cervical spine, and great vessels. Pneumothorax, pneumomediastinum, and subcutaneous emphysema may be the presenting signs, in addition to endotracheal bleeding and airway compromise. Internal injuries such

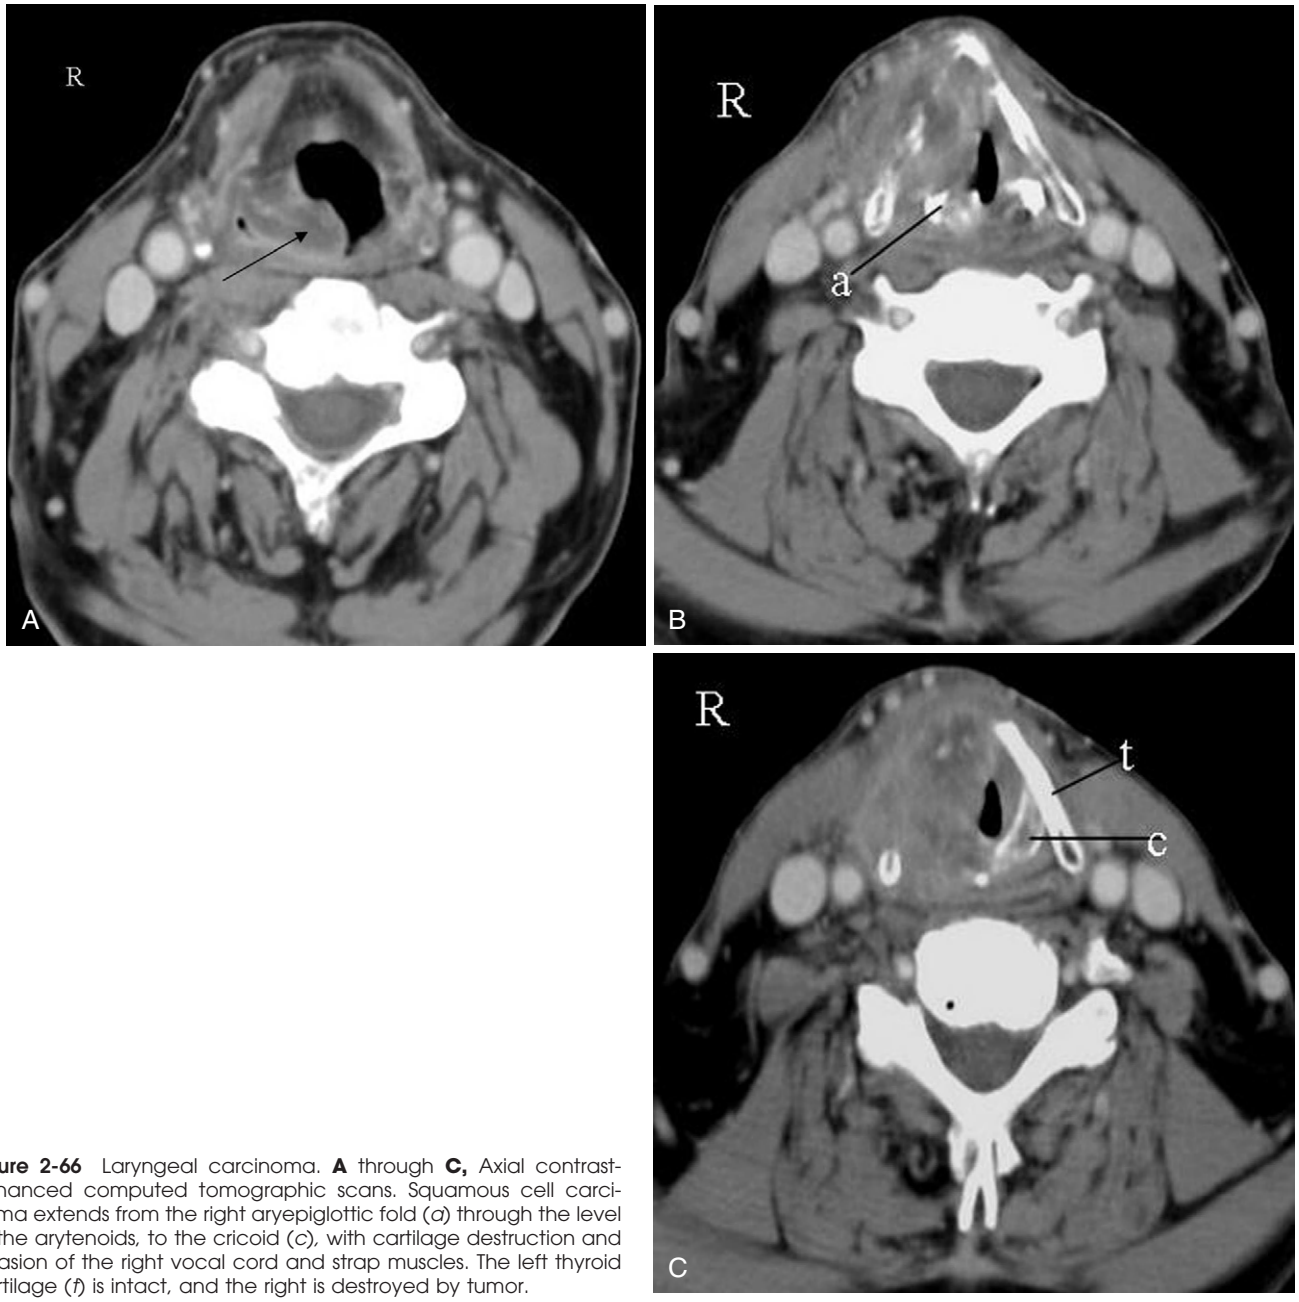

Figure 2-66 Laryngeal carcinoma. **A** through **C,** Axial contrast-enhanced computed tomographic scans. Squamous cell carcinoma extends from the right aryepiglottic fold (*a*) through the level of the arytenoids, to the cricoid (*c*), with cartilage destruction and invasion of the right vocal cord and strap muscles. The left thyroid cartilage (*t*) is intact, and the right is destroyed by tumor.

as chemical and thermal injury to the airway result in mucosal edema and subsequent airway compromise.

IATROGENIC INJURY. A late complication of translaryngeal intubation is stenosis at the cuff site, tip, or stoma site of the tracheostomy. Cuff trauma is related to pressure necrosis, in which the cuff pressure exceeds the capillary pressure. The incidence of this complication has decreased significantly since the introduction of the high-volume, low-pressure cuff, which is more pliable and can mold to the contours of the trachea. The blood supply to the anterior cartilages is susceptible to pressure effects, and anterior tracheal scarring may occur. With increased pressure, the posterior membranous part of the trachea can become affected, and the scarring becomes more circumferential. This type of injury is related to the position of the cuff and is seen radiographically as smooth tapering over one or two cartilage segments. Symptoms may arise from 2 weeks to months after extubation. Less common long-term complications of endotracheal intubation include tracheomalacia and tracheoesophageal fistula (TEF).[13,51]

Early tracheostomy complications are usually related to an abnormal angulation of the tube. In contrast to endotracheal intubation, tracheostomy is not affected by changes in head and neck position because it is not anchored at the nose or mouth. Angulation of the tracheostomy tube may result in increased airway resistance, difficulty in clearing secretions, erosion, or perforation of the trachea.

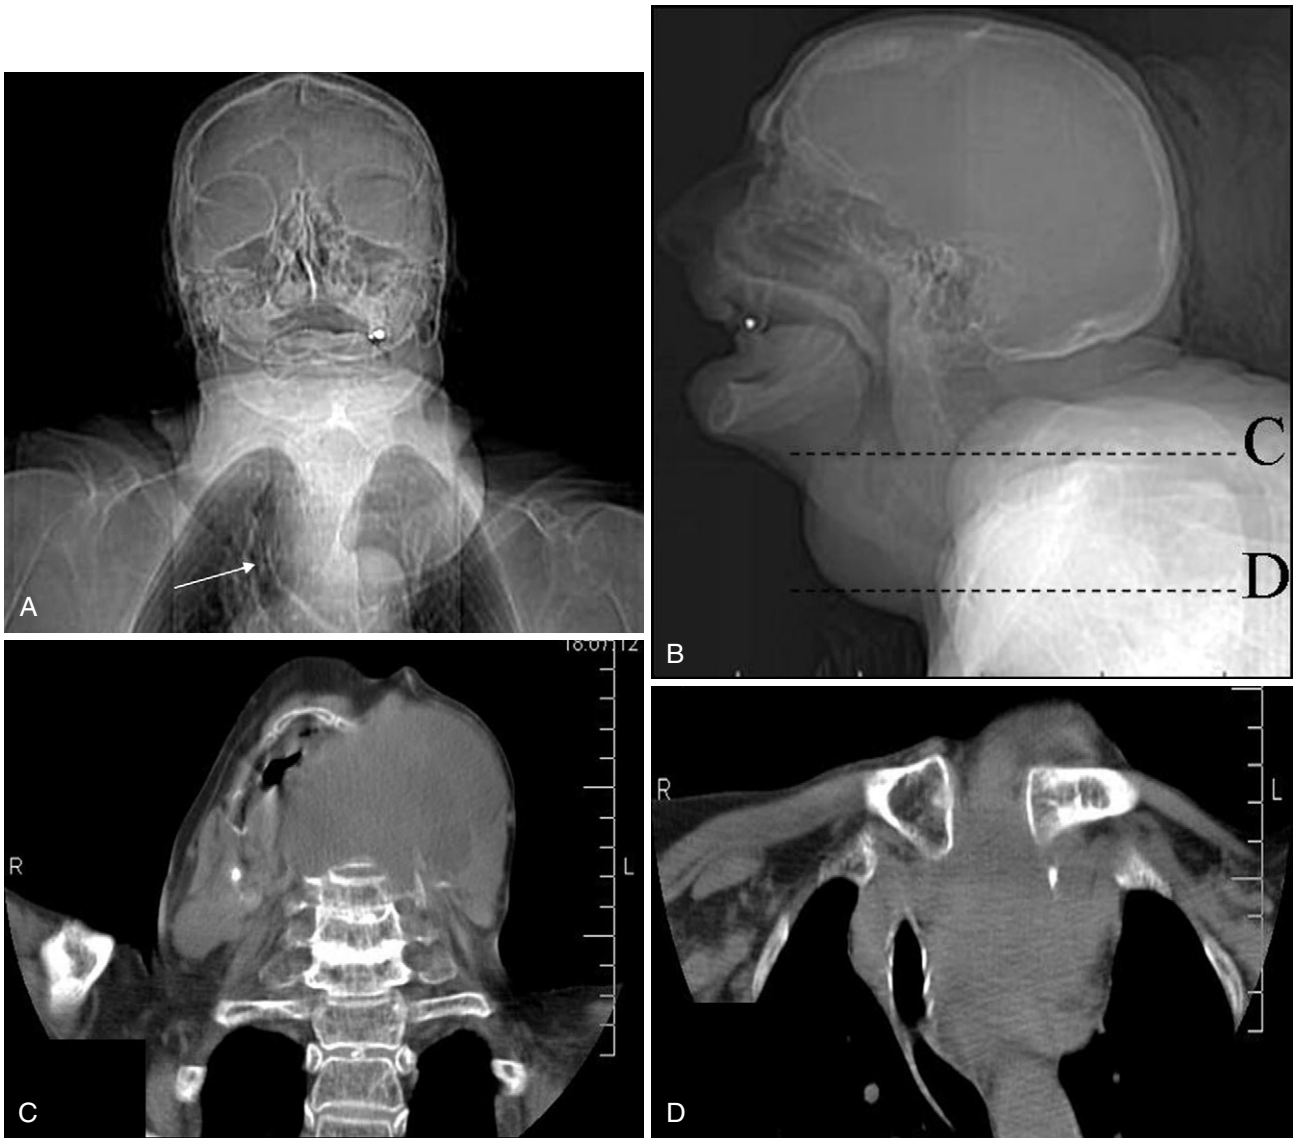

Figure 2-67 Goiter. Anteroposterior computed tomogram **(A)** and lateral scout film **(B)** demonstrate a clinically obvious thyroid mass. Notice the tracheal deviation in image **A** (*arrow*) and the anterior displacement of the airway in image **B. C** and **D,** Axial images (referenced on the lateral scout view) further demonstrate the mass effect on the airway from the level of the hyoid to the thoracic inlet.

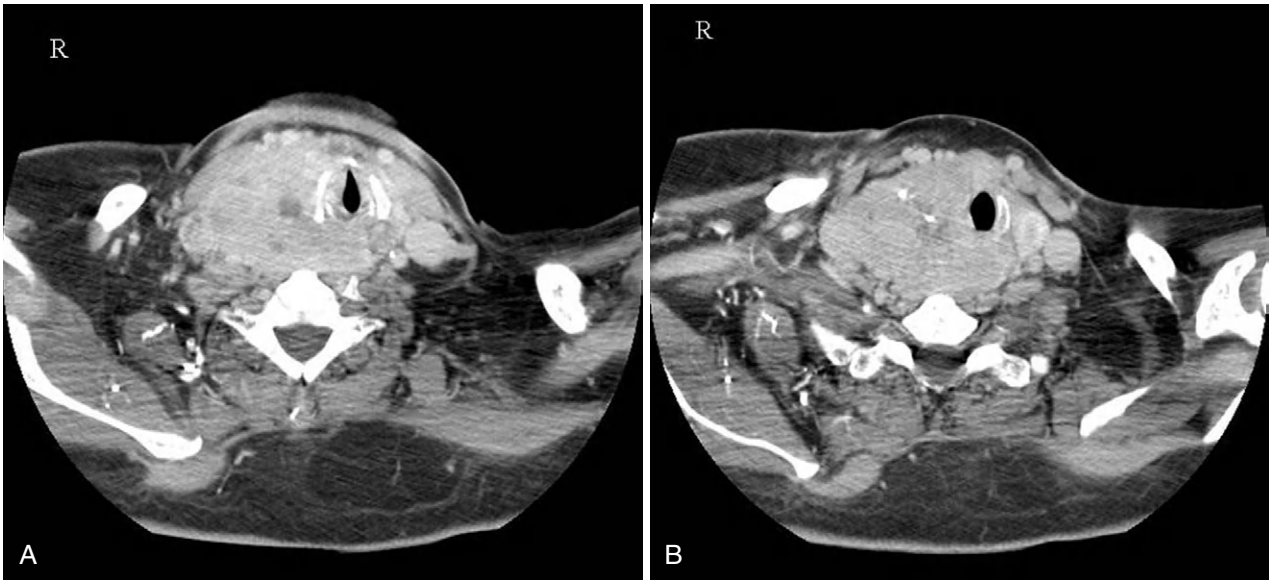

Figure 2-68 Tracheal displacement and effacement on axial computed tomography (CT) scans of a patient with medullary carcinoma of the thyroid. **A,** CT scan demonstrates the right thyroid mass displacing the airway anteriorly and to the contralateral side. **B,** The tumor has destroyed the cricoid cartilage on the right and abuts the subglottic airway.

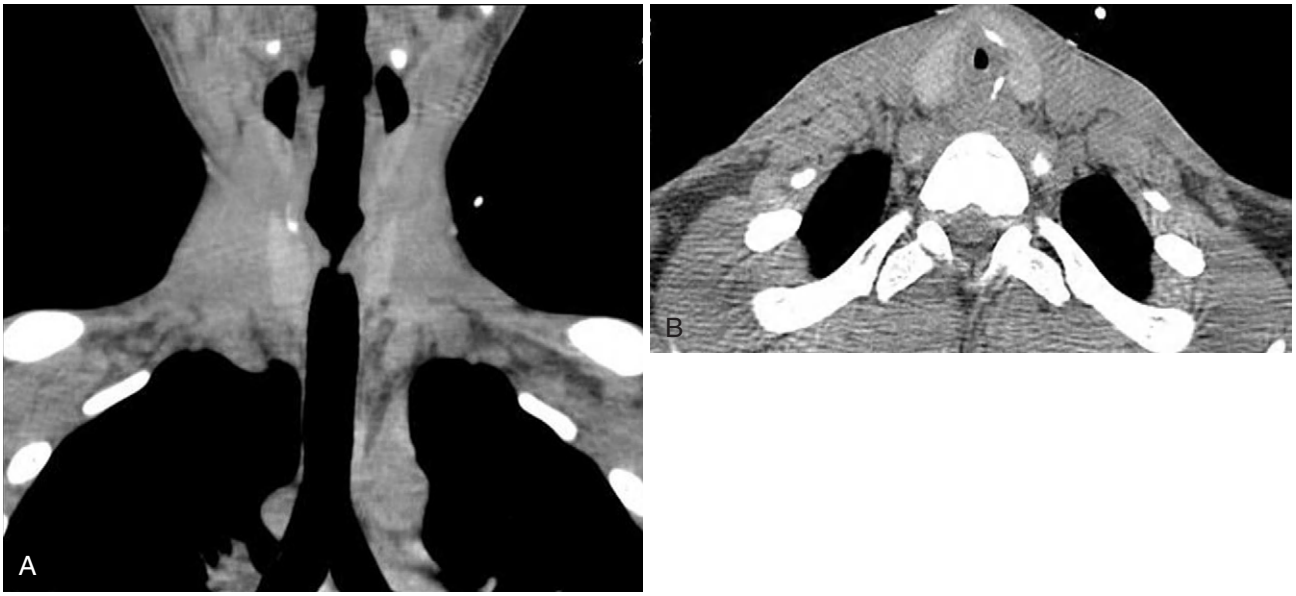

Figure 2-69 Tracheal stenosis. **A,** Coronal reformatted computed tomographic (CT) image in a child demonstrates marked subglottic narrowing of the trachea. **B,** Axial CT in the same patient further defines the severity of narrowing.

c. NON-NEOPLASTIC TRACHEAL NARROWING

The intrinsic pathology of diffuse tracheal narrowing results from trauma due to aspiration of heat or of caustic or acid chemicals, radiation therapy, or intubation injury; additional unusual causes include sarcoidosis, Wegener's granulomatosis, fungal infection, croup, and congenital conditions (Fig. 2-69).

TRACHEOMALACIA. Tracheomalacia is characterized by abnormal flaccidity of the trachea resulting in collapse of the thoracic tracheal segment during expiration. There is softening of the supporting cartilage and widening of the posterior membranous wall, which may balloon anteriorly into the airway. Tracheomalacia can be divided into primary intrinsic and secondary extrinsic forms. Patients may have minimal or severe symptoms depending on the degree of airway obstruction.

CONGENITAL STENOSIS (SUBGLOTTIC OR TRACHEAL). Congenital stenosis is uncommon and is usually associated with other congenital anomalies. The affected segment has rigid walls with a narrowed lumen, and the cartilages can be complete rings. The stenotic segment can be focal, or the entire trachea may be affected. Symptoms usually arise within the first few weeks or months of age. Most patients are treated conservatively.

TRACHEOESOPHAGEAL FISTULA. TEF is a common congenital anomaly, with an incidence of 1 in 3000 to 4000 births. TEF is often associated with esophageal atresia.[50] There are several forms of TEF. The most common is a proximal esophageal atresia with a distal TEF. This anomaly may be associated with severe neonatal respiratory distress and may necessitate emergent tracheostomy. It is not uncommon for more than one fistula to be present, and there may be other associated anomalies affecting the cardiovascular, gastrointestinal, renal, or central nervous system (Fig. 2-70).

d. TUMORS AND OTHER CONDITIONS

Most benign tracheal neoplasms are found in pediatric patients. Squamous cell papilloma, fibroma, and hemangioma are the most common types. In adults, the most common benign tumors are chondroma, papilloma, fibroma, hemangioma, and granular cell myoblastoma.

Primary malignant neoplasms of the trachea are uncommon; laryngeal and bronchial primary tumors are

Figure 2-70 Tracheoesophageal fistula (TEF). Oblique radiograph from a swallow study with contrast outlines a classic H-type TEF. (Courtesy of Dr. Netta Marlyn Blitman, Montefiore Medical Center, Bronx, NY.)

Figure 2-71 Tracheal invasion from follicular carcinoma of the thyroid. Axial computed tomography scan demonstrates a mass on the right that is deviating and invading the trachea.

much more common. In adults, however, primary neoplasms of the trachea are more common than benign tumors. The most common malignant tumor is SCC.[50]

The trachea may be secondarily involved by metastatic disease, either from a remote primary tumor or by direct invasion, such as from a thyroid primary (Fig. 2-71).

V. CONCLUSIONS

Rapid technological advances in the field of radiology now allow excellent visualization of airway structures and provide anesthesiologists with essential information to formulate a safe and effective anesthetic plan. However, radiology is not a part of the curriculum of any anesthesia residency training program, and therefore most anesthesiologists do not know how to analyze the radiologic studies, such as MRI and CT, that are usually a part of the preoperative surgical evaluation. We hope that this chapter, by updating anesthesiologists on the principles of MRI and CT and illustrating how airway structures are displayed by these new imaging modalities, can provide clinicians with good basic skills in gathering clinically useful information from these imaging studies. In addition, we hope that clinicians will not only incorporate the information from radiologic studies to provide better care to their patients but also consider using new imaging modalities as powerful research tools to study the airway.

VI. CLINICAL PEARLS

- In children and in adults during flexion, the anterior atlantodental interval (AADI) is normally about 5 mm. In adults, it is generally accepted that the AADI is 3 mm or less.
- Although the majority of head extension occurs at the atlanto-occipital joint, some extension can also occur at C1-C2. In patients with limited or no extension possible at the atlanto-occipital joint, general extension of the head actually brings the larynx "anterior," thereby limiting the visibility of the larynx on laryngoscopy.
- A nonunited terminal dental ossification center (os terminale) may be mistaken for a fracture of the odontoid tip.
- Conditions that are associated with odontoid hypoplasia are the Morquio, Klippel-Feil, and Down syndromes; neurofibromatosis; dwarfism; spondyloepiphyseal dysplasia; osteogenesis imperfecta; and congenital scoliosis. Patients with these conditions are predisposed to atlantoaxial subluxation and craniocervical instability, and hyperextension of the head for intubation should be avoided.
- Counterclockwise rotation of the larynx should be suspected if the frontal view of the cervical spine demonstrates a deviated tracheal air column.
- In addition to partial or total choanal atresia, nasal airway obstruction may result from rhinitis or from turbinate hypertrophy.
- In a patient with radiation-induced changes to the neck, the increased rigidity of the soft tissues should be taken into account during laryngoscopy for endotracheal intubation and in selecting the correct size of a laryngeal mask airway (LMA). Specifically, the LMA needs to be one or even two sizes smaller than predicted by the patient's weight.

VII. **Conclusions**

VIII. **Clinical Pearls**

I. INTRODUCTION

Ultrasonography (USG) has many potential advantages: It is safe, quick, repeatable, portable, and widely available and gives real-time dynamic images. USG must be used *dynamically* in direct conjunction with the airway procedures for maximum benefit in airway management. For example, if the transducer is placed on the neck, the endotracheal tube (ETT) can be visualized passing into the trachea or the esophagus *while* it is being placed, whereas the location of the ETT is difficult to visualize if the transducer is placed on the neck of a patient who already has an ETT in place.

II. THE ULTRASOUND IMAGE AND HOW TO OBTAIN IT

Ultrasound refers to sound frequencies beyond 20,000 Hz; frequencies from 2 to 15 MHz are typically used for medical imaging. Ultrasound transducers act as both transmitters and receivers of reflected sound. Tissues exhibit differing acoustic impedance values, and sound reflection occurs at the interfaces between different types of tissues. The impedance difference is greatest at interfaces of soft tissue with bone or air. Some tissues give a strong echo (e.g., fat, bone); these are called *hyperechoic* structures, and they appear *white*. Other tissues let the ultrasound beam pass easily (e.g., fluid collections, blood in vessels) and therefore create only a weak echo; these are *hypoechoic* structures and appear *black* on the screen. When the ultrasound beam reaches the surface of a bone, a strong echo (i.e., a strong white line) appears, and there is a strong absorption of ultrasound, resulting in depiction of only a limited depth of the bony tissue. Nothing is seen beyond the bone because of acoustic shadowing. Cartilaginous structures such as the thyroid cartilage, the cricoid cartilage, and the tracheal rings, appear homogeneously hypoechoic (black), but the cartilages tend to calcify with age.[1]

Muscles and connective tissue membranes are hypoechoic but have a more heterogeneous, striated appearance than cartilage does. Glandular structures such as the submandibular and thyroid glands are homogeneous and mildly to strongly hyperechoic in comparison with adjacent soft tissues. Air is a very weak conductor of ultrasound, so when the ultrasound beam reaches the border between a tissue and air, a strong reflection (strong white line) appears, and everything on the screen beyond that point represents only artifacts, especially reverberation artifacts, which create multiple parallel white lines on the screen. However, the artifacts that arise from the pleura/lung border often reveal useful information. Visualization of structures such as the posterior pharynx, posterior commissure, and posterior wall of the trachea is prevented by intraluminal air.[1] In B-mode USG, an array of transducers simultaneously scans a plane through the body that can be viewed as a two-dimensional image on the screen, depicting a "slice" of tissue.

In M-mode USG (M = motion), a rapid sequence of B-mode scans representing one single line through the tissue is obtained. The images follow each other in sequence on the screen, enabling the sonographer to see and measure range of motion as the organ boundaries that produce reflections move relative to the probe. In color Doppler USG, velocity information is presented as a color-coded overlay on top of a B-mode image.

The higher the frequency of the ultrasound wave, the higher the image resolution and the less penetration in depth. All modern ultrasound transducers used in airway management have a range of frequencies that can be adjusted during scanning to optimize the image. The linear high-frequency transducer (Fig. 3-1) is the most suitable for imaging superficial airway structures (within 2 to 3 cm from the skin). The curved low-frequency transducer is most suitable for obtaining sagittal and parasagittal views of structures in the submandibular and supraglottic regions, mainly because of its wider field of view.[1] The micro convex transducer gives a wide view of the pleura between two ribs. If only one transducer must be chosen, then a linear high-frequency transducer will enable performance of most ultrasound examinations that are relevant for airway management.

Because air does not conduct ultrasound, the probe must be in full contact with the skin or mucosa without any interfacing air.[2] This is achieved by applying judicious amounts of conductive gel between the probe and the skin. Because of the prominent thyroid cartilage, it is sometimes a challenge to avoid air under the probe when performing a sagittal midline scan from the hyoid bone to the suprasternal notch in a male patient. Portable machines can provide accurate answers to basic questions and are sufficient for airway USG.[3]

III. VISUALIZING THE AIRWAY AND THE ADJACENT STRUCTURES

With conventional transcutaneous USG, the airway can be visualized from the tip of the chin to the midtrachea, along with the pleural aspect of the most peripheral alveoli and the diaphragm. Additional parts of the airway can be seen with special techniques: Trachea can be seen from the esophagus when performing transesophageal USG, and the tissue surrounding the more distal airway from the midtrachea to the bronchi can be visualized with endoscopic USG via a bronchoscope. These special techniques are not covered in detail in this chapter.

Figure 3-1 Laptop-sized ultrasound machine with transducers *(left to right)*: linear 7- to 12-MHz high-frequency transducer; small linear 6- to 10-MHz high-frequency "hockey-stick" transducer; curved, convex 2- to 6-MHz low-frequency transducer; micro convex 4- to 10-MHz transducer *(foreground)*. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

A. Mouth and Tongue

USG is a simple method for examination of the mouth and its contents. The tongue is composed of an anterior mobile part situated in the oral cavity and a fixed pharyngeal portion. The lingual musculature is divided into the extrinsic muscles (which have a bony insertion and alter the position of the tongue) and intrinsic muscles, whose fibers alter the shape of the tongue.[4] The tongue can be visualized from within the mouth, but the image may be difficult to interpret.[5,6]

The floor of the mouth and the tongue are easily visualized by placing the transducer submentally. If the transducer is placed in the coronal plane just posterior to the mentum and from there moved posteriorly until the hyoid bone is reached, one can perform a thorough evaluation of all the layers of the floor of the mouth, the muscles of the tongue, and any possible pathologic processes (Fig. 3-2). The scanning image will be flanked by the acoustic shadow of the mandible on each side. The dorsal lingual surface is clearly identified.[7] The width of

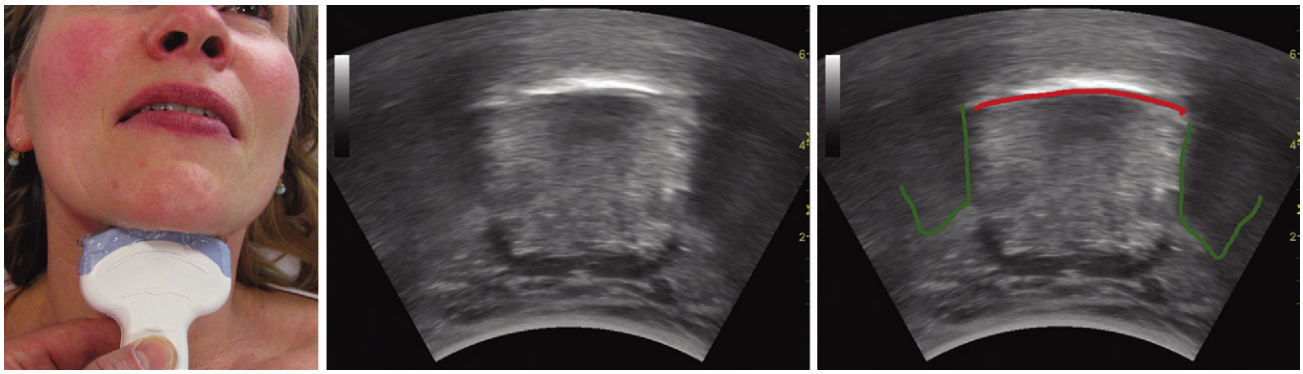

Figure 3-2 Transverse scan of the floor of the mouth and the tongue. *Left,* Placement of the transducer. *Middle,* The resulting ultrasound image. *Right,* The dorsal surface of the tongue is indicated by a red line, and shadows arising from the mandible are outlined in green. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

the tongue base can be measured in a standardized way by locating the two lingual arteries with Doppler ultrasound and measuring the distance between these arteries where they enter the tongue base at its lower lateral borders.[8] A longitudinal scan of the floor of the mouth and the tongue is obtained if the transducer is placed submentally in the sagittal plane. If a large convex transducer is used, the whole length of the floor of the mouth and the majority of the length of the tongue can be seen in one image (Fig. 3-3). The acoustic shadows from the symphysis of the mandible and from the hyoid bone form the anterior and posterior limits of this image. Detailed imaging of the function of the tongue, including bolus holding, lingual propulsion, lingual-palatal contact, tongue tip and dorsum motion, bolus clearance, and hyoid excursion, can be evaluated in this plane.[7]

When the tongue is in contact with the palate, the palate can be visualized; if there is no contact with the palate, the air at the dorsum of the tongue will make visualization of the palate impossible. An improved image is achievable if water is ingested and retained in the oral cavity. The water eliminates the air-tissue border and allows visualization of most of the oral cavity including the palate (Fig. 3-4), as well as a better differentiation of the hard palate from the soft palate.[4]

The tongue can be visualized in detail with the use of three-dimensional USG.[9] In a child, the major anatomic components of the tongue and mouth are covered by four scanning positions: the midline sagittal, the parasagittal, the anterior coronal, and the posterior coronal planes.[10] In the transverse midline plane just cranial to the hyoid bone, the tongue base and the floor of the mouth are seen. In the transverse (axial) plane in the midline, the lingual tonsils and the valleculae can be imaged. The vallecula is seen just below the hyoid bone, and when the probe is angled caudally, the preglottic and paraglottic spaces and the infrahyoid part of the epiglottis are seen.[11]

B. Oropharynx

Imaging of a part of the lateral border of the mid-oropharynx can be obtained by placing the transducer vertically with its upper edge approximately 1 cm below

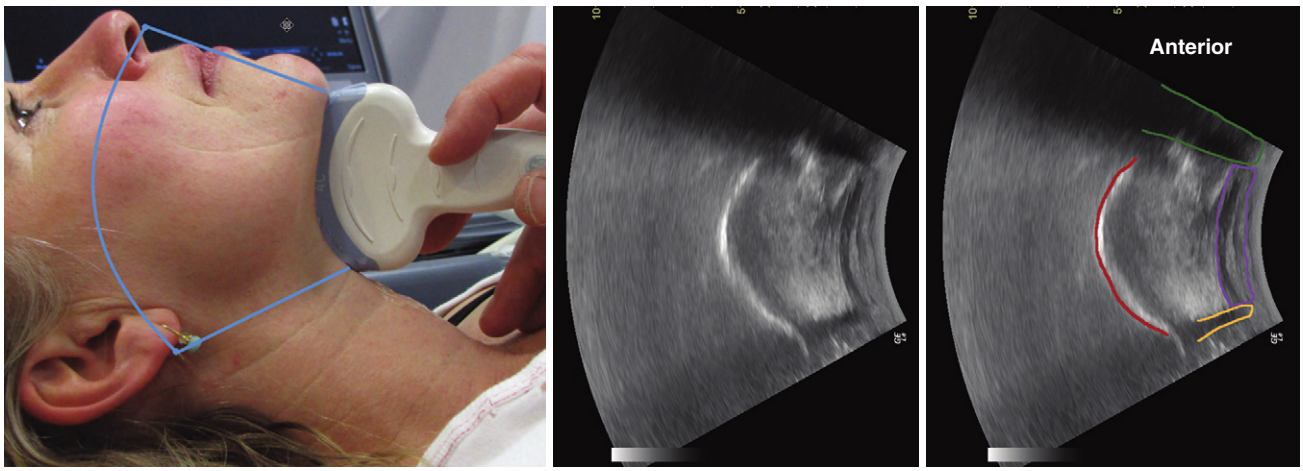

Figure 3-3 Longitudinal scan of the floor of the mouth and the tongue. *Left,* Placement of the curved low-frequency transducer. The area covered by the scan is outlined in light blue. *Middle,* The resulting ultrasound image. *Right,* The shadow from the mentum of the mandible is outlined in green, the muscles in the floor of the mouth in purple, the shadow from the hyoid bone in light orange, and the dorsal surface of the tongue in red. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

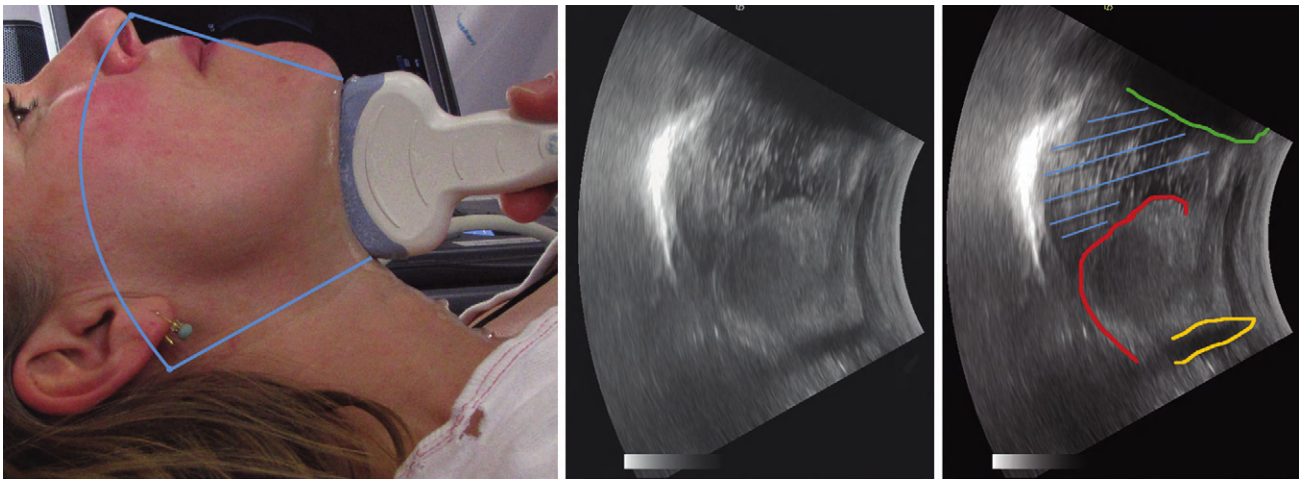

Figure 3-4 The tongue and the mouth are filled with water. Placement of the transducer is the same as in Figure 3-3. The shadow from the mentum of the mandible is outlined in green, the shadow from the hyoid bone in light orange, and the dorsal surface of the tongue in red. The blue lines indicate the water in the mouth. The large white line represents the strong echo from the hard palate. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

the external auditory canal.[7] The lateral pharyngeal border and the thickness of the lateral parapharyngeal wall can be determined.[12] The parapharyngeal space can also be visualized via the mouth by placing the probe directly over the mucosal lining of the lateral pharyngeal wall, but this approach is difficult for the patient to tolerate.[13]

C. Hypopharynx

By performing USG through the thyrohyoid membrane, cricothyroid space, cricothyroid membrane (CTM), and thyroidal cartilage lamina and along the posterior edge of the thyroid lamina, it is possible to locate and classify hypopharyngeal tumors with a success rate as high as that achieved with computed tomography (CT) scanning.[14]

D. Hyoid Bone

The hyoid bone is a key landmark that separates the upper airway into two scanning areas: the suprahyoid and infrahyoid regions. The hyoid bone is visible on the transverse view as a superficial, hyperechoic, inverted U–shaped, linear structure with posterior acoustic shadowing. On the sagittal and parasagittal views, the hyoid bone is visible in cross section (see Fig. 3-4) as a narrow, hyperechoic, curved structure that casts an acoustic shadow.[1]

E. Larynx

Because of the superficial location of the larynx, USG offers images of higher resolution than CT or magnetic resonance imaging (MRI) when a linear high-frequency transducer is used.[11] The different parts of the laryngeal skeleton have different sonographic characteristics.[15] The hyoid bone is calcified early in life, and its bony shadow is an important landmark. The thyroid and cricoid cartilages show variable but progressive calcification throughout life, whereas the epiglottis stays hypoechoic. The true vocal cords overlie muscle that is hypoechoic, whereas the false cords contain echoic fat.

The thyrohyoid membrane runs between the caudal border of the hyoid bone and the cephalad border of the thyroid cartilage and provides a sonographic window through which the epiglottis can be visualized in all subjects when the linear transducer is oriented in the transverse plane (with varying degrees of cephalad or caudad angulation).[1] The midline sagittal scan through the upper larynx from the hyoid bone cranially to the thyroid cartilage distally (Fig. 3-5) reveals the thyrohyoid ligament, the pre-epiglottic space containing echogenic fat, and, posterior to that, a white line representing the laryngeal surface of the epiglottis.[15] On parasagittal view, the epiglottis appears as a hypoechoic structure with a curvilinear shape; on transverse view, it is shaped like an inverted C. It is bordered anteriorly by the hyperechoic, triangular pre-epiglottic space and lined posteriorly by a hyperechoic air-mucosa interface.[16] In a convenience sample of 100 subjects, the transverse midline scan cranially to the thyroid cartilage depicted the epiglottis in all subjects and revealed an average epiglottis thickness of 2.39 mm.[17]

In the cricothyroid region, the probe can be angled cranially to assess the vocal cords and the arytenoid cartilages and thereafter moved distally to access the cricoid cartilages and the subglottis.[11] With transverse scanning in the paramedian position, the following structures can be visualized (starting cranially and moving distally): faucial tonsils, lateral tongue base, lateral vallecula, strap muscles, laminae of the thyroid cartilage, the lateral cricoid cartilage, and, posteriorly, the piriform sinuses and the cervical esophagus.[11]

The laryngeal cartilage is noncalcified in the child, but calcification starts in some individuals before 20 years of age, and it increases with age. In subjects with noncalcified cartilage, the thyroid cartilage is visible on sagittal and parasagittal views as a linear, hypoechoic structure with a bright air-mucosa interface at its posterior surface. On the transverse view, it has an inverted V

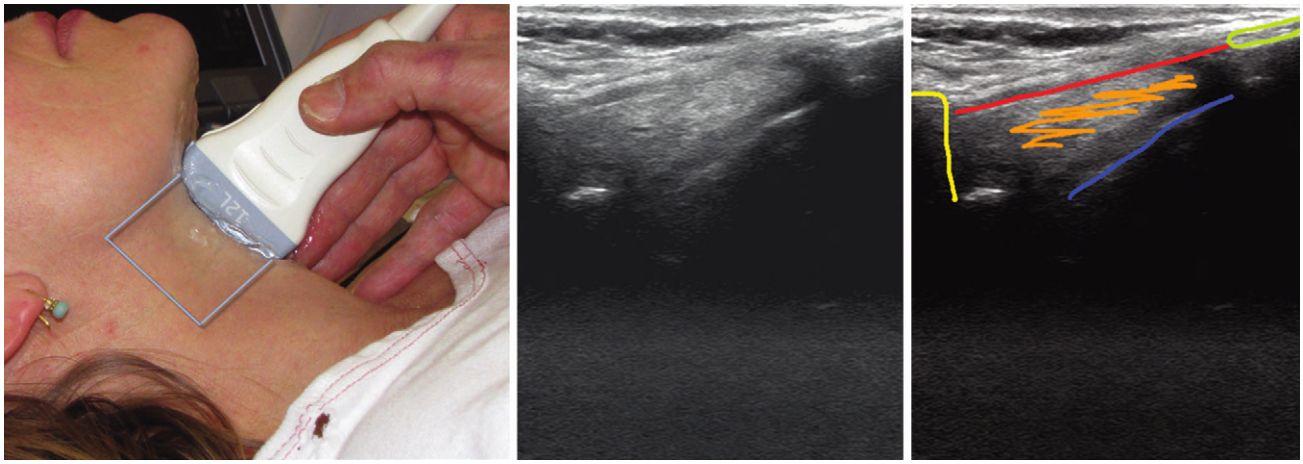

Figure 3-5 Midline sagittal scan from the hyoid bone to the proximal part of the thyroid cartilage. *Left,* The light blue outline shows the area covered by the scan. *Middle,* The scanning image. *Right,* The shadow from the hyoid bone is marked in yellow, the thyrohyoid membrane in red, the posterior surface of part of the epiglottis in blue, the pre-epiglottic fat in orange, and the thyroid cartilage in green. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

shape (Fig. 3-6), within which the true and false vocal cords are visible.[1] By 60 years of age, all individuals show signs of partial calcification, and approximately 40% of the cartilage at the level of the vocal cords is calcified.[18] The calcification is seen as a strong echo with posterior acoustic shadowing. Often the anatomic structures can be visualized despite the calcifications by angling the transducer. In a population of patients who were examined due to suspicion of laryngeal pathology, a sufficient depiction of the false cords was obtained in 60% of cases, of the vocal cords in 75%, of the anterior commissure in 64%, and of the arytenoid region in 71%; in 16% of cases, no endolaryngeal structures could be depicted.[18]

F. Vocal Cords

In individuals with noncalcified thyroid cartilages, the false and the true vocal cords can be visualized through the thyroid cartilage.[15] In individuals with calcified thyroid cartilage, the vocal cords and the arytenoid cartilages can still be seen by combining the scan obtained by placing the transducer just cranially to the superior thyroid notch angling it caudally with the scans obtained from the CTM in the midline and on each side with the transducer angled 30 degrees cranially.[11] In a study group of 24 volunteers with a mean age of 30 years, the thyroid cartilage provided the best window for imaging the vocal cords. In all participants, it was possible to visualize and distinguish the true and false vocal cords by moving the transducer in a cephalocaudad direction over the thyroid cartilage.[1]

The true vocal cords appear as two triangular, hypoechoic structures (the vocalis muscles) outlined medially by the hyperechoic vocal ligaments (see Fig. 3-6). They are observed to oscillate and move toward the midline during phonation.[1] In a study of 229 participants ranging in age from 2 months to 81 years, the true and false cords were visible in all female participants. In males, the visibility was 100% for those younger than 18 years and gradually decreased to less than 40% in males 60 years of age and older.[19] The false vocal cords lie parallel and cephalad to the true cords, are more hyperechoic in appearance, and remain relatively immobile during phonation.

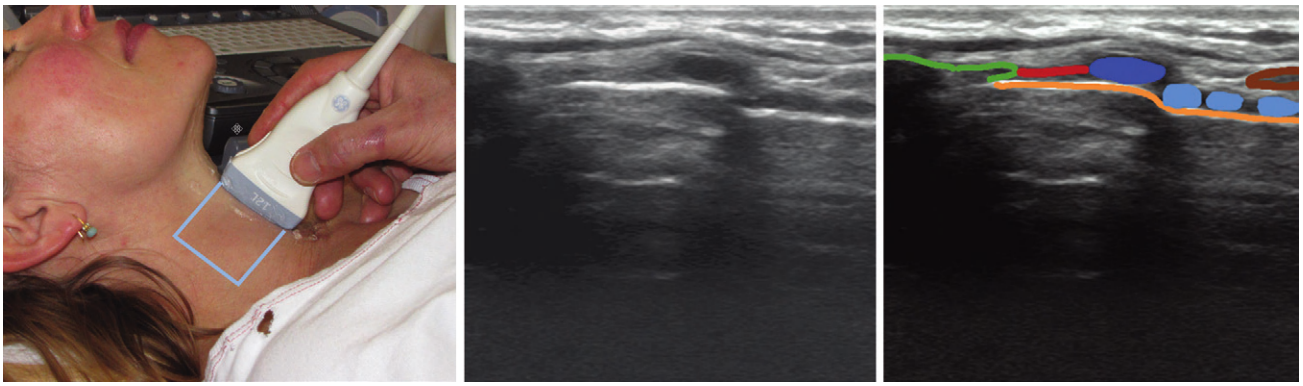

Figure 3-7 Cricothyroid membrane (CTM). *Left,* The linear high-frequency transducer is placed in the midsagittal plane. The scanning area is marked with light blue. *Middle,* The scanning image. *Right,* The thyroid cartilage is marked in green, the cricoid cartilage in dark blue, the tracheal rings in light blue, the CTM in red, the tissue-air border in orange, and the isthmus of the thyroid gland in brown. Below the orange line, only artifacts are seen. (From Kristensen MS: Ultrasonography in the management of the airway *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

G. Cricothyroid Membrane and Cricoid Cartilage

The CTM runs between the caudal border of the thyroid cartilage and the cephalad border of the cricoid cartilage. It is clearly seen on sagittal (Fig. 3-7) and parasagittal views as a hyperechoic band linking the hypoechoic thyroid and cricoid cartilages.[1] The cricoid cartilage has a round, hypoechoic appearance on the parasagittal view and an arch-like appearance on the transverse view.

H. Trachea

The location of the trachea in the midline of the neck makes it a useful reference point for transverse ultrasound imaging. The cricoid cartilage marks the superior limit of the trachea; it is thicker than the tracheal rings below and is seen as a hypoechoic, rounded structure. It serves as a reference point during performance of the sagittal midline scan (see Fig. 3-7). Often the first six tracheal rings can be imaged when the neck is in mild extension.[13] The trachea is covered by skin, subcutaneous fat, the strap muscles, and, at the level of the second or third tracheal ring, the isthmus of the thyroid gland (see Fig. 3-7). The strap muscles appear hypoechoic and are encased by thin hyperechoic lines from the cervical fascia.[13] A high-riding innominate artery may be identified above the sternal notch as a transverse anechoic structure crossing the trachea.[13] The tracheal rings are hypoechoic, and they resemble a "string of beads" in the parasagittal and sagittal plane (see Fig. 3-7). In the transverse view, they resemble an inverted U highlighted by a hyperechoic air-mucosa interface (Fig. 3-8) and by reverberation artifact posteriorly.[1]

I. Esophagus

The cervical esophagus is most often visible posterolateral to the trachea on the left side at the level of the suprasternal notch (see Fig. 3-8). The concentric layers of esophagus result in a characteristic "bull's-eye" appearance on USG. The esophagus can be seen to compress

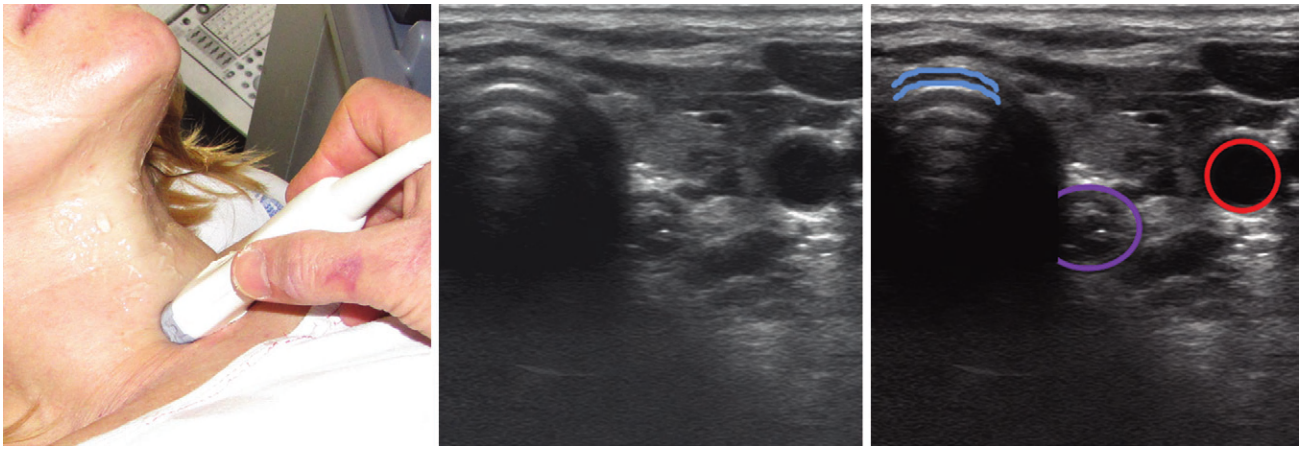

Figure 3-8 Trachea and esophagus. *Left,* A transverse scan is performed just cranial to the suprasternal notch and to the patient's left side of the trachea. *Middle,* The scanning image. *Right,* The anterior part of the tracheal cartilage is outlined in light blue, the esophagus in purple, and the carotid artery in red. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

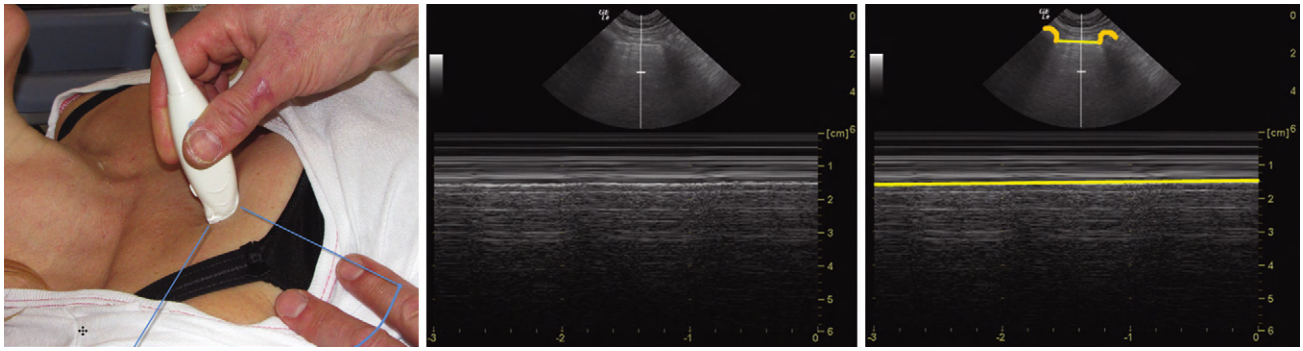

Figure 3-9 Lung sliding. *Left,* A micro convex probe is placed over an interspace between two ribs during normal ventilation. The light blue line indicates the scanning area. *Middle,* The scanning image, showing B-mode scanning above and M-mode scanning below. *Right,* The pleural line is marked in yellow and the ribs in orange (the curved lines at each end of the straight line). Notice that the outline of the ribs and the pleural line forms the image of a flying bat, the "bat sign." In the M-mode image, it is easy to distinguish the nonmoving tissue above the pleural line from the artifact caused by respiratory movement of the visceral pleura relative to the parietal pleura. This is called the "seashore sign" or the "sandy beach sign" because the nonmoving part resembles waves and the artifact pattern below resembles a sandy beach. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

and expand with swallowing, and this feature can be used for accurate identification.[13] The patient may be placed in a modified position for examining the esophagus by slightly flexing the neck with a pillow under the head and turning the head 45 degrees to the opposite side while the neck is scanned on either side; this technique makes the esophagus visible also on the right side in 98% of cases.[20]

J. Lower Trachea and Bronchi

Transesophageal USG displays a part of the lower trachea. When a saline-filled balloon is introduced in the trachea during cardiopulmonary bypass, it is possible to perform USG through the trachea, thus displaying the proximal aortic arch and the innominate artery.[21] The bronchial wall and its layers can be visualized from within the airway by passing a flexible ultrasound probe through the working channel of a flexible bronchoscope. This technique, called *end bronchial ultrasound*, reliably distinguishes between airway infiltration and compression by tumor.[22]

K. Peripheral Lung and Pleura

The ribs are identifiable by their acoustic shadow, and between two ribs a hyperechoic line is visible. This line, called the *pleural line*, represents the interface between the soft tissue of the chest wall and air (Fig. 3-9). In the normal breathing or ventilated subject, one can identify a kind of to-and-fro movement synchronous with ventilation; this is called "pleural sliding" or "lung sliding."[23] The movement is striking because the surrounding tissue is motionless.[24] Lung sliding is best seen dynamically, in real time or on video.[25]

The investigation should always start by placing the probe perpendicular to the ribs and in such a way that two rib shadows are identified. The succession of the upper rib, pleural line, and lower rib outlines a characteristic pattern, the "bat sign" (see Fig. 3-9) and must be recognized to correctly identify the pleural line and avoid interpretation errors due to a parietal emphysema. Lung ultrasound examination should therefore be considered not feasible if the bat sign is not identified.[26] Lung sliding can be objectified using the time-motion mode, which highlights a clear distinction between a wave-like pattern located above the pleural line and a sand-like pattern below, called the "seashore sign" (see Fig. 3-9).[26]

In breath-holding or apnea, there is no lung sliding, but a "lung pulse"—small movements synchronous with the heartbeat—is seen instead (Fig. 3-10). The lung pulse can be explained as the vibrations of the heart are transmitted through a motionless lung. The lung pulse can also be demonstrated in the time-motion M-mode scanning. There is a strong echo from the pleural line, and dominant reverberation artifacts of varying strength are seen. They appear as lines parallel to the pleural line and spaced with the same distance as the distance from the skin surface to the pleural line. These "A-lines" are seen in both the normal and the pathologic lung.[26]

The "B-line" is an artifact with seven features: It is (1) a hydrometric comet-tail artifact that (2) arises from the pleural line, (3) is hyperechoic, (4) is well defined, (5) spreads up indefinitely (i.e., spreads to the edge of the screen without fading—up to 17 cm with a probe reaching 17 cm[26]), (6) erases A-lines, and (7) moves with lung sliding when lung sliding is present.[27] Sparse B-lines occur in normal lungs but three or more B-lines indicates pathology (e.g., interstitial syndrome).[27] B-lines are also called "ring-down" artifacts.[28]

L. Diaphragm

The diaphragm and its motion can be imaged by placing a convex transducer in the subxiphoid window in the middle upper abdominal region, just beneath the xiphoid process and the lower margin of the liver. The transducer is tilted 45 degrees cephalad, and bilateral diaphragm motion is noticed.[29] The bilateral diaphragm moves toward the abdomen when the lungs are ventilated and toward the chest during the relaxation phase. The liver and spleen movements represent the whole movement of the right and left diaphragm during respiration and can be visualized by placing the probe in the longitudinal

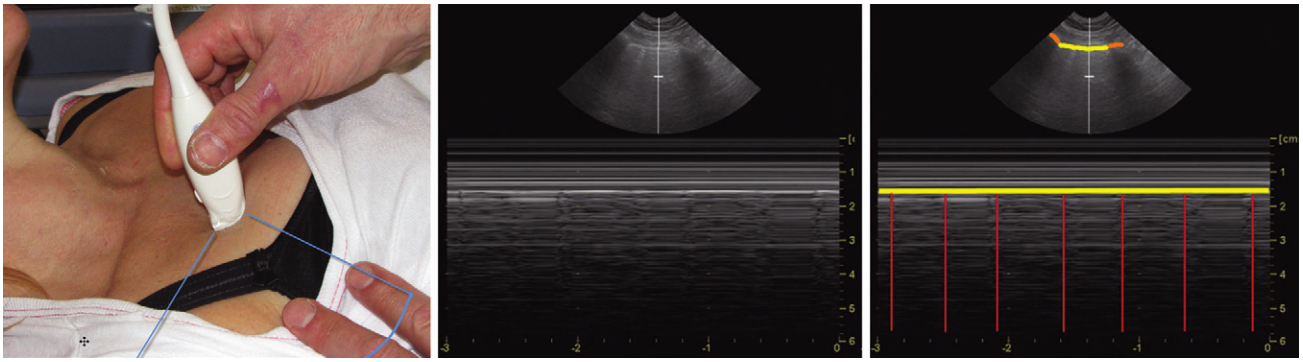

Figure 3-10 Lung pulse. *Left,* Placement of the transducer. *Middle,* The scanning image, showing B-mode scanning above and M-mode scanning below. In this nonventilated lung, the only movement is that caused by the heartbeat, which creates a subtle movement of the lungs and the pleura. This movement is visualized in the M-mode image synchronous with the heartbeat and is called the "lung pulse." *Right,* The pleural line is marked in yellow and the superficial outline of the ribs in orange. The red lines indicate the lung pulse. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

plane along the right anterior axillary line and the left posterior axillary line, respectively. The movement of the most caudal margin of the liver and spleen with respiration is measured.[30]

IV. CLINICAL APPLICATIONS

A. Prediction of Difficult Laryngoscopy in Surgical Patients

In a pilot study of 27 elective surgical patients, it was found that failure to identify the epiglottis and trachea with sublingual USG was a more accurate predictor of a Cormack-Lehane grade 3 or greater laryngoscopy score than the Mallampati classification was.[31] However, the interpretation of the sublingual USG approach was later reevaluated, and it remains to be determined whether this approach is useful in predicting airway difficulties.[6]

In 50 morbidly obese patients, the distance from the skin to the anterior aspect of the trachea, measured at the level of the vocal cords and the suprasternal notch, was significantly greater in those patients in whom laryngoscopy was difficult, even after optimization of laryngoscopy by laryngeal manipulation. However, these findings could not be reproduced when the end point was laryngoscopy grade without the use of laryngeal manipulation for optimization of the laryngoscopic view.[32,33]

B. Evaluation of Pathology That May Influence the Choice of Airway Management Technique

Subglottic hemangiomas, laryngeal stenosis, laryngeal cysts, and respiratory papillomatosis (Fig. 3-11) can be visualized with USG. A pharyngeal pouch (Zenker's diverticulum), representing a source of regurgitation and

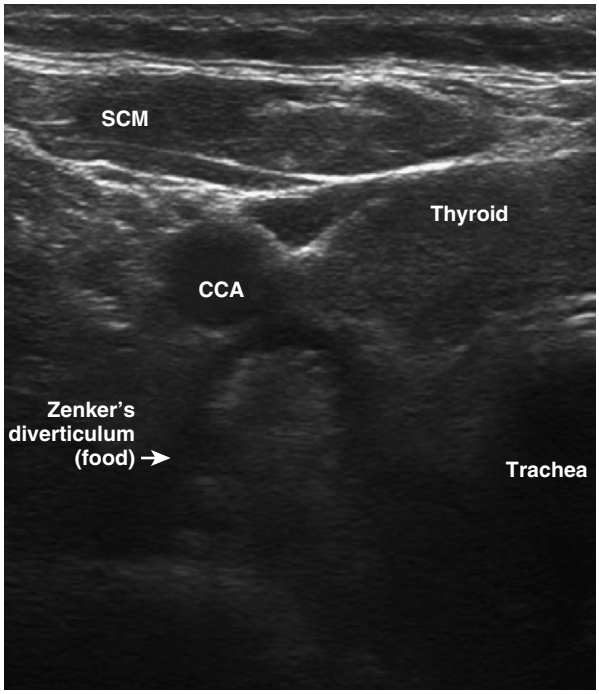

Figure 3-12 Zenker's diverticulum is seen laterally to the trachea on a transverse scan on the anterior neck above the suprasternal notch. *CCA,* Common carotid artery; *SCM,* sternocleidomastoid muscle. (Courtesy of Peter Cheng, Kaiser Permanente Riverside Medical Center, Riverside, CA.)

aspiration, is seen on a transverse linear high-frequency scan of the neck and is located at the posterolateral aspect of the left thyroid lobe (Fig. 3-12).[11,34-36] Malignancies and their relationship with the airway can be seen and quantified.

Fetal airway abnormalities, such as extrinsic obstruction caused by adjacent tumors (e.g., lymphatic malformation, cervical teratoma), can be visualized by prenatal USG (Fig. 3-13).[37] With this information, airway management can be planned, either at birth or as an ex utero intrapartum treatment (EXIT) procedure. The EXIT maneuver can consist of performing a cesarean section and endotracheal intubation or tracheostomy while the newborn is still attached to the umbilical cord and thus maintains fetal circulation.

C. Diagnosis of Obstructive Sleep Apnea

The width of the tongue base, measured by USG, was found to correlate with the severity of sleep-related breathing disorders, including a patient's sensation of choking during the night. The width was measured as the distance between the lingual arteries where they enter the tongue base at its lower lateral borders.[8] The thickness of the lateral pharyngeal wall, as measured with USG, is significantly higher in patients with obstructive sleep apnea than in patients without this condition.[12]

D. Evaluation of Prandial Status

Twenty subjects were randomized to either fasting or nonfasting status and had their stomach examined with USG. The technique was found to be specific in identifying a full stomach but only moderately reliable in identifying an empty stomach. After the subjects drank water, the stomach was identified 100% of the time by all observers in both conditions. Recent publications have suggested clinical usefulness of USG in determining prandial status.[38-40]

E. Prediction of the Appropriate Diameter of an Endotracheal, Endobronchial, or Tracheostomy Tube

In children and young adults, USG is a reliable tool for measuring the diameter of the subglottic upper airway and correlates well with MRI, which is the gold standard.[41,42]

The diameter of the left main stem bronchus, and therefore the proper size of a left-sided double-lumen tube, can be estimated with USG. Immediately before anesthesia in a series of patients, the outer diameter of the trachea was measured by USG just above the sternoclavicular joint in the transverse section. The ratio between the diameter of the trachea and that of the left main stem bronchus was obtained from CT images. The ratio between left main stem bronchus diameter on CT imaging and outer tracheal diameter measured with USG was 0.68. The results were comparable to those obtained with chest radiography as a guide for selecting left double-lumen tube size.[43]

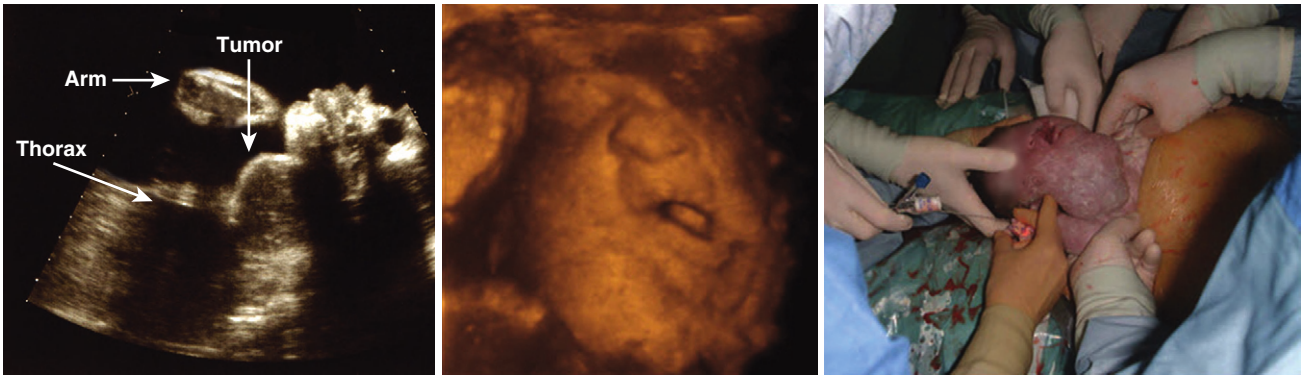

Figure 3-13 *Left,* A large tumor is seen on the neck of a fetus. *Middle,* Three-dimensional ultrasonographic image. *Right,* The head is delivered, and the airway is managed while the fetal circulation is still intact. (Courtesy of Connie Jørgensen, Rigshospitalet, Copenhagen, Denmark.)

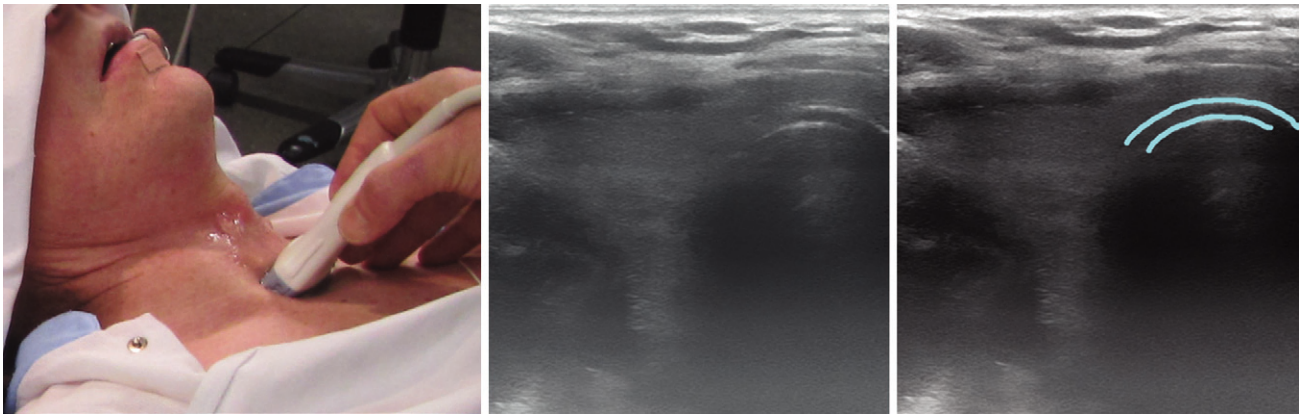

Figure 3-14 Tracheal deviation. *Left,* The transducer is placed transversely in the midline over the suprasternal notch. *Middle,* The scanning image reveals lateral deviation of the middle part of the trachea. *Right,* The cartilage of the tracheal ring (light blue) is deviated to the patient's left side. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

In children with tracheostomy, USG measurement of the tracheal width and of the distance from the skin to the trachea can be used to predict the size and shape of a potential replacement tracheostomy tube, and adequate images can be obtained by placing the ultrasound probe just superior to the stomach.[44]

F. Localization of the Trachea

Obesity, a short thick neck, neck mass, previous surgery or radiotherapy to the neck, and thoracic pathology resulting in tracheal deviation can make accurate localization of the trachea challenging and cumbersome. Even the addition of chest radiography and techniques of needle aspiration to locate the trachea may be futile.[45] This situation is even more challenging in emergency cases and in cases where awake tracheostomy is chosen because of a predicted difficult mask ventilation or difficult endotracheal intubation. Under such circumstances, preoperative USG for localization of the trachea (Fig. 3-14) is very useful.[45]

G. Localization of the Cricothyroid Membrane

The CTM plays a crucial role in airway management, but it was correctly identified by anesthesiologists in only 30% of cases when identification was based on surface landmarks and palpation alone.[46] USG allows reliable, quick, and easily learned identification of the CTM.[46-48] USG is a useful technique to identify the trachea before elective transtracheal cannulation or emergency cricothyrotomy. This was demonstrated by a case concerning an obese patient with Ludwig's angina in whom it was not possible to identify the trachea by palpation. A portable ultrasound machine was used to locate the trachea 2 cm lateral to the midline.[49] Accurate localization of the trachea allows the clinician to approach the difficult airway by placing a transtracheal catheter or performing a tracheostomy before anesthesia. In cases of awake intubation, it provides the added safety of having localized the CTM in advance in case the intubation should fail and an emergency transcricoid access should become necessary.

One method for localizing the CTM is described as follows: A transverse, midline scan is performed from the clavicles to the mandible with a 10-MHz linear array probe, and the CTM is identified by its characteristic echogenic artifact, the cricothyroid muscles lateral to it, and the thyroid cartilage cephalad.[48] In a study of 50 emergency department patients, the craniocaudal level of the CTM was located by performing a longitudinal sagittal midline scan and then sliding the probe bilaterally to localize the lateral borders of the CTM. The mean time to visualization of the CTM was 24.3 seconds.[47] A simple and systematic approach to localizing the CTM is shown in Figure 3-15.

H. Airway-Related Nerve Blocks

USG has casuistically been used to identify and block the superior laryngeal nerve as part of the preparation for awake fiberoptic intubation. The greater horn of the hyoid bone and the superior laryngeal artery were identified, and the local analgesic was injected between them.[50] In 100 ultrasound examinations for the superior laryngeal nerve space (i.e., the space delimited by the hyoid bone, the thyroid cartilage, the pre-epiglottic space, the thyrohyoid muscle, and the membrane between the hyoid bone and the thyroid cartilage), all components of the space were seen in 81% of cases, and there was a suboptimal, but still useful, depiction of the space in the remaining 19% of cases. The superior laryngeal nerve itself was not seen.[51]

I. Confirmation of Endotracheal Tube Placement

Confirmation of whether the ETT has entered the trachea or the esophagus can be made directly, in real time, by scanning the anterior neck during the intubation or indirectly by looking for ventilation at the pleural or the diaphragmatic level, or by a combination of these techniques. Direct confirmation has the advantage that an accidental esophageal intubation is recognized immediately, before ventilation is initiated and therefore before air is forced into the stomach resulting in an increased

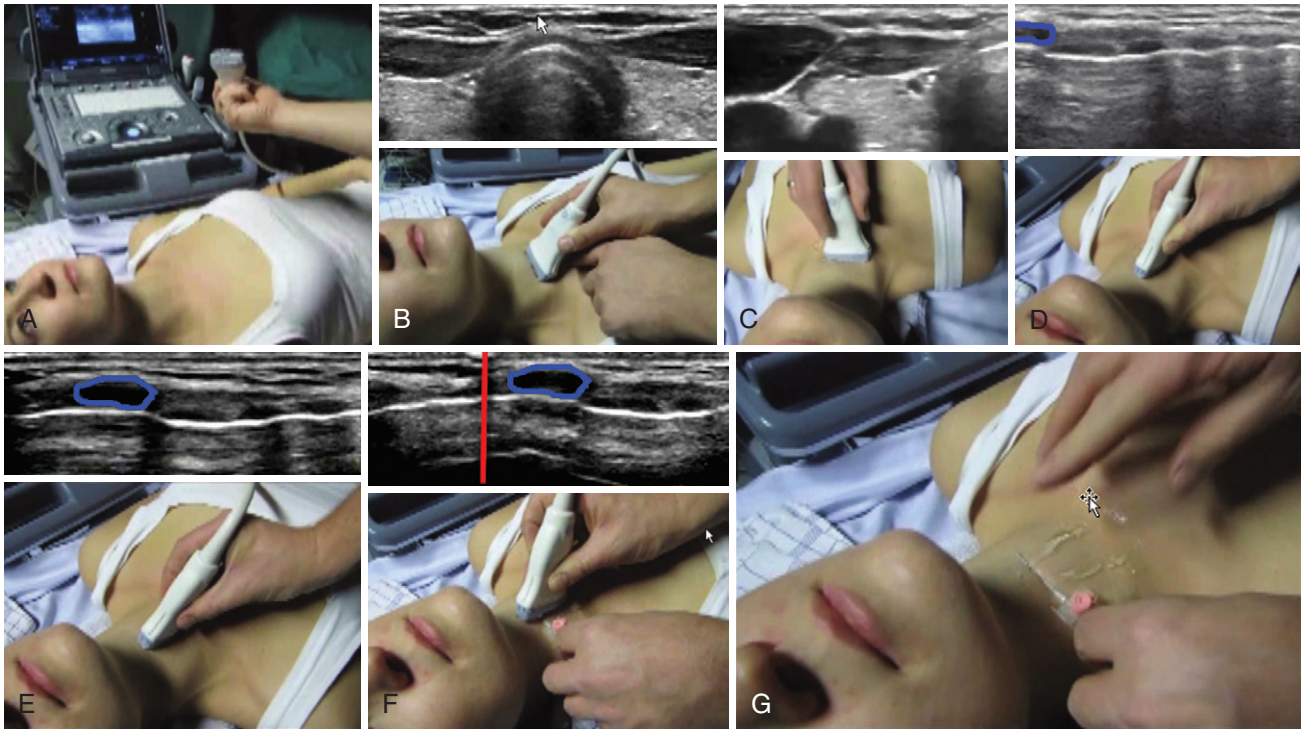

Figure 3-15 Localization of the cricothyroid membrane (CTM). **A,** The patient is lying supine, and the operator stands on the patient's right side, facing the patient. **B,** The linear high-frequency transducer is placed transversely over the neck just above the suprasternal notch (*below*), and the trachea is seen in the midline on the scan *(above)*. **C,** The transducer is moved to the patient's right side so that the right border of the transducer is superficial to the midline of the trachea. **D,** The right end of the transducer is kept in the midline of the trachea while the left end is rotated into the sagittal plane, resulting in a longitudinal scan of the midline of the trachea. The caudal part of the cricoid cartilage is seen on the scan and is outlined in blue. **E,** The transducer is moved cranially, and the cricoid cartilage (blue) is seen as a slightly elongated structure that is significantly larger and located more anteriorly than the tracheal rings. **F,** A needle is moved under the transducer from the cranial end; it is used only as a marker. Its shadow (red line) is just cephalad to the cranial border of the cricoid cartilage (blue). **G,** The transducer is moved, and the needle indicates the distal part of the CTM. (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

risk of emesis and aspiration. Confirmation at the pleural level has the advantage of distinguishing, at least to some extent, between tracheal and endobronchial intubation.

Both the direct and the indirect confirmation techniques have the advantage over capnography because they can be applied in very-low-cardiac-output situations. USG has the advantage over stethoscopy in that it can be performed in noisy environments, such as in helicopters. In a cadaver model in which a 7.5-MHz curved probe was placed longitudinally over the CTM, it was possible for residents given only 5 minutes of training in the technique to correctly identify esophageal intubation (97% sensitivity) with dynamic examination at the time of intubation. When the examination was performed after the intubation, statically, the sensitivity was very poor.[52]

In 40 elective patients, a 3- to 5-MHz curved transducer placed at the level of the CTM and held at a 45-degree angle facing cranially allowed detection of all five accidental esophageal intubations. Tracheal passage of the ETT was seen as a brief flutter deep to the thyroid cartilage, whereas esophageal intubation created a clearly visible bright (hyperechoic) curved line with a distal dark area (shadowing) appearing on one side of, and deep to, the trachea.[53]

In another study, 33 patients with normal airways were intubated electively in both trachea and esophagus in random order and had a linear 5- to 10-MHz probe placed transversely on the anterior neck just superior to the suprasternal notch. USG allowed detection of both tracheal and esophageal intubation in all 33 patients. It was concluded that skilled ultrasonographers, in a controlled operating room setting, can consistently detect the passage of an ETT into either the trachea or the esophagus in normal airways.[54]

In children, direct confirmation of ETT placement by scanning via the CTM required multiple views; the USG examination was apparently performed after the intubation, making comparison to other studies difficult, and the feasibility of that approach has been challenged.[55,56]

Indirect confirmation of ETT placement in 15 patients was performed with the use of a portable, handheld ultrasound machine and routine scanning in the third and fourth intercostal spaces on both sides during the phases of preoxygenation, apnea, bag-mask ventilation, intubation, and positive-pressure ventilation after intubation. ETT placement was determined in all cases.[57]

The color power Doppler function has been used as a supplement during observation of lung sliding to detect that a lung was ventilated.[57] The distinction between tracheal and endobronchial intubation can be made by scanning the lung bilaterally. If there is pleural sliding on one side and lung pulse on the other side, the tip of the tube is in the main stem bronchus on the side on which lung sliding is observed. The ETT is then withdrawn until

lung sliding is observed bilaterally, indicating that the tip of the tube is again placed in the trachea.[58] Indirect confirmation of intubation by detection of a "sliding lung" was studied in fresh ventilated cadavers; the tip of the ETT was placed in either the esophagus, the trachea, or the right main stem bronchus. A high sensitivity (95% to 100%) was found for detection of esophageal versus airway (trachea or bronchus) intubation. The sensitivity for distinguishing a right main stem bronchus intubation from an endotracheal intubation was lower (69% to 78%), most likely because of transmitted movement of the left lung due to expansion of the right lung.[59]

Indirect confirmation of intubation by depiction of the movement of the diaphragm bilaterally was shown to be useful for distinguishing between esophageal and endotracheal intubation in a pediatric population.[29] However, when the technique was used to distinguish between main stem bronchus and endotracheal intubation, diaphragmatic ultrasound was not equivalent to chest radiography for determining ETT placement within the airway.[60]

The *combination* of the direct transverse scan on the neck at the level of the CTM and lung ultrasound detecting lung sliding in 30 emergency department patients who needed endotracheal intubation correctly detected the three cases of esophageal intubation, even in the presence of four cases of pneumohemothorax.[61] The combination of the direct transverse scan on the neck at the level of the thyroid lobes, combined with lung ultrasound, has casuistically demonstrated its value by enabling detection of esophageal intubation in a patient in whom laryngoscopy was difficult in the clinical emergency setting.[62]

Filling the cuff with fluid helps in seeing the cuff position on USG.[63] Use of a metal stylet does not augment visualization of the ETT.[64] In children, when the transducer was placed at the level of the glottis, the vocal cords were always visible; the passing of the ETT was visible in all children and was characterized by widening of the vocal cords.[65] USG is also useful in confirming the correct position of a double-lumen tube.[43]

The following procedure is recommended for USG confirmation of ETT placement: Perform a transverse scan over the trachea, just above the sternal notch. Note the location and appearance of the esophagus. Let the intubation be performed. If the ETT is visualized passing into the esophagus, remove it without starting to ventilate the patient and make another intubation attempt, possibly using another technique. If the ETT is not seen, or if it is seen in the trachea, have the patient ventilated via the tube. Move the transducer to the midaxillary lines and look for lung sliding bilaterally. If there is bilateral lung sliding, it is a confirmation that the ETT is in the airway, but a main stem bronchus intubation cannot be ruled out. If there is lung sliding on one side and lung pulse on the other side, then a main stem bronchus intubation is likely, and the tube can be removed gradually until bilateral sliding is present. If there is no lung sliding on either side but lung pulse is present, there is a small risk that the tube has entered the esophagus. If there is neither lung pulse nor lung sliding, then a pneumothorax should be expected.

J. Tracheostomy

Accurate localization of the trachea in the absence of surface landmarks can be very challenging and cumbersome. Preoperative USG for localization of the trachea (see Fig. 3-14) is very suitable for both surgical tracheostomy and percutaneous dilatational tracheostomy (PDT).[45] In children, preoperative USG is of value in verifying the precise tracheostomy position and thereby preventing subglottic damage to the cricoid cartilage and the first tracheal ring, hemorrhage due to abnormally placed or abnormally large blood vessels, and pneumothorax.[66]

K. Percutaneous Dilatational Tracheostomy

USG allows localization of the trachea, visualization of the anterior tracheal wall and pretracheal tissue including blood vessels, and selection of the optimal intercartilaginous space for placement of the tracheostomy tube.[67,68] The distance from the skin surface to the tracheal lumen can be measured to predetermine the length of the puncture cannula that is needed to reach the tracheal lumen without perforating the posterior wall.[69] The same distance can be used to determine the optimal length of the tracheostomy cannula.[70]

Ultrasound-guided PDT was applied in a case in which bronchoscope-guided technique had been abandoned.[69] Autopsy in cases of fatal bleeding after PDT revealed that the tracheostomy level was much more caudal than intended and that the innominate vein and the arch of the aorta had been eroded. It is likely that the addition of a USG examination to determine the level for the PDT and to avoid blood vessels could diminish this risk.[71] PDT results in a significantly lower rate of cranial misplacement of the tracheostomy tube compared with "blind" placement.[68] Bronchoscope-guided PDT often results in considerable hypercapnia, whereas Doppler ultrasound–guided PDT does not.[72]

In a prospective series of 72 PDTs, the combination of USG and bronchoscopy was applied. Before the procedures, all subjects had their pretracheal space examined with USG; the findings led to a change in the planned puncture site in 24% of cases and to a change of procedure to surgical tracheostomy in one case in which the ultrasound examination revealed a goiter with extensive subcutaneous vessels.[73] A different approach, namely trying to follow the needle during its course through the tissue overlying the trachea, was tried in a cadaver model. A small curved transducer was used in the transverse plane to localize the tracheal midline and was then turned to the longitudinal plane to allow needle puncture in the inline plane and to follow the needle's course from skin surface to trachea. After guidewire insertion a CT scan was performed that demonstrated that although all punctures had successfully entered the trachea on the first (89%) or second (11%) attempt, the guidewire was placed laterally to the ideal midline position in five of nine cadavers.[74] Another approach using real-time ultrasound guidance with visualization of the needle path by means of a linear high-frequency transducer placed transversely over the trachea was more successful and resulted

in visualization of the needle path und satisfactory guidewire placement in all of 13 patients.[75]

L. Confirmation of Gastric Tube Placement

Abdominal USG performed in the intensive care unit (ICU) had a 97% sensitivity for detecting correct gastric placement of a weighted-tip nasogastric (NG) tube. Immediately after insertion of the NG tube, the metal stylet was removed and a 2- to 5-MHz convex transducer was used to examine the duodenum in the middle gastric area. If the NG tube was not visualized, the probe was oriented toward the left upper abdominal quadrant to visualize the gastric area. If the NG tube tip was still not visible, 5 mL normal saline mixed with 5 mL air was injected into the tube to visualize the hyperechoic "fog" exiting the tip. The tip of the NG tube was considered to be correctly located when it was seen to be surrounded by fluid and echogenic moving formations (related to peristalsis). The tip of the NG tube was visualized by sonography in 34 of 35 cases. Radiography correctly identified all 35 catheters, but the radiographic confirmation lasted on average 180 minutes (range, 113 to 240 minutes); in contrast, the sonographic examinations lasted 24 minutes on average (range, 11 to 53 minutes). The authors concluded that bedside USG performed by nonradiologists is a sensitive method for confirming the position of weighted-tip NG feeding tubes, that it is easily taught to ICU physicians, and that conventional radiography can be reserved for cases in which USG is inconclusive.[76]

A Sengstaken-Blakemore tube may be applied for severe esophageal variceal bleeding, but there are considerable complications, including death, from esophageal rupture after inadvertent inflation of the gastric balloon in the esophagus.[77] USG of the stomach can aid in the rapid confirmation of correct placement. If the Sengstaken tube is not directly visible, inflation of 50 mL air via the gastric lumen (not the gastric balloon!) of the tube should lead to a characteristic jet of echogenic bubbles within the stomach. The gastric balloon is slowly inflated under direct USG control and usually appears as a growing echogenic circle within the stomach.[77]

M. Diagnosis of Pneumothorax

USG is as effective as chest radiography in detecting or excluding pneumothorax.[28] It is even more sensitive in the ICU setting: USG was able to establish the diagnosis in the majority of patients in whom a pneumothorax was invisible on plain radiographs but diagnosed by CT scan.[26] In patients with multiple injuries, USG was faster and had a higher sensitivity and accuracy compared to chest radiography.[78]

The presence of lung sliding or lung pulse on USG examination indicates that two pleural layers are in close proximity to each other at that specific point under the transducer (i.e., there is no pneumothorax there). If there is free air (pneumothorax) in the part of the pleural cavity underlying the transducer, no lung sliding or lung pulse will be seen, and A-lines (Fig. 3-16) will be more dominant.[26] In the M-mode, the "stratosphere sign" will be seen: only parallel lines through all of the depth of the image (see Fig. 3-16). If the transducer is placed right at the border of the pneumothorax, where the visceral pleura intermittently is in contact with the parietal pleura, the lung point will be seen. This is a sliding lung alternating with A-lines, synchronous with ventilation. The lung point is pathognomonic for pneumothorax (see Fig. 3-16). If a pneumothorax is suspected, the rib interspaces of the thoracic cavity can be systematically "mapped" to confirm or rule out a pneumothorax. An online video is available to view the lung point (http://www.airwaymanagement.dk/index.php?option=com_content&view=article&id=3&Itemid=2 [accessed January 2011]).[25]

The detection of lung sliding has a negative predictive value of 100%, meaning that when lung sliding is seen, a pneumothorax of the part of the lung beneath the ultrasound probe is ruled out.[24] For diagnosis of occult pneumothorax, the abolition of lung sliding alone had a sensitivity of 100% and a specificity of 78%. Absent lung sliding plus the A-line sign had a sensitivity of 95% and a specificity of 94%. The lung point had a sensitivity of 79% and a specificity of 100%.[26]

A systematic approach is recommended when examining the supine patient. The anterior chest wall can be divided into quadrants and the probe first placed at the most superior aspect of the thorax with respect to gravity (i.e., the lower part of the anterior chest wall in supine patients). The probe is then positioned on each of the four quadrants of the anterior area, followed by the lateral chest wall between the anterior and posterior axillary lines and the rest of the accessible part of the thorax.[26]

If the suspicion of a pneumothorax arises intraoperatively, USG is the fastest way to confirm or rule it out, especially considering that an anterior pneumothorax is often undiagnosed in a supine patient subjected to plain anteroposterior radiography and that CT, the gold standard, is very difficult to apply in this situation. USG is an obvious first choice in diagnostics if a pneumothorax is suspected during or after central venous cannulation or nerve blockade, especially if USG is already in use for the procedure itself and thus immediately available.

N. Differentiation Among Different Types of Lung and Pleura Pathology

Seventy percent of the pleural surface is accessible to ultrasound examination.[28] In a study of 260 dyspneic medical-ICU patients with acute respiratory failure, the results of lung USG (performed by a dedicated specialist in lung USG) on initial presentation in the ICU were compared with the final diagnosis by the ICU team. Three items were assessed: artifacts (horizontal A-lines or vertical B-lines indicating interstitial syndrome), lung sliding, and alveolar consolidation or pleural effusion or both. Predominant A-lines plus lung sliding indicated asthma or chronic obstructive pulmonary disease with 89% sensitivity and 97% specificity. Multiple anterior diffuse B-lines with lung sliding indicated pulmonary edema with 97% sensitivity and 95% specificity. The use of these profiles would have provided correct diagnoses

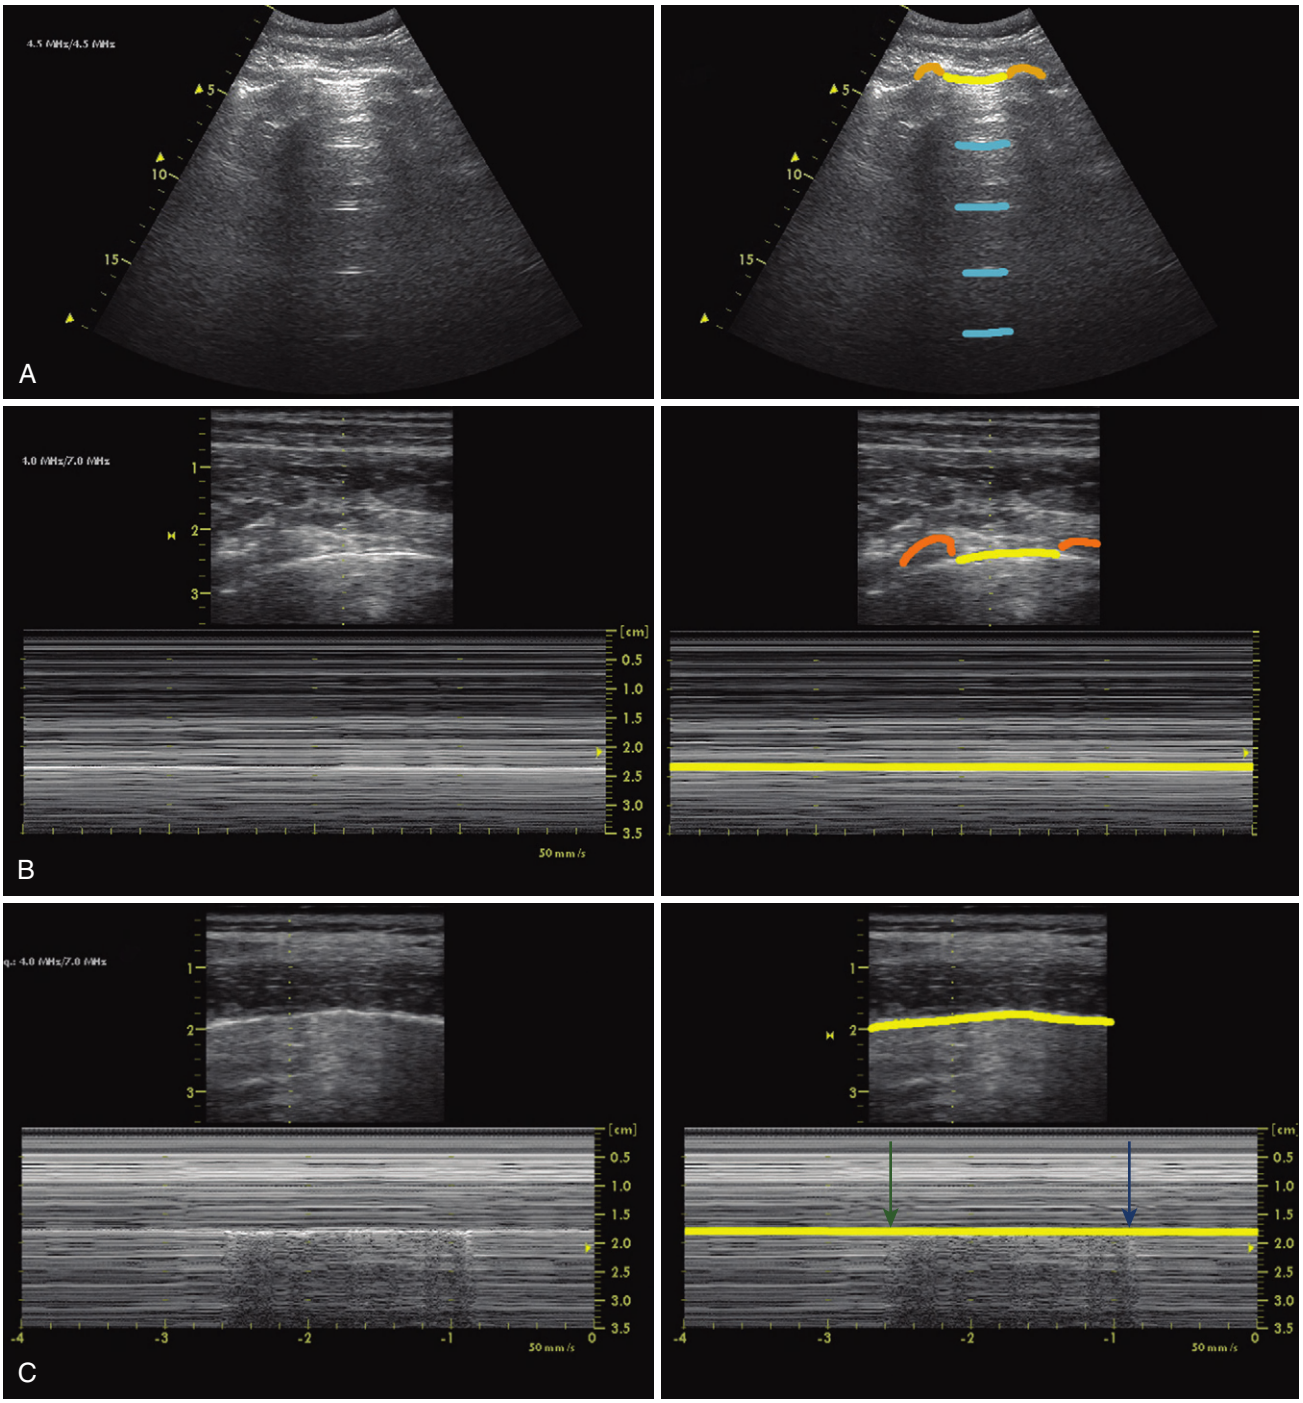

Figure 3-16 Pneumothorax. The scanning images are shown on the *left* and the marked-up images on the *right*. **A,** Image obtained with a convex transducer in a rib interspace. The pleural line *(yellow)* represents the surface of the parietal pleura. The ribs *(orange)* create underlying shadows. The "A-lines" *(light blue)* are reverberation artifacts from the pleural line; notice that they are dispersed with the same distance between the A-lines as between the skin surface and the pleural line. **B,** Again, the pleural line is marked in *yellow* and the ribs in *orange*. Everything posterior to the pleural line is artifact. There is absence of pleural sliding and absence of lung pulse. The M-mode image consists only of parallel lines, called the "stratosphere sign." **C,** The *green arrow* represents the "lung point," the moment in which the visceral pleura just comes in contact with the parietal pleura at the exact location of the transducer. For the time interval from the green to the *blue arrow,* the two pleural layers are in contact with each other and form the "lung sliding" pattern. After the time represented by the blue arrow, the two pleural layers are no longer in contact, and the "stratosphere sign" is seen. The lung point can be difficult to see on the static B-mode image, whereas it is easy to recognize with dynamic, real time, B-mode scanning. (**C,** Courtesy of Erik Sloth, Aarhus University Hospital, Skejby, Denmark.) (From Kristensen MS: Ultrasonography in the management of the airway. *Acta Anaesthesiol Scand* 55:1155–1173, 2011.)

in 90.5% of cases. It was concluded that lung ultrasound can help the clinician make a rapid diagnosis in patients with acute respiratory failure.[27]

USG can detect pleural effusion and differentiate between pleural fluid and pleural thickening, and it is more accurate and preferable to radiographic measurement in the quantification of pleural effusion.[28] Routine use of lung USG in the ICU setting can lead to a reduction of the number of chest radiographs and CT scans performed.[79]

O. Prediction of Successful Extubation

In a study of adult ventilator-treated patients, the transducer was placed on the CTM with a transverse view of the larynx. The width of the air column was significantly smaller in the group of patients who developed postextubation stridor.[80] However, the number of patients in the stridor group was small ($n = 4$), and these results need to be evaluated in larger studies.

Intubated patients receiving mechanical ventilation in a medical ICU had their breathing force evaluated by USG. The probe was placed along the right anterior axillary line and the left posterior axillary line for measurement of liver and spleen displacement in craniocaudal aspects, respectively. The cutoff value of diaphragmatic displacement for predicting successful extubation was determined to be 1.1 cm. The liver and spleen displacements measured in the study were thought to reflect the "global" functions of the respiratory muscles, and this method provided a good parameter of respiratory muscle endurance and predictor of extubation success.[30]

V. SPECIAL TECHNIQUES AND FUTURE ASPECTS

The lateral position of a laryngeal mask airway cuff can be seen on USG if the cuff is filled with fluid, but the fluid damages the cuff on subsequent autoclaving.[63] Airway obstruction due to a prevertebral hematoma after difficult central line insertion may be prevented by using USG for this procedure.[81] The larynx can be depicted from the luminal side by filling the larynx and the trachea above the cuff of the ETT with 0.9% saline to obtain sufficient tissue connection and to prevent the retention of air bubbles in the anterior commissure. The technique involves use of a thin-catheter high-frequency probe with a rotating mirror to spread the ultrasound ray, which produces a 360-degree image rectilinear to the catheter.[82,83] Three-dimensional, pocket-size USG devices are likely to move the boundaries for both the quality and the availability of USG imaging of the airway.

VI. LEARNING ULTRASONOGRAPHY

The following studies provide insight into what (and how little) is required to learn basic airway USG. After 8.5 hours of focused training comprising a 2.5-hour didactic course that included essential views of normal and pathologic conditions and three hands-on sessions of 2 hours each, physicians without previous knowledge of USG were able to competently perform basic general USG examinations. The examinations were aimed at diagnosing the presence of pleural effusion, intra-abdominal effusion, acute cholecystitis, intrahepatic biliary duct dilation, obstructive uropathy, chronic renal disease, and deep venous thrombosis. In addition, the physicians correctly answered 95% of questions with a potential therapeutic impact.[3]

The USG experience needed to make a correct diagnosis is probably task specific. In other words, the basic skill required to detect a pleural effusion may be acquired in minutes and may then improve with experience.[84] A 25-minute instructional session, including both a didactic portion and hands-on practice, was given to critical care paramedics/nurses who were part of a helicopter critical care transport team. The instructional session focused solely on detection of the presence or absence of lung sliding, including secondary techniques such as power Doppler and M-mode USG. The participants' performance was studied on fresh ventilated cadavers. The presence or absence of lung sliding was correctly identified in 46 of 48 trials, for a sensitivity of 96.9% and a specificity of 93.8%. In a follow-up after 9 months, the presence or absence of lung sliding was correctly identified in all of 56 trials, resulting in a sensitivity and specificity of 100%.[85]

As mentioned earlier, residents given only 5 minutes of training were able to correctly identify esophageal intubation with 97% sensitivity when USG was performed dynamically, whereas the sensitivity was very poor when the examination was performed after the intubation.[52]

VII. CONCLUSIONS

Important structures relevant to airway management can be identified with the use of USG. These include a large part of the airway and adjacent structures from the mouth and tongue via the larynx and esophagus to the midtrachea, the pleural layers and their movement, the diaphragm, and the gastric antrum. Ultrasonography used dynamically, immediately before, during, and after airway interventions, gives real-time images highly relevant for several aspects of airway management. Esophageal intubation is detected without the need for ventilation or circulation, the cricothyroid membrane is identified before management of a difficult airway, ventilation is seen by observing lung sliding bilaterally, which is also the first choice for ruling out a suspected intraoperative pneumothorax, and percutaneous dilatational tracheostomy is facilitated by identifying the correct tracheal-ring interspace and depth from the skin to the tracheal wall.

VIII. CLINICAL PEARLS

- USG has many advantages for imaging the airway: It is safe, quick, repeatable, portable, and widely available and gives real-time dynamic images.
- USG must be used dynamically for maximum benefit and in direct conjunction with the airway management (immediately before, during, and after airway interventions).

- Direct observation can be made of whether an ETT is entering the trachea or the esophagus by placing the ultrasound probe transversely on the neck at the level of the suprasternal notch during intubation; in this way, intubation can be confirmed without the need for ventilation or circulation.
- The cricothyroid membrane (CTM) can easily be identified by USG prior to management of a difficult airway.
- Ventilation can be confirmed by observing lung sliding bilaterally.
- USG should be the first-choice diagnostic approach when a pneumothorax is suspected intraoperatively or during initial trauma evaluation.
- Percutaneous dilatational tracheostomy (PDT) can be improved by using USG for identifying the correct tracheal-ring interspace, avoiding blood vessels, and determining the depth from the skin to the tracheal wall.
- Numerous conditions that affect airway management can be diagnosed by preanesthetic USG, but it remains to be determined in which patients the predictive value of such an examination is high enough to recommend this as a routine approach to airway management planning.

I. THE GAS LAWS

A. Ideal Gases

Air is a fluid. Understanding the fundamentals of basic fluid mechanics is essential in grasping the concepts of airway flow. Because air is also a gas, it is important to understand the laws that govern its gaseous behavior. Gases are usually described in terms of pressure, volume, and temperature. Pressure is most often quantified clinically in terms of mm Hg (or torr), volume in mL, and temperature in degrees Celsius. However, calculations often require conversion from one set of units to another

and therefore can be quite tedious. We have included a small section at the end of the chapter to simplify these conversions.

Perhaps the most important law of gas flow in airways is the ideal (or perfect) gas law, which can be written as follows[1]:

$$PV = nRT \quad (1)$$

where
P = pressure of gas (pascals or mm Hg)
V = volume of gas (m^3 or cm^3 or mL)
n = number of moles of the gas in volume V
R = gas constant (8.3143 J g-mol^{-1}·K^{-1}, assuming P in pascals, V in m^3)
T = absolute temperature (in kelvins or K; 273.16 K = 0° C)

One mole of gas contains 6.023×10^{23} molecules, and this quantity is termed Avogadro's number. One mole of an ideal gas takes up 22.4138 L at standard temperature and pressure (STP); standard temperature is 273.16 K, and standard pressure is 1 atmosphere (760 mm Hg).[1] Avogadro also stated that equal volumes of all ideal gases at the same temperature and pressure contain the same number of molecules.

The ideal gas law incorporates the laws of Boyle and Charles.[1] Boyle's law states that, at a constant temperature, the product of pressure and volume (P × V) is equal to a constant. Consequently, P is proportional to 1/V ($P \propto 1/V$) at constant T. However, gases do not obey Boyle's law at temperatures approaching their point of liquefaction (i.e., the point at which the gas becomes a liquid).

Boyle's law concerns perfect gases and is not obeyed by real gases over a wide range of pressures (see Section II for a discussion of nonideal gases). However, at infinitely low pressures, all gases obey Boyle's law. Boyle's law does not apply to anesthetic gases and many other gases because of the van der Waals attraction between molecules (i.e., they are nonideal gases).

Charles' law states that, at a constant pressure, volume is proportional to temperature (i.e., $V \propto T$ at constant P). Gay-Lussac's law states that, at a constant volume, pressure is proportional to temperature (i.e., $P \propto T$ at constant V).[1] Often, these two laws are shortened for convenience to Charles' law. When a gas obeys both Charles' law and Boyle's law, it is said to be an ideal gas and obeys the ideal gas law.

In clinical situations, gases are typically mixtures of several "pure" gases. Quantifiable properties of mixtures may be determined using Dalton's law of partial pressures. Dalton's law states that the pressure exerted by a mixture of gases is the sum of the pressures exerted by the individual pure gases[1,2]:

$$P_{total} = P_A + P_B + P_C + \ldots + P_N \quad (2)$$

where P_A, P_B, and P_C are the partial pressures of pure ideal gases.

B. Nonideal Gases: The van der Waals Effect

Ideal gases have no forces of interaction, but real gases have intermolecular attraction, which requires that the pressure-volume gas law be rewritten as follows[1,2]:

$$\left(P + \frac{a}{V^2}\right) \times (V - b) = nRT \quad (3)$$

where
P = pressure of gas (pascals or mm Hg)
V = volume of gas (m^3 or cm^3 or mL)
n = number of moles of the gas in volume V
R = gas constant (8.3143 J g- mol^{-1}·K^{-1}, assuming P in pascals, V in m^3)
T = absolute temperature (K)
a and b = physical constants for a given gas

The values of *a* and *b* for a given gas may be found in physical chemistry textbooks and other sources.[1-5] This formulation, provided by van der Waals, accounts for intramolecular forces fairly well.

C. Diffusion of Gases

Clinically, diffusion of gases through a membrane is most applicable to gas flow across lung and placental membranes. The most commonly used relation to govern diffusion is Fick's first law of diffusion, which states that the rate of diffusion of a gas across a barrier is proportional to the concentration gradient for the gas. Fick's law may be expressed mathematically as follows[6]:

$$\text{Flux} = -D\frac{\Delta C}{\Delta X} \quad (4)$$

where
Flux = the number of molecules crossing the membrane each second (molecules/cm^2/s)
ΔC = the concentration gradient (molecules/cm^3)
ΔX = the diffusion distance (cm)
D = the diffusion coefficient (cm^2/s)

In general, the value of D is inversely proportional to the gas's molecular weight as well as intrinsic properties of the membrane.

Because gases partially dissolve when they come into contact with a liquid, Henry's law becomes important in some instances. It states that the mass of a gas dissolved in a given amount of liquid is proportional to the pressure of the gas at constant temperature. As a result, the gas concentration (in solvent) is equal to a constant × P (at constant T).[1]

D. Pressure, Flow, and Resistance

The laws of fluid mechanics dictate an intricate relationship among pressure, flow, and resistance. Pressure is defined as force per unit area. It is usually measured

clinically in mm Hg or cm H_2O, but it is most commonly measured scientifically in pascals (Pa), or newtons of force per square meter (1 Pa = 1 N/m^2).

Flow (i.e., the rate of flow) is equal to the change in pressure (pressure drop or pressure difference) divided by the resistance experienced by the fluid. For example, if the flow is 100 mL/s at a pressure difference of 100 mm Hg, the resistance is 100 mm Hg/100 mL/s, or 1 mm Hg/mL/s. In laminar flow systems only, the resistance is constant, independent of the flow rate.[7,8]

An important formula that quantifies the relationship of pressure, flow, and resistance in laminar flow systems is given by the Hagen-Poiseuille equation. Poiseuille's law states that the fluid flow rate through a horizontal straight tube of uniform bore is proportional to the pressure gradient (ΔP), and the fourth power of the radius (π) and is related inversely to the viscosity of the gas (μ, in g/cm·s) and the length of the tube (L, in cm). This law, which is valid for laminar flow only, may be stated as follows[7,8]:

$$\Delta P = \frac{8\,\mu L}{\pi^4} \times \text{Flow} \qquad (5)$$

See the discussion of laminar flow in Section II for further details.

When the flow rate exceeds a *critical velocity* (the flow velocity below which flow is laminar), the flow loses its laminar parabolic velocity profile, becomes disorderly, and is termed *turbulent* (Fig. 4-1). If turbulent flow exists, the relationship between pressure drop and flow is no longer governed by the Hagen-Poiseuille equation. Instead, the pressure gradient required (or the resistance encountered) during turbulent flow varies as the square of the flow rate. See the discussion of turbulent flow in Section II.

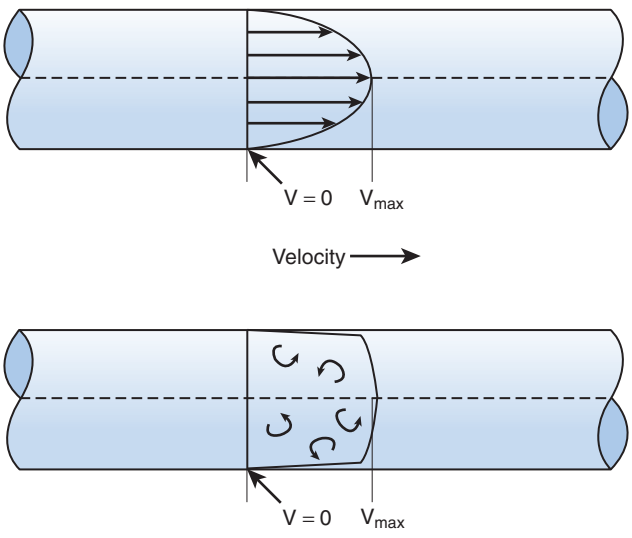

Figure 4-1 Laminar and turbulent flow. *Top,* Laminar flow in a long smooth pipe is characterized by smooth and steady flow with little or no fluctuations. The flow profile is parabolic in nature, with fluid traveling most quickly at the center of the tube and stationary at the edges. *Bottom,* Turbulent flow is characterized by fluctuating and agitated flow. Its flow profile is essentially flat, with all fluid traveling at the same velocity except at tube edges. *V,* Velocity.

Viscosity, μ, characterizes the resistance within a fluid to the flow of one layer of molecules over another (shear characteristics).[7] Blood viscosity is influenced primarily by hematocrit, so that at low hematocrit blood flow is easier—that is, blood is more dilute. The critical velocity at which turbulent flow begins depends on the ratio of viscosity (μ) to density (ρ), which is defined as the *kinematic viscosity* (υ)—that is, $\upsilon = \mu/\rho$. (This is illustrated with an example in the section on turbulent flow).[7-9] The unit for viscosity is g/cm·s (poise). The typical unit for kinematic viscosity is cm^2/s.

The viscosity of water is 0.01 poise at 25° C and 0.007 poise at 37° C. The viscosity of air is 183 micropoise at 18° C. Its density (dry) is 1.213 g/L.[10]

Density is defined as mass per unit volume (g/cm^3 or g/mL). The density of water is 1 g/mL. The general relation for the density of a gas is given by the following equation:

$$D = D_0\left(\frac{T_0 P}{T P_0}\right) \qquad (6)$$

where D_0 is a known density of the gas at temperature T_0 and pressure P_0, and D is the density of the gas at temperature T and pressure P. For dry air at 18° C and 760 mm Hg (atmospheric pressure), D = 1.213 g/L.[4]

The fall in pressure at points of flow constriction (where the flow velocity is higher) is known as the Bernoulli effect (Fig. 4-2).[7,8] This phenomenon is used in apparatus employing the Venturi principle, such as gas nebulizers, Venturi flowmeters, and some oxygen face masks. The lower pressure related to the Bernoulli effect sucks in (entrains) air to mix with oxygen.

One final consideration that is important in the study of the airway is Laplace's law for a sphere (Fig. 4-3). It states that, for a sphere with one air-liquid interface (e.g., an alveolus), the relation between the transmural pressure difference, surface tension, and sphere radius is described by the following equation[11]:

$$P = \frac{2T}{r} \qquad (7)$$

where
P = transmural pressure difference ($dynes/cm^2$; 1 $dyne/cm^2$ = 0.1 Pa = 0.000751 torr)
T = surface tension (dynes/cm)
R = sphere radius (cm)

The key point in Laplace's law is that the smaller the sphere radius, the higher the transmural pressure. However, real (in vivo) alveoli do *not* obey Laplace's law because of the action of pulmonary surfactant, which decreases the surface tension disproportionately compared with what is predicted on the basis of physical principles. When pulmonary surfactant is missing from the lungs, the lungs take on the behavior described by Laplace's law.

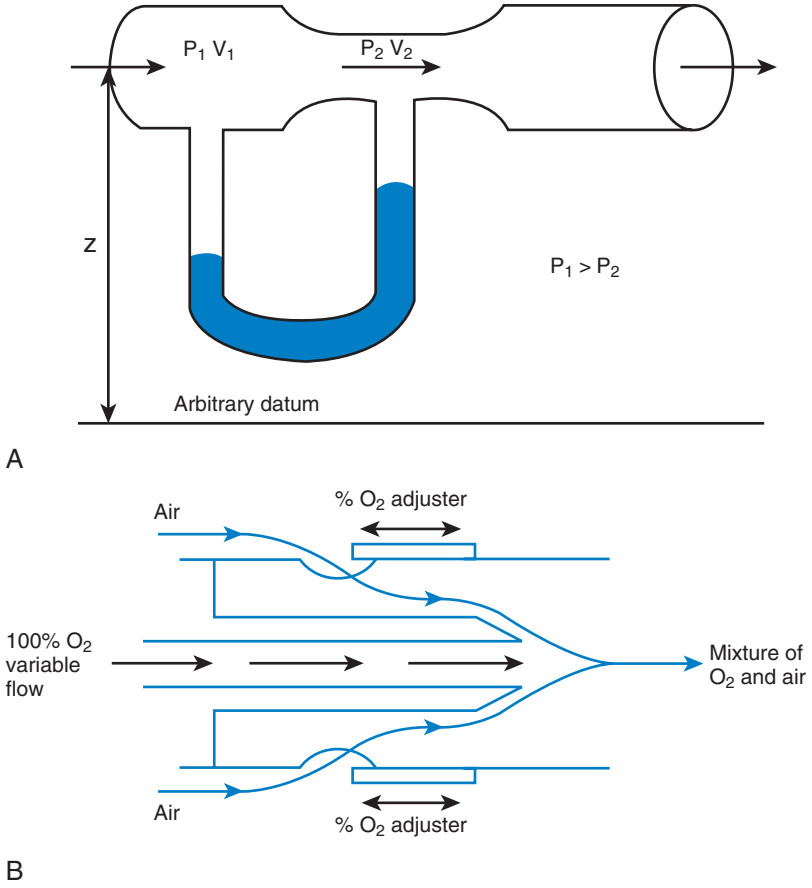

Figure 4-2 Bernoulli effect. **A,** Diagram shows fluid flow through a tube with varying diameters. At the point of flow constriction, fluid pressure is less than at the distal end of the tube, as indicated by the height of the manometer fluid column. This effect is described by the Bernoulli equation. In the case of a horizontal pipe, the distance between the centerline of the pipe and an arbitrary datum at two different points will be the same (*Z*). **B,** Venturi tube. The lower pressure caused by the Bernoulli effect entrains air to mix with oxygen. *P,* Pressure; *V,* velocity.

E. Example: Analysis of Transtracheal Jet Ventilation

Transtracheal jet ventilation (TTJV) has been used to oxygenate and ventilate patients who would otherwise perish because of a lost airway.[6] It is a temporizing measure that is used only until an airway can be secured. It is usually employed using equipment commonly available in the operating or emergency room and often using the 50-psi wall oxygen source.[6,12-14]

1. Analysis

The gas flow through a catheter depends on both the resistance of the catheter-connection hose assembly and the driving pressure applied to it. If the resistance of the assembly is R, the flow (F) from the catheter is $F = P_d/R$, where P_d is the pressure difference between the ends of the catheter-connection assembly. R itself certainly depends on F when the flow becomes turbulent, but the flow relationship still holds. However, P_d is very close to the driving pressure (P) applied to the ventilation catheter, because the lung offers little relative back pressure. (At back pressures greater than 100 cm H_2O, the lung is likely to burst, and P is often chosen to be 50 psi, or about 3500 cm H_2O.) Therefore, the flow relationship may be simplified to $F = P/R$.

Next, TTJV is applied through a sequence of "jet pulses," each resulting in a given tidal volume (e.g., 500 mL). Ignoring entrained air effects, the delivered tidal volume is equal to catheter flow × pulse duration. For a catheter flow of 30 L/min, a jet pulse lasting 1 second results in a tidal volume of 30 L/min × $\frac{1}{16}$ min = 0.5 L.

In a TTJV setup consisting of a 14-G angiographic catheter connected to a regulated oxygen source by a 4.5-foot polyvinyl chloride (PVC) tube of $\frac{7}{32}$-inch inner diameter (ID), for oxygen flows between 10 and 60 L/min, the resistance was found to be relatively constant between 0.6 and 0.8 psi/L/min.[15]

Many systems for TTJV choose 50 psi for convenience (50 psi being the oxygen wall outlet pressure), although a regulator is very often used to permit lower pressures. However, 50 psi may not be an optimal pressure choice for TTJV. Using the preceding data, the pressure required for TTJV for a tidal volume of 500 mL can be calculated. Assuming that the setup resistance is 0.7 psi/L/min and the desired flow rate is 30 L/min, the driving pressure should be 0.7 × 30 = 21 psi.

Similar analyses can be carried out for other arrangements derived from experiments to obtain resistance data.

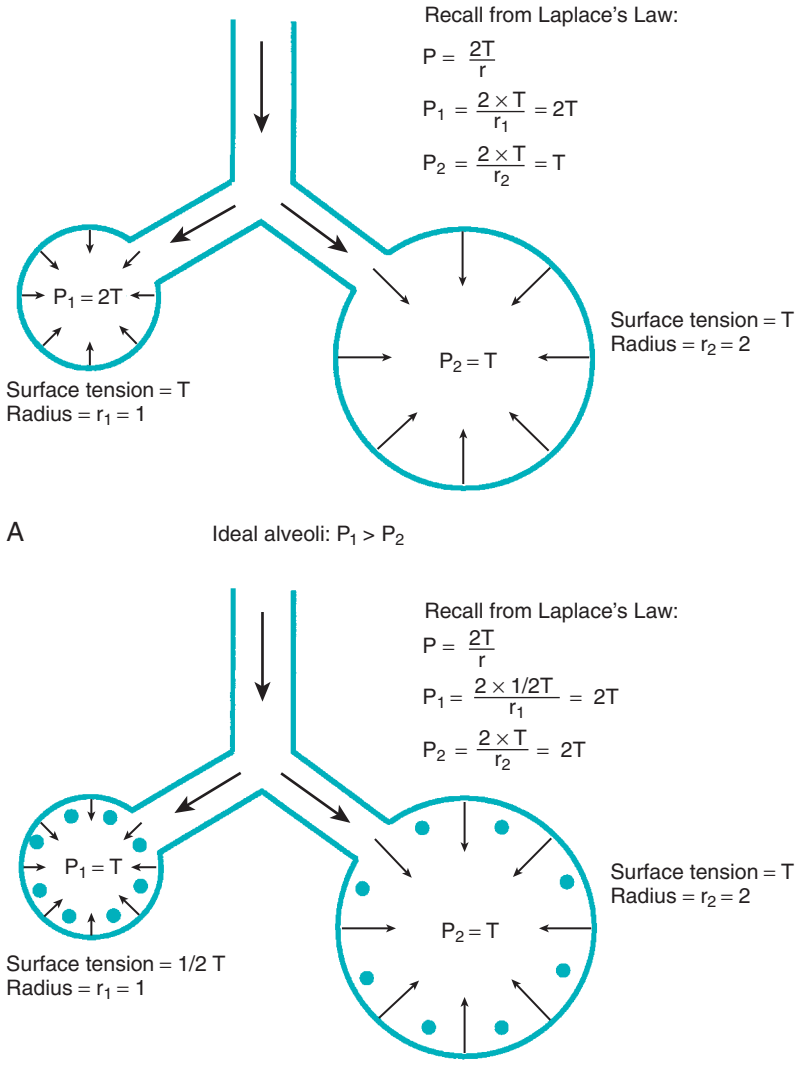

Figure 4-3 Laplace's law for a sphere. **A,** Laplace's law dictates that for two alveoli of unequal size but equal surface tension, the smaller alveolus experiences a larger intra-alveolar pressure than the larger alveolus. This causes air to pass into the larger alveolus and causes the smaller alveolus to collapse. **B,** Collapse of the smaller alveolus is prevented through the action of pulmonary surfactant. Surfactant serves to decrease alveolar surface tension in the smaller alveolus, which results in equal pressure in both alveoli. *P,* Transmural pressure difference; *r,* sphere radius.

II. GAS FLOW

A. Laminar Flow

In laminar flow, fluid particles flow along smooth paths in layers, or laminas, with one layer gliding smoothly over an adjacent layer.[7] Any tendencies toward instability and turbulence are damped out by viscous shear forces that resist the relative motion of adjacent fluid layers. Under laminar flow conditions through a tube, the flow velocity is greatest at the center of the tube flow and zero at the inner edge of the tube (Fig. 4-4; see also Fig. 4-1). The flow profile has a parabolic shape. Under these conditions in a horizontal tube, the relation between flow, tube, and gas characteristics is given by the Hagen-Poiseuille equation (Equation 5), restated as follows[7-9]:

$$\dot{V} = \frac{\pi \Delta P r^4}{8 \mu L} \quad (8)$$

where
$\dot{V}$ = flow rate (cm^3/s)
π = 3.1416
ΔP = pressure gradient (pascals)
r = tube radius (cm)
L = tube length (cm)
μ = gas viscosity (g/cm·s)

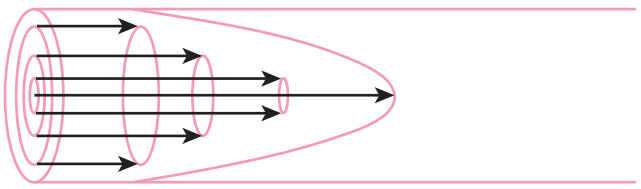

Figure 4-4 Laminar flow. Laminar gas flow through long straight tube of uniform bore has a velocity profile that is parabolic in shape, with the gas traveling most quickly at center of tube. Conceptually, it is helpful to view laminar gas flow as a series of concentric cylinders of gas, with the central cylinder moving most rapidly. (From Nunn JF: *Nunn's applied respiratory physiology,* ed 4, Stoneham, MA, 1993, Butterworth-Heinemann.)

Typical units are shown in parentheses. The dot indicates rate of change: V represents volume, and $\dot{V}$ represents the *rate of change of volume*, or *flow rate*. Another way of looking at this concept is that, under conditions of laminar flow through a tube of known radius, the pressure difference across the tube is given by the following proportionality (which is also essentially the same as Equation 5):

$$\Delta\text{Pressure} \propto \frac{\text{Flow} \times \text{Viscosity} \times \text{Length}}{\text{Radius}^4} \quad (9)$$

The pressure gradient through the airway increases proportionately with flow, viscosity, and tube length but increases exponentially as the tube radius decreases.

The conditions under which flow through a tube is predominantly laminar can be estimated from *critical flow* rates. The critical flow is the flow rate below which flow is predominantly laminar in a given airflow situation.

1. Laminar Flow Example

Assume a tube of uniform bore that is 1 cm in diameter and 3 m in length. A pressure difference of 5 cm H_2O exists between the ends of the tube, and air is the fluid flowing through the tube. Assuming laminar flow, what flow rate should be expected?

ANSWER:

The relevant variables are expressed in the centimeter-gram-second (CGS) system of units:

r = 0.5 cm
L = 3000 cm
μ = 183 micropoise = 183×10^{-6} poise = 183×10^{-6} g/(cm·s)
ΔP = 0.5 cm H_2O = 490 dynes/cm^2

Using the Hagen-Poiseuille equation, the laminar flow is determined as follows:

$$\text{Flow} = \frac{\pi \times 490 \times (0.5)^4}{8 \times 183 \times 10^{-6} \times 3000} = 219.06\ \text{cm}^3/\text{s} \quad (10)$$

B. Turbulent Flow

Flow in tubes below the critical flow rate remains mostly laminar. However, at flows greater than the critical flow rate, the flow becomes increasingly turbulent. Under turbulent flow conditions, the parabolic flow pattern is lost, and the resistance to flow increases with flow itself. Turbulence may also be created where sharp angles, changes in diameter, and branches are encountered (Fig. 4-5). The flow-pressure drop relationship is given approximately by the following equation[7,8]:

$$V \propto \sqrt{\Delta P} \quad (11)$$

where
V = mean fluid velocity (cm/s)
ΔP = pressure (pascals)

1. Reynolds Number Calculation Example

The Reynolds number (Re) represents the ratio of inertial forces to viscous forces.[7,8,16] It is useful because it characterizes the flow through a long, straight tube of uniform bore. It is a dimensionless number having the following form:

$$\text{Re} = \frac{V \times D \times \rho}{\mu} = \frac{V \times D}{\nu} = \frac{2 \times \dot{V} \times \rho}{\pi \times r \times \mu} \quad (12)$$

where
Re = Reynolds number
$\dot{V}$ = flow rate (mL/s)
ρ = density (g/mL)
μ = viscosity (poise or g/cm·s)
r = radius (cm)
ν = kinematic viscosity (cm^2/s) = μ/ρ
D = diameter (cm)
V = mean fluid velocity (cm/s)

Typical units are shown in brackets. For tubes that are long compared with their diameter (i.e., length ÷ diameter > 0.06 × Re),[8] the flow is laminar when Re is less than 2000. For shorter tubes, flow is turbulent at Re values as low as 280.

When a tube's radius exceeds its length, it is an orifice; flow through an orifice is always turbulent. Under these conditions, the flow is influenced by the density rather than the viscosity of the fluid.[17] This characteristic explains why heliox (e.g., the mixture of 70% He and

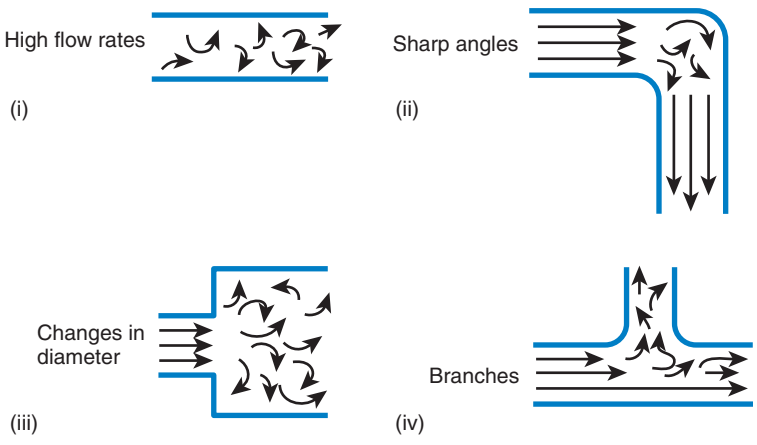

Figure 4-5 Turbulent flow. Four circumstances likely to produce turbulent flow. (From Nunn JF: *Nunn's applied respiratory physiology*, ed 4, Stoneham, MA, 1993, Butterworth-Heinemann.)

30% O_2) flows better in a narrow edematous glottis: as the following data suggest, helium has a very low density and thus presents less resistance to flow through an orifice.

	Viscosity at 20° C	Density at 20° C
Helium	194.1 micropoise	0.179 g/L
Oxygen	210.8 micropoise	1.429 g/L

How can one predict whether a given gas flow through an endotracheal tube (ETT) is laminar or turbulent? One approach is first to identify the physical conditions. For example, consider the case of an ETT with a 6-mm ID and a length of 27 cm through which 1 L/min of air is passing. In this setting,

L = 27 cm
r = 0.3 cm (size 6 mm ETT)
flow ($\dot{V}$) = 60 L/min = 1000 mL/s
viscosity (μ) = 183 micropoise = 183 × 10^{-6} g/cm·s (air at 18° C)
density (ρ) = 1.21 g/L = 0.001213 g/mL (dry air at 18° C)

With this information, one can calculate the Reynolds number:

$$\mathrm{Re} = \frac{2 \times 1000 \times 0.001213}{\pi \times 0.3 \times 183 \times 10^{-6}} = 1.41 \times 10^{4} \qquad (13)$$

Because this number greatly exceeds 2000, flow is probably quite turbulent.

C. Critical Velocity

The *critical velocity* is the point at which the transition from laminar to turbulent flow begins. This point is reached when Re becomes the critical Reynolds number, Re_{crit}. Critical velocity, the flow velocity below which flow is laminar, is calculated by the following equation[8]:

$$V_{crit} = V_c = \frac{\mathrm{Re}_{crit} \times \mathrm{Viscosity}}{\mathrm{Density} \times \mathrm{Diameter}} \qquad (14)$$

where Re_{crit} = 2000 for circular tubes.

As can be seen from this equation, the critical velocity is proportional to the viscosity of the gas and is related inversely to the density of the gas and the radius of the tube. (Viscosity has the dimensions of pascal-second (Pa × s), (equivalent to N × s/m^2, or kg/[m × s].)

The critical velocity at which turbulent flow begins depends on the ratio of viscosity to density, that is, μ/ρ. This ratio is known as the *kinematic viscosity*, υ, and has typical units of centimeters squared per second (cm^2/s). The actual measurement of viscosity of a fluid is carried out with the use of a viscometer, which consists of two rotary cylinders with the test fluid flowing between.

1. Critical Velocity Calculation Example

Using the same data as in the previous Reynolds number calculation, one can calculate the critical velocity at which laminar flow starts to become turbulent:

$$V_c = \frac{(2000) \times (183 \times 10^{-6}\ \mathrm{poise})}{(0.001213\ \mathrm{g/cm^3}) \times (2 \times 0.3\ \mathrm{cm})}$$
$$V_c = 502.8 \frac{\mathrm{poise}}{(\mathrm{g/cm^3}) \times \mathrm{cm}} = 502.8 \frac{\mathrm{cm}}{\mathrm{s}} \qquad (15)$$

D. Flow Through an Orifice

Flow through an orifice (defined as flow through a tube whose length is smaller than its radius) is always somewhat turbulent.[17] Clinically, airway-obstructing conditions such as epiglottitis or swallowed obstructions are often best viewed as breathing through an orifice (Fig. 4-6). Under such conditions, the approximate flow across the orifice varies inversely with the square root of the gas density:

$$\dot{V} \propto \frac{1}{\sqrt{\mathrm{Gas\ density}}} \qquad (16)$$

This is in contrast to laminar flow conditions, in which gas flow varies inversely with gas viscosity. The viscosity values for helium and oxygen are similar, but their densities are very different (Table 4-1). Table 4-2 provides useful data to allow comparison of gas flow rates through an orifice.[18]

1. Helium-Oxygen Mixtures

The low density of helium allows it to play a significant clinical role in the management of some forms of airway obstruction.[19-22] For instance, Rudow and colleagues described the use of helium-oxygen (heliox) mixtures in a patient with severe airway obstruction related to a large thyroid mass (see next section for clinical examples).[18]

The available percentage mixtures of helium and oxygen are typically 80:20 and 70:30. These mixtures are usually administered by a rebreathing face mask to patients who have an increased work of breathing due to airway pathology (e.g., edema) but for whom it is preferable to withhold endotracheal intubation at present.

Although the use of heliox mixtures in patients with upper airway obstruction has met with considerable success, the hope that this approach would also work well for patients with severe asthma has not been borne out. In a systematic review of seven clinical trials involving 392 patients with acute asthma, the authors cautioned that "existing evidence does not provide support for the

TABLE 4-1
Viscosity and Density Differences of Anesthetic Gases

	Viscosity at 300 K	Density at 20° C
Air	18.6 μPa × s	1.293 g/L
Nitrogen	17.9 μPa × s	1.250 g/L
Nitrous oxide	15.0 μPa × s	1.965 g/L
Helium	20.0 μPa × s	0.178 g/L
Oxygen	20.8 μPa × s	1.429 g/L

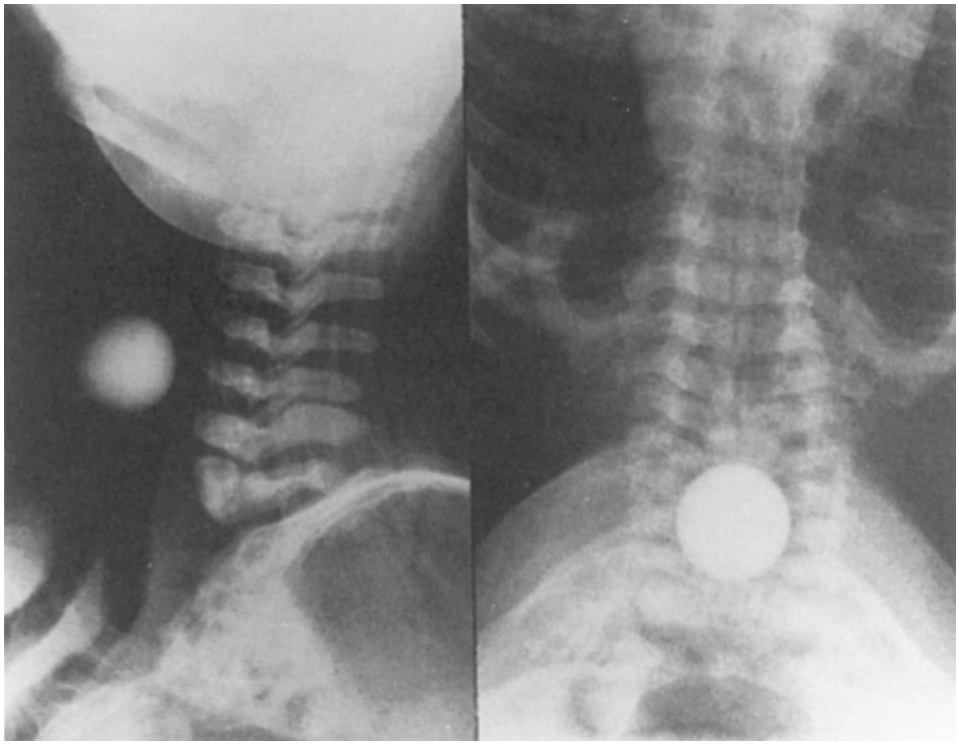

Figure 4-6 Airway obstruction. Anterior-posterior and lateral radiographs of 18-month-old infant who had swallowed a marble. The presence of this esophageal foreign body caused acute airway obstruction from extrinsic compression of the trachea. (From Badgwell JM, McLeod ME, Friedberg J: Airway obstruction in infants and children. *Can J Anaesth* 34:90, 1987.)

administration of helium-oxygen mixtures to emergency department patients with moderate-to-severe acute asthma."[23] A similar study noted that "heliox may offer mild-to-moderate benefits in patients with acute asthma within the first hour of use, but its advantages become less apparent beyond 1 hour, as most conventionally treated patients improve to similar levels, with or without it"; however, the authors suggested that its effect "may be more pronounced in more severe cases." They concluded that "there are insufficient data on whether heliox can avert endotracheal intubation, or change intensive care and hospital admission rates and duration, or mortality."[24]

2. Clinical Vignettes

Rudow and colleagues reported the following clinical illustration of heliox therapy.[18] A 78-year-old woman with both breast cancer and ophthalmic melanoma developed airway obstruction from a thyroid carcinoma that extended into her mediastinum and compressed her trachea. She had a 2-month history of worsening dyspnea, especially when positioned supine. On examination, inspiratory and expiratory stridor was present. The chest radiograph showed a large superior mediastinal mass and pulmonary metastases. A solid mass was identified on a thyroid ultrasound scan. Computed tomography revealed a large mass at the thoracic inlet and extending caudally. Clinically, the patient was exhausted and in respiratory distress.

A 78:22 heliox mixture was administered and provided almost instant relief, with improvements in measured tidal volume and oxygenation. Later, a thyroidectomy was carried out to alleviate the obstruction. For this procedure, topical anesthesia was applied to the airway and awake laryngoscopy and intubation were performed with the patient in the sitting position. After the airway was secured with the use of an armored tube, the patient was given a general anesthetic by intravenous induction.

TABLE 4-2

Gas Flow Rates Through an Orifice

	%	Density (g/L)	$(\text{Density})^{-1/2}$	Relative Flow
Air	100	1.293	0.881	1.0
Oxygen	100	1.429	0.846	0.96
Helium (He)	100	0.179	2.364	2.68
He-oxygen	20/80	1.178	0.922	1.048
He-oxygen	60/40	0.678	1.215	1.381
He-oxygen	80/20	0.429	1.527	1.73

From Rudow M, Hill AB, Thompson NW, et al: Helium-oxygen mixtures in airway obstruction due to thyroid carcinoma. *Can Anaesth Soc J* 33:498, 1986.

Extubation after the surgery was performed without complication.

Another interesting clinical scenario was published by Khanlou and Eiger.[25] They presented the case of a 69-year-old woman in whom bilateral vocal cord paralysis developed after radiation therapy. Heliox was successfully used for temporary management of the resultant upper airway obstruction until the patient was able to receive a tracheostomy.

A final clinical vignette was reported by Polaner,[26] who used the laryngeal mask airway and an 80:20 heliox mixture to administer anesthesia to a 3-year-old boy with asthma and a large anterior mediastinal mass. Clinical management involved an unusual combination of management strategies: the child was kept in the sitting position, spontaneous ventilation with a halothane-in-heliox inhalation induction was used, and airway stimulation was minimized by use of the laryngeal mask airway. However, the author cautioned that cases such as these can readily take a deadly turn, noting that "one must, of course, always be prepared to intervene with either manipulations of patient position in the event of airway compromise (including upright, lateral, and prone) or more aggressive strategies, such as rigid bronchoscopy and even median sternotomy (in the case of intractable cardiovascular collapse), or to allow the patient to awaken if critical airway or cardiovascular compromise becomes evident at any time during the course of the anesthesia."[26]

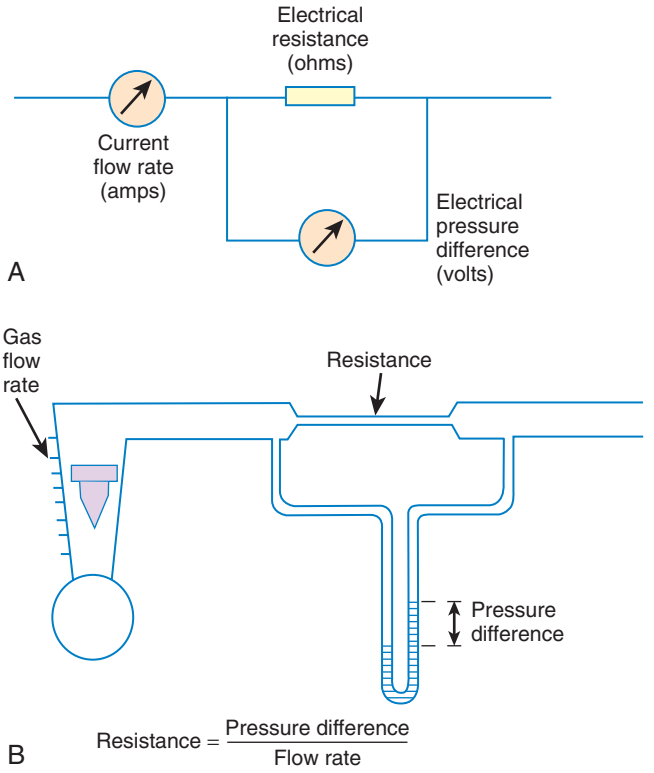

Figure 4-7 Analogy between laminar gas flow and flow of electricity through a resistor. **A,** Electrical flow rate (current) is measured in amperes; pressure difference (voltage) is measured in volts; resistance is measured in ohms and described by Ohm's law. **B,** Gas flow rate is measured as volume/second (e.g., mL/s); pressure difference is measured as force/area (e.g., dynes/cm^2); resistance is described by Poiseuille's law. For gases, pressure difference = flow rate × resistance; for electricity, potential difference (voltage) = current × resistance. (From Nunn JF: *Nunn's applied respiratory physiology*, ed 4, Stoneham, MA, 1993, Butterworth-Heinemann.)

E. Pressure Differences

From the analysis of equations governing laminar flow and turbulent flow, the pressure drop along the noncompliant portion of the airway is given approximately by the Rohrer equation[27]:

$$\Delta P = K_1\dot{V} + K_2\dot{V}^2 \qquad (17)$$

K_1 and K_2 are known as Rohrer constants. The physical interpretation of this equation is that airway pressure is governed by the sum of two terms:

1. Effects proportional to gas flow (laminar flow effects)
2. Effects proportional to the square of the gas flow (turbulent flow effects)

It can be seen that the lowest pressure loss across the airway (ΔP) would occur when $\dot{V}$ is small (i.e., with predominantly laminar flow). However, it is known that under conditions of laminar flow, K_1 is largely influenced by viscosity rather than density, and K_2 (the turbulent term) is influenced primarily by density and not viscosity.

F. Resistance to Gas Flow

When pressure readings are taken at each end of a horizontal tube with a fluid flowing through it, one notices that they are not identical: The pressure at the distal end of the tube is less than the pressure at the proximal end (with fluid flowing from the proximal to the distal end). This pressure loss is attributable to frictional losses incurred by the fluid when in contact with the inside of the tube. This is analogous to heat losses incurred by resistors in an electrical circuit (Fig. 4-7).

Frictional losses are irreversible; that is, the energy lost cannot be recovered by the fluid and is mostly lost as heat. If the tube is not horizontal, there are additional pressure differences attributable to height differences. The most common relation that describes the flow in a tube is the Bernoulli equation, which is valid for both laminar and turbulent flow[8]:

$$\frac{V_1^2}{2g} + \frac{P_1}{\rho g} + Z_1 = \frac{V_2^2}{2g} + \frac{P_2}{\rho g} + Z_2 + h_f \qquad (18)$$

where
V = velocity (m/s)
g = gravitational constant (9.81 m/s^2 or 9.81 N/kg)
P = pressure (pascals or N/m^2)
ρ = density of fluid (kg/m^3)
Z = height from an arbitrary point (datum) (m)
h_f = frictional losses (m)

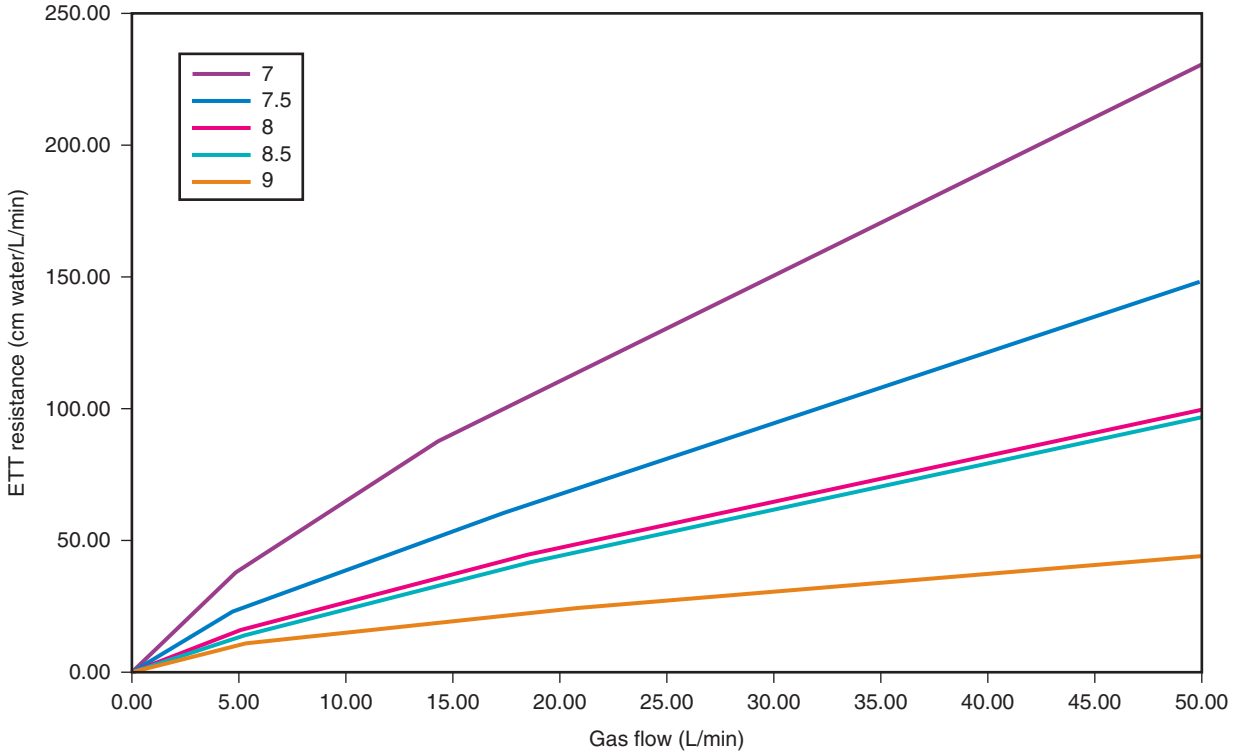

Figure 4-8 Dependence of endotracheal tube (ETT) on flow. The data provided by Hicks in Table 4-3 can be used to show that ETT resistance increases nonlinearly with flow (because of turbulence effects). For pure laminar flow, resistance would be constant, regardless of flow.

Typical units are shown in square brackets. Equation 18 is in units of meters and is termed "meters of head loss." This is typical of fluid mechanics equations. As mentioned previously, the Bernoulli equation is valid for both laminar and turbulent flow.

1. Endotracheal Tube Resistance

ETTs, like all tubes, offer resistance to fluid flow (Fig. 4-8). However, ETTs do not add external resistance to the normal airway; rather, they act as a substitute for the normal resistance of the airway from the mouth to the trachea, which accounts for 30% to 40% of normal airway resistance.[28] This is important because, although mechanical ventilators can overcome impedance to inspiratory flow during extended periods of artificial respiration, they do not augment passive exhalation. Resistance to exhalation through a long, small-diameter ETT, which is compounded by turbulence, can seriously constrain ventilation rate and tidal volume.[29,30]

The use of the ETT influences respiration in a number of ways. First, it decreases effective airway diameter and therefore increases the resistance to breathing. Resistance is further increased by the curved nature of the tube; resistance measurements are typically about 3% higher than if the tubes were straight.[31] Also, the passage from the mouth to the larynx is not a smooth curve and may create additional turbulence. Second, studies show that intubated patients experience decreased peak flow rates (inspiratory and expiratory), decreased forced vital capacity, and decreased forced expiratory volume in 1 second (FEV_1).[32] However, the tube may paradoxically increase peak flow rates during forced expiration by preventing dynamic compression of the trachea.[32] Finally, the tube may cause mechanical irritation of the larynx and trachea that may lead to a reflex constriction of the airway distal to the tube.[33]

The combination of tube and connector may cause higher resistance than the tube alone. Moreover, because of turbulence at component connections, the total resistance of a system is not necessarily the sum of the resistances of its component parts, especially if sharp-angled connectors are used (see Fig. 4-5).[25,34] In addition, humidified gases contribute to slightly higher resistances because of the increased density of moist gas, and the resistance of single-lumen tubes is generally lower than that of double-lumen tubes.[35]

The resistance associated with ETTs may be reduced by increasing the tube diameter, decreasing tube length, or decreasing the gas density (hence, the occasional use of heliox mixtures). It has been suggested that the presence of an ETT may double the work of breathing in chronically intubated adults and may lead to respiratory failure in some infants.[31] Therefore, it is important to use as large an ETT as is practical in patients who exhibit respiratory dysfunction.

ETT resistance can be measured in the laboratory using differential pressure and flow measurement techniques,[36,37] most commonly by the method of Gaensler and colleagues.[38] Theoretical estimates of resistance under laminar flow conditions can also be obtained by using the Poiseuille equation. In vivo measurements of ETT resistance are generally higher than in vitro measurements, perhaps because of secretions, head or neck position, tube deformation, or increased turbulence.[10,39]

Airway resistance may be established from first principles using Poiseuille's law if the gas flow is laminar. If gas flow is turbulent, resistance is no longer independent of material properties, and empirical measurements become the only feasible means of characterizing resistance. Intrinsic airway resistance is determined by measuring the transairway pressure—that is, the pressure drop between the airway opening and the alveoli. The following relationship applies[40]:

$$R = \frac{P_{airway} - P_{alveolar}}{\dot{V}} \quad (19)$$

where
R = airway resistance (cm H_2O/L/s)
P_{airway} = proximal airway pressure (cm H_2O)
$P_{alveolar}$ = alveolar pressure (cm H_2O)
$\dot{V}$ = gas flow rate (L/s)

Typical units used are shown in parentheses.

In clinical practice, airway resistance is most easily determined by using a whole-body plethysmograph. However, this apparatus is unsuitable for critically ill patients. An alternative method of presenting airway resistance was provided by Hicks,[40] who used the following equation and constants:

$$\Delta P = a\dot{V}^b \quad (20)$$

where
ΔP = pressure difference (cm H_2O)
$\dot{V}$ = gas flow (L/min)
a and b = empirical constants

The values for the coefficients *a* and *b* depend on tube size and are provided in Table 4-3.

Figure 4-8 depicts the effects of tube diameter and flow rate on ETT resistance. Notice that resistance is increased as a result of increasing turbulence caused by decreasing ETT diameter and increasing flow rate.

Clinically, the issue of ETT resistance is perhaps most important in pediatrics and during T-piece trials. In a laboratory study, Manczur and coworkers sought to determine the resistances of ETTs commonly used in neonatal and pediatric intensive care units.[41] They examined straight tubes with IDs of 2.5 to 6 mm and shouldered (Cole) tubes with ratios of ID to outer diameter ranging from 2.5/4 to 3.5/5 mm. Predictably, they found that resistance increased as ETT diameter decreased. The resistances of the 6-mm ID ETTs were 3.1 and 4.6 cm H_2O/L/s at flows of 5 and 10 L/min, respectively, and the resistances of the 2.5-mm ID ETT were 81.2 and 139.4 cm H_2O/L/s, respectively. The authors reported that shortening an ETT to a length appropriate for the patient (e.g., shortening a 4.0-mm ID ETT from 20.7 to 11.3 cm) reduced resistance on average by 22%. They also noted that the resistance of a Cole tube was "about 50% lower than that of a straight tube with an ID corresponding to the narrow part of the shouldered tube."

Using an acoustic reflection research method, Straus and associates sought to study the influence of ETT resistance during T-piece trials by comparing the work of breathing in 14 successfully extubated patients at the end of a 2-hour trial and after extubation.[42] They found that work of breathing was identical in both groups and there was no significant difference between the beginning and the end of the T-piece trial. The work caused by the ETT amounted to about 11.0% of the total work of breathing, and the supralaryngeal airway resistance was significantly smaller than the ETT resistance. The authors concluded that "a 2 hr trial of spontaneous breathing through an ETT well mimics the work of breathing performed after extubation, in patients who pass a weaning trial and do not require reintubation."

TABLE 4-3
Coefficients for Airway Resistance Computations

Tube	a	b
7.0	9.78	1.81
7.5	7.73	1.75
8.0	5.90	1.72
8.5	4.61	1.78
9.0	3.90	1.63

III. WORK OF BREATHING

Breathing comprises a two-part cycle: inspiration and expiration. During normal breathing, inspiration is an active, energy-consuming process, and expiration is ordinarily a passive process in which the diaphragm and intercostal muscles relax (Figs. 4-9 and 4-10). However, expiration becomes an active process during forced expiration, such as during exercise or during expiration against a resistance load. Several studies have examined the work of breathing in various clinical settings.[43-48]

Considering only normal breathing, the work of breathing is given by the following formulas:

Work = force × distance
Force = pressure × area
Distance = volume ÷ area
Work = (pressure × area) × (volume/area) × pressure × volume

Because the air pressure in the lung varies with lung volume and pressure measurements are obtained distal to the end of the ETT, work may be expressed as follows[49]:

$$WORK_{INSPIRATION} = \int_{FRC}^{FRC+TV} P\,dV \quad (21)$$

where
P = airway pressure (cm H_2O)
dV = (infinitesimal) volume of gas added to the lung (mL)
FRC = functional residual capacity of the lungs (mL)
TV = tidal volume breathed in during respiration (mL)

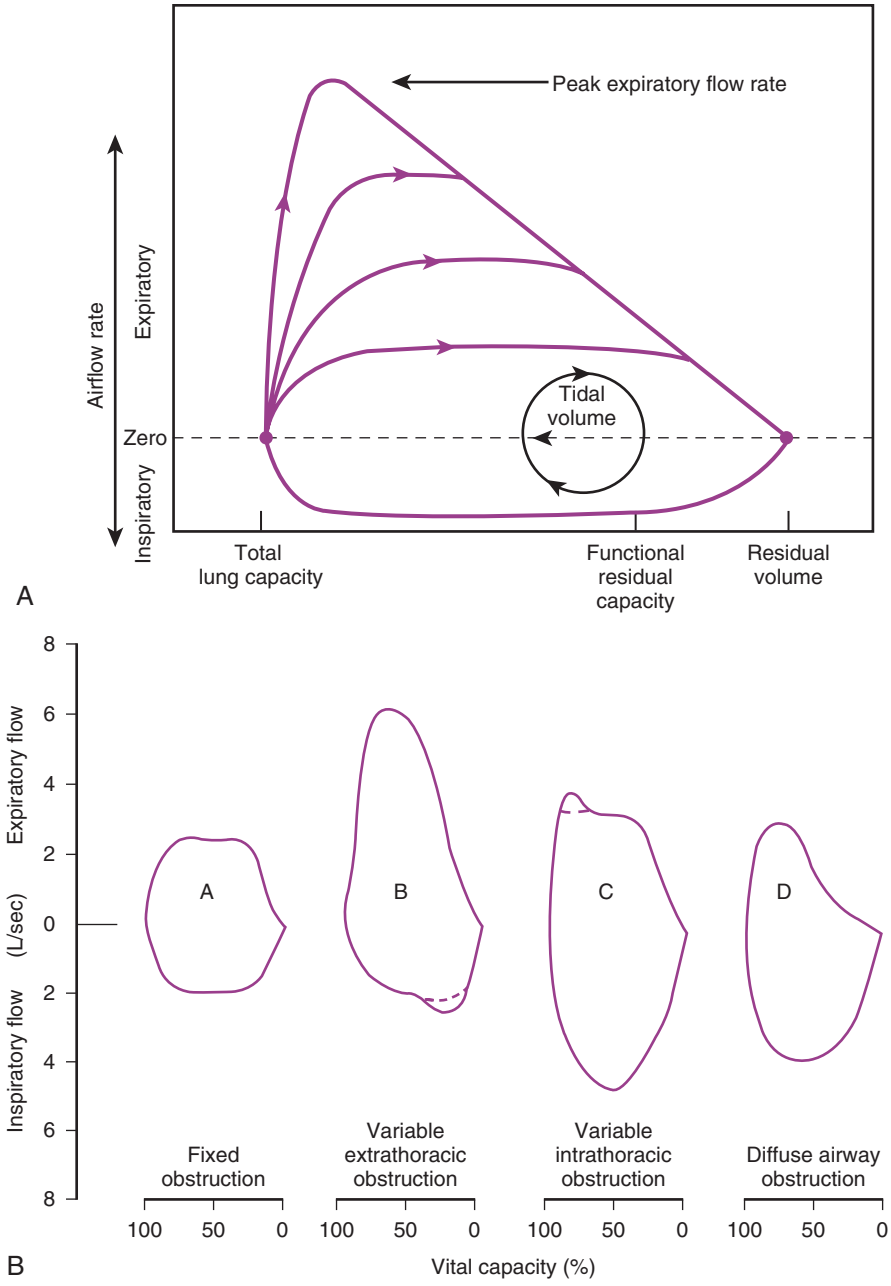

Figure 4-9 Flow-volume curves. **A,** A flow-volume curve consists of a plot of gas flow against lung volume. Four loops are shown, corresponding to four different levels of expiratory effort. Peak expiratory flow is effort dependent, but toward the end of expiration the curves converge (as flow is limited by dynamic airway collapse). From a diagnostic viewpoint, the expiratory portion of the loop is of more value than the inspiratory portion. **B,** Maximum inspiratory and expiratory flow-volume curves (flow-volume loops) in four types of airway obstruction. (**A,** From Nunn JF: *Nunn's applied respiratory physiology*, ed 4, Stoneham, MA, 1993, Butterworth-Heinemann; **B,** from Gal TJ: *Anesthesia*, ed 2, New York, 1986, Churchill Livingstone.)

When the pressure varies as a function of time, Equation 21 may be integrated in the following manner:

$$\text{LET } dV = \frac{dV}{dt} \times dt = \dot{V}\, dt \qquad (22)$$

Changing the limits of integration yields the following:

$$\text{WORK}_{\text{INSPIRATION}} = \int_{t_1}^{t_2} P(t)\, \dot{V}(t)\, dt \qquad (23)$$

where
t_1 = time at the beginning of inspiration (s)
t_2 = time at the end of inspiration (s)
P = pressure measured at a point of interest in the airway (e.g., at the tip of the ETT or at the carina) (cm H_2O)
$\dot{V}$ = flow (mL/s)

The preceding equation is cumbersome to integrate quickly. However, it is sometimes reasonable to assume that the pressure during inspiration remains fairly constant. Under these circumstances, integration of the original work equation during constant-pressure inspiration yields the following approximation:

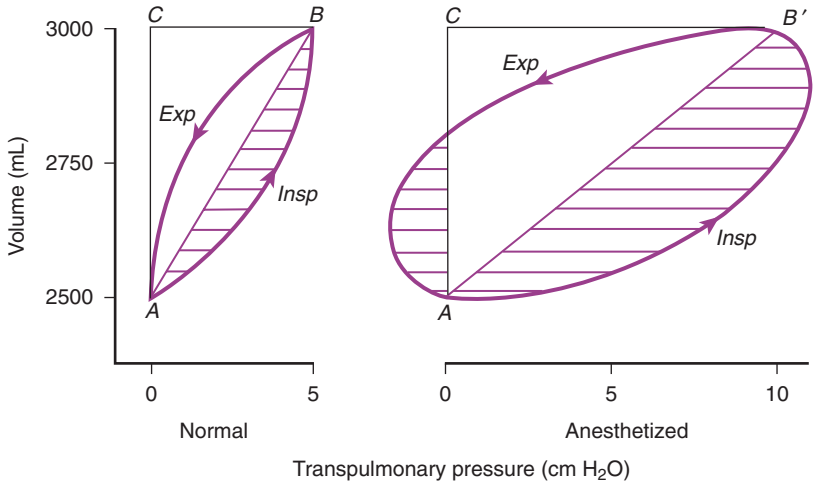

Figure 4-10 Work of breathing. Lung volume is plotted against transpulmonary pressure in a pressure-volume diagram for an awake ("Normal") patient and an anesthetized patient. The total area within the oval and triangles has the dimensions of pressure multiplied by volume and represents the total work of breathing. The hatched area to the right of lines *AB* and *AB′* represents the active inspiratory work necessary to overcome resistance to airflow during inspiration (*Insp*). The hatched area to the left of the triangle *AB′C* represents the active expiratory work necessary to overcome resistance to airflow during expiration (*Exp*) in the anesthetized subject. Expiration is passive in the normal subject because sufficient potential energy is stored during inspiration to produce expiratory airflow. The fraction of total inspiratory work necessary to overcome elastic resistance is shown by triangles *ABC* and *AB′C*. The anesthetized patient has decreased compliance and increased elastic resistance work (triangle *AB′C*) compared with the normal patient's compliance and elastic resistance work (triangle *ABC*). The anesthetized patient shown has increased airway resistance to both inspiratory and expiratory work. (From Benumof JL: *Anesthesia*, ed 2, New York, 1986, Churchill Livingstone.)

$$\text{WORK}_{\text{INSPIRATION}} = P_{AVE} \times TV \quad (24)$$

where
P_{AVE} = mean airway pressure during inspiration (cm H_2O)
TV = tidal volume of inspiration (mL)

During anesthesia, an ETT is often inserted, and additional energy is required to overcome the friction effects of the ETT. The added work of breathing presented by an ETT is given by the following equation:

$$\text{WORK}_{\text{ETT}} = \int_{\text{FRC}}^{\text{FRC+TV}} \Delta P \, dV \quad (25)$$

where ΔP is the pressure drop across the tube.

Often, the pressure gradient ΔP is relatively constant during inspiration, and therefore:

$$\text{WORK}_{\text{ETT}} = \Delta P \int_{\text{FRC}}^{\text{FRC+TV}} dV = \Delta P \times \Delta V \quad (26)$$

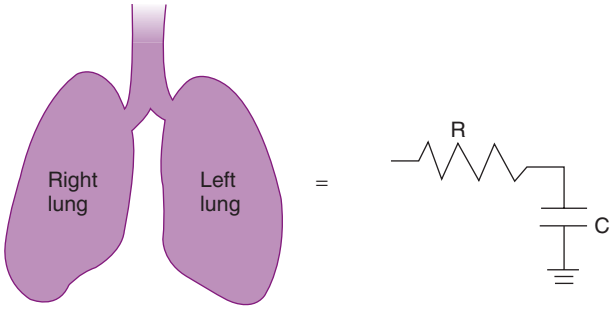
where
ΔP = pressure drop across ETT during inspiration (mm Hg)
ΔV = volume added to lungs = tidal volume (mL)

The total work done, measured in joules ($kg \times m^2/s^2$), is as follows:

$$\text{WORK}_{\text{TOTAL}} = \text{WORK}_{\text{ETT}} + \text{WORK}_{\text{INSPIRATION}} \quad (27)$$

IV. PULMONARY BIOMECHANICS

A. The Respiratory Mechanics Equation



Approximately 3% of the body's total energy is required to maintain normal respiratory function.[11] Energy is required to overcome three main forces: (1) the elastic resistance of the lungs, which restores the lungs to their original size after inflation; (2) the force required to move the rib cage, diaphragm, and appropriate visceral contents; and (3) the dissipative resistance of the airway and any breathing apparatus.[50] The respiratory system is commonly modeled as the frictional airway R_L that is in series with the lung compliance C_L. Such a model is analogous to a resistor and capacitor in series that form a resistive-capacitive (R_C) circuit (Fig. 4-11).

A transmural (P_{TM}) pressure gradient exists between the airway at the mouth (i.e., at atmospheric pressure) and the pressure inside the pleural cavity. This pressure gradient is responsible for the lungs' "hugging" the thoracic cavity as the chest enlarges during inspiration. The presence of an external breathing apparatus causes a further pressure loss (P_{EXT}). The total pressure drop between the atmosphere and the pleural cavity is given by the respiratory mechanics equation and may be modeled as follows[50]:

$$P_{TOTAL} = P_{EXT} + P_{TM} = R_{EXT}\dot{V} + \frac{V}{C_L} + R_L\dot{V} \quad (28)$$

$$P_{EXT} = R_{EXT}\dot{V} \quad (29)$$

$$P_{TM} = \frac{V}{C_L} + R_L\dot{V} \quad (30)$$

$$R = \text{Resistance} = \frac{\text{Pressure change}}{\text{Flow rate}}$$

$$C = \text{Compliance} = \frac{\text{Volume change}}{\text{Pressure change}}$$

Figure 4-11 Resistance-compliance (RC) model of the lungs. Resistance of lungs to airflow and natural ability to resist stretch (compliance) enable lungs to be modeled as an electrical circuit. A resistor of resistance R placed in series with a capacitor of capacitance C is a simple and convenient analogy on which to base pulmonary biomechanics.

where
P_{TOTAL} = pressure drop between atmosphere and pleural cavity
P_{EXT} = pressure drop across external breathing apparatus
P_{TM} = transmural pressure gradient
R_{EXT} = external apparatus resistance (e.g., an ETT)
$\dot{V} = dV/dt$ = gas flow rate into the lungs
C_L = lung compliance
R_L = airway resistance
V = volume of gas above the functional residual capacity (FRC) in the lungs

Thus, the pressure required to inflate the lungs depends on both lung compliance and gas flow rate. The time required to inflate the lungs is measured in terms of a pulmonary time constant. This time constant (t) is simply the product $R_L \times C_L$. However, determination of the time constant is not a trivial matter, and attention is now turned to that determination.

1. The Pulmonary Time Constant

Using the previous formula (Equation 29) in the case that no external resistance exists, one can show that, during passive expiration, the volume in the lungs in excess of FRC takes on the following form[51]:

$$V = V_0 e^{-t/\tau} \tag{31}$$

where V_0 is the volume taken in during inspiration and $\tau = R_L C_L$ is the time constant for the lungs.

Flow from the lungs is obtained by differentiating this equation with respect to time:

$$\dot{V} = \frac{dV}{dt} = V_0 \frac{d(e^{-t/\tau})}{dt} = V_0 e^{-t/\tau}\left(-\frac{1}{\tau}\right) = -\frac{V_0}{\tau} e^{-t/\tau} \tag{32}$$

Tau (τ) may be now estimated by dividing the preceding equation by the first one:

$$\frac{\dot{V}}{V} = \frac{V_0 e^{-t/\tau}\left(-\frac{1}{\tau}\right)}{V_0 e^{-t/\tau}} = -\frac{1}{\tau} \tag{33}$$

Therefore, τ can be estimated as the negative of the reciprocal of the average slope of the plot of flow ($\dot{V}$) against volume (V) during expiration. Another means of estimating τ is by taking the natural logarithm of the volume equation $V = V_0 e^{-t/\tau}$.

The value of τ can also be estimated as the negative of reciprocal of the average slope of the natural logarithm of the lung volume plotted against time.

$$\ln V = \ln(V_0) - \frac{t}{\tau} = \frac{d(\ln V)}{dt} = -\frac{1}{\tau} \tag{34}$$

2. Determination of Rohrer's Constants

A more complete approach to modeling the pressure-flow relationship of the respiratory system assumes that a single time constant τ may be inadequate to describe pulmonary biomechanics in some situations. The classical form of the equation,[27]

$$\frac{V}{\dot{V}} = -\tau = C_L \times R_L \tag{35}$$

can be changed to a more elaborate form of:

$$\frac{V}{\dot{V}} = -C_L(K_1 + K_2\dot{V}) \tag{36}$$

where K_1 and K_2 are known as Rohrer's constants and $(K_1 + K_2)$ is a form of R_L.

In this situation, the resistance of the pulmonary system is not assumed to be constant; rather, it is assumed to be flow dependent:

$$R = K_1 + K_2\dot{V} \tag{37}$$

When this equation is expressed in the following form,

$$\frac{V}{C_L\dot{V}} = -(K_1 + K_2\dot{V}) \tag{38}$$

K_1 and K_2 may be determined as the intercept and slope, respectively, of a plot of $V/C_L\dot{V}$ against $\dot{V}$.

3. Compliance

Pulmonary compliance measurements reflect the elastic properties of the lungs and thorax and are influenced by factors such as degree of muscular tension, degree of interstitial lung water, degree of pulmonary fibrosis, degree of lung inflation, and alveolar surface tension.[52] Total respiratory system compliance is given by the following calculation[40]:

$$C = \frac{\Delta V}{\Delta P} \tag{39}$$

where
ΔV = change in lung volume
ΔP = change in airway pressure

This total compliance may be related to lung compliance and thoracic (chest wall) compliance by the following relation:

$$\frac{1}{C_T} = \frac{1}{C_L} + \frac{1}{C_{Th}} \quad (40)$$

where
C_T = total compliance (e.g., 100 mL/cm H_2O)
C_L = lung compliance (e.g., 200 mL/cm H_2O)
C_{Th} = thoracic compliance (e.g., 200 mL/cm H_2O)

The values shown in parentheses are some typical normal adult values that can be used for modeling purposes.[40] *Elastance*, the reciprocal of compliance, offers notational advantage over compliance in some physiologic problems. However, its use has not been popular in clinical practice.

Compliance may be estimated using the pulmonary time constant, τ. If a linear resistance of known value (ΔR) is added to the patient's airway, the time constant will change to τ', as follows[27]:

$$\tau' = (R_L + \Delta R) \times C_L = \tau + (C_L \times \Delta R) = \tau + \Delta\tau \quad (41)$$

Therefore, if ΔR is known and τ and τ' are determined experimentally, one can solve for C_L and then for R_L:

$$C_L = \frac{\tau' - \tau}{\Delta R} = \frac{\Delta\tau}{\Delta R} \qquad R_L = \tau \times \frac{\Delta R}{\Delta\tau} = \frac{\tau \times \Delta R}{\tau' - \tau} \quad (42)$$

B. An Advanced Formulation of the Respiratory Mechanics Equation

An alternative to the elementary respiratory mechanics equation may be used to describe the physical behavior of the lungs. The original formulation of this advanced respiratory mechanics equation was carried out by Rohrer during World War I, but the first completely correct formulation was devised by Gaensler and colleagues and has the following form[38]:

$$P = \frac{V}{C} + K_1\dot{V} + K_2\dot{V}^2 \quad (43)$$

where
P = airway pressure
V = lung volume
$\dot{V}$ = gas flow rate into (out of) lung
C = compliance of the pulmonary system
K_1 and K_2 = empirical Rohrer's constants

This equation is more advanced than the elementary respiratory mechanics equation because it is able to account for flow losses attributable to turbulence. Because turbulent flow conditions are most likely to exist during anesthesia, the $\dot{V}^2$ term is very important in accurately quantifying the pressure losses of respiration. In addition, the advanced equation combines the resistance losses into the constants K_1 and K_2, which require only empirical determination.

V. ANESTHESIA AT MODERATE ALTITUDE

The parameters that govern the administration of anesthesia are altered slightly when the elevation above sea level is increased. Generally, a change in the atmospheric (or barometric) pressure is responsible for these differences. This section briefly examines the consequences of a moderate change in altitude.

The approximate alveolar gas equation is a useful tool in quantifying the differences that occur at higher elevations[53]:

$$P_{AO_2} = P_{IO_2} - \frac{P_{aCO_2}}{R} P_{IO_2} = (P_B - 47) \times F_{IO_2} \quad (44)$$

where
P_{AO_2} = alveolar oxygen tension
P_{IO_2} = inspired oxygen tension partial pressure
P_{aCO_2} = arterial carbon dioxide tension
R = 0.8 → gas exchange coefficient (CO_2 produced/O_2 consumed)
P_B = barometric pressure (760 mm Hg at sea level)
47 = water vapor pressure at 37° C
F_{IO_2} = fraction of inspired oxygen = 0.21 at all altitudes (room air)

All tensions are in mm Hg (torr).

A. Altered Partial Pressure of Gases

The effect of altitude is very apparent on the partial pressure of administered gases. The partial pressure of oxygen is given by $P_{IO_2} = (P_B - P_{H_2O}) \times 0.21$. At 1524 m (5000 ft) above sea level, P_{IO_2} is reduced to 128 mm Hg from 158 mm Hg at sea level, so that the maximum P_{aO_2} is about 83 mm Hg (assuming P_{aCO_2} = 36).[54] At 3048 m (10,000 ft), P_{IO_2} is 111 mm Hg, and the maximum P_{aO_2} is 65 mm Hg.[54] In order to counteract the effects of the hypoxia, ventilation is increased, so that at 5000 ft P_{aCO_2} = 36 mm Hg, and at 3048 m P_{aCO_2} = 34 mm Hg on average.[54] The effectiveness of nitrous oxide (N_2O) decreases with altitude because of an absolute reduction of its partial pressure (tension).

B. Oxygen Analyzers

There are five main types of oxygen analyzers: paramagnetic analyzers, fuel cell analyzers, oxygen electrodes, mass spectrometers, and Raman spectrographs. All respond to oxygen partial pressure (not concentration) so that the output changes with barometric pressure. At 1524 m, an analyzer set to measure 21% O_2 at sea level reads 17.4%. If these devices were to calculate the amount of oxygen in terms of partial pressure, the scale readings would reflect the true state of oxygen availability, but clinical practice dictates that a percentage scale be used anyway.

C. Carbon Dioxide Analyzers and Vapor Analyzers

Absorption of infrared radiation by gas is the usual analytic method used to determine the amount of CO_2 in a gas mixture, although other methods (e.g., Raman spectrographs) also work well. This type of method measures partial pressures, not percentages. To operate accurately, these machines must either be calibrated using known CO_2 concentrations at the correct barometric pressure or have the scale converted to read partial pressures.

Similar arguments apply to modern vapor analyzers, all of which respond to partial pressures, not concentrations, despite the fact that the output of these devices, by clinical custom, is usually calculated in percentages.

D. Vapors and Vaporizers

Practically speaking, the saturated vapor pressure of a volatile agent depends only on its temperature. At a given temperature, the concentration of a given mass of vapor increases as barometric pressure decreases, but its partial pressure remains unchanged. Similarly, the output of calibrated vaporizers is altered with changes in barometric pressure. Only the concentration of the vapor changes; the partial pressure remains the same, as does the patient's response at a given setting as compared with sea level. This assumes that the vaporizer characteristics do not change with altered density and viscosity of the carrier gases.

E. Flowmeters

Most flowmeters measure the drop in pressure that occurs when a gas passes through a resistance and correlate this pressure drop with flow. The pressure drop depends on gas density and viscosity. If the resistance is an orifice, resistance depends primarily on gas density. For laminar flow through a tube, viscosity determines resistance (Hagen-Poiseuille equation). Some flowmeters employ a floating ball or bobbin supported by the stream of gas in a tapered tube. The float is fluted so that it remains in the center of the flow. At low flow, the device depends primarily on laminar flow, and as the float moves up the tube, the resistance behaves progressively more like an orifice.

The density of a gas changes, of course, with barometric pressure, but the viscosity changes little, being primarily dependent on temperature. Gas flow through an orifice is inversely proportional to the square root of gas density: As the density falls, flow increases (orifice size being constant). Therefore, at high altitude, the actual flowmeter flow is greater than that indicated by the float position:

$$\text{Actual flow} = \text{Nominal flow} \times \sqrt{\frac{760\ \text{mm Hg}}{P_B}} \tag{45}$$

F. Flowmeter Calibration

The calibration of standard flowmeters, such as the Thorpe tube, depends on gas properties. Usually, a particular flowmeter is calibrated for a particular gas, such as oxygen or air. The factor used to convert nominal flow measurements to actual flow measurements is given by the following equation[53]:

$$k = \frac{\sqrt{GMW_A}}{\sqrt{GMW_B}} \tag{46}$$

where A is the gas for which the flowmeter was originally designed, B is the gas actually used, and GMW is the gram molecular weight of the gas in question.

TABLE 4-4
Gram Molecular Weight (GMW) for Some Common and Anesthetic Gases

Name	Symbol	GMW
Hydrogen	H	1.00797
Helium	He	4.0026
Nitrogen (molecular)	N_2	28.0134
Oxygen (molecular)	O_2	31.9988
Neon	Ne	20.183
Argon	Ar	39.948
Xenon	Xe	131.30
Halothane	$CF_3CClBrH$	197
Isoflurane	$CF_2H\text{-}O\text{-}CHClCF_3$	184.5
Enflurane	$CF_2H\text{-}O\text{-}CF_2CFHCl$	184.5
Nitrous oxide	N_2O	44.013

A list of common anesthetic gases and their respective GMWs is presented in Table 4-4.

1. Example Calculation 1

Determine the actual flow rate of a 70:30 heliox mixture if it is passed through an oxygen flowmeter that reads 10 L/min.

Answer:

$$GMW_{O_2} = 32\ \text{g/mol} \tag{47}$$

$$GMW_{\text{heliox}} = 0.3(32) + 0.7(4) = 12.4\ \text{g/mol} \tag{48}$$

The actual flow rate of heliox is given by the following equation:

$$\text{Actual flow rate} = 10 \times \frac{\sqrt{GMW_{O_2}}}{\sqrt{GMW_{\text{heliox}}}} = 10 \times \frac{\sqrt{32}}{\sqrt{12.4}} = 16.1\ \text{L/min} \tag{49}$$

2. Example Calculation 2

Determine the appropriate multiplier if oxygen is passed through an airflow meter.

Answer:

$$\text{Multiplier} = \frac{\sqrt{GMW_{AIR}}}{\sqrt{GMW_{O_2}}} = \frac{\sqrt{0.21(32) + 0.79(28)}}{\sqrt{32}} = 0.95 \tag{50}$$

G. Anesthetic Implications

At 10,000 ft, a 30% O_2 mixture has the same partial pressure as a 20% O_2 mixture at sea level.[54] In addition, the reduction in partial pressure of N_2O that occurs seriously impairs the effectiveness of the agent, and its administration may be of no benefit. The concept of minimum alveolar concentration (MAC) does not apply at higher altitudes and should be replaced by the concept of minimal alveolar partial pressure (MAPP) (Table 4-5). The use of this concept would eliminate many of the problems identified earlier.

VI. ESTIMATION OF GAS RATES

A. Estimation of Carbon Dioxide Production Rate

The carbon dioxide production rate ($\dot{V}_{CO_2}$) of a patient may be estimated in the following manner. The CO_2 production rate can be described as the product of the amount of CO_2 produced per breath and the number of breaths per minute (BPM), with typical units of mL/min. Therefore, $\dot{V}_{CO_2}$ may be expressed as follows:

$$\dot{V}_{CO_2} = CO_2 \text{ produced per breath} \times BPM \quad (51)$$

$$\dot{V}_{CO_2} = V_{CO_2} \times BPM \quad (52)$$

The amount of CO_2 produced per breath is calculated as follows:

$$V_{CO_2} = \int_{t=0}^{t=t_{\text{end expiration}}} C_{CO_2}(t) \times Q(t) \times \gamma dt \quad (53)$$

where
$C_{CO_2}(t)$ = capnogram signal (mm Hg)
$Q(t)$ = gas flow rate signal (mL/min)
γ = scaling factor to switch dimensions from mm Hg to concentration % = 100% ÷ 760 mm Hg = 0.1312

B. Estimation of Oxygen Consumption Rate

The oxygen consumption rate may be estimated similarly to $\dot{V}_{CO_2}$. The oxygen consumption rate can be expressed as the product of oxygen consumed per breath and the number of breaths per minute. Mathematically, this may be written as follows:

$$\dot{V}_{O_2} = O_2 \text{ consumed per breath} \times \text{number of breaths per minute} \quad (54)$$

$$\dot{V}_{O_2} = V_{O_2} \times BPM \quad (55)$$

The amount of O_2 consumed per breath can now be expressed as follows:

$$V_{O_2} = \int_{t=0}^{t=t_{\text{end expiration}}} (P_{IO_2} - C_{O_2}) \times Q(t) \times \gamma dt \quad (56)$$

where
P_{IO_2} = inspiratory oxygen pressure = $(P_B - 47) \times F_{IO_2}$ (mm Hg)
C_{O_2}= oxygen signal (mm Hg)
$Q(t)$ = gas flow rate signal (mL/min)
γ = scaling factor = 0.1312

C. Interpretation of Carbon Dioxide Production and Oxygen Consumption Rates

The rates $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are linked by the respiratory exchange coefficient RQ ($RQ = \dot{V}_{CO_2}/\dot{V}_{O_2}$), which is governed largely by diet; some diets produce less CO_2 than others and have a smaller RQ). Typically, RQ = 0.8. $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ both go up with increases in metabolism, which may be related to factors such as fever, sepsis, light anesthesia, shivering, malignant hyperthermia, and thyroid storm. Decreases in $\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ may also have many causes (e.g., hypothermia, deep anesthesia, hypothyroidism).

VII. MATHEMATICAL MODELING RELATED TO THE AIRWAY

A. Overview

In this section, the role of "ready-to-use" numeric analysis software for physiologic model building is discussed, using the respiratory system as a basis for discussion. This software is based on well-established physiologic principles, and it allows some "what if" physiologic questions

TABLE 4-5
Minimum Alveolar Concentration (MAC) at Various Altitude Levels and Comparative Values for Minimal Alveolar Partial Pressure (MAPP)

	MAC (%)			MAPP	
Agent	*Sea Level*	*5000 ft*	*10,000 ft*	*(kPa)*	*(mm Hg)*
Nitrous oxide	105.0	126.5	152.2	106.1	798.0
Ethyl ether	1.92	2.31	2.78	1.94	14.6
Halothane	0.75	0.90	1.09	0.76	5.7
Enflurane	1.68	2.02	2.43	1.70	12.8
Isoflurane	1.2	1.45	1.73	1.22	9.1

MAPP = MAC × 0.01 × 760 mm Hg.

to be answered that could not have been answered in the past due to experimental complexity or ethical considerations. Because the model is based on simple equations accepted by the physiology community, the results obtained are directly credible, and many of the difficulties of direct experimentation are avoided.

The model concept is explored through a discussion of four oxygen transport problems, some of which are too complex in experimental design for empirical study to be practical. However, considerable insight can be obtained using numerical methods alone.

B. Background

Some physiologic systems are especially well suited to physiologic modeling. For example, physiologic modeling of the cardiopulmonary system may be performed to examine issues such as the determinants of pulmonary gas exchange. For instance, both Doyle and Viale and their coauthors have written custom software to explore the determinants of the arterial-alveolar oxygen tension ratio, and Torda has explored the determinants of the alveolar-arterial oxygen tension difference in a similar manner.[55-57] Before the common use of digital computers, graphic techniques were sometimes used for solving respiratory physiologic models. A well-known example is the early work by Kelman and colleagues on the influence of cardiac output (CO) on arterial oxygenation.[58] Central to the construction of such a mathematical model is the existence of a number of equations relating physiologic parameters. Examples of physiologic relationships in the respiratory system that are well described by equations include (1) the alveolar gas equation,[53,59] (2) the pulmonary shunt equation,[60] (3) the blood oxygen content equation,[60] and (4) various equations describing the oxyhemoglobin dissociation curve.[61-65]

C. Problems in Model Solving

Although many physiologic problems are readily solved by direct analytic methods, frequently their solution is hampered by nonlinearities, self-referencing (circular) equations, or other complexities. (An example of a nonlinearity is the equation $y = x^2$; an example of a self-referencing equation set is the equation pair $y = 1/x$; $x = y + 1$.) Experience has shown that early conventional spreadsheet programs were poorly equipped to solve systems of this kind because they were not generally designed for iterative equation-solving methods. Newer spreadsheets usually contain an iterative solver of some kind.

Some authors have applied successive approximation methods with custom-written software to solve equation sets of this kind.[55] However, this approach may involve considerable effort, even by experienced computer programmers. Furthermore, many physiologists have limited experience and training in writing computer programs. The next section describes how equation-solving computer programs can be used to advantage to solve complex physiologic modeling equations. TK SOLVER (Universal Technical Systems, Inc., Rockford, IL) is the equation-solver package used in most of the examples given here, but many other packages could also have been used.

D. Description of TK SOLVER

TK SOLVER (the TK stands for "tool kit") is a software package for equation solving.[2,26,47,66,67] Although intended primarily for engineering applications, TK SOLVER functions well in a variety of other application areas. On start-up, TK SOLVER displays 2 "sheets" or tables out of a total of 13. The Variable Sheet is presented on the bottom "window," and the Rule Sheet goes on the top. Equations are entered in the Rule Sheet using a built-in editor; the variables associated with the equations are then automatically entered in the variable sheet by TK SOLVER. Errors such as unmatched parentheses are automatically detected. Figure 4-12 shows sample Rule and Variable Sheets for a pulmonary exchange model.

Once the equations are entered, TK SOLVER is ready to find solutions. In some cases, the equation set can be solved in "direct-solver" mode, but complex equation sets usually must be solved in "iterative-solver" mode on the basis of initial guesses for all variables. A discussion of the methods used to obtain solutions has been presented by Konopasek and Jayaraman.[68] A book reviewing TK SOLVER from a user's viewpoint is also available.[69]

E. Example 1: Application of Mathematical Modeling to the Study of Gas Exchange Indices

Gas exchange indices are commonly used in anesthesia and critical care medicine to assess pulmonary function from an oxygen transport viewpoint. Although the determination of pulmonary shunt would be viewed by many as a gold standard preferable to any index, measurement of true pulmonary shunt requires pulmonary artery catheterization—a relatively expensive and risky procedure that is not always clinically warranted. Four gas exchange indices are in common use:

1. Alveolar-arterial oxygen tension difference ($P_{AO_2} - Pa_{O_2}$)[57,69-71]
2. Arterial-alveolar oxygen tension ratio (Pa_{O_2}/P_{AO_2})[55,56,72-74]
3. Respiratory index (RI) = $(P_{AO_2} - Pa_{O_2})/P_{AO_2}$[75,76]
4. Pa_{O_2}/F_{IO_2} ratio[34]

The importance of these indices and the controversies surrounding their clinical application are reflected in the many publications concerning their use and limitations.[34,66,77-79]

1. Analysis

The pulmonary shunt equation is used as a foundation upon which arterial oxygenation and gas exchange indices can be studied. It may be expressed as follows:

$$\frac{Qs}{Qt} = \frac{Cc'_{O_2} - Ca_{O_2}}{Cc'_{O_2} - C\bar{v}_{O_2}} \quad (57)$$

where
Q_s/Q_t = shunt fraction
Cc'_{O_2} = pulmonary end-capillary oxygen content
Ca_{O_2} = arterial oxygen content
$C\bar{v}_{O_2}$ = mixed venous oxygen content

```

```

Figure 4-12 Sample TK SOLVER Rule Sheet (*top*) and Variable Sheet (*bottom*). In this case, equations relate factors that determine arterial oxygen tension (Pa_{O_2}). All variables are defined in comment section of variable sheet. The first equation in the Rule Sheet is from Torda and Doyle.[55,57] The second and third equations are from Hill.[64]

By algebraic manipulation of the shunt equation, it is possible to relate arterial oxygen tension to its influencing factors[55,57]:

$$Ca - \bar{v}O_2 \times \frac{\frac{Qs}{Qt}}{1-\frac{Qs}{Qt}} - 1.34 \times$$

$$Pa_{O_2} = P_{A_{O_2}} - \frac{(Sc'_{O_2} - Sa_{O_2}) \times Hb}{0.0031} \qquad (58)$$

where $P_{A_{O_2}}$ (mm Hg) is the alveolar oxygen tension; $Ca-\bar{v}O_2$ (vol%) is the arterial–mixed venous oxygen content difference (= $Ca_{O_2} - C\bar{v}_{O_2}$), Sc'_{O_2} is the pulmonary end-capillary fractional saturation, Sa_{O_2} is the arterial oxygen saturation, and Hb is the blood hemoglobin concentration (g/dL). The full alveolar gas equation is used to determine $P_{A_{O_2}}$:

$$P_{A_{O_2}} = (P_B - P_{H_2O}) \times F_{I_{O_2}} - Pa_{CO_2} \times \left(F_{I_{O_2}} + \frac{1-F_{I_{O_2}}}{R}\right) \qquad (59)$$

where P_B is the barometric pressure (assumed to be 760 mm Hg), P_{H_2O} is the patient's water vapor pressure (assumed to be 47 mm Hg), Pa_{CO_2} is the arterial CO_2 tension (usually assumed to be 40 mm Hg), and R is the gas exchange ratio (assumed to be 0.8).

Equation 58 does not explicitly show the influence of P_{50} (the oxygen tension corresponding to 50% hemoglobin saturation) on arterial oxygen tension; such influences are mediated indirectly, principally through the Sa_{O_2} term. To make explicit the influence of Pa_{O_2} and P_{50} on Sa_{O_2}, we use the relationship given by Hill's equation[64]:

$$Sa_{O_2} = \frac{Pa_{O_2}^n}{Pa_{O_2}^n + P_{50}^n} \qquad (60)$$

where n is an empirical constant (usually taken as 2.65).

A similar expression relates $P_{A_{O_2}}$, P_{50}, and Sc'_{O_2}.

The arterial oxygen tension (Pa_{O_2}), the alveolar-arterial oxygen tension difference ($P_{A_{O_2}} - Pa_{O_2}$), and the arterial-alveolar oxygen tension ratio ($Pa_{O_2}/P_{A_{O_2}}$) can then be obtained using Equations 58, 59, and 60 for specific choices of physiologic variables. Unfortunately, Equation 58 is not easily solved because it requires the solution of

two simultaneous nonlinear equations (i.e., equations 58 and 60). In the past, a custom, computer-based successive approximation method was employed to obtain a solution. This amounted to iteratively making successively more accurate estimates of Pa_{O_2} levels that satisfied both of those equations. In the case of Doyle,[55] Equation 58 was solved in this way to an accuracy of 0.1 mm Hg for various values of Hb, $Ca-\bar{v}_{O_2}$, F_{IO_2}, Pa_{CO_2}, and Q_s/Q_t. The process is considerably simplified when TK SOLVER is used, as can be seen by examining the equation sheets presented in Figure 4-12.

F. Example 2: Theoretical Study of Hemoglobin Concentration Effects on Gas Exchange Indices

It is of both theoretical and clinical interest to know what changes in gas exchange indices might be expected with changes in Hb when other physiologic parameters are kept constant. Figure 4-13 shows the results of varying Hb under the following conditions:

Alveolar oxygen tension (P_{AO_2}) = 100 mm Hg
Cardiac output (CO) = 5 L/min
Oxygen consumption ($\dot{V}_{O_2}$) = 250 mL/min
Shunt fraction (Q_s/Q_t) = 0.1
P_{50} = 27 mm Hg

Based on this model, increasing Hb can be expected to improve both Pa_{O_2} and the gas exchange indices under study. Such data would be almost impossible to obtain experimentally because of the difficulty of varying Hb independent of other physiologic factors such as CO.

G. Example 3: Modeling the Oxygenation Effects of P_{50} Changes at Altitude

It is well known that the oxyhemoglobin dissociation curve shifts in response to physiologic changes. Acidosis, hypercarbia, increased temperature, and increased levels of 2,3-diphosphoglycerate (2,3-DPG) all shift the curve to the right, reducing the affinity of hemoglobin for oxygen and thereby facilitating release of oxygen into tissues. Patients with chronic anemia, for example, have increased intraerythrocyte levels of 2,3-DPG and a right-shifted oxyhemoglobin curve.[80] Teleologically, this would also appear to be an appropriate response to high-altitude hypoxemia, but in fact the opposite is true: Animals that have successfully adapted to high-altitude hypoxemia have left-shifted curves,[81-83] as do Sherpas.[82,84] In the example that follows, computer modeling is used to develop a possible explanation for this finding.

It can be theorized that a left-shifted curve is beneficial in high-altitude hypoxemia because it increases arterial oxygen content by virtue of increasing pulmonary

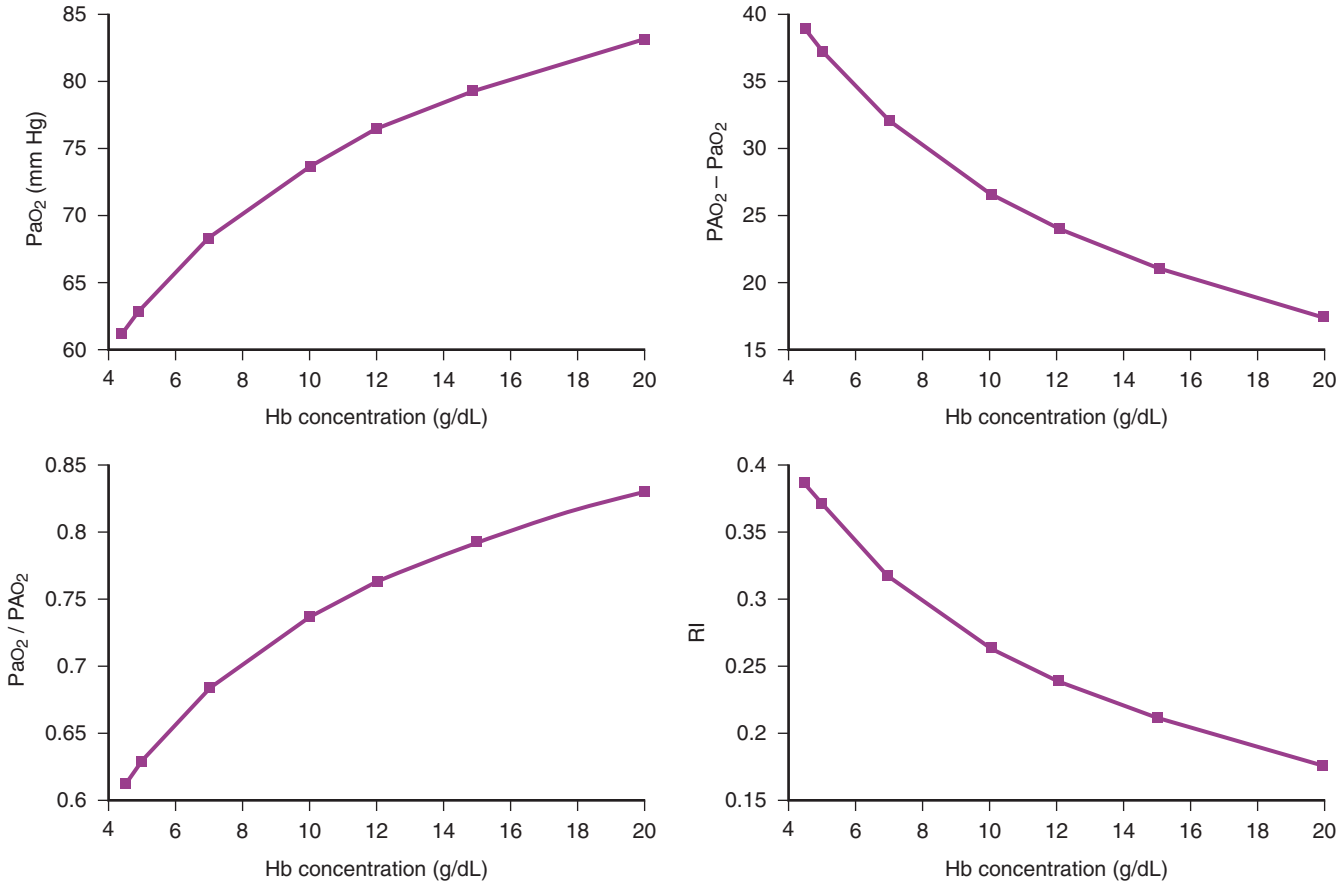

Figure 4-13 Effect of hemoglobin concentration (Hb) on various gas exchange indices according to the TK SOLVER model. *Top left,* Effect on arterial oxygen tension *(Pa_{O_2}); top right,* effect on alveolar-arterial oxygen tension difference *($PA_{O_2} - Pa_{O_2}$); bottom left,* effect on arterial-alveolar oxygen tension ratio *(Pa_{O_2}/PA_{O_2}); bottom right,* effect on the respiratory index *(RI).*

end-capillary oxygen content. The shunt equation described earlier (Equation 57) can be rearranged as follows:

$$Ca\bar{v}O_2 = Cc'O_2 - \frac{\frac{Qs}{Qt}}{1-\frac{Qs}{Qt}} \times Ca\bar{v}O_2 \qquad (61)$$

This shows that, with a constant pulmonary shunt and constant arteriovenous oxygen content difference, increases in pulmonary end-capillary oxygen content will increase the arterial oxygen content.

Now, the pulmonary end-capillary oxygen content, $Cc'O_2$, consists of two terms, the oxygen bound to hemoglobin and the oxygen dissolved in plasma:

$$Cc'O_2 = 1.34\,Hb\,Sc'O_2 + 0.0031\,PAO_2 \qquad (62)$$

where
Hb = hemoglobin concentration (g/dL)
$Sc'O_2$ = pulmonary end-capillary oxygen saturation
PAO_2 = alveolar oxygen tension (mm Hg)

PAO_2 is determined only by the alveolar gas equation and is independent of the position of the oxyhemoglobin curve.[60] Therefore, the dissolved oxygen portion of $Cc'O_2$ is also independent of the curve position. However, the $Sc'O_2$ term does vary with curve position, increasing with a left-shifted curve. Therefore, $Cc'O_2$ also increases with a left shift, taking on a maximum value of

$$[Cc'O_2]_{max} = 1.34\,Hb + 0.0031\,PAO_2 \qquad (63)$$

This analysis demonstrates that a left-shifted curve increases arterial oxygen content by increasing pulmonary end-capillary oxygen content.

We now consider the effects of P_{50} changes in two situations.

1. In Situation A, a patient has high-altitude hypoxemia as a result of a PAO_2 of 50 mm Hg. With a CO of 5 L/min, an Hb of 15 g/dL, oxygen consumption ($\dot{V}O_2$) of 250 mL/min, and a shunt fraction (Q_s/Q_t) of 0.1, it can be shown (Table 4-6) that CaO_2 changes from 16.41 vol% with a P_{50} of 27 mm Hg to 18.44 vol% with a P_{50} of 18 mm Hg—a significant increase.
2. In Situation B, a patient has a large pulmonary shunt ($Q_s/Q_t = 0.4$), a normal PAO_2 (100 mm Hg), and other parameters as in situation A. In this case, CaO_2 goes from 16.47 vol% with a P_{50} of 27 mm Hg to 16.87 vol% with a P_{50} of 18 mm Hg—an insignificant change (see Table 4-6).

Figure 4-14 illustrates this concept in more detail, showing the two examples for P_{50} values ranging from 10 to 50 mm Hg. The data provided in situations A and B and in Figure 4-14 were obtained by using the preceding mathematical computer model of the oxyhemoglobin dissociation curve. Hill's equation relating saturation, tension, and P_{50} was used in conjunction with Doyle's equation for arterial oxygen tension and solved with the use of TK SOLVER.[55,64]

TABLE 4-6
Oxygenation Effects of P_{50} Changes at Altitude

Oxygen Variable	Altitude Case*		Shunt Case	
	$P_{50} = 27$	$P_{50} = 18$	$P_{50} = 27$	$P_{50} = 18$
PaO_2	46.6	43.3	46.9	33.1
$P\bar{v}O_2$	29.7	23.3	29.8	20.6
SaO_2	0.809	0.911	0.812	0.834
$S\bar{v}O_2$	0.563	0.665	0.566	0.587
$Sc'O_2$	0.837	0.937	0.970	0.989
CaO_2	16.41	18.44	16.47	16.87
CvO_2	11.41	13.44	11.47	11.87
$Cc'O_2$	16.99	19.00	19.80	20.20

*Detailed figures for altitude case (PAO_2 = 50 mm Hg) and for shunt case ($Q_s/Q_t = 0.4$). Other parameters are given in the text. Note that a shift from a P_{50} of 27 to a P_{50} of 18 significantly increases arterial oxygen content (CaO_2) in the altitude case but not in the shunt case.

These two situations demonstrate that a leftward shift of the oxyhemoglobin dissociation curve significantly improves arterial oxygen content in the case of high-altitude hypoxemia but not in the case of a large shunt. This observation is consistent with the general finding of a right-shifted curve in patients, such as those with cyanotic heart disease, who have a right-to-left shunt.[62] In these cases, a left-shifted curve is not beneficial because only a trivial improvement in $Cc'O_2$ (and thus in PAO_2) is obtained. Teleologically, it may be argued that in the presence of hypoxemia, at approximately equal arterial oxygen contents, the body prefers higher oxygen tensions (i.e., right shift), but if arterial oxygen content can be significantly improved, despite a decrease in oxygen tension, a left shift is preferred.

H. Example 4: Mathematical/Computer Model for Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is sometimes used to treat respiratory failure that is refractory to more conservative measures.[16] Clinical experience with ECMO is limited, and even clinicians familiar with the therapy may disagree about its potential benefits in a particular clinical setting. This is especially true if the patient has a high CO (e.g., 20 L/min) and the ECMO pump is limited to much smaller flows (e.g., 5 L/min). In the example that follows, we describe how a computer model may be designed to facilitate management decisions for patients being considered for venovenous ECMO.

A mathematical model of the venovenous ECMO situation may be developed on the basis of the shunt equation,[56] the Hill model for the oxyhemoglobin dissociation curve,[57] Doyle's equation for arterial oxygen tension as a function of cardiorespiratory parameters,[58] and the schematic diagram for venovenous ECMO shown in Figure 4-15. The relevant equations are given in Figure 4-16. The model may be solved for various hypothetical clinical circumstances using an equation solver package. In this instance, we used EUREKA (Borland International, Scotts Valley, CA), a DOS-based

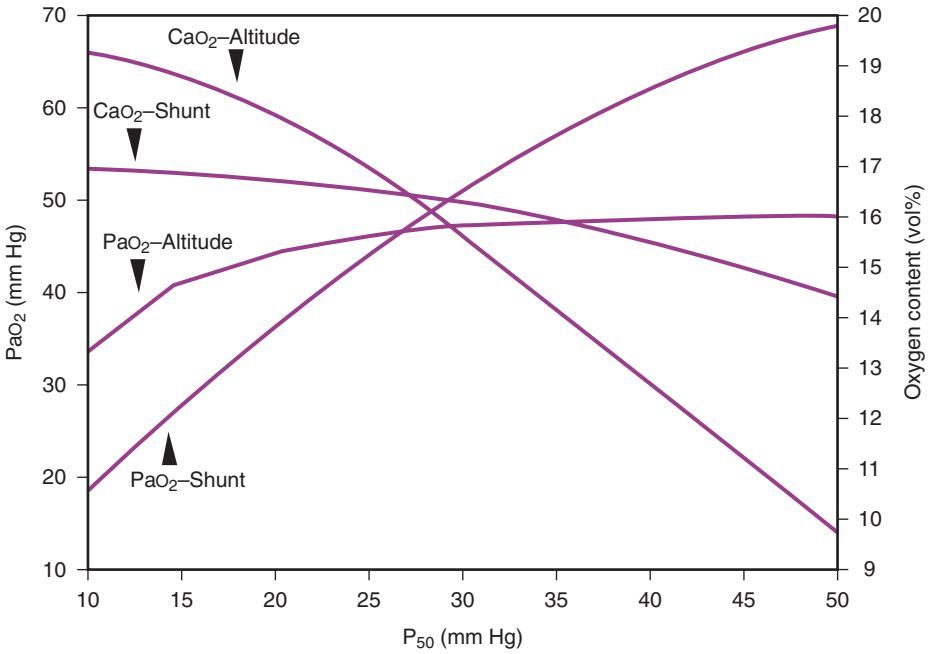

Figure 4-14 Arterial oxygen tension (Pao_2) and arterial oxygen content (Cao_2) as a function of oxygen tension corresponding to 50% hemoglobin saturation (P_{50}) for cases depicted in situations A (altitude hypoxemia) and B (shunt hypoxemia) in the text. Notice that a decrease in P_{50} (left-shifted curve) significantly increases oxygen content in the altitude case but not in the shunt case. (From Doyle DJ: Simulation in medical education: Focus on anesthesiology. *Can J Anaesth* 39:A89, 1992.)

commercial computer software package for solving systems of equations.

Some sample results are shown in Figure 4-17. The patient's parameters were as follows: CO = 5 L/min; $\dot{V}_{O_2}$ = 250 mL/min; Hb = 15 g/dL; Q_s/Q_t = 0.5; P_{AO_2} = 200 mm Hg. The oxygenator oxygen tension output was sufficient to result in complete hemoglobin saturation.

I. Discussion

Many questions in physiology are not easily answered by direct experimentation, either because it is impractical (or impossible) to control all the pertinent variables or because of ethical considerations. For example, in studying the influence of Hb on pulmonary gas exchange indices, it would be difficult to achieve rigorous experimental control of CO, total body oxygen consumption, and other variables. The modeling approach presented here offers several advantages:

1. It relies on well-established physiologic relationships (e.g., alveolar gas equation, pulmonary shunt equation).
2. It permits insight into physiologic issues not generally attainable in other ways.
3. It is inexpensive.
4. It potentially reduces the need to carry out animal experimentation.

Three drawbacks to the method exist:

1. It is no better than the equations on which it is based.
2. It may not be convincing to some physiologists who would be satisfied only by confirmatory experimental results.
3. Errors can occur in model building.

One potential difficulty with such modeling methods is that the results obtained depend critically on the equations used. If the equations are known from first principles (e.g., alveolar gas equation, pulmonary shunt equation), this is not an issue, but with empirical formulas, alternative equations may possibly produce different results. An example is the equation for the oxyhemoglobin dissociation curve, which has many competing formulations.[61-64] In that example, we used the formulation given by Hill.[64]

J. Utility

Where can such a model be useful? In a specific patient with severe adult respiratory distress syndrome and resulting severe hypoxemia, clinicians might be interested to know, for instance, how ECMO would be expected to improve oxygenation. From pulmonary artery catheterization and arterial blood samples, one can obtain the Hb concentration, CO, P_{50} level on the dissociation curve, arterial and mixed venous (arterial blood gas) measurements, and other data relevant to carrying out oxygen transport modeling.

On the basis of a model constructed for the time point when the data were gathered, one could explore, for example, the effect of augmenting CO and mixed venous oxygen tension in the ECMO situation. Without a model to describe this problem, the best that can be done is to fit empirical curves to experimental data. However, with a model, one can easily ask "what if" questions, such as, What happens when the ratio of pump oxygenator flow to CO is set at a particular value?.[80]

A good example is a question frequently asked in respiratory physiology: How does a patient's alveolar-arterial oxygen tension difference change with reduced

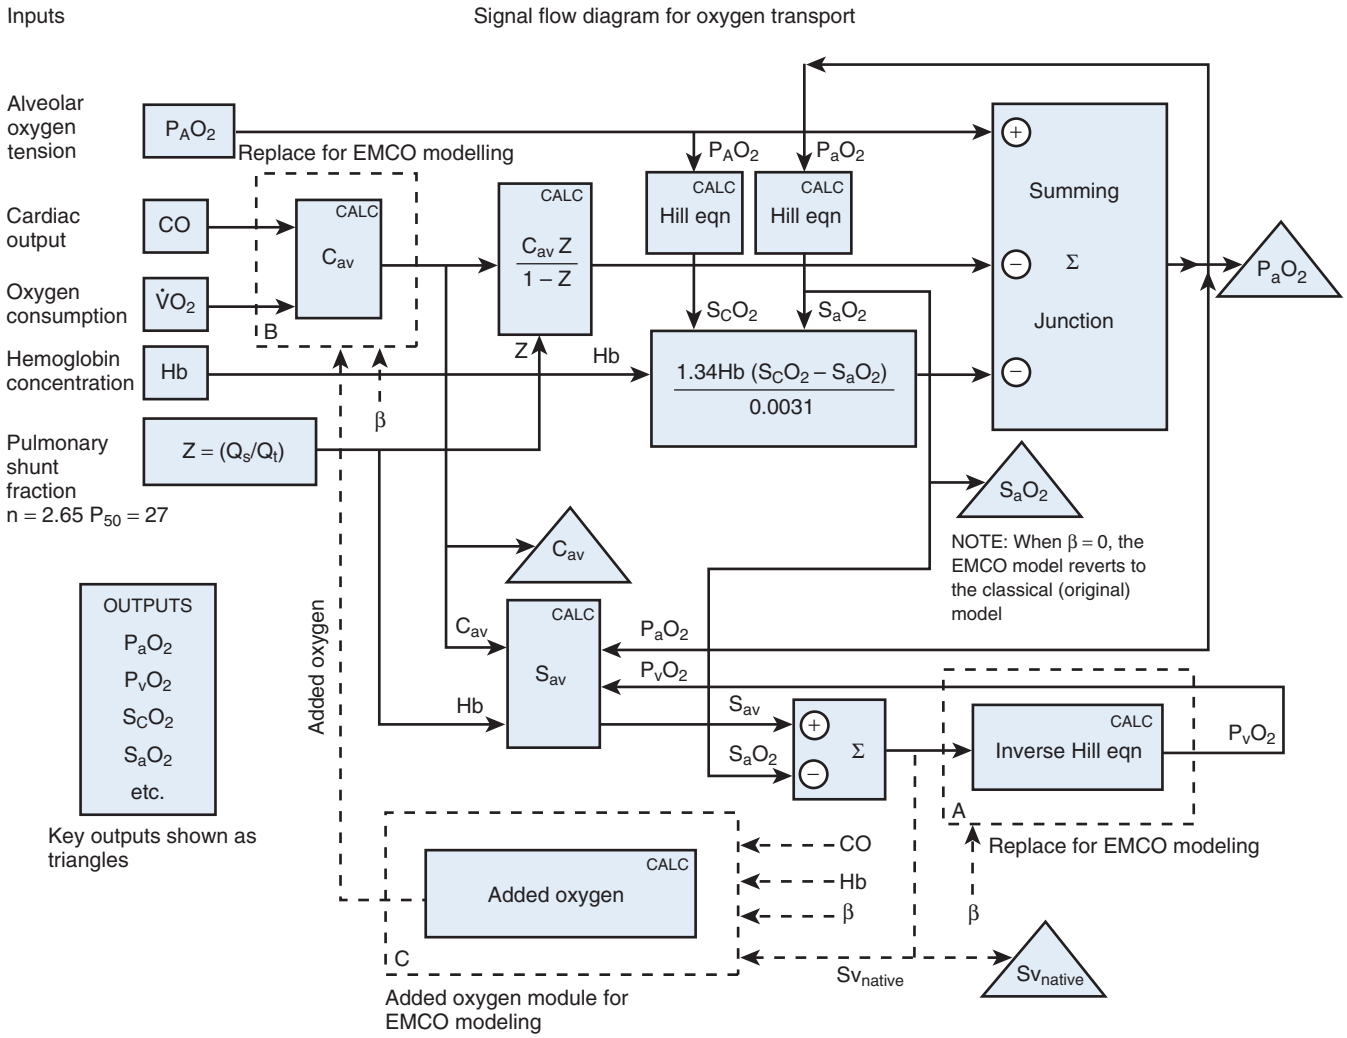

Figure 4-15 *β,* Ratio of ECMO flow to cardiac output; C_{av}, arteriovenous oxygen content difference; *CO,* cardiac output; *Hb,* hemoglobin concentration (g/dL); P_{50}, oxygen partial pressure corresponding to 50 percent hemoglobin oxygen saturation; P_aO_2, arterial oxygen tension (mm Hg); P_AO_2, alveolar oxygen tension (mm Hg); P_vO_2, oxygen partial pressure for mixed venous blood; Q_s/Q_t, pulmonary shunt fraction (= Z); S_aO_2, arterial oxygen saturation; S_{av}, arteriovenous oxygen saturation content difference; S_CO_2, pulmonary end-capillary oxygen saturation; $\dot{V}O_2$, oxygen consumption; Sv_{native}, mixed venous oxygen saturation in the absence of ECMO support.

inspired oxygen tension? The first attempt at answering this question used pulse oximetry to infer arterial oxygen tension in volunteers subjected to controlled hypoxia by rebreathing.[81] A subsequent study took a more direct approach by cannulating the radial artery of elderly respiratory patient volunteers and drawing off serial arterial blood samples as the patients were subjected to hypoxemia in a hypobaric chamber.[83] Both of these studies were performed in 1974. The latter investigation was sufficiently invasive (and possibly risky) that many hospital ethics committees would not have approved it under current guidelines.

If more than one set of equations exist to describe a physiologic relationship, one can explore the effect of equation choice. However, if several equations exist and all do a good job of representing the underlying data, equation choice would not be expected to have a great influence on the results obtained. With modeling, one can obtain meaningful information about the interaction of several physiologic variables in a few days or even a few hours, provided that the relationships describing the variables are available in equation form. By contrast, actual experimentation requires time, funds, and effort that may not always be available.

In fields such as oxygen transport, many relevant equations are simple, well-known physiologic principles written in equation form; examples include the alveolar gas equation, the pulmonary shunt equation, the oxyhemoglobin dissociation curve, and the definitions of oxygen transport parameters. To the extent that one accepts these physiologic principles, the results obtained should also be credible (provided that model design and implementation have been done correctly). In this respect, three issues exist:

1. How meaningful are the equations used? Are they a mathematical form of a well-known physiologic principle?
2. How accurate are the equations in describing the data on which they are based?
3. Has the model been appropriately designed and implemented?

Figure 4-16 Equations for venovenous extracorporeal membrane oxygenation (ECMO) model obtained by using EUREKA, an equation solver similar to TK SOLVER but somewhat easier to learn. The first seven lines indicate the values of physiologic parameters that are held constant. The next three lines are comments not used by EUREKA. Lines 11 through 13 and 17 through 21 list basic equations to be solved. Lines 14 through 16 provide initial estimates for EUREKA's iterative solver. Lines 22 through 25 give some physiologic constraints that cannot be violated (e.g., arterial oxygen tension must be less than alveolar oxygen tension). (EUREKA is also available in a shareware version known as Mercury, which runs under MS-DOS.) (Adapted from Doyle DJ: Computer model for veno-veno extracorporeal membrane oxygenation. *Can J Anaesth* 39:A34, 1992.)

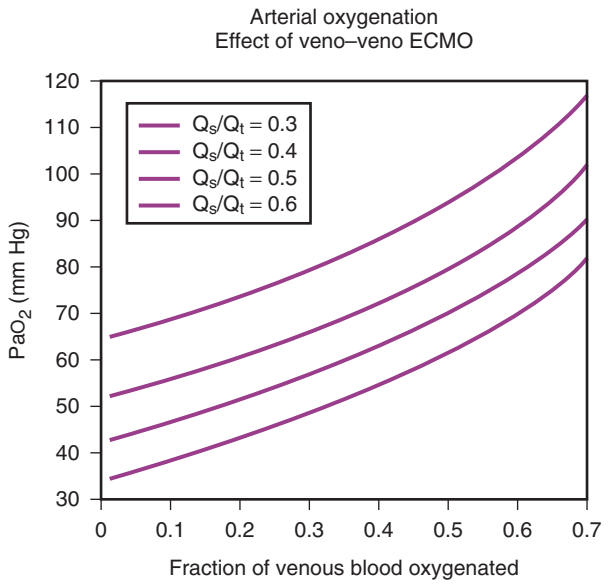

Figure 4-17 Sample results obtained with a mathematical model of venovenous extracorporeal membrane oxygenation *(ECMO)* for various levels of relative flow through the ECMO oxygenator. Arterial oxygen tension *(Pao_2)* is plotted as a function of the fraction of venous blood passing through the ECMO oxygenator for various values of pulmonary shunt *(Q_s/Q_t, or Z)*. (Adapted from Doyle DJ: Computer model for veno-veno extracorporeal membrane oxygenation. *Can J Anaesth* 39:A34, 1992.)

K. Software

Several platforms exist to do such computations in the IBM-PC environment. TK SOLVER is still available (in a "Plus" form) from software distributors but does not have the market share of MATHCAD (PTC; Needham, MA), a widely available, popular mathematical modeling package with strong graphical features. MATHCAD has equation-solving features similar to those of TK SOLVER that would make it appropriate for mathematical model building. Another suitable package is Mercury, a shareware equation solver derived from EUREKA. All of these packages take some effort to master. In particular, the manner in which each package handles convergence to solution greatly affects ease of use and reliability. In general, the three packages mentioned (TK SOLVER, MATHCAD, and Mercury) work reasonably well with some effort. It is more difficult to do this modeling using ordinary computer spreadsheets (e.g., early releases of Lotus 1-2-3)—first, because it is somewhat awkward for working with equations, and second, because most spreadsheets are not set up to handle complicated iterative equation solving.

L. Computational Flow Diagrams

Mathematical modeling of complex physiologic systems can sometimes be facilitated by representing the relevant equations with the use of a computational flow diagram.

The concept is most easily understood by reviewing the examples mentioned previously.

Example 1. Computation of the alveolar-arterial oxygen tension gradient
Example 2. Computation of alveolar oxygen tension
Example 3. Computation of arterial oxygen tension
Example 4. Modeling the effects of venovenous ECMO

For those situations involving feedback (Examples 3 and 4), special iterative methods are necessary to obtain a solution. Not all spreadsheets are able to do this.

VIII. SELECTED DIMENSIONAL EQUIVALENTS

Discussions regarding physics in anesthesia may be confusing because of the variety of units used in the clinical literature. The list in Box 4-1 is a compilation of units and equivalents that one is likely to encounter.

BOX 4-1 Selected Dimensional Equivalents

Length

1 m = 3.2808 ft = 39.37 in
1 ft = 0.3048 m
1 m = 100 cm = 1000 mm = 1,000,000 μm = 10,000,000 Å = 10^{-3} km
1 km = 0.621 mi
1 in = 2.54 cm = 0.254 m

Volume

1 US gal = 0.13368 ft^3 = 3.785541 L
1 Imp gal = 4.546092 L
1 m^3 = 1000 L
1 mL = 1 cm^3

Mass

1 kg = 1000 g = 2.2046 lb_m = 0.068521 slugs
1 lb_m = 0.453592 kg
1 slug = 1 $lb_f \times s^2/ft$ = 32.174 lb_m

Force

1 lb_f = 4.448222 N = 4.448 × 10^5 dynes
1 N = 1 kg × m/s^2 = 10,000 dynes = 10,000 g × cm/s^2

Pressure

1 N/m^2 = 10 dynes/cm^2 = 1 Pa = 0.007501 mm Hg
1 atmosphere = 1013.25 millibars = 760 mm Hg = 101,325 Pa = 14.696 lb_f/in^2
1 cm H_2O = 0.735 mm Hg
1 lb_f/in^2 = 51.71 mm Hg
1 dyne/cm^2 = 0.1 Pa = 145.04 × 10^{-7} lb_f/in^2
1 bar = 10^5 N/m^2 = 14.504 lb_f/in^2 = 106 dynes/cm^2

Viscosity

1 kg/(m × s) = 1 N × s/m^2 = 0.6729 $lb_m/(ft \times s)$ = 10 poise

Energy

1 joule (J) = 1 kg × m^2/s^2
1 Btu = 778.16 ft × lb_f = 1055.056 J = 252 cal = 1.055 × 10^{10} ergs
1 cal = 4.1868 J

Power

1 watt (W) = 1 kg × m^2/s^3 = 1 J/s
1 hp = 550 ft × lb_f/s = 745.699 W

IX. CONCLUSIONS

An understanding of a number of basic principles of physics can be very helpful in clinical airway management. This is especially true for the physics of fluid flow, such as the relationships between pressure, flow, and resistance under laminar and turbulent flow conditions.

In addition to the application of basic physics principles to airway situations, the application of mathematical methods and physiologic modeling can sometimes be enormously helpful in obtaining insights into complex physiologic systems related to the airway, such as the determination of arterial blood oxygenation under various conditions. In many cases, such modeling can produce results that would be extremely difficult to obtain by recourse to pure experimentation alone.

X. CLINICAL PEARLS

- An important formula that quantifies the relationship of pressure, flow, and resistance in laminar flow systems is given by the Hagen-Poiseuille equation. This law states that the fluid flow rate through a horizontal straight tube of uniform bore is proportional to the pressure gradient and the fourth power of the radius and is related inversely to the viscosity of the gas and the length of the tube. This law is valid for laminar flow conditions only.
- When the flow rate exceeds a *critical velocity* (the flow velocity below which flow is laminar), the flow loses its laminar parabolic velocity profile, becomes disorderly, and is termed *turbulent*. If turbulent flow exists, the relationship between pressure drop and flow is no longer governed by the Hagen-Poiseuille equation. Instead, the pressure gradient required (or the resistance encountered) during turbulent flow varies as the square of the gas flow rate. In addition, flow becomes inversely related to gas density rather than viscosity (as occurs with laminar flow).
- Clinically, airway-obstructing conditions such as epiglottitis or inhaled foreign bodies are often best modeled as breathing through an orifice. Under such conditions, the approximate flow across the orifice varies inversely with the square root of the gas density, in contrast to laminar flow conditions, in which gas flow varies inversely with gas viscosity. In such conditions, the low density of helium allows it to play a significant clinical role in the management of some forms of airway obstruction.
- Laplace's law predicts that for two alveoli of unequal size but equal surface tension, the smaller alveolus experiences a larger intra-alveolar pressure than the larger alveolus, causing the smaller alveolus to collapse. In real life, however, collapse of the smaller alveolus is prevented through the action of pulmonary surfactant, which serves to decrease alveolar surface tension in the smaller alveolus, resulting in equal pressure in both alveoli.

- One of the most important gas laws in physiology is the ideal (or perfect) gas law, PV = nRT (where P = pressure of gas, V = volume of gas, n = number of moles of the gas in volume V, R = gas constant, and T = absolute temperature). This is the equation for ideal gases, which experience no forces of interaction. Real gases, however, experience intermolecular attraction (van der Waals forces), which requires that the pressure-volume gas law be written in a more complex form.
- Most flowmeters measure the drop in pressure that occurs when a gas passes through a known resistance and correlate this pressure drop to flow. When the resistance is an orifice, resistance depends primarily on gas density. Usually, a given flowmeter is calibrated for a particular gas, such as oxygen or air, with conversion tables available to provide flow data for other gases.
- Fick's law of diffusion, applicable to gas flow across lung and placental membranes, states that the rate of diffusion of a gas across a barrier is proportional to the concentration gradient for the gas and inversely proportional to the diffusion distance over which the gas molecules must travel.
- There are five main types of oxygen analyzers: paramagnetic analyzers, fuel cell analyzers, oxygen electrodes, mass spectrometers, and Raman spectrographs. All respond to oxygen partial pressure and not to oxygen concentration.
- The concept of minimum alveolar concentration (MAC) does not apply at higher altitudes and should be replaced by the concept of minimal alveolar partial pressure (MAPP).
- The pulmonary shunt equation is used as a foundation upon which arterial oxygenation and gas exchange indices can be studied. Calculation of pulmonary shunt requires the following information: (1) pulmonary end-capillary oxygen content, (2) arterial oxygen content, and (3) mixed venous oxygen content.

I. NORMAL RESPIRATORY PHYSIOLOGY (NONANESTHETIZED)

Anesthesiologists require an extensive knowledge of respiratory physiology to care for patients in the operating room and the intensive care unit. Mastery of the normal respiratory physiologic processes is a prerequisite to understanding the mechanisms of impaired gas exchange that occur during anesthesia, during surgery, and with disease. This chapter is divided into two sections. The first section reviews the normal (gravity-determined) distribution of perfusion and ventilation, the major nongravitational determinants of resistance to perfusion and ventilation, transport of respiratory gases, and the pulmonary reflexes and special functions of the lung. In the second section, these processes and concepts are

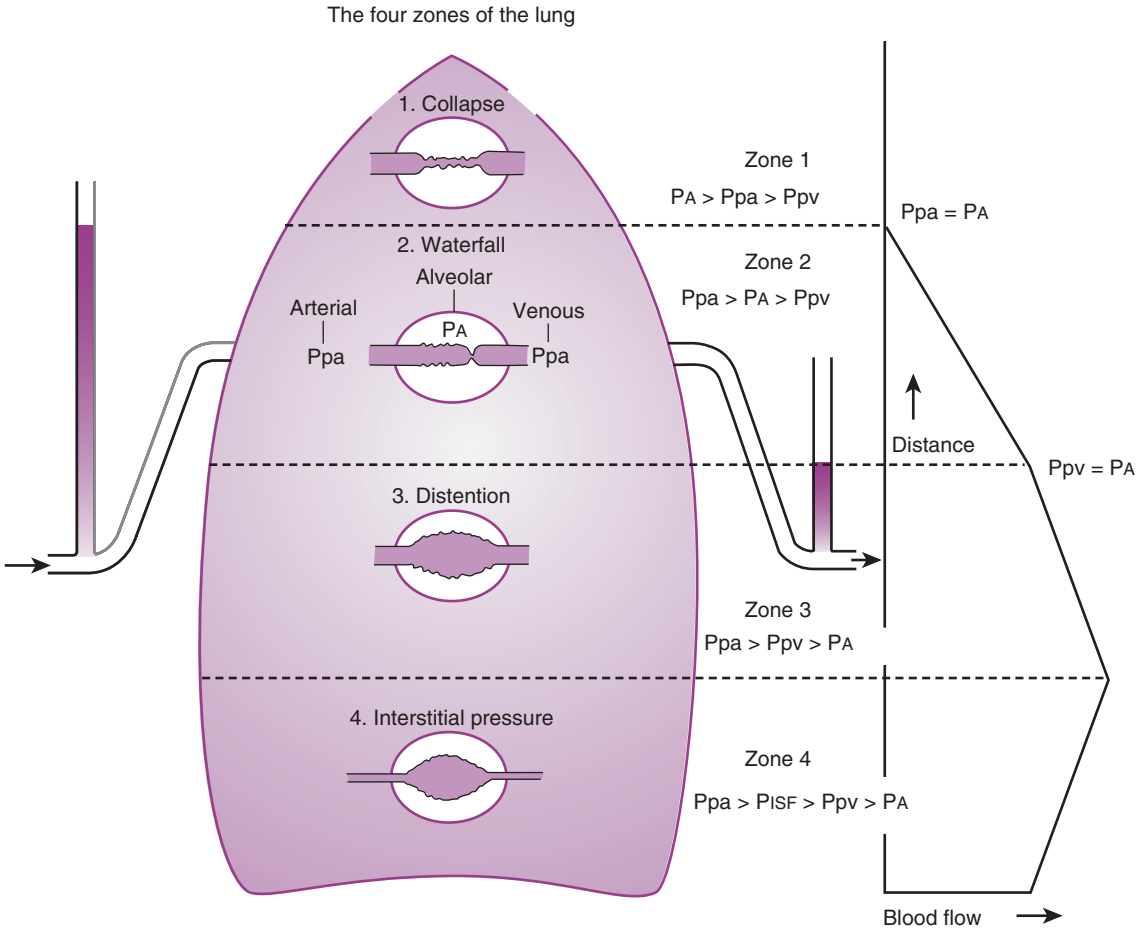

Figure 5-1 Schematic diagram showing the distribution of blood flow in the upright lung. In zone 1, alveolar pressure *(PA)* exceeds pulmonary artery pressure *(Ppa)*, and no flow occurs because the intra-alveolar vessels are collapsed by the compressing alveolar pressure. In zone 2, Ppa exceeds PA, but PA exceeds pulmonary venous pressure *(Ppv)*. Flow in zone 2 is determined by the Ppa-PA difference (Ppa – PA) and has been likened to an upstream river flowing over a dam. Because Ppa increases down zone 2 whereas PA remains constant, perfusion pressure increases, and flow steadily increases down the zone. In zone 3, Ppv exceeds PA, and flow is determined by the Ppa – Ppv difference, which is constant down this portion of the lung. However, transmural pressure across the wall of the vessel increases down this zone, so the caliber of the vessels increases (resistance decreases), and therefore flow increases. Finally, in zone 4, pulmonary interstitial pressure *(PISF)* becomes positive and exceeds both Ppv and PA. Consequently, flow in zone 4 is determined by the Ppa – PISF difference. (Redrawn with modification from West JB: *Ventilation/Blood flow and gas exchange*, ed 4, Oxford, 1970, Blackwell Scientific, 1970.)

discussed in relation to the general mechanisms of impaired gas exchange that occur during anesthesia and surgery.

A. Gravity-Determined Distribution of Perfusion and Ventilation

1. Distribution of Pulmonary Perfusion

Contraction of the right ventricle imparts kinetic energy to the blood in the main pulmonary artery. As this energy is dissipated in climbing a vertical hydrostatic gradient, the absolute pressure in the pulmonary artery (Ppa) decreases by 1 cm H_2O per centimeter of vertical distance up the lung (Fig. 5-1). At some height above the heart, Ppa becomes zero (i.e., equal to atmospheric pressure), and still higher in the lung, Ppa becomes negative.[1] In this region, then, alveolar pressure (PA) exceeds Ppa and pulmonary venous pressure (Ppv), which is very negative at this vertical height. Because the pressure outside the vessels is greater than the pressure inside the vessels, the vessels in this region of the lung are collapsed, and no blood flow occurs; this is known as *zone 1* (PA > Ppa > Ppv). Because there is no blood flow, no gas exchange is possible, and the region functions as alveolar dead space, or wasted ventilation. Little or no zone 1 exists in the lung under normal conditions,[2] but the amount of zone 1 lung may be greatly increased if Ppa is reduced, as in oligemic shock, or if PA is increased, as in the application of excessively large tidal volumes (VT) or levels of positive end-expiratory pressure (PEEP) during positive-pressure ventilation.

Further down the lung, absolute Ppa becomes positive, and blood flow begins when Ppa exceeds PA (*zone 2*, Ppa > PA > Ppv). At this vertical level in the lung, PA exceeds Ppv, and blood flow is determined by the mean Ppa – PA difference rather than by the more conventional Ppa – Ppv difference (see later discussion).[3] In zone 2, the relationship between blood flow and alveolar pressure has the same physical characteristics as a waterfall flowing over a dam. The height of the upstream river (before reaching the dam) is equivalent to Ppa, and the height of

the dam is equivalent to P_A. The rate of water flow over the dam is proportional to only the difference between the height of the upstream river and the dam (Ppa – P_A), and it does not matter how far below the dam the downstream riverbed (Ppv) is. This phenomenon has various names, including the waterfall, Starling resistor, weir (dam made by beavers), and sluice effect. Because mean Ppa increases down this region of the lung but mean P_A is relatively constant, the mean driving pressure (Ppa – P_A) increases linearly, and therefore mean blood flow increases linearly as one descends down this portion of the lung. However, respiration and pulmonary blood flow are cyclic phenomena. Therefore, absolute instantaneous Ppa, Ppv, and P_A are changing continuously, and the relationships among Ppa, Ppv, and P_A are dynamically determined by the phase lags between the cardiac and respiratory cycles. Consequently, a given point in zone 2 may actually be in either a zone 1 or a zone 3 condition at a given moment, depending on whether the patient is in respiratory systole or diastole or in cardiac systole or diastole.

Still lower in the lung, there is a vertical level at which Ppv becomes positive and also exceeds P_A. In this region, blood flow is governed by the pulmonary arteriovenous pressure difference, Ppa – Ppv (*zone 3*, Ppa > Ppv > P_A), for here both these vascular pressures exceed P_A, and the capillary systems are thus permanently open and blood flow is continuous. In descending zone 3, gravity causes both absolute Ppa and Ppv to increase at the same rate, so the perfusion pressure (Ppa – Ppv) is unchanged. However, the pressure outside the vessels—namely, pleural pressure (Ppl)—increases less than Ppa and Ppv. Therefore, the transmural distending pressures (Ppa – Ppl and Ppv – Ppl) increase down zone 3, the vessel radii increase, vascular resistance decreases, and blood flow consequently increases further.

Finally, whenever pulmonary vascular pressures (Ppa) are extremely high, as they are in a severely volume-overloaded patient, in a severely restricted and constricted pulmonary vascular bed, in an extremely dependent lung (far below the vertical level of the left atrium), and in patients with pulmonary embolism or mitral stenosis, fluid can transude out of the pulmonary vessels into the pulmonary interstitial compartment. In addition, pulmonary interstitial edema can be caused by extremely negative Ppl and perivascular hydrostatic pressure, such as may occur in a vigorously spontaneously breathing patient with an obstructed airway due to laryngospasm (most commonly) or upper airway masses (e.g., tumors, hematoma, abscess, edema), strangulation, infectious processes (e.g., epiglottitis, pharyngitis, croup), or vocal cord paralysis; with rapid reexpansion of lung; or with the application of very negative Ppl during thoracentesis.[4,5] Transuded pulmonary interstitial fluid can significantly alter the distribution of pulmonary blood flow.

When the flow of fluid into the interstitial space is excessive and the fluid cannot be cleared adequately by the lymphatics, it accumulates in the interstitial connective tissue compartment around the large vessels and airways and forms peribronchial and periarteriolar edema fluid cuffs. The transuded pulmonary interstitial fluid fills the pulmonary interstitial space and may eliminate the normally present negative and radially expanding interstitial tension on the extra-alveolar pulmonary vessels. Expansion of the pulmonary interstitial space by fluid causes pulmonary interstitial pressure (P_{ISF}) to become positive and to exceed Ppv (*zone 4*, Ppa > P_{ISF} > Ppv > P_A).[6,7] In addition, the vascular resistance of extra-alveolar vessels may be increased at a very low lung volume (i.e., residual volume); at such volumes, the tethering action of the pulmonary tissue on the vessels is also lost, and as a result, P_{ISF} increases positively (see later discussion of lung volume).[8,9] Consequently, zone 4 blood flow is governed by the arteriointerstitial pressure difference (Ppa – P_{ISF}), which is less than the Ppa – Ppv difference, and therefore zone 4 blood flow is less than zone 3 blood flow. In summary, zone 4 is a region of the lung from which a large amount of fluid has transuded into the pulmonary interstitial compartment or is possibly at a very low lung volume. Both these circumstances produce positive interstitial pressure, which causes compression of extra-alveolar vessels, increased extra-alveolar vascular resistance, and decreased regional blood flow.

It should be evident that as Ppa and Ppv increase, three important changes take place in the pulmonary circulation—namely, recruitment or opening of previously unperfused vessels, distention or widening of previously perfused vessels, and transudation of fluid from very distended vessels.[10,11] Thus, as mean Ppa increases, zone 1 arteries may become zone 2 arteries, and as mean Ppv increases, zone 2 veins may become zone 3 veins. The increase in both mean Ppa and Ppv distends zone 3 vessels according to their compliance and decreases the resistance to flow through them. Zone 3 vessels may become so distended that they leak fluid and become converted to zone 4 vessels. In general, pulmonary capillary recruitment is the principal change as Ppa and Ppv increase from low to moderate levels, distention is the principal change as Ppa and Ppv increase from moderate to high levels, and transudation is the principal change when Ppa and Ppv increase from high to very high levels.

2. Distribution of Ventilation

Gravity also causes differences in vertical Ppl, which in turn causes differences in regional alveolar volume, compliance, and ventilation. The vertical gradient of Ppl can best be understood by imagining the lung as a plastic bag filled with semifluid contents; in other words, it is a viscoelastic structure. Without the presence of a supporting chest wall, the effect of gravity on the contents of the bag would cause the bag to bulge outward at the bottom and inward at the top (i.e., it would assume a globular shape). Inside the supporting chest wall, the lung cannot assume a globular shape. However, gravity still exerts a force on the lung to assume a globular shape; this force creates relatively more negative pressure at the top of the pleural space (where the lung pulls away from the chest wall) and relatively more positive pressure at the bottom of the lung (where the lung is compressed against the chest wall) (Fig. 5-2). The density of the lung determines the magnitude of this pressure gradient. Because the lung has about one fourth the density of water, the gradient of Ppl (in cm H_2O) is about one fourth the height of the upright

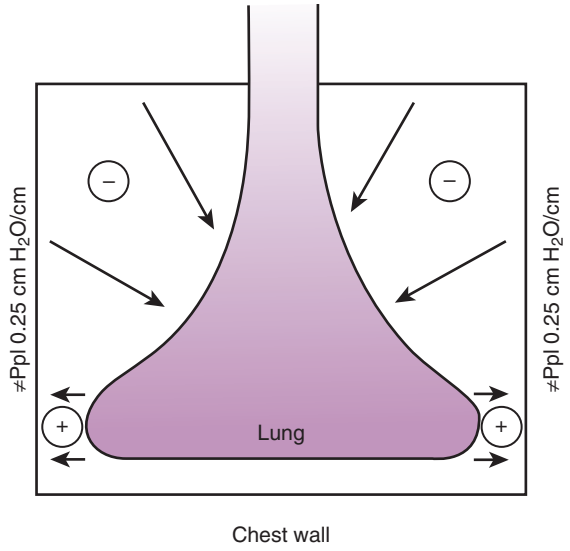

Figure 5-2 Schematic diagram of the lung within the chest wall showing the tendency of the lung to assume a globular shape because of gravity and the lung's viscoelastic nature. The tendency of the top of the lung to collapse inward creates a relatively negative pressure at the apex of the lung, and the tendency of the bottom of the lung to spread outward creates a relatively positive pressure at the base of the lung. Therefore, alveoli at the top of the lung tend to be held open and are larger at end-exhalation, whereas those at the bottom tend to be smaller and compressed at end-exhalation. Pleural pressure increases by 0.25 cm H_2O per centimeter of lung dependence.

lung (30 cm). Thus, Ppl increases positively by 30/4 = 7.5 cm H_2O from the top to the bottom of the lung.[12]

Because P_A is the same throughout the lung, the Ppl gradient causes regional differences in transpulmonary distending pressure (P_A – Ppl). Ppl is most positive (least negative) in the dependent basilar lung regions, so alveoli in these regions are more compressed and are therefore considerably smaller than the superior, relatively noncompressed apical alveoli. (The volume difference is approximately fourfold.)[13] If regional differences in alveolar volume are translated to a pressure-volume (compliance) curve for normal lung (Fig. 5-3), the dependent small alveoli are on the midportion, and the nondependent large alveoli are on the upper portion of the S-shaped compliance curve. Because the different regional slopes of the composite curve are equal to the different regional lung compliance values, dependent alveoli are relatively compliant (steep slope), and nondependent alveoli are relatively noncompliant (flat slope). Therefore, most of the V_T is preferentially distributed to dependent alveoli which expand more per unit pressure change than the nondependent alveoli.

3. The Ventilation-Perfusion Ratio

Blood flow and ventilation (both shown on the left vertical axis of Fig. 5-4) increase linearly with distance down the normal upright lung (horizontal axis, reverse polarity).[14] Because blood flow increases from a very low value and more rapidly than ventilation does with distance down the lung, the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$,

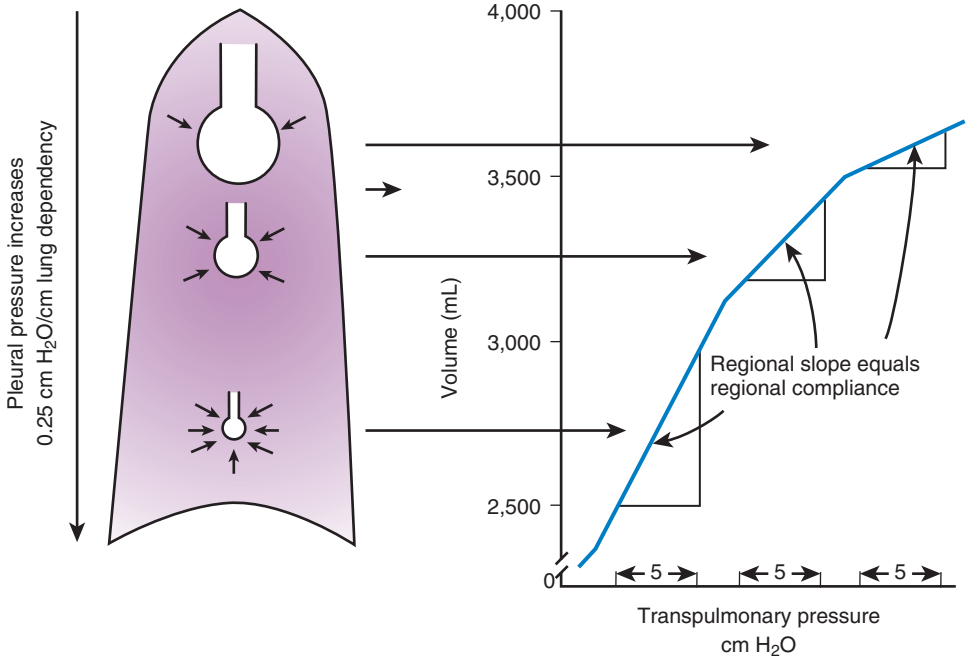

Figure 5-3 Pleural pressure increases by 0.25 cm H_2O every centimeter down the lung. This increase in pleural pressure causes a fourfold decrease in alveolar volume from the top of the lung to the bottom. The caliber of the air passages also decreases as lung volume decreases. When regional alveolar volume is translated to a regional transpulmonary pressure–alveolar volume curve, small alveoli are seen to be on a steep portion of the curve (large slope), and large alveoli are on a flat portion of the curve (relatively small slope). Because the regional slope equals regional compliance, the dependent small alveoli normally receive the largest share of the tidal volume. Over the normal tidal volume range the pressure-volume relationship is linear: lung volume increases by 500 mL, from 2500 mL (normal functional residual capacity) to 3000 mL. The lung volume values in this diagram are derived from the upright position.

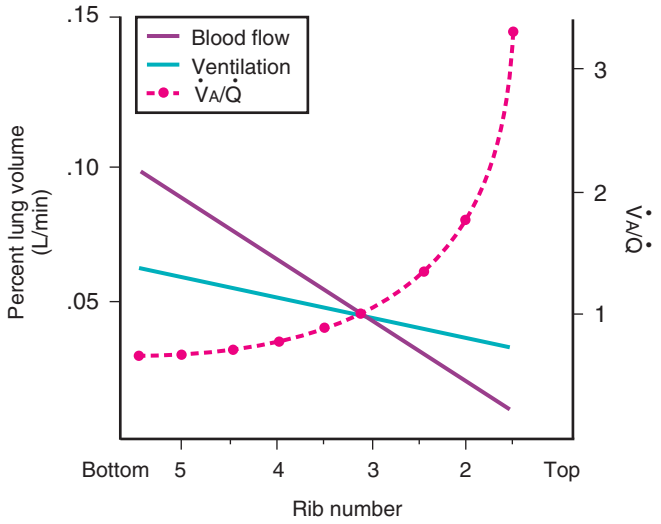

Figure 5-4 Distribution of ventilation and blood flow (left vertical axis) and the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$, right vertical axis) in normal upright lung. Both blood flow and ventilation are expressed in liters per minute per percentage of alveolar volume and have been drawn as smoothed-out linear functions of vertical height. The closed circles mark the $\dot{V}_A/\dot{Q}$ ratios of horizontal lung slices (three of which are shown in Fig. 5-5). A cardiac output of 6 L/min and a total minute ventilation of 5.1 L/min were assumed. (Redrawn with modification from West JB: *Ventilation/Blood flow and gas exchange*, ed 4, Oxford, 1970, Blackwell Scientific.)

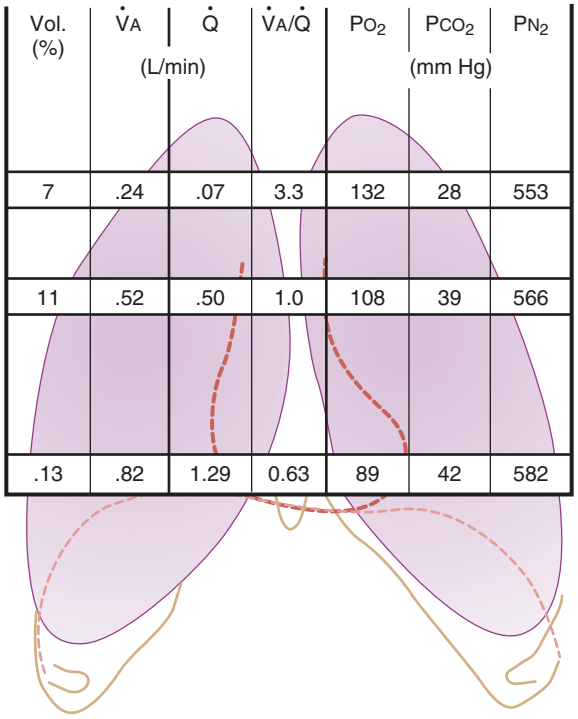

Figure 5-5 Ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$) and the regional composition of alveolar gas. Values for regional flow ($\dot{Q}$), ventilation ($\dot{V}_A$), partial pressure of oxygen (P_{O_2}), and partial pressure of carbon dioxide (P_{CO_2}) were derived from Figure 5-4. Partial pressure of nitrogen (P_{N_2}) represents what remains from total gas pressure (760 mm Hg including water vapor, which equals 47 mm Hg). The percentage volumes (*Vol.*) of the three lung slices are also shown. When compared with the top of the lung, the bottom of the lung has a low $\dot{V}_A/\dot{Q}$ ratio and is relatively hypoxic and hypercapnic. (Redrawn from West JB: Regional differences in gas exchange in the lung of erect man. *J Appl Physiol* 17:893, 1962.)

right vertical axis of Fig. 5-4) decreases rapidly at first and then more slowly.

$\dot{V}_A/\dot{Q}$ best expresses the amount of ventilation relative to perfusion in any given lung region. For example, alveoli at the base of the lung are overperfused in relation to their ventilation ($\dot{V}_A/\dot{Q} < 1$). Figure 5-5 shows the calculated ventilation ($\dot{V}_A$) and blood flow ($\dot{Q}$), the $\dot{V}_A/\dot{Q}$ ratio, and the alveolar partial pressures of oxygen (P_{AO_2}) and carbon dioxide (P_{ACO_2}) for horizontal slices from the top (7% of lung volume), middle (11% of lung volume), and bottom (13% of lung volume) of the lung.[15] P_{AO_2} increases by more than 40 mm Hg, from 89 mm Hg at the base to 132 mm Hg at the apex, whereas P_{CO_2} decreases by 14 mm Hg, from 42 mm Hg at the bottom to 28 mm Hg at the top. Therefore, in keeping with the regional $\dot{V}_A/\dot{Q}$ ratio, the bottom of the lung is relatively hypoxic and hypercapnic compared with the top of the lung.

$\dot{V}_A/\dot{Q}$ inequalities have different effects on arterial CO_2 tension (P_{aCO_2}) than on arterial O_2 tension (P_{aO_2}). Blood passing through underventilated alveoli tends to retain its CO_2 and does not take up enough O_2; blood traversing overventilated alveoli gives off an excessive amount of CO_2 but cannot take up a proportionately increased amount of O_2 because of the flatness of the oxygen-hemoglobin (oxy-Hb) dissociation curve in this region (see Fig. 5-25). A lung with uneven $\dot{V}_A/\dot{Q}$ relationships can eliminate CO_2 from the overventilated alveoli to compensate for the underventilated alveoli. As a result, with uneven $\dot{V}_A/\dot{Q}$ relationships, P_{ACO_2}-to-P_{aCO_2} gradients are small, and P_{AO_2}-to-P_{aO_2} gradients are usually large.

In 1974, Wagner and colleagues described a method of determining the continuous distribution of $\dot{V}_A/\dot{Q}$ ratios within the lung based on the pattern of elimination of a series of intravenously infused inert gases.[16] Gases of differing solubility are dissolved in physiologic saline solution and infused into a peripheral vein until a steady state is achieved (20 minutes). Toward the end of the infusion period, samples of arterial and mixed expired gas are collected, and total ventilation and total cardiac output ($\dot{Q}_T$) are measured. For each gas, the ratio of arterial to mixed venous concentration (retention) and the ratio of expired to mixed venous concentration (excretion) are calculated, and retention-solubility and excretion-solubility curves are drawn. The retention- and excretion-solubility curves can be regarded as fingerprints of the particular distribution of $\dot{V}_A/\dot{Q}$ ratios that give rise to them.

Figure 5-6 shows the types of distributions found in young, healthy subjects breathing air in the semirecumbent position.[17] The distributions of both ventilation and blood flow are relatively narrow. The upper and lower 9% limits shown (vertical interrupted lines) correspond to $\dot{V}_A/\dot{Q}$ ratios of 0.3 and 2.1, respectively. Note that these young, healthy subjects had no blood flow perfusing areas with very low $\dot{V}_A/\dot{Q}$ ratios, nor did they have

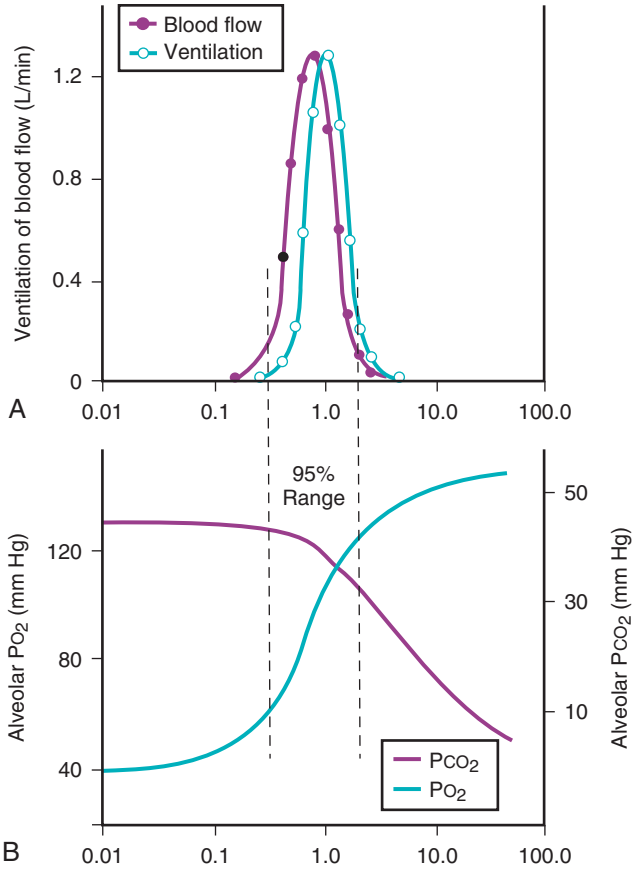

Figure 5-6 **A,** Average distribution of ventilation-perfusion ratios ($\dot{V}_A/\dot{Q}$) in normal, young, semirecumbent subjects. The 95% range (between dashed lines) is 0.3 to 2.1. **B,** Corresponding variations in partial pressures of oxygen *(P_{O_2})* and carbon dioxide *(P_{CO_2})* in alveolar gas. (Redrawn from West JB: Blood flow to the lung and gas exchange. *Anesthesiology* 41:124, 1974.)

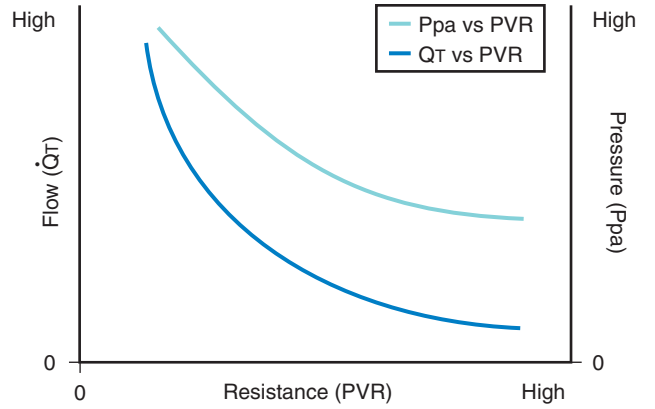

Figure 5-7 Passive changes in pulmonary vascular resistance *(PVR)* as a function of pulmonary artery pressure *(Ppa)* and pulmonary blood flow *($\dot{Q}_T$)*: PVR = Ppa/$\dot{Q}_T$. As $\dot{Q}_T$ increases, Ppa also increases, but to a lesser extent, and PVR decreases. As $\dot{Q}_T$ decreases, Ppa also decreases, but to a lesser extent, and PVR increases. (Redrawn with modification from Fishman AP: Dynamics of the pulmonary circulation. In Hamilton WF, editor: *Handbook of physiology. Section 2: Circulation*, vol 2, Baltimore, 1963, Williams & Wilkins, p 1667.)

any blood flow to unventilated or shunted areas ($\dot{V}_A/\dot{Q}$ = 0) or unperfused areas ($\dot{V}_A/\dot{Q}$ = 8). Figure 5-6 also shows P_{AO_2} and P_{ACO_2} in respiratory units with different $\dot{V}_A/\dot{Q}$ ratios. Within the 95% range of $\dot{V}_A/\dot{Q}$ ratios (i.e., 0.3 to 2.1), P_{O_2} ranges from 60 to 123 mm Hg, whereas the corresponding P_{CO_2} range is 44 to 33 mm Hg.

B. Nongravitational Determinants of Blood Flow Distribution

1. Passive Processes

a. CARDIAC OUTPUT

The pulmonary vascular bed is a high-flow, low-pressure system in health. As $\dot{Q}_T$ increases, pulmonary vascular pressures increase minimally.[18] However, increases in $\dot{Q}_T$ distend open vessels and recruit previously closed vessels. Accordingly, pulmonary vascular resistance (PVR) drops because the normal pulmonary vasculature is quite distensible (and partly because of the addition of previously unused vessels to the pulmonary circulation). As a result of the distensibility of the normal pulmonary circulation, an increase in Ppa increases the radius of the pulmonary vessels, which causes PVR to decrease (Fig. 5-7). Conversely, the opposite effect occurs within the pulmonary vessels during a decrease in $\dot{Q}_T$. As $\dot{Q}_T$ decreases, pulmonary vascular pressures decrease, the radii of the pulmonary vessels are reduced, and PVR consequently increases. The pulmonary vessels of patients with significant pulmonary hypertension are less distensible and act more like rigid pipes. In this setting, Ppa increases much more sharply with any increase in $\dot{Q}_T$ because PVR in these stiff vessels does not decrease significantly due to minimal expansion of their radii.

Understanding the relationships among Ppa, PVR, and $\dot{Q}_T$ during passive events is a prerequisite to recognition of active vasomotion in the pulmonary circulation (see Lung Volume). Active vasoconstriction occurs whenever $\dot{Q}_T$ decreases and Ppa either remains constant or increases. Increased Ppa and PVR have been found to be "a universal feature of acute respiratory failure."[19]

Active pulmonary vasoconstriction can increase Ppa and Ppv, contributing to the formation of pulmonary edema, and in that way it has a role in the pathophysiology of adult respiratory distress syndrome (ARDS). Active vasodilation occurs whenever $\dot{Q}_T$ increases and Ppa either remains constant or decreases. When deliberate hypotension is achieved with sodium nitroprusside, $\dot{Q}_T$ often remains constant or increases, but Ppa decreases, and therefore so does PVR.

b. LUNG VOLUME

Lung volume and PVR have an asymmetric, U-shaped relationship because of the varying effect of lung volume on small intra-alveolar and large extra-alveolar vessels, which in both cases is minimal at functional residual capacity (FRC). FRC is defined as the amount of volume (gas) in the lungs at end-exhalation during normal tidal breathing. Ideally, this means that the patient is inspiring a normal V_T, with minimal or no muscle activity or pressure difference between the alveoli and atmosphere at end-exhalation. Total PVR is increased when lung volume is either increased or decreased from FRC

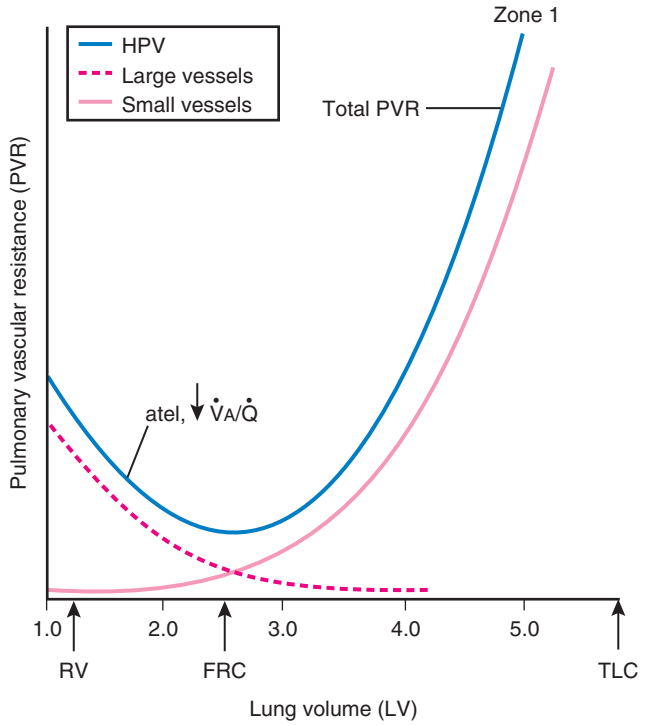

Figure 5-8 Total pulmonary vascular resistance *(PVR)* relates to lung volume as an asymmetric, U-shaped curve. The trough of the curve occurs when lung volume equals functional residual capacity *(FRC)*. Total PVR is the sum of the resistance in small vessels (increased by increasing lung volume *(LV)* and the resistance in large vessels (increased by decreasing LV). The end point for increasing LV toward total lung capacity *(TLC)* is the creation of zone 1 conditions, and the end point for decreasing LV toward residual volume *(RV)* is the creation of low ventilation-perfusion ($\dot{V}_A/\dot{Q}$) and atelectatic *(atel)* areas that demonstrate hypoxic pulmonary vasoconstriction *(HPV)*. (Data fromr Bhavani-Shankar K, Hart NS, Mushlin PS: Negative pressure induced airway and pulmonary injury. *Can J Anaesth* 44:78, 1997; Berggren SM: The oxygen deficit of arterial blood caused by non-ventilating parts of the lung. *Acta Physiol Scand Suppl* 4:11, 1942; and Benumof JL: One lung ventilation: Which lung should be PEEPed? *Anesthesiology* 56:161, 1982.)

(Fig. 5-8).[20–22] The increase in total PVR above FRC results from alveolar compression of small intra-alveolar vessels, which results in an increase in small-vessel PVR (i.e., creation of zone 1 or zone 2).[23] As a relatively small mitigating or counterbalancing effect to the compression of small vessels, the large extra-alveolar vessels can be expanded by the increased tethering of interstitial connective tissue at high lung volumes (and with spontaneous ventilation only—the negativity of perivascular pressure at high lung volumes). The increase in total PVR below FRC results from an increase in the PVR of large extra-alveolar vessels (passive effect). The increase in large-vessel PVR is partly due to mechanical tortuosity or kinking of these vessels (passive effect). In addition, small or grossly atelectatic lungs become hypoxic, and it has been shown that the increased large-vessel PVR in these lungs is also caused by an active vasoconstrictive mechanism known as hypoxic pulmonary vasoconstriction (HPV).[24] The effect of HPV (discussed in greater detail in "Alveolar Gases") is significant whether the chest is open or closed and whether ventilation is by positive pressure or spontaneous.[25]

2. Active Processes and Pulmonary Vascular Tone

Four major categories of active processes affect the pulmonary vascular tone of normal patients: (1) local tissue (endothelial- and smooth muscle–derived) autocrine or paracrine products, which act on smooth muscle (Table 5-1); (2) alveolar gas concentrations (chiefly hypoxia), which also act on smooth muscle; (3) neural influences; and (4) humoral (or hormonal) effects of circulating products within the pulmonary capillary bed. The neural and humoral effects work by means of either receptor-mediated mechanisms involving the autocrine/paracrine molecules listed in Table 5-1 or related mechanisms ultimately affecting the smooth muscle cell.[26] These four interrelated systems, each affecting pulmonary vascular tone, are briefly reviewed in sequence.

a. TISSUE (ENDOTHELIAL- AND SMOOTH MUSCLE–DERIVED) PRODUCTS

The pulmonary vascular endothelium synthesizes, metabolizes, and converts a multitude of vasoactive mediators and plays a central role in the regulation of PVR. However, the main effecter site of pulmonary vascular tone is the pulmonary vascular smooth muscle cell (which both senses and produces multiple pulmonary vasoactive compounds).[27] The autocrine/paracrine molecules listed in Table 5-1 are all actively involved in the regulation of pulmonary vascular tone during various conditions. Numerous additional compounds bind to receptors on the endothelial or smooth muscle cell membranes and modulate the levels (and effects) of these vasoactive molecules.

Nitric oxide (NO) is the predominant endogenous vasodilatory compound. Its discovery by Palmer and

TABLE 5-1
Local Tissue (Autocrine/Paracrine) Molecules Involved in Active Control of Pulmonary Vascular Tone

Molecule	Subtype	Site of Origin	Site of Action	Response
Nitric oxide	NO	Endothelium	Sm. muscle	Vasodilation
Endothelin	ET-1	Endothelium	Sm. muscle (ETA receptor)	Vasoconstriction
			Endothelium (ETB receptor)	Vasodilation
Prostaglandin	PGI_2	Endothelium	Endothelium	Vasodilation
Prostaglandin	$PGF_{2\alpha}$	Endothelium	Sm. muscle	Vasoconstriction
Thromboxane	TXA_2	Endothelium	Sm. muscle	Vasoconstriction
Leukotriene	LTB_4–LTE_4	Endothelium	Sm. muscle	Vasoconstriction

ETA receptor, ET-1 receptor located on the smooth muscle cell membrane; *ETB receptor,* ET-1 receptor located on the endothelial cell membrane; *Sm. muscle,* Pulmonary arteriole smooth muscle cell.

colleagues 25 years ago ended the long search for the so-called endothelium-derived relaxant factor (EDRF).[28] Since then, a massive amount of laboratory and clinical research has demonstrated the ubiquitous nature of NO and its predominant role in vasodilation of both pulmonary and systemic blood vessels.[29] In the pulmonary endothelial cell, L-arginine is converted to L-citrulline by means of nitric oxide synthase (NOS) to produce the small, yet highly reactive NO molecule.[30] Because of its small size, NO can diffuse freely across membranes into the smooth muscle cell, where it binds to the heme moiety of guanylate cyclase (which converts guanosine triphosphate to cyclic guanosine monophosphate [cGMP]).[31] cGMP activates protein kinase G, which dephosphorylates the myosin light chains of pulmonary vascular smooth muscle cells and thereby causes vasodilation.[31] NOS exists in two forms: constitutive (cNOS) and inducible (iNOS). cNOS is permanently expressed in some cells, including pulmonary vascular endothelial cells, and produces short bursts of NO in response to changing levels of calcium and calmodulin and shear stress. The cNOS enzyme is also stimulated by linked membrane-based receptors that bind numerous molecules in the blood (e.g., acetylcholine, bradykinin).[31] In contrast, iNOS is usually produced only as a result of inflammatory mediators and cytokines and, when stimulated, produces large quantities of NO for an extended duration.[31] It is well known that NO is constitutively produced in normal lungs and contributes to the maintenance of low PVR.[32,33]

Endothelin-1 (ET-1) is a pulmonary vasoconstrictor.[34] The endothelins are 21-amino-acid peptides that are produced by a variety of cells. ET-1 is the only family member produced in pulmonary endothelial cells, and it is also produced in vascular smooth muscle cells.[34] ET-1 exerts its major vascular effects through activation of two distinct G protein–coupled receptors (ETA and ETB). ETA receptors are found in the medial smooth muscle layers of the pulmonary (and systemic) blood vessels and in atrial and ventricular myocardium.[34] When stimulated, ETA receptors induce vasoconstriction and cellular proliferation by increasing intracellular calcium.[35] ETB receptors are localized on endothelial cells and some smooth muscle cells.[36] Activation of ETB receptors stimulates the release of NO and prostacyclin, thereby promoting pulmonary vasodilation and inhibiting apoptosis.[30] Bosentan, an ET-1 receptor antagonist, has produced modest improvement in the treatment of pulmonary hypertension.[37] The more selective ETA receptor antagonist, sitaxsentan, showed additional benefit in improving pulmonary hypertension.[38] However, both of these ET-1 receptor antagonists are associated with an increased risk of liver toxicity.[39] In summary, it appears that there is a normal balance between NO and ET-1, with a slight predominance toward NO production and vasodilation in health.

Similarly, various eicosanoids are elaborated by the pulmonary vascular endothelium, with a balance toward the vasodilatory compounds in health. Prostaglandin I_2 (PGI_2), now known as epoprostenol (previously known as prostacyclin), causes vasodilation and is continuously elaborated in small amounts in healthy endothelium. In contrast, thromboxane A_2 and leukotriene B_4 are elaborated under pathologic conditions and are thought to be involved in the pathophysiology of pulmonary artery hypertension (PAH) associated with sepsis and reperfusion injury.[26]

Therapeutically, epoprostenol has been used successfully to decrease PVR in patients with chronic PAH when infused or inhaled.[40,41] Currently, the synthetic PGI_2 (iloprost) is the most commonly used inhaled eicosanoid for reduction of PVR in patients with PAH.[41] Although most patients with chronic PAH are unresponsive to an acute vasodilator challenge with short-acting agents such as epoprostenol, adenosine, or NO,[42] long-term administration of epoprostenol has been shown to decrease PVR in these patients.[43] Furthermore, some patients with previously severe PAH have been weaned from epoprostenol after long-term administration, with dramatically decreased PVR and improved exercise tolerance.[42] The vascular remodeling required to provide such a dramatic reduction in PVR is probably the result of mechanisms besides simple local vasodilation, as predicted by Fishman in an editorial in 1998.[44] One such mechanism that appears to be important is the increased clearance of ET-1 (a potent vasoconstrictor and mitogen) with long-term epoprostenol administration.[45]

b. ALVEOLAR GASES

Hypoxia-induced vasoconstriction constitutes a fundamental difference between pulmonary vessels and all other systemic blood vessels (which vasodilate in the presence of hypoxia). Alveolar hypoxia of in vivo and in vitro whole lung, unilateral lung, lobe, or lobule of lung results in localized pulmonary vasoconstriction. This phenomenon is widely referred to as HPV and was first described more than 65 years ago by Von Euler and Liljestrand.[46] The HPV response is present in all mammalian species and serves as an adaptive mechanism for diverting blood flow away from poorly ventilated to better ventilated regions of the lung and thereby improving $\dot{V}_A/\dot{Q}$ ratios.[47] The HPV response is also critical for fetal development because it minimizes perfusion of the unventilated lung.

The HPV response occurs primarily in pulmonary arterioles of about 200 μm internal diameter (ID) in humans (60 to 700 μm ID in other species).[48] These vessels are advantageously situated anatomically in close relation to small bronchioles and alveoli, which permits rapid and direct detection of alveolar hypoxia. Indeed, blood may actually become oxygenated in small pulmonary arteries because of the ability of O_2 to diffuse directly across the small distance between the contiguous air spaces and vessels.[49] This direct access that gas in the airways has to small arteries makes possible a rapid and localized vascular response to changes in gas composition.

The O_2 tension at the HPV stimulus site (P_{SO_2}) is a function of both P_{AO_2} and mixed venous O_2 pressure ($P\bar{v}O_2$).[50] The P_{SO_2}-HPV response is sigmoid, with a 50% response when P_{AO_2}, $P\bar{v}O_2$, and P_{SO_2} are approximately 30 mm Hg. Usually, P_{AO_2} has a much greater effect than $P\bar{v}O_2$ does because O_2 uptake is from the alveolar space to the blood in the small pulmonary arteries.[50]

Numerous theories have been developed to explain the mechanism of HPV.[46,51–53] Many vasoactive substances have been proposed as mediators of HPV, including leukotrienes, prostaglandins, catecholamines, serotonin, histamine, angiotensin, bradykinin, and ET-1, but none has been identified as the primary mediator. In 1992, Xuan proposed that NO has a pivotal role in modulating PVR.[54] NO is involved, but not precisely in the way that Xuan first proposed. There are multiple sites of O_2 sensing with variable contributions from the NO, ET-1, and eicosanoid systems (described earlier). In vivo, HPV is currently thought to result from the synergistic action of molecules produced in both endothelial cells and smooth muscle cells.[55] However, HPV can proceed in the absence of intact endothelium, suggesting that the primary O_2 sensor is in the smooth muscle cell and that endothelium-derived molecules modulate only the primary HPV response.

The precise mechanism of HPV is still under investigation. However, current data support a mechanism involving the smooth muscle mitochondrial electron transport chain as the HPV sensor (Fig. 5-9).[56] In addition, reactive oxygen species (possibly H_2O_2 or superoxide) are released from complex III of the electron transport chain and probably serve as second messengers to increase calcium in pulmonary artery smooth muscle cells during acute hypoxia.[57] However, alternative (less likely) mechanisms are still being investigated.[58] One alternative hypothesis suggests that smooth muscle microsomal reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidoreductase or sarcolemmal NADPH oxidase is the sensing mechanism.[58] Another, previously popular theory posited that voltage-sensitive potassium (K_V) channels were required for the HPV response. However, K_V channels are no longer believed to be obligate but instead are thought to be attenuators, because a study demonstrated that inhibition of K_V channels failed to inhibit the HPV response.[58]

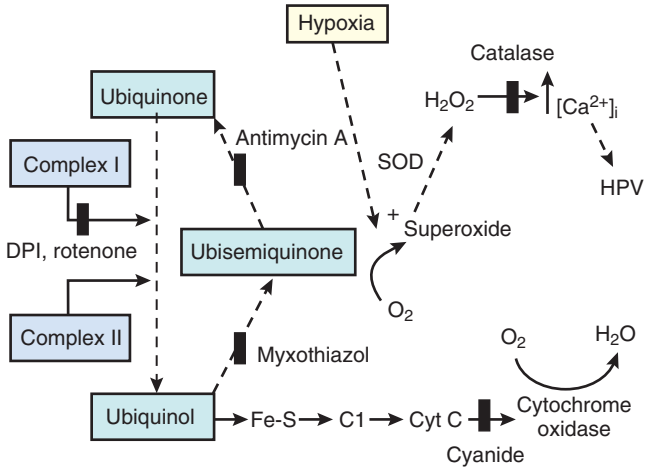

Figure 5-9 Schematic model of the mitochondrial O_2-sensing and effector mechanism probably responsible for hypoxic pulmonary vasoconstriction *(HPV)*. In this model, reactive O_2 species (ROS) are released from electron transport chain complex III and act as second messengers in the hypoxia-induced calcium *(Ca2+)* increase and resultant HPV. The solid arrows represent electron transfer steps; solid bars show sites of electron chain inhibition. Normal mitochondrial electron transport involves the movement of reducing equivalents generated in the Krebs cycle through complex I or II and then through complex III (ubiquinone) and complex IV (cytochrome oxidase). The Q cycle converts the dual electron transfer in complex I and II into a single electron transfer step used in complex IV. The ubisemiquinone (a free radical) created in this process can generate superoxide, which in the presence of superoxide dismutase *(SOD)* produces H_2O_2, the probable mediator of the hypoxia-induced increased $Ca2^+$ and HPV. This process is amplified during hypoxia. Diphenyleneiodonium *(DPI)*, rotenone, and myxothiazol (not shown in figure) are inhibitors of the proximal portion of the electron transport chain. (From Waypa GB, Marks JD, Mack MM, et al: Mitochondrial reactive oxygen species trigger calcium increases during hypoxia in pulmonary artery myocytes. *Circ Res* 91:719, 2002.)

In summary, HPV probably results from a direct action of alveolar hypoxia on pulmonary smooth muscle cells, sensed by the mitochondrial electron transport chain, with reactive O_2 species (probably H_2O_2 or superoxide) serving as second messengers to increase calcium and smooth muscle vasoconstriction. The endothelium-derived products serve to both potentiate (ET-1) and attenuate (NO, PGI_2) the HPV response. Additional mechanisms (humoral and neurogenic influences) may also modulate the baseline pulmonary vascular tone and affect the magnitude of the HPV response.

Elevated P_{ACO_2} has a pulmonary vasoconstrictor effect. Both respiratory acidosis and metabolic acidosis augment HPV, whereas respiratory and metabolic alkalosis cause pulmonary vasodilation and serve to reduce HPV.

The clinical effects of HPV in humans can be classified under three basic mechanisms. First, life at high altitude or whole-lung respiration of a low inspired concentration of O_2 (F_{IO_2}) increases Ppa. This is true for newcomers to high altitude, for the acclimatized, and for natives.[53] The vasoconstriction is considerable; in healthy people breathing 10% O_2, Ppa doubles whereas pulmonary wedge pressure remains constant.[59] The increased Ppa increases perfusion of the apices of the lung (through recruitment of previously unused vessels), which results in gas exchange in a region of lung not normally used (i.e., zone 1). Therefore, with a low F_{IO_2}, P_{AO_2} is greater and the alveolar-arterial O_2 tension difference and the ratio between dead space and tidal volume (V_D/V_T) are less than would be expected or predicted on the basis of a normal (sea level) distribution of ventilation and blood flow. High-altitude pulmonary hypertension is an important component in the development of mountain sickness subacutely (hours to days) and cor pulmonale chronically (weeks to years).[60] There is now good evidence that in both patients with chronic obstructive pulmonary disease (COPD) and those with obstructive sleep apnea (OSA), nocturnal episodes of arterial O_2 desaturation (caused by episodic hypoventilation) are accompanied by elevations in Ppa that can eventually lead to sustained pulmonary hypertension and cor pulmonale.[61]

Second, hypoventilation (low $\dot{V}_A/\dot{Q}$ ratio), atelectasis, or nitrogen ventilation of any region of the lung usually causes a diversion of blood flow away from the hypoxic to the nonhypoxic lung (40% to 50% in one lung, 50% to 60% in one lobe, 60% to 70% in one lobule) (Fig. 5-10).[62] The regional vasoconstriction and blood flow diversion are of great importance in minimizing transpulmonary shunting and normalizing regional $\dot{V}_A/\dot{Q}$ ratios during disease of one lung, one-lung anesthesia (see

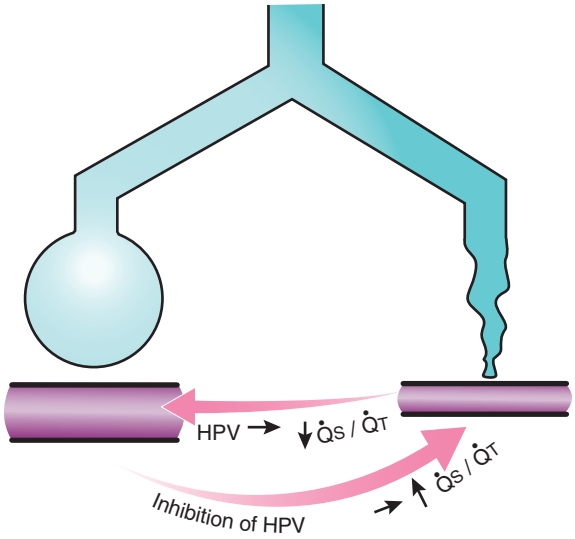

Figure 5-10 Schematic drawing of regional hypoxic pulmonary vasoconstriction *(HPV);* one-lung ventilation is a common clinical example of regional HPV. HPV in the hypoxic atelectatic lung causes redistribution of blood flow away from the hypoxic lung to the normoxic lung, thereby diminishing the amount of shunt flow *($\dot{Q}_S/\dot{Q}_T$)* that can occur through the hypoxic lung. Inhibition of hypoxic lung HPV causes an increase in the amount of shunt flow through the hypoxic lung, thereby decreasing the alveolar oxygen tension (P_{AO_2}).

Chapter 26), inadvertent intubation of a main stem bronchus, and lobar collapse.

Third, in patients who have COPD, asthma, pneumonia, or mitral stenosis but not bronchospasm, administration of pulmonary vasodilator drugs such as isoproterenol, sodium nitroprusside, or nitroglycerin inhibits HPV and causes a decrease in Pa_{O_2} and PVR and an increase in right-to-left transpulmonary shunting.[63] The mechanism for these changes is thought to be deleterious inhibition of preexisting and, in some lesions, geographically widespread HPV without concomitant and beneficial bronchodilation.[63] In accordance with the latter two lines of evidence (one-lung or regional hypoxia and vasodilator drug effects on whole-lung or generalized disease), HPV is thought to divert blood flow away from hypoxic regions of the lung, thereby serving as an autoregulatory mechanism that protects Pa_{O_2} by favorably adjusting regional $\dot{V}_A/\dot{Q}$ ratios. Factors that inhibit regional HPV are extensively discussed elsewhere.[64,65]

c. NEURAL INFLUENCES ON PULMONARY VASCULAR TONE

The three systems used to innervate the pulmonary circulation are the same ones that innervate the airways: the sympathetic, parasympathetic, and nonadrenergic noncholinergic (NANC) systems.[26] Sympathetic (adrenergic) fibers originate from the first five thoracic nerves and enter the pulmonary vessels as branches from the cervical ganglia, as well as from a plexus of nerves arising from the trachea and main stem bronchi. These nerves act mainly on pulmonary arteries down to a diameter of 60 μm.[26] Sympathetic fibers cause pulmonary vasoconstriction through α_1-receptors. However, the pulmonary arteries also contain vasodilatory α_2-receptors and β_2-receptors. The α_1-adrenergic response predominates during sympathetic stimulation, such as occurs with pain, fear, and anxiety.[26] The parasympathetic (cholinergic) nerve fibers originate from the vagus nerve and cause pulmonary vasodilation through an NO-dependent process.[26] Binding of acetylcholine to a muscarinic (M_3) receptor on the endothelial cell increases intracellular calcium and stimulates cNOS.[26] NANC nerves cause pulmonary vasodilation through NO-mediated systems by using vasoactive intestinal peptide as the neurotransmitter. The functional significance of this system is still under investigation.[26]

d. HUMORAL INFLUENCES ON PULMONARY VASCULAR TONE

Numerous molecules are released into the circulation that either affect pulmonary vascular tone (by binding to pulmonary endothelial receptors) or are acted on by the pulmonary endothelium and subsequently become activated or inactivated (Table 5-2). The entire topic of nonrespiratory function of the lung is fascinating but beyond the scope of this chapter. Here, we highlight the effects that circulating molecules have on pulmonary vascular tone.

Although we understand the basic effect that various circulating factors have on pulmonary vascular tone, it is

TABLE 5-2
Effect of Compounds Passing Through Pulmonary Circulation

Molecule	Activated	Unchanged	Inactivated
Amines		Dopamine Epinephrine Histamine	5-Hydroxytryptamine Norepinephrine
Peptides	Angiotensin I	Angiotensin II Oxytocin Vasopressin	Bradykinin Atrial natriuretic peptide Endothelins
Eicosanoids	Arachidonic acid	PGI_2 PGA_2	PGD_2 PGE_1, PGE_2 $PGF_{2\alpha}$ Leukotrienes
Purine derivatives			Adenosine ATP, ADP, AMP

ADP, Adenosine diphosphate; *AMP,* adenosine monophosphate; *ATP,* adenosine triphosphate; *PG,* prostaglandin.

unlikely that these compounds are modulators of pulmonary vascular tone in normal circumstances. However, they have marked effects during disease (e.g., ARDS, sepsis).

Endogenous catecholamines (epinephrine and norepinephrine) bind to both α_1- (vasoconstrictor) and β_2- (vasodilator) receptors on the pulmonary endothelium, but when elaborated in high concentration, they have a predominant α_1 (vasoconstrictor) effect. The same is true for exogenously administered catecholamines. Other amines (e.g., histamine, serotonin) are elaborated systemically or locally after various challenges and have variable effects on PVR. Histamine can be released from mast cells, basophils, and elsewhere. When histamine binds directly to H_1 receptors on endothelium, NO-mediated vasodilation occurs (as seen after epinephrine-induced pulmonary vasoconstriction). Direct stimulation of H_2 receptors on smooth muscle cell membranes also causes vasodilation. In contrast, stimulation of H_1 receptors on the smooth muscle membrane results in vasoconstriction. Serotonin (5-hydroxytryptamine) is a potent vasoconstrictor that can be elaborated from activated platelets (e.g., after pulmonary embolism) and can lead to acute severe pulmonary hypertension.[66]

Numerous peptides circulate and cause either pulmonary vasodilation (e.g., substance P, bradykinin, vasopressin [a systemic vasoconstrictor]) or vasoconstriction (e.g., neurokinin A, angiotensin). These peptides produce clinically detectable effects on PVR only when administered in high concentration, such as with exogenous administration or in disease.

Two other classes of molecules must be mentioned for completeness: eicosanoids (whose vasoactive effects were discussed earlier) and purine nucleosides (which are similarly highly vasoactive).[26] Adenosine is a pulmonary vasodilator in normal subjects, whereas adenosine triphosphate (ATP) has a variable normalizing effect, depending on baseline pulmonary vascular tone.[67]

3. Alternative (Nonalveolar) Pathways of Blood Flow Through the Lung

Blood can use several possible pathways to travel from the right side of the heart to the left without being fully oxygenated or oxygenated at all. Blood flow through poorly ventilated alveoli (regions of low $\dot{V}_A/\dot{Q}$ with an F_{IO_2} <0.3 have a right-to-left shunt effect on oxygenation) and blood flow through nonventilated alveoli (in atelectatic or consolidated regions, $\dot{V}_A/\dot{Q} = 0$ at all F_{IO_2} values) are sources of right-to-left shunting. Low-$\dot{V}_A/\dot{Q}$ and atelectatic lung units occur in conditions in which the FRC is less than the closing capacity (CC) of the lung (see "Lung Volumes, Functional Residual Capacity, and Closing Capacity").

Several right-to-left blood flow pathways through the lungs and heart do not pass by or involve the alveoli at all. The bronchial and pleural circulations originate from systemic arteries and empty into the left side of the heart without being oxygenated; these circulations constitute the 1% to 3% true right-to-left shunt normally present. With chronic bronchitis, the bronchial circulation may carry 10% of the cardiac output, and with pleuritis, the pleural circulation may carry 5% of the cardiac output. Consequently, as much as a 10% or a 5% obligatory right-to-left shunt may be present, respectively, under these conditions.

Intrapulmonary arteriovenous anastomoses are normally closed, but in the presence of acute pulmonary hypertension, such as may be caused by a pulmonary embolus, they may open and result in a direct increase in right-to-left shunting. The foramen ovale is patent (PFO) in 20% to 30% of individuals but it usually remains functionally closed because left atrial pressure normally exceeds right atrial pressure. However, any condition that causes right atrial pressure to be greater than left atrial pressure may produce a right-to-left shunt, with resultant hypoxemia and possible paradoxical embolization. Such conditions include the use of high levels of PEEP, pulmonary embolization, pulmonary hypertension, COPD, pulmonary valvular stenosis, congestive heart failure, and postpneumonectomy states.[68] Even such common events as mechanical ventilation and reaction to the presence of an endotracheal tube (ETT) during the excitement phase of emergence from anesthesia have caused right-to-left shunting across a PFO and severe arterial desaturation (with the potential for paradoxical embolization).[69,70]

Transesophageal echocardiography has been demonstrated to be a sensitive modality for diagnosing a PFO in anesthetized patients with elevated right atrial pressure.[71] Esophageal to mediastinal to bronchial to pulmonary vein pathways have been described and may explain in part the hypoxemia associated with portal hypertension and cirrhosis. There are no known conditions that selectively increase thebesian channel blood flow. (Thebesian vessels nourish the left ventricular myocardium and originate and empty into the left side of the heart.)

C. Nongravitational Determinants of Pulmonary Compliance, Resistance, Lung Volume, Ventilation, and Work of Breathing

1. Pulmonary Compliance

For air to flow into the lungs, a pressure gradient (ΔP) must be developed to overcome the elastic resistance of the lungs and chest wall to expansion. These structures are arranged concentrically, and their elastic resistance is therefore additive. The relationship between ΔP and the resultant volume increase (ΔV) of the lungs and thorax is independent of time and is known as total compliance (C_T), as expressed in the following equation:

$$C_T\ (\text{L/cm } H_2O) = \Delta V\ (\text{L})/\Delta P\ (\text{cm } H_2O) \qquad (1)$$

The C_T of lung plus chest wall is related to the individual compliance of the lungs (C_L) and of the chest wall (C_{CW}) according to the following expression:

$$1/C_T = 1/C_L + 1/C_{CW}\ [\text{or } C_T = (C_L)(C_{CW})/C_L + C_{CW}] \qquad (2)$$

Normally, C_L and C_{CW} each equal 0.2 L/cm H_2O; hence, C_T = 0.1 L/cm H_2O. To determine C_L, ΔV and the transpulmonary pressure gradient (P_A – Ppl, the ΔP for the lung) must be known; to determine C_{CW}, ΔV and the

transmural pressure gradient (Ppl – $P_{ambient}$, the ΔP for the chest wall) must be known; and to determine C_T, ΔV and the transthoracic pressure gradient (PA – $P_{ambient}$, the ΔP for the lung and chest wall together) must be known. In clinical practice, only C_T is measured, which can be done dynamically or statically, depending on whether a peak or a plateau inspiratory ΔP (respectively) is used for the C_T calculation.

During a positive- or negative-pressure inspiration of sufficient duration, transthoracic ΔP first increases to a peak value and then decreases to a lower plateau value. The peak transthoracic pressure value is the pressure required to overcome both elastic and airway resistance (see "Airway Resistance"). Transthoracic pressure decreases to a plateau value after the peak value because with time, gas is redistributed from stiff alveoli (which expand only slightly and therefore have only a short inspiratory period) into more compliant alveoli (which expand a great deal and therefore have a long inspiratory period). Because the gas is redistributed into more compliant alveoli, less pressure is required to contain the same amount of gas, which explains why the pressure decreases. In practical terms, dynamic compliance is the volume change divided by the peak inspiratory transthoracic pressure, and static compliance is the volume change divided by the plateau inspiratory transthoracic pressure. Therefore, static C_T is usually greater than dynamic C_T, because the former calculation uses a smaller denominator (lower pressure) than the latter. However, if the patient is receiving PEEP, that pressure must first be subtracted from the peak or plateau pressure before thoracic compliance is calculated (i.e., compliance is equal to the volume delivered divided by the peak or plateau pressure – PEEP).

Alveolar pressure deserves special comment. The alveoli are lined with a layer of liquid. When a curved surface (a sphere or cylinder, such as the alveoli, bronchioles, and bronchi) is lined with liquid, a surface tension is created that tends to make the surface area that is exposed to the atmosphere as small as possible. Simply stated, water molecules crowd much closer together on the surface of a curved layer of water than elsewhere in the fluid. As lung or alveolar size decreases, the degree of curvature and the retractive surface tension increase.

According to the Laplace expression, shown in equation (3), the pressure in an alveolus (P, in dynes per square centimeter) is higher than ambient pressure by an amount that depends on the surface tension of the lining liquid (T, in dynes per centimeter) and the radius of curvature of the alveolus (R, in centimeters). This relationship is expressed in the following equation:

$$P = 2T/R \tag{3}$$

Although surface tension contributes to the elastic resistance and retractive forces of the lung, two difficulties must be resolved. First, the pressure inside small alveoli should be higher than that inside large alveoli, a conclusion that stems directly from the Laplace equation (R in the denominator). From this reasoning, one would expect a progressive discharge of each small alveolus into a larger one until eventually only one gigantic alveolus would be left (Fig. 5-11A). The second problem concerns the relationship between lung volume and transpulmonary ΔP (P_A – Ppl). Theoretically, the retractive forces of the lung should increase as lung volume decreases. If this were true, lung volume would decrease in a vicious circle, with an increasingly progressive tendency to collapse as lung volume diminishes.

These two problems are resolved by the fact that the surface tension of the fluid lining the alveoli is variable and decreases as its surface area is reduced. The surface tension of alveolar fluid can reach levels that are well below the normal range for body fluids such as water and plasma. When an alveolus decreases in size, the surface tension of the lining fluid falls to an extent greater than the corresponding reduction in radius; as a result, the transmural pressure gradient (equal to 2T/R) diminishes. This explains why small alveoli do not discharge their contents into large alveoli (see Fig. 5-11B) and why the elastic recoil of small alveoli is less than that of large alveoli.

The substance responsible for the reduction (and variability) in alveolar surface tension is secreted by the intra-alveolar type II pneumocyte; it is a lipoprotein called *surfactant*, which floats as a 50-Å-thick film on the surface of the fluid lining the alveoli. When the surface film is reduced in area and the concentration of surfactant at the surface is increased, the surface-reducing pressure is increased and counteracts the surface tension of the fluid lining the alveoli.

2. Airway Resistance

For air to flow into the lungs, a pressure gradient (ΔP) must also be developed to overcome the nonelastic airway resistance (R_{AW}) of the lungs to airflow. The R_{AW} describes the relationship between ΔP and the rate of airflow ($\dot{V}$).

$$R\ (\text{cm } H_2O/\text{L/sec}) = \frac{\Delta P\ (\text{cm } H_2O)}{\Delta \dot{V}\ (\text{L/sec})} \tag{4}$$

The ΔP along the airway depends on the caliber of the airway and the rate and pattern of airflow. There are three main patterns of airflow. Laminar flow occurs when the gas passes down parallel-sided tubes at less than a certain critical velocity. With laminar flow, the pressure drop down the tube is proportional to the flow rate and may be calculated from the equation derived by Poiseuille:

$$\Delta P = \dot{V} \times 8\ L \times \mu/\pi r^4 \tag{5}$$

where ΔP is the pressure drop (in cm H_2O), $\dot{V}$ is the volume flow rate (in mL/sec), μ is viscosity (in poises), L is the length of the tube (in cm), and r is the radius of the tube (in cm).

When flow exceeds the critical velocity, it becomes turbulent. The significant feature of turbulent flow is that the pressure drop along the airway is no longer directly proportional to the flow rate but is proportional to the square of the flow rate according to equation (6) for turbulent flow:

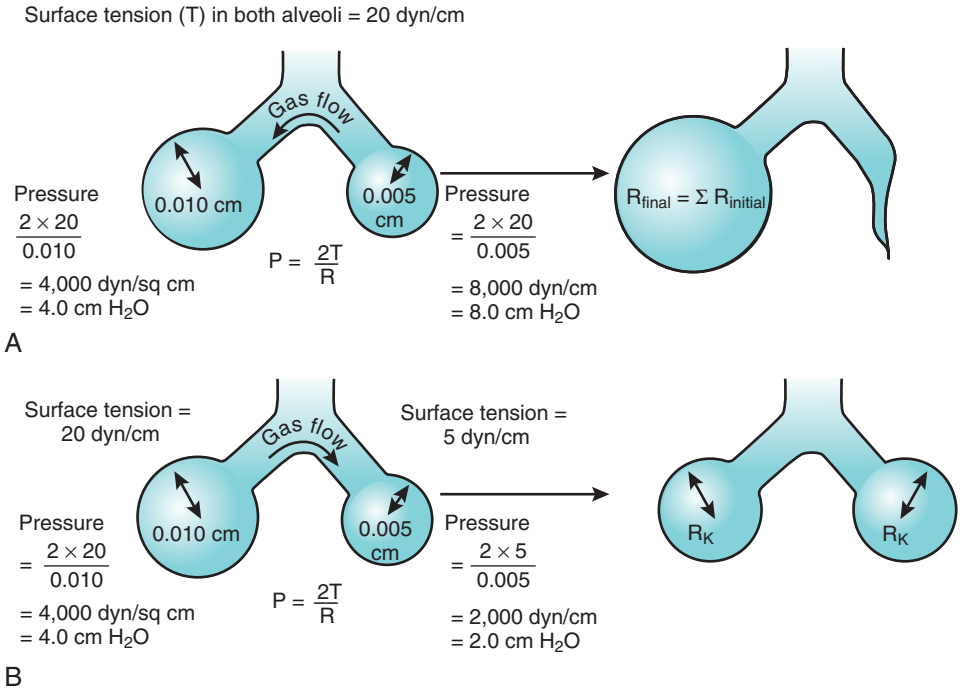

Figure 5-11 Relationship between surface tension *(T)*, alveolar radius *(R)*, and alveolar transmural pressure *(P)*. The left side of the diagrams shows the starting condition, the right side shows the expected result in alveolar size (using the Laplace equation to calculate the starting pressure). In **A,** the surface tension in the fluid lining both the large and the small alveolus is the same (no surfactant). Accordingly, the direction of gas flow is from the higher-pressure small alveolus to the lower-pressure large alveolus, which results in one large alveolus ($R_{final} = \Sigma R_{initial}$). **B** shows the expected changes in surface tension when surfactant lines the alveolus (less tension in the smaller alveolus). The direction of gas flow is from the larger to the smaller alveolus until the two are of equal size and are volume stable (R_K). *K*, Constant; *ΣR*, sum of all individual radii.

$$\Delta P = \dot{V}^2 pfL/4\pi^2 r^5 \quad (6)$$

where ΔP is the pressure drop (in cm H_2O), $\dot{V}$ is the volume flow rate (in mL/sec), ρ is the density of the gas (or liquid), *f* is a friction factor that depends on the roughness of the tube wall, and r is the radius of the tube (in cm).[72] With increases in turbulent flow (or orifice flow, as described in the next paragraph), ΔP increases much more than $\dot{V}$ and therefore R_{AW} also increases more, as predicted by equation (4).

Orifice flow occurs at severe constrictions such as a nearly closed larynx or a kinked ETT. In these situations, the pressure drop is also proportional to the square of the flow rate, but density replaces viscosity as the important factor in the numerator. This explains why a low-density gas such as helium diminishes the resistance to flow (by threefold in comparison with air) in severe obstruction of the upper airway.

Because the total cross-sectional area of the airways increases as branching occurs, the velocity of airflow decreases in the distal airways; laminar flow is therefore chiefly confined to the airways below the main bronchi. Orifice flow occurs at the larynx, and flow in the trachea is turbulent during most of the respiratory cycle. By examining the components that constitute each of the preceding airway pressure equations, one can see that many factors can affect the pressure drop down the airways during respiration. However, variations in diameter of the smaller bronchi and bronchioles are particularly critical, because bronchoconstriction may convert laminar flow to turbulent flow and the pressure drop along the airways can become much more closely related to the flow rate.

3. Different Regional Lung Time Constants

Thus far, the compliance and airway resistance properties of the chest have been discussed separately. In the following analysis, pressure at the mouth is assumed to increase suddenly to a fixed positive value (Fig. 5-12) that overcomes both elastic and airway resistance and to be maintained at this value during inflation of the lungs.[73] The ΔP required to overcome nonelastic airway resistance is the difference between the fixed mouth pressure and the instantaneous height of the dashed line in Figure 5-12 and is proportional to the flow rate during most of the respiratory cycle.

The ΔP required to overcome nonelastic airway resistance is maximal initially but then decreases exponentially (see Fig. 5-12, A, hatched lines). The rate of filling therefore also declines in an approximately exponential manner. The remainder of the pressure gradient overcomes the elastic resistance (the instantaneous height of the dashed line in Fig. 5-12A) and is proportional to the change in lung volume. The ΔP required to overcome elastic resistance is minimal initially but then increases exponentially, as does lung volume. Alveolar filling ceases (lung volume remains constant) when the pressure

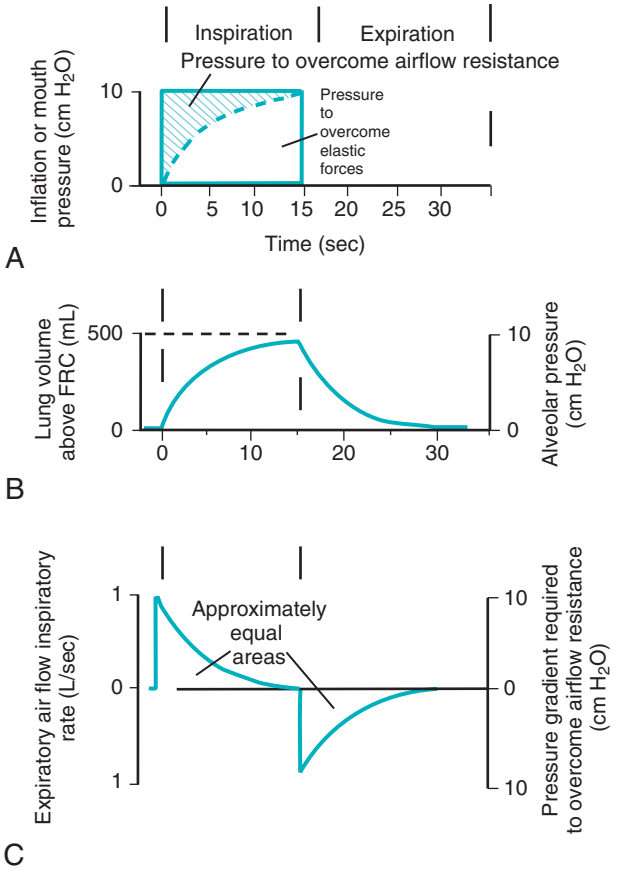

Figure 5-12 Artificial ventilation by intermittent application of constant pressure (square wave) followed by passive expiration. The pressure required to overcome airway resistance (*hatched lines* in **A**) and the airflow rate (in **C**) from equation (4) in the text are proportional to one another and decrease exponentially (assuming that resistance to airflow is constant). The pressure required to overcome the elastic forces (*height of the dashed line* in **A**) and lung volume **(B)** are proportional to one another and increase exponentially. Values shown are typical for an anesthetized supine paralyzed patient: total dynamic compliance, 50 mL/cm H_2O; pulmonary resistance, 3 cm H_2O/L/sec; apparatus resistance, 7 cm H_2O/L/sec; total resistance, 10 cm H_2O/L/sec; time constant, 0.5 seconds. *FRC,* Functional residual capacity. (Redrawn from Lumb AB: Artificial ventilation. In Lumb AB, editor: *Nunn's applied respiratory physiology,* ed 5, London, 2000, Butterworths, p 590.)

resulting from the retractive elastic forces balances the applied (mouth) pressure (see Fig. 5-12A, dashed line).

Because only a finite time is available for alveolar filling and because alveolar filling occurs in an exponential manner, the degree of filling obviously depends on the duration of the inspiration. The rapidity of change in an exponential curve can be described by its time constant τ, which is the time required to complete 63% of an exponentially changing function if the total time allowed for the function change is unlimited (2τ = 87%, 3τ = 95%, and 4τ = 98%). For lung inflation, $\tau = C_T \times R$; normally, C_T = 0.1 L/cm H_2O, R = 2.0 cm H_2O/L/sec, τ = 0.2 sec, and 3τ = 0.6 sec.

When this equation is applied to individual alveolar units, the time taken to fill such a unit clearly increases as airway resistance increases. The time required to fill an alveolar unit also increases as compliance increases, because a greater volume of air is transferred into a more compliant alveolus before the retractive force equals the applied pressure. The compliance of individual alveoli differs from top to bottom of the lung, and the resistance of individual airways varies widely depending on their length and caliber. Therefore, various time constants for inflation exist throughout the lung.

4. Pathways of Collateral Ventilation

Collateral ventilation is another nongravitational determinant of the distribution of ventilation. Four pathways of collateral ventilation are known. First, interalveolar communications (pores of Kohn) exist in most species; their number ranges from 8 to 50 per alveolus, and they may increase with age and with the development of obstructive lung disease. Their precise role has not been defined, but they probably function to prevent hypoxia in neighboring but obstructed lung units. Second, distal bronchiole-to-alveolus communications are known to exist (channels of Lambert); their function in vivo is speculative but may be similar to that of the pores of Kohn. Third, respiratory bronchiole–to–terminal bronchiole connections have been found in adjacent lung segments (channels of Martin) in healthy dogs and in humans with lung disease. Fourth, interlobar connections exist; the functional characteristics of interlobar collateral ventilation through these connections have been described in dogs,[74] and they have been observed in humans as well.[75]

5. Work of Breathing

The pressure-volume characteristics of the lung also determine the work of breathing (WOB). Because

$$\begin{aligned} \text{Work} &= \text{Force} \times \text{Distance} \\ \text{Force} &= \text{Pressure} \times \text{Area} \\ \text{Distance} &= \text{Volume/Area} \end{aligned} \tag{7}$$

work is defined by the equation

$$\text{Work} = (\text{Pressure} \times \text{Area})(\text{Volume/Area}) = \text{Pressure} \times \text{Volume} \tag{8}$$

and ventilatory work may be analyzed by plotting pressure against volume.[76] In the presence of increased airway resistance or decreased C_L, increased transpulmonary pressure is required to achieve a given V_T with a consequent increase in the WOB. The metabolic cost of the WOB at rest constitutes only 1% to 3% of the total O_2 consumption in healthy subjects, but it is increased considerably (up to 50%) in patients with pulmonary disease.

Two different pressure-volume diagrams are shown in Figure 5-13. During normal inspiration, transpulmonary pressure increases from 0 to 5 cm H_2O while 500 mL of air is drawn into the lung. Potential energy is stored by the lung during inspiration and is expended during expiration; as a consequence, the entire expiratory cycle is passive. The hatched area plus the triangular area ABC represents pressure multiplied by volume and is the WOB during one breath. Line AB is the lower section of the pressure-volume curve of Figure 5-13. The triangular

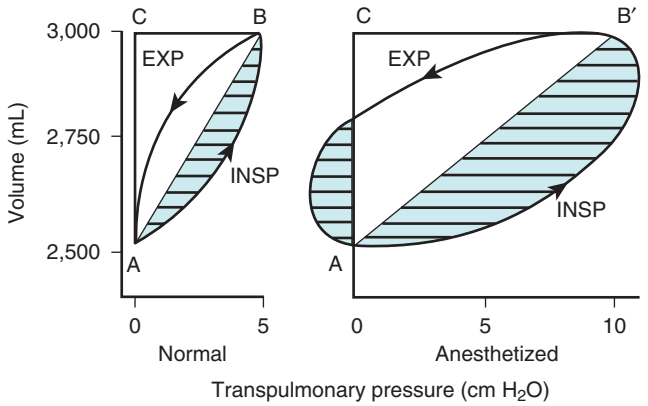

Figure 5-13 Lung volume plotted against transpulmonary pressure in a pressure-volume diagram for a healthy awake patient (Normal) and an anesthetized patient. The lung compliance of the awake patient (slope of line AB = 100 mL/cm H_2O) equals that shown for the small dependent alveoli in Figure 5-3. The lung compliance of the anesthetized patient (slope of line AB′ = 50 mL/cm H_2O) equals that shown for the medium midlung alveoli in Figure 5-3 and for the anesthetized patient in Figure 5-12. The total area within the oval and triangles has the dimensions of pressure multiplied by volume and represents the total work of breathing. The hatched areas to the right of lines AB and AB′ represent the active inspiratory work necessary to overcome resistance to airflow during inspiration *(INSP)*. The hatched area to the left of the triangle AB′C represents the active expiratory work necessary to overcome resistance to airflow during expiration *(EXP)*. Expiration is passive in the healthy subject because sufficient potential energy is stored during inspiration to produce expiratory airflow. The fraction of total inspiratory work necessary to overcome elastic resistance is shown by the triangles ABC and AB′C. The anesthetized patient has decreased compliance and increased elastic resistance work (triangle AB′C) compared with the healthy patient's compliance and elastic resistance work (triangle ABC). The anesthetized patient represented in this figure has increased airway resistance to both inspiratory and expiratory work.

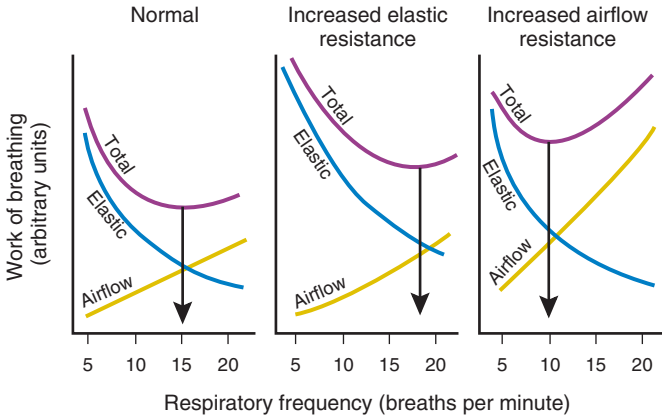

Figure 5-14 The diagrams show the work done against elastic and airflow resistance, both separately and summed to indicate the total work of breathing at different respiratory frequencies. The total work of breathing has a minimal value at approximately 15 breaths/min under normal circumstances. For the same minute volume, minimal work is performed at higher frequencies with stiff (less compliant) lungs and at lower frequencies when airflow resistance is increased. (Redrawn with modification from Lumb AB: Pulmonary ventilation: Mechanisms and the work of breathing. In Lumb AB, editor: *Nunn's applied respiratory physiology*, ed 5, London, 2000, Butterworths, p 128.)

area ABC is the work required to overcome elastic forces (C_T), whereas the hatched area is the work required to overcome airflow or frictional resistance (R). The second graph applies to an anesthetized patient with diffuse obstructive airway disease resulting from the accumulation of mucous secretions. There is a marked increase in both the elastic (triangle AB′C) and the airway (hatched area) resistive components of respiratory work. During expiration, only 250 mL of air leaves the lungs during the passive phase when intrathoracic pressure reaches the equilibrium value of 0 cm H_2O. Active effort-producing work is required to force out the remaining 250 mL of air, and intrathoracic pressure actually becomes positive.

The full WOB over time must include the ventilatory frequency. The following equation depicts the variables included in the WOB equation:

$$WOB = \dot{V}_E \times \frac{R_{AW}}{C_L} \quad (9)$$

Evaluating each component in the WOB equation, $\dot{V}_E$ is the minute ventilation ($rr \times V_T$) required to achieve a normal $Paco_2$. When patients have an increased CO_2 production (as occurs with fever) the $\dot{V}_E$, and hence the WOB, will need to be higher. When the dead space (either alveolar or anatomic) is increased, the $\dot{V}_E$ will need to increase to achieve a normal $Paco_2$. Similarly, when airway resistance (R_{AW}) is increased, or compliance (C_L) is decreased, there will be a corresponding increase in the WOB.

Furthermore, for any constant minute volume, the work done against elastic resistance is increased when breathing is deep and slow. On the other hand, the work done against airflow resistance is increased when breathing is rapid and shallow. If the two components are summed and the total work is plotted against respiratory frequency, there is an optimal respiratory frequency at which the total WOB is minimal (Fig. 5-14).[77] In patients with diseased lungs in which elastic resistance is high (e.g., pulmonary fibrosis, pulmonary edema, infants), the optimal frequency is increased, and rapid, shallow breaths are favored. As with other muscles, respiratory muscles can become fatigued, especially with rapid, shallow breathing.[78] When airway resistance is high (e.g., asthma, obstructive lung disease), the optimal frequency is decreased, and slow, deep breaths are favored. Although the optimal frequency is slow (allowing a prolonged expiratory phase), a rapid, shallow breathing pattern also develops in these patients when fatigued and further exacerbates their primary (airway resistance) problem.[78]

6. Lung Volumes, Functional Residual Capacity, and Closing Capacity

a. LUNG VOLUMES AND FUNCTIONAL RESIDUAL CAPACITY

FRC is defined as the volume of gas in the lung at the end of a normal expiration when there is no airflow and P_A equals ambient pressure. Under these conditions, expansive chest wall elastic forces are exactly balanced by retractive lung tissue elastic forces (Fig. 5-15).[79]

The expiratory reserve volume is part of FRC; it is the additional gas beyond the end-tidal volume that can be

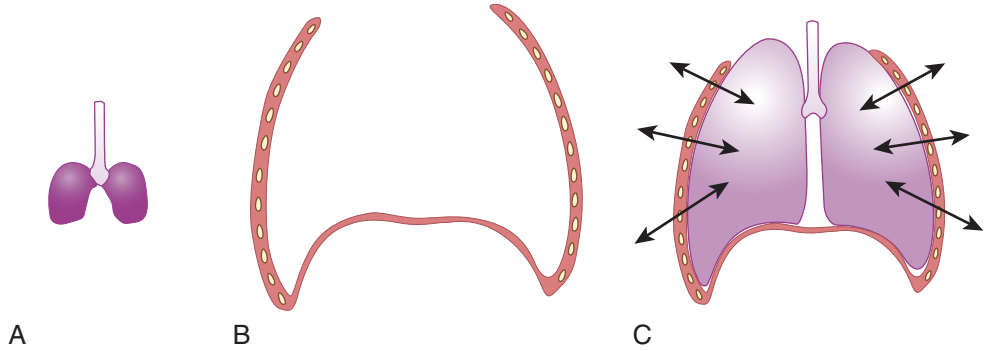

Figure 5-15 **A,** The resting state of normal lungs when they are removed from the chest cavity; that is, elastic recoil causes total collapse. **B,** The resting state of a normal chest wall and diaphragm when the thoracic apex is open to the atmosphere and the thoracic contents are removed. **C,** The lung volume that exists at the end of expiration is the functional residual capacity (FRC). At FRC, the elastic forces of the lung and chest walls are equal and in opposite directions. The pleural surfaces link these two opposing forces. (Redrawn with modification from Shapiro BA, Harrison RA, Trout CA: The mechanics of ventilation. In Shapiro BA, Harrison RA, Trout CA, editors: *Clinical application of respiratory care,* ed 3, Chicago, 1985, Year Book, p 57.)

consciously exhaled, resulting in the minimum volume of lung possible, known as residual volume. Therefore, FRC equals residual volume plus expiratory reserve volume (Fig. 5-16). With regard to the other lung volumes shown in Figure 5-16, V_T, vital capacity, inspiratory capacity, inspiratory reserve volume, and expiratory reserve volume can be measured by simple spirometry. Total lung capacity (TLC), FRC, and residual volume contain a fraction (residual volume) that cannot be measured by simple spirometry. However, if one of these three volumes is measured, the others can easily be derived, because the other lung volumes, which relate these three volumes to one another, can be measured by simple spirometry.

Residual volume, FRC, and TLC can be measured by any of three techniques: (1) nitrogen washout, (2) inert gas dilution (e.g., helium washin), and (3) total-body plethysmography. The first method, the nitrogen washout technique, is based on measuring expired nitrogen concentrations before and after the patient breathes pure O_2 for several minutes; the difference is the total quantity of nitrogen eliminated. If, for example, 2 L of N_2 is eliminated and the initial alveolar N_2 concentration was 80%, the initial volume of the lung was 2.5 L. The second method, the inert gas dilution technique, uses the washin of an inert tracer gas such as helium. If 50 mL of helium is introduced into the lungs and, after equilibration, the helium concentration is found to be 1%, the volume of the lung is 5 L. The third method, the total-body plethysmography technique, uses Boyle's law ($P_1V_1 = P_2V_2$, where P_1= initial pressure, V_1 = initial volume). The subject is confined within a gas-tight box (plethysmograph) so that changes in the volume of the body during respiration may be readily determined as a change in pressure within the sealed box. Although each technique has technical limitations, all are based on sound physical and physiologic principles and provide accurate results in normal patients. Disparity between FRC as measured in the body plethysmograph and as determined by the helium dilution method is often used as a way of detecting large, nonventilating air-trapped blebs.[80] Obviously, there are difficulties in applying the body plethysmograph to anesthetized patients.

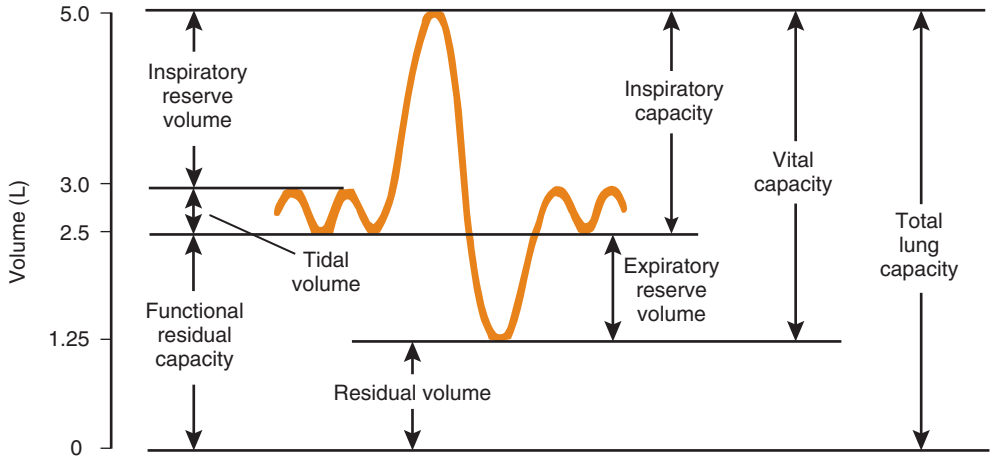

Figure 5-16 The dynamic lung volumes that can be measured by simple spirometry are tidal volume, inspiratory reserve volume, expiratory reserve volume, inspiratory capacity, and vital capacity. The static lung volumes are residual volume, functional residual capacity, and total lung capacity. Static lung volumes cannot be measured by simple spirometry and require separate methods of measurement (e.g., inert gas dilution, nitrogen washout, total-body plethysmography).

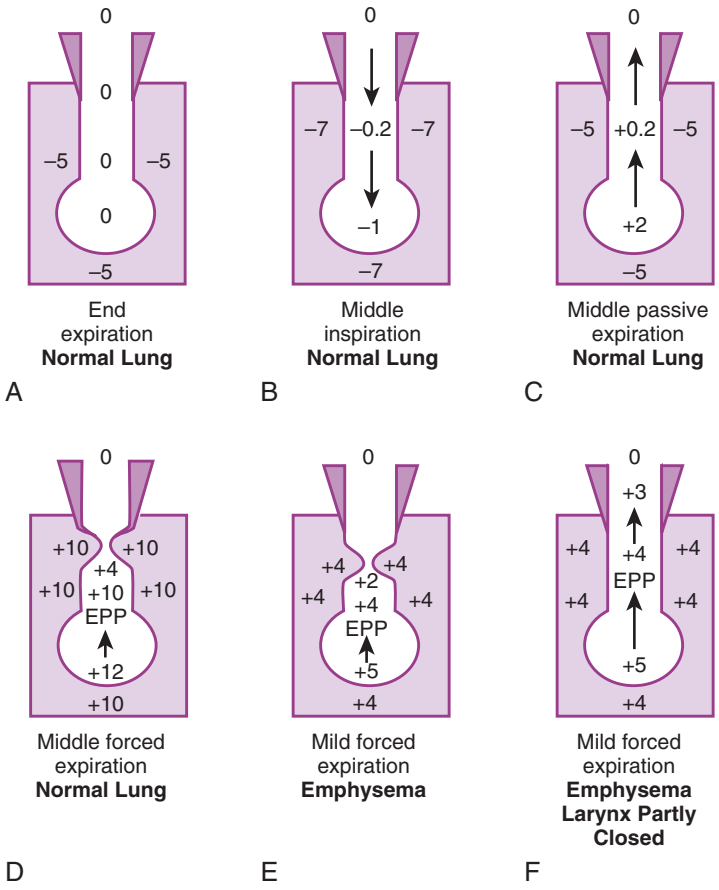

Figure 5-17 Pressure gradients across the airways. The airways consist of a thin-walled intrathoracic portion (near the alveoli) and a more rigid (cartilaginous) intrathoracic and extrathoracic portion. During expiration, the pressure from elastic recoil is assumed to be +2 cm H_2O in normal lungs (**A** through **D**) and +1 cm H_2O in abnormal lungs (**E** and **F**). The total pressure inside the alveolus is pleural pressure plus elastic recoil. The arrows indicate the direction of airflow. *EPP,* Equal pressure point. See text for explanation. (Redrawn with modification from Benumof JL: *Anesthesia for thoracic surgery,* ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

b. AIRWAY CLOSURE AND CLOSING CAPACITY

As discussed earlier (see "Distribution of Ventilation"), Ppl increases from the top to the bottom of the lung and determines regional alveolar size, compliance, and ventilation. Of even greater importance to the anesthesiologist is the recognition that these gradients in Ppl may lead to airway closure and collapse of alveoli.

PATIENT WITH NORMAL LUNGS. Figure 5-17A illustrates the normal resting end-expiratory (FRC) position of the lung–chest wall combination. The distending transpulmonary ΔP and the intrathoracic air passage transmural ΔP are 5 cm H_2O, and the airways remain patent. During the middle of a normal inspiration (see Fig. 5-17B), there is an increase in transmural ΔP (to 6.8 cm H_2O) that encourages distention of the intrathoracic air passages. During the middle of a normal expiration (see Fig. 5-17C), expiration is passive; P_A is attributable only to the elastic recoil of the lung (2 cm H_2O), and there is a decrease (to 5.2 cm H_2O) but still a favorable (distending) intraluminal transmural ΔP. During the middle of a severe forced expiration (see Fig. 5-17D), Ppl increases far higher than atmospheric pressure and is communicated to the alveoli, which have a pressure that is still higher because of the elastic recoil of the alveolar septa (an additional 2 cm H_2O).

At high gas flow rates, the pressure drop down the air passage is increased, and there is a point at which intraluminal pressure equals either the surrounding parenchymal pressure or Ppl; that point is termed the *equal pressure point* (EPP). If the EPP occurs in small intrathoracic air passages (distal to the 11th generation, the airways have no cartilage and are called *bronchioles*), they may be held open at that particular point by the tethering effect of the elastic recoil of the immediately adjacent or surrounding lung parenchyma. If the EPP occurs in large extrathoracic air passages (proximal to the 11th generation, the airways have cartilage and are called *bronchi*), they may be held open at that particular point by their cartilage. Downstream of the EPP (in either small or large airways), transmural ΔP is reversed (–6 cm H_2O), and airway closure occurs. Thus, the patency of airways distal to the 11th generation is a function of lung volume, and the patency of airways proximal to the 11th generation is a function of intrathoracic (pleural) pressure. In extrathoracic bronchi with cartilage, the posterior membranous sheath appears to give first by invaginating into the lumen.[81] If lung volume were abnormally decreased (e.g., because of splinting) and expiration were still forced, the caliber of the airways would be relatively reduced at all times, which would cause the EPP and point of collapse to move progressively from larger to smaller air passages (closer to the alveolus).

In adults with normal lungs, airway closure can still occur even if exhalation is not forced, provided that residual volume is approached closely enough. Even in patients with normal lungs, as lung volume decreases toward residual volume during expiration, small airways

(0.5 to 0.9 mm in diameter) show a progressive tendency to close, whereas larger airways remain patent.[82,83] Airway closure occurs first in the dependent lung regions (as directly observed by computed tomography) because the distending transpulmonary pressure is less and the volume change during expiration is greater.[32] Airway closure is most likely to occur in the dependent regions of the lung whether the patient is in the supine or the lateral decubitus position and whether ventilation is spontaneous or positive-pressure ventilation.[32,84,85]

PATIENTS WITH ABNORMAL LUNGS. Airway closure occurs with milder active expiration, lower gas flow rates, and higher lung volumes, and it occurs closer to the alveolus in patients with emphysema, bronchitis, asthma, or interstitial pulmonary edema. In all four conditions, the increased airway resistance causes a larger decrease in pressure from the alveoli to the larger bronchi, thereby creating the potential for negative intrathoracic transmural ΔP and narrowed and collapsed airways. In addition, the structural integrity of the conducting airways may be diminished because of inflammation and scarring, and therefore these airways may close more readily for any given lung volume or transluminal ΔP.

In emphysema, the elastic recoil of the lung is reduced (to 1 cm H_2O in Fig. 5-17 E), the air passages are poorly supported by the lung parenchyma, the point of airway resistance is close to the alveolus, and transmural ΔP can become negative quickly. Therefore, during only a mild forced expiration in an emphysematous patient, the EPP and the point of collapse are near the alveolus (see Fig. 5-17E). The use of pursed-lip or grunting expiration (the equivalents of partly closing the larynx during expiration), PEEP, and continuous positive airway pressure in an emphysematous patient restores a favorable (distending) intrathoracic transmural air ΔP (see Fig. 5-17F). In bronchitis, the airways are structurally weakened and may close when only a small negative transmural ΔP is present (as with mild forced expiration). In asthma, the middle-sized airways are narrowed by bronchospasm, and if expiration is forced, they are further narrowed by a negative transmural ΔP. Finally, with pulmonary interstitial edema, perialveolar interstitial edema compresses the alveoli and acutely decreases FRC; the peribronchial edema fluid cuffs (within the connective tissue sheaths around the larger arteries and bronchi) compress the bronchi and acutely increase closing volume.[86–88]

MEASUREMENT OF CLOSING CAPACITY. CC is a sensitive test of early small-airways disease and is performed by having the patient exhale to residual volume (Fig. 5-18).[89] As inhalation from residual volume toward TLC is begun, a bolus of tracer gas (e.g., xenon 133, helium) is injected into the inspired gas. During the initial part of this inhalation from residual volume, the first gas to enter the alveolus is the V_D gas and the tracer bolus. The tracer gas enters only alveoli that are already open (presumably the apices of the lung) and does not enter alveoli that are already closed (presumably the bases of the lung). As the inhalation continues, the apical alveoli complete filling and the basilar alveoli begin to open and fill, but with gas that does not contain any tracer gas.

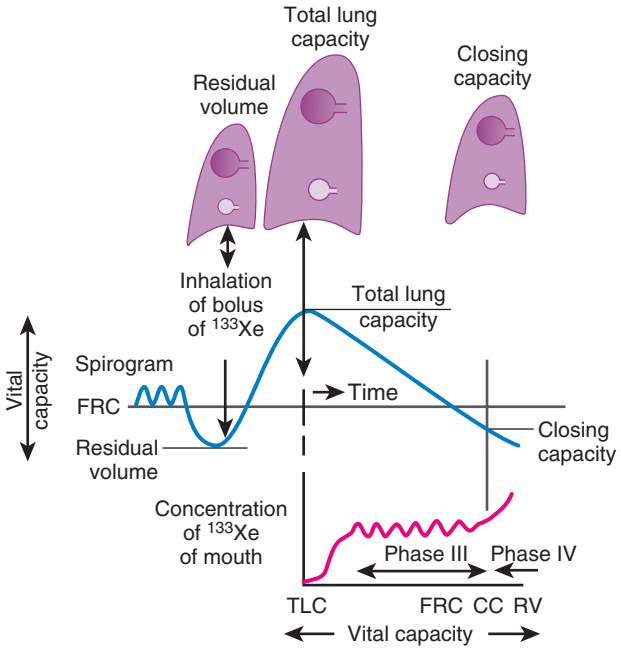

Figure 5-18 Measurement of closing capacity *(CC)* with the use of a tracer gas such as xenon 133 *(^{133}Xe)*. The bolus of tracer gas is inhaled near residual volume *(RV)* and, because of airway closure in the dependent lung, is distributed only to nondependent alveoli whose air passages are still open. During expiration, the concentration of tracer gas becomes constant after the dead space is washed out. This plateau *(phase III)* gives way to a rising concentration of tracer gas *(phase IV)*, when there is once again closure of the dependent airways because the only contribution made to expired gas is by the nondependent alveoli with a high ^{133}Xe concentration. *FRC,* Functional residual capacity; *TLC,* total lung capacity. (Redrawn with modification from Lumb AB: Respiratory system resistance: Measurement of closing capacity. In Lumb AB, editor: *Nunn's applied respiratory physiology,* ed 5, London, 2000, Butterworths, p 79.)

A differential tracer gas concentration is thus established, with the gas in the apices having a higher tracer concentration than that in the bases (see Fig. 5-18). As the subject exhales and the diaphragm ascends, a point is reached at which the small airways just above the diaphragm start to close and thereby limit airflow from these areas. The airflow now comes more from the upper lung fields, where the alveolar gas has a much higher tracer concentration, which results in a sudden increase in the tracer gas concentration toward the end of exhalation (phase IV of Fig. 5-18).

Closing volume (CV) is the difference between the onset of phase IV and residual volume; because it represents part of a vital capacity maneuver, it is expressed as a percentage of vital lung capacity. CV plus residual volume is known as CC and is expressed as a percentage of TLC. Smoking, obesity, aging, and the supine position increase CC.[90] In healthy individuals at a mean age of 44 years, CC = FRC in the supine position, and at a mean age of 66 years, CC = FRC in the upright position.[91]

RELATIONSHIP BETWEEN FUNCTIONAL RESIDUAL CAPACITY AND CLOSING CAPACITY. The relationship between FRC and CC is far more important than consideration of FRC or CC alone, because it is this relationship that determines whether a given respiratory unit is normal or atelectatic

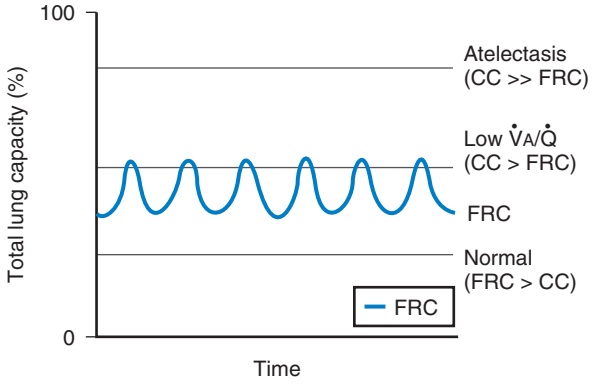

Figure 5-19 Relationship between functional residual capacity *(FRC)* and closing capacity *(CC)*. FRC is the amount of gas in the lungs at end-exhalation during normal tidal breathing, shown by the level of each trough of the sine wave tidal volume. CC is the amount of gas that must be in the lungs to keep the small conducting airways open. This figure shows three different CCs, as indicated by the three different straight lines. See the text for an explanation of why the three different FRC-CC relationships depicted result in normal or low ventilation-perfusion ($\dot{V}_A/\dot{Q}$) relationships or atelectasis. The abscissa is time. (Redrawn from Benumof JL: *Anesthesia for thoracic surgery*, ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

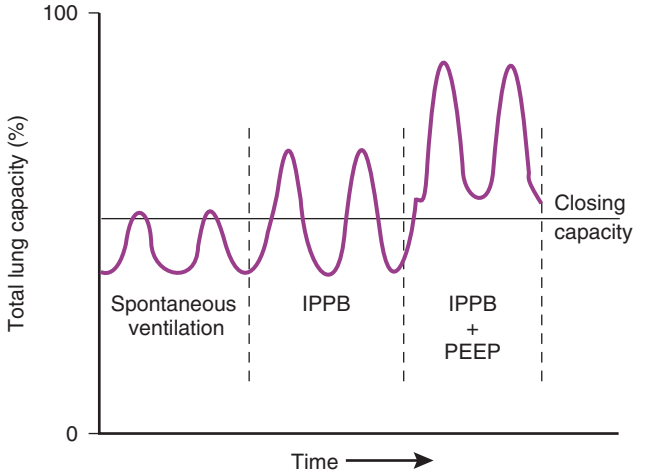

Figure 5-20 Relationship of functional residual capacity (FRC) to closing capacity (CC) during spontaneous ventilation, intermittent positive-pressure breathing *(IPPB)*, and IPPB with positive end-expiratory pressure *(IPPB + PEEP)*. See the text for an explanation of the effect of the two ventilatory maneuvers (IPPB and PEEP) on the relationship of FRC to CC. The abscissa is time.

or has a low $\dot{V}_A/\dot{Q}$ ratio. The relationship between FRC and CC is as follows. When the volume of the lung at which some airways close is greater than the whole of V_T, lung volume never increases enough during tidal inspiration to open any of these airways. As a result, these airways stay closed during the entire tidal respiration. Airways that are closed all the time are equivalent to atelectasis (Fig. 5-19). If the CV of some airways lies within V_T, as lung volume increases during inspiration, some previously closed airways open for a short time until lung volume recedes once again below the CV of these airways. Because these opening and closing airways are open for a shorter time than normal airways are, they have less chance or time to participate in fresh gas exchange, a circumstance equivalent to a low-$\dot{V}_A/\dot{Q}$ region. If the CC of the lung is below the whole of tidal respiration, no airways are closed at any time during tidal respiration; this is a normal circumstance. Anything that decreases FRC relative to CC or increases CC relative to FRC converts normal areas to low-$\dot{V}_A/\dot{Q}$ and atelectatic areas,[83] which causes hypoxemia.

Mechanical intermittent positive-pressure breathing (IPPB) may be efficacious because it can take a previously spontaneously breathing patient with a low-$\dot{V}_A/\dot{Q}$ relationship (in which CC is greater than FRC but still within V_T, as depicted in Figure 5-20, right panel) and increase the amount of inspiratory time that some previously closed (at end-exhalation) airways spend in fresh gas exchange, thereby increasing $\dot{V}_A/\dot{Q}$ (see Fig. 5-20, middle panel). However, if PEEP is added to IPPB, PEEP increases FRC to a lung volume equal to or greater than CC, thereby restoring a normal FRC-to-CC relationship so that no airways are closed at any time during the tidal respiration depicted in Figure 5-20 (left panel) (IPPB + PEEP). Thus, anesthesia-induced atelectasis (identified by crescent-shaped densities on computed tomography) in the dependent regions of patients' lungs has not been reversed with IPPB alone but has been reversed with IPPB plus PEEP (5 to 10 cm H_2O).[32]

D. Oxygen and Carbon Dioxide Transport

1. Alveolar and Dead Space Ventilation and Alveolar Gas Tensions

In normal lungs, approximately two thirds of each breath reaches perfused alveoli to take part in gas exchange. This constitutes the effective or alveolar ventilation ($\dot{V}_A$). The remaining third of each breath takes no part in gas exchange and is therefore termed the total (or physiologic) dead space ventilation (V_D). The relationship is as follows: alveolar ventilation ($\dot{V}_A$) = frequency (f) ($V_T - V_D$). The physiologic (or total) dead space ventilation ($V_{D_{physiologic}}$) may be further divided into two components: a volume of gas that ventilates the conducting airways, the anatomic dead space ($V_{D_{anatomic}}$), and a volume of gas that ventilates unperfused alveoli, the alveolar dead space ($V_{D_{alveolar}}$). Clinical examples of $V_{D_{alveolar}}$ ventilation include zone 1, pulmonary embolus, and destroyed alveolar septa; such ventilation does not participate in gas exchange. Figure 5-21 shows a two-compartment model of the lung in which the anatomic and alveolar dead space compartments have been combined into the total (physiologic) dead space compartment; the other compartment is the alveolar ventilation compartment, whose idealized $\dot{V}_A/\dot{Q}$ ratio is 1.0.

The $V_{D_{anatomic}}$ varies with lung size and is approximately 2 mL/kg of body weight (150 mL in a 70-kg adult). In a normal healthy adult lying supine, $V_{D_{anatomic}}$ and total V_D are approximately equal to each other, because $V_{D_{alveolar}}$ is normally minimal. In the erect posture, the uppermost alveoli may not be perfused (zone 1), and $V_{D_{alveolar}}$ may increase from a negligible amount to 60 to 80 mL. Figure 5-21 illustrates that in a steady state, the volume of CO_2 entering the alveoli ($\dot{V}CO_2$) is equal to the volume of CO_2 eliminated in the expired gas, ($\dot{V}_E$)

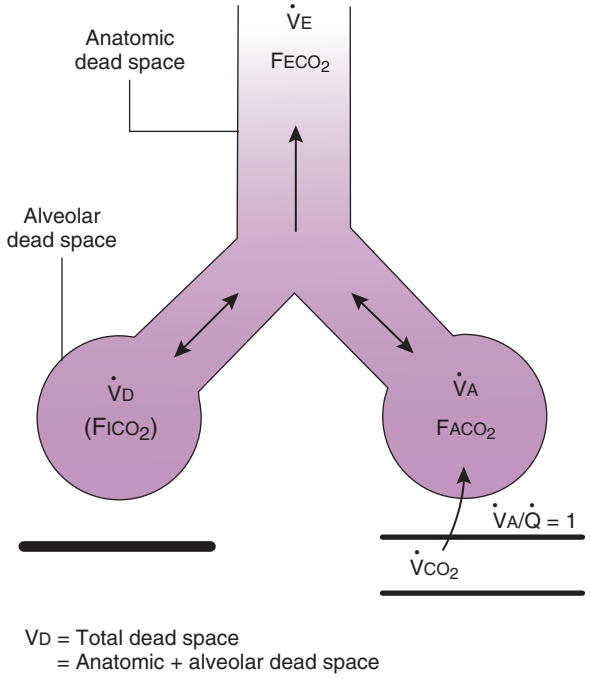

Figure 5-21 Two-compartment model of the lung in which the anatomic and alveolar dead space compartments have been combined into the total (physiologic) dead space ($\dot{V}D$). F_{ACO_2} = alveolar CO_2 fraction; F_{ECO_2} = mixed expired CO_2 fraction; F_{ICO_2} = inspired CO_2 fraction; $\dot{V}A$ = alveolar ventilation; $\dot{V}CO_2$ = carbon dioxide production; $\dot{V}E$ = expired minute ventilation. $\dot{V}A/\dot{Q} = 1$ means that ventilation and perfusion are equal in liters per minute. Normally, the amount of CO_2 eliminated at the airway ($\dot{V}E \times F_{ECO_2}$) equals the amount of CO_2 removed by alveolar ventilation ($\dot{V}A \times F_{ACO_2}$) because there is no CO_2 elimination from alveolar dead space ($F_{ICO_2} = 0$).

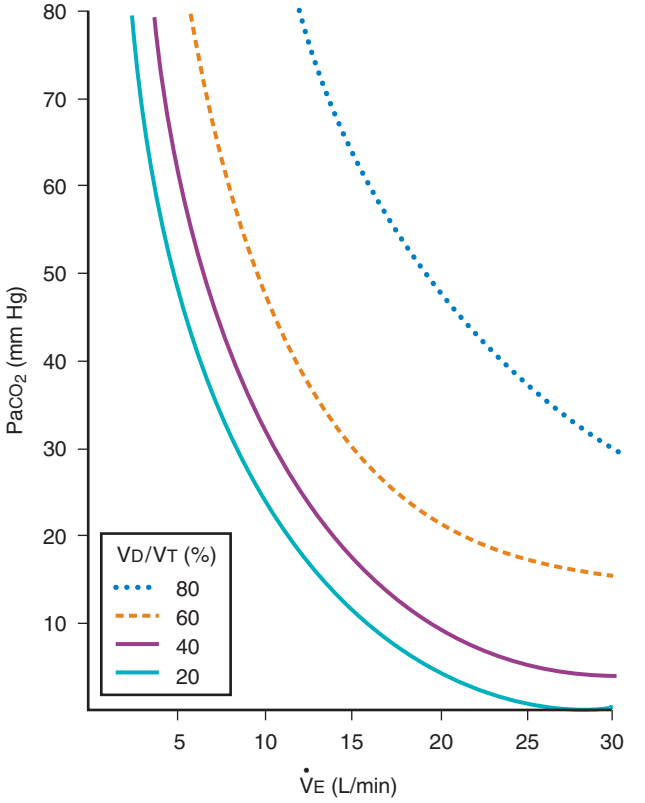

Figure 5-22 Relationship between minute ventilation ($\dot{V}E$, *L/min*) and arterial partial pressure of carbon dioxide (P_{ACO_2}) for a family of ratios of total dead space to tidal volume (V_D/V_T). These curves are hyperbolic and rise steeply at low $\dot{V}E$ values. See equation (10) in the text.

(F_{ECO_2}), where $\dot{V}E$ = minute ventilation and F_{ECO_2} = fraction of expired CO_2. Thus, $\dot{V}CO_2 = (\dot{V}E)(F_{ECO_2})$. However, the expired gas volume consists of alveolar gas, $(\dot{V}A)(F_{ACO_2})$, and $\dot{V}D$ gas, $(\dot{V}D)(F_{ICO_2})$, where F_{ACO_2} and F_{ICO_2} are the alveolar and inspired fractions of CO_2, respectively. Thus, $\dot{V}CO_2 = (\dot{V}A)(F_{ACO_2}) + (\dot{V}D)(F_{ICO_2})$. Setting the first equation equal to the second equation and using the relationship, $\dot{V}E = \dot{V}A + \dot{V}D$, subsequent algebraic manipulation, including setting P_{ACO_2} equal to P_{aCO_2}, results in the modified Bohr equation:

$$V_D/V_T = (P_{aCO_2} - P_{ECO_2})/P_{aCO_2} \qquad (10)$$

The CO_2 tension in expired gas, P_{ECO_2}, may be obtained by measuring exhaled CO_2 in a large (Douglas) bag or, more commonly, by using end-tidal CO_2 tension (P_{ETCO_2}) as a surrogate. In severe lung disease, physiologic V_D/V_T provides a useful expression of the inefficiency of ventilation. In a healthy adult, this ratio is usually less than 30%; that is, ventilation is more than 70% efficient. In a patient with COPD, V_D/V_T may increase to 60% to 70%. Under these conditions, ventilation is obviously grossly inefficient. Figure 5-22 shows the relationship between $\dot{V}E$ and P_{aCO_2} for several V_D/V_T values. As $\dot{V}E$ decreases, P_{aCO_2} increases for all V_D/V_T values. As V_D/V_T increases, a given decrease in $\dot{V}E$ causes a much greater increase in P_{aCO_2}. If P_{aCO_2} is to remain constant while V_D/V_T increases, $\dot{V}E$ must increase more.

The alveolar concentration of a gas is equal to the difference between the inspired concentration and the ratio of the output (or uptake) of the gas to $\dot{V}A$. Thus, for gas X during dry conditions, $P_{AX} = (P_{dry\ atm})(F_{IX}) \pm \dot{V}X$ (output or uptake)/$\dot{V}A$, where P_{AX} = alveolar partial pressure of gas X, F_{IX} = inspired concentration of gas X, $P_{dry\ atm}$ = dry atmospheric pressure = $P_{wet\ atm} - P_{H_2O} = 760 - 47 = 713$ mm Hg, $\dot{V}X$ = output or uptake of gas X, and $\dot{V}A$ = alveolar ventilation.

For CO_2, $P_{ACO_2} = 713(F_{ICO_2} + \dot{V}CO_2/\dot{V}A)$. Because $F_{ICO_2} = 0$ and using standard conversion factors:

$$P_{ACO_2} = 713[\dot{V}CO_2\ (mL/min\ STPD)/\dot{V}A\ (L/min/BTPS)(0.863)] \qquad (11)$$

where BTPS = body temperature and pressure, saturated (i.e., 37° C, P_{H_2O} = 47 mm Hg) and STPD = standard temperature and pressure, dry. For example, 36 mm Hg = (713)(200/4000).

For O_2,

$$P_{AO_2} = 713[F_{IO_2} - \dot{V}O_2\ (mL/min)/\dot{V}A\ (mL/min)] \qquad (12)$$

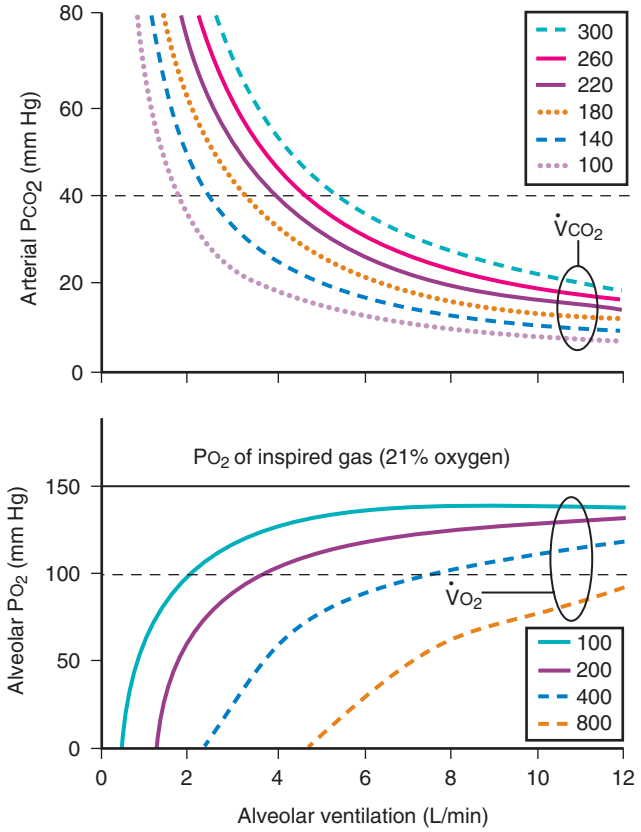

Figure 5-23 *Top,* The relationship between alveolar ventilation and arterial carbon dioxide tension (P_{aCO_2}) for a group of different CO_2 production values ($\dot{V}CO_2$). *Bottom,* The relationship between alveolar ventilation and alveolar oxygen tension (P_{AO_2}) for a group of different O_2 consumption values ($\dot{V}O_2$). Values are derived from equations (10) and (11) in the text, and the curves are hyperbolic. As alveolar ventilation increases, P_{AO_2} and P_{aCO_2} approach inspired concentrations. Decreases in alveolar ventilation to less than 4 L/min are accompanied by precipitous decreases in P_{AO_2} and increases in P_{aCO_2}.

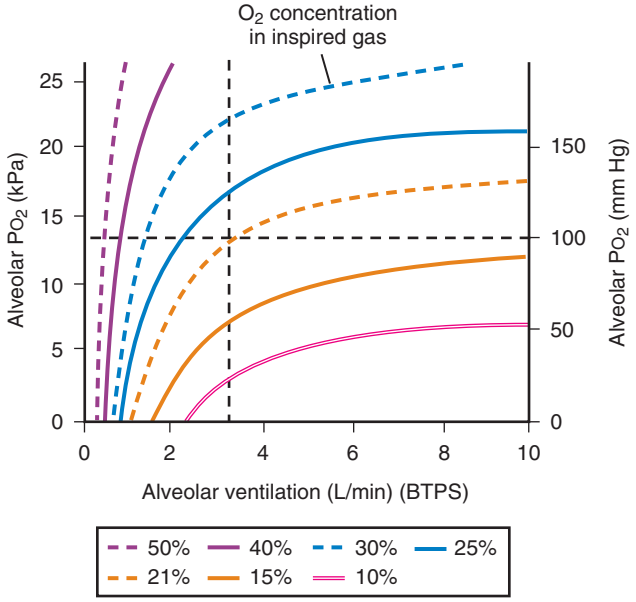

Figure 5-24 For any given O_2 concentration in inspired gas, the relationship between alveolar ventilation and alveolar O_2 tension (P_{AO_2}) is hyperbolic. As the inspired O_2 concentration is increased, the amount that alveolar ventilation must decrease to produce hypoxemia is greatly increased. *BTPS,* Body temperature, ambient pressure, saturated. (Redrawn from Lumb AB: Respiratory system resistance: Measurement of closing capacity. In Lumb AB, editor: *Nunn's applied respiratory physiology,* ed 5, London, 2000, Butterworths, p 79.)

For example, 100 mm Hg = 713(0.21 - 225/3200).

Figure 5-23 shows the hyperbolic relationships expressed in equations (10) and (11) between P_{aCO_2} and $\dot{V}A$ (see Fig. 5-22) and between P_{AO_2} and $\dot{V}A$ for different levels of $\dot{V}CO_2$ and $\dot{V}O_2$, respectively. P_{aCO_2} is substituted for P_{ACO_2} because P_{ACO_2}-to-P_{aCO_2} gradients are small (as opposed to P_{AO_2}-to-P_{aO_2} gradients, which can be large). Note that as $\dot{V}A$ increases, the second term on the right side of equations (11) and (12) approaches zero and the composition of the alveolar gas approaches that of the inspired gas. In addition, Figures 5-22 through Figure 5-24 show that, because anesthesia is usually administered with an oxygen-enriched gas mixture, hypercapnia is a more common result of hypoventilation than hypoxemia is.

2. Oxygen Transport

a. OVERVIEW

The principal function of the heart and lungs is supporting O_2 delivery to and CO_2 removal from the tissues in accordance with metabolic requirements while maintaining arterial blood O_2 and CO_2 partial pressures within a narrow range. The respiratory and cardiovascular systems are linked in series to accomplish this function over a wide range of metabolic requirements, which may increase 30-fold from rest to heavy exercise. The functional links in the O_2 transport chain are as follows: (1) ventilation and distribution of ventilation with respect to perfusion, (2) diffusion of O_2 into blood, (3) chemical reaction of O_2 with Hb, (4) total cardiac output of arterial blood, and (5) distribution of blood to tissues and release of O_2 (Table 5-3). The system is seldom stressed except at exercise, and the earliest symptoms of cardiac or respiratory diseases are often seen only during exercise.

The maximum functional capacity of each link can be determined independently. Table 5-3 lists these measured functional capacities for healthy, young men. Because theoretical maximal O_2 transport at the ventilatory step or at the diffusion and chemical reaction step (approximately 6 L/min in healthy humans at sea level) exceeds the O_2 transportable by the maximum cardiac output and distribution steps, the limit to O_2 transport is the cardiovascular system. Respiratory diseases would not be expected to limit maximum O_2 transport until functional capacities are reduced by 40% to 50%.

b. OXYGEN-HEMOGLOBIN DISSOCIATION CURVE

As a red blood cell (RBC) passes by the alveolus, O_2 diffuses into plasma and increases P_{AO_2}. As P_{AO_2} increases, O_2 diffuses into the RBC and combines with Hb. Each Hb molecule consists of four heme molecules attached to a globin molecule. Each heme molecule consists of glycine, α-ketoglutaric acid, and iron in the ferrous (Fe^{2+}) form. Each ferrous ion has the capacity to bind with one

TABLE 5-3
Functional Capacities and Potential Maximum O_2 Transport of Each Link in the O_2 Transport Chain in Normal Humans* at Sea Level

Link in Chain	Functional Capacity in Normal Humans	Theoretical Maximum O_2 Transport Capacity
Ventilation	200 L/min (MVV)	0.030 × MVV = 6.0 L O_2/min
Diffusion and chemical reaction		DLO_2 = 6.1 L O_2/min
Cardiac output	20 L/min	
O_2 extraction	75%	0.16 × Cardiac output = 3.2 L O_2/min
($CaO_2 - C\bar{v}O_2$ difference)	(16 mL O_2/100 mL or 0.16)	

*Hemoglobin = 15 g/dL; physiologic dead space in percentage of tidal volume = 0.25; partial alveolar pressure of oxygen >110 mm Hg.

O_2 molecule in a loose, reversible combination. As the ferrous ions bind to O_2, the Hb molecule begins to become saturated.

The oxy-Hb dissociation curve relates the saturation of Hb (rightmost y-axis in Fig. 5-25) to P_{AO_2}. Hb is fully saturated (100%) by a P_{O_2} of approximately 700 mm Hg. The saturation at normal arterial pressure (point a on upper, flat part of the oxy-Hb curve in Figure 5-25) is 95% to 98%, achieved by a P_{aO_2} of about 90 to 100 mm Hg. When P_{O_2} is less than 60 mm Hg (90% saturation), saturation falls steeply, and the amount of Hb uncombined with O_2 increases greatly for a given decrease in P_{O_2}. Mixed venous blood has a P_{O_2} ($P\bar{v}O_2$) of about 40 mm Hg and is approximately 75% saturated, as indicated by the middle of the three points ($\bar{v}$) on the oxy-Hb curve in Figure 5-25.

The oxy-Hb curve can also relate the O_2 content (C_{O_2}) (vol%, or mL of O_2 per dL of blood; see Fig. 5-25) to P_{O_2}. Oxygen is carried both in solution in plasma (0.003 mL of O_2/mm Hg P_{O_2} per dL) and combined with Hb (1.39 mL of O_2/g of Hb), to the extent (percentage) that Hb is saturated. Therefore,

$$C_{O_2} = (1.39)(Hb)(\text{percent saturation}) + 0.003(P_{O_2}) \quad (13)$$

For a patient with an Hb content of 15 g/dL, a P_{AO_2} of 100 mm Hg, and a $P\bar{v}O_2$ of 40 mm Hg, the arterial O_2 content (CaO_2) = (1.39)(15)(1) + (0.003)(100) = 20.9 + 0.3 = 21.2 mL/dL; the mixed venous O_2 content ($C\bar{v}O_2$) = (1.39)(15)(0.75) + (0.003)(40) = 15.6 + 0.1 = 15.7 mL/dL. Therefore, the normal arteriovenous O_2 content difference is approximately 5.5 mL/dL of blood.

Note that equation (13) uses the constant 1.39, which means that 1 g of Hb can carry 1.39 mL of O_2. Controversy exists over the magnitude of this number. Originally, 1.34 had been used,[92] but with determination of the molecular weight of Hb (64,458), the theoretical

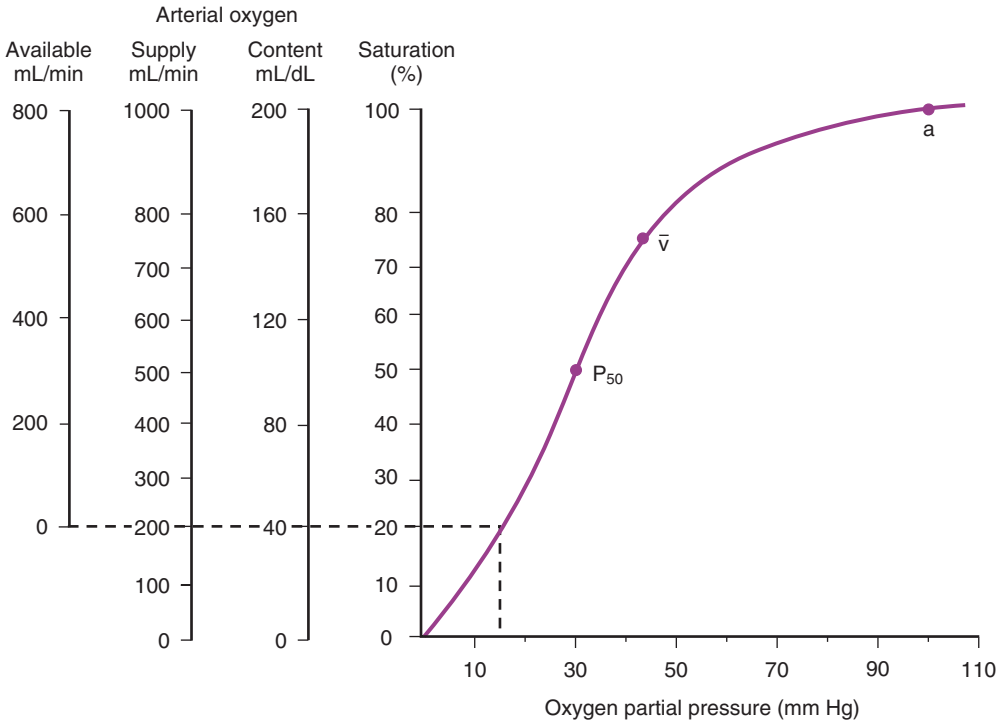

Figure 5-25 Oxygen-hemoglobin dissociation curve. Four different ordinates are shown as a function of oxygen partial pressure (the abscissa). In order from right to left, they are arterial O_2 saturation (%), O_2 content (mL of O_2/dL of blood), O_2 supply to peripheral tissues (mL/min), and O_2 available to peripheral tissues (mL/min), which is O_2 supply minus the approximately 200 mL/min that cannot be extracted below a partial pressure of 20 mm Hg. Three points are shown on the curve: *a*, normal arterial pressure; $\bar{v}$, normal mixed venous pressure; P_{50}, the partial pressure (27 mm Hg) at which hemoglobin is 50% saturated.

value of 1.39 became popular.[93] After extensive human studies, Gregory observed in 1974 that the applicable value was 1.31 mL O_2/g of Hb in human adults.[94] That the clinically measured C_{O_2} is lower than the theoretical 1.39 is probably due to the small amount of methemoglobin (MetHb) and carboxyhemoglobin (COHb) normally present in blood.

The oxy-Hb curve can also relate O_2 transport (L/min) to the peripheral tissues (see Fig. 5-25) to P_{O_2}. The term O2 *transport* is synonymous with the term O2 *delivery*. This value is obtained by multiplying the O_2 content by $\dot{Q}_T$ (O_2 transport = $\dot{Q}_T \times Ca_{O_2}$). To do this multiplication, one must convert the content unit of mL/dL to mL/L by multiplying by 10; subsequent multiplication of mL/L against $\dot{Q}_T$ in L/min yields mL/min. Thus, if $\dot{Q}_T$ = 5 L/min and Ca_{O_2} = 20 mL of O_2/dL, the arterial point corresponds to 1000 mL O_2/min going to the periphery, and the venous point corresponds to 750 mL O_2/min returning to the lungs, with $\dot{V}_{O_2}$ = 250 mL/min.

The oxy-Hb curve can also relate the O_2 actually available to the tissues (leftmost y axis in Fig. 5-25) as a function of P_{O_2}. Of the 1000 mL/min of O_2 normally going to the periphery, 200 mL/min of O_2 cannot be extracted because it would lower P_{O_2} below the level at which organs such as the brain can survive (rectangular dashed line in Fig. 5-25); the O_2 available to tissues is therefore 800 mL/min. This amount is approximately three to four times the normal resting $\dot{V}_{O_2}$. When $\dot{Q}_T$ = 5 L/min and arterial saturation is less than 40%, the total flow of O_2 to the periphery is reduced to 400 mL/min; the available O_2 is then 200 mL/min, and O_2 supply just equals O_2 demand. Consequently, with low arterial saturation, tissue demand can be met only by an increase in $\dot{Q}_T$ or, in the longer term, by an increase in Hb concentration.

The affinity of Hb for O_2 is best described by the P_{O_2} level at which Hb is 50% saturated (P_{50}) on the oxy-Hb curve. The normal adult P_{50} is 26.7 mm Hg (see Fig. 5-25).

The effect of a change in P_{O_2} on Hb saturation is related to both P_{50} and the portion of the oxy-Hb curve at which the change occurs.[95] In the region of normal Pa_{O_2} (75 to 100 mm Hg), the curve is relatively horizontal, and shifts of the curve have little effect on saturation. In the region of mixed venous P_{O_2}, where the curve is relatively steep, a shift of the curve leads to a much greater difference in saturation. A P_{50} lower than 27 mm Hg describes a left-shifted oxy-Hb curve, which means that at any given P_{O_2}, Hb has a higher affinity for O_2 and is therefore more saturated than normal. This lower P_{50} may require higher than normal tissue perfusion to produce the normal amount of O_2 unloading. Causes of a left-shifted oxy-Hb curve are alkalosis (metabolic and respiratory—the Bohr effect), hypothermia, abnormal fetal Hb, carboxyhemoglobin, methemoglobin, and decreased RBC 2,3-diphosphoglycerate (2,3-DPG) content. (The last condition may occur with the transfusion of old acid citrate-dextrose–stored blood; storage of blood in citrate-phosphate-dextrose minimizes changes in 2,3-DPG with time.[95]) A P_{50} higher than 27 mm Hg describes a right-shifted oxy-Hb curve, which means that at any given P_{O_2}, Hb has a low affinity for O_2 and is less saturated than normal. This higher P_{50} may allow a lower tissue perfusion than normal to produce the normal amount of O_2 unloading. Causes of a right-shifted oxy-Hb curve are acidosis (metabolic and respiratory—the Bohr effect), hyperthermia, abnormal Hb, increased RBC 2,3-DPG content, and inhaled anesthetics (see later discussion).[95] Abnormalities in acid-base balance result in alteration of 2,3-DPG metabolism to shift the oxy-Hb curve to its normal position. This compensatory change in 2,3-DPG requires between 24 and 48 hours. Therefore, with acute acid-base abnormalities, O_2 affinity and the position of the oxy-Hb curve change. However, with more prolonged acid-base changes, the reciprocal changes in 2,3-DPG levels shift the oxy-Hb curve and O_2 affinity back toward normal.[95]

Many inhaled anesthetics have been shown to shift the oxy-Hb dissociation curve to the right.[96] Isoflurane shifts P_{50} to the right by 2.6 ± 0.07 mm Hg at a vapor pressure of approximately 1 minimum alveolar concentration (MAC) (1.25%).[97] On the other hand, high-dose fentanyl, morphine, and meperidine do not alter the position of the curve.

c. EFFECT OF $\dot{Q}_S/\dot{Q}_T$ ON ALVEOLAR OXYGEN TENSION

P_{AO_2} is directly related to F_{IO_2} in normal patients. P_{AO_2} and F_{IO_2} also correspond to Pa_{O_2} when there is little to no right-to-left transpulmonary shunt ($\dot{Q}_S/\dot{Q}_T$). Figure 5-26 shows the relationship between F_{IO_2} and Pa_{O_2} for a family of right-to-left transpulmonary shunts; the calculations assume a constant and normal $\dot{Q}_T$ and Pa_{CO_2}. With no $\dot{Q}_S/\dot{Q}_T$, a linear increase in F_{IO_2} results in a linear increase in P_{AO_2} (solid straight line). As the shunt is increased, the $\dot{Q}_S/\dot{Q}_T$ lines relating F_{IO_2} to Pa_{O_2} become progressively flatter.[98] With a shunt of 50% of $\dot{Q}_T$, an increase in F_{IO_2} results in almost no increase in Pa_{O_2}. The solution to the problem of hypoxemia secondary to a large shunt is not increasing the F_{IO_2} but rather causing a reduction in the shunt (e.g., PEEP, patient

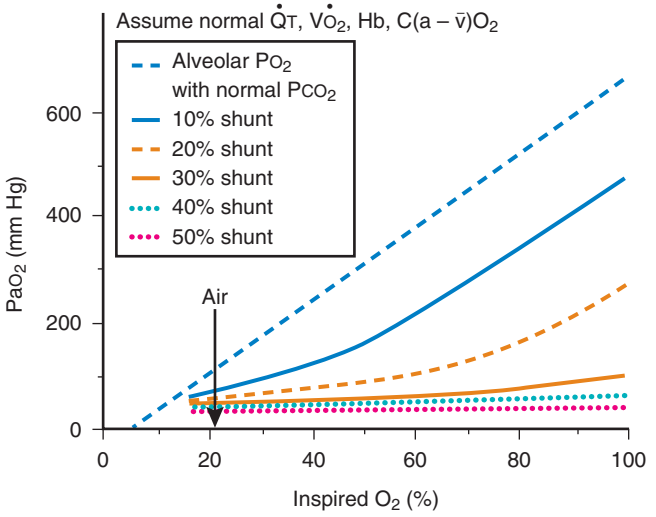

Figure 5-26 Effect of changes in inspired oxygen concentration on arterial oxygen tension *(Pa_{O_2})* for various right-to-left transpulmonary shunts. Cardiac output *($\dot{Q}_T$)*, hemoglobin *(Hb)*, oxygen consumption *($\dot{V}_{O_2}$)*, and arteriovenous oxygen content differences ($C(a-\bar{v})_{O_2}$) are assumed to be normal. P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen.

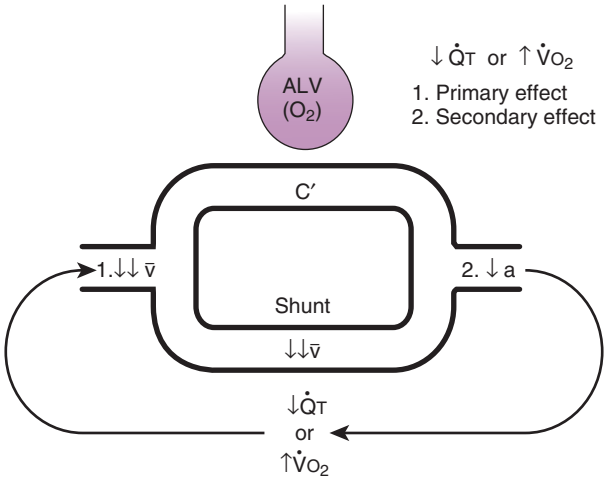

Figure 5-27 Effect of a decrease in cardiac output ($\dot{Q}_T$) or an increase in oxygen consumption ($\dot{V}O_2$) on mixed venous and arterial oxygen content. Mixed venous blood ($\bar{v}$) either perfuses ventilated alveolar capillaries *(ALV)* and becomes oxygenated end-pulmonary capillary blood *(c′)*, or it perfuses whatever true shunt pathways exist and remains the same in composition (i.e., desaturated). These two pathways must ultimately join together to form mixed arterial *(a)* blood. If $\dot{Q}_T$ decreases or $\dot{V}O_2$ increases, or both, the tissues must extract more oxygen per unit volume of blood than under normal conditions. Thus, the primary effect of a decrease in $\dot{Q}_T$ or an increase in $\dot{V}O_2$ is a decrease in mixed venous oxygen content. The mixed venous blood with a decreased oxygen content must flow through the shunt pathway as before (which may remain constant in size) and lower the arterial content of oxygen. Thus, the secondary effect of a decrease in $\dot{Q}_T$ or an increase in $\dot{V}O_2$ is a decrease in arterial oxygen content.

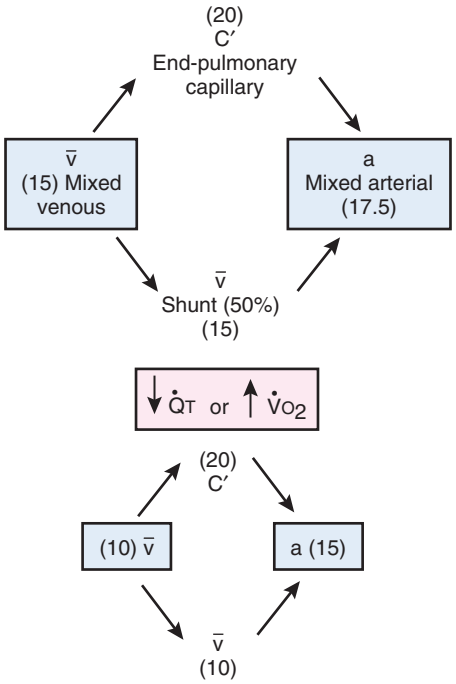

Figure 5-28 The equivalent circuit of the pulmonary circulation in a patient with a 50% right-to-left shunt. Oxygen content is in mL/dL of blood. A decrease in cardiac output *($\dot{Q}_T$)* or an increase in O_2 consumption *($\dot{V}O_2$)* can cause a decrease in mixed venous oxygen content, from 15 to 10 mL/dL in this example, which in turn causes a decrease in the arterial content of oxygen, from 17.5 to 15.0 mL/dL). In this 50% shunt example, the decrease in mixed venous oxygen content was twice the decrease in arterial oxygen content.

positioning, suctioning, fiberoptic bronchoscopy, diuretics, antibiotics).

d. EFFECT OF $\dot{Q}_T$ AND $\dot{V}O_2$ ON ARTERIAL OXYGEN CONTENT

In addition to an increased $\dot{Q}S/\dot{Q}T$, CaO_2 is decreased by decreased $\dot{Q}T$ (for a constant $\dot{V}O_2$) and by increased $\dot{V}O_2$ (for a constant $\dot{Q}T$). In either case, along with a constant right-to-left shunt, the tissues must extract more O_2 from blood per unit blood volume, and therefore, $C\bar{v}O_2$ must primarily decrease (Fig. 5-27). When blood with lower $C\bar{v}O_2$ passes through whatever shunt exists in the lung and remains unchanged in its $\dot{V}O_2$, it must inevitably mix with oxygenated end-pulmonary capillary blood (c′ flow) and secondarily decrease CaO_2. The amount of O_2 flowing per minute through any particular lung channel, as depicted in Figure 5-27, is a product of blood flow times the O_2 content of that blood. Thus, $\dot{Q}T \times CaO_2 = \dot{Q}c' \times Cc'O_2 + \dot{Q}S \times C\bar{v}O_2$. With $\dot{Q}c' = \dot{Q}T - \dot{Q}S$ and further algebraic manipulation,[99]

$$\dot{Q}S/\dot{Q}T = Cc'O_2 - CaO_2/Cc'O_2 - C\bar{v}O_2 \qquad (14)$$

The larger the intrapulmonary shunt, the greater is the decrease in CaO_2, because more venous blood with lower $C\bar{v}O_2$ can admix with end-pulmonary capillary blood (c′) (see Fig. 5-37).[100,101] Therefore, the alveolar-arterial oxygen difference $P(A-a)O_2$ is a function both of the size of the $\dot{Q}S/\dot{Q}T$ and of what is flowing through the $\dot{Q}S/\dot{Q}T$—namely, $C\bar{v}O_2$—and $C\bar{v}O_2$ is a primary function of $\dot{Q}T$ and $\dot{V}O_2$. Figure 5-28 shows the equivalent circuit of the pulmonary circulation in a patient with a 50% shunt, a normal $C\bar{v}O_2$ of 15 mL/dL, and a moderately low CaO_2 of 17.5 mL/dL. Decreasing $\dot{Q}T$ or increasing $\dot{V}O_2$, or both, causes a larger primary decrease in $C\bar{v}O_2$ to 10 mL/dL and a smaller but still significant secondary decrease in CaO_2 to 15 mL/dL; the ratio of change in $C\bar{v}O_2$ to change in CaO_2 in this example of 50% $\dot{Q}S/\dot{Q}T$ is 2:1.

If a decrease in $\dot{Q}T$ or an increase in $\dot{V}O_2$ is accompanied by a decrease in $\dot{Q}S/\dot{Q}T$, there may be no change in PaO_2 (i.e., a decreasing effect on PaO_2 is offset by an increasing effect on PaO_2) (Table 5-4). These changes sometimes occur in diffuse lung disease. However, if a decrease in $\dot{Q}T$ or an increase in $\dot{V}O_2$ is accompanied by an increase in $\dot{Q}S/\dot{Q}T$, PaO_2 may be greatly decreased (i.e., a decreasing effect on PaO_2 is compounded by another decreasing effect on PaO_2). These changes sometimes occur in regional ARDS and atelectasis.[102]

e. FICK PRINCIPLE

The Fick principle allows calculation of $\dot{V}O_2$ and states that the amount of O_2 consumed by the body ($\dot{V}O_2$) is equal to the amount of O_2 leaving the lungs ($\dot{Q}T$)(CaO_2) minus the amount of O_2 returning to the lungs ($\dot{Q}T$) ($C\bar{v}O_2$):

$$\dot{V}O_2 = (\dot{Q}T)(CaO_2) - (\dot{Q}T)(C\bar{v}O_2) = \dot{Q}T(CaO_2 - C\bar{v}O_2)$$

TABLE 5-4
Relationship Between Cardiac Output ($\dot{Q}_T$), Shunt ($\dot{Q}_S/\dot{Q}_T$), and Venous ($P\bar{v}O_2$) and Arterial (PaO_2) Oxygenation

Changes	Clinical Situation
If $\dot{Q}_T \downarrow \rightarrow \downarrow P\bar{v}O_2$ and $\dot{Q}_S/\dot{Q}_T = 0 \rightarrow PaO_2\downarrow$	Decreased cardiac output, stable shunt
If $\dot{Q}_T \downarrow \rightarrow \downarrow P\bar{v}O_2$ and $\dot{Q}_S/\dot{Q}_T \downarrow \rightarrow PaO_2 = 0$	Application of PEEP in ARDS
If $\dot{Q}_T \downarrow \rightarrow \downarrow P\bar{v}O_2$ and $\dot{Q}_S/\dot{Q}_T \uparrow \rightarrow PaO_2 \downarrow\downarrow$	Shock combined with ARDS or atelectasis

ARDS, Adult respiratory distress syndrome; *0,* no change; *PEEP,* positive end-expiratory pressure; ↓, decrease; ↑, increase.

Condensing the content symbols yields the usual expression of the Fick equation:

$$\dot{V}O_2 = (\dot{Q}T)[C(a\text{-}\bar{v})O_2] \quad (15)$$

This equation states that O_2 consumption is equal to $\dot{Q}_T$ times the arteriovenous O_2 content difference $[C(a - \bar{v})\,O_2]$. Normally, (5 L/min)(5.5 mL)/dL = 0.27 L/min (see "Oxygen-Hemoglobin Dissociation Curve").

$$\dot{V}O_2 = \dot{V}E(FIO_2) - \dot{V}E(FEO_2) = \dot{V}E(FIO_2 - FEO_2) \quad (16)$$

Similarly, the amount of O_2 consumed by the body ($\dot{V}O_2$) is equal to the amount of O_2 brought into the lungs by ventilation ($\dot{V}I$)(FIO_2) minus the amount of O_2 leaving the lungs by ventilation ($\dot{V}E$)(FEO_2), where $\dot{V}E$ is expired minute ventilation and FEO_2 is the mixed expired O_2 fraction: $\dot{V}O_2 = (\dot{V}I)(FIO_2) - (\dot{V}E)(FEO_2)$. Because the difference between $\dot{V}I$ and $\dot{V}E$ is due to the difference between $\dot{V}O_2$ (normally 250 mL/min) and $\dot{V}CO_2$ (normally 200 mL/min) and is only 50 mL/min (see later discussion), $\dot{V}I$ essentially equals $\dot{V}E$.

Normally, $\dot{V}O_2$ = 5.0 L/min(0.21 − 0.16) = 0.25 L/min. In determining $\dot{V}O_2$ in this way, $\dot{V}E$ can be measured with a spirometer, FIO_2 can be measured with an O_2 analyzer or from known fresh gas flows, and FEO_2 can be measured by collecting expired gas in a bag for a few minutes. A sample of the mixed expired gas is used to measure PEO_2. To convert PEO_2 to FEO_2, one simply divides PEO_2 by dry atmospheric pressure: $PEO_2/713 = FEO_2$.

In addition, the Fick equation is useful in understanding the impact of changes in $\dot{Q}_T$ on PaO_2 and $P\bar{v}O_2$. If $\dot{V}O_2$ remains constant (K) and $\dot{Q}_T$ decreases (↓), the arteriovenous O_2 content difference has to increase (↑):

$$\dot{V}O_2 = K = (\downarrow)\dot{Q}T\ x(\uparrow)C(a\text{-}\bar{v})O_2$$

The $C(a - \bar{v})O_2$ difference increases because a decrease in $\dot{Q}_T$ causes a much larger and primary decrease in $C\bar{v}O_2$ versus a smaller and secondary decrease in CaO_2, as follows[101]:

$$(\uparrow)C(a\text{-}\bar{v})O_2 = C(\downarrow a\text{-}\downarrow\downarrow \bar{v})O_2$$

Thus, $C\bar{v}O_2$ and $P\bar{v}O_2$ are much more sensitive indicators of $\dot{Q}_T$ because they change more with changes in $\dot{Q}_T$ than CaO_2 (or PaO_2) does (see Figs. 5-27 and 5-37).

3. Carbon Dioxide Transport

The amount of CO_2 circulating in the body is a function of both CO_2 elimination and CO_2 production. Elimination of CO_2 depends on pulmonary blood flow and alveolar ventilation. Production of CO_2 ($\dot{V}CO_2$) parallels O_2 consumption ($\dot{V}O_2$) according to the respiratory quotient (RQ):

$$RQ = \frac{\dot{V}CO_2}{\dot{V}O_2} \quad (17)$$

Under normal resting conditions, RQ is 0.8; that is, only 80% as much CO_2 is produced as O_2 is consumed. However, this value changes as the nature of the metabolic substrate changes. If only carbohydrate is used, the RQ is 1.0. Conversely, with the sole use of fat, more O_2 combines with hydrogen to produce water, and the RQ value drops to 0.7. CO_2 is transported from mitochondria to the alveoli in a number of forms. In plasma, CO_2 exists in physical solution, hydrated to carbonic acid (H_2CO_3), and as bicarbonate (HCO_3^-). In the RBC, CO_2 combines with Hb as carbaminohemoglobin (Hb-CO_2). The approximate values of H_2CO_3 ($H_2O + CO_2$), HCO_3^-, and Hb-CO_2 relative to the total CO_2 transported are 7%, 80%, and 13%, respectively.

In plasma, CO_2 exists both in physical solution and as H_2CO_3:

$$H_2O + CO_2 \rightarrow H_2CO_3 \quad (18)$$

The CO_2 in solution can be related to PCO_2 by the use of Henry's law.[103]

$$PCO_2 \times a = [CO_2] \text{ in solution} \quad (19)$$

where a is the solubility coefficient of CO_2 in plasma (0.03 mmol/L/mm Hg at 37° C). However, the major fraction of CO_2 produced passes into the RBC. As in plasma, CO_2 combines with water to produce H_2CO_3. However, unlike the slow reaction in plasma, in which the equilibrium point lies toward the left, the reaction in an RBC is catalyzed by the enzyme carbonic anhydrase. This zinc-containing enzyme moves the reaction to the right at a rate 1000 times faster than in plasma. Furthermore, almost 99.9% of the H_2CO_3 dissociates to HCO_3^- and hydrogen ions (H^+):

$$H_2O + CO_2 \xrightarrow[H_2CO_3 \rightarrow H^+ + HCO_3^-]{\text{carbonic anhydrase}} H_2CO_3 \quad (20)$$

The H^+ produced from H_2CO_3 in the production of HCO_3^- is buffered by Hb (H^+ + Hb ⇌ HHb). The HCO_3^- produced passes out of the RBC into plasma to perform its function as a buffer. To maintain electrical neutrality within the RBC, chloride ion ($^-$) moves in as HCO_3^- moves out ($^-$ shift). Finally, CO_2 can combine with Hb in the erythrocyte (to produce Hb-CO_2). Again,

as in HCO_3^- release, an H^+ ion is formed in the reaction of CO_2 and Hb. This H^+ ion is also buffered by Hb.

4. Bohr and Haldane Effects

Just as the percent saturation of Hb with O_2 is related to P_{O_2} (described by the oxy-Hb curve), so the total CO_2 in blood is related to P_{CO_2}. In addition, Hb has variable affinity for CO_2; it binds more avidly in the reduced state than as oxy-Hb.[95] The Bohr effect describes the effect of P_{CO_2} and $[H^+]$ ions on the oxy-Hb curve. Hypercapnia and acidosis both shift the curve to the right (reducing the O_2-binding affinity of hemoglobin), and hypocapnia and alkalosis both shift the curve to the left. Conversely, the Haldane effect describes the shift in the CO_2 dissociation curve caused by oxygenation of Hb. Low P_{O_2} shifts the CO_2 dissociation curve to the left so that the blood is able to pick up more CO_2 (as occurs in capillaries of rapidly metabolizing tissues). Conversely, oxygenation of Hb (as occurs in the lungs) reduces the affinity of Hb for CO_2, and the CO_2 dissociation curve is shifted to the right, thereby increasing CO_2 removal.

E. Pulmonary Microcirculation, Interstitial Space, and Fluid (Pulmonary Edema)

The ultrastructural appearance of an alveolar septum is depicted schematically in Figure 5-29.[104] Capillary blood is separated from alveolar gas by a series of anatomic layers: capillary endothelium, endothelial basement membrane, interstitial space, epithelial basement membrane, and alveolar epithelium (of the type I pneumocyte).

On one side of the alveolar septum (the thick, upper, fluid- and gas-exchanging side), the epithelial and endothelial basement membranes are separated by a space of variable thickness containing connective tissue fibrils, elastic fibers, fibroblasts, and macrophages. This connective tissue is the backbone of the lung parenchyma; it forms a continuum with the connective tissue sheaths around the conducting airways and blood vessels. Thus, the pericapillary perialveolar interstitial space is continuous with the interstitial tissue space that surrounds terminal bronchioles and vessels, and both spaces constitute the connective tissue space of the lung. There are no lymphatics in the interstitial space of the alveolar septum. Instead, lymphatic capillaries first appear in the interstitial space surrounding terminal bronchioles, small arteries, and veins.[105]

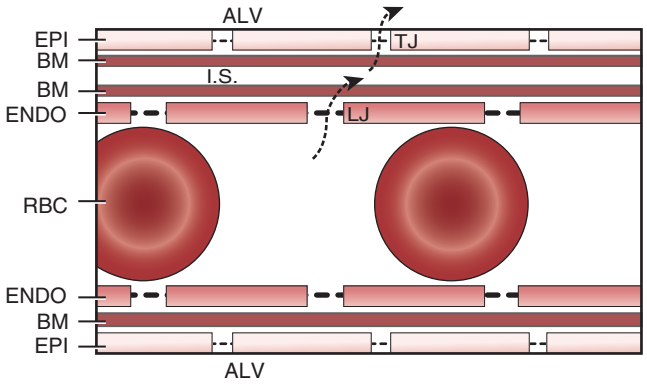

Figure 5-29 Schematic summary of the ultrastructure of a pulmonary capillary. On the upper side of the capillary, the endothelial *(ENDO)* and epithelial *(EPI)* basement membranes *(BM)* are separated by an interstitial space *(I.S.),* whereas the lower side contains only fused ENDO and EPI BMs. The dashed arrows indicate a potential pathway for fluid to move from the intravascular space to the I.S. through loose junctions *(LJ)* in the endothelium and from the I.S. to the alveolar space *(ALV)* through tight junctions *(TJ)* in the epithelium. *RBC,* Red blood cell. (Redrawn from Fishman AP: Pulmonary edema: The water-exchanging function of the lung. *Circulation* 46:390, 1972.)

The opposite side of the alveolar septum (the thin, down, gas-exchanging-only side) contains only fused epithelial and endothelial basement membranes. The interstitial space is greatly restricted on this side because of fusion of the basement membranes. Interstitial fluid cannot separate the endothelial and epithelial cells from one another. As a result the space and distance barrier to fluid movement from the capillary to the alveolar compartment is reduced; it is composed of only the two cell linings with their associated basement membranes.[106]

Between the individual endothelial and epithelial cells are holes or junctions that provide a potential pathway for fluid to move from the intravascular space to the interstitial space and finally from the interstitial space to the alveolar space (see Fig. 5-29). The junctions between endothelial cells are relatively large and are therefore termed "loose"; the junctions between epithelial cells are relatively small and are therefore termed "tight." Pulmonary capillary permeability is a direct function of, and essentially equivalent to, the size of the holes in the endothelial and epithelial linings.

To understand how pulmonary interstitial fluid is formed, stored, and cleared, it is necessary first to develop the concepts that (1) the pulmonary interstitial space is a continuous space between the periarteriolar and peribronchial connective tissue sheath and the space between the endothelial and epithelial basement membranes in the alveolar septum and (2) the space has a progressively negative distal-to-proximal ΔP.

The concepts of a continuous connective tissue sheath–alveolar septum interstitial space and a negative interstitial space ΔP are prerequisite to understanding interstitial fluid kinetics. After entering the lung parenchyma, both the bronchi and the arteries run within a connective tissue sheath that is formed by an invagination of the pleura at the hilum and ends at the level of the bronchioles (Fig. 5-30A).This results in a potential perivascular space between the arteries and the connective tissue sheath and a potential peribronchial space between the bronchi and the connective tissue sheath. The negative pressure in the pulmonary tissues surrounding the perivascular connective tissue sheath exerts a radial outward traction force on the sheath. This radial traction creates negative pressure within the sheath that is transmitted to the bronchi and arteries and tends to hold them open and increase their diameters.[106] The alveolar septum interstitial space is the space between the capillaries and alveoli (or, more precisely, the space between the endothelial and epithelial basement membranes) and is continuous with the interstitial tissue space that surrounds the larger

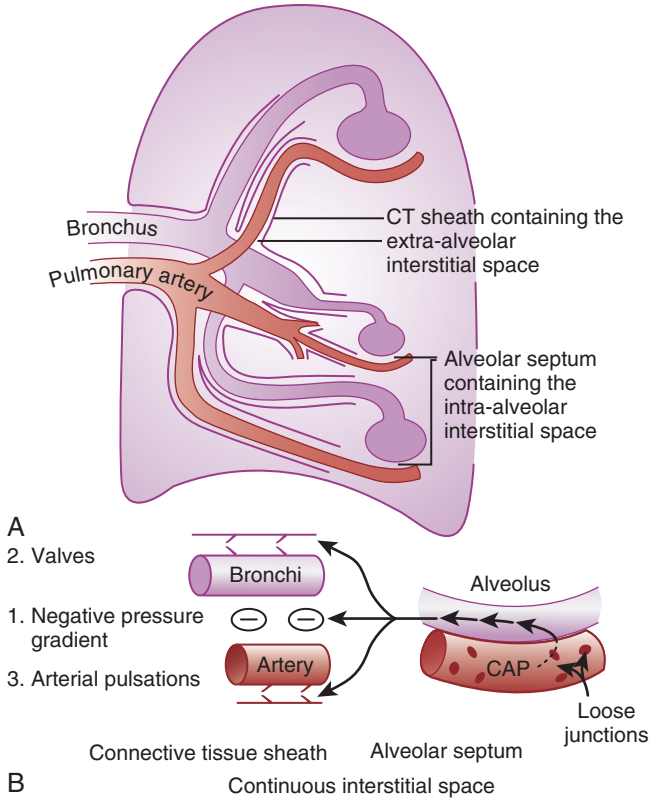

Figure 5-30 **A,** Schematic diagram of the concept of a continuous connective tissue sheath–alveolar septum interstitial space. The entry of the main stem bronchi and pulmonary artery into the lung parenchyma invaginates the pleura at the hilum and forms a surrounding connective tissue sheath. The connective tissue sheath ends at the level of the bronchioles. The space between the pulmonary arteries and bronchi and the interstitial space is continuous with the alveolar septum interstitial space. The alveolar septum interstitial space is contained within the endothelial basement membrane of the capillaries and the epithelial basement membrane of the alveoli. **B,** Schematic diagram showing how interstitial fluid moves from the alveolar septum interstitial space (no lymphatics) to the connective tissue interstitial space (lymphatic capillaries first appear). The mechanisms are a negative-pressure gradient (sump), the presence of one-way valves in the lymphatics, and the massaging action of arterial pulsations. *CAP,* Capillary. (Redrawn with modification from Benumof JL: *Anesthesia for thoracic surgery,* ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

arteries and bronchi. Studies indicate that the alveolar interstitial pressure is also uniquely negative but not as much so as the negative interstitial space pressure around the larger arteries and bronchi.[107]

The forces governing net transcapillary–interstitial space fluid movement are as follows. The net transcapillary flow of fluid (F) out of pulmonary capillaries (across the endothelium and into the interstitial space) is equal to the difference between pulmonary capillary hydrostatic pressure (P_{inside}) and interstitial fluid hydrostatic pressure ($P_{outside}$) and the difference between capillary colloid oncotic pressure (π_{inside}) and interstitial colloid oncotic pressure ($\pi_{outside}$). These four forces produce a steady-state fluid flow (F) during a constant capillary permeability (K) as predicted by the Starling equation:

$$F = K[(P_{inside} - P_{outside}) - (\pi_{inside} - \pi_{outside})] \qquad (21)$$

Box 5-1 Causes of Extremely Negative Pulmonary Interstitial Fluid Pressure ($P_{outside}$) in Pulmonary Edema

- Vigorous spontaneous ventilation against an obstructed airway
  - Laryngospasm
  - Infection, inflammation, edema
  - Upper airway mass (e.g., tumor, hematoma, abscess, foreign body)
  - Vocal cord paralysis
  - Strangulation
- Rapid reexpansion of lung
- Vigorous pleural suctioning (thoracentesis, chest tube)

K is a capillary filtration coefficient expressed in mL/min/mm Hg/100 g. The filtration coefficient is the product of the effective capillary surface area in a given mass of tissue and the permeability per unit surface area of the capillary wall to filter the fluid. Under normal circumstances and at a vertical height in the lung that is at the junction of zones 2 and 3, intravascular colloid oncotic pressure (≈ 26 mm Hg) acts to keep water in the capillary lumen; working against this force, pulmonary capillary hydrostatic pressure (≈ 10 mm Hg) acts to force water across the loose endothelial junctions into the interstitial space. If these were the only operative forces, the interstitial space and, consequently, the alveolar surfaces would be constantly dry and there would be no lymph flow. In fact, alveolar surfaces are moist, and lymphatic flow from the interstitial compartment is constant (≈ 500 mL/day). This can be explained in part by $\pi_{outside}$ (≈ 8 mm Hg) and in part by the negative $P_{outside}$ (–8 mm Hg).

Negative (subatmospheric) interstitial space pressure would promote, by suction, a slow loss of fluid across the endothelial holes.[108] Indeed, extremely negative pleural (and perivascular hydrostatic) pressure, such as may occur in a vigorously spontaneously breathing patient with an obstructed airway, can cause pulmonary interstitial edema (Box 5-1).[109] Relative to the vertical level of the junction of zones 2 and 3, as lung height decreases (lung dependence), absolute P_{inside} increases, and fluid has a propensity to transudate; as lung height increases (lung nondependence), absolute P_{inside} decreases, and fluid has a propensity to be reabsorbed. However, fluid transudation induced by an increase in P_{inside} is limited by a concomitant dilution of proteins in the interstitial space and therefore a decrease in $\pi_{outside}$.[110] Any change in the size of the endothelial junctions, even if the foregoing four forces remain constant, changes the magnitude and perhaps even the direction of fluid movement. Increased size of endothelial junctions (increased permeability) promotes transudation, whereas decreased size of endothelial junctions (decreased permeability) promotes reabsorption.

No lymphatics are present in the interstitial space of the alveolar septum. The lymphatic circulation starts as blind-ended lymphatic capillaries, first appearing in the interstitial space sheath surrounding terminal bronchioles and small arteries, and ends at the subclavian veins. Interstitial fluid is normally removed from the alveolar

interstitial space into the lymphatics by a sump (pressure gradient) mechanism, which is caused by the presence of more negative pressure surrounding the larger arteries and bronchi.[3,111] The sump mechanism is aided by the presence of valves in the lymph vessels. In addition, because the lymphatics run in the same sheath as the pulmonary arteries, they are exposed to the massaging action of arterial pulsations. The differential negative pressure, the lymphatic valves, and the arterial pulsations all help propel the lymph proximally toward the hilum through the lymph nodes (pulmonary to bronchopulmonary to tracheobronchial to paratracheal to scalene and cervical nodes) to the central venous circulation depot (see Fig. 5-30B). An increase in central venous pressure, which is the backpressure for lymph to flow out of the lung, would decrease lung lymph flow and perhaps promote pulmonary interstitial edema.

If the rate of entry of fluid into the pulmonary interstitial space exceeds the capability of the pulmonary interstitial space to clear the fluid, the pulmonary interstitial space fills with fluid; the fluid, now under an increased and positive driving force (P_{ISF}), crosses the relatively impermeable epithelial wall holes, and the alveolar space fills. Intra-alveolar edema fluid also causes alveolar collapse and atelectasis, thereby promoting further accumulation of fluid and worsening right-to-left transpulmonary shunt.

II. RESPIRATORY FUNCTION DURING ANESTHESIA

Arterial oxygenation is impaired in most patients during anesthesia with either spontaneous or controlled ventilation.[112–117] In otherwise normal patients, it is generally accepted that the impairment in arterial oxygenation during anesthesia is more severe in elderly persons,[118,119] obese people,[120] and smokers.[121] In various studies of healthy young to middle-aged patients under general anesthesia, venous admixture (shunt) has been found to average 10%, and the scatter in $\dot{V}_A/\dot{Q}$ ratios is small to moderate.[119,122] In patients with a more marked deterioration in preoperative pulmonary function, general anesthesia causes considerable widening of the $\dot{V}_A/\dot{Q}$ distribution and large increases in both low-$\dot{V}_A/\dot{Q}$ ($0.005 < \dot{V}_A/\dot{Q} < 0.1$) (underventilated) regions and shunting.[118,121,123] The magnitude of shunting correlates closely with the degree of atelectasis.[118,123]

In addition to these generalizations concerning respiratory function during anesthesia, the effect of a given anesthetic on respiratory function depends on the depth of general anesthesia, the patient's preoperative respiratory condition, and the presence of special intraoperative anesthetic and surgical conditions.

A. Anesthetic Depth and Respiratory Pattern

The respiratory pattern is altered by the induction and deepening of anesthesia. When the depth of anesthesia is inadequate (less than MAC), the respiratory pattern may vary from excessive hyperventilation and vocalization to breath-holding. As anesthetic depth approaches or equals MAC (light anesthesia), irregular respiration progresses to a more regular pattern that is associated with a larger than normal V_T. However, during light but deepening anesthesia, the approach to a more regular respiratory pattern may be interrupted by a pause at the end of inspiration (a "hitch" in inspiration), followed by a relatively prolonged and active expiration in which the patient seems to exhale forcefully rather than passively. As anesthesia deepens to moderate levels, respiration becomes faster and more regular but shallower. The respiratory pattern is a sine wave losing the inspiratory hitch and lengthened expiratory pause. There is little or no inspiratory or expiratory pause, and the inspiratory and expiratory periods are equivalent. Intercostal muscle activity is still present, and there is normal movement of the thoracic cage with lifting of the chest during inspiration.

The respiratory rate is generally slower and the V_T larger with nitrous oxide–narcotic anesthesia than with anesthesia involving halogenated drugs. During deep anesthesia with halogenated drugs, increasing respiratory depression is manifested by increasingly rapid and shallow breathing (panting). On the other hand, with deep nitrous oxide–narcotic anesthesia, respirations become slower but may remain deep. In the case of very deep anesthesia with all inhaled drugs, respirations often become jerky or gasping in character and irregular in pattern. This situation results from loss of the active intercostal muscle contribution to inspiration. As a result, a rocking boat movement occurs in which there is out-of-phase depression of the chest wall during inspiration, flaring of the lower chest margins, and billowing of the abdomen. The reason for this type of movement is that inspiration is dependent solely on diaphragmatic effort. Independent of anesthetic depth, similar chest movements may be simulated by upper or lower airway obstruction or by partial paralysis.

B. Anesthetic Depth and Spontaneous Minute Ventilation

Despite the variable changes in respiratory pattern and rate as anesthesia deepens, overall spontaneous $\dot{V}_E$ progressively decreases. In the normal awake response to breathing CO_2, an increasing end-tidal P_{CO_2} causes a linear increase in $\dot{V}_E$ (Fig. 5-31). The slope of the line relating $\dot{V}_E$ to the end-tidal CO_2 concentration (P_{CO_2}) in awake individuals is approximately 2 L/min/mm Hg. (In healthy individuals, the variation in the slope of this response is large.) Figure 5-31 shows that increasing the halothane concentration displaces the ventilation-response curve progressively to the right (i.e., at any end-tidal P_{CO_2}, ventilation is less than before), decreases the slope of the curve, and shifts the apneic threshold to a higher end-tidal P_{CO_2}.[124] Similar alterations are observed with narcotics and other halogenated anesthetics.[125] Figures 5-22 to 5-24 show that decreases in $\dot{V}_E$ cause increases in P_{aCO_2} and decreases in P_{aO_2}. The relative increase in P_{aCO_2} caused by depression of $\dot{V}_E$ (<1.24 MAC) by halogenated anesthetics is desflurane = isoflurane > sevoflurane > halothane. At higher concentrations, desflurane causes increasing ventilatory depression, even

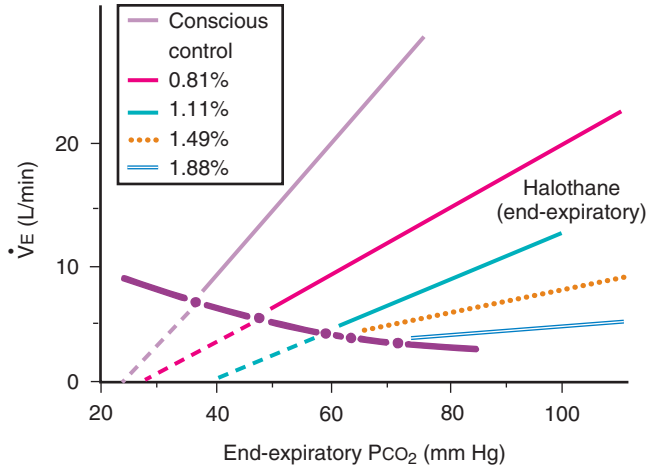

Figure 5-31 In conscious controls, increasing end-expiratory concentration of carbon dioxide (P_{CO_2}, x-axis) increases pulmonary minute volume ($\dot{V}_E$, y-axis). The dashed line is an extrapolation of the CO_2 response curve to zero ventilation and represents the apneic threshold. Increases in end-expiratory anesthetic (halothane) concentration progressively diminish the slope of the CO_2 response curve and shift the apneic threshold to a higher P_{CO_2}. The heavy line interrupted by dots shows the decrease in minute ventilation and the increase in P_{CO_2} that occur with increasing depth of anesthesia. (Redrawn with modification from Munson ES, Larson CP Jr, Babad AA, et al: The effects of halothane, fluroxene and cyclopropane on ventilation: A comparative study in man. *Anesthesiology* 27:716, 1966.)

more than isoflurane, and sevoflurane causes a degree of ventilatory depression similar to isoflurane.

C. Preexisting Respiratory Dysfunction

Anesthesiologists are frequently required to care for (1) patients with acute chest disease (pulmonary infection, atelectasis) or systemic diseases (sepsis, cardiac and renal failure, multiple trauma) who require emergency operations, (2) heavy smokers with subtle pathologic airway and parenchymal conditions and hyperreactive airways, (3) patients with classic emphysematous and bronchitic problems, (4) obese people susceptible to decreases in FRC during anesthesia,[126] (5) patients with chest deformities, and (6) extremely old patients.

The nature and magnitude of these preexisting respiratory conditions determine, in part, the effect of a given standard anesthetic on respiratory function. For example, in Figure 5-32, the FRC-CC relationship is depicted for normal, obese, bronchitic, and emphysematous patients. In a healthy patient, FRC exceeds CC by approximately 1 L. In the latter three respiratory conditions, CC is 0.5 to 0.75 L less than FRC. If anesthesia causes a 1-L decrease in FRC in a healthy patient, there is no change in the qualitative relationship between FRC and CC. In patients with special respiratory conditions, however, a 1-L decrease in FRC causes CC to exceed FRC and changes the previous marginally normal FRC-CC relationship to either a grossly low $\dot{V}_A/\dot{Q}$ or an atelectatic FRC-CC relationship. Similarly, patients with chronic bronchitis, who have copious airway secretions, may suffer more than other patients from an anesthetic-induced decrease in mucus velocity flow. Finally, if an

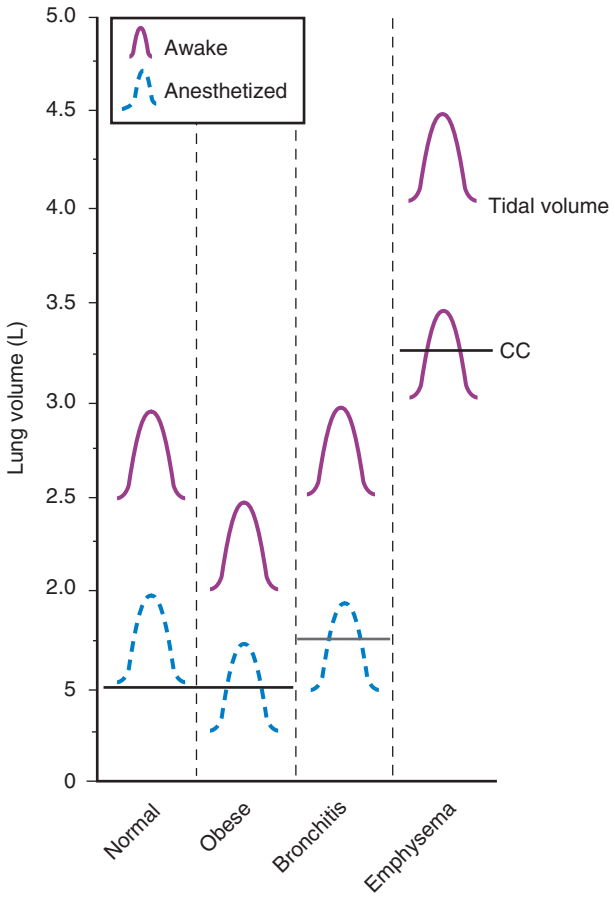

Figure 5-32 The lung volume (ordinate) at which tidal volume is breathed decreases (by 1 L) from the awake state to the anesthetized state. Functional residual capacity (FRC), which is the volume of gas existing in the lung at the end of a tidal breath, therefore also decreases (by 1 L) from the awake to the anesthetized state. In healthy, obese, bronchitic, and emphysematous patients, the awake FRC considerably exceeds the closing capacity (*CC*, horizontal lines), but the anesthetized state causes FRC to be less than CC. In healthy patients, anesthesia causes FRC to equal CC.

anesthetic inhibits HPV, the drug may increase shunting more in patients with preexisting HPV than in those without preexisting HPV. Thus, the effect of a standard anesthetic can be expected to produce varying degrees of respiratory change in patients who have different degrees of preexisting respiratory dysfunction.

D. Special Intraoperative Conditions

Some special intraoperative conditions (e.g., surgical position, massive blood loss, surgical retraction on the lung) can cause impaired gas exchange. For example, some of the surgical positions (i.e., the lithotomy, jackknife, and kidney rest positions) and surgical exposure requirements may decrease $\dot{Q}_T$, cause hypoventilation in a spontaneously breathing patient, and reduce FRC. The type and severity of preexisting respiratory dysfunction, as well as the number and severity of special intraoperative conditions that can embarrass respiratory function, magnify the respiratory depressant effects of any anesthetic.

E. Mechanisms of Hypoxemia During Anesthesia

1. Equipment Malfunction

a. MECHANICAL FAILURE OF ANESTHESIA APPARATUS TO DELIVER OXYGEN TO THE PATIENT

Hypoxemia resulting from mechanical failure of the O_2 supply system (see Chapter 14) or the anesthesia machine is a recognized hazard of anesthesia. Disconnection of the patient from the O_2 supply system (usually at the juncture of the ETT and the elbow connector) is by far the most common cause of mechanical failure to deliver O_2 to the patient. Other reported causes of failure of the O_2 supply during anesthesia include the following: an empty or depleted O_2 cylinder, substitution of a nonoxygen cylinder at the O_2 yoke because of absence or failure of the pin index, an erroneously filled O_2 cylinder, insufficient opening of the O_2 cylinder (which hinders free flow of gas as pressure decreases), failure of gas pressure in a piped O_2 system, faulty locking of the piped O_2 system to the anesthesia machine, inadvertent switching of the Schrader adapters on piped lines, crossing of piped lines during construction, failure of a reducing valve or gas manifold, inadvertent disturbance of the setting of the O_2 flowmeter, use of the fine O_2 flowmeter instead of the coarse flowmeter, fractured or sticking flowmeters, transposition of rotameter tubes, erroneous filling of a liquid O_2 reservoir with N_2, and disconnection of the fresh gas line from machine to in-line hosing.[127–131] Monitoring of the inspired O_2 concentration with an in-line F_{IO_2} analyzer and monitoring of airway pressure should detect most of these causes of failure to deliver O_2 to the patient.[127–131]

b. IMPROPER ENDOTRACHEAL TUBE POSITION

Esophageal intubation results in almost no ventilation. Aside from disconnection, almost all other mechanical problems with ETTs (e.g., kinking, blockage of secretions, herniated or ruptured cuffs) cause an increase in airway resistance that may result in hypoventilation. Intubation of a main stem bronchus (see Chapter 7) results in absence of ventilation of the contralateral lung. Although potentially minimized by HPV, some perfusion to the contralateral lung always remains, and shunting increases and Pa_{O_2} decreases. A tube previously well positioned in the trachea may enter a bronchus after the patient or the patient's head is turned or moved into a new position.[132] Flexion of the head causes the tube to migrate deeper (caudad) into the trachea, whereas extension of the head causes cephalad (outward) migration of the ETT.[132] A high incidence of main stem bronchial intubation after the institution of a 30-degree Trendelenburg position has been reported.[133] Cephalad shift of the carina and mediastinum during the Trendelenburg position caused the previously "fixed" ETT to migrate into a main stem bronchus. Main stem bronchial intubation may obstruct the ipsilateral upper lobe in addition to the contralateral lung.[134,135] Infrequently, the right upper bronchus or one of its segmental bronchi branches from the lateral wall of the trachea (above the carina) and may be occluded by a properly positioned ETT.

2. Hypoventilation

Patients under general anesthesia may have a reduced spontaneous V_T for two reasons. First, increased WOB can occur during general anesthesia as a result of increased airway resistance and decreased C_L. Airway resistance can be increased because of reduced FRC, endotracheal intubation, the presence of the external breathing apparatus and circuitry, and possible airway obstruction in patients whose tracheas are not intubated.[136–138] C_L is reduced as a result of some (or all) of the factors that can decrease FRC.[89] Second, patients may have a decreased drive to breathe spontaneously during general anesthesia (i.e., decreased chemical control of breathing) (see Fig. 5-31).

Decreased V_T may cause hypoxemia in two ways.[117] First, shallow breathing can promote atelectasis and cause a decrease in FRC (see "Ventilation Pattern [Rapid Shallow Breathing]").[40,139] Second, decreased $\dot{V}_E$ decreases the overall $\dot{V}_A/\dot{Q}$ ratio of the lung, which decreases Pa_{O_2} (see Figs. 5-23 and 5-24).[117] This is likely to occur with spontaneous ventilation during moderate to deep levels of anesthesia, in which the chemical control of breathing is significantly altered.

3. Hyperventilation

Hypocapnic alkalosis (hyperventilation) can occasionally be associated with a decreased Pa_{O_2} due to several indirect mechanisms: decreased $\dot{Q}_T$ and increased $\bar{V}_{O_2}$[140,141] (see "Decreased Cardiac Output and Increased Oxygen Consumption"),[99,101,140,141] a left-shifted oxy-Hb curve (see "Oxygen-Hemoglobin Dissociation Curve"), decreased HPV (see "Inhibition of Hypoxic Pulmonary Vasoconstriction"),[142] and increased airway resistance and decreased compliance (see "Increased Airway Resistance").[143] Although these theoretical causes of hypoxemia exist, they are seldom a major factor in the clinical realm.

4. Decrease in Functional Residual Capacity

The effect of decreased FRC on hypoxemia is very significant clinically. Induction of general anesthesia is consistently accompanied by a pronounced (15% to 20%) decrease in FRC,[32,83,144] which usually causes a decrease in compliance.[89] The maximum decrease in FRC appears to occur within the first few minutes of anesthesia,[32,145] and in the absence of any other complicating factor, FRC does not seem to decrease progressively during anesthesia. During anesthesia, the reduction in FRC is of the same order of magnitude whether ventilation is spontaneous or controlled. Conversely, in awake patients, FRC is only slightly reduced during controlled ventilation.[146] In obese patients, the reduction in FRC is far more pronounced than in normal patients, and the decrease is inversely related to the body mass index (BMI).[147] The reduction in FRC continues into the postoperative period.[148] For individual patients, the reduction in FRC correlates well with the increase in the alveolar-arterial P_{O_2} gradient during anesthesia with spontaneous breathing,[149] during anesthesia with artificial ventilation,[146] and in the postoperative period.[148] The reduced FRC can be restored to normal or above normal by the application of

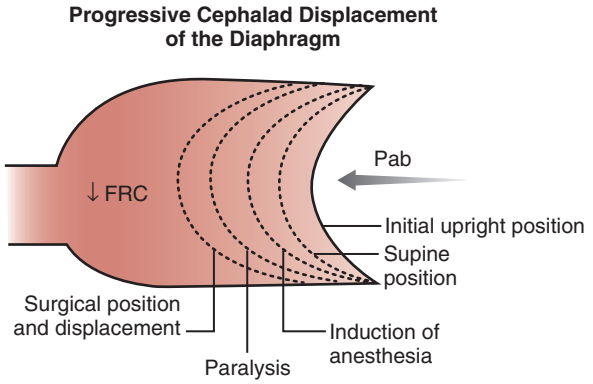

Figure 5-33 Anesthesia and surgery may cause a progressive cephalad displacement of the diaphragm. The sequence of events involves assumption of the supine position, induction of anesthesia, establishment of paralysis, assumption of several surgical positions, and displacement by retractors and packs. Cephalad displacement of the diaphragm results in decreased functional residual capacity *(↓ FRC). Pab,* Pressure of abdominal contents. (Redrawn with modification from Benumof JL: *Anesthesia for thoracic surgery,* ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

PEEP.[82,150] The following discussion considers the most common causes of reduced FRC.

a. SUPINE POSITION

Anesthesia and surgery are usually performed with the patient in the supine position. With change from the upright to the supine position, FRC decreases by 0.5 to 1.0 L[32,83,144] because of a 4-cm cephalad displacement of the diaphragm by the abdominal viscera (Fig. 5-33). Pulmonary vascular congestion can also contribute to the decrease in FRC in the supine position, particularly in patients who experienced orthopnea preoperatively.

b. INDUCTION OF GENERAL ANESTHESIA: CHANGE IN THORACIC CAGE MUSCLE TONE

At the end of a normal (awake) exhalation, there is slight tension in the inspiratory muscles and no tension in the expiratory muscles. Therefore, at the end of a normal exhalation, there is a force tending to maintain lung volume and no force decreasing lung volume. After induction of general anesthesia, there is a loss of inspiratory tone and an appearance of end-expiratory tone in the abdominal expiratory muscles at the end of exhalation. The end-expiratory tone in the abdominal expiratory muscles increases intra-abdominal pressure, forces the diaphragm cephalad, and decreases FRC (see Fig. 5-33).[145,151] Thus, after the induction of general anesthesia, there is loss of the force tending to maintain lung volume and gain of the force tending to decrease lung volume. Indeed, Innovar (droperidol and fentanyl citrate) may increase tone in expiratory muscles to such an extent that the reduction in FRC with Innovar anesthesia alone is greater than that with Innovar plus paralysis induced by succinylcholine.[151,152]

With emphysema, exhalation may be accompanied by pursing the lips or grunting (i.e., with a partially closed larynx). An emphysematous patient exhales in either of these ways because both these maneuvers cause an expiratory retardation that produces PEEP in the intrathoracic air passage and decreases the possibility of airway closure and a decrease in FRC (see Fig. 5-17F). Endotracheal intubation bypasses the lips and glottis and can abolish the normally present pursed-lip or grunting exhalation in a patient with COPD and in that way contributes to airway closure and loss of FRC in some spontaneously breathing patients.

c. PARALYSIS

In an upright subject, FRC and the position of the diaphragm are determined by the balance between lung elastic recoil pulling the diaphragm cephalad and the weight of the abdominal contents pulling it caudad.[153] There is no transdiaphragmatic pressure gradient.

The situation is more complex in the supine position. The diaphragm separates two compartments of markedly different hydrostatic gradients. On the thoracic side, pressure increases by approximately 0.25 cm H_2O/cm of lung height,[38,154] and on the abdominal side, it increases by 1.0 cm H_2O/cm of abdominal height.[153] Therefore, in horizontal postures, progressively higher transdiaphragmatic pressure must be generated toward dependent parts of the diaphragm to keep the abdominal contents out of the thorax. In an unparalyzed patient, this tension is developed either by passive stretch and changes in shape of the diaphragm (causing an increased contractile force) or by neurally mediated active tension. With acute muscle paralysis, neither of these two mechanisms can operate, and a shift of the diaphragm to a more cephalad position occurs (see Fig. 5-33).[155] The latter position must express the true balance of forces on the diaphragm, unmodified by any passive or active muscle activity.

The cephalad shift in the FRC position of the diaphragm as a result of expiratory muscle tone during general anesthesia is equal to the shift observed during paralysis (awake or anesthetized patients).[145,156] The equal shift suggests that the pressure on the diaphragm caused by an increase in expiratory muscle tone during general anesthesia is equal to the pressure on the diaphragm caused by the weight of the abdominal contents during paralysis. It is quite probable that the magnitude of these changes in FRC related to paralysis also depends on body habitus.

d. LIGHT OR INADEQUATE ANESTHESIA AND ACTIVE EXPIRATION

Induction of general anesthesia can result in increased expiratory muscle tone,[151] but the increased expiratory muscle tone is not coordinated and does not contribute to the exhaled volume of gas. In contrast, spontaneous ventilation during light general anesthesia usually results in a coordinated and moderately forceful active exhalation and larger exhaled volumes. Excessively inadequate anesthesia (relative to a given stimulus) results in very forceful active exhalation, which can produce exhaled volumes of gas equal to an awake expiratory vital capacity.

As during an awake expiratory vital capacity maneuver, forced expiration during anesthesia raises intrathoracic and alveolar pressure considerably above atmospheric pressure (see Fig. 5-17). This increase in pressure results in rapid outflow of gas, and because part of the expiratory

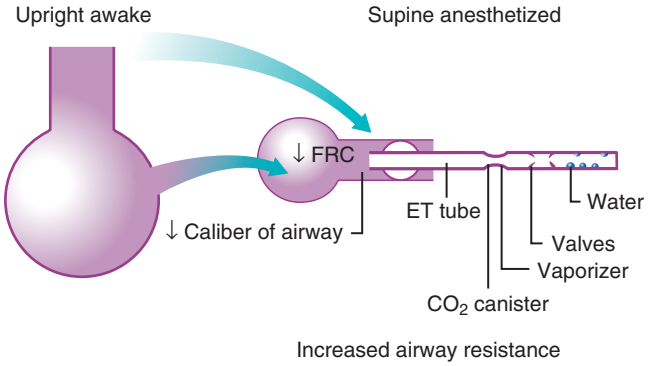

Figure 5-34 An anesthetized patient in the supine position has increased airway resistance as a result of decreased functional residual capacity *(FRC)*, decreased caliber of the airways, endotracheal intubation, and connection of the endotracheal tube *(ET)* to the external breathing apparatus and circuitry. ↓, Decreased. (Redrawn with modification from Benumof JL: *Anesthesia for thoracic surgery*, ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

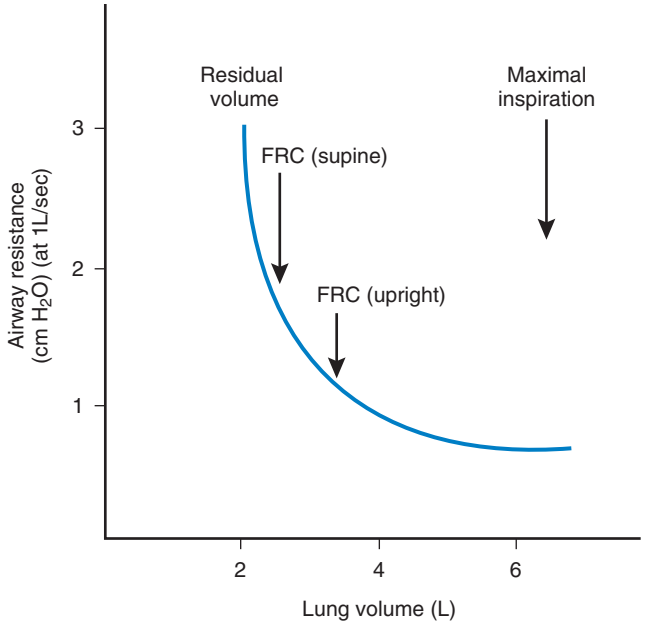

Figure 5-35 Airway resistance is an increasing hyperbolic function of decreasing lung volume. Functional residual capacity *(FRC)* decreases with a change from the upright to the supine position. (Redrawn with modification from Lumb AB: Respiratory system resistance. In Lumb AB, editor: *Nunn's applied respiratory physiology*, ed 5, London, 2000, Butterworths, p 67.)

resistance lies in the smaller air passages, a drop in pressure occurs between the alveoli and the main bronchi. Under these circumstances, intrathoracic pressure rises considerably above the pressure within the main bronchi. Collapse occurs if this reversed pressure gradient is sufficiently high to overcome the tethering effect of the surrounding parenchyma on the small intrathoracic bronchioles or the structural rigidity of cartilage in the large extrathoracic bronchi. Such collapse occurs in a normal subject during a maximal forced expiration and is responsible for the associated wheeze in both awake and anesthetized patients.[157]

In a paralyzed, anesthetized patient, the use of a subatmospheric expiratory pressure phase is analogous to a forced expiration in a conscious subject; the negative phase may set up the same adverse ΔP, which can cause airway closure, gas trapping, and a decrease in FRC. An excessively rapidly descending bellows of a ventilator during expiration has caused subatmospheric expiratory pressure and resulted in wheezing.[158]

e. INCREASED AIRWAY RESISTANCE

The overall reduction in all components of lung volume during anesthesia results in reduced airway caliber, which increases airway resistance and any tendency toward airway collapse (Fig. 5-34). The relationship between airway resistance and lung volume is well established (Fig. 5-35). The decreases in FRC caused by the supine position (≈ 0.8L) and induction of anesthesia (≈ 0.4L) are often sufficient to explain the increased resistance seen in a healthy anesthetized patient.[137]

In addition to this expected increase in airway resistance in anesthetized patients, there are a number of special potential sites of increased airway resistance, including the ETT (if present), the upper and lower airway passages, and the external anesthesia apparatus. Endotracheal intubation reduces the size of the trachea, usually by 30% to 50% (see Fig. 5-34). Pharyngeal obstruction, which can be considered to be a normal feature of unconsciousness, is most common. A minor degree of this type of obstruction occurs in snoring. Laryngospasm and obstructed ETTs (e.g., secretions, kinking, herniated cuffs) are not uncommon and can be life-threatening.

The respiratory apparatus often causes resistance that is considerably higher than the resistance in the normal human respiratory tract (see Fig. 5-34).[89] When certain resistors such as those shown in Figure 5-34 are joined in series to form an anesthetic gas circuit, their effects are generally additive and produce larger resistance (as with resistance in series in an electrical circuit). The increase in resistance associated with commonly used breathing circuits and ETTs can impose an additional WOB that is two to three times normal.[136]

f. SUPINE POSITION, IMMOBILITY, AND EXCESSIVE INTRAVENOUS FLUID ADMINISTRATION

Patients undergoing anesthesia and surgery are often kept supine and immobile for long periods. In these cases, some of the lung can be continually dependent and below the left atrium and therefore in zone 3 or 4 condition. Being in a dependent position, the lung is predisposed to accumulation of fluid. Coupled with excessive fluid administration, conditions sufficient to promote transudation of fluid into the lung are present and result in pulmonary edema and decreased FRC.

When mongrel dogs were placed in a lateral decubitus position and anesthetized for several hours (Fig. 5-36), expansion of the extracellular space with fluid caused the P_{O_2} of blood draining the dependent lung to decrease precipitously to mixed venous levels (no O_2 uptake).[159] Blood draining the nondependent lung maintained its P_{O_2} for a period but declined after 5 hours in the presence of the extracellular fluid expansion. Transpulmonary shunting progressively increased. If the animals were turned every hour (and received the same fluid

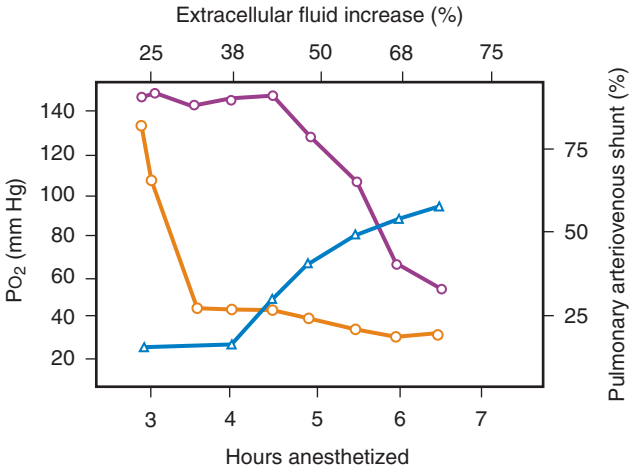

Figure 5-36 Mongrel dogs anesthetized with pentobarbital were placed in a lateral decubitus position and subjected to progressive extracellular fluid expansion. They had a marked decrease in the partial pressure of oxygen *(P_{O_2})* of blood draining the dependent lung *(yellow line)* and a smaller, much slower decrease in the P_{O_2} of blood draining the nondependent lung *(purple line)*. The pulmonary arteriovenous shunt rose progressively *(blue line)*. (Redrawn from Ray JF, Yost L, Moallem S, et al: Immobility, hypoxemia, and pulmonary arteriovenous shunting. *Arch Surg* 109:537, 1974.)

challenge), only the dependent lung, at the end of each hour period, suffered a decrease in oxygenation. If the animals were turned every half-hour and received the same fluid challenge, neither lung suffered a decrease in oxygenation.

In patients who undergo surgery in the lateral decubitus position (e.g., pulmonary resection, in which they have or will have a restricted pulmonary vascular bed) and receive excessive intravenous fluids, the risk of the dependent lung's becoming edematous is certainly increased. These considerations also explain, in part, the beneficial effect of a continuously rotating (side-to-side) bed on the incidence of pulmonary complications in critically ill patients.[160]

g. HIGH INSPIRED OXYGEN CONCENTRATION AND ABSORPTION ATELECTASIS

General anesthesia is usually administered with an increased F_{IO_2}. In patients who have areas of moderately low $\dot{V}_A/\dot{Q}$ ratios (0.1 to 0.01), administration of F_{IO_2} greater than 0.3 adds enough O_2 into the alveolar space in these areas to eliminate the shunt-like effect that they have, and total measured right-to-left shunting decreases. However, when patients with a significant amount of blood flow perfusing lung units with very low $\dot{V}_A/\dot{Q}$ ratios (0.01 to 0.0001) have a change in F_{IO_2} from room air to 1.0, the very low $\dot{V}_A/\dot{Q}$ units virtually disappear, and a moderately large right-to-left shunt appears.[16,17,161] In these studies, the increase in shunting was equal to the amount of blood flow previously perfusing the areas with low $\dot{V}_A/\dot{Q}$ ratios during the breathing of air. Thus, the effect of breathing O_2 was to convert units that had low $\dot{V}_A/\dot{Q}$ ratios into shunt units. The pathologic basis for these data is the conversion of low $\dot{V}_A/\dot{Q}$ units into atelectatic units. The cause of the atelectatic shunting during O_2 breathing is presumably a large increase in O_2 uptake by lung units with low $\dot{V}_A/\dot{Q}$ ratios.[161,162] A unit that has a low $\dot{V}_A/\dot{Q}$ ratio during breathing of air will have a low P_{AO_2}. When an enriched O_2 mixture is inspired, P_{AO_2} rises, and the rate at which O_2 moves from alveolar gas to capillary blood increases greatly. The O_2 flux may increase so much that the net flow of gas into blood exceeds the inspired flow of gas, and the lung unit becomes progressively smaller. Collapse is most likely to occur if F_{IO_2} is high, the $\dot{V}_A/\dot{Q}$ ratio is low, the time of exposure of the unit with low $\dot{V}_A/\dot{Q}$ to high F_{IO_2} is long, and $C\bar{v}O_2$ is low. Given the right $\dot{V}_A/\dot{Q}$ ratio and time of administration, an F_{IO_2} as low as 50% can produce absorption atelectasis.[161,162] This phenomenon is of considerable significance in the clinical situation for two reasons. First, enriched O_2 mixtures are often used therapeutically, and it is important to know whether this therapy is causing atelectasis. Second, the amount of shunt is often estimated during breathing of 100% O_2, and if this maneuver results in additional shunt, the measurement is hard to interpret.

h. SURGICAL POSITION

SUPINE POSITION. In the supine position, the abdominal contents force the diaphragm cephalad and reduce FRC.[83,145,151,156] The Trendelenburg position allows the abdominal contents to push the diaphragm further cephalad so that the diaphragm must not only ventilate the lungs but also lift the abdominal contents out of the thorax. The result is a predisposition to decreased FRC and atelectasis.[163] The decrease in FRC related to Trendelenburg position is exacerbated in obese patients.[147] Increased pulmonary blood volume and gravitational force on the mediastinal structures are additional factors that may decrease pulmonary compliance and FRC. In the steep Trendelenburg position, most of the lung may be below the left atrium and therefore in a zone 3 or 4 condition. In this condition, the lung may be susceptible to the development of pulmonary interstitial edema. Thus, patients with elevated Ppa, such as those with mitral stenosis, do not tolerate the Trendelenburg position well.[164]

LATERAL DECUBITUS POSITION. In the lateral decubitus position, the dependent lung experiences a moderate decrease in FRC and is predisposed to atelectasis, whereas the nondependent lung may have increased FRC. The overall result is usually a slight to moderate increase in total-lung FRC.[165] The kidney and lithotomy positions also cause small decreases in FRC above that caused by the supine position. The prone position may increase FRC moderately.[165]

i. VENTILATION PATTERN (RAPID SHALLOW BREATHING)

Rapid shallow breathing is often a regular feature of anesthesia. Monotonous shallow breathing can cause a decrease in FRC, promote atelectasis, and decrease compliance.[40,139,166] These changes with rapid shallow breathing are probably due to progressive increases in surface tension.[166] Initially, these changes may cause hypoxemia with normocapnia and may be prevented or reversed by periodic large mechanical inspirations, spontaneous sighs, PEEP, or a combination of these techniques.[166–168]

j. DECREASED REMOVAL OF SECRETIONS (DECREASED MUCOCILIARY FLOW)

Tracheobronchial mucous glands and goblet cells produce mucus, which is swept by cilia up to the larynx, where it is swallowed or expectorated. This process clears inhaled organisms and particles from the lungs. The secreted mucus consists of a surface gel layer lying on top of a more liquid sol layer in which the cilia beat. The tips of the cilia propel the gel layer toward the larynx (upward) during the forward stroke. As the mucus streams upward and the total cross-sectional area of the airways diminishes, absorption takes place from the sol layer to maintain a constant depth of 5 mm.[169]

Poor systemic hydration and low inspired humidity reduce mucociliary flow by increasing the viscosity of secretions and slowing the ciliary beat.[170–172] Mucociliary flow varies directly with body or mucosal temperature (low inspired temperature) over a range of 32° to 42° C.[173,174] High FIO_2 decreases mucociliary flow.[175] Inflation of an ETT cuff suppresses tracheal mucus velocity,[176] an effect that occurs within 1 hour, and apparently it does not matter whether a low- or high-compliance cuff is used. Passage of an uncuffed tube through the vocal cords and keeping it in situ for several hours does not affect tracheal mucus velocity.[176]

The mechanism for suppression of mucociliary clearance by the ETT cuff is speculative. In the report of Sackner and colleagues,[176] mucus velocity was decreased in the distal portion of the trachea, but the cuff was inflated in the proximal portion. Therefore, the phenomenon cannot be attributed solely to damming of mucus at the cuff site. One possibility is that the ETT cuff caused a critical increase in the thickness of the layer of mucus proceeding distally from the cuff. Another possibility is that mechanical distention of the trachea by the ETT cuff initiated a neurogenic reflex arc that altered mucous secretions or the frequency of ciliary beating.

Other investigators showed that when all the foregoing factors were controlled, halothane reversibly and progressively decreased but did not stop mucus flow over an inspired concentration of 1 to 3 MAC.[177] The halothane-induced depression of mucociliary clearance was probably due to depression of the ciliary beat, an effect that caused slow clearance of mucus from the distal and peripheral airways. In support of this hypothesis is the finding that cilia are morphologically similar throughout the animal kingdom. Inhaled anesthetics in clinical doses, including halothane, have been found to cause reversible depression of the ciliary beat of protozoa.[115]

5. Decreased Cardiac Output and Increased Oxygen Consumption

Decreased $\dot{Q}T$ in the presence of constant O_2 consumption ($\dot{V}O_2$), increased $\dot{V}O_2$ in the presence of a constant $\dot{Q}T$, and decreased $\dot{Q}T$ concomitant with increased $\dot{V}O_2$ must all result in lower $C\bar{v}O_2$. Venous blood with lowered $C\bar{v}O_2$ then flows through whichever shunt pathways exist, mixes with the oxygenated end-pulmonary capillary blood, and lowers CaO_2 (see Figs. 5-27 and 5-28). Figure 5-37 shows these relationships quantitatively for several different intrapulmonary shunts.[100,101] The larger the intrapulmonary shunt, the greater the decrease in CaO_2, because more venous blood with lower $C\bar{v}O_2$ can admix with end-pulmonary capillary blood. Decreased $\dot{Q}T$ may occur with myocardial failure and hypovolemia; the specific causes of these two conditions are beyond the scope of this chapter. Increased $\dot{V}O_2$ may occur with excessive stimulation of the sympathetic nervous system, hyperthermia, or shivering and can further contribute to impaired oxygenation of arterial blood.[178]

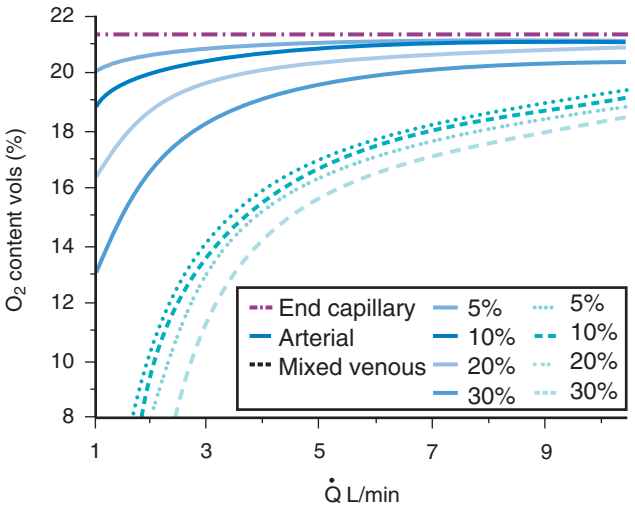

Figure 5-37 Effects of changes in cardiac output ($\dot{Q}$) on the O_2 content of end-pulmonary capillary, arterial *(solid lines)*, and mixed venous *(dashed lines)* blood for various transpulmonary right-to-left shunts. The magnitudes of the shunts are indicated by the percentages; the oxygen content of end-capillary blood is unaffected by the degree of shunting. Note that a given decrease in $\dot{Q}$ results in a greater decrease in the arterial content of O_2 with larger shunts. (Redrawn from Kelman GF, Nunn JF, Prys-Roberts C, et al: The influence of the cardiac output on arterial oxygenation: A theoretical study. *Br J Anaesth* 39:450, 1967.)

6. Inhibition of Hypoxic Pulmonary Vasoconstriction

Decreased regional PAO_2 causes regional pulmonary vasoconstriction, which diverts blood flow away from hypoxic regions of the lung to better ventilated normoxic regions. The diversion of blood flow minimizes venous admixture from the underventilated or nonventilated lung regions. Inhibition of regional HPV could impair arterial oxygenation by permitting increased venous admixture from hypoxic or atelectatic areas of the lung (see Fig. 5-9).

Because the pulmonary circulation is poorly endowed with smooth muscle, any condition that increases the pressure against which the vessels must constrict (i.e., Ppa) decreases HPV. Numerous clinical conditions can increase Ppa and therefore decrease HPV. Mitral stenosis,[179] volume overload,[179] low (but greater than room air) FIO_2 in nondiseased lung,[74] a progressive increase in the amount of diseased lung,[74] thromboembolism,[74] hypothermia,[180] and vasoactive drugs can all increase Ppa.[64] Direct vasodilating drugs (e.g., isoproterenol, nitroglycerin, sodium nitroprusside),[64,59] inhaled anesthetics,[65] and hypocapnia can directly decrease HPV.[64,142] Selective application of PEEP to only the nondiseased lung can selectively increase PVR in the nondiseased lung and may divert blood flow back into the diseased lung.[181]

7. Paralysis

In the supine position, the weight of the abdominal contents pressing against the diaphragm is greatest in the dependent or posterior part of the diaphragm and least in the nondependent or anterior part of the diaphragm. In an awake patient breathing spontaneously, active tension in the diaphragm is capable of overcoming the weight of the abdominal contents, and the diaphragm moves most in the posterior portion (because the posterior of the diaphragm is stretched higher into the chest, it has the smallest radius of curvature, and therefore it contracts most effectively) and least in the anterior portion. This circumstance is healthy because the greatest amount of ventilation occurs in areas with the most perfusion (posteriorly or dependently), and the least amount occurs in areas with the least perfusion (anteriorly or nondependently). During paralysis and positive-pressure breathing, the passive diaphragm is displaced by the positive pressure preferentially in the anterior, nondependent portion (where there is the least resistance to diaphragmatic movement) and is displaced minimally in the posterior, dependent portion (where there is the most resistance to diaphragmatic movement). This circumstance is unhealthy because the greatest amount of ventilation now occurs in areas with the least perfusion, and the least amount occurs in areas with the most perfusion.[156] However, the magnitude of the change in the diaphragmatic motion pattern with paralysis varies with body position.[156,182]

8. Right-to-Left Interatrial Shunting

Acute arterial hypoxemia from a transient right-to-left shunt through a PFO has been described, particularly during emergence from anesthesia.[70] However, unless a real-time technique of imaging the cardiac chambers is used (e.g., transesophageal echocardiography with color flow Doppler imaging),[71] it is difficult to document an acute and transient right-to-left intracardiac shunt as a cause of arterial hypoxemia. Nonetheless, right-to-left shunting through a PFO has been described in virtually every conceivable clinical situation that afterloads the right side of the heart and increases right atrial pressure. When right-to-left shunting through a PFO is identified, administration of inhaled NO can decrease PVR and functionally close the PFO.[183]

9. Involvement of Mechanisms of Hypoxemia in Specific Diseases

In any given pulmonary disease, many of the mechanisms of hypoxemia listed earlier may be involved.[117] Pulmonary embolism (air, fat, thrombi) (Fig. 5-38) and the evolution of ARDS (Fig. 5-39) are used to illustrate this point. A significant pulmonary embolus can cause severe increases in Ppa, and these increases can result in right-to-left transpulmonary shunting through opened arteriovenous anastomoses and the foramen ovale (possible in 20% of patients), pulmonary edema in nonembolized regions of the lung, and inhibition of HPV. The embolus can cause hypoventilation through increased dead space ventilation. If the embolus contains platelets, serotonin can be released, and such release can cause hypoventilation as a result of bronchoconstriction and pulmonary edema as a result of increased pulmonary capillary permeability. Finally, the pulmonary embolus can increase PVR (by platelet-induced serotonin release,[4] among other mechanisms) and decrease cardiac output.

After major hypotension, shock, blood loss, sepsis, or other conditions, noncardiogenic pulmonary edema may occur and lead to acute respiratory failure or ARDS.[184] The syndrome can evolve during and after anesthesia and has the hallmark characteristics of decreased FRC and compliance and hypoxemia. After shock and trauma, plasma levels of serotonin, histamine, kinins, lysozymes, reactive oxygen species, fibrin degradation products, products of complement metabolism, and fatty acids all increase. Sepsis and endotoxemia may be present. Increased levels of activated complement stimulate neutrophils into chemotaxis in patients with trauma and

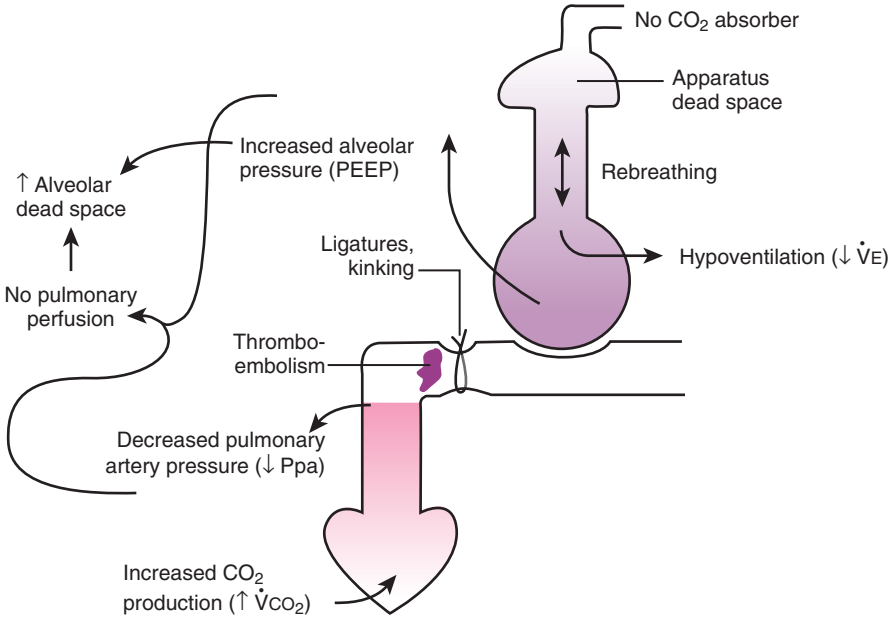

Figure 5-40 Schematic diagram of the causes of hypercapnia during anesthesia. An increase in carbon dioxide *(CO_2)* production ($\dot{V}CO_2$) increases the arterial partial pressure of CO_2 ($PaCO_2$) with a constant minute ventilation ($\dot{V}E$). Several events can increase alveolar dead space: a decrease in pulmonary artery pressure *(Ppa),* the application of positive end-expiratory pressure *(PEEP),* thromboembolism, and mechanical interference with pulmonary arterial flow (ligatures and kinking of vessels). Most commonly in trauma, surgery, and critical care, hypovolemia due to hemorrhage or third spacing leads to increased alveolar dead space and consequently to increased $PaCO_2$. A decrease in $\dot{V}E$ causes an increase in $PaCO_2$ with a constant $\dot{V}CO_2$. It is possible for some anesthesia systems to cause rebreathing of CO_2. Finally, the anesthesia apparatus may increase the anatomic dead space, and inadvertent switching off of a CO_2 absorber in the presence of low fresh gas flow can increase $PaCO_2$. ↑, increase; ↓, decrease. (Redrawn with modification from Benumof JL: *Anesthesia for thoracic surgery,* ed 2, Philadelphia, 1995, Saunders, Chapter 8.)

pancreatitis; activated neutrophils can damage endothelial cells. These factors, along with pulmonary contusion (if it occurs), can individually or collectively increase pulmonary capillary permeability. After shock, acidosis, increased circulating catecholamines and sympathetic nervous system activity, leukotriene and prostaglandin release, histamine release, microembolism (with serotonin release), increased intracranial pressure (with head injury), and alveolar hypoxia can occur and may individually or collectively (particularly after resuscitation) cause a moderate increase in Ppa. After shock, the normal compensatory response to hypovolemia is movement of a protein-free fluid from the interstitial space into the vascular space to restore vascular volume. Dilution of vascular proteins by protein-free interstitial fluid can cause decreased capillary colloid oncotic pressure. Increased pulmonary capillary permeability and Ppa along with decreased capillary colloid oncotic pressure results in fluid transudation and pulmonary edema. In addition, decreased $\dot{Q}T$, inhibition of HPV, immobility, the supine position, excessive fluid administration, and an excessively high FIO_2 can contribute to the development of ARDS.

F. Mechanisms of Hypercapnia and Hypocapnia During Anesthesia

1. Hypercapnia

Hypoventilation, increased dead space ventilation, increased CO_2 production, and inadvertent switching off of a CO_2 absorber can all cause hypercapnia (Fig. 5-40).

2. Hypoventilation

Patients spontaneously hypoventilate during anesthesia because it is more difficult to breath (abnormal surgical position, increased airway resistance, decreased compliance) and because they are less willing to breath (decreased respiratory drive due to anesthetics). Hypoventilation results in hypercapnia (see Figs. 5-22 and 5-23).

3. Increased Dead Space Ventilation

A decrease in Ppa, as during deliberate hypotension,[185] can cause an increase in zone 1 and alveolar dead space ventilation. An increase in airway pressure (as with PEEP) can also cause an increase in zone 1 and alveolar dead space ventilation. Pulmonary embolism, thrombosis, and vascular obliteration (e.g., kinking, clamping, blocking of the pulmonary artery during surgery) can increase the amount of lung that is ventilated but unperfused. Vascular obliteration can also increase dead space ventilation; this occurs with age ($VD/VT\% = 33 + age/3$). Rapid, short inspirations may be distributed preferentially to noncompliant (short time constant for inflation) and badly perfused alveoli, whereas slow inspiration allows time for distribution to more compliant (long time constant for inflation) and better perfused alveoli. Thus, rapid, short inspirations may have a dead space ventilation effect.

The anesthesia apparatus increases total dead space (VD/VT) for two reasons. First, the apparatus simply increases the anatomic dead space. Inclusion of normal apparatus dead space increases the total VD/VT ratio from 33% to about 46% in intubated patients and to

TABLE 5-5
Cardiovascular Response to Hypoxemia

Hemodynamic Variable O_2 Saturation (%)	Heart Rate	Systemic Blood Pressure	Stroke Volume	Cardiac Output	SVR	Predominant Response
>80	↑	↑	↑	↑	No change	Reflex, excitatory
60–80	↑ Baroreceptor	↓	No change	No change	↓	Local, depressant > reflex, excitatory
<60	↓	↓	↓	↓	↓	Local, depressant

SVR, Systemic vascular resistance; ↑, increase; ↓, decrease.

about 64% in patients breathing through a mask.[186] Second, anesthesia circuits cause rebreathing of exhaled gases, which is equivalent to dead space ventilation. The rebreathing classification by Mapleson during spontaneous ventilation with Mapleson circuits is A (Magill), D, C, and B. The order of increasing rebreathing (decreasing clinical merit) during controlled ventilation is D, B, C, and A. There is no rebreathing in system E (Ayre's T-piece) if the patient's respiratory diastole is long enough to permit washout with a given fresh gas flow (a common event) or if the fresh gas flow is greater than the peak inspiratory flow rate (an uncommon event).

The effects of an increase in dead space can usually be counteracted by a corresponding increase in the respiratory $\dot{V}_E$. If, for example, the $\dot{V}_E$ is 10 L/min and the V_D/V_T ratio is 30%, alveolar ventilation is 7 L/min. If a pulmonary embolism occurred and resulted in an increase in the V_D/V_T ratio to 50%, $\dot{V}_E$ would need to be increased to 14 L/min to maintain an alveolar ventilation of 7 L/min (14 L/min × 0.5).

4. Increased Carbon Dioxide Production

All causes of increased O_2 consumption also increase CO_2 production; these causes include hyperthermia, shivering, catecholamine release (light anesthesia), hypertension, and thyroid storm. If $\dot{V}_E$, total dead space, and $\dot{V}_A/\dot{Q}$ relationships are constant, an increase in CO_2 production results in hypercapnia.

5. Inadvertent Switching Off of a Carbon Dioxide Absorber

Many factors, such as patients' ventilatory responsiveness to CO_2 accumulation, fresh gas flow, circle system design, and CO_2 production, determine whether hypercapnia results from accidental switching off or depletion of a circle CO_2 absorber. However, high fresh gas flows (≥5 L/min) minimize the problem with almost all systems for almost all patients.

6. Hypocapnia

The mechanisms of hypocapnia are the reverse of those that produce hypercapnia. Thus, all other factors being equal, hyperventilation (spontaneous or controlled ventilation), decreased V_D ventilation (e.g., change from a mask airway to an ETT airway, decreased PEEP, increased Ppa, decreased rebreathing), and decreased CO_2 production (e.g., hypothermia, deep anesthesia, hypotension) lead to hypocapnia. By far the most common mechanism of hypocapnia is passive hyperventilation by mechanical means.

G. Physiologic Effects of Abnormalities in Respiratory Gases

1. Hypoxia

The end products of aerobic metabolism (oxidative phosphorylation) are CO_2 and water, both of which are easily diffusible and lost from the body. The essential feature of hypoxia is the cessation of oxidative phosphorylation when mitochondrial P_{O_2} falls below a critical level. Anaerobic pathways, which produce energy (ATP) inefficiently, are then used. The main anaerobic metabolites are hydrogen and lactate ions, which are not easily excreted. They accumulate in the circulation, where they can be quantified in terms of the base deficit and the lactate-pyruvate ratio.

Because the various organs have different blood flow and O_2 consumption rates, the manifestations and clinical diagnosis of hypoxia are usually related to symptoms arising from the most vulnerable organ. This organ is usually the brain in an awake patient and the heart in an anesthetized patient (see later discussion), but in special circumstances it may be the spinal cord (e.g., aortic surgery), kidney (e.g., acute tubular necrosis), liver (e.g., hepatitis), or limb (e.g., claudication, gangrene).

The cardiovascular response to hypoxemia is a product of both reflex (neural and humoral) and direct effects (Table 5-5).[187–189] The reflex effects occur first and are excitatory and vasoconstrictive. The neuroreflex effects result from aortic and carotid chemoreceptor, baroreceptor, and central cerebral stimulation, and the humoral reflex effects result from catecholamine and renin-angiotensin release. The direct local vascular effects of hypoxia are inhibitory and vasodilatory and occur late. The net response to hypoxia in a subject depends on the severity of the hypoxia, which determines the magnitude and balance between the inhibitory and excitatory components; the balance may vary according to the type and depth of anesthesia and the degree of preexisting cardiovascular disease.

Mild arterial hypoxemia (arterial saturation less than normal but still 80% or higher) causes general activation of the sympathetic nervous system and release of catecholamines. Consequently, the heart rate, stroke volume, $\dot{Q}_T$, and myocardial contractility—as measured by a shortened pre-ejection period (PEP), left ventricular ejection time (LVET), and a decreased PEP/LVET ratio—are increased (Fig. 5-41).[190] Changes in systemic vascular resistance (SVR) are usually slight. However, in patients under anesthesia with β-blockers, hypoxia (and hypercapnia when present) may cause circulating

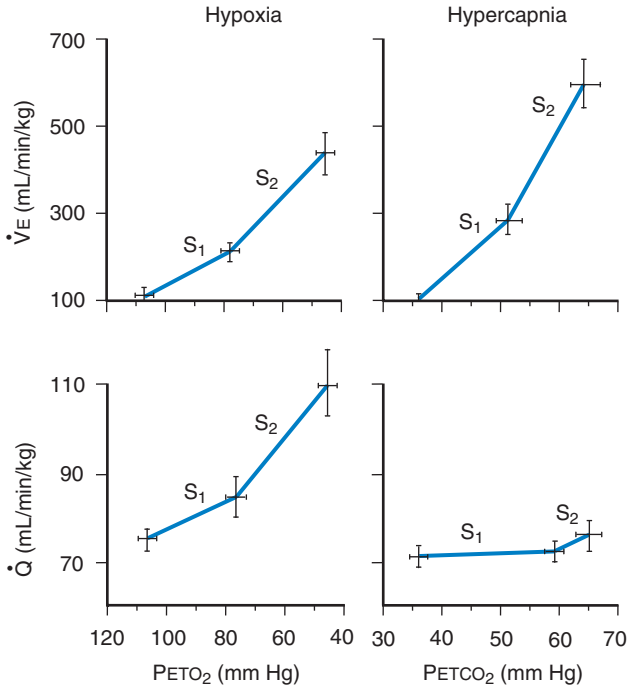

Figure 5-41 Changes in the minute ventilation and in the circulation of healthy awake humans during progressive isocapnic hypoxia and hyperoxic hypercapnia. P_{ETCO_2}, End-tidal P_{CO_2}; P_{ETO_2}, end-tidal P_{O_2}; $\dot{Q}$, cardiac output; S_1, slope during the first phase of slowly increasing ventilation and/or circulation; S_2, slope during the second phase of sharply increasing ventilation and/or circulation; $\dot{V}_E$, expired minute ventilation. (Redrawn from Serebrovskaya TV: Comparison of respiratory and circulatory human responses to progressive hypoxia and hypercapnia. *Respiration* 59:35, 1992.)

catecholamines to have only an α-receptor effect, the heart may be unstimulated (even depressed by a local hypoxia effect), and SVR may be increased. Consequently, $\dot{Q}_T$ may be decreased in these patients. With moderate hypoxemia (arterial O_2 saturation 60% to 80%), local vasodilation begins to predominate and SVR and blood pressure decrease, but the heart rate may continue to be increased because of a systemic hypotension-induced stimulation of baroreceptors. Finally, with severe hypoxemia (arterial saturation <60%), local depressant effects dominate and blood pressure falls rapidly; the pulse slows, shock develops, and the heart either fibrillates or becomes asystolic.

Significant preexisting hypotension converts a mild hypoxemic hemodynamic profile into a moderate hypoxemic hemodynamic profile and converts a moderate hypoxemic hemodynamic profile into a severe hypoxemic hemodynamic profile. Similarly, in well-anesthetized or sedated patients, early sympathetic nervous system reactivity to hypoxemia may be reduced and the effects of hypoxemia may be expressed only as bradycardia with severe hypotension and, ultimately, circulatory collapse.[191]

Hypoxemia can also promote cardiac dysrhythmias, which may in turn potentiate the already mentioned deleterious cardiovascular effects. Hypoxemia-induced dysrhythmias can be caused by multiple mechanisms; the mechanisms are interrelated because they all cause a decrease in the myocardial O_2 supply-demand ratio, which in turn increases myocardial irritability. First, arterial hypoxemia can directly decrease the myocardial O_2 supply. Second, early tachycardia may result in increased myocardial O_2 consumption, and decreased diastolic filling time may lead to decreased myocardial O_2 supply. Third, early increased systemic blood pressure can cause an increased afterload on the left ventricle, which increases left ventricular O_2 demand. Fourth, late systemic hypotension may decrease myocardial O_2 supply because of decreased diastolic perfusion pressure. Fifth, coronary blood flow reserve may be exhausted by a late, maximally increased coronary blood flow as a result of maximal coronary vasodilation.[192] The level of hypoxemia that causes cardiac dysrhythmias cannot be predicted with certainty because the myocardial O_2 supply-demand relationship in a given patient is not known (i.e., the degree of coronary artery atherosclerosis may not be known). However, if a myocardial area (or areas) become hypoxic or ischemic, or both, unifocal or multifocal premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation may occur.

The cardiovascular response to hypoxia includes a number of other important effects. Cerebral blood flow increases (even if hypocapnic hyperventilation is present). Ventilation is stimulated regardless of the reason for the hypoxia (see Fig. 5-41). The pulmonary distribution of blood flow is more homogeneous because of increased pulmonary artery pressure. Chronic hypoxia causes an increased Hb concentration and a right-shifted oxy-Hb curve (as a result of either an increase in 2,3-DPG or acidosis), which tends to raise tissue P_{O_2}.

2. Hyperoxia (Oxygen Toxicity)

The dangers associated with inhalation of excessive O_2 are multiple. Exposure to high O_2 tension clearly causes pulmonary damage in healthy individuals.[193,194] A dose-time toxicity curve for humans is available from a number of studies.[193–195] Because the lungs of normal human volunteers cannot be directly examined to determine the rate of onset and the course of toxicity, indirect measures such as onset of symptoms have been used to construct dose-time toxicity curves. Examination of the curve indicates that 100% O_2 should not be administered for more than 12 hours, 80% O_2 for more than 24 hours, and 60% O_2 for more than 36 hours.[193–195] No measurable changes in pulmonary function or blood-gas exchange occur in humans during exposure to less than 50% O_2, even for long periods.[195] Nevertheless, it is important to note that in the clinical setting, these dose-time toxicity relationships are often obscured because of the complex multivariable nature of the clinical setting.[196]

The dominant symptom of O_2 toxicity in human volunteers is substernal distress, which begins as mild irritation in the area of the carina and may be accompanied by occasional coughing.[197] As exposure continues, the pain becomes more intense, and the urge to cough and to deep-breathe also becomes more intense. These symptoms progress to severe dyspnea, paroxysmal coughing, and decreased vital capacity when the F_{IO_2} has been 1.0 for longer than 12 hours. If excessive O2 is discontinued at this point, recovery of mechanical lung function usually occurs within 12 to 24 hours, but more than 24 hours

may be required in some individuals.[195] As toxicity progresses, results of other pulmonary function studies such as compliance and blood gases show deterioration. Pathologically, in animals, the lesion progresses from tracheobronchitis (exposure for 12 hours to a few days), to involvement of the alveolar septa with pulmonary interstitial edema (exposure for a few days to 1 week), to pulmonary fibrosis of the edema (exposure for >1 week).[198]

Ventilatory depression can occur in patients who, by reason of drugs or disease, have been ventilating in response to a hypoxic drive. By definition, ventilatory depression that results from removal of a hypoxic drive through increasing the inspired O_2 concentration causes hypercapnia but does not necessarily produce hypoxia (because of the increased F_{IO_2}).

Absorption atelectasis was described earlier (see "High Inspired Oxygen Concentration and Absorption Atelectasis"). Retrolental fibroplasia, an abnormal proliferation of the immature retinal vasculature of a prematurely born infant, can occur after exposure to hyperoxia. Extremely premature infants are most susceptible to retrolental fibroplasia (i.e., those <1.0 kg in birth weight and <28 weeks of gestation). The risk of retrolental fibroplasia exists whenever F_{IO_2} causes P_{aO_2} to be greater than 80 mm Hg for longer than 3 hours in an infant whose gestational age plus life age combined is less than 44 weeks. If the ductus arteriosus is patent, arterial blood samples should be drawn from the right radial artery; umbilical or lower-extremity P_{aO_2} is lower than the P_{aO_2} to which the eyes are exposed because of ductal shunting of unoxygenated blood.

The mode of action of O_2 toxicity in tissues is complex, but interference with metabolism seems to be widespread. Most importantly, many enzymes, particularly those with sulfhydryl groups, are inactivated by O_2-derived free radicals.[196] Neutrophil recruitment and release of mediators of inflammation occur next and greatly accelerate the extent of endothelial and epithelial damage and impairment of the surfactant systems.[196] The most acute toxic effect of O_2 in humans is a convulsive effect, which occurs during exposure to pressures in excess of 2 atmospheres (atm) absolute.

High inspired O_2 concentrations can be of use therapeutically. Clearance of gas loculi in the body may be greatly accelerated by the inhalation of 100% O_2. Inhalation of 100% O_2 creates a large nitrogen gradient from the gas space to the perfusing blood. As a result, nitrogen leaves the gas space and the space diminishes in size. Administration of O_2 to remove gas may be used to ease intestinal gas pressure in patients with intestinal obstruction, to decrease the size of an air embolus, and to aid in the absorption of pneumoperitoneum, pneumocephalus, and pneumothorax.

3. Hypercapnia

The effects of CO_2 on the cardiovascular system are as complex as those of hypoxia. Like hypoxemia, hypercapnia appears to cause direct depression of both cardiac muscle and vascular smooth muscle, but at the same time it causes reflex stimulation of the sympathoadrenal system, which compensates to a greater or lesser extent for the primary cardiovascular depression (see Fig. 5-41).[189,192] With moderate to severe hypercapnia, a hyperkinetic circulation results with increased $\dot{Q}_T$ and increased systemic blood pressure.[190] Even in patients under halothane anesthesia, plasma catecholamine levels increase in response to increased CO_2 levels in much the same way as in conscious subjects. Thus, hypercapnia, like hypoxemia, may cause increased myocardial O_2 demand (tachycardia, early hypertension) and decreased myocardial O_2 supply (tachycardia, late hypotension).

Table 5-6 summarizes the interaction of anesthesia with hypercapnia in humans; increased $\dot{Q}_T$ and decreased SVR should be emphasized.[199,200] The increase in $\dot{Q}_T$ is most marked during anesthesia with drugs that enhance sympathetic activity and least marked with halothane and nitrous oxide. The decrease in SVR is most marked during enflurane anesthesia and hypercapnia. Hypercapnia is a potent pulmonary vasoconstrictor even after the inhalation of 3% isoflurane for 5 minutes.[199]

Dysrhythmias have been reported in unanesthetized humans during acute hypercapnia, but they have seldom been of serious import. A high P_{aCO_2} level is, however, more dangerous during general anesthesia. With halothane anesthesia, dysrhythmias frequently occur above a P_{aCO_2} arrhythmic threshold that is often constant for a particular patient. Furthermore, halothane, enflurane, and isoflurane have been shown to prolong the QT_C interval in humans, thereby increasing the risk for torsades de pointes ventricular tachycardia, which in turn is notorious for decompensating into ventricular fibrillation.[201]

The maximum stimulatory respiratory effect is attained by a P_{aCO_2} of about 100 mm Hg. With a higher P_{aCO_2}, stimulation is reduced, and at extremely high levels, respiration is depressed and later ceases altogether. The P_{CO_2} ventilation-response curve is generally displaced to the right, and its slope is reduced by anesthetics and other depressant drugs.[202] With profound anesthesia, the

TABLE 5-6

Cardiovascular Responses to Hypercapnia (P_{aCO_2} = 60–83 mm Hg) During Various Types of Anesthesia (1 MAC Equivalent Except for Nitrous Oxide)*

Anesthesia	Heart Rate	Contractility	Cardiac Output	Systemic Vascular Resistance
Conscious	↑↑	↑↑	↑↑↑	↓
Nitrous oxide	0	↑	↑↑	↓↓
Halothane	0	↑	↑	↓
Isoflurane	↑↑	↑↑↑	↑↑↑	↓

*The increase in the partial arterial pressure of carbon dioxide (P_{aCO_2}) in conscious subjects was 11.5 mm Hg from a normal level of 38 mm Hg.
↑, <10% increase; ↑↑, 10–25% increase; ↑↑↑, >25% increase; 0, no change; ↓, <10% decrease; ↓↓, 10–25% decrease; ↓↓↓, >25% decrease; *MAC*, minimum alveolar concentration for adequate anesthesia in 50% of subjects.

response curve may be flat or even sloping downward, and CO_2 then acts as a respiratory depressant. In patients with ventilatory failure, CO_2 narcosis occurs when P_{ACO_2} rises to greater than 90 to 120 mm Hg. A 30% CO_2 concentration is sufficient for the production of anesthesia, and this concentration causes total but reversible flattening of the electroencephalogram.[203] As expected, hypercapnia causes bronchodilation in both healthy persons and patients with lung disease.[204] Quite apart from the effect of CO_2 on ventilation, it exerts two other important effects that influence the oxygenation of the blood.[117] First, if the concentration of nitrogen (or other inert gas) remains constant, the concentration of CO_2 in alveolar gas can increase only at the expense of O_2, which must be displaced. Thus, P_{AO_2} and Pa_{O_2} may decrease. Second, hypercapnia shifts the oxy-Hb curve to the right, thereby facilitating tissue oxygenation.[95]

Chronic hypercapnia results in increased reabsorption of bicarbonate by the kidneys, which further raises the plasma bicarbonate level and constitutes a secondary or compensatory metabolic alkalosis. The decrease in renal reabsorption of bicarbonate in patients with chronic hypocapnia results in a further fall in plasma bicarbonate and produces a secondary or compensatory metabolic acidosis. In each case, arterial pH returns toward the normal value, but the bicarbonate ion concentration departs even further from normal.

Hypercapnia is accompanied by leakage of potassium from cells into plasma. Much of the potassium comes from the liver, probably from glucose release and mobilization, which occur in response to the rise in plasma catecholamine levels.[205] Because the plasma potassium level takes an appreciable time to return to normal, repeated bouts of hypercapnia at short intervals result in a stepwise rise in plasma potassium. Finally, hypercapnia can predispose the patient to other complications in the operating room; for example, the oculocephalic response is far more common during hypercapnia than during eucapnia.[206]

4. Hypocapnia

In this section, hypocapnia is considered to be produced by passive hyperventilation (by the anesthesiologist or ventilator). Hypocapnia can cause a decrease in $\dot{Q}_T$ by three separate mechanisms. First, if it is present, an increase in intrathoracic pressure decreases $\dot{Q}_T$. Second, hypocapnia is associated with withdrawal of sympathetic nervous system activity, and such withdrawal can decrease the inotropic state of the heart. Third, hypocapnia can increase pH, and the increased pH can decrease ionized calcium, which may in turn decrease the inotropic state of the heart. Hypocapnia with alkalosis also shifts the oxy-Hb curve to the left, which increases Hb affinity for O_2 and thus impairs O_2 unloading at the tissue level. The decrease in peripheral flow and the impaired ability to unload O_2 to the tissues are compounded by an increase in whole-body O_2 consumption as a result of increased pH-mediated uncoupling of oxidation from phosphorylation.[207] A Pa_{CO_2} of 20 mm Hg increases tissue O_2 consumption by 30%. Consequently, hypocapnia may simultaneously increase tissue O_2 demand and decrease tissue O_2 supply. To have the same amount of O_2 delivery to the tissues, $\dot{Q}_T$ or tissue perfusion has to increase at a time when it may not be possible for it to do so. The cerebral effects of hypocapnia may be related to a state of cerebral acidosis and hypoxia because hypocapnia can cause a selective reduction in cerebral blood flow and also shifts the oxy-Hb curve to the left.[208]

Hypocapnia can cause $\dot{V}_A/\dot{Q}$ abnormalities by inhibiting HPV or by causing bronchoconstriction and decreased C_L. Finally, passive hypocapnia promotes apnea.

III. CONCLUSIONS

The primary purpose of the respiratory system is to facilitate gas exchange of O_2 and CO_2 in the alveoli. At the alveoli, O_2 combines with hemoglobin and is transported throughout the body by the circulatory system, while at the same time CO_2 which has been transported from the tissues is removed to be exhaled via the alveoli. These respiratory functions are achieved by coordinated action of the upper and lower airways, alveoli, pulmonary blood flow, respiratory muscles, and metabolic sensors, along with medullary and neural-based control centers.

The lungs also serve a number of very important nonpulmonary metabolic and humoral functions, as described in this chapter.

Ventilation is the process of bringing in O_2 rich air through the airways to the alveoli (inhalation), where gas exchange occurs; then, during exhalation, the O_2-depleted air (along with CO_2 produced in tissues) is returned to the external environment. The process of ventilation is tightly regulated by neural and non-neural mechanisms.

Perfusion relates to the quantity of blood flowing by the alveoli. Pulmonary perfusion is generally equal to cardiac output, unless shunts occur. Ventilation is closely coupled with perfusion of the alveoli. The interaction between ventilation and perfusion (ventilation-perfusion [$\dot{V}_A/\dot{Q}$] relationship) ultimately determines the gas exchange in the lungs.

The transport of O_2 requires reversible binding of O_2 to Hb, which is then unloaded at the tissues. The O_2 flows through its concentration gradient to the extracellular space and cells. Intracellular concentrations of O_2 vary within the cell, with the mitochondrial PO_2 being very low compared to arterial and even mixed venous blood values. Furthermore, interaction of the circulatory system with the respiratory system adds another level of fine-tuning and complexity to the process of perfusion, ventilation, and ventilation-perfusion interaction.

Cardiac and respiratory functions are closely integrated with numerous feedback mechanisms designed to match ventilation with perfusion. The lungs and the heart are the only organs that receive the full $\dot{Q}_T$. Accordingly, the lungs are anatomically well situated to perform many of the secondary (nonpulmonary) functions. The list of nonpulmonary functions continues to grow and includes filtering of metabolic products, conversion of important enzymes, and immune protection.

Pulmonary and nonpulmonary functions adapt to constantly changing needs of the body. Understanding the basic physiologic mechanisms involved in pulmonary and nonpulmonary functions of the lungs is the key to appreciating the pathophysiology of respiratory disorders and

the rational management of respiratory function during resuscitation, perioperative management, and critical care.

IV. CLINICAL PEARLS

- The ventilated gas that participates in gas exchange is referred to as alveolar ventilation ($\dot{V}_A$). The amount of gas that is wasted is referred to as dead space ventilation (V_D). The aggregate total of dead space ventilation is referred to as the physiologic dead space ($V_{D_{physiologic}}$) and is divided into two subcomponents. The volume of gas that ventilates the conducting airways is called the anatomic dead space ($V_{D_{anatomic}}$), and the volume of gas that ventilates nonperfused alveoli is the alveolar dead space ($V_{D_{alveolar}}$).
- Ventilation-perfusion ($\dot{V}/\dot{Q}$) relationships are important in pulmonary gas exchange. At the top of the lung there is relatively high $\dot{V}/\dot{Q}$, whereas at the bottom, there is relatively low $\dot{V}/\dot{Q}$. However, most of the perfusion and most of the ventilation occur at the base, and perfusion is fairly well matched throughout the lung in normal, young, healthy individuals. Alveolar ventilation without perfusion results in alveolar dead space, and alveolar perfusion without ventilation results in a right-to-left transpulmonary shunt.
- The functional residual capacity (FRC) is the amount of gas in the lungs at end-exhalation during normal tidal breathing. The FRC is also equal to the sum of the expiratory reserve volume and the residual volume. The FRC has important clinical significance because it represents the major reservoir of oxygen in the body and is directly related to the time until desaturation after apnea. The FRC is also inversely proportional to the degree of low-$\dot{V}/\dot{Q}$ alveoli and shunt. For example, morbidly obese patients have low FRCs, tend to desaturate quickly, and have many more atelectatic alveoli and shunt units than normal, age-matched patients.
- Lung compliance (C_L, volume/pressure) is the inverse of elastance. C_L is bimodal: it is low at low lung volumes, highest at normal lung volumes (normal FRC), and low at very high lung volumes. The formula for compliance is analogous to the mathematical formula used to calculate capacitance in electronics.
- Factors that affect airway resistance include lung volume, bronchial smooth muscle tone, and the density/viscosity of the inhaled gas.
- Pulmonary vessels constrict in response to hypoxia, hypercarbia, and acidosis, whereas systemic vessels dilate when exposed to these factors.
- Clinically, the work of breathing (WOB) can be simplified to an equation, because it is directly related to the minute ventilation ($\dot{V}_E$) and airway resistance (R_{AW}) and inversely related to C_L (see Equation 9).
- Increased O_2 affinity shifts the oxygen-hemoglobin (oxy-Hb) dissociation curve to the left (i.e., increases the affinity of Hb for O_2, thus reducing P_{50}, the oxygen concentration at which Hb is 50% saturated), whereas decreased O_2 affinity shifts the oxy-Hb curve to the right (i.e., decreases Hb affinity for O_2 and thus increases P_{50}). The four primary processes that shift the oxy-Hb curve to the right are increased hydrogen ion concentration ($[H^+]$), increased carbon dioxide tension (P_{CO_2}), increased 2,3-diphosphoglycerate (2,3-DPG), and increased temperature.
- The Bohr effect refers to the effect of P_{CO_2} and $[H^+]$ ions on the oxy-Hb curve (i.e., increasing the propensity for O_2 to offload from Hb).
- The Haldane effect describes the shift in the CO_2 dissociation curve caused by oxygenation of Hb. Low P_{O_2} shifts the CO_2 dissociation curve to the left so that the blood is able to pick up more CO_2 (e.g., in capillaries of rapidly metabolizing tissues). Highly oxygenated Hb (as occurs in the lungs) reduces the affinity of Hb for CO_2, shifting the CO_2 dissociation curve to the right and thereby increasing CO_2 removal.
- CO_2 is transported in the blood primarily in three different forms: physically dissolved in blood, bound to amino groups of proteins (e.g., Hb) as carbamate compounds, and as bicarbonate ions.

VI. Conclusions

VII. Clinical Pearls

I. INTRODUCTION

Airway pharmacology is concerned with the effect of drug action on airway function, with relevance to anesthesia and critical care. We define a *drug* as a medicinal substance prescribed and administered with therapeutic intent. This definition excludes unprescribed substances consumed for social or recreational purposes. Drugs should be used rationally, with knowledge of *effect* (efficacy, the therapeutic intent) and *side effect* (toxicity). A measure of the safety margin between efficacy and toxicity is the *therapeutic ratio*, and the expected benefit should reasonably outweigh the risk. Drug selection should be a rational choice based on three principles:

1. *Pharmacodynamics:* concerned with drug action, both positive (efficacy) and negative (toxicity)

2. *Pharmacokinetics:* concerned with optimal delivery and removal of the drug from sites of action (the biophase)
3. *Pharmacoeconomics:* concerned with cost-effectiveness in the selection of drug.

In common with all forms of medical treatment, drug therapy carries risk, which should be considered and managed. Drug therapy must be viewed in context. Airway management involves the application of knowledge, skills, and attitudes. Drug administration is only one part of this process, used as part of an overall therapeutic plan. Use of drugs must be viewed within the context of this plan and individualized for a particular patient with a particular set of challenges.

This chapter offers a clinical perspective on airway pharmacology. It is divided into two parts. The first part reviews the actions of common anesthetic drugs on normal airway physiology. The second part reviews the use of drugs in managing the most common airway disorder, asthma, and its analog, intraoperative bronchospasm.

The effects of drugs on the upper airway (nares to glottis) and on the lower airway (glottis to terminal bronchioles) are integral to the practice of safe and effective airway management. Drug administration is often deliberate, either as a treatment for airway pathology or as part of an airway management plan for anesthesia. On occasion, however, there are unwanted effects that may contribute to airway compromise.

II. AIRWAY PHARMACOLOGY IN NORMAL AIRWAY PHYSIOLOGY

A. Clinical Issues

The relevance of airway pharmacology can be considered in relation to a number of clinically important issues.

1. Airway Patency

Maintenance of upper airway patency is critical to achieving adequate ventilation and is affected by a variety of drugs that influence motor tone or sensory feedback or both. Drugs may act directly (e.g., topically administered local anesthetics) or, more commonly, indirectly (e.g., analgesics, sedatives) by acting on the central nervous system (CNS) to compromise upper airway patency.

The lower airway behaves somewhat differently in response to changes in muscle tone, but the drug effects can also have an impact on ventilation and gas exchange.

2. Airway Protection

By similar direct and indirect mechanisms, drugs that are given to optimize the upper airway for airway management interfere with the generation of protective reflexes and thus affect a patient's ability to prevent aspiration.

3. Airway Reactivity

Because the irritability of the upper and lower airways is influenced by centrally-acting and locally-acting drugs used in anesthetic practice, skill in judgment of anesthetic depth is critical to safe airway management. Similarly, endotracheal intubation success is maximized and the risk of laryngeal trauma is minimized by drugs that provide nonreactive vocal cords and an open glottis.

4. Adverse Reactions

Drugs involved in airway management can result in a variety of unwanted sequelae, both local and systemic. These are considered in relation to specific drugs later in this chapter.

5. Optimizing Conditions for Instrumentation of the Airway

Airway management is most likely to be successful when conditions are ideal in terms of airway patency and reactivity. However, the potential reversibility of airway pharmacology must also be considered if the initial airway management plan proves unsuccessful. In this situation, a clinical decision may be taken to reverse the effects of the airway-active drugs as part of an airway rescue plan.

6. Management of the Obstructed Airway

Management of the obstructed airway is considered in Chapter 43.

B. Physiology of the Upper Airway

Physiology of the upper airway is considered in detail in Chapter 5. In the awake patient, airway patency is maintained by muscle tone in the head and neck, particularly the pharynx and tongue. The upper airway muscles are influenced by afferent information from a number of sources (Fig. 6-1), including receptors in the upper airway and lung that respond to changes in airway pressure and a variety of chemical and mechanical stimuli.

A number of nonpharmacologic factors influence the patency of the upper airway. These include the following.

1. Anatomy

Age, body habitus, and posture are all relevant factors. The increased amount of cervical adipose tissue in obesity decreases the volume of the upper airway. The influence of gravity on airway patency is such that tissues have a tendency to fall backward in the supine patient. Head-on-neck extension and jaw thrust move the hyoid bone

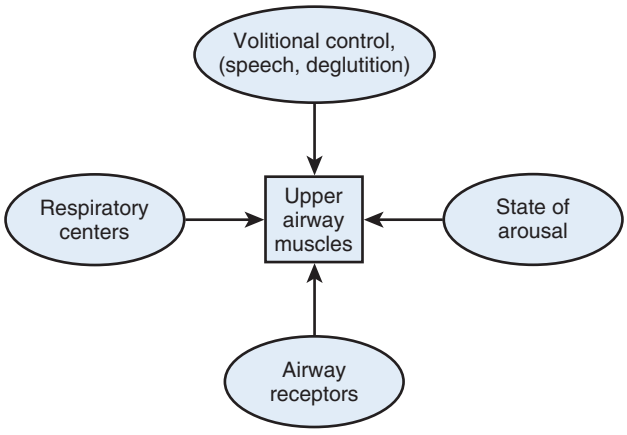

Figure 6-1 Influences modulating the activity of upper airway muscles.

and attached structures anteriorly, helping to relieve any obstruction.

2. Neuromuscular Function

Many of the upper airway muscles can be classed as either airway constricting or airway dilating. These muscles regulate upper airway function by regulating the shape of the upper airway, but their relationships are complex.

3. Autonomic Nervous System

Increased sympathetic nervous activity dilates the upper and lower airways. Sleep has the reverse effect, increasing upper airway resistance. General anesthesia blunts the sympathetic responses to noxious stimuli such as pain. Conversely, during exercise, neurogenic and chemical stimuli trigger dilation of the upper airway to cope with the increase in gas flow. The upper airway muscles, in conjunction with the diaphragm and chest wall muscles, respond to the stresses of hypoxia and hypercarbia to increase upper airway patency, in tandem with the increased ventilatory drive and improved lower airway function.

4. Voluntary Regulation of Airway Patency

Factors involving voluntary regulation of airway patency include speech and swallowing.

5. Disease

Malignancy, infection, neuromuscular disease, and obstructive sleep apnea can affect airway patency.

C. Effects of Drugs on the Airway

1. Direct Effect

Several types of drugs can be administered topically to the airway.

1. *Local anesthetics* attenuate the afferent limbs of the powerful reflexes that serve to protect the upper airway from aspiration of foreign material.
2. *Sympathomimetics*, such as epinephrine and phenylephrine, cause local vasoconstriction to minimize tissue vascularity or reduce edema.
3. *Volatile inhalational agents* cross the alveolar-capillary membrane to have an indirect effect on the respiratory tract via the CNS, but they also have direct effects, including bronchodilation and mucosal irritation.
4. *Bronchodilators* are commonly administered topically, as reviewed in the second part of this chapter.

2. Indirect Effect

Drugs that are administered intravenously (IV) as part of general anesthesia often affect the airway systemically.

1. *Sedatives and analgesics* affect central and peripheral neurologic pathways, largely motor but also sensory, to lessen muscle tone in the upper and lower airways and thereby affect patency and gas flow. Secondary effects on O_2 and CO_2 tension also affect airway tone.
2. *Neuromuscular blocking* (NMB) agents clearly affect skeletal muscle tone and have a major influence on airway management under general anesthesia.
3. *Lidocaine*, given intravenously, affects airway reactivity.
4. *Antihistamines*, used topically in the treatment of rhinitis, can be administered systemically to attenuate histamine-induced reflex bronchoconstriction.
5. *Antimuscarinics*, such as atropine, inhibit the parasympathetic nervous system to reduce salivary gland secretions and dry the upper airway. Upper airway tone is not significantly affected by this antiparasympathetic action, but lower airway resistance is reduced and airway reactivity is attenuated when drugs such as ipratropium bromide are given parenterally or are inhaled.
6. *Respiratory stimulants*, such as doxapram, are used occasionally to provoke spontaneous respiratory effort on cessation of general anesthesia. IV doxapram stimulates chemoreceptors in the carotid arteries, which in turn stimulate the respiratory center in the brainstem to increase respiratory muscle activity. Potentially serious side effects include cardiovascular instability and cerebral irritation.

III. DRUGS WITH A DIRECT EFFECT ON THE AIRWAY

A. Local Anesthetics

Local anesthetics produce a rapid, reversible depression of nerve conduction, particularly with regard to sensory nerves, by binding to sodium channels and interfering with their function, thereby preventing propagation of action potentials. Chemically, they usually consist of a lipophilic group connected to an ionizable group, typically a tertiary amine, by either an ester or an amide link (Fig. 6-2).

Local anesthetics are usually effective topically on airway mucosa. The clinical effect is to reduce airway reactivity. At the same time, there is a reduction in airway caliber and a reduction in the reflexes that protect against aspiration.

Topicalization of the upper airway is a common technique in the "awake" management of a difficult airway (DA), and it is also used during general anesthesia to facilitate upper airway instrumentation when NMB agents are being deliberately avoided. Topical local anesthesia is also used as an adjunct to general anesthesia in both upper airway and lower airway surgery.

Most local anesthetics are weak bases; they are formulated as chloride salts by combining them with acids to maximize their solubility. In plasma, they remain largely in the ionized or protonated form (BH^+) before converting to the non-ionized (lipophilic) form to penetrate the nerve. The proportion of the drug in non-ionized form depends on its acid dissociation constant (pKa): the lower the pKa (i.e., the closer to pH 7.4), the more "free base" (B) available to enter the nerve cell, and the more rapid the action. This relationship is defined by the Henderson-Hasselbalch equation:

$$\log[BH^+]/[B] = pKa - pH$$

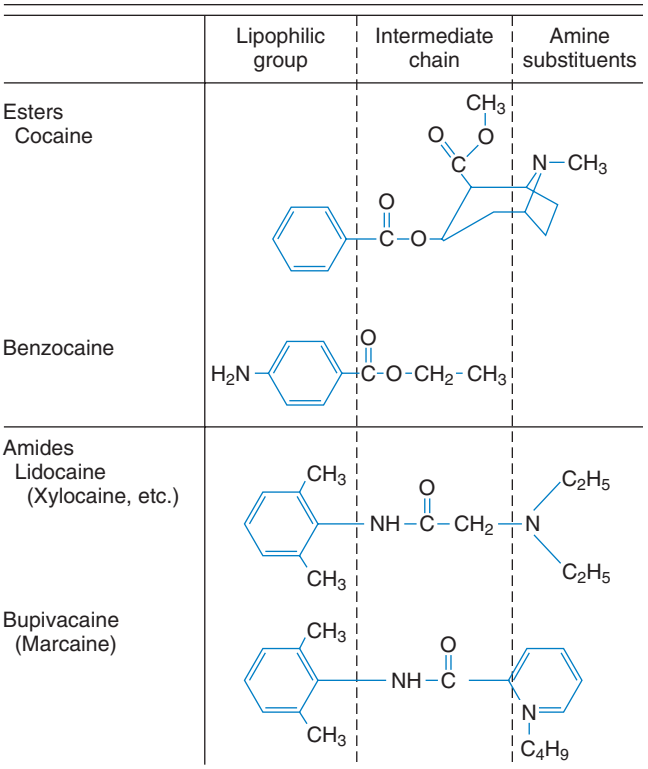

Figure 6-2 Structure of local anesthetics used for topical airway anesthesia.

1. Complications of Airway Local Anesthesia

In infected tissues, topical local anesthesia is often ineffective because of the lower pH of the tissues; this results in a relative increase in the ionized form of the drug, which will not enter the nerve. Alternative techniques may be required.

A reduction in upper airway patency has been demonstrated after topicalization of the airway.[1,2] This occurs because of the loss of afferent feedback and the resultant decrease in motor tone, which may lead to upper airway obstruction, particularly in an airway that is already compromised. Hence, care is needed when considering an awake airway management technique in a patient with evidence of upper airway narrowing.

Systemic toxicity is extremely rare in patients receiving local anesthesia for instrumentation or examination of the upper or lower airway. Most reports suggest that plasma lidocaine levels very rarely approach the reported toxic plasma concentration of 5 to 6 µg/mL. However, one study demonstrated near-toxic levels after gargling of large volumes of lidocaine.[3] Toxicity tends to involve the CNS with irritability or convulsions and the cardiovascular system with circulatory compromise. The safe maximum dose for airway administration for the most commonly used agent, lidocaine, is uncertain, but in one study in which patients received 9 mg/kg lidocaine, none had plasma concentrations in excess of 5 mg/mL.[4] However, the death of a healthy volunteer due to presumed lidocaine toxicity after topicalization for fiberoptic bronchoscopy has been reported in the literature, so some consideration of the dose administered is advisable.[5] The British Thoracic Society recommendation for the use of topical lidocaine with a flexible fiberoptic bronchoscope in adults is not to exceed 8.2 mg/kg.[6]

Topical lidocaine, particularly in higher doses, is an irritant to the upper airway and may stimulate unwanted reflexes. Other side effects include cardiotoxicity, allergy, and abuse potential.

2. Specific Local Anesthetic Agents

a. LIDOCAINE

Lidocaine is by far the most commonly used topical local anesthetic in airway management. It is available for upper airway use in formulations of 2% to 10%, with the 2% strength potentially lacking in potency for effective topicalization and the 10% having more potential for airway irritation. Duration of action is variable, anywhere from 15 and 90 minutes. There are few data concerning any dose-response relationship for intensity or duration of anesthesia. Case reports of toxicity from topical use are rare.

b. BUPIVACAINE

Bupivacaine has been used for topical airway anesthesia, but not commonly. It has the advantage of a more prolonged action but has a slower onset and an increased potential for toxicity compared with lidocaine.

c. BENZOCAINE

Benzocaine is available as a 20% solution for topical use and has a duration of action similar to that of lidocaine; although its toxic potential is low, it has a comparatively low potency. Absorbed benzocaine can produce methemoglobinemia with the potential to compromise O_2 transport.

d. COCAINE

Cocaine, available in solutions of 1% to 10%, provides excellent topical anesthesia and has the advantage of providing intense vasoconstriction, which is often desirable as part of topicalization of the nasal passages before intubation. However, concerns about sympathomimetic toxicity and abuse potential have reduced its use in recent years, particularly in children, since a fatality was reported.[7]

B. Sympathomimetics

The use of sympathomimetics to influence vascular blood flow in airway mucosal vessels is a technique that is commonly used in cases of acutely compromised upper airway in an attempt to reduce swelling. The most common agent used for this purpose is epinephrine, administered via a nebulizer.[8] Vasoconstrictors such as phenylephrine are also used electively to reduce the potential for bleeding during upper airway instrumentation (e.g., nasotracheal intubation).

Topical vasoconstrictors such as epinephrine can also be used to minimize systemic absorption of topical local anesthetics and thereby reduce toxicity, improve efficacy, and increase duration of action.[9] Unwanted effects of sympathomimetics are uncommon and largely relate to

systemic absorption of the drug, which can result in an increase in cardiac work.

C. Inhaled Volatile Agents

Inhaled anesthetic agents have a number of direct effects. For example, all volatile agents cause bronchodilation (i.e., increase in the diameter of the lower airways). Isoflurane appears to have the most potent effect, whereas desflurane also has the potential to cause the reverse effect and induce airway constriction.[10]

Airway irritation with increased salivary, laryngeal, and bronchial secretions (caused by an increase in mucus production and a decrease in mucociliary flow rates) varies among agents, with sevoflurane and halothane being essentially nonirritant and isoflurane and desflurane being potential irritants. This stimulation of airway receptors also appears to be responsible for the tachycardia and hypertension observed when desflurane is administered in high concentrations. The depressed mucociliary function seen with volatile agents is likely to contribute to impaired clearance of secretions and potentially to postoperative respiratory complications. The concomitant use of IV opioids lessens the irritant effect of inhaled volatile agents such as desflurane.[11]

Inhibition of hypoxic pulmonary vasoconstriction results in ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, with an increase in intrapulmonary shunt fraction.

IV. DRUGS WITH AN INDIRECT EFFECT ON THE AIRWAY

A. Sedatives and Upper Airway Patency

The effect of general anesthetic agents on the upper airway is crucial to the practice of safe airway management, largely in terms of airway patency but also in terms of airway reactivity and airway protection against aspiration. There is a decrease in muscle tone associated with the loss of wakefulness, and this is compounded by specific drug-induced inhibition of upper airway neural and muscle activity and suppression of protective arousal responses. These processes tend to narrow the airway lumen, leading to airway obstruction. The mechanism of the reduction in muscle electrical activity relates, in part, to depressed hypoglossal nerve activity that occurs in excess of a similar depressant effect on other respiratory muscles, such as the diaphragm or intercostal muscles, which are more resistant to this dose-dependent loss of muscle tone.[12] This reduction in hypoglossal nerve activity results in reduced tone in the muscles of the tongue and soft palate.

The differential suppression of respiratory muscles seems to vary among sedative agents, being less pronounced, for example, with ketamine than with other agents.[13] Ketamine also has an indirect effect on the lower airways, causing bronchodilation by inducing the release of endogenous catecholamines. However, the loss of muscle tone caused by sedatives may not only relate to a specific effect of motor nerves. The depressed state of arousal results in a reduction of inputs from the reticular activating system to these motor nerves. This theory is borne out by changes in upper airway patency demonstrated during natural sleep, which show similarities to those induced by sedative drugs.

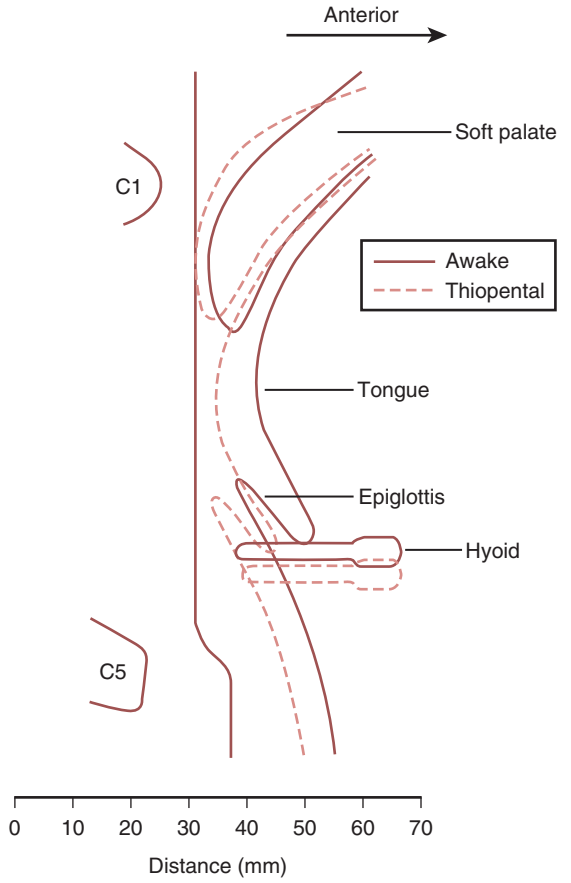

Figure 6-3 Effects of thiopental anesthesia on airway dimensions. Notice that the primary site of obstruction is at the level of the soft palate. (Modified from: Nandi PR, Charlesworth CH, Taylor SJ, et al: Effect of GA on the pharynx. *Br J Anaesth* 66:157, 1991.)

Originally, the upper airway narrowing associated with anesthesia was attributed to a posterior shift of the base of the tongue. Evidence now suggests that the soft palate and, to a lesser extent, the epiglottis are more relevant (Fig. 6-3). One study using lateral radiography demonstrated that occlusion of the airway under general anesthesia occurred most consistently at the level of the soft palate and sometimes at the level of the epiglottis, but in no patient did the tongue base come into contact with the posterior pharyngeal wall.[14]

Despite the assumption that loss of upper airway patency relates to a reduction in tone of the surrounding muscles, a consistent relationship between electromyographic activity and upper airway resistance has not been demonstrated. Thiopental causes measurable changes in muscular activity, but the changes are inconsistent and do not correlate with the onset of airway obstruction.[15] Similarly, benzodiazepines increase upper airway resistance but again do not appear to have a consistent effect on genioglossus activity.[16] Therefore, airway obstruction under general anesthesia may not relate to a simple diminution of muscular activity but to a disruption of the normal coordination of muscle activity that provides overall control of upper airway function.

The phase of the respiratory cycle is also relevant to the patency of the upper airway during spontaneous ventilation under general anesthesia. In a study by Nandi and colleagues, the movement of the soft palate during expiration was similar to that during apnea. However, during attempted inspiration, there was a significant reduction in the airway lumen at all levels, with the tongue now reaching the posterior pharyngeal wall in some cases and thus contributing further to the airway obstruction.[14] This has relevance when one considers upper airway patency during anesthesia with or without muscle paralysis. The *dynamic* collapse of the upper airway that occurs during spontaneous inspiration anesthesia may be insignificant when pharmacologic paralysis is achieved. Similarly, the application of continuous positive airway pressure (CPAP) may also reduce this effect and help to maintain gas flow.

In summary, the increased collapsibility associated with anesthesia and sedation seems to be universal, regardless of whether the route of administration is inhalational or parenteral. Although this collapsibility lessens with decreasing anesthetic depth, the two do not necessarily have a linear relationship.[17,18] The extent of the upper airway narrowing may vary subtly among agents, but the only clinically relevant difference appears to be the described lesser effect with ketamine.

At a laryngeal level, the effect of general anesthesia is probably different. One study demonstrated that the width of the laryngeal vestibule increased after administration of thiopental and succinylcholine.[19]

B. Effect of Sedatives on Airway Reactivity and Airway Protection

Airway reflexes such as coughing, the expiration reflex, breath-holding, and laryngospasm are important in protecting the airway against contamination. These airway reflexes are usually obtunded by general anesthesia, although the exact relationship between specific agents and this suppression of activity has not been fully explored. Propofol, for example, has been shown to depress these reflexes,[20] but vigorous airway reflexes have been demonstrated under baseline propofol anesthesia, suggesting that the depression with propofol as a lone agent is relatively limited in moderate doses. Combination with fentanyl, however, appears to have a significant influence on lessening airway reflexes.[21]

C. Sedatives and the Potential to Produce Apnea

All sedatives have the potential to abolish respiratory drive, either transiently or for more prolonged periods, and this effect is largely dose dependent. This may be desirable during upper airway instrumentation, but it potentially may also contribute to life-threatening hypoxemia. Propofol, particularly if it is administered as a bolus, produces apnea extremely readily. Other IV sedative agents, such as thiopental and benzodiazepines, also do so, but less potently.

Inhalational agents have a lesser tendency to produce prolonged apnea, so inhalational induction of anesthesia in a predicted difficult airway scenario remains a favored technique. Sevoflurane is the most commonly used agent now. It has a low blood-gas partition coefficient and is minimally irritating, which facilitates rapid, smooth induction of anesthesia to a depth that may be suitable to permit airway instrumentation. However, transient apnea can occur, as can airway obstruction, so the technique is not without complications.

D. Sedatives and the Lower Airway

All sedative agents that reduce muscular tone are likely to contribute to a reduction in a patient's functional residual capacity (FRC) and an increased work of breathing. Benzodiazepines appear not to have a significant effect on lower airway patency, despite causing an apparent relaxation of tracheal smooth muscle and potentially attenuating reflex bronchoconstriction. The effect of IV anesthetic agents on bronchial smooth muscle is also unlikely to be of clinical significance. In vitro data suggest that propofol has a direct relaxant action.[22] However, case reports and studies of IV induction agents used in asthmatics suggest that ketamine is the only agent with a significant bronchodilatory action. In contrast, volatile agents are fairly potent bronchodilators and have been used in the treatment of status asthmaticus.[23,24]

Multiple mechanisms contribute to the relaxation of smooth muscle produced by sedatives. These mechanisms involve both neural effects, predominantly relating to interference in vagal motor pathways that cause reflex bronchoconstriction, and direct effects on smooth muscle, such as attenuating increases in intracellular calcium. For example, bronchoconstriction caused by airway instrumentation is neurally mediated, whereas in anaphylaxis, the lower airway narrowing is caused by the release of inflammatory mediators. The latter is more likely to respond to a drug that has a *direct* effect on the airway smooth muscle.

E. Opioid Analgesics and the Airway

When fentanyl is combined with propofol, the depressant effect on upper airway reflexes is considerably more profound than with propofol alone, with the cough reflex being the most suppressed reflex and laryngospasm being the most resistant.[21] The central mechanisms for this depression of reflexes are unclear and are probably complex.

Muscle rigidity associated with opioid use has been described[25]; although rare, it may be the direct cause of a significant increase in lower airway resistance that can make ventilation extremely difficult. Others suggest that this rare phenomenon in fact has more to do with vocal cord closure than with decreased pulmonary compliance secondary to chest wall rigidity.[26] If the increase in airway resistance is truly linked to muscle rigidity, then its clinical manifestation is unpredictable and relates to many factors, including the opioid drug, its dose, its speed of administration, the effects of concomitant sedatives and muscle relaxants, and the age of the patient.

Short-acting narcotics are used at times in place of NMB agents, in combination with sedatives, to facilitate

endotracheal intubation. However, upper airway conditions for airway instrumentation may be inferior, and the risks of arterial hypotension and laryngeal trauma may be higher.[27]

Remifentanil merits specific discussion because it is a relatively new drug in anesthesia and its use in facilitating safe and effective airway management is increasing. It is a potent, ultrashort-acting synthetic opioid that is administered typically by continuous infusion because it is immediately metabolized in the plasma. It causes profound respiratory depression and therefore is used clinically to successfully prevent spontaneous respiratory effort when assisted ventilation is the chosen mode of gas exchange. It also reduces muscle tone considerably and can be used to facilitate endotracheal intubation in the absence of NMB drugs.[28] Use of remifentanil to facilitate smooth extubation is well described, and for some anesthesiologists,[29] this technique has replaced deep general anesthesia extubation. Continuing remifentanil while discontinuing sedation results in a predominant effect of suppression of upper airway reflexes, in excess of any sedative effect. This allows extubation with good endotracheal tube (ETT) tolerance and a minimum of coughing. However, care is required when using the drug because of its potency. Apnea is likely and can even occur in a patient who is receiving remifentanil alone for conscious sedation.[30] As with other synthetic opioids, muscle rigidity is described but not common.[31]

The main effect of opioids on the lower airway is similar to that described earlier, namely reduced airway reactivity and attenuated reflex bronchoconstriction. Mechanisms of action are again a combination of a neural effect and a direct dose-dependent effect in relaxing airway smooth muscle. For example, there is evidence that morphine attenuates vagally mediated bronchoconstriction in asthmatics.[32] Opioid administration has been shown to cause histamine release, and there is also evidence that they cause an increase in tracheal smooth muscle tone, but neither effect has been associated with clinically demonstrable bronchoconstriction. A condition termed wooden chest syndrome has been described after administration of IV opioids, particularly if given at high dose; in this syndrome, thoracic and abdominal muscle rigidity apparently results in difficulty with assisted ventilation. The clinical significance of this finding is uncertain, but it has not restricted the use of these drugs worldwide.

F. Neuromuscular Blockade and the Airway

NMB agents have several properties that may affect airway function. They are used in clinical practice to facilitate endotracheal intubation by abolishing airway reflexes and to facilitate mechanical ventilation by eliminating spontaneous respiratory effort. Similar to the effects of sedative agents on the respiratory muscles, these drugs also demonstrate a differential effect, with the diaphragm and the adductor muscles of the larynx being more resistant to paralysis than some of the muscles affecting upper airway patency.[33] This relative sparing of the diaphragm permits the maintenance of respiratory effort even during complete paralysis of peripheral

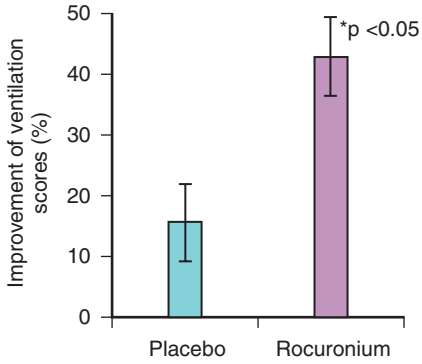

Figure 6-4 Efficacy of facemask ventilation in anesthetized patients with or without neuromuscular blockade. (From: Szabo TA, Spinale FG, et al: Neuromuscular blockade facilitates mask ventilation. *Anesthesiology* 109:A184, 2008.)

muscles. However, it also means that upper airway patency may be compromised at levels of paralysis that otherwise permit maintenance of normal spontaneous ventilation. Clinically, this is most relevant at extubation. A patient with residual NMB drug may maintain adequate ventilation with an artificial airway, such as an ETT or a supralaryngeal airway (SLA), in situ. After removal of the device, airway obstruction leading to hypoxemia may develop.

Removal of protective airway reflexes can have negative consequences if there is a risk of aspiration. Similarly, elimination of spontaneous respiratory effort may be deleterious if assisted ventilation cannot be delivered. Hence, care and experience are required for the safe use of NMB agents, and in certain clinical scenarios, it may be prudent to withhold them. However, the major clinical debate regarding their use seems to relate to their effect on upper airway patency. There is evidence that paralysis of the upper airway musculature *improves* upper airway patency. A recent study published data indicating that NMB using rocuronium facilitated bag-mask ventilation in anesthetized patients (Fig. 6-4).[34]

Another study on the physiologic comparison of spontaneous ventilation and positive-pressure ventilation (PPV) in laryngotracheal stenosis concluded that spontaneous ventilation creates a negative inspiratory extrathoracic intratracheal pressure that causes indrawing of the mobile tracheal segments, further narrowing the airway.[35] During expiration, there is positive intratracheal pressure, and a similar reduction in airflow does not occur. During PPV with muscle paralysis, however, a positive intraluminal pressure is created during inspiration that improves ventilation. Whether the conclusions of this paper can be extrapolated to the management of the upper airway under general anesthesia per se is uncertain, but several leading airway experts feel strongly that they should. The argument states that muscle relaxation makes upper airway management easier (and therefore safer) in terms of ventilation through a facemask or SLA and in terms of airway instrumentation, including intubation.[36,37]

Historically, there has been a fear that the prolonged effect of muscle paralysis during failing airway management under anesthesia contributes to severe hypoxic damage, but there does not appear to be any convincing

evidence to support this supposition. The fear appears to relate to the loss of reversibility of the anesthetic technique, although it can never be certain whether the awakening of a patient during failing airway management is feasible before catastrophic desaturation occurs. The evidence suggests that, when faced with impossible bag-mask ventilation, very few anesthesiologists choose to discontinue the general anesthesia or avoid NMB.[38] Most choose to provide oxygenation by intubating the trachea or by ventilating through an SLA device or performing an emergency cricothyrotomy. If ventilation is possible but intubation has been unsuccessful, "wake up" is strongly advocated by discontinuing any sedative drugs while reestablishing muscular tone and respiratory drive and maintaining oxygenation.

Impaired neuromuscular transmission secondary to partial pharmacologic blockade, even to a degree insufficient to evoke respiratory symptoms, markedly impairs upper airway dimensions and function. This may be explained by an impairment of the balance between upper airway dilating forces and the negative intraluminal pressure generated during inspiration. The same effect does not appear to occur during expiration.[39] Furthermore, reflex glottic activity may be preserved, with a tendency toward coughing and laryngospasm, and it may also have a negative effect on gas flow. Complete muscular paralysis necessitating assisted PPV appears to have the reverse effect and increases upper airway patency.

The lower airway behaves differently under muscle paralysis, with a potential loss of airway patency when NMB agents are administered. This may relate to the loss of the subatmospheric intrapleural pressure that normally supports the intrathoracic bronchial tree. Therefore, whereas muscle paralysis may benefit upper airway patency, it may hinder lower airway patency. This can be clinically relevant during management of the scenarios of acute upper and lower airway obstruction.

Histamine release, caused by many of the muscle relaxants, tends to increase lower airway resistance, although clinically this is rarely significant. Some agents, such as atracurium and suxamethonium, are more likely to cause histamine release, although a relationship between these drugs and bronchoconstriction is not clear. Severe bronchoconstriction secondary to anaphylactoid or anaphylactic reactions is described for most muscle relaxants.

Monitoring of the degree of NMB during anesthesia involving muscle relaxants is indicated, but there are limitations with the available techniques. The degree of blockade is frequently monitored by the response of the adductor pollicis to stimulation of the ulnar nerve, although this muscle is more sensitive than the diaphragm to paralysis.[33] At present, monitoring methods that would reliably demonstrate the return of power required to maintain and protect the airway with an effective cough are lacking, and anesthesiologists tend to use a combination of monitoring and clinical assessment.

Reversal of nondepolarizing NMB before extubation and discontinuation of assisted ventilation is standard anesthetic practice. Use of a cholinesterase inhibitor, such as neostigmine, to flood the neuromuscular junction with acetylcholine and thereby restore neuromuscular function has traditionally been the only technique available for reversing the paralysis. These drugs could theoretically cause bronchospasm, but they appear to have no significant effect on airway resistance when combined with an anticholinergic drug such as atropine or glycopyrrolate. More importantly, inadequate reversal of the block, which is probably much more common than most anesthesiologists appreciate, can result in respiratory compromise, morbidity, and mortality.[40] A meta-analysis of current reports of NMB in anesthesia revealed a 41.3% incidence of residual paralysis.[41]

The recent introduction of sugammadex has provided an option for immediate and complete reversal of profound nondepolarizing NMB—when aminosteroid agents such as rocuronium or vecuronium have been used for muscle relaxation—to promote a rapid return of full muscle power and spontaneous respiratory effort. Sugammadex is a geometric donut with a lipophilic core and a hydrophilic periphery; it works in the plasma rather than the neuromuscular junction. The drug encapsulates rocuronium, binding it to its lipophilic core.

G. Other Drugs with Indirect Effect on the Upper Airway

IV lidocaine affects airway tone and reactivity, tending to relax smooth muscle and attenuate reflex bronchoconstriction such as that caused by intubation in asthmatics.[42] However, the effect is unpredictable, and reports of IV lidocaine's actually *causing* bronchoconstriction have been published.[43] Historically, IV lidocaine has been used to improve intubation and extubation conditions by reducing upper airway reactivity.

Administration of IV antihistamine (e.g., chlorpheniramine) reduces histamine-induced airway narrowing, largely affecting the lower airway via antagonism of the H_1 histamine receptors. Administration of such drugs is also recommended in the management of anaphylaxis, in which the upper airway may also be affected. Paradoxically, H_2 antagonists (e.g., ranitidine) may *increase* airway reactivity, although the mechanism of action is unclear.

V. AIRWAY PHARMACOLOGY FOR THE TREATMENT OF ASTHMA

Asthma (from the Greek, *asthma*, "panting"), as defined by the Global Initiative for Asthma (GINA),[44] is a "chronic inflammatory disorder of the airways in which many cellular elements play a role. The chronic inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment."

A. Overview

The complex, recursive interplay of inflammation, hyperresponsiveness, and airflow limitation determines the

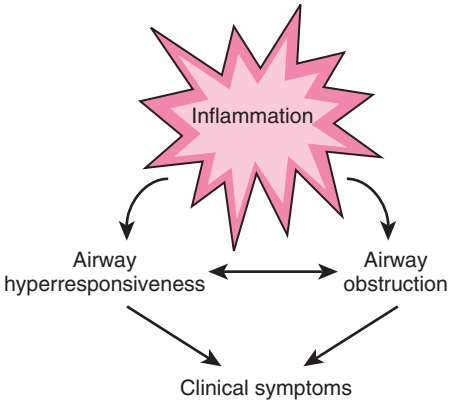

Figure 6-5 Interplay of airway inflammation, hyperresponsiveness, and obstruction. (Adapted from National Asthma Education and Prevention Program: Expert Panel Report III: Guidelines for the diagnosis and management of asthma. Summary report 2007. *J Allergy Clin Immunol* 120(Suppl 5):S94–S138, 2007.)

disease course, which over time produces structural airway changes, termed *remodeling*. There is presently greater recognition of the essentially inflammatory nature to asthma, with treatment directed at reducing this component over the long term as well as providing treatment to alleviate symptoms.[45] An idea of the interplay of these factors is shown in Figure 6-5.

1. Diagnosis

Asthma is a clinical diagnosis, based on the symptoms and signs. Symptoms are variable, with one or more of the following being present: wheeze, breathlessness, cough, and chest tightness.[46,47] None of these symptoms is specific to asthma. For example, wheeze is a function of any airway narrowing as a consequence of reduction of FRC. Signs of asthma include clinical verification by auscultation, spirometry, and lung function testing, which may include gas transfer measurements.[48]

There are no standard definitions for types of symptoms, nor for frequency or severity.[47]

2. Prevalence

Worldwide, asthma is estimated to affect more than 300 million people, 7% to 10% of the global population.[49] About 15 million daily adjusted life-years (DALYs) are lost each year, which places asthma 20th in the current disability ranking, similar to schizophrenia and diabetes. There are about 225,000 asthma deaths each year, amounting to 1 in 250 deaths from all causes.[50] In the United States, 7.3% of the population is diagnosed with asthma, and asthma accounted for 17 million physician consultations in 2006.[51] The worldwide prevalence of asthma is predicted to increase by another 100 million by 2025.[46]

3. Distribution

There are marked differences in national and geographic distribution. Although methodologic factors may confound accurate measurement, there is widespread agreement that asthma is a disease of industrialized nations.[46] Indoor aeroallergens, especially house dust mite[52]; tobacco smoking[53]; and obesity are some implicated factors.[54,55]

Genetic factors may contribute. Inheritance of an "asthmatic genotype" is complex with variable transmission.[56] *Atopy*, the development of immunoglobulin E (IgE) antibodies to specific allergens, is the strongest identifiable risk for developing asthma.[46,57,58] A family history of asthma, particularly on the maternal side, is a strong risk factor.[59] Other inheritable traits are the forced expiratory volume in 1 second (FEV_1) and response to drug therapies.[56]

Additionally, there are gender differences, with a higher incidence of asthma in prepubertal boys compared to girls.[60] In middle age, however, there is a higher incidence among women.

4. Pathology

The pathology of asthma is incompletely understood and is an area of active research.[61,62]

a. AIRFLOW LIMITATION

Airflow limitation results from a combination of bronchoconstriction, inflammatory edema, and hypersecretion of mucus with airway plugging. Blood vessel hyperemia may also narrow small airways.[63,64] These factors, either individually or collectively, narrow airways with impairment of respiratory gas exchange.

Mucus has a complex and variable structure. It is composed of long chains of mucin glycoproteins covalently cross-linked by disulphide bonds, polymerized DNA (from dead cells, particularly eosinophils), and polymerized (fibrous) F-actin together with a mixture of chemical mediators, modulators, and active, inactive, dead, or dying inflammatory cells[65] (Fig. 6-6).

Green sputum is common but is not always indicative of infection, rather resulting from an abundance of eosinophils.[66] When infection occurs, it is usually viral. Bacterial infection is uncommon.[67] Most asthma exacerbations attributed to infection are from viruses,[68] particularly rhinovirus.[69]

b. HYPERREACTIVITY

Hyperreactivity is an exaggerated defense response to potentially noxious stimuli such as inhaled allergens (aeroallergens). It results from a complex interplay of cells and signals, both chemical and neural.

c. INFLAMMATION

One crucial aspect of asthma is considered to be the relative dominance of pro-inflammatory over anti-inflammatory factors driven by a variety of cell types in complex, dynamic, and variable ways. $CD4^+$ lymphocytes, particularly the T helper type 2 (Th2) subtype, are presently thought to have a key role, with a predominance of this population over the T helper 1 (Th1) group. Relative overactivity of the Th2 group, especially at crucial developmental (childhood) stages, with expression of inflammatory cytokines such as interleukin-4 (IL-4), IL-5, IL-9, and IL-13, is considered to play a pivotal role.[70]

The inflammatory cytokines recruit and activate mast cells and eosinophils, leading to cellular infiltration, the density of which is often linked to disease severity.[71] Some interleukins (IL-4 and IL-13) promote B-lymphocyte production of IgE in response to inhalation of allergens

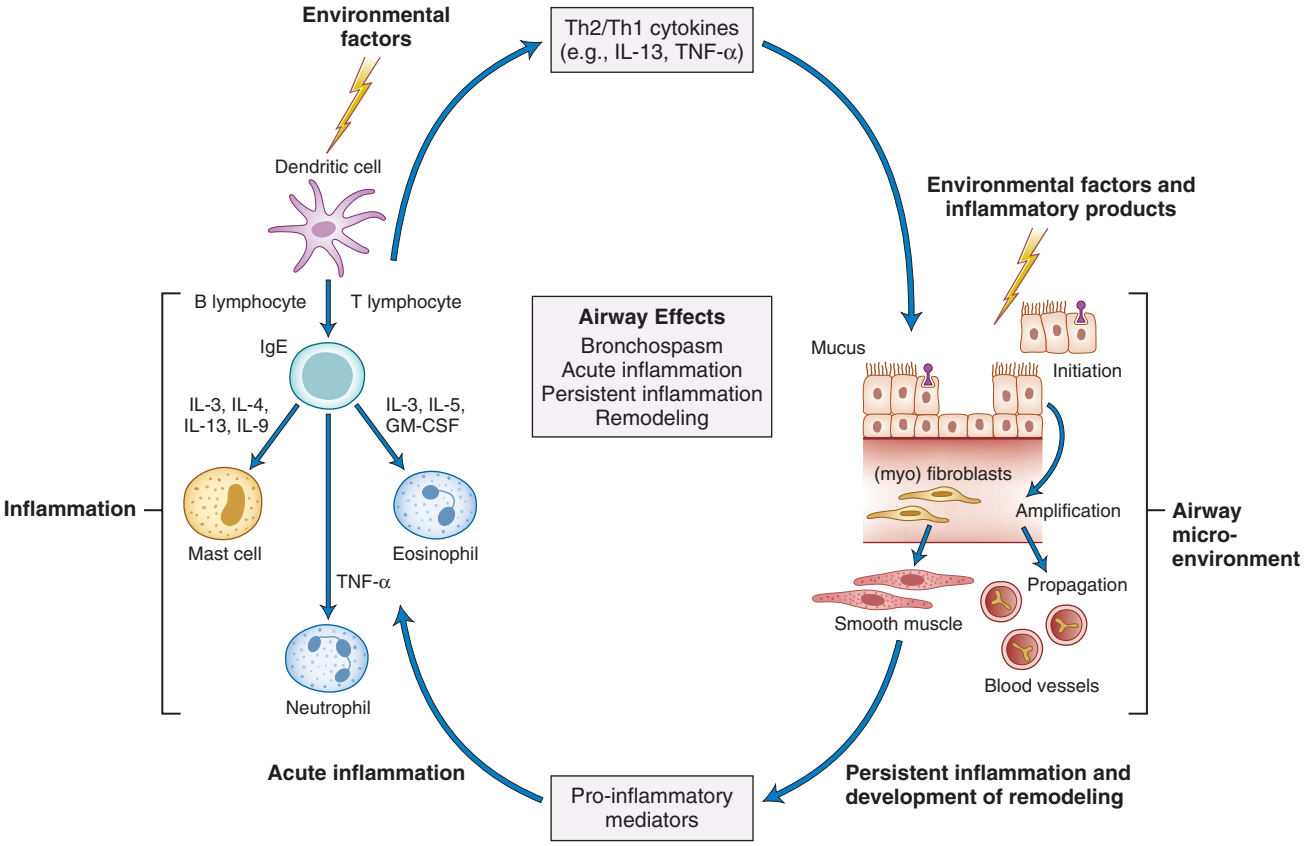

Figure 6-6 Factors limiting airflow in acute and persistent asthma. *GM-CSF,* Granulocyte-macrophage colony-stimulating factor; *IgE,* immunoglobulin E; *IL,* interleukin; *Th1* and *Th2,* helper T lymphocyte subtypes; *TNF-α,* tumor necrosis factor-α. (Adapted and redrawn from Holgate ST, Polosa R: The mechanisms, diagnosis and management of severe asthma in adults. *Lancet* 368:780–793, 2006.)

(aeroallergens). IgE binds to mast cell surface receptors, conferring immunologic memory and triggering release of mast cell contents (degranulation) when exposed to the specific aeroallergen.

A variety of substances such as histamine, proteases (including mast cell tryptase, a time-sensitive marker of degranulation), and cysteinyl-leukotrienes are released.[72] At least 100 mediators have been described.[73] Other stimuli, such as mechanical changes around these cells, may account for mast cell degranulation in response to cold-induced and exercise-induced asthma.[74]

Other cells, such as natural killer cells,[75] Th17 cells,[76] regulatory T cells,[77] dendritic cells,[78,79] macrophages,[80] mast cells,[81] and neutrophils, may be involved.[82] Neutrophil activity is associated with severe disease and sudden deterioration.[83]

d. REMODELING

Poorly controlled asthma may be complicated by anatomic changes in airway structure, which are often correlated to worsening of the disease[84] but may start before diagnosis.[85] A variety of cells are implicated in causing smooth muscle hypertrophy and hyperplasia, subepithelial fibrosis, angiogenesis, and mucus gland hyperplasia—collectively called the epithelial-mesenchymal trophic unit.

Recent attention has focused on the role of pulmonary blood flow in asthmatics, which is higher at rest compared with control subjects and increases during episodes of asthma enough to interfere with airflow.[86]

5. Treatment of Asthma

Major guidelines on treatment have been published by the National Asthma Education and Prevention Program (NAEPP) in the United States,[45] by GINA,[46] and by the British Thoracic Society in association with the Scottish Intercollegiate Guideline Network (SIGN) in the United Kingdom.[47] Management strategies for asthma in adults (including pregnant women), babies, and young children are covered. Treatment is broadly similar, but there are some differences in drugs chosen and doses used. Intensive care and intraoperative management of critical asthma generally lie outside the scope of these guidelines and therefore are covered in more detail in this chapter.

The guidelines specify two major treatment goals: relief of symptoms and risk reduction. Four treatment domains are described—assessment with monitoring, education, risk factor reduction, and drug treatment—covering therapies in four clinical states—episodic asthma, persistent asthma, exacerbation of asthma, and severe acute asthma.

The guidelines aim to provide common terms describing asthma, but other terms are often used within the literature in general, and definitions vary (Table 6-1). Of note is the term *status asthmaticus,* which refers to a life-threatening condition that mandates immediate

TABLE 6-1
Terms Describing the Severity of Acute Asthma

Descriptor	Features
Exacerbation, moderate	PF 50%-75% of predicted
Exacerbation, severe	PF 30%-50% of predicted, tachypnea (>25 breaths/min), tachycardia (>110 beats/min)
Life-threatening	Reduced GCS, systemic hypotension, "silent chest," hypoxemia
Near-fatal	As for life-threatening, plus arterial hypercarbia, need for ventilation
Brittle	Sudden, severe exacerbation or high PF variability to 50%-75% of predicted
Status asthmaticus	Either life-threatening or near-fatal

GCS, Glasgow Coma Score; *PF,* peak expiratory flow rate.

attention, treatment, or escalation of therapy. This term can be applied to severe asthmatic episodes that are resistant to orthodox therapy or require mechanical ventilation.

6. Routes of Drug Delivery

Three routes of drug delivery are available—inhaled, oral and parenteral—which are used alone or in combination.

Inhalation therapy offers the best potential for optimal delivery to the lungs with reduction in systemic side effects. The development and distribution of inhaler drugs and technologies have brought about major improvements in the prevention and treatment of asthma, so that most patients with access to treatment can lead an essentially normal life.

Drugs for inhalation require a dedicated device for delivery.[87] Three main types are available: dry-powder inhalers (DPI), pressurized metered-dose inhalers (pMDI), and nebulizers. All are designed to produce an aerosol for delivery to the lungs. An aerosol is a group of particles having a low settling volume. A practical measure is given by the mass mean aerodynamic diameter (MMAD), a product of mean diameter and square root density. Effective MMAD for therapeutic aerosols is between 0.5 and 5 μm.[88]

For lower values, the particles do not impact the airway and are exhaled. For larger values, impaction occurs in the upper airway,[89] with loss of efficacy and potential for local complications (e.g., oral candidiasis for inhaled glucocorticoids [IGCs])[90] and for systemic toxicity resulting from swallowing deposited drug. The aerosol dose reaching the lungs is called the *respirable mass*. Additional factors influencing drug response include patient compliance, inhalation technique, and the use of adjuncts to aid delivery from the device to the patient.

DPIs have no propellant; they require actuation by the patient with a high inspiratory flow (>40 L/min), and the drug can aggregate. This can be reduced by formulation with other powders, such as lactose, and by the use of baffles within the device to disaggregate the powder.

pMDIs contain drug with propellants, originally chlorofluorocarbons (CFC11 and CFC12). These chemicals contributed to atmospheric ozone depletion and have now been replaced by halogenated fluoroalkanes (HFA227 and HFA134A). Use of HFA as a propellant has allowed reduction of MMAD for steroids from 4 to 1 μm, which increases the respirable mass and allows dosage from the device to be reduced. pMDIs require breath actuation during inspiration with a sustained, but slow, inspiratory flow. Patient technique can be learned but is variable. The use of an adjunct, such as a spacer device with a face mask or mouthpiece, helps.[91] Devices with breath-actuated valves are superior. Selection of the face mask is important, and both size and seal must be considered. For small children, the dead space of some face masks is greater than their tidal volume (V_T).[92] If the face mask seal is poor, aerosol leakage considerably reduces efficacy.[93] Use of a mouthpiece produces superior drug delivery, compared with a face mask, but requires greater patient coordination.[94] Older spacing devices accumulated static charge that reduced aerosol delivery. Newer versions are "charge-reduced."[95]

Nebulizers vary in concept and design. The most common type is the jet nebulizer. It uses a high flow of driving gas through a narrow orifice, creating a Venturi effect, which draws the liquid drug into droplets that can be inhaled.[96] The aerosol produced is a mixture of droplet sizes (polydisperse). Compared with other devices, drug delivery is less efficient overall, with proportions of the drug lost as mist. In general, however, nebulizer therapy does not require patient technique, allows drug doses to be changed, and permits delivery in O_2.[87] Use of a patient mouthpiece, where possible, increases efficiency.[94]

Newer nebulizer devices that coordinate drug delivery with inspiration are now available.[97] pMDIs and nebulizers can be used to deliver drugs during anesthesia via breathing system and airway devices (e.g., an ETT).[98] Use in this setting is highly inefficient with, at best, only 10% of the administered drug reaching the lungs.[99] Most of the drug is deposited in the tubing or airway, termed *rain out*.[100] Delivery can be somewhat increased by actuating the pMDI during inspiratory flow,[99] prolonging inspiration, increasing V_T, and using wider ETTs.[101,102] For anesthesia, nebulization into the breathing system is superior to pMDI use.[102] Blockage of tubes by water lock must be avoided.

Oral medication is reserved for treatment of poorly responsive types of asthma, urgent treatment, and situations in which there are difficulties with inhalation therapy (e.g., poor technique due to age or illness). Oral formulations of inhaled drugs are used for severe disease (oral GCs) or when drugs that are available only for oral use (e.g., methylxanthines) are chosen.

Parenteral administration is reserved for severe and emergent treatment.

B. Drug Treatments for Asthma

Drug treatment for asthma is complex and changing. Currently, drugs are termed *relievers*, which provide symptomatic relief with β-adrenoceptor agonists (BA), or *controllers* (preventers), which reduce risk of disease exacerbation, such as GCs. Apart from the isolated use of a BA for symptom relief, combinations of these agents are

TABLE 6-2
Stepwise Approach to Asthma Management in Adults

Asthma Treatment Step	Drug Therapy
1. Mild intermittent asthma	SABA ± chromone
2. Regular controller therapy	SABA with IGC
3. Add-on controller therapy	LABA with IGC (LM and/or MX)
4. Therapy for persistent poor control	Increase IGC (increase LABA or add oral BA and/or LM and/or MX)
5. Therapy with continual or frequent systemic GC	Increase IGC (add alternative agents)

BA, β-agonist; *GC,* glucocorticoid; *IGC,* inhaled glucocorticoid; *LABA,* long-acting β-agonist; *LM,* leukotriene modifier; *MX,* methylxanthine; *SABA,* short-acting β-agonist.
For drugs listed in parentheses, consider addition of one or more agents.

used, with a variety of dose regimens and schedules. A stepwise approach is advised,[45-47] as outlined in Table 6-2. A suggested response to asthma exacerbation, with severity estimated by peak expiratory flow, is shown in Table 6-3.

For sustained control of asthma, a high degree of patient compliance is needed, which is problematic when the patient is very young or mentally or physically infirm. Indeed, the most common cause of "failed" treatment results from poor compliance or administration.[103]

Drug therapy for asthma is mainly based on modifications of natural substances that have been used since antiquity.[104] This section provides a description of the drugs used, followed by consideration of drug therapy for an additional and critical asthma-related state, intraoperative bronchospasm.

1. β-Adrenoceptor Agonists

BAs are the most potent and most widely used bronchodilators in clinical use. BAs bind to specific β-adrenoceptors.

TABLE 6-3
Drug Therapy for Asthma Exacerbation

Phase	Severity/Response	Treatment Options
A. First hour	If PF >60%	O_2 (aim for Spo_2 >90%), I SABA continuous
	If PF <60%	Move to phase B
B. Next hour	Moderate PF 60-80%	O_2, I SABA, I AC, O GC
	Severe PF <60%	O_2, I SABA, I AC, O/IV GC, IV Mg
C. Thereafter	Good PF >70%	O_2, IV SABA, I AC, O GC
	Incomplete PF <60%	O_2, I SABA, I AC, IV Mg, IV GC
	Poor PF <30%	O_2, I SABA, I AC, IV Mg; consider adding IV MX, IV SABA, IPPV

PF, Peak expiratory flow rate; *I AC,* inhaled anticholinergic; *I SABA,* inhaled short-acting β-agonist; *IPPV,* intermittent positive-pressure ventilation; *IV GC,* intravenous glucocorticoid; *IV Mg,* intravenous magnesium; *IV MX,* intravenous methylxanthine; *IV SABA,* intravenous short-acting β-agonist; *OGC,* oral glucocorticoid; *Spo_2,* oxygen saturation by pulse oximetry.

These are G protein-coupled receptors, members of a large protein family of cell-surface, transmembrane receptors that recognize extracellular signal molecules and activate a *signal transduction pathway* resulting in specific cellular responses to the received signal. BA binding results in a conformational (structural) change in the receptor, activating an associated G protein; the G protein detaches and stimulates a linked enzyme, adenylate cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), the *second messenger*. cAMP enhances intracellular phosphorylation reactions catalyzed by specific protein kinases, particularly protein kinase A, resulting in reduced intracellular contractile processes. In the lung, this relaxes bronchial smooth muscle; decreases mast cell degranulation; inhibits a variety of cells, including lymphocytes, eosinophils, and neutrophils; and modulates vascular tone and mucociliary transport. cAMP is inactivated by the phosphodiesterase enzyme group.

The medicinal plant, *Ephedra*, yields ephedrine, which has been used in China as *Ma Huang* for more than 5000 years. Inhaled ephedrine was reported as a bronchodilator in 1910.[105] The in vitro bronchodilator effect of epinephrine (adrenaline) was reported in 1907, and it was first administered in clinical use as a nebulized solution by Percy Camps.[104]

Isoprenaline (isoproterenol), a synthetic agent with less significant cardiovascular effects, was introduced clinically in the 1940s and was a popular choice for the treatment of asthma.

Ahlquist demonstrated a rank order of potency for sympathomimetic agents, distinguishing α- from β-receptors, with further division into β_1 (heart) and β_2 (lung) receptors.[106]

Albuterol (salbutamol) was the first selective β_2-agonist, and it remains the most commonly used bronchodilator worldwide.[107,108] It is formulated as a racemic mixture of R and S forms. It has 29 times greater selectivity for β_2- than β_1-receptors. Subsequent side-chain modifications of the parent molecule have resulted in longer-acting agents, such as salmeterol and formoterol.[104]

a. PHARMACODYNAMICS

The therapeutic respiratory action of BA involves binding to membrane (β_2-subtype) adrenoreceptors on smooth muscle cell in the lung, which stimulates production of the second messenger catalyst, adenylate cyclase, and increases the intracellular concentration of cAMP.[109] The exact mechanism of action of cAMP remains unclear, but it probably decreases the intracellular calcium concentration and directly affects systems regulating the cellular contractile apparatus.[110,111] These effects produce bronchodilation. In addition, BA may also provide beneficial effects by modulating neurotransmission in the cholinergic and perhaps other neural systems, affecting the function of inflammatory cells, modulating bronchial blood flow, stimulating mucociliary transport, and influencing the composition of mucus secretions.[112] BA activity is enhanced by GCs.[113,114]

Selective agonists have varying degrees of selectivity for the β_2-adrenoreceptors, increasing their specificity for the lung and presumably decreasing undesired side effects,

especially in the cardiovascular system. Like most other selective receptor agonists, however, these agents are *relatively* selective, with specificity decreasing as dose increases. *Mixed agonists* have effects on both β_1- and β_2-adrenergic receptors.

DURATION OF ACTION. One classification of BAs is by duration of action. *Short-acting agents* (<4 hours) are typified by isoproterenol (isoprenaline), which can be inhaled as a nebulized solution or given via pMDI. When it is nebulized, the adult dose is 0.5 mL of a 0.5% solution diluted in 2.5 mL of water. IV administration is not advised because of cardiovascular complications.[115]

Intermediate-acting BAs (4 to 6 hours) include albuterol (salbutamol), which is most often administered via pMDI in outpatients, with 1 puff delivering 90 μg of drug. The usual dose in ambulatory patients is 2 puffs given four times daily or immediately before exposure to exercise or other known stimuli. It is also available as a solution for nebulization, in tablet form (including a sustained-release preparation), and as a syrup for pediatric use.

The superiority of the R-isomer of albuterol (levalbuterol) compared to racemic (R and S) albuterol is controversial.[116] Some studies report that levalbuterol is as effective as racemic albuterol with less tremor and tachycardia, whereas others do not support this conclusion.[117-120]

Terbutaline is available as an aerosol inhaler or in tablets. Inhaled terbutaline is clinically equal to inhaled albuterol.[121] In the United States, it is the only selective β_2-agonist available for parenteral use, with the usual subcutaneous dose similar to that of epinephrine (0.25 to 0.5 mg SQ). When used in this way, its duration of action exceeds that of epinephrine, and it may have cumulative effects on repeated administration. The elimination half-life is approximately 6 hours. About 40% is converted in the liver to a sulfate conjugate. Both conjugate and unchanged drug are excreted by the kidneys.

Pirbuterol and metaproterenol also have intermediate duration of action.

Long-acting BAs (10 to 12 hours) include salmeterol and formoterol. These agents are now combined with an IGC and are administered twice a day for long-term control of asthma symptoms. The duration of action remains unexplained.[122] Bambuterol is the pro drug for terbutaline; it is activated by plasma cholinesterases, giving a longer duration of action. Use of long-acting BAs as monotherapy leads to tolerance or desensitization and a small increased risk of death.[123,124] Use of BAs alone is now contraindicated.[46]

An *ultralong-acting BA* (24 hours), indacaterol, was recently described.[125]

Epinephrine (adrenaline) is a potent inotrope and vasopressor with actions at α-, β_1-, and β_2-receptors. It can be given subcutaneously, intravenously, or via a pMDI or nebulizer. Nebulized epinephrine is not superior to other inhaled BAs.[126] The onset of action is rapid, making it often the first parenteral drug administered in an ambulatory emergency setting, to provide acute therapy until long-term measures can be instituted. The usual SQ dose is 0.4 mL of a 1:1000 solution in adults (0.005 mL/kg in pediatric patients), which may be repeated at 15-minute intervals. Side effects include hypertension, tachycardia, dysrhythmias, hyperglycemia, and acidosis. An IV dose regimen is described in the section on reactive management.

ADVERSE EFFECTS. Side effects complicate BA therapy. Acutely, they include dose-related tremor, nervousness, nausea, hypertension, tachycardia, and dysrhythmias. These effects are related to stimulation of adrenergic receptors in the cardiovascular system and are more prominent with mixed agonists, although they may also occur with selective BAs, especially at higher doses. Side effects of high-dose BA therapy include hypokalemia, which is increased with use of GCs and methylxanthines (MXs). Lactic acidosis often develops; it results from increased lipolysis and leads to liberation of free fatty acids, which inhibit oxidative metabolism.[127] MXs and GCs enhance β-receptor sensitivity to agonist activation and indirectly promote lactate production.[128] For chronic use, there are concerns regarding the safety of BA in the longer-term treatment of bronchospasm.[129]

Despite use of antiasthma medications in the last decades of the 20th century, the morbidity and mortality associated with asthma increased—a situation referred to as the *asthma paradox*.[130] Increased use of BAs has been implicated as one of the factors responsible. Studies have shown that therapy solely with β_2-agonists over treatment times ranging from 15 days to 1 year may actually enhance airway reactivity.[131-133] Others have found that regular use of inhaled BA bronchodilators is associated with an increased risk of death or near-death in asthmatics.[134,135]

It has been suggested that the chronic use of BAs may relieve symptoms without treating the underlying chronic inflammatory process that is apparently responsible for asthma.[130] This process can lead to irreversible thickening of the airway wall that ultimately worsens hyperreactivity. However, others have questioned this association.[136]

b. PHARMACOKINETICS

In general, BAs are cleared by a combination of hepatic conjugation reactions and renal excretion of unchanged drug. Albuterol is hydrolyzed by tissue esterases to inactive colterol. Additionally, hepatic conjugation with sulfate occurs.

Epinephrine, which is converted to metanephrine or normetanephrine, has an elimination half-time of a few minutes.

c. UTILITY

BAs are available in a variety of formulations, such as DPIs, nebulizer solutions, pMDIs, oral liquids, tablets, and IV preparations. BAs are used for reliever therapy by inhalation at all asthma treatment steps[45-47] (see Table 6-2). For step 1, use of an inhaled short-acting β-agonist (SABA) may be the only treatment needed. If two or more aerosol inhaler canisters are used per month, escalation to step 2 is advised.[46] For steps 2 and above, BAs are used as add-on therapies in combination with other agents.

Inhaler combinations of long-acting BAs with IGCs are often highly effective and may show synergistic

activity.[137] These are now considered to be the most effective therapy available.[104]

BAs have utility for emergency treatment of asthma exacerbations of varying severity. Again, other agents should also be used, particularly a course of systemic GC, which is usually given by the oral route (50 mg/day prednisolone, or equivalent, for an adult) for 5 days without tapering the dose.[47,138,139] Nebulized ipratropium can also be added.[140,141]

For urgent cases, inhaled administration of BA is the reasonable choice, primarily with repeated doses of pMDI administered via a holding chamber, escalating to nebulized therapy. Repeated treatment at intervals of 15 to 30 minutes with doses of 5 to 10 mL/hr may be needed for adults.[47]

For severe acute asthma, administration of BA by continuous nebulization has efficacy equal to that of intermittent administration, with less tachycardia and hypokalemia.[142] IV BA is reserved for life-threatening asthma, usually together with nebulized BA.[47]

Sellers and Messahel used rapidly repeated IV salbutamol (albuterol) boluses for emergency treatment of acute severe asthma in seven patients (children and young adults).[143] All patients had received nebulized BA and systemic GC, and additionally two had received aminophylline by infusion. The dosage scheme was 5 μg/kg IV for children (250 μg for adults) given over 1 to 2 minutes, repeated every 2 minutes. The number of boluses given ranged from 2 to 7, and all were administered within 30 minutes. All patients showed clinical benefit.

An alternative to repeat bolus therapy was reported by Browne and Wilkins.[144] They used a single bolus of salbutamol 15 μg/kg (over 10 minutes), followed by an infusion of 1 to 5 μg/kg/min. For refractory cases, IV epinephrine, 0.35 to 0.7 mg/kg, may be given over 5 minutes, followed by an infusion of 0.5 to 2 μg/kg/min.

For the treatment of severe acute asthma in the emergency setting, the addition of MX to BA therapy is not generally advised.[145,146] A therapeutic response to MX in this setting is rare.[4]

2. Glucocorticoids

GCs are the most effective controllers of asthma, with no other drug treatment available matching their efficacy. Other names for these drugs include corticosteroids, glucocorticosteroids, and simply "steroids."

Solis-Cohen, a Philadelphia physician, demonstrated that "adrenal substance pills" were helpful in asthma.[147] This effect was originally attributed to epinephrine (adrenaline), but oral preparations of natural catecholamines (e.g., epinephrine) are inactivated in the gut, so it is likely that GCs were the effective components.[104]

Kendall and Reichstein independently isolated and synthesized cortisol (and adrenocorticotropic hormone [ACTH]), receiving the Nobel Prize (with Hench of the Mayo Clinic) for this work in 1950.[150] Boardley and colleagues reported rapid improvement in five asthma patients receiving ACTH,[148] and soon oral cortisone treatment gained widespread popularity for management of a wide variety of inflammatory illnesses, including asthma.[149] However, systemic side effects were common, and inhaled cortisone was ineffective. After concerted efforts, a range of topical GC preparations were introduced for application to the skin (for eczema) and to the lungs. Topical efficacy, on either skin or lungs, is related to skin blanching, now called the MacKenzie test.[150]

The introduction of inhaled beclomethasone dipropionate, an effective drug with a high therapeutic index, heralded the era of IGC as the mainstay for asthma control.[151]

a. PHARMACODYNAMICS

GCs are anti-inflammatory agents that act mainly through alteration of nuclear DNA activity, a genomic effect by which the expression of target genes is activated or repressed. This is a highly complex and coordinated set of processes involving the production of an array of inflammatory and anti-inflammatory enzymes, receptors, cytokines, chemokines, and adhesion molecules.[152,153]

The overall effect of GC action is decreased inflammatory cell recruitment, survival, accumulation, and activity.[154,155] This takes hours to days to achieve. There are two types of GC receptors (α and β); both are intracellular. GC action is mediated by the α variant and inhibited by the β. GCs bind to the cytosolic α variant (not the β), with subsequent translocation of the complex into the nucleus, dimerization, and binding to specific domains of DNA—the glucocorticoid response elements (GREs) within promoter genes. The binding may result in activation or suppression of target gene transcription. Activation typically results in transcriptive and translative activity producing anti-inflammatory proteins.[156]

Suppression of gene activity results in decreased expression of inflammatory genes (switching off). This is achieved by action of the GC-receptor complex to activate histone deacetylase, an enzyme that removes acetyl groups from histone proteins involved in packing DNA. Deacetylation alters histone conformation, closing the associated DNA sequences and rendering the DNA less accessible for transcription.[157]

The β form of GC receptor (which does not bind with GC) can also bind to GREs, and this may provide an inhibitory pathway for overall GC activity.[158] Additionally, GC may enhance degradation of messenger RNA (mRNA) coding for inflammatory proteins, a post-transcriptional mechanism of anti-inflammatory regulation.[159,160]

GCs also enhance the actions of BA (and MX), explaining the synergistic therapeutic effects of these agents.[137] This is achieved by increased transcription of the β_2-receptor genes,[161,162] protection from β_2-receptor downregulation, and prevention of uncoupling of β_2 receptors from their G proteins (which is promoted by some inflammatory mediators, such as IL-1), thereby sustaining β_2 activity.[163,164] Reciprocally, BAs may increase GC activity by increasing translocation of GC receptor complexes into the nucleus.[165]

GCs have other nongenomic effects. These actions are rapid and are insensitive to blockers of gene transcription (e.g., actinomycin D) or protein synthesis (e.g., cyclohexidine).[159,166,167] These nongenomic actions have therapeutic import. Asthma is associated with an increase in pulmonary blood flow, and this may interfere with

TABLE 6-4
Equipotent Daily Doses of Inhaled Glucocorticoids

Drug	Low Dose (mg)	Medium Dose (mg)	High Dose (mg)
Beclomethasone diproprionate	200-500	>500-1000	>1000-2000
Budenoside	200-400	>400-800	>800-1600
Ciclesonide	80-160	>160-320	>320-1280
Flunisolide	500-1000	>1000-2000	>2000
Fluticasone propionate	100-250	>250-500	>500-1000
Mometasone furoate	200-400	>400-800	>800-1200
Triamcinolone acetate	400-1000	>1000-2000	>2000

airflow[63,64]; IGCs reduce this effect.[168,169] Additionally, reduction in lung hyperperfusion may prolong the bioavailability of inhaled BAs, which are cleared from the lung by the pulmonary circulation.[170]

Side effects of GC therapy are well known. Systemic therapy risks dose-dependent suppression of the hypothalamopituitary axis, osteoporosis, osteonecrosis, systemic hypertension, diabetes mellitus, obesity, skin thinning, myopathy, cataracts, and glaucoma.[46] For those patients who need systemic steroids to achieve asthma control (step 6), these complications are a serious risk, and this is the rationale for adding steroid-sparing therapies as outlined previously.

Inhalation therapy markedly reduces systemic toxicity but does not eliminate it.[171] IGC can be absorbed in two ways—from the lungs or after swallowing oropharyngeal deposited drug. Side effects are usually apparent with large doses (>400 µg/day budenoside or equivalent in an adult). Easy bruising, adrenal suppression, cataracts, and glaucoma have been described.[46] Local toxicity results in sore throat with oral candidiasis.[90]

b. PHARMACOKINETICS

With optimal technique, IGCs achieve rapid and efficient delivery to the airways. With poor technique, however, drug is deposited in the oropharynx, where it can be a local irritant or be swallowed.[90]

Oral GCs are usually rapidly absorbed and have a high volume of distribution. They are typically inactivated by the cytochrome group of enzymes, a set of heme-thiolate monooxygenases in liver microsomes.

c. UTILITY

IGCs are used as controller (preventer) medications at steps 2 through 4, and systemic (oral) GCs are used for step 5 (see Table 6-2). IGCs are currently the most effective anti-inflammatory therapy available. They reduce symptoms of asthma,[172] improve lung function[172] and quality of life,[172] and reduce airway reactivity.[172,173] The frequency and severity of exacerbations are reduced,[174] as is mortality.[175]

A wide variety of IGCs are available, either as a single formulation (pMDI or DPI) or in combination with a long-acting BA. Examples include beclomethasone (beclometasone) diproprionate, budenoside, fluticasone propionate, and mometasone furoate. Ciclesonide is a pro-drug that is activated in the lung by ester hydrolysis; its use aims to reduce oropharyngeal irritation and systemic uptake of swallowed drug. The variety of IGCs has led to advice on standardization of IGC dosage as "budenoside equivalents" in low, medium, and high daily dose regimens,[46] as shown in Table 6-4.

Systemic GCs include prednisone, prednisolone, methylprednisone, methylprednisolone, betamethasone, dexamethasone, and hydrocortisone. These may be given by oral, IV, or intramuscular (IM) routes, with similar efficacies. Deflazacort and cortisone acetate are formulated for oral administration, and triamcinolone is reserved for intra-articular or IM use. The relative potencies of these drugs are shown in Table 6-5.

Oral GCs are used for treatment of exacerbation. Systemic drug should be given for "all but the mildest exacerbations"[46] for 5 days and may be stopped without tapering.[46] Oral GCs are usually effective but take at least 4 hours to produce clinical improvement. A usual single daily dose of methylprednisone, 60 to 80 mg, or hydrocortisone, 300 to 400 mg, in divided doses is advised.[46]

For patients who are unable to take or absorb oral medication and for those with life-threatening asthma, systemic (usually IV) administration is needed. Hydrocortisone, up to 4 mg/kg given three to four times a day (or equivalent) is used for life-threatening disease.

The rapid nongenomic effect of IGC in reducing lung hyperemia may have a therapeutic role in the treatment of exacerbation.[176,177] For example, one study showed equal efficacy of 3 mg nebulized fluticasone and 100 mg hydrocortisone in nonintubated patients with acute severe asthma.[178]

3. Methylxanthines

The MXs are a group of phosphodiesterase inhibitors. They include caffeine, present in coffee, and theophylline and theobromine, present in tea. Extracts have been used historically for treatment of respiratory disorders. In

TABLE 6-5
Equivalent Doses of Systemic Glucocorticoids

Glucocorticoid	Equivalent Dose
Prednisolone	5 mg
Betamethasone	750 µg
Cortisone acetate	25 mg
Deflazacort	6 mg
Dexamethasone	750 µg
Hydrocortisone	20 mg
Methylprednisolone	4 mg
Triamcinolone acetate	14 mg

1886, Henry Hyde Salter, a family physician in London, reported that drinking strong coffee on an empty stomach eased his asthma.[179] The solubility of MXs is low and is enhanced by the formation of complexes with other compounds; for example, aminophylline is a complex of theophylline and ethylenediamine. Before the widespread adoption of BA therapy, IV administration of a soluble MX was the standard first-line treatment for severe asthma.[104] Other preparations, such as salts of theophylline (e.g., oxytriphylline) and covalently modified derivatives (e.g., dyphylline), are available.

a. PHARMACODYNAMICS

MXs have multiple mechanisms of action, and the effects of clinical importance remain controversial.[180,181] Originally, they were thought to act as phosphodiesterase inhibitors. Phosphodiesterases are a group of enzymes, one action of which is inactivation of cAMP, the second messenger for adrenoceptor activation. Such inhibition increases intracellular cAMP, thereby enhancing adrenoceptor activity and resulting in bronchodilation.[182]

The phosphodiesterase isozymes 3 and 4 are implicated,[104] but the drug concentrations needed to demonstrate this effect in vitro may exceed those present at therapeutic levels in vivo.[183] Moreover, not all phosphodiesterase inhibitors are effective in asthma, and theophylline-induced relaxation of airway smooth muscle in vitro occurs without changes in intracellular cAMP levels.[184,185] Other mechanisms demonstrable in laboratory preparations, including antagonism of adenosine and stimulation of endogenous catecholamine release, also do not appear to be significant to the clinical action of theophylline.[186,187]

Some of the therapeutic actions of MXs may result from effects other than relaxation of smooth muscle. These drugs may improve mucociliary clearance, stimulate ventilatory drive,[184] and increase diaphragm contractility,[188,189] actions that may be beneficial in patients with reactive airways disease. MXs also have significant cardiovascular effects, including direct positive chronotropic and inotropic effects on the heart, reductions in preload and afterload, and diuresis, which may be beneficial in patients with cardiovascular disease.

There is increased evidence to support anti-inflammatory and immunomodulatory roles for MXs in asthma.[190,191] Theophylline increases the activity and number of suppressor T cells and reduces the activity of many inflammatory cells implicated in asthma.[192,193] More recently, MXs have been shown to stimulate histone deacetylase. The action of this nuclear enzyme results in reduced exposure of DNA elements to transcription, which may render inflammatory genes less active, an effect that is synergistic with GC.[194]

Because MXs have multiple systemic actions, side effects are common, mainly involving the CNS and the cardiovascular system.[195] CNS effects include stimulation, insomnia, and tremor, leading to convulsions at toxic plasma levels (considered to be >20 μg/mL). For the cardiovascular system, toxic levels may produce ventricular and atrial dysrhythmias. In addition to phosphodiesterase inhibition, adenosine receptor activation may be important.[104] Gastrointestinal disturbances ranging from epigastric discomfort to nausea and vomiting may also occur.

b. PHARMACOKINETICS

There are many MX formulations. Most vary the physical preparation of theophylline rather than chemical modification of it. Several forms of anhydrous theophylline are available in microcrystalline preparations to enhance rapid and reliable absorption. Sustained-release forms are also currently popular, providing dosing convenience and (perhaps) less fluctuation in blood levels. For IV administration, aminophylline (containing 85% anhydrous theophylline by weight) is used because of its greater aqueous solubility.

All MXs are eliminated primarily by hepatic metabolism. Plasma clearance varies widely even among healthy subjects, with the elimination half-life ranging from about 3 hours in children to 8 hours in adults.[196] The hepatic cytochrome P450 enzyme group (particularly CYP 1A2) clears MX. The activity of these enzymes may be enhanced, for example by smoking and by concurrent therapy with carbamazepine or rifampicin, leading to greater clearance. Conversely, the enzymes may be inhibited by drugs such as cimetidine and ciproxin, resulting in greater MX bioavailability. Disease states such as liver or cardiac failure alter clearance. Unpredicted changes in clearance may result in toxicity in critically ill patients, so measurement of plasma levels is important.

Regardless of the preparation chosen, plasma concentrations of theophylline should be monitored to ensure that levels are in the therapeutic range (5 to 20 μg/mL). For children receiving less than 10 mg/kg/day, monitoring is not considered necessary.[46]

c. UTILITY

With other therapeutic advances in the pharmaceutical treatment of asthma, some have questioned the continued role of MX in the management of reactive airways.[197] However, MXs still have a number of therapeutic roles, and it may become more popular again with increased recognition of the immunomodulatory and anti-inflammatory properties of these drugs.[198-200]

There are presently three main indications for MX use. First, for the relatively small group of patients who are unable to manage inhaler therapies, MXs may be used as primary controller therapy.[46]

Second, MXs have utility as add-on controller therapy to IGCs,[201-203] although the therapeutic effect is usually less than that achieved by adding long-acting BAs to IGCs.[204,205] When properly used, these drugs remain safe and effective for the chronic management of asthma and in some patients with chronic obstructive pulmonary disease (COPD).[206] With effective clinical support and plasma drug monitoring, adverse incidents are rare. One study of 36,000 patients receiving 225,000 prescriptions over 9 years reported that the incidence of hospital admission resulting from MX toxicity was less than 1 per 1000 patient-years.[207]

Third, for patients with severe exacerbation of asthma whose management is problematic, add-on therapy with IV aminophylline may be considered. This is not generally advised for all patients, and response to treatment in

this situation is described as rare.[47,146] The initial loading dose is 5 mg/kg, administered over 30 minutes to minimize toxicity. This is followed by an infusion of 0.5 to 0.7 mg/kg/hr, which provides therapeutic levels in most patients. This loading dose and rate may need to be increased in smokers or decreased in severely ill patients and in those with liver disease or congestive heart failure. All dose recommendations are guidelines, and patients must be monitored with plasma theophylline concentrations (daily for the emergency patients).[47]

4. Leukotriene Modifiers

Leukotriene modifiers (LMs) include the cysteinyl-luekotriene-1 receptor antagonists (montelukast, pranlukast, and zafirlukast) and the 5-lipoxygenase inhibitor (5-LO), zileuton. They are inhibitors of arachidonic acid metabolites.

In 1938, Feldberg and Kelloway isolated substances with bronchoconstrictive and vasoactive properties from guinea pig lung perfused with cobra venom.[208] In 1960, these substances were shown to be released during anaphylactic shock and were named slow-reacting substance of anaphylaxis (SRS-A).[209] In 1979, Murphy and colleagues identified SRS-A as a mixture of lipids, later called leukotrienes—so named because they are produced by leucocytes and posses a carbon chain with three double-bonds.[104,210] Leukotrienes were later shown to have potent bronchoconstrictor properties when inhaled by asthmatics.[211] Inhibitory agents affecting this metabolic pathway, the first new class of drugs for asthma therapy in 30 years, were introduced into clinical practice in the 1990s.

a. PHARMACODYNAMICS

In response to pro-inflammatory stimuli directed toward various leucocytes (eosinophils, basophils, neutrophils, and macrophages), arachidonic acid is oxidized by 5-LO (with a membrane-bound helper protein called 5-lipoxygenase activating protein, or FLAP) to an unstable intermediate, leukotriene A_4 (LTA_4). This may be transformed into two types of derivatives, the cysteinyl-leukotrienes (cysLTs) LTC_4, LTD_4, and LTE_4, which are mainly produced by eosinophils and basophils, and LTB_4, from neutrophils and macrophages.

The cysLTs are formed in a sequential pathway involving initial conjugation of LTA_4 with the tripeptide glutathione to form LTC_4, which is exported out of the cell, where it rapidly changes to LTD_4 (by loss of a glutamyl residue) and to LTE_4 (by loss of a glycine residue). A number of variations in the enzymatic pathway exist. Genetic variation, or polymorphism, has been associated with aspirin-induced asthma (AIA).[212]

The cysLTs bind to a number of transmembrane-spanning G protein–coupled receptors found on a variety of leucocytes, smooth muscle cells, glandular epithelial cells, and endothelial cells. The target receptors are called cysLT1R and cysLT2R. Activation of cysLT1R (in the potency order $LTD_4 > LTC_4 > LTE_4$) results in bronchoconstriction, edema, and glandular secretion.[213-215] Activation of cysLT1R on fibroblasts may promote proliferation, a possible factor in airway remodeling and inflammatory cell recruitment.[216] CysLT2R activation has effects on endothelial permeability and leucocyte activity.[217,218]

LTB_4 binds to the receptors BLT1R and BLT2R. BLT1R activation has been implicated in stimulation of T lymphocytes and mast cells.[219,220]

Montelukast (available in Europe and the United States), zafirlukast (in the United States), and pranlukast (in Japan) are cysLT1R antagonists that inhibit the effect of cysLTs only. Zileuton is a 5-LO inhibitor and therefore reduces formation of both cysLTs and LTB_4.

LMs are generally well tolerated, the most common complaints being abdominal discomfort, muscle weakness, and pain. Initial concerns that montelukast therapy was associated with mental disorder and suicidal ideation have not been supported.[221] Zileuton has been associated with liver toxicity, and liver function monitoring is advised.[222] There is an apparent association of LMs with Churg-Strauss syndrome,[223] but this may be related to the drugs' ability to spare steroid.[224,225]

b. PHARMACOKINETICS

LMs are given orally and are well absorbed after oral administration, which is an advantage. They are available in chewable formulations for pediatric use. Once-daily (montelukast), twice-daily (zafirlukast and pranlukast), and four-times-daily (zileuton) dosing is needed.

c. UTILITY

LMs may be used as controller medications in conjunction with other agents. They have a small, variable bronchodilator effect with anti-inflammatory activity and may reduce asthma exacerbations.[226-228] They may reduce cough[229] and may be useful for symptom control in viral-associated bronchospasm[230-233] and AIA.[234-236] When used alone as controller therapy, LMs are usually less effective than IGCs,[237] but when used in conjunction with IGCs, they can provide a steroid-sparing effect.[238]

LMs are not effective for management of acute asthma. A multicenter, randomized trial of high-dose zafirlukast performed in an emergency department showed only a small reduction in admissions in the treatment group.[239]

5. Anticholinergic Agents

Anticholinergic agents are muscarinic receptor antagonists (MRAs) that inhibit the action of the transmitter acetylcholine in the parasympathetic nervous system. Herbal preparations of jimson weed and thornapple (*Datura* spp.) containing atropine have been smoked in India for relief of respiratory symptoms, as have preparations of henbane *(Hyocyanamus muticus)* containing hyoscine (scopolamine) in Egypt.

Anticholinergic drugs are bronchodilators, pulmonary vasodilators, and inhibitors of tracheobronchial secretion. They lack anti-inflammatory action.[104] They also decrease salivary, gastric, and intestinal secretions. The parent agent is atropine. Other tropane alkaloids include hyoscine, ipratropium, oxtropium, glycopyrrolate, and tiotropium.

a. PHARMACODYNAMICS

Parasympathetic vagal efferent (autonomic motor) nerves form ganglia around large- and medium-diameter

airways.[240,241] Postganglionic fibers supply bronchial smooth muscle, blood vessels, and mucus glands. Muscarinic receptors are located on the target cell membrane and are G protein–coupled receptors. Three types of muscarinic receptors are reported: M_1, M_2, and M_3.[242-244]

M_1 receptors are postjunctional within ganglia, facilitating transmission in parasympathetic pathways that innervate the airways, so antagonism of this effect should be beneficial. M_2 cholinergic receptors are also located within ganglia but are prejunctional (autoreceptors). Their activation decreases ganglionic transmission, inhibiting the release of acetylcholine from postganglionic nerves; antagonism of this effect may increase acetylcholine release and thus actually increase airway responsiveness.

M_3 receptors are located at postganglionic terminals at the effector sites; antagonism of their effects may be beneficial. The overall effect of MRAs depends on the balance of receptor activation, and those drugs with M_3 selectivity (e.g., tiotropium, glycopyrrolate) should therefore have greater utility.[104]

b. PHARMACOKINETICS

The parasympathetic nervous system is widely distributed and has multiple actions. MRAs with systemic activity produce many unwanted side effects, such as tachycardia, dysrhythmias, dry mouth, blurred vision, and confusion. MRA activity confined to the lung is optimal; inhalation therapy with minimal absorption is ideal.

Atropine (the prototypic muscarinic antagonist) and hyoscine may decrease airway resistance and attenuate airway reactivity when given parenterally or when inhaled, but systemic side effects have limited their use specifically as bronchodilators.

Ipratropium bromide is a quaternary ammonium derivative of tropane and is positively charged at physiologic pH. It is poorly absorbed from the lungs (<1%), does not readily cross the blood-brain barrier, and can be administered by inhalation at high dose and with minimal systemic side effects.[245,246] This and similar agents have slow onset times, up to 90 minutes.[247,248] Tiotropium, although not licensed for use in asthma, has a long duration of action, up to a week.[104]

c. UTILITY

Ipratropium is a clinically useful bronchodilator, but its slow onset limits efficacy as reliever medication, and BAs are first-line agents. Ipratropium may be useful as additive step-up therapy for patients with moderate impairment (FEV_1 50% to 70% predicted).[45] Ipratropium is available as a pMDI (18 µg/puff). The usual dose is 2 puffs given four times daily. For patients with COPD that includes a reversible component of bronchospasm, nebulized ipratropium may have benefits over BAs, including a longer duration of action and efficacy in some patients in whom BAs have little effect.[249]

In severe asthma, a combination of nebulized ipratropium and BA is superior to BA alone for adults and children.[250-252] A meta-analysis of 16 randomized, controlled trials comparing salbutamol and ipratropium versus salbutamol and placebo, showed reduction in hospital admission with improved lung function.[253] Multiple doses of ipratropium are superior to single use.[254]

Ipratropium may also be useful for treatment of bronchospasm induced by beta-blockers.[250] Tiotropium bromide is currently approved for bronchodilator therapy in COPD but not in asthma. In a recent trial in patients with moderately persistent asthma, tiotropium was reported to be equivalent to either doubling of the dose of inhaled beclomethasone or addition of inhaled salmeterol.[255] This finding shows therapeutic promise.

6. Chromoglycates (Chromones)

Cromolyn sodium, disodium cromoglycate, and nedocromil sodium are chromoglycates (chromoglicates) or chromones; they are clinically used as controller drugs with modest efficacy.[46] The parent compound, khellin, is derived from the medicinal plant, *Amni visnaga*, which is found around the eastern Mediterranean. They are useful only in the prevention of bronchospasm, not treatment.

a. PHARMACODYNAMICS

Cromolyn contains one chromone ring, nedocromil two. They are often called chromones, but nedocromil is structurally termed a pyranoquinolone. The first drug, chromolyn, was marketed as Intal (*in*hibi*t*or of *al*lergy).[256] Chromolyn and nedocromil inhibit release of inflammatory mediators from various cell types associated with asthma, especially lung mast cells, particularly in response to airway irritants such as cold air or sulfur dioxide.[257,258]

The mechanism of action is not fully known, but two actions are proposed[104]: phosphorylation of a moesin-like membrane protein (a natural terminator of granule release) and inhibition of chloride-channel opening in response to mechanical (structural or osmotic) stresses imposed on mast cells.[74,259]

Side effects include oropharyngeal irritation and symptoms, such as cough, caused by the direct irritant effect of the powder. Serious complications (anaphylaxis) are very rare.

b. PHARMACOKINETICS

These drugs are poorly absorbed and are administered by inhalation of powdered drug via a pMDI. In the United States, chromolyn is also formulated for nebulization, but nedocromil is currently not marketed. In the United Kingdom, pMDI devices using HFA as propellant are available for both drugs. Absorbed drug is not significantly metabolized and is excreted in urine and bile.

c. UTILITY

Chromones are controller drugs, useful both as a single preventive treatment, when taken 15 minutes before exercise or exposure to antigens, and as therapy as an alternative to IGCs.[45,260,261] Efficacy in individual patients varies widely, and at present a therapeutic trial is the only way of determining which patients will benefit. The two drugs are equally effective in clinical use.[258] Neither agent has been studied as an adjunct to airway management in the perioperative period.

7. Alternative Agents

For refractory asthma, with relapse despite maximal therapies resorting to chronic or multiple courses of systemic GC, immune-suppressant and immune-modulating drugs have been used, as have novel inhalation therapies. These drugs may allow reduction of the systemic steroid dose, but they are generally limited by modest and variable response, by side effects such as opportunistic infection, and by uncertainty over long-term safety. In general, a 3- to 6-month trial is advised.[262,263] For some agents, treatment numbers have often been small and study design may be questionable.

Anti-IgE therapy with omalizumab is an option for those patients who need chronic systemic GC or multiple rescue courses.[264] Omalizumab is generally well tolerated.[265] In the United Kingdom, serum IgE levels higher than 700 IU/L need to be demonstrated.[47]

Methotrexate given for 3 months allows a 20% reduction in systemic steroid dose for about 60% of patients, but the risk-benefit ratio does not usually support its use.[266-268] Opportunistic infection is a risk, and there have been reports of *Pneumocystis* pneumonia.[266,269]

Cyclosporine, a lipophilic cyclic 11-residue peptide, also has steroid-sparing effects in about half of patients with severe asthma. The primary target is T cells. Cyclosporine binds to intracellular cyclophilins, forming a complex that inhibits a calcium/calmodulin-dependent phosphodiesterase and reducing transcription of a group of nuclear family proteins. This results in decreased cytokine production, particularly IL-2, but also IL-4 and IL-5. Cyclosporine may also promote apoptosis (cell death) of CD4+ T cells.[270] IL-1 production from monocytes and macrophages is also reduced.

A systematic review (of three trials) showed that cyclosporine reduces daily steroid use by 1 mg or less.[271] In one study of five children taking more than 10 mg of prednisone daily, cyclosporine allowed weaning of steroid in three children and small improvements in lung spirometry.[272] Cyclosporine has a narrow therapeutic index, and drug level testing is needed. Opportunistic infection, renal injury, and hypertension are the main side effects.

Tacrolimus is a fungal macrolide that has effects similar to those of cyclosporine.

Macrolide antibiotics have antimicrobial activity and also anti-inflammatory actions through reduction in the expression of IL-8, a neutrophil activator. Some asthma patients may be chronically infected with *Chlamydophila* or *Mycoplasma* susceptible to macrolide treatment.[273-275] In addition, some patients with severe asthma that is resistant to conventional treatment may have a neutrophilic disease process (as opposed to increased eosinophil activity) and may benefit from macrolide therapy.[276] However, a systematic review of the use of macrolides (clarithromycin, troleandomycin, and roxithromycin) in asthmatic patients and did not find enough evidence to form a meta-analysis.[277] Liver toxicity is a risk.

Gold therapy results in a small reduction in systemic steroid use. Proteinuria is a side effect.[278]

Colchicine is used to treat gout and familial Mediterranean fever with few side effects. A prospective, multicenter study of its use in patients with asthma did not show benefit of this drug over placebo.[279]

Hydroxychloroquine has established uses as an antimalarial agent and for connective tissue disease management. Retinopathy is the major risk. Its efficacy in asthma management is controversial, with conflicting reports of efficacy.[280,281]

Dapsone is an anti-inflammatory agent that is used in leprosy treatment. One small study showed therapeutic promise in asthma treatment, with a large steroid-sparing effect but complicated by anemia.[282] There are currently no published data from well-designed trials, leading to a conclusion that strong evidence supporting its use in asthma is lacking.[283]

Intravenous immunoglobulin has anti-inflammatory actions, but large trials have not supported its use in asthma, and side effects such as fever and urticaria are common.[284,285]

Antifungal therapy is another potential treatment of asthma. Environmental fungal exposure is virtually ubiquitous. Many asthma patients show IgE responses (sensitization) to common fungi such as the dermatophyte *Trichophyton*. This may be incidental to the overall disease process for asthma, or it may in certain patients be a major pathologic problem, called severe asthma with fungal sensitivity (SAFS).[286] In general, asthma severity is associated with specific IgE responses to *Trichophyton*; a trial in 2009 showed modest spirometric improvement during long-term antifungal treatment,[287] but this was not sustained on discontinuation of antifungal therapy.[288]

One disease, allergic bronchopulmonary aspergillosis, is characterized by lung colonization and major allergic response to the common fungus, *Aspergillus fumigatus*. Many of these patients have an asthma-like disease. Itraconazole is an effective antifungal treatment.[289]

Tumor necrosis factor α (TNF-α) is implicated in asthma.[290] *Anti-TNF-α agents* include etanercept, a soluble TNF-α receptor fusion protein that binds to TNF-α, as well as infliximab and golimumab, monoclonal antibodies that bind to TNF-α. Trials with etanercept,[291] infliximab, and golimumab have not supported their use.[292,293]

Interleukin antibody therapy is another potential treatment of asthma. IL-2 and its receptor, IL2R, are produced by Th2 cells in response to allergen exposure and stimulate sensitized Th2 proliferation. Monoclonal antibody to IL2R (daclizumab) inhibits this response. Intravenous daclizumab therapy resulted in small improvements in asthma control.[294]

IL-5 promotes eosinophil activation, and this is an important part of the disease process for a group of patients with eosinophilic asthma.[295] In this group, treatment with antibody to IL-5 (mepolizumab) has been shown to have clinical utility,[296] but not in the general asthma population.[297]

Heparin has anti-inflammatory and anti-eosinophilic properties.[298] Nebulized heparin may have therapeutic promise for asthma treatment.[299] Coagulopathy does not complicate therapy.

Nebulized lidocaine also has potential,[300] but the therapeutic effect remains controversial.[301]

The 2007 Expert Panel Report of the National Asthma Education and Prevention Program gave recommendations for use of alternative agents.[45] The report stated that "the data at present are insufficient" to recommend

macrolide therapy. Moreover, the "current evidence does not support" the use of methotrexate, IL-4 receptor antibody, antibodies to IL-5 and IL-12, intravenous immunoglobulin, colchicine, troleandomycin, gold, or cyclosporine.

8. Investigative Drug Therapies

Investigative drug therapies provide an active and fast-changing area of research. It is uncertain which agents, if any, will be of practical patient benefit. As of early 2011, some drug targets include ADAM8 (a matrix metalloproteinase),[302] peroxisome proliferator-activated receptors (PPARs),[303] arginase,[304] and adenosine receptor.[305]

Nucleotide synthesis inhibitors (mycophenolate, leflunomide, and brequinar) may have clinical utility. They interfere with DNA replication, and lymphocytes are considered to be relatively more vulnerable.[262]

9. Other Agents

The mucolytic *N*-acetyl-L-cysteine (NAC), inhaled or ingested, has no proven efficacy in the management of asthma (or COPD or cystic fibrosis).[87] The aerosol form has a pH of 2.2, provokes airway secretions, and is an airway irritant.[306]

Other mucolytic agents have been used in the treatment of cystic fibrosis, including aerosol formulations of a DNase (dornase alfa) that hydrolyzes the DNA component of mucus. There are isolated reports of dornase delivered via a bronchoscope in status asthmaticus.[307] A newer agent, thymosin-β4, has hydrolytic activity for the fibrous form of actin in mucus.[65]

Antihistamines do not have clinical efficacy for asthma treatment.[46,104] It is ironic that the first isolated mediator in asthma, histamine,[308] is not amenable to blockade.

C. Anesthetic Management of Asthma

Given the worldwide prevalence of asthma, many patients present for surgery, planned or otherwise. A core feature of anesthetic practice is provision of airway control, often with instrumentation. Because asthmatic patients have, as a primary component of their disease, airway hyperreactivity, they are at risk for perioperative exacerbation, especially intraoperative bronchospasm (IOB). IOB develops when offensive factors (collectively termed *noxious stimuli*), such as airway instrumentation or surgery (e.g., incision, manipulation, traction) are greater than defensive factors provided by preoperative drug management or anesthetic technique. Surgery within major body cavities, especially cardiothoracic or abdominal surgery, is considered to pose a greater risk for IOB.[46]

Patients who do not have optimal control of their asthma and those who have a history of a previous perioperative exacerbation are also considered to be at risk for IOB.[100] Conversely, those patients with optimal control are not considered to pose an extra risk.[46]

Management is twofold—proactive and, if necessary, reactive. The proactive approach includes optimizing current therapies with provision of preventive strategies. The reactive approach involves therapies applied after IOB has developed.

1. Proactive Management: Prevention of Bronchospasm

The proactive strategy involves optimization and prevention. Each of these approaches is designed to reduce the risk of bronchospasm resulting from noxious intraoperative stimuli.

a. OPTIMIZATION

Optimization is best achieved with advice from a respiratory physician, so that treatment matches the disease severity. Compliance with prescribed medication should be confirmed. These interventions are practical for elective or scheduled surgery, if sufficient time is available. These opportunities are lost when urgent or emergent surgery is needed.

Smoking cessation 2 months before surgery is advised.[309] Control of gastroesophageal reflux is advised.[310] Patients with asthma have been reported to have three times the prevalence of reflux disease compared with patients without asthma. Long-term treatment, however, has not improved overall asthma control.[311,312]

b. PREOPERATIVE PREVENTION

Prevention includes preoperative and perioperative phases. Interventions are matched to the severity and stability of the disease. Preoperative prevention includes these options:

SYSTEMIC GLUCOCORTICOIDS. A preoperative course of systemic GC therapy (oral prednisolone, 40 to 60 mg/day for 5 days, or IV hydrocortisone, 100 mg three times daily) is advised for those patients with an FEV_1 less than 80% of predicted.[309] Treatment can be stopped without tapering (weaning the dose).[46]

For patients who have received systemic GC within the previous 6 months, a course of supplemental GC is advised (e.g., IV hydrocortisone 300 mg/day in divided doses) before surgery of intermediate or major intensity.[46] This can be stopped after 24 hours.[313]

BRONCHODILATORS. Short-acting inhaled bronchodilators are also advised.[309] pMDIs have efficacy equal to that of nebulized therapy provided technique is optimal. A preoperative combination of GC and BA is advised for patients with severe or brittle asthma and for those needing major surgery.[313,314]

GC and BA therapy, singly or combined, may result in electrolyte imbalances, particularly potassium and magnesium deficiencies. This should be anticipated and prevented by supplementation or corrected.[309]

ANXIOLYTICS. Fear (and pain) can be potent triggers for bronchospasm. Effective treatment with anxiolytics reduces this risk. Benzodiazepines do not provoke bronchoconstriction. There are reports of either no alteration in bronchial tone or decreased tone caused by direct effects in the lung (mediated by γ-aminobutyric acid [GABA] receptors) or by indirect effects in the CNS.[315-318]

Kil and associates reported no clinically measurable effect of oral midazolam 0.5 mg/kg on cardiorespiratory function in treated children with mild or moderate

asthma who were presenting for dental extractions.[319] Benzodiazepines are therefore a reasonable choice. α_2-Agonists (dexmedetomidine or clonidine) provide dose-dependent sedation and bronchodilation with drying. These agents have therapeutic appeal but have not been formally investigated in the setting of perioperative asthma management.[100]

ANALGESICS. Multimodal analgesic regimens optimize pain relief before and after surgery. This approach avoids the use of single-analgesic therapy, which generally has restricted efficacy with increased risk of dose-dependent toxicity.

Naturally sourced opiates, such as morphine, have a traditionally considered capacity to provoke mast cell degranulation, but strong evidence for consistently provoking bronchospasm is lacking. Whereas morphine provokes degranulation from skin mast cells, it does not do this for mast cells in the lung.[320] Morphine may have bronchodilator effects in asthmatic patients.[321]

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) for analgesia is traditionally controversial. They are generally considered safe to use in patients with well-controlled asthma and no known sensitivity.[322] The notable exception is in patients with AIA. This is a clinical syndrome of asthma that is worsened with aspirin and nasal polyposis, termed *Samter's triad*. Aspirin inhibits the cyclooxygenase pathway, diverting arachidonic acid metabolites into the lipoxygenase pathway and leading to an increase in cystLTs. Some estimate that up to 20% of asthmatics carry this risk.[323] AIA is associated with cigarette smoking.[324] Patients may have cross-reactivity with other NSAIDs, and referral to an allergy clinic has been advised.[325]

The general principles of anesthetic management for the asthmatic are the same as for any patient, namely protection of the patient from the stressors of surgical (and anesthetic) technique and provision of conditions amenable to successful surgery.

c. PERIOPERATIVE PREVENTION

Perioperative prevention involves a multimodal approach. List planning is important. Asthmatic patients should receive priority on a surgical list for two reasons: First, anxiety provoked by waiting can be reasonably reduced, and second, an early scheduled case allows more time for recovery during normal hospital hours.

A risk-benefit analysis of the available agents and techniques should be considered, and an individualized anesthetic plan (with an alternative) should be made for the induction, maintenance, and recovery phases. Agents and techniques implicated in a previous episode of bronchospasm should be avoided if possible. If these agents are deemed necessary, additional protective measures should be used.

A regional technique, either with sedation or with general anesthesia, may be appropriate. Systemic absorption (from a regional technique) of local anesthetic can attenuate bronchoconstriction. Shono and colleagues reported a case of a patient with asthma whose wheeze was reduced after extradural anesthesia with 2% lidocaine and returned after discontinuation of the drug.[326]

For general anesthesia, the principles of balanced anesthesia with hypnosis and reflex suppression apply. Induction is a time of risk. Combinations of synergistic agents, such as hypnotics with one or more opioids, benzodiazepines, α_2-agonists, or ketamine, can provide a smooth and sustained induction profile. Rapid administration of opioids has been reported to provoke the so-called rigid chest, even at low doses; this may, in part, result from laryngospasm.[26,327] These complications may be misinterpreted as bronchospasm. The antitussive effect of opioids is, however, reported to be therapeutic.[314]

Airway instrumentation is a risk factor for bronchospasm,[328] particularly with endotracheal intubation.[329] The effect of endotracheal intubation even in symptom-free asthmatics was shown in 10 volunteers who underwent the procedure with topical anesthesia. Intubation resulted in falls in FEV_1 in up to 50% of the subjects. This fall was attenuated in subjects receiving inhaled BA.[328] The response to mechanical stimuli is mediated by the parasympathetic nervous system and by direct local stimulation with release of mediators[330] such as neurokinin A and substance P from peripheral nerve terminals of C-fiber afferents.[331] Whereas endotracheal intubation is provocative, laryngeal mask airway insertion is not.[332]

INDUCTION. Preoperative anticholinergic therapy may protect against bronchospasm, and nebulized therapy has been reported to have utility.[333]

Inhaled lidocaine can attenuate airway reflexes in asthmatics and normal volunteers receiving inhaled histamine, but its efficacy is controversial.[300,301,334] A combination of topical lidocaine and BA has been used to attenuate reflexes for awake intubation in normal volunteers.[329] Lidocaine inhalation may provoke minor airway irritation, such as cough, breath-holding, or, more seriously, bronchospasm,[301,335-339] which can be attenuated with coadministration of IV lidocaine.[340] Lidocaine-provoked airway irritability can be reduced by anticholinergic or BA treatment.[336]

Propofol has been shown to have bronchodilator properties in animals and isolated human airway preparations.[22,341,342] Propofol is generally considered to be the most reasonable agent for induction,[343] superior to thiopental or etomidate.[20,344,345] Propofol modulates the slow inward calcium influx in smooth muscle and also reduces production of cytokines IL-1, IL-6, IL-8, and TNF-α. It is generally a bronchodilating agent,[346-348] but there are isolated reports of bronchospasm developing in association with propofol.[349] Formulations with preservatives are implicated, and those with irritable airways, such as smokers (and asthmatics), may be at greater risk.[350]

In contrast, thiopental may provoke bronchospasm when given to asthmatic patients. Wheeze was demonstrated in 48% of asthmatic patients receiving thiopental.[351]

Ketamine is a bronchodilator; it has a direct relaxant effect on airway smooth muscle through potentiation of catecholamines and inhibition of neutrally provoked bronchoconstriction.[348,352] Ketamine has been advised as an induction agent for asthmatic patients. In a case series of 40 patients with medically controlled asthma who received induction with ketamine, 26 patients had

reduced bronchospasm.[353] For patients with severe asthma (persistent asthma or exacerbation) presenting for surgery, ketamine is advised as the hypnotic drug of choice for induction.[354] A case series of 5 patients with status asthmaticus needing emergency intubation reported rapid improvement of arterial CO_2 content after IV induction with ketamine.[355]

Ketamine may, however, provoke both upper and lower airway secretion. Prior administration of an anticholinergic (e.g., IV glycopyrrolate) is useful. Conventional induction doses of ketamine are associated with emergence delirium and dysphoria. These risks can be reduced by coadministration of a benzodiazepine. Ketamine has a slower induction course, which should be taken into account before proceeding to airway instrumentation.

Inhalational induction is an option for motivated patients. Sevoflurane is a reasonable choice. An inhalation induction with either isoflurane or desflurane causes initial upper airway irritation and may provoke coughing, breath-holding, and laryngospasm.[356]

Lidocaine, given systemically before instrumentation, may be bronchoprotective. In asthmatic volunteers, IV lidocaine (up to 2 mg/kg) reduced histamine bronchoprovocation. Groeben and colleagues showed that either IV lidocaine or inhaled albuterol reduced histamine-provoked wheeze and concluded that both agents should be used before induction of anesthesia.[357] This conclusion was not supported by another study of 60 asthmatic patients,[358] and bronchospasm after IV lidocaine has been reported.[43]

NMB agents without bronchoconstrictive properties should be chosen. Release of mast-cell histamine has been reported with atracurium, increasing airway resistance and provoking bronchospasm.[359,360] Mivacurium is also implicated.[361] Atracurium also enhances vagal activity, which may be involved in increases in bronchomotor tone.[362]

Suxamethonium increases airway resistance and sensitivity to acetylcholine in animal models.[363,364] There are rare case reports of suxamethonium associated with bronchospasm and anaphylaxis.[365-367]

NMB drugs that have activity at the M_2 receptor group, such as rapacuronium, pipecuronium, and gallamine, can provoke bronchoconstriction.[309,368] Rapacuronium, initially a promising, rapidly acting blocker, was withdrawn because of this problem.[369]

Vecuronium, rocuronium, cisatracurium, and pancuronium are considered reasonable choices,[370] but anaphylaxis[371]—albeit rare—is a risk.

MAINTENANCE. Airway gases and vapors should be warmed and humidified. Volatile agents are usually used for the maintenance phase of anesthesia. In general, these agents depress contractility of the smooth muscle of the lower airways and are potent bronchodilators. They reduce responses to bronchoconstricting stimuli in both humans and animals[10,372-376] and also reduce baseline airway resistance in animals.[10,372-377] Effects on baseline airway resistance in human subjects are more difficult to interpret because of confounding influences such as endotracheal intubation and decreases in lung volume associated with general anesthesia, but it appears that these agents may also reduce resting airway smooth muscle tone in humans.[378,379]

Multiple mechanisms contribute to the relaxation of airway smooth muscle produced by volatile anesthetics attenuating reflex bronchoconstriction, in part by depressing neural pathways that mediate these reflexes.[380-382]

Bronchodilation has been observed with the use of high-speed computed tomography.[383] The exception is desflurane, which lacks bronchodilator activity.[384] Whereas sevoflurane is a popular choice for maintenance anesthesia, its bronchodilating efficacy is presently uncertain.

Rooke and coworkers compared the bronchodilating effects of sevoflurane, isoflurane, and halothane, concluding that sevoflurane reduced airway resistance more than the others did.[385] However, Habre and colleagues studied the effect of sevoflurane anesthesia on children with or without asthma and concluded that respiratory resistance increased only in the asthmatic group[386] and could be prevented by preoperative salbutamol (albuterol) therapy.[387]

Sevoflurane anesthesia (in pigs) may increase the production of inflammatory mediators such as LC_4 and nitrogen oxides in the lungs.[388] Because tone in airway smooth muscle helps regulate the matching of ventilation to perfusion, suppression of normal airway smooth muscle tone may contribute to impaired gas exchange in the perioperative period with all volatile agents. Animal studies have shown that sevoflurane anesthesia (in rats) may result in impaired gas exchange within the lung as a result of changes in peripheral lung compliance.[389]

COMPLETION. Completion of surgery and anesthesia is a crucial time when airway reflexes return, although in a modified state. Removal of airway devices (especially ETTs), coupled with clearance maneuvers such as suction, is provocative. Options include airway interventions done during deep anesthesia, but these may compromise airway patency and protection and should be performed after a risk-benefit analysis. Changing an ETT for an SLA can permit satisfactory emergence conditions—the so-called bridge to extubation, described when one is weaning a patient with resolved status asthmaticus from invasive ventilator support in critical care.[390,391] IV lidocaine may attenuate airway irritation at this stage.[392]

REVERSAL. Reversal of NMB with neostigmine (a cholinesterase inhibitor) has the potential to provoke bronchospasm by enhancing acetylcholine concentration. When it is given with antimuscarinic agents (atropine or glycopyrrolate), there is no reported effect on airway resistance.[393] However, bronchospasm has been reported, and this is a risk for patients with renal impairment.[100,394] Some authors advise allowing NMB to wear off without recourse to reversal agents.[100,309] Sugammadex offers an alternative method for reversal of rocuronium.[395]

In the postoperative phase, warmed, humidified O_2 therapy, physiotherapy, incentive spirometry, and motivated mobilization are important factors. Restoration of optimal drug therapy is also important. A course of nebulized SABA may be helpful. Temporary noninvasive

BOX 6-1 Structured Response to Intraoperative Bronchospasm

Recognize the nature and scope of the problem
Review the situation and exclude confounding issues
Request help
Rescue using rational application of drugs and techniques
Resource the situation with drugs, equipment, and personnel
Recovery including consideration of critical care

ventilation has been described.[100] Relief of pain and fear is a major goal.

2. Reactive Management: Treatment of Intraoperative Bronchospasm

IOB develops when the noxious stimuli of anesthetic or surgical techniques are not counteracted by planned protective anesthetic strategies. The reported incidence ranges from 1.7% to 16% of a general surgical patient population.[100] Isolated IOB may be the only recognized manifestation of anaphylaxis; it has been reported in 19% of patients subsequently shown to have anaphylaxis.[396] Recognized risk factors include reactive airways disease (asthma and COPD), tobacco smoking, and endotracheal intubation.[397] A gradation of severity can occur, from mild and transient to severe and sustained with threat to life. Critical IOB is an emergency and mandates immediate treatment. This is equivalent to the intensive care scenario of status asthmaticus,[346] from which much experience in management has been gained.

Treatment should be matched to severity, bearing in mind that the time course of IOB is variable and unpredictable. Escalation of drug therapies may be necessary. Rehearsed responses, with drugs available and doses calculated, are wise preemptive moves. A six-step reactive strategy outlines the necessary responses (Box 6-1).

a. RECOGNITION

Recognition is the first step. Vigilance is the key, with detection of change accomplished by use of clinical skills aided by appropriate use of monitors with suitably enabled alarms. Direct clinical examination of the patient, if possible, is important. Use of the human senses can yield vital information, confirming (or otherwise) a patient-centered problem.

Initial visible signs of IOB include rise in airway pressures, falls in delivered V_T, and decreased chest movement. Auscultation may reveal noisy breath sounds with expiratory wheeze predominating, but when IOB is severe, these signs are lost: *The "silent chest" is dangerous.* Auscultation of the expiratory limb of the breathing system may be helpful if the patient is isolated from direct examination.[100]

Bronchoconstriction results in an increase in airway resistance. If this increase is sufficient to increase the overall expiratory time constant beyond the maximal expiratory time, the lung relaxation volume cannot be reached, and inspiratory gas trapping ("breath stacking") occurs. Residual volume, FRC, and total lung volume are increased,[398] and these effects may be directly visible. With critical IOB, pneumothorax can ensue. Barotrauma is associated with high inspiratory and plateau pressures during the respiratory cycle.[399] Whereas an inspiratory pressure greater than 50 cm H_2O is considered dangerous, it is not as indicative as plateau pressure.[400-402] Longer expiratory time and a lower V_T and rate are advised.[346] This results in hypercarbia but is far less dangerous than barotrauma resulting from attempts to "normalize" CO_2 tension.[402] Dynamic hyperinflation, termed *pulmonary tamponade* or a "tourniquet to the right heart," can compromise right ventricular function.[100,346,403] Cardiac arrhythmia may complicate the situation. It results from a combination of hypoxia, hypercarbia, acidosis, and sympathetic drive, either from the patient or due to drugs.[404] *These immediate concerns should be communicated to the team.*

b. REVIEW

It is important to exclude confounding causes of obstruction that can arise along the ventilatory pathway. Malfunction of the breathing system, such as internal blockage or external compression of the tubing, must be excluded. Valve and ventilator function must be assessed. An alternative breathing system can be used to exclude residual doubt, using hand ventilation to assess overall compliance.

Because wheeze can result from any cause of airway narrowing (i.e., any fall in FRC), other causes, such as airway plugging, pulmonary aspiration, and pneumothorax, should be directly considered and excluded. Appropriate depth of anesthesia must be confirmed, because anesthesia that is too light is a common cause of IOB.

c. REQUEST HELP

Severe IOB is complex, risky, uncertain, and dynamic.[405] Skilled help and support can make a real difference to outcome.

d. RESCUE

No single therapy can be reliably predicted to effectively treat IOB, especially when it is critical. A major distinction between IOB and severe asthma in awake, self-ventilating patients is the difference in bioavailability of inhaled drugs. Patients with IOB invariably have an airway device (face mask, SLA, or ETT) connected to a breathing system. The great majority of any aerosolized drug is deposited in this device, with only 3% to 9% of drug reaching the lung. This is about 10 times less efficient than administration in self-ventilating patients.[99,100] A combination of inhaled and IV drugs may confer additive or synergistic effect, and a number of drug interventions are available for use in an escalating sequence.

As for any scenario, especially an emergency, in which task saturation is a risk, safe drug selection and timing of use are crucially important. The therapeutic rescue options available are listed in the following paragraphs.

INCREASING ANESTHETIC DEPTH. Increasing the anesthetic depth is a simple approach. Additional doses of induction agent and opioid are used, or the inspiratory fraction of the volatile agent is increased.

USE OF A VOLATILE AGENT. A volatile agent may be used to increase the agent in use or to change to an alternative.[100] Diethyl ether,[406] halothane,[24,407,408] enflurane,[409] and isoflurane[410] have been used. Use of sevoflurane, either for induction or in conjunction with other agents,[411-413] has also been reported. Failures have been described (i.e., with isoflurane).[414] Desflurane is not regarded as a bronchodilator.[384]

INHALED BRONCHODILATORS. Inhaled short-acting bronchodilators are given, either as a nebulized solution (using an in-line nebulizer) or from a pMDI via an airway adaptor. Because most of the drug will deposit in the breathing system[99,309] (rain out), about 10 canister activations are initially used for an adult.[100]

INTRAVENOUS BRONCHODILATORS. The use of intravenous bronchodilators has received the most support in the management of severe asthma (in nonintubated patients).[415] Intravenous therapy is reported to be superior to the inhalational route.[416] Sellers and Massahel report giving 5 µg/kg IV albuterol to children, 250 µg to adults; the dose can be repeated.[143] Browne and Wilkins advised use of a single bolus of albuterol (salbutamol), 15 µg/kg over 10 minutes, followed by an infusion of 1 to 5 µg/kg/min.[144]

For refractory cases, parenteral epinephrine may be used. Cydulka and colleagues described the effective use of subcutaneous epinephrine in the emergency department.[417] For adults, they advise 0.3 mg SQ epinephrine every 20 minutes. Intramuscular doses for adults range from 0.5 to 1.0 mg. Intravenous epinephrine may also be given. Suggested doses for adults are 10 to 100 µg IV, repeated as needed. A suggested infusion scheme is 0.35 to 0.7 mg/kg IV epinephrine given over 5 minutes, followed by an infusion of 0.5 to 2 µg/kg/min.

These treatments produce profound cardiovascular stimulation with tachycardia and hypertension, alleviated by concurrent use of magnesium.[418] Lactic acidosis is a recognized complication of the treatment of severe asthma and IOB with high dose BAs.[127,128] Hypokalemia and hypomagnesemia complicate high-dose BA therapy.[47]

INTRAVENOUS GLUCOCORTICOIDS. Intravenous GC may provide delayed effect a number of hours later.[100,309,419]

INHALED GLUCOCORTICOIDS. Recognizing that GC can have therapeutic effect by nongenomic mechanisms, such as decreased airway hyperemia and mucosal edema,[168,169] nebulized IGCs may be useful.[346] One study showed equal efficacy of 3 mg nebulized fluticasone and 100 mg hydrocortisone in nonintubated patients with acute severe asthma.[420]

KETAMINE. Most experience with ketamine comes from anecdotal management of severe acute asthma or status asthmaticus.[414,421-426] Doses between 0.5 and 2 mg/kg IV are described, followed by an infusion of 0.5 to 2 mg/kg/hr. In a placebo-controlled, double-blind trial of 14 mechanically ventilated patients with bronchospasm, 7 patients received 1 mg/kg IV ketamine with improvement in oxygenation; CO_2 clearance was unchanged in the treated group but increased in the control group.[424] One study on use of 3 mg/kg/hr has been published.[426]

One investigation did not support superiority of ketamine in the treatment of severe acute asthma in awake patients. This was a randomized, double-blind study of 53 consecutive patients. The protocol was an IV bolus of 0.2 mg/kg ketamine, followed by an infusion of 0.5 mg/kg/hr. Dysphoric reactions in the first 9 recruits prompted the reduction of the bolus dose by half.[427]

MAGNESIUM. Intravenous magnesium therapy used in the treatment of severe acute asthma was found to be beneficial and safe,[428] based on the results of a multicenter, randomized, controlled trial in the emergency department giving 20 to 40 mg/kg IV over 10 minutes.[429] Tachycardia provoked by sympathetic stimulants is reduced, and NMB is prolonged.[418,430] Inhaled magnesium (sulfate) has been used therapeutically in the treatment of severe asthma,[431] but it can be an airway irritant. Other systematic reviews of inhaled and IV magnesium therapy have concluded that it can have therapeutic benefit.[432]

HELIUM-OXYGEN CARRIER GASES. Helium-oxygen (heliox) mixtures are not bronchodilators, and the potential for improvement in gas exchange and respiratory mechanics is limited to their duration of use. They improve transport of gases, vapors, and aerosols by sustaining laminar flow in breathing systems (including nebulizers) and airways,[433] but a major limitation is reduced inspiratory fraction of O_2.[47,100,346] Heliox mixtures have been used in the setting of severe acute asthma and status asthmaticus.[434-437] Use of heliox for critical IOB in ventilated patients is limited.[47,346,437] Systematic reviews have not provided firm evidence to support widespread use.[438,439]

NITRATES. There are sparse reports of the therapeutic use of nitroglycerin in severe IOB.[440-442]

LIDOCAINE. Intravenous lidocaine has been used to treat IOB.[443]

METHYLXANTHINES. MXs were used traditionally, but recent evidence does not support their general use for IOB, and response in the setting of severe acute asthma is rare.[47]

NEBULIZED FUROSEMIDE. Nebulized furosemide has been used in the management of acute asthma. Initial reports were encouraging,[444] but other studies have not supported this finding,[445-447] including a critical review.[448]

ANTIBIOTICS. Bacterial infection with acute asthma is rare.[67] Unless bacterial infection is clinically apparent, routine use of antibiotics is not supported.[449]

e. RESOURCES

As with any perioperative problem, timely provision of resources, including drugs, equipment, and people, can make all the difference.

f. RECOVERY

The place and time for recovery should be carefully considered, depending on IOB severity and response to treatment. Postoperative deterioration (biphasic effect) has been described in up to 20% of patients, especially those with bronchospasm associated with anaphylaxis.[450,451] Critical care admission is a realistic option.[100]

If the episode of IOB was unpredicted, testing for anaphylaxis should be considered.[371,452]

VI. CONCLUSIONS

Drugs can affect the upper and lower airways directly or indirectly to produce a variety of desirable and undesirable effects. Knowledge of the pharmacology of such drugs is essential to the safe practice of airway management for the conscious patient and for the patient requiring sedation or anesthesia. These drugs can be delivered locally to the respiratory tree or systemically, producing clinical effects on healthy airways (e.g., anesthesia) or therapeutic effects on diseased airways (e.g., bronchodilation).

Agents acting directly on the airway include local anesthetic agents, sympathomimetics, and bronchodilators. They are used to provide topical anesthesia and optimally dilated upper and lower airways but on occasion may produce unwanted effects such as airway irritability. Indirectly acting agents can influence the CNS and the musculoskeletal system to produce effects on airway patency, airway reactivity, and respiratory drive. These effects may optimize the upper airway and lower respiratory tract in terms of reactivity or patency. However, indirect deleterious effects, such as a loss of airway tone, loss of airway protective reflexes, and loss of respiratory drive, can result in airway-related morbidity or mortality.

This chapter began with a review of the effects of drugs for safe, effective anesthesia and sedation. Drug management for asthma, based on nationally devised guidelines, was then discussed, followed by therapies to prevent and treat perioperative bronchospasm.

VII. CLINICAL PEARLS

- Topical application of local anesthetic to the airway is unlikely to cause systemic toxicity, although the safe maximum dose is uncertain. Doses greater than 9 mg/kg may risk toxicity.
- Asthma is now recognized as an inflammatory disease of the airways, and the use of inhaled glucocorticoid (IGC) for prevention is a major therapeutic advance.
- General anesthesia for asthmatic patients requires optimization with inhaled β-agonist (BA) therapy, consideration of systemic GC therapy, and avoidance of triggering factors.
- Propofol and volatile agents, except desflurane, are bronchodilators.
- Intraoperative bronchospasm (IOB) results when airway stimulation, typically by instrumentation, is not countered by perioperative technique. A planned, rehearsed response is needed for safe and effective management.

VI. Conclusions

VII. Clinical Pearls

I. BACKGROUND

Laryngoscopy, endotracheal intubation, and other airway manipulations (e.g., placement of a nasopharyngeal or oropharyngeal supralaryngeal airway) are noxious stimuli that may induce profound changes in cardiovascular physiology, primarily through reflex responses. Although these responses may be of short duration and of little consequence in healthy individuals, serious complications can occur in patients with underlying coronary artery disease,[1,2] reactive airways,[3,4] or intracranial neuropathology.[5,6]

II. CARDIOVASCULAR RESPONSES DURING AIRWAY MANIPULATION

A. Cardiovascular Reflexes

The cardiovascular responses to noxious airway manipulation are initiated by proprioceptors responding to tissue irritation in the supraglottic region and in the trachea.[7] Located in close proximity to the airway mucosa, these proprioceptors consist of mechanoreceptors with small-diameter myelinated fibers, slowly-adapting stretch receptors with large-diameter myelinated fibers, and polymodal endings of nonmyelinated nerve fibers.[8] (The

superficial location of these proprioceptors and their nerves explains why topical local anesthesia of the airway is such an effective means of blunting cardiovascular responses to airway interventions.) The glossopharyngeal and vagal afferent nerves transmit these impulses to the brainstem, which, in turn, causes widespread autonomic activation through the sympathetic and parasympathetic nervous systems. Bradycardia, often elicited in infants and small children during laryngoscopy or intubation, is the autonomic equivalent of the laryngospasm response. Although seen only rarely in adults, this reflex results from an increase in vagal tone at the sinoatrial node and is virtually a monosynaptic response to a noxious stimulus in the airway.

In adults and adolescents, the more common response to airway manipulation is hypertension (HTN) and tachycardia mediated by the cardioaccelerator nerves and sympathetic chain ganglia. This response includes widespread release of norepinephrine from adrenergic nerve terminals and secretion of epinephrine from the adrenal medulla.[9] Some of the hypertensive response to endotracheal intubation also results from activation of the renin-angiotensin system, including release of renin from the renal juxtaglomerular apparatus, which is innervated by β-adrenergic nerve terminals.

In addition to activation of the autonomic nervous system, laryngoscopy and endotracheal intubation result in stimulation of the central nervous system, as evidenced by increases in electroencephalographic (EEG) activity, cerebral metabolic rate, and cerebral blood flow (CBF).[10] In patients with compromised intracranial compliance, the increase in CBF may result in elevated intracranial pressure (ICP), which, in turn, may result in herniation of brain contents and severe neurologic compromise.

The effects of endotracheal intubation on the pulmonary vasculature are probably less well understood than the responses elicited in the systemic circulation. They are often coupled with changes in airway reactivity associated with intubation. Acute bronchospasm or a main stem bronchial intubation results in a marked maldistribution of perfusion to poorly ventilated lung units, causing desaturation of pulmonary venous blood and subsequent reduction in systemic arterial oxygen (O_2) tension. In addition, institution of positive end-expiratory pressure (PEEP) after endotracheal intubation causes a reduction in cardiac output related to impaired venous return to the left side of the heart from the pulmonary circulation. The impact of these changes can be profound in patients with severely compromised myocardial function or intravascular volume depletion.

B. Intubation in the Presence of Cardiovascular Disease

Myocardial ischemia results when there is an imbalance between myocardial O_2 supply and demand. In the presence of a stable O_2 content of whole blood (the product of hemoglobin concentration and saturation, with a minor contribution from dissolved O_2), the myocardial O_2 supply is almost entirely determined by coronary blood flow and distribution, because O_2 extraction at the cellular level is at or near maximum even under resting conditions.

The chief components on the demand side of the myocardial O_2 balance equation are beat frequency or heart rate (HR) and myocardial wall tension. Of the two, increases in HR are of greatest concern, because cardiac inotropism (contractility) subserves cardiac chronotropism (rate). Not only does tachycardia increase myocardial O_2 consumption per minute at constant wall tension, but elevations in rate effectively reduce the diastolic period. Because full diastolic relaxation may be impaired, a subsequent increase in resting wall tension will impair subendocardial blood flow, thereby reducing myocardial O_2 supply. Concomitantly, the rate of intraventricular pressure development in systole (dP/dT), a measure of myocardial contractility and another determinant of myocardial O_2 demand, will also increase.

It follows, then, that neuroendocrine responses to airway manipulation resulting in tachycardia and HTN may result in a variety of complications in patients with cardiac disease, myocardial ischemia chief among them. This set of circumstances is responsible for episodes of ischemic electrocardiographic ST-segment depression and increased pulmonary artery diastolic blood pressure (BP) that may be seen when intubation is performed in patients with arteriosclerosis; occasionally, these episodes presage the occurrence of a perioperative myocardial infarction.[2] However, short ischemic episodes (<10 minutes) evidenced by electrocardiographic ST-segment depression, such as those that may be experienced only during airway manipulation, have not been shown to correlate with postoperative myocardial infarction. In contrast, ST-segment changes of a single duration lasting longer than 20 minutes (mean SD 20 ± 30 minutes) or cumulative durations of longer than 1 hour (mean SD 1 ± 2 hours) do seem to be an important factor associated with adverse perioperative cardiac outcomes.[11,12]

Patients with aneurysmal disease of the cerebral and aortic circulation may also be at particular risk of complications related to a sudden increase in BP during airway instrumentation. Laplace's law defines the transmural wall tension of a blood vessel (the determinant of its likelihood of rupture) as the product of the pressure inside the vessel and its radius divided by the wall thickness. The presence of a thin-walled vascular aneurysm (higher transmural wall tension at baseline) combined with a sudden increase in intraluminal pressure can lead to rupture of the affected vessel and abrupt deterioration in the patient's status. Leaking aortic aneurysms are partially tamponaded by intra-abdominal pressure but can suddenly expand into the retroperitoneal space during arterial HTN. The results are significant blood loss and additional technical problems for the surgeon trying to resect the lesion and insert a vascular prosthesis.

C. Implications for Patients with Neurovascular Disease

Intracranial aneurysms and arteriovenous malformations (AVMs) often arise with a small "sentinel" hemorrhage that serves as a warning of worse things to come. During subsequent periods of elevated arterial BP, these lesions

are likely to rebleed, resulting in sudden and permanent neurologic injury. Many neurosurgeons and interventional neuroradiologists attempt to stabilize cerebral aneurysms and AVMs soon after hospitalization in an effort to minimize the risk of rebleeding. This means that the patient presents for anesthesia at a time when the clot tamponading the aneurysm or AVM is particularly delicate, and a small increase in arterial transmural pressure could cause rerupture. One of the times at which this is most likely to occur is when the arterial BP and the HR are increased in response to endotracheal intubation.[5] Therefore, neurosurgical anesthesiologists pay meticulous attention to attenuating these responses during the course of anesthetic induction and endotracheal intubation.

D. Intubation in Patients with Neuropathologic Disorders

Reflex responses to endotracheal intubation are also a potential hazard to patients with compromised intracranial compliance resulting from neuropathologic processes such as intracranial mass lesions, brain edema, or acute hydrocephalus. Uncontrolled coughing can result in a marked increase in intrathoracic and intra-abdominal pressure that, in turn, increases cerebrospinal fluid pressure and may result in impairment of cerebral perfusion. In patients with impaired cerebral autoregulation (e.g., brain trauma, cerebrovascular accidents, neoplasms), the normal tendency for CBF to remain constant over the mean BP range of 50 to 150 mm Hg is impaired. When endotracheal intubation causes an increase in arterial BP, there is a marked increase in CBF and cerebral blood volume, which in turn can cause dangerous increases in ICP.[6] This effect is magnified by the fact that noxious stimuli, such as airway manipulation, result in increased CBF, which summates with the hypertensive BP response, occasionally causing profound increases in ICP (Fig. 7-1).

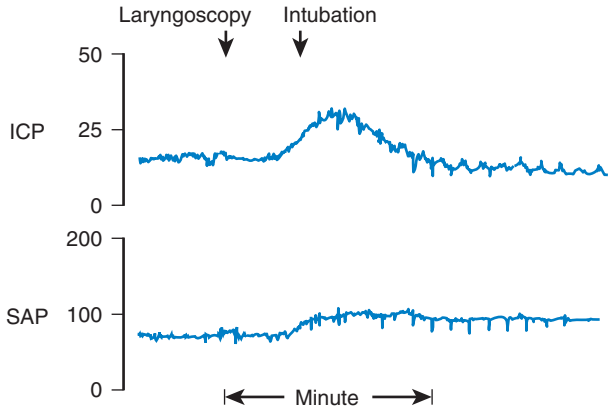

Figure 7-1 Increases in systemic arterial pressure *(SAP)* and intracranial pressure *(ICP)* in response to endotracheal intubation in a patient with a small brain tumor. Notice the minimal response to rigid laryngoscopy. There is a sustained increase in systemic arterial pressure but only a transient increase in ICP, which returns to normal as cerebrovascular autoregulation becomes operative. (From Bedford RF: Circulatory responses to tracheal intubation. *Probl Anesth* 2:201, 1988.)

E. Neuromuscular Blocking Drugs and Cardiovascular Responses

Neuromuscular blocking drugs (NMB) are often administered to optimize conditions for intubation. Accordingly, it is appropriate to consider the cardiovascular and cerebrovascular responses to the administration of these agents. Indeed, the hypertensive-tachycardic response to endotracheal intubation was not identified until NMB agents were introduced into clinical practice, because before that time intubation was performed only with the patient under such deep levels of anesthesia that relatively little cardiovascular response was generated.[13]

The depressor effects of benzylisoquinolinium relaxants (atracurium and mivacurium) are mediated by histamine release.[14] This effect could be viewed as a potential antagonist to the pressor response to laryngoscopy and endotracheal intubation. In the case of patients at risk for intracranial HTN, however, histamine-induced cerebral vasodilation may produce increases in ICP even as the BP falls.[15] By contrast, pancuronium, rocuronium, and, to a lesser extent, vecuronium may initiate a hyperdynamic cardiovascular state that can potentiate the cardiovascular responses seen after endotracheal intubation in lightly anesthetized patients. The faster onset of rocuronium (doses of up to 2 mg/kg have a 90% chance of providing perfect intubating conditions) are the reason for its current widespread use as an alternative to succinylcholine for rapid-sequence intubation (RSI) and in operations expected to last longer than 1 hour.[16]

Succinylcholine, or diacetylcholine, is associated with bradycardia in children, particularly when doses are repeated, but is a cardiovascular stimulant in adults. This phenomenon is often associated with activation of the EEG, and patients with brain tumors may sustain marked increases in ICP after succinylcholine administration if intracranial compliance is compromised and cerebrovascular autoregulation is impaired.[17] This has been shown in dogs to be a result of increased CBF related primarily to succinylcholine-induced increases in afferent muscle spindle activity at the time of fasciculation and secondarily to an elevated arterial carbon dioxide tension from fasciculation-induced carbon dioxide production.[18] The evidence to substantiate the clinical relevance of these findings is lacking, however. Whereas it has been reported that succinylcholine administered to patients with brain tumors may elevate ICP by a mean of 5 to 12 torr, cerebral perfusion pressure does not change significantly, and a negative effect on neurologic outcome has not been documented.[19,20] Additionally, this phenomenon can be prevented by pretreatment with defasciculating doses of nondepolarizing NMB drugs.[19] Further, when adequate ventilation is maintained, succinylcholine administered to intubated patients being treated for intracranial HTN of various causes or to those who have suffered severe head injuries caused by blunt trauma had no effect on ICP, cerebral perfusion pressure, or CBF.[21,22] As a result, succinylcholine is still considered a first-line agent for RSI in patients with acute head injury but is ideally used after pretreatment with a nondepolarizing agent and in the presence of slight hypocapnia.

F. Cardiopulmonary Consequences of Positive-Pressure Ventilation

Venous return is defined by the pressure gradient between the mean systemic pressure in the peripheral venous system and the mean right atrial pressure. An increase in mean intrathoracic pressure due to positive-pressure ventilation (PPV) may be transmitted to the thin-walled, compressible superior and inferior venae cavae, effectively elevating the downstream pressure for venous return and thereby reducing venous blood return to the right atrium. Because the left side of the heart can only pump what the right side delivers, cardiac output and subsequently arterial BP may fall with PPV. Patients with decreased intravascular volume may have an exaggerated hypotensive response as a result of this phenomenon.

Those with impaired myocardial reserve may also be sensitive to the effects of PPV. However, a failing heart may also benefit from the combined effects of decreased preload and decreased afterload. In other words, PPV, particularly PEEP or continuous positive airway pressure (CPAP), diminishes the transmural wall tension of the left heart by raising juxtacardiac pressures. One common clinical scenario is a patient who responds to intubation with a brisk increase in BP and then suddenly develops acute hypotension as PPV is instituted. In such a situation, volume expansion, positional changes, and judicious use of α-adrenergic agents such as phenylephrine may be needed.

It should also be noted that both hypoxemia and hypercapnia lead to a stress-induced catecholamine response, which may mask other potential causes of hypotension. This becomes readily apparent only after intubation in critically ill patients. Prophylactic volume expansion and the immediate availability of vasoactive infusions decrease severe hemodynamic collapse in this situation.[23]

III. PREVENTION OF CARDIOVASCULAR RESPONSES

A. Technical Considerations: Minimizing Stimulation of Airway Proprioceptors

As a general rule, cardiovascular responses to airway maneuvers can be minimized by limiting airway proprioceptor stimulation, starting with manipulation of the larynx itself. For instance, cricoid cartilage pressure with a posterior force of 4.5 kg is widely used to prevent regurgitation of gastric contents or to facilitate laryngeal visualization. In a double-blind study, cricoid pressure resulted in a significantly greater HR and BP response to endotracheal intubation than occurred in patients whose cricoid area was gently palpated.[24] This is a little-recognized effect of cricoid pressure that should be considered when estimating the risk-benefit ratio of this procedure in individual patients.

Laryngoscopy itself is a moderately stimulating procedure, and use of a straight blade (Miller blade) with elevation of the vagally innervated posterior aspect of the epiglottis results in significantly higher arterial BP than does use of a curved blade (Macintosh or Corazzelli–London–McCoy [CLM]).[25] Newer video and optical laryngoscopes, which do not require alignment of the laryngeal axes for adequate visualization of the vocal cord inlet and subsequent intubation, have the potential to minimize the pressor response to airway manipulation by reducing the amount of force needed to displace oropharyngeal tissues and limiting cervical spine motion compared to traditional laryngoscopy with a Macintosh laryngoscope blade.[26] Nonetheless, reports documenting this advantage are few.

Use of the Pentax-AWS video laryngoscope (Pentax, Tokyo, Japan) has been reported to attenuate the hemodynamic response to endotracheal intubation after fentanyl/propofol induction when compared to either the GlideScope (Verathon, Bothell, WA) or the Macintosh laryngoscope (Fig. 7-2).[27] This finding is not universal. An earlier study comparing the Pentax-AWS to Macintosh laryngoscopy reported no significant differences in systolic BP, diastolic BP, or HR after intubation, and a separate study comparing the GlideScope and Macintosh laryngoscopy also failed to find significant differences in hemodynamic values at any point in the study.[28] None of these studies included patients with known cardiac disease or chronic HTN, who often have exaggerated pressor responses to stimulation; the newer airway devices may have greater value among this group compared with traditional laryngoscopy.

The act of passing an endotracheal tube (ETT) is far more hemodynamically stimulating than just laryngoscopy. Surprisingly, the use of a lighted intubation stylet fails to prevent hemodynamic stimulation when the ETT is advanced past the vocal cords.[29] Insertion of a conventional laryngeal mask airway (LMA) after induction of general anesthesia with thiopental or propofol and fentanyl has been shown to cause less cardiovascular and endocrine response than laryngoscopy or endotracheal intubation.[30-33] The LMA has the advantage of avoiding the vagally mediated infraglottic stimulation entailed by the use of a laryngoscope, thus enabling lighter levels of general anesthesia. Furthermore, because muscle relaxation is not required for airway control, spontaneously initiated ventilation is possible, with avoidance of the adverse hemodynamic consequences of PPV. In contrast, endotracheal intubation using the intubating LMA (iLMA) resulted in a hemodynamic and endocrine response similar to that resulting from direct laryngoscopy and intubation after propofol induction.[34] Therefore, if endotracheal intubation is necessary, there does not appear to be a hemodynamic advantage to instrumenting the airway with the iLMA.

Whatever the technique employed to manage the airway, it must be emphasized that the hypertensive-tachycardic response to intubation is a manifestation of insufficient anesthesia. Insofar as the pressor response can also be influenced by prolonged intubation time, rapid first-attempt success is also of particular importance.[7]

B. Topical and Regional Anesthesia

Topical anesthesia applied to the upper airway is effective in blunting hemodynamic responses to endotracheal intubation,[35,36] but it has almost invariably proved to be

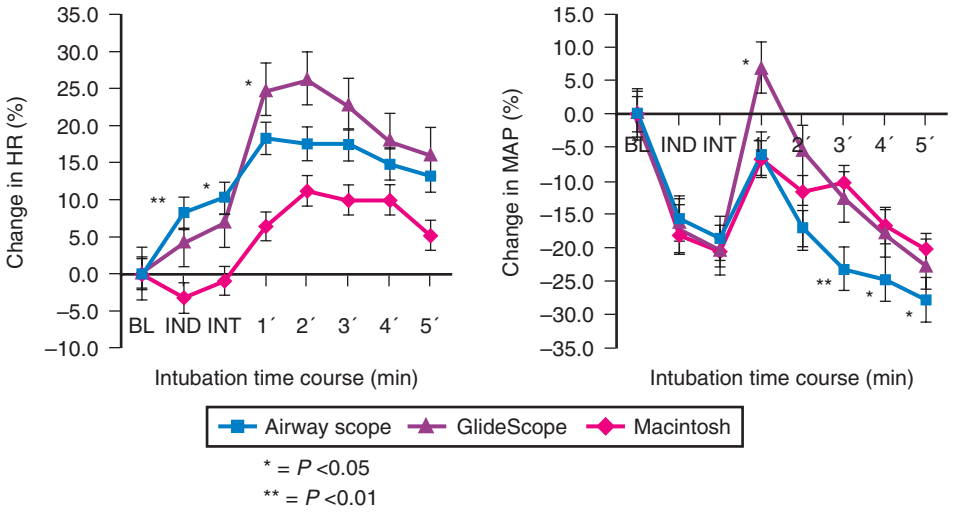

Figure 7-2 Percentage change from baseline in heart rate (HR, *left*) and mean arterial pressure (MAP, *right*) associated with endotracheal intubation using an Airway Scope, GlideScope, or Macintosh laryngoscope. Data values are presented as mean ± standard error. *$P < 0.05$ compared to Macintosh group. **$P < 0.01$ compared to Macintosh group. *BL,* Baseline; *IND,* 1 minute after induction; *INT,* at intubation; *1′* through *5′*, minutes after endotracheal intubation. (From Tsai P, Chen B: Hemodynamic responses to endotracheal intubation comparing the airway scope, GlideScope, and Macintosh laryngoscopes. *Internet J Anesthesiol* 24(2), 2010.)

less effective than systemic administration of lidocaine. During general anesthesia, rigid laryngoscopy and instillation of lidocaine solution initiate the same adverse reflexes caused by placement of an ETT (Fig. 7-3).[37] Furthermore, a laryngotracheal spray of lidocaine solution may, in itself, produce profound cardiovascular stimulation in adults, and in children it may produce the same sort of bradycardic response associated with endotracheal intubation.[38] If topical lidocaine is administered to the upper airway, there should be an intervening period of at least 2 minutes to allow initiation of anesthetic effect before airway instrumentation begins.[39]

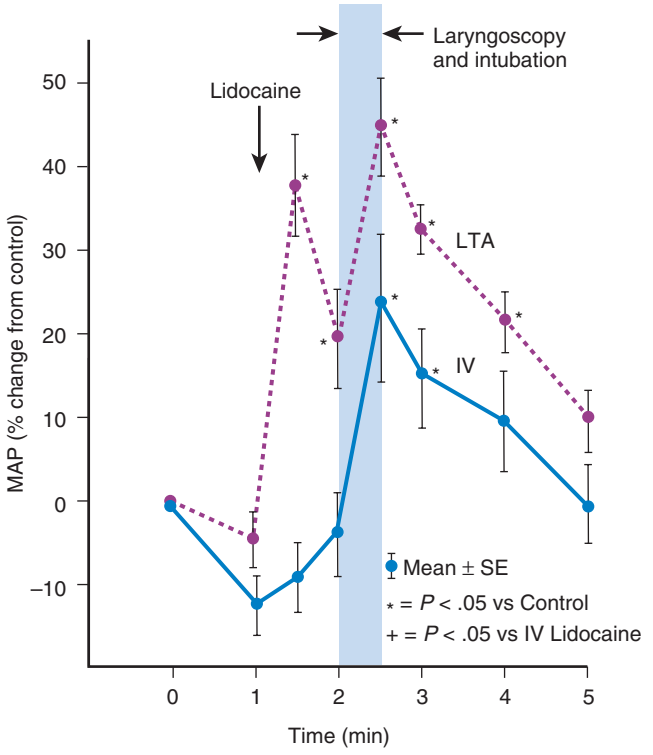

Figure 7-3 Mean arterial pressure *(MAP)* response to endotracheal intubation after either intravenous *(IV)* or intratracheal *(LTA)* lidocaine instillation. (From Hamill JF, Bedford RF, Weaver DC, Colohan AR: Lidocaine before endotracheal intubation: IV or laryngotracheal? *Anesthesiology* 55:578, 1981.)

Excellent topical anesthesia of the airway obtained before awake flexible fiberoptic intubation was responsible for reports suggesting that there was less cardiovascular stimulation after this procedure than after intubation with a rigid laryngoscope.[40] Later studies performed with patients under general anesthesia demonstrated no difference between the two modes of intubation with regard to hemodynamic impact, probably because the more profound stimulus results from placement of the ETT below the level of the glottis.[41-44]

Increasing the concentration of lidocaine used, and thus the total dose, also does not appear to mitigate this effect, although it may improve intubating conditions during awake flexible fiberoptic intubation.[45,46] Although both 2% and 4% lidocaine administered through an epidural catheter in the working channel of the flexible fiberoptic bronchoscope by a "spray-as-you-go" technique provided similar intubating conditions and hemodynamic profiles, the former resulted in a smaller overall dose, lower plasma levels, and therefore less chance for toxicity reactions.[46] Lower concentrations of lidocaine (1%) provided lower plasma levels and similar hemodynamics but appeared to provide less optimal intubating conditions than atomized 2% lidocaine when used for topical anesthesia before airway manipulation.[45]

In contrast to topical anesthesia of the airway, which appears to provide inconsistent benefit, regional nerve blocks involving the sensory pathways from the airway prevent hemodynamic responses to intubation. The superior laryngeal nerve (SLN) innervates the superior surface of the larynx, and the glossopharyngeal nerve innervates the oropharynx. Depositing local anesthetic on each

cornu of the hyoid bone can block the SLN. Blockade of the glossopharyngeal nerve at the tonsillar pillars (sensory distribution above the level of the epiglottis) potentiates this effect by decreasing the stimulus of laryngoscopy.[47] The inferior surfaces of the larynx and trachea require topical anesthesia, however, because they are innervated by the recurrent laryngeal nerve and the vagus, which cannot be directly blocked. With the preceding combination, awake patients exhibit little response as the ETT is inserted.

Instillation of lidocaine via an ETT to prevent alterations in cerebrovascular hemodynamics in patients with severe head injury may be of some benefit. A dose of 1.7 mg/kg lidocaine instilled at body temperature given slowly (1 mL/sec) through a fine tube advanced to the end of the ETT but not in contact with the tracheal mucosa was reported to be efficacious in half of the patients treated.[48]

C. Inhalational Anesthetics

Defining the anesthetic dose requirement for effectively blocking (or even blunting) hemodynamic and ICP responses to endotracheal intubation has remained an elusive goal. Airway maneuvers are typically brief interventions that produce short-lived responses during a dynamic perioperative period, with drug concentrations rapidly fluctuating both in blood and at effect sites. Agents that are capable of preventing responses may also produce profound cardiovascular depression before and after the stimulation of endotracheal intubation. Accordingly, there are relatively few well-controlled dose-response studies, and those that are available often give information that is not useful for the clinical anesthesiologist.

For inhalational anesthetics, endotracheal intubation using doses in the range of the minimum alveolar concentration (1 MAC) resulted in marked cardiovascular stimulation during anesthesia with nitrous oxide (N_2O) supplemented with either halothane or morphine.[49] It should not be surprising that 1 MAC is insufficient, because it is known that approximately 1.5 to 1.6 MAC is needed to block the adrenergic and cardiovascular responses to a simple surgical skin incision (MAC-BAR).[50] The dose of anesthetic required to prevent coughing during endotracheal intubation with sevoflurane may exceed MAC by a factor of 2.86 in adults,[51] although this factor appears to be close to 1.3 in children.[52]

Accordingly, it appears that the dose of volatile anesthetic required to block the cardiovascular response to endotracheal intubation must be inordinately high, resulting in profound cardiovascular depression before endotracheal intubation.[53] From a cerebrovascular viewpoint, this approach is totally impractical, because high doses of volatile anesthetics cause cerebral vasodilation and marked increases in ICP in patients with compromised intracranial compliance. Furthermore, from a cardiovascular point of view, the arterial hypotension and reduced cerebral perfusion pressure before intubation would be entirely unacceptable for patients with cerebrovascular disease or brain injury.

D. Intravenous Agents

Propofol, barbiturates, and benzodiazepines are all associated with profound hypotension at doses that suppress the hemodynamic and ICP responses to intubation.[54-56] In the case of etomidate, the effective dose for blocking the cardiovascular response to intubation can be identified by a burst-suppression pattern on the cortical surface EEG, indicating fairly deep cerebral depression.[57] Because etomidate supports BP at such deep levels of anesthesia, it is probably the only contemporary agent that, by itself, can achieve suppression of cardiovascular responses without first producing undue arterial hypotension and compromise of coronary and cerebral perfusion.

Because it is clinically impractical to achieve sufficient anesthetic depth for preventing a hyperdynamic response to intubation solely with an intravenous (IV) or inhalational agent (etomidate excepted), a wide variety of anesthetic drug combinations, adjuvants, or both have been used in attempts to potentiate anesthetic effects while minimizing hemodynamic depression.

Opioids are the adjuvants most commonly administered in addition to other IV or inhaled agents to facilitate induction of anesthesia and subsequent airway manipulation. Their use in this capacity relates to their historical use as part of a N_2O-narcotic anesthetic often used in patients with marginal cardiac reserve. For example, Bennet and Stanley compared the cardiovascular responses after administration of N_2O-morphine 0.4 mg/kg versus N_2O-fentanyl 4 µg/kg 10 minutes before intubation. The HR, cardiac output, and systolic and mean BP were reduced compared to baseline and remained unaffected by intubation in the N_2O-fentanyl group, but these parameters were all significantly elevated compared with preanesthetic controls in the N_2O–morphine group.[58] Whereas the assumed potency of fentanyl in this study was 100 times that of morphine, the lack of effect of morphine suggests that, with respect to suppression of pressor responses to laryngotracheal manipulation, fentanyl is more than 100 times as potent.

As reported by Bennett and Stanley[58] and later by other investigators,[59] fentanyl may not achieve its peak central nervous system effect until 10 minutes after bolus IV injection. Fentanyl appears to provide blunting of hemodynamic responses in a graded manner: 2 µg/kg IV given several minutes before induction only partially prevented HTN and tachycardia during an RSI with thiopental and succinylcholine. In this situation, 6 µg/kg was considerably more effective.[60] Chen and coworkers reported almost complete suppression of hemodynamic response to intubation with both 11 and 15 µg/kg of IV fentanyl, whereas higher IV doses (30 to 75 µg/kg) allowed only a very occasional response to intubation.[61]

In doses that prevent hemodynamic response to intubation, however, fentanyl is not a short-acting agent, and the risk of prolonged postoperative respiratory depression must be weighed against the advantages of perioperative cardiovascular stability. With this risk in mind, it has been observed that pretreatment with 2 µg/kg IV fentanyl given 10 minutes before intubation during an infusion of propofol sufficient to reduce the Bispectral Index Score to 45 prevented a significant increase in HR or BP

compared with awake preanesthetic values.[10] Similar results were observed when intubation was performed after administration of fentanyl, 2 μg/kg, and propofol bolus doses of 2.0 to 3.5 mg/kg.[10]

Fentanyl and propofol require 6.4 and 2.9 minutes, respectively, to achieve effect-site equilibrium after IV bolus administration.[10] Therefore, the common practice of administering 1 to 2 mL (50 to 100 μg) just before or almost simultaneously with other induction medications would not be expected to have any effect based on inadequate dose and inappropriate timing of administration. Rather, this may provide a more plausible explanation for hypotension during the minutes-long quiescent period between endotracheal intubation and actual surgical incision. It is strongly recommended that laryngoscopy and intubation be timed to coincide with the peak effect of these agents.

Opioids with shorter onset and offset times have some advantages over fentanyl for modulating circulatory responses to intubation. Alfentanil has a smaller steady-state distribution volume and shorter terminal elimination half-life than fentanyl.[62] Ausems and colleagues demonstrated that an alfentanil plasma concentration of 600 ng/mL effectively prevented hemodynamic responses to intubation during induction of N_2O anesthesia.[63] This was achieved by a 30-second infusion of alfentanil at 150 μg/kg. During this induction period, N_2O and succinylcholine were also administered. Only 5 of the 35 patients studied sustained an increase in HR or BP greater than 15% above preinduction values.

Remifentanil has been found to be highly effective in preventing hemodynamic responses to intubation, albeit always with the cost of impressive bradycardia or hypotension, or both, before and after airway manipulation.[64] Many studies have used vagolytic agents to avoid bradycardia, at the risk of an elevated HR response after intubation. Remifentanil's half-time for equilibration between blood and effect site is 1.3 minutes,[65] and it has a brief half-life of 3 to 5 minutes due to hydrolysis by tissue and blood esterases.[66] Typical remifentanil infusion rates used for blunting hemodynamic responses are 0.25 to 1.0 μg/kg/min in association with cautious propofol administration and nondepolarizing neuromuscular blockade.[67] For RSI with thiopental and succinylcholine, the optimal dose of remifentanil appears to be 1.0 μg/kg administered over 30 seconds, with laryngoscopy performed 1 minute after induction. A bolus dose of 1.25 μg/kg was associated with unsatisfactory bradycardia, whereas 0.5 μg/kg resulted in excessive cardiovascular stimulation.[68] This dosing recommendation is supported by another report that found remifentanil 1 μg/kg given over 30 seconds, followed by thiopental 5 mg/kg and rocuronium 1 mg/kg 100 seconds later, was more effective than lidocaine and esmolol in attenuating the hemodynamic response to RSI.[69]

IV lidocaine may also blunt hemodynamic and cerebrovascular responses to intubation. When given in a bolus of 1.5 mg/kg IV, it adds approximately 0.3 MAC of anesthetic potency.[70] Significant reductions in hemodynamic response to endotracheal intubation have been noted when lidocaine (3 mg/kg) was used as an adjunct to high-dose fentanyl anesthesia,[71] as well as during other light anesthetic techniques, such as thiopental-N_2O-O_2.[72] However, smaller doses of lidocaine (1.5 mg/kg) have not been consistently reported to be effective in reducing the hemodynamic response to laryngoscopy and endotracheal intubation.[73,74]

The general anesthetic properties of lidocaine tend to reduce cerebral metabolic rate for O_2 and CBF, thus lowering ICP in patients with compromised intracranial compliance.[75] Theoretically, these properties of lidocaine might be exploited to mitigate rises in ICP during airway manipulation in those patients with acute intracranial pathology or compromised intracranial compliance. However, only a single human study has been reported specifically evaluating the ability of IV lidocaine to blunt intubation-related elevations in ICP. Bedford and colleagues compared 1.5 mg/kg IV lidocaine with placebo in 20 patients diagnosed with brain tumor. When administered 2 minutes before intubation, lidocaine failed to prevent a rise in ICP from the preanesthesia baseline, although the increase was more modest than that observed with the placebo (–12.1 mm Hg; 95% confidence interval, –22.8 to –1.4 mm Hg; $P = 0.03$).[76] This dearth of direct benefit was underscored by a systematic review that also failed to identify any evidence that pretreatment with IV lidocaine before RSI consistently reduced ICP or positively affected neurologic outcome.[77] This review is now more than a decade old, but because no new direct evidence has been published in the interim, its conclusion remains valid.

With regard to the patient at risk for intracranial HTN, it is important that agents used to control cardiovascular responses to intubation also have a minimal adverse impact on ICP. Agents that act as cerebral vasodilators, such as volatile anesthetics, nitroglycerin, nitroprusside, or hydralazine, are generally avoided if there is a serious risk of intracranial HTN.

E. Nonanesthetic Adjuvant Agents

A final means for modifying the cardiovascular responses to endotracheal intubation is prophylactic administration of vasoactive substances that directly affect the cardiovascular system. This approach was introduced in 1960 by DeVault and associates, who found that pretreatment with phentolamine, 5 mg IV, prevented the hypertensive-tachycardic response to endotracheal intubation during a light barbiturate-succinylcholine anesthetic technique.[78] Since then, a large number of articles have appeared advocating the use of various vasodilators and adrenergic blocking agents as pretreatment before endotracheal intubation, including diltiazem, verapamil, and nicardipine[79-82]; hydralazine[83]; nitroprusside[84]; nitroglycerin[85]; labetalol[86]; esmolol[80,87-89]; and clonidine.[90,91] Virtually all of these agents appear to be somewhat effective when compared to placebo, particularly when used in high doses.

Esmolol is the best studied of the group. In a large, multicenter, placebo-controlled trial, esmolol at doses of 100 or 200 mg suppressed the hemodynamic response to endotracheal intubation, particularly when combined with a moderate-dose opiate.[87] However, esmolol doses of 200 mg were associated with a doubling of the

incidence of hypotension compared to placebo. In another study, smaller doses of esmolol (1 mg/kg) had no effect on the hemodynamic response to laryngoscopy and intubation compared to placebo.[80] Most recently, the combination of lidocaine (1.5 mg/kg) and esmolol at a dose of 1 mg/kg effectively attenuated the pressor response to intubation but was not as effective as 1 μg/kg remifentanil.[69] Currently, the optimal use of any of these agents is undefined, although their use as adjuncts to RSI is reasonable taking into account evidence-based dosing recommendations for the situation.

IV. AIRWAY EFFECTS OF ENDOTRACHEAL INTUBATION

A. Upper Airway Reflexes

Because the upper airway protects the respiratory gas exchange surface from noxious substances, it is appropriate that the nose, mouth, pharynx, larynx, trachea, and carina have an abundance of sensory nerve endings and brisk motor responses. Anesthesiologists are especially familiar with the glottic closure reflex (laryngospasm), which is invariably encountered early in their training. The sneeze, cough, and swallow reflexes are equally important upper airway reflexes.

Afferent pathways for laryngospasm and the cardiovascular responses to endotracheal intubation are initiated by the glossopharyngeal nerve when stimulation occurs superior to the anterior surface of the epiglottis and by the vagus nerve when stimulation occurs from the level of the posterior epiglottis down into the lower airway. Because the laryngeal closure reflex is mediated by vagal efferents to the glottis, it is virtually a monosynaptic response, occurring primarily when a patient is lightly anesthetized as vagally innervated sensory endings in the upper airway are stimulated and conscious respiratory efforts cannot override the reflex.

B. Dead Space

Patients with severe chronic lung disease may find it easier to breathe after intubation or a tracheostomy. The improvement is most likely due to reduced dead space. The normal extrathoracic anatomic dead space, based on cadaver measurements, is between 70 and 75 mL.[92] The exact volume (V) of the ETT is easily calculated as that of a cylinder using the formula $V = r^2l$, where r is the radius of the tube and l is the length. For example, an ETT that has an 8-mm inner diameter (ID) of 25 cm and a length of 25 cm has a volume of 12.6 mL. Intubation would therefore result in a reduction in dead space of approximately 60 mL.

Tracheostomy tubes are shorter than oral ETTs and have an even smaller dead space, although the difference as a proportion of tidal volume (V_t) is negligible. In normal individuals, the reduction in dead space with insertion of a tracheostomy tube is negligible compared with the normal V_t, so there is little benefit. In a patient with severe restrictive lung disease such as in end-stage kyphoscoliosis, V_t may be as low as 100 mL and intubation can confer a major benefit. Similarly, patients with emphysema who are changed from mouth breathing to tracheostomy demonstrate a reduction in minute volume required and a decrease in total body O_2 consumption, presumably due to a decreased work of breathing.[93] Most likely, the decreased volume required more than compensates for the slight increase in resistance.

The decreases in dead space described here refer only to the volume of the ETT alone and are applicable only during T-piece breathing. Any extensions or Y-pieces added to the breathing circuit and attached to the ETT must also be added to the total.

C. Upper Airway Resistance

Anesthesiologists are well aware that in most anesthetized patients, adequate ventilation can be maintained with an ETT as small as 6 mm ID in place. Intensivists caring for a patient with respiratory failure often insist that an ETT must have a minimum ID of 8 mm. These tube sizes are each appropriate for the clinical situations described. The high resistance of the 6 mm ETT is inconsequential for the low minute ventilation required under general anesthesia, but the high flow rates required for a patient with respiratory failure may render the resistance of a small ETT prohibitive.

The ETT creates a mechanical burden for a spontaneously breathing patient in the form of a fixed upper airway resistance; that is, it decreases airway caliber and increases resistance to breathing. Gas flow across an ETT is determined by the pressure difference across the tube and the resistance of the ETT. Gas flows whenever there is a pressure difference across the ETT, whether it is caused by subatmospheric pressure generated during spontaneous breathing or by positive pressure generated from a mechanical ventilator.

The apparent resistance of an ETT is influenced by the shape of the tube and by two types of friction: the friction among the gas molecules and the friction between the tube wall and the gas molecules.[94,95] Irregular surfaces created by secretions or by ridges from wire reinforcement may create greater friction and greater resistance.[96] ETTs and tracheostomies have a higher resistance than the normal upper respiratory tract.[97,98]

The relationship between pressure difference and flow rate depends on the nature of the flow: laminar, turbulent, or a mixture of the two. In an ETT, turbulent flow predominates. During turbulent flow, the measured resistance is not a constant but varies with the flow rate, becoming markedly higher at high flow rates. Instead of the laminar flow relationship of pressure being directly proportional to flow, the pressure required to move the gas through an ETT with turbulent flow is proportional to the square of the flow. The relationship can therefore be described by a parabolic curve, as in Figure 7-4. The apparent resistance of a tube is proportional to the fourth power of the radius during laminar flow (Poiseuille's law) but to the fifth power during turbulent flow. Assuming turbulent flow, the relative resistance of a 6-mm ETT versus an 8-mm ETT is $4^5/3^5$, or 4.2 times as great. However, because flow patterns are not entirely predictable, the exact respiratory pressure-flow relationships may not be predictable without empiric determination.

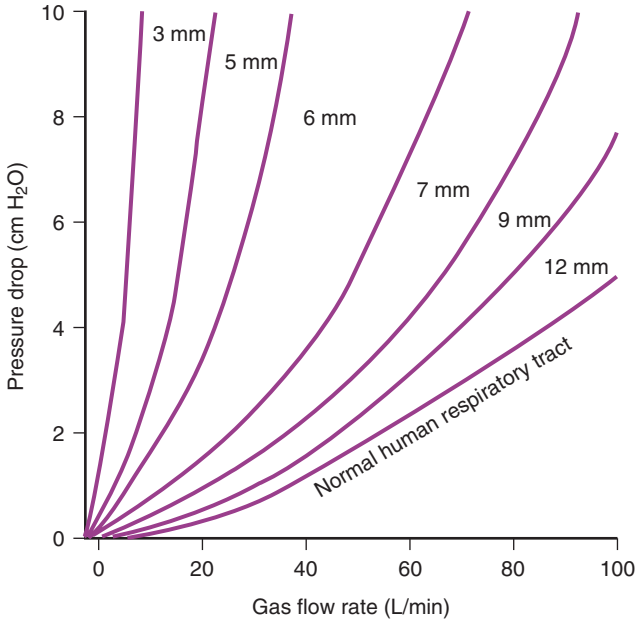

Figure 7-4 Pressure drop across endotracheal tubes of various sizes at flow rates ranging from 0 to 100 L/min. Note the wide disparity between 6- and 7-mm tubes as flow rate increases to the range typically seen in patients with respiratory failure. (Adapted from Nunn JF: *Applied respiratory physiology*, London, 1987, Butterworths.)

Such determinations are depicted in Figure 7-4. The slope of the pressure-flow graph is the apparent resistance. The parabolic shape of the graphs demonstrates the primarily turbulent nature of the flow through an ETT.

Although the resistance of the ETT may be several-fold greater than the resistance of the normal human upper airway, this is of relatively little consequence at low minute ventilation.[99] With a typical peak inspiratory flow of 25 to 30 L/min, approximately 0.5 cm H_2O pressure must be generated to overcome the resistance of the upper respiratory tract. This represents about 10% of the total work of breathing. Even a doubling or tripling of that resistance by placement of an ETT does not result in a clinically worrisome increase in the total work of breathing.[100]

As flow rates increase, however, flow becomes more turbulent and tube resistance may become a problem. For flow rates greater than 15 L/min, flow through any tube smaller than 10 mm ID becomes turbulent.[101] At the high flows required by patients in respiratory failure, the resistance of smaller tubes becomes prohibitive.[102] At the time of weaning patients with respiratory failure from mechanical ventilation, the importance of tube size often becomes a critical factor, with a common question being whether to change a 7-mm to a larger size. Note in Figure 7-4 that the pressure drop between 7-mm and 9-mm tubes is minimal at low inspiratory flows, but is considerable at flows of 60 L/min and higher.

Theoretically, the patient's native airway should have less resistance than any size ETT. However, a patient who has been intubated for an extended period may not have a normal upper airway. Indeed, some evidence suggests that work of breathing may actually increase after extubation, perhaps due to high upper airway resistance.[103,104] Therefore, if the patient is close to successful weaning, a reasonable approach may be to attempt extubation rather than to change ETTs, recognizing that the need for reintubation is a possibility. Alternatively, pressure support ventilation can be used to compensate for the added work of breathing through the smaller tube until extubation is warranted.[105]

Tracheostomy tubes have lower resistance than ETTs of comparable diameters because they are shorter. However, there is little, if any, difference in the work of breathing imposed by fresh tracheostomy tubes and ETTs of comparable ID.[106] On the other hand, tracheostomy does appear to decrease the work of breathing in patients who have undergone prolonged intubation and mechanical ventilation. This paradox may be explained by a reduction in the ID of an ETT over time, perhaps as a result of inspissated secretions or conformational changes.[107] This size reduction may explain the observation that patients being weaned from mechanical ventilation are sometimes more rapidly weaned after a tracheostomy is performed,[108] although it may also reflect the increased comfort of clinicians in discontinuing ventilatory support after the airway is secured.

D. Lower Airway Resistance

Bronchospasm after induction of anesthesia is a relatively uncommon but well-recognized event and is likely related to a reflex response to endotracheal intubation. Several studies provide some evidence regarding the frequency of bronchospasm. Tiret and associates studied complications at the time of induction of anesthesia and noted that bronchospasm accounted for 5.3% of fatal or near-fatal peri-induction complications.[109] The largest population was reported by Olsson, who found 246 cases of bronchospasm to have occurred out of a total of 136,929 anesthesia inductions, for an incidence of 1.7 per 1000.[110] However, the exact incidence undoubtedly depends substantially on the patient population.

The incidence of postintubation bronchospasm may be decreasing because of the increasing use of propofol as an induction agent (propofol being more effective than thiopental at preventing this complication). However, ventilation problems combined with hypoxia due to acute bronchospasm still represent important sentinel anesthesia events.[111]

Whereas the incidence of overt clinical bronchospasm is low, a reflex increase in airway resistance may occur much more often. Receptors in the larynx and upper trachea may cause large airway constriction distal to the tube, which in turn may extend to the smaller peripheral airways.[112] Support for this hypothesis comes from the work of Gal, who found an increase in lower airway resistance in a series of volunteers whose tracheas were intubated after topical anesthesia (Fig. 7-5).[113]

Bronchoconstriction also occurs after endotracheal intubation of normal subjects who have received thiopental/narcotic anesthesia.[114] In a series of patients pretreated before anesthesia with either a β-adrenergic

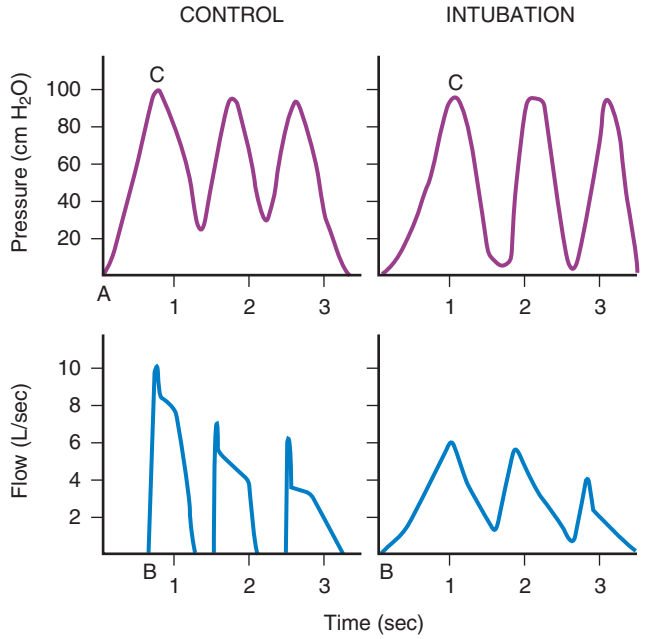

Figure 7-5 Pressure and flow curves (labeled *A* and *B,* respectively) generated during a burst of three successive coughs *(C)* by a volunteer before (control) and after endotracheal intubation. Notice that the flows and pressures generated are only modestly diminished after intubation. (From Gal TJ: How does tracheal intubation alter respiratory mechanics. *Probl Anesth* 2:191, 1988.)

agonist (albuterol) or an inhaled anticholinergic agent (ipratropium bromide), measured airway resistance after intubation was markedly lower compared with placebo treatment (Fig. 7-6).

Increases in airway resistance may result from changes in intrinsic smooth muscle tone, airway edema, or intraluminal secretions. These factors are, in turn, controlled by a series of intracellular and extracellular events,

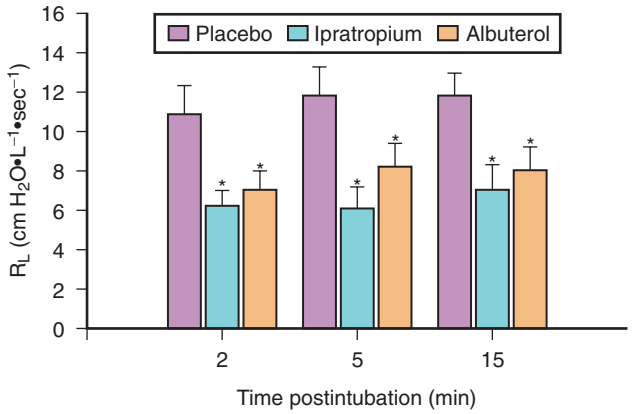

Figure 7-6 Lung resistance *(R_L)* at 2, 5, and 15 minutes after intubation in patients pretreated with either a placebo, the β-adrenergic agonist albuterol, or the anticholinergic drug ipratropium bromide. Each of the drugs markedly diminished lung resistance for longer than 15 minutes after endotracheal intubation under thiopental-narcotic anesthesia. (From Kil HK, Rooke GA, Ryan-Dykes MA, et al: Effect of prophylactic bronchodilator treatment on lung resistance after tracheal intubation. *Anesthesiology* 81:43, 1994.)

including neural and hormonal factors. Rapid changes in airway caliber after airway instrumentation are thought to result largely from parasympathetic nervous system activation of airway smooth muscle.[115,116] Cholinergic innervation predominates in the larger central airways, with efferent nerves arising in the vagal nuclei of the brain stem and synapsing with ganglia in the airway walls. Postganglionic parasympathetic nerves release acetylcholine, activating muscarinic receptors on airway smooth muscle that lead to smooth muscle constriction. Such responses can be blocked via muscarinic blockade, using either systemic or inhaled anticholinergic agents.

Endotracheal intubation also may induce bronchospasm by causing coughing. A cough reduces lung volume, which in turn markedly increases bronchoconstriction in response to a stimulus.[117] In the patient with known reactive airways, prevention of coughing at the time of endotracheal intubation by use of either a deep level of anesthetic or a muscle relaxant may help to minimize the likelihood of bronchospasm.

E. Endotracheal Tube Resistance and Exhalation

In normal patients breathing at moderately elevated minute ventilation, exhalation is usually completed well before the next inhalation begins. By contrast, patients with obstructive airways disease may not complete full exhalation before the start of the next inhalation. In other words, inhalation begins before exhalation to functional residual capacity (FRC), resulting in persistent positive pressure in the alveoli. This phenomenon has been called auto-PEEP or dynamic hyperinflation, and it results in air trapping, elevated intrathoracic pressure, and hemodynamic compromise.[118]

Auto-PEEP most commonly occurs in patients with obstructive lung disease and high minute ventilation, but it may also rarely occur in patients with relatively normal airways who are ventilated at very high minute ventilation. This has been observed in patients with burns or sepsis, who may require as much as 30 to 40 L of minute ventilation. Under these circumstances, the resistance of the ETT may limit expiratory flow so that full exhalation does not occur. This has been demonstrated experimentally, with the magnitude of the auto-PEEP correlating directly with the resistance of the ETT.[119] Among patients under anesthesia, major resistance to exhalation caused by the ETT is of no consequence in routine cases and is only rarely seen in critically ill patients. However, low levels of auto-PEEP due to tube resistance probably occur frequently in patients with high minute ventilation[108] and during single-lung ventilation via a double-lumen ETT.

F. Functional Residual Capacity

The effect of endotracheal intubation on FRC has been a subject of considerable controversy. Intensivists are well aware of patients recovering from respiratory failure in whom oxygenation improved after extubation. The improvement has been attributed to "physiologic PEEP"—the presumption that a small positive pressure is

normally created by the glottis and that this leads to breathing at a higher lung volume. The assumption is that an ETT removes the glottic barrier and may, therefore, lower lung volume. However, the existence of positive intratracheal pressure has never been documented, and in a study of volunteers who underwent awake intubation, no consistent change in FRC could be measured.[120-122]

By contrast, a different conclusion was reached in a series of patients who were studied just before and after extubation following recovery from respiratory failure. In this situation, both FRC and arterial oxygen tension (PaO_2) were found to increase after extubation, supporting the concept that the presence of an ETT decreases FRC.[123] Resolution of these disparate results was suggested by a rabbit study in which normal rabbits did not demonstrate a difference in oxygenation or tracheal pressure after intubation, but after respiratory failure was induced, endotracheal intubation worsened oxygenation.[124] These results suggest that the rabbits compensated for respiratory failure by using glottic closure to maintain a positive intratracheal pressure and that the effect of an ETT on FRC depends on that underlying respiratory state.

G. Cough

Although it is widely recognized that cough efficiency is reduced whenever an ETT is in place, it is a common observation that a disconnected ETT is likely to produce a plug of sputum whenever the patient is stimulated to cough. In awake intubation volunteers, peak airway flow was reduced but was still adequate to enable secretion clearance.[113] However, the ETT prevented collapse of the trachea by acting as a stent. Therefore, although secretions could be moved to the central airways, the ETT prevented maximum efficiency of expectoration. Large airway collapse is important for producing maximum force against secretions, and this explains why moving secretions from the trachea out through the ETT often requires the use of a suction catheter.

H. Humidification of Gases

Under normal circumstances, the upper airway warms, humidifies, and filters 7000 to 10,000 L of inspired air daily, adding up to 1 L of moisture to the gases. When the upper airway is bypassed by intubation, the gas must be warmed and humidified in the trachea if it is not adequately humidified before inhalation. In an anesthetized patient breathing dry gases, up to 10% of the average metabolic rate may be required to perform these tasks.[125] Delivery of cool, dry gases may also have a significant effect on mucociliary transport, a critical defense mechanism of the respiratory tract. Inhalation of unconditioned gas rapidly leads to abnormal mucosal ciliary motion, with subsequent encrustation and inspissation of tracheal secretions.[126,127] These changes occur as early as 30 minutes after intubation and, theoretically, may lead to an increase in postoperative complications in patients with limited chest excursion. Accordingly, assurance of adequate gas conditioning should be standard in all but very brief endotracheal intubations.

V. CONTROL AND TREATMENT OF THE RESPIRATORY RESPONSES TO AIRWAY INSTRUMENTATION

A. Preventing Upper Airway Responses

Cough and laryngospasm in response to intubation appear to be sound protective reflexes. Under most circumstances, the body needs to prevent further intrusion by a foreign body and to expel it from the airway. However, these responses can be troublesome during induction of anesthesia or at the time of extubation. Cough can lead to bronchospasm as lung volume is reduced, and it can also result in desaturation as the lung volume drops to residual volume. Laryngospasm may result in life-threatening abnormalities of blood gases. Consequently, anesthesiologists routinely try to prevent these responses with the use of medications delivered topically, via inhalation, or intravenously.

Inhibition of upper airway reflexes can certainly be accomplished by performing endotracheal intubation after the administration of NMB agents. However, both laryngeal and tracheal reflexes are difficult to inhibit by deep levels of general anesthesia alone.[128] When circumstances preclude the use of NMB agents, the clinician must give consideration to how best to prevent discomfort, gagging, coughing, and laryngospasm during endotracheal intubation: avoidance of endotracheal intubation, use of regional and topical anesthesia, very deep general anesthesia, or a combination of all modalities.

1. Technical Considerations: Minimizing Airway Stimulation

Although placement of an LMA is likely to be less noxious than direct laryngoscopy and endotracheal intubation, it remains a highly stimulating procedure. For example, Scanlon and colleagues found a 60% incidence of gagging, a 30% incidence of laryngospasm, and a 19% incidence of coughing when the LMA was placed after induction with thiopental 5 mg/kg.[129] Induction with propofol 2.5 mg/kg reduced these events by two thirds but did not ablate them. Therefore, instrumentation of the upper airway by any technique will illicit protective reflexes that must be obtunded with local or general anesthesia (or both).

2. Regional and Topical Anesthesia

The surfaces of the mouth and nose are easily anesthetized with topical anesthetic sprays or gels. Lidocaine is equally effective as cocaine and less toxic; it can be combined with a vasoconstrictor to give equivalent intubating conditions.[130-132] Administration of an antisialagogue 30 to 60 minutes before application of the topical anesthetic results in better anesthesia as well as better intubating conditions. The lack of secretions probably minimizes dilution of the applied anesthetic and also results in better intubating conditions.

The mouth and pharynx derive their sensory innervation from the trigeminal and glossopharyngeal nerves. The supraglottic larynx derives its sensory innervation from the SLN, a branch of the vagus, and intubation can be facilitated by blocking it bilaterally.[133] The nerve block

relies on the consistent relationship of the SLN to the lateral horns of the hyoid bone. When combined with topical anesthesia of the nose or mouth and adequate anesthesia of the infraglottic larynx, the nerve block provides excellent intubating conditions, and most patients are able to accept an ETT without cough, gag, or laryngospasm. Equal success in blunting upper airway reflexes can be achieved by careful spraying of the larynx with topical anesthesia. A nasal trumpet helps ensure that solution reaches the larynx. Topical anesthesia spares the patient the need for two injections.

The infraglottic larynx derives sensory innervation from the recurrent laryngeal nerves, which run along the posterolateral surfaces of the trachea. Again, topical anesthesia rather than nerve block is the method of choice for obtunding reflexes. Injection of several milliliters of 4% lidocaine via the cricothyroid membrane routinely results in excellent blockade of sensation.

The efficacy of topical and nerve block anesthesia at suppressing airway reflexes during intubation is evident. Several studies have documented that topical anesthesia applied preoperatively (for brief cases) or intraoperatively can suppress cough and laryngospasm at the time of extubation.[134] A randomized study of patients undergoing tonsillectomy found that the incidence of stridor or laryngospasm at the time of extubation could be reduced from 12% to 3% by application of topical lidocaine at the time of intubation.[135] The LITA endotracheal tube (Laryngotracheal Instillation of Topical Anesthetic, Sheridan Corporation, Argyle, NY) contains a small channel that can be used to spray the upper airway while an ETT is in place. When this method was used to spray the ETT before extubation, coughs were reduced by more than 60%, and the severity of the coughing was decreased.[136]

The use of liquid, in the form of a lidocaine-bicarbonate mixture, rather than air to inflate the cuff of the ETT after intubation has also been reported to be effective in diminishing emergence phenomena.[137,138] Inflating the ETT cuff with 40 mg of lidocaine (2 mL of 2% solution) and then adding 3 to 7 mL of 8.4% sodium bicarbonate ($NaHCO_3$) until no cuff leak was present resulted in significant reductions in coughing, restlessness, and BP during emergence. In addition, sore throat complaints assessed at 15 minutes and at 1, 2, 3, and 24 hours postoperatively; postoperative dysphonia; and hoarseness after extubation were all reduced when compared to cuff inflation with air. When this technique was used, more than 50% of the original 40 mg of lidocaine still remained in solution at 2 hours after inflation of the cuff, and only about 75% was released even after 6 hours of surgery (Fig. 7-7).[137] Because standard 8.4% $NaHCO_3$ is a basic solution with a calculated pH of 7.8 (range 7 to 8.5), the addition of more than 2 mL of bicarbonate to the 2 mL of 2% lidocaine (calculated pH 6, range 5 to 7) already injected into the ETT cuff results in a solution with a pH 7.95 to 8.09; this leads to concern about tracheal mucosal damage from flash burn injury in the event of a cuff rupture. However, a direct comparison between solutions of 2 mL of 2% lidocaine with 8.4% versus 1.4% bicarbonate reported similar efficacy in reducing postoperative sore throat complaints and the occurrence of various

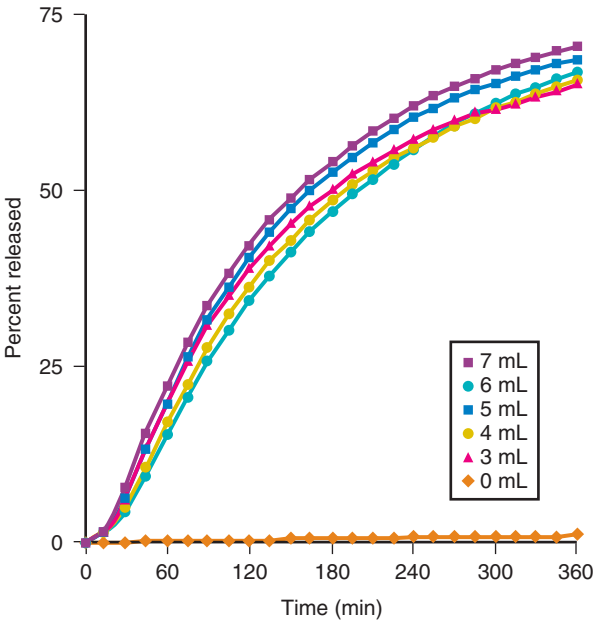

Figure 7-7 Percentage of lidocaine released in vitro as a function of time from an endotracheal tube (ETT) cuff filled with 40 mg lidocaine hydrochloride and additional 8.4% sodium bicarbonate solution equal to 0, 3, 4, 5, 6, or 7 mL. (From Estebe JP, Dollo G, Le Corre P, et al: Alkalinization of intracuff lidocaine improves ETT-induced emergence phenomena. *Anesth Analg* 94:227–230, 2002.)

emergence phenomena.[138] Therefore, in actual clinical practice, a favorable risk-benefit balance can be achieved by using the following combination in a 10-mL syringe: 5 mL 1% lidocaine, 1 mL 8.4% $NaHCO_3$ solution, and 4 to 5 mL of sterile diluent (J.P. Estebe, personal communication, 2010).

3. Intravenous Agents

Given a high enough dose, virtually all agents used as IV anesthetics will suppress the cough response to intubation. However, different agents appear to vary in their ability to inhibit upper airway reflexes when judged on the basis of equal potency in depressing consciousness and in depressing the cardiovascular system. Propofol/narcotic anesthesia may be adequate for intubating the trachea in some patients even without the use of muscle relaxants.[139] On the other hand, ketamine clinically appears to enhance laryngeal reflexes at doses that provide adequate anesthesia for surgery.

IV lidocaine is frequently used to prevent cough and laryngospasm at the time of intubation or extubation. Although the studies are not uniform in documenting efficacy, the preponderance of evidence supports the use of lidocaine.[140,141] Studies that did not document efficacy are sometimes flawed by the lack of documentation that adequate serum levels were reached. The maximal efficacy of IV lidocaine occurs 1 to 3 minutes after injection and requires a dose of 1.5 mg/kg or more. This corresponded to a plasma level in excess of 4 μg/mL.

The ability of IV lidocaine to suppress cough appears to be related to factors beyond induction of general anesthesia, because cough suppression occurs at levels routinely seen in awake patients being treated with the drug.

A comparison of the antitussive effects of lidocaine compared with meperidine and thiopental demonstrated that severe respiratory depression occurs with the latter drugs in achieving the same antitussive efficacy that can be achieved with lidocaine with virtually no respiratory depression.[142]

Whether IV lidocaine suppresses laryngospasm remains controversial. A study in which tonsillectomy patients were given 2 mg/kg of IV lidocaine and then extubated 1 minute later found suppression of laryngospasm.[143] Another study of tonsillectomy patients given 1.5 mg/kg of lidocaine found no clear effect.[144] A major difference in the latter study was the authors' design of not extubating the patient until swallowing had begun. This may have resulted in a significant difference in the anesthetic depth at which the children were extubated.

B. Preventing Bronchoconstriction

Bronchoconstriction results routinely after endotracheal intubation. In healthy subjects it appears to be of moderate degree, but the exaggerated response seen in patients with hyperactive airways can be life-threatening. Prevention or treatment of this response can be achieved with the use of topical or IV agents. Inhaled anesthetic agents also inhibit the response through direct absorption by smooth muscle or inhibition of reflexes.

Bronchospasm after intubation may be cholinergically mediated. Afferent parasympathetic fibers travel to bronchial smooth muscle and then produce bronchoconstriction by stimulating the M_3 cholinergic receptors on bronchial smooth muscle. In addition, stimulation of M_2 cholinergic receptors on airway smooth muscle potentiates bronchospasm by inhibiting β-adrenergic–mediated smooth muscle relaxation.[145]

1. Technical Considerations: Minimizing Airway Stimulation

Avoidance of endotracheal intubation is the most logical first step in terms of limiting airway irritation and bronchoconstriction. If general anesthesia is required, the LMA may be preferable to the ETT in terms of provocation of bronchospasm, but, as alluded to earlier, the LMA will not prevent coughing in the absence of NMB.[129] However, the LMA does appear to result in reduced lower airway resistance when compared with endotracheal intubation after induction of general anesthesia. This difference is assumed to result from induction of reversible bronchospasm by the ETT.[146,147] In addition, use of the LMA results in fewer pulmonary complications and improved pulmonary function when compared with endotracheal intubation in infants born prematurely with bronchopulmonary dysplasia and in adults without lung disease.[148,149]

2. Topical Anesthesia

The studies of Gal and Surratt demonstrated a doubling of lower airway resistance after endotracheal intubation of awake volunteers under topical anesthesia.[120] The bronchoconstrictive response must indeed be a powerful one if local anesthesia sufficient to permit volunteers to be intubated was not sufficient to prevent the reflex bronchoconstriction. A study of awake fiberoptic intubation in asthmatics demonstrated a marked decrease in forced expiratory volume in 1 minute (FEV_1) after intubation. This decrease was somewhat mitigated by topical lidocaine although lidocaine was not as effective as albuterol in preventing the bronchoconstriction.[150] However, a lidocaine aerosol given to dogs before a challenge with inhaled citric acid did not attenuate the response to this irritant.[151] Because the aerosol itself produces a slight increase in lung resistance, the efficacy of the inhaled aerosol lidocaine may in part have been due to IV absorption of the drug. Given these considerations and the time required to administer the aerosol compared to the immediacy and efficacy of IV drugs or other inhaled drugs, aerosolized lidocaine is probably a poor choice for the attenuation of bronchoconstriction associated with endotracheal intubation.

3. Intravenous Agents

A variety of drugs have been studied for their bronchodilating properties. Although IV β-agonists clearly produce bronchodilation, there is no benefit to parenteral administration of these drugs rather than inhalational administration. Among anesthetic induction agents, considerable experimental evidence suggests that ketamine has both direct and indirect relaxant effects on airway smooth muscle through non–β-receptor mechanisms.[152-157] However, the clinical data supporting the use of ketamine for prevention or treatment of bronchospasm is largely anecdotal,[158] or in more rigorous trials unimpressive.[159-161] This may relate to reluctance to routinely use ketamine at high doses because of its side effects, including dysphoria and sympathetic stimulation, rather than a lack of benefit of the drug.

Propofol, midazolam, and etomidate all relax airway smooth muscle in vitro, although generally at higher site concentrations than would be used clinically.[162-166] In contrast, barbiturates may have direct bronchoconstricting effects.[167] Propofol may also have indirect effects on airway constriction, perhaps though inhibition of vagal tone.[157,168] Clinically, propofol has been shown to be superior to the barbiturates and to etomidate in reducing wheezing and airway resistance in both asthmatic and nonasthmatic subjects.[169-171] When asthmatics were induced with either thiopental, methohexital, or propofol at equipotent doses, none of the patients given propofol wheezed after endotracheal intubation, whereas both of the barbiturates resulted in a significant incidence of wheezing (Fig. 7-8).[169]

In animals, IV lidocaine has been reported to attenuate bronchoconstriction induced by a variety of experimental means.[172,173] In humans with bronchial hyperreactivity, IV lidocaine reduced the bronchoconstrictor response to histamine challenge and had an additive effect with albuterol in reducing this response.[174] However, a double-blind, placebo-controlled trial of IV lidocaine (1.5 mg/kg) or inhaled albuterol in asthmatics found that albuterol but not lidocaine prevented postintubation bronchoconstriction.[175] Although lidocaine may inhibit reflex-induced bronchospasm, it may also cause contraction of bronchial smooth muscle in the absence of reflex mechanisms. In a study of 15 asthmatics, IV lidocaine

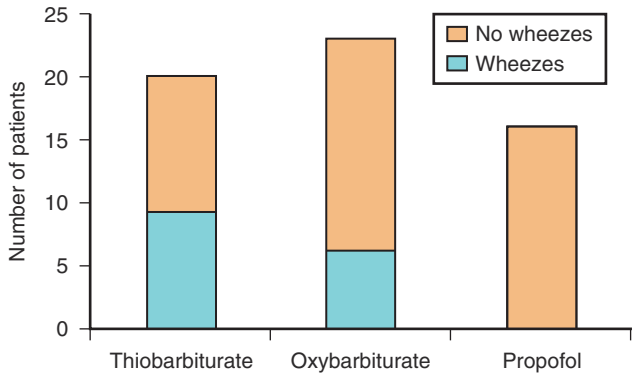

Figure 7-8 Incidence of wheezing after endotracheal intubation in asthmatics when induction was performed with either an oxybarbiturate, a thiobarbiturate, or propofol ($P < 0.05$ for either thiobarbiturate or oxybarbiturate versus propofol). (From Pizow R, Brown RH, Weiss YS, et al: Wheezing during induction of general anesthesia in patients with and without asthma: A randomized, blinded trial. *Anesthesiology* 81:1111, 1995.)

reduced airway diameter at total lung capacity assessed by computed tomography and resulted in significant decreases in FEV_1.[176] These untoward effects were underscored by a case report in which IV lidocaine 1.5 mg/kg administered to facilitate intubation was temporally associated with transient bronchospasm in a 17-month-old child with mild intermittent asthma.[177] A published best-evidence review also failed to find good evidence for use of IV lidocaine during intubation in patients with status asthmaticus.[178] Therefore, the evidence in support of IV lidocaine to prevent postintubation bronchospasm when used without the concomitant administration of an inhaled β-agonist is scant, and there is a potential risk of worsening airway resistance with its use. Therefore, the use of IV lidocaine for this indication cannot be endorsed.

4. Inhaled Agents

All of the volatile anesthetics have direct and perhaps indirect relaxant effects on airway smooth muscle in experimental models.[94,179-182] Although these agents have differences in potency in vitro, the clinical importance of these differences is unclear.[180,182,183] In adult patients, sevoflurane is more effective than isoflurane, desflurane, or halothane in reducing airway resistance after endotracheal intubation,[184-186] but does not prevent an increase in airway resistance after intubation of asthmatic children.[187] However, given the available data, sevoflurane is probably the volatile agent of choice, and desflurane is a poor choice for use in high-risk patients (Fig. 7-9).

There are no prospective, controlled studies comparing deep inhalation anesthesia to IV induction with bronchoprotective agents such as ketamine or propofol in high-risk patients. Achieving a deep plane of anesthesia with a bronchoprotective agent before intubation is likely the most important point in preventing severe bronchospasm in high-risk patients, rather than the choice of IV versus inhalation induction techniques.

Pretreatment of patients with inhaled β_2-adrenergic agonists or an inhaled anticholinergic markedly reduced lung resistance following endotracheal intubation and should be used routinely in patients known to have bronchospasm.[114,188]

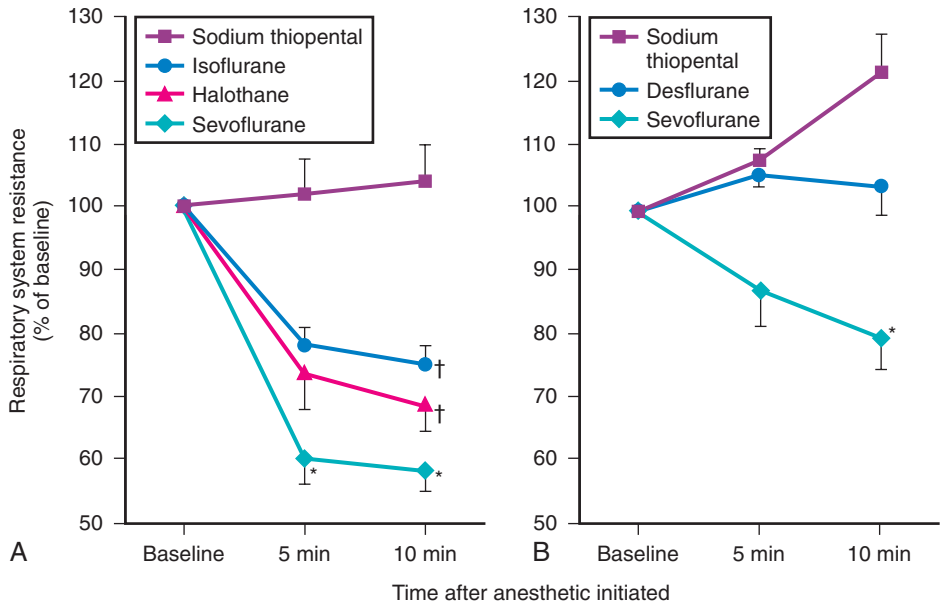

Figure 7-9 Respiratory system resistance (percent of baseline) during maintenance anesthesia. **A,** Isoflurane, halothane, and sevoflurane are compared with thiopental 0.25 mg/kg/min plus 50% nitrous oxide. *$P < 0.05$ versus isoflurane, halothane, and thiopental. †$P < 0.05$ versus thiopental. **B,** Desflurane and sevoflurane are compared with thiopental 0.25 mg/kg/min. *$P < 0.05$ versus desflurane and thiopental. (**A,** Adapted from Rooke GA, Choi JH, Bishop MJ: The effect of isoflurane, halothane, sevoflurane, and thiopental/nitrous oxide on respiratory system resistance after tracheal intubation. *Anesthesiology* 86:1294, 1997; **B,** From Goff MJ, Arain SR, Ficke DJ, et al: Absence of bronchodilation during desflurane anesthesia: A comparison to sevoflurane and thiopental. *Anesthesiology* 93:404, 2000.)

5. Choice of Neuromuscular Blocking Drug

The choice of muscle relaxants can influence bronchial tone after endotracheal intubation. Rapacuronium was withdrawn from the market after a number of reports of severe bronchospasm, most likely due to antagonism at the M_2 receptor.[189] Mivacurium releases significant amounts of histamine and leads to mast cell degranulation; it should be used extremely cautiously, if at all, in patients with a history of atopy or asthma.[190] Studies in France and Norway have suggested a high incidence of anaphylaxis with rocuronium, although this finding does not appear to be supported in literature from other countries.

VI. CONCLUSIONS

Airway manipulations of any kind can result in reflex-mediated changes in cardiopulmonary physiology. The type and depth of anesthesia provided must be individualized for the type of airway being used and the clinical situation for which it is required. Additionally, airway managers should be prepared to treat profound alterations in HR, BP, airways resistance, or ICP occurring during or immediately consequent to airway manipulation. Although these responses may be of short duration and of little consequence in healthy individuals, serious complications can occur in patients with underlying coronary artery disease, reactive airways, or intracranial neuropathology.

VII. CLINICAL PEARLS

- Laryngoscopy can induce bradycardia, by increasing vagal tone at the sinoatrial node, or HTN and tachycardia mediated by the cardioaccelerator nerves and sympathetic chain ganglia. The former is most common in infants and children, whereas the latter is typical for adolescents and adults.
- Laryngoscopy and intubation result in stimulation of the CNS and may increase cerebral blood flow (CBF), which may result in elevation of intracranial pressure (ICP) and brain herniation.
- Ischemic electrocardiographic changes lasting less than 10 minutes during airway manipulation have not been shown to correlate with postoperative myocardial infarction.
- Succinylcholine is associated with bradycardia in children, particularly when doses are repeated, but it is a cardiovascular stimulant in adults.
- Succinylcholine may directly elevate CBF and ICP, an effect that can be blunted by pretreatment with a nondepolarizing agent and strict maintenance of normocapnia.
- The application of cricoid pressure can result in greater HR and BP response to endotracheal intubation than when it is not used, and it should be considered when estimating the risk-benefit ratio of this procedure in individual patients.
- Fentanyl provides a graded response in blunting hemodynamic responses to intubation, with 2 µg/kg IV fentanyl given several minutes before induction only partially preventing hypertension and tachycardia during a rapid-sequence intubation (RSI).
- Fentanyl and propofol require 6.4 and 2.9 minutes, respectively, to achieve effect-site equilibrium after IV bolus administration. Therefore, the commonly observed practice of administering 1 to 2 mL of fentanyl (50 to 100 µg) just before or almost simultaneously with administration of other induction medications would not be expected to have any effect based on inadequate dose and inappropriate timing of administration.
- When given in a bolus of 1.5 mg/kg IV, lidocaine adds approximately 0.3 MAC of anesthetic potency, but it is not reliable at blunting the cardiovascular or airway response to laryngoscopy or intubation. Additionally, pretreatment with IV lidocaine before RSI does not consistently reduce ICP or positively affect neurologic outcome.
- For surgeries lasting longer than 2 hours, cough and throat complaints may be decreased by inflating the cuff of the ETT with a buffered solution containing 40 mg of lidocaine. This can be accomplished by using a 10-mL syringe containing 5 mL 1% lidocaine, 1 mL 8.4% $NaHCO_3$ solution, and 4 to 5 mL of sterile diluent and inflating the cuff until no leak is present.
- Propofol, midazolam, and etomidate are preferred to barbiturates for anesthetic induction in patients with known reactive airways and in those in whom acute bronchoconstriction is to be avoided.

III. Conclusions
IV. Clinical Pearls

I. INTRODUCTION

The fundamental responsibility of an anesthesiologist is to ensure adequate gas exchange for the patient. Failure to maintain oxygenation for more than a few minutes can result in catastrophic anoxic injury. Data from closed claims of respiratory-related malpractice in 1990 reported brain damage or death in more than 85% of patients.[1] In the closed claims data from 2006, improvements in airway management techniques and monitoring standards had reduced the number of intubation-related claims,[2] but difficulties with airway management during emergence remained among the leading causes of serious perioperative problems. It has been estimated that the inability to successfully manage a difficult airway (DA) is responsible for as many as 30% of deaths directly attributable to anesthesia.[2]

In general, greater degrees of difficulty in maintaining airway patency are more likely to engender greater risk of brain damage or death. Before discussing the specific management of a DA, we must define the DA, classify the degrees of difficulty in maintaining a patent airway, and determine the incidence of each class or type of DA. In this discussion, it is assumed that a reasonably well-trained anesthesia provider always attempts to maintain airway patency.

II. DEFINITION AND CLASSIFICATION OF THE DIFFICULT AIRWAY

There are three common ways of maintaining airway patency and gas exchange. First, mask ventilation can deliver inspired gas via a mask that is sealed to the patient's face, while the natural airway from the face to the vocal cords is kept patent with or without external jaw thrust maneuvers or internal upper airway devices. Second, inspired gas can be delivered via a supraglottic airway device (SGA), such as a laryngeal mask airway (LMA; LMA North America, San Diego, CA). Third, with tracheal intubation, inspired gases are delivered via a tube that traverses the vocal cords, providing continuity from the respiratory circuit to the trachea.

The term *difficult airway* spans a spectrum of clinical situations (Fig. 8-1), from difficulty or inability to provide mask ventilation to difficulty or inability to intubate the trachea. The combined "cannot intubate, cannot ventilate" (CICV) scenario carries the highest risk of brain

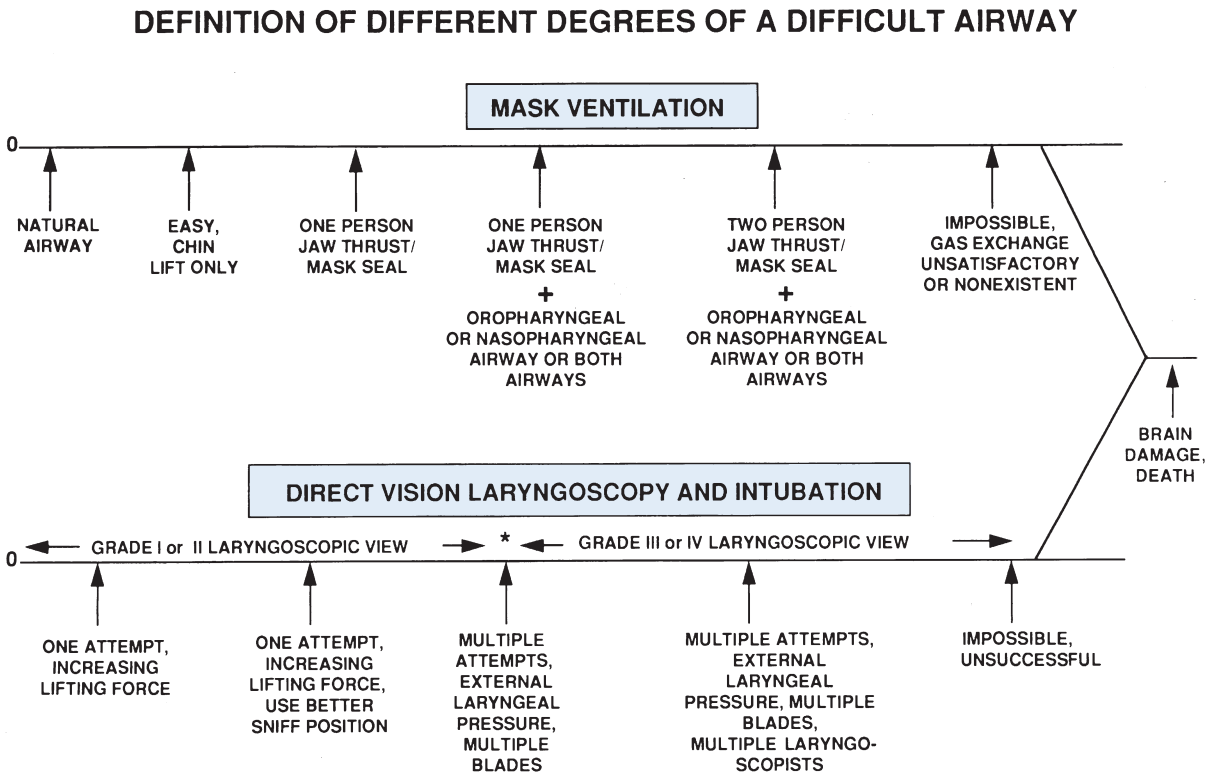

Figure 8-1 Conceptualization of a difficult airway. Difficult intubation refers to one or more of the following: difficult laryngoscopy, difficult video laryngoscopy, or difficult flexible bronchoscopic visualization. The widespread use of supraglottic airways has elevated them to immediate rescue devices in "cannot intubate, cannot ventilate" situations. The triad of difficult mask ventilation, difficult supraglottic airway placement, and difficult intubation increases the risk of hypoxic brain injury and death.

damage or death. To better describe the layers of difficulty, we have chosen several categories of difficult or impossible mask ventilation; difficult placement of, or ventilation via an SGA; difficult laryngoscopy; and difficult intubation using direct laryngoscopy, video laryngoscopy, or flexible bronchoscopy.

A. Difficult or Impossible Face Mask Ventilation

1. Causes of Difficult Mask Ventilation

There are two main causes of inadequate face mask ventilation. One is inability to establish an adequate seal between the face and the mask, which results in a leak of respiratory gas. The second cause is inadequate patency of the airway at the level of the nasopharynx, oropharynx, hypopharynx, larynx, or trachea. These conditions manifest as either inability to generate airway pressure that is adequate to drive gas into the lungs or inability to move gas into the lungs despite an adequate driving pressure.

2. Definition of Difficult Mask Ventilation

The simplest mask ventilation scale in contemporary literature was described by Han and colleagues in 2004 (Table 8-1).[3] In that scale, the progressive grades of difficulty are (1) ventilation by mask; (2) ventilation by mask with oral airway or other adjuvant with or without muscle relaxant; (3) difficult mask ventilation, defined as "inadequate, unstable, or requires two providers" with or without muscle relaxant; and (4) impossible mask ventilation with an inability to mask ventilate with or without muscle relaxant.

Langeron and colleagues defined difficult face mask ventilation as "the inability of an unassisted anesthesiologist to maintain oxygen saturation >92%, as measured by pulse oximetry, or to prevent or reverse signs of inadequate ventilation during positive-pressure mask ventilation under general anesthesia."[4] In their study, mask

TABLE 8-1
Han Mask Ventilation Scale and Incidence of Difficult Mask Ventilation

Grade	Description	Incidence (*n*, [%])
1	Ventilated by mask	37,857 (71.3%)
2	Ventilated by mask with oral airway or other adjuvant with or without muscle relaxant	13,966 (26.3%)
3	Difficult ventilation (inadequate, unstable, or requiring two providers) with or without muscle relaxant	1,141 (2.2%)
4	Unable to mask ventilate with or without muscle relaxant	77 (0.15%)

From Han R, Tremper KK, Kheterpal S, O'Reilly M: Grading scale for mask ventilation. *Anesthesiology* 101:267, 2004.

ventilation was considered difficult if one or more of six criteria were present:

1. Inability for the unassisted anesthesiologist to maintain oxygen saturation >92% using 100% oxygen and positive-pressure mask ventilation
2. Important gas flow leak by the face mask
3. Need to increase gas flow to >15 L/min and to use the oxygen flush valve more than twice
4. No perceptible chest movement
5. Need to perform a two-handed mask ventilation technique
6. Change of operator required.

El-Ganzouri and coworkers defined difficult mask ventilation as the "inability to obtain chest excursion sufficient to maintain a clinically acceptable capnogram waveform despite optimal head and neck positioning and use of muscle paralysis, use of an oral airway, and optimal application of a face mask by anesthesia personnel."[5]

3. Incidence of Difficult Mask Ventilation

Two studies by Kheterpal and associates on difficult and impossible mask ventilation represent the largest investigations to date on the topic. The incidence of difficult mask ventilation was 1.4% in 22,660 patients and 2.2% in a subsequent study of 50,000 patients.[6,7] The incidence of impossible ventilation ranged from 0.15% to 0.16% in these two large studies. Langeron and colleagues reported a 5% incidence of difficult mask ventilation, with 1 of every 1502 patients impossible to ventilate with a face mask (0.07%).[4] In other large, prospective studies the incidence has ranged from 0.07% to 1.4%,[5,8,9] although this was not the primary outcome being assessed. In summary, difficult mask ventilation can be expected 1 or 2 times in every 100 anesthesias, and impossible mask ventilation 1 or 2 times in 1000 anesthesias.

Methods used to improve airway patency include the head-tilt, jaw-thrust, and chin-lift maneuvers as well as insertion of oral or nasal airways. If mask seal is poor, the practitioner may choose a different face mask, use a two-hand or two-person technique, insert bolsters between the alveolar ridge and the cheeks, or employ other methods to improve the interface between the face and the mask. When two persons are needed, ideally the primary anesthesiologist stands at the patient's head and initiates jaw thrust with the left hand at the angle of the left mandible and left-sided mask seal while the right hand compresses the reservoir bag. The standard position for the primary anesthesiologist appears in Figure 8-2. The secondary (helping) person stands at the patient's side, at the level of the patient's shoulder, facing the primary anesthesiologist. The right hand of the secondary anesthesiologist should cover the left hand of the primary anesthesiologist and contribute to left-sided jaw thrust and mask seal, and the left hand of the secondary person initiates right-sided jaw thrust and mask seal. In this way, all four hands are doing something important without interfering with one another, and there is almost no redundant effort. With this positioning, the secondary person can watch the monitors continuously, manipulate the larynx externally, and hand equipment to the primary anesthesiologist.

Figure 8-2 Optimal two-person mask ventilation effort. The primary anesthesiologist stands at the head of the patient and uses left and right hands in classic fashion. The secondary (helping) person stands facing the primary anesthesiologist at the level of the patient's shoulder and uses the right hand to help achieve left-sided jaw thrust and mask seal while the left hand achieves right-sided jaw thrust and mask seal.

B. Difficulties with Supraglottic Airway Devices

The last two decades have seen a phenomenal increase in the use of SGAs for elective and rescue purposes. Most studies of SGA devices describe first-attempt and overall success rates. Difficulties with the devices include failure of insertion, failure to form a clear passage to the trachea, and failure to form an effective seal in the airway.[10]

Most of the studies reporting difficulties with SGAs have focused on LMAs. Among these, the failure rate is 1% for the intubating and ProSeal models and 2% for the LMA classic and flexible models.[10]

1. Definition of Difficult Placement

Success rates after one, two, or three attempts are an accepted way to describe difficult SGA device placement. Other methods include time taken for successful placement, Likert-based difficulty scales (very easy, easy, or difficult), and secondary measures such as evidence of trauma during insertion.

2. Incidence of Success

For the ProSeal laryngeal mask airway (PLMA), first-attempt success rates range from 76% to 100% (mean, 87.3%), and overall insertion success rates range from 90% to 100% (mean, 98.4%).[11] One of the important rescue functions of the LMA is as a conduit for flexible bronchoscopic intubation. The inability to visualize vocal cords using a trans-LMA flexible bronchoscopic technique is a significant impediment to successful tracheal intubation. The incidence of difficult laryngeal visualization ranges from 0% to 26% with the PLMA.[11] Although it is possible that success rates with other SGA devices may differ, the inherent variability in success is an important learning point. Early recognition of unsuccessful

placement and institution of alternative airway plans are essential to prevent morbidity from failure of an SGA device.

C. Difficult Direct Laryngoscopy

1. Laryngeal Visualization

The appearance of the laryngeal inlet on direct laryngoscopy is best described by the Cormack and Lehane grade of laryngeal view.[12] Difficult laryngoscopy is most commonly defined as presence of a grade 3 or 4 view on laryngoscopy.[6,7] Several maneuvers have been shown to improve the laryngeal view on laryngoscopy, but in general, poorer laryngeal views contribute progressively to greater difficulty in achieving successful tracheal intubation (Fig. 8- 3).[12-14] As the view worsens, increasing the anterior lifting force with the laryngoscope blade, reinstituting the optimal sniff position, making multiple attempts, manipulating the larynx externally (see Chapter 17 and Fig. 17-10), or opting for alternative devices or laryngoscopists may be required to achieve intubation.

There is a learning curve for management of a DA, and a poor laryngeal view observed by an inexperienced laryngoscopist may easily be improved by a more experienced or skillful individual with perhaps a different blade. Although a severe grade 3 (epiglottis tip) or grade 4 (just soft palate) laryngoscopic view (see Fig. 8-3) may be overcome by the occasional successful "blind" intubation, these views more often render intubation impossible. Therefore, early recognition of a DA and immediate availability of skilled help and advanced equipment for airway management are essential components of DA management.

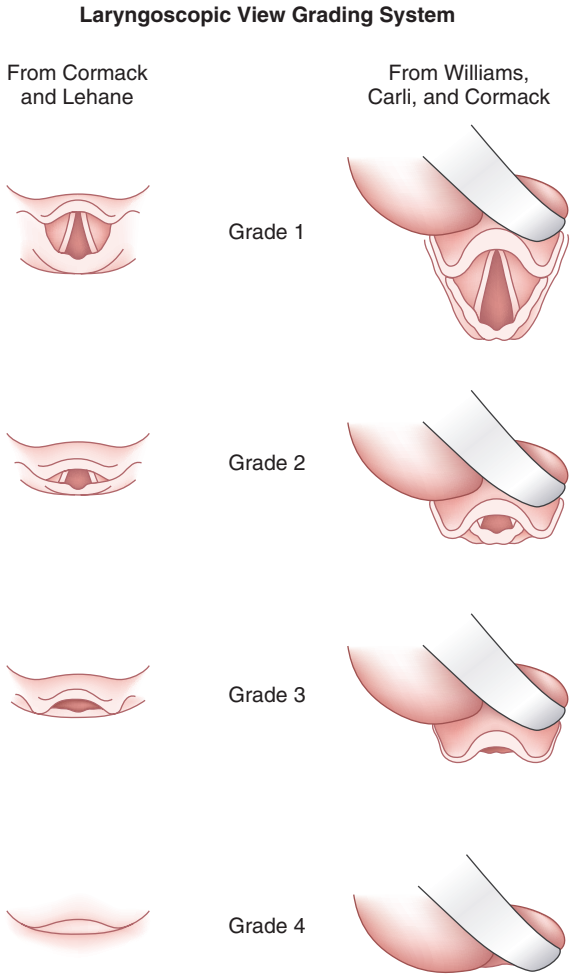

Figure 8-3 Four grades of laryngoscopic view. *Grade 1* is visualization of the entire laryngeal aperture; *grade 2* is visualization of just the posterior portion of the laryngeal aperture; *grade 3* is visualization of only the epiglottis; and *grade 4* is visualization of just the soft palate. It is assumed that care has been taken to get the best possible view of the vocal cords (see text for details). (Adapted from Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics. *Anaesthesia* 39:1105, 1984; and Williams KN, Carli F, Cormack RS: Unexpected difficult laryngoscopy: A prospective survey in routine general surgery. *Br J Anaesth* 66:38, 1991.)

2. Incidence of Difficult Laryngeal Visualization

The incidence of difficult laryngoscopy or intubation in the general surgical population varies greatly depending on the laryngeal view, the individual study population, and the definition of a DA. A grade 2 or 3 laryngoscopic view requiring multiple attempts or blades (and presumably external laryngeal pressure) is relatively common and is found in 1% to 18% of cases (Table 8-2). Grade 3 laryngeal views result in a successful intubation at a rate of 1% to 4%. Intubation is unsuccessful in between 5 and 35 of every 10,000 patients, and the CICV scenario occurs in 0.01 to 2 patients per 10,000.

For studies of difficult laryngoscopy to be reliable and for the laryngoscopic grading system to be helpful, the reported grades must describe the best view that was obtained, which, in turn, depends on the best possible performance of laryngoscopy. The components of best performance of laryngoscopy consist of the optimal sniff position, good complete muscle relaxation, firm forward traction on the laryngoscope, and, if necessary, firm external laryngeal manipulation. For example, the application of external laryngeal pressure may reduce the incidence of a grade 3 view from 9% to between 5.4% and 1.3%.[9] In doubtful cases, the anesthesiologist, while performing laryngoscopy with the left hand, should quickly apply external pressure over the hyoid, thyroid, and cricoid cartilages with the right hand. The pressure point that affords the best laryngeal view can be determined in a matter of seconds.

Having found the position that gives the best view, the laryngoscopist should ask the assistant to carefully press on the same spot. Optimal external laryngeal manipulation by the assistant must be directed by the laryngoscopist, even if the assistant is fully trained. The best performance of laryngoscopy avoids awkward high-arm postures, positioning of the laryngoscope blade over the middle of the tongue, gripping of the laryngoscope at the junction of the handle and blade with rotation about a horizontal axis, choosing the wrong blade size or shape, and placing the blade incorrectly. Theoretically, if the components of best performance of laryngoscopy are used and the pitfalls are avoided, all laryngoscopists (novice and expert) should obtain almost the same laryngoscopic view.

TABLE 8-2
Incidence of Various Levels of Difficult Intubation

Degree of Difficulty with Intubation	RANGE OF INCIDENCE		References
	n per 10,000	%	
ETT intubation successful but multiple attempts and/or blades may be required; probable laryngoscopic grade 2 or 3	100-1800	1-18	9, 12
ETT intubation successful but multiple attempts and/or blades and/or laryngoscopists required; laryngoscopic grade 3	100-400	1-4	9, 14, 24
ETT intubation not successful; laryngoscopic grade 3 or 4	5-35	0.05-0.35	9, 12, 14
Cannot ventilate by mask, cannot intubate; transtracheal jet ventilation, tracheostomy, brain damage, or death	0.01-2.0	0.0001-0.02	9, 18, 19, 20, 23

ETT, Endotracheal tube.

D. Difficult Intubation During Direct Laryngoscopy

Unlike difficult mask ventilation and difficult laryngoscopy, there is no uniformly accepted method of classifying difficult intubation. The Intubation Difficulty Score (IDS) validated by Adnet and colleagues[15] describes a spectrum of intubation difficulty. The assessment variables for the IDS are number of additional attempts, number of additional operators, number of alternative intubation techniques used, Cormack-Lehane laryngeal view minus 1, need for excessive lifting force, need for laryngeal pressure, and vocal cord adduction. Each variable carries one point, and difficult intubation is defined as an IDS score greater than 5, indicating moderate to major difficulty, with infinity (∞) being assigned to an impossible intubation. Kheterpal and associates defined difficult intubation as intubation requiring more than three attempts by anesthesia attending staff to secure the airway with an endotracheal tube.[6,7]

1. Incidence of Difficult Intubation

The incidence of difficult intubation was 10.3% in a recent study of emergent tracheal intubations in a university hospital.[16] The incidence of failed tracheal intubation ranges from 0.05% to 0.35%; the low and high ends of this range are associated with elective surgical and obstetric patients, respectively. The incidence of failed intubation is approximately 8 times higher in the obstetric population than in others, with a 13-fold increase in the risk of death.[17]

2. Combined Difficult Mask Ventilation and Difficult Intubation

In one study, the incidence of combined difficult mask ventilation and difficult intubation was 0.37%.[6] Patients whose lungs were impossible to ventilate via mask had a risk for difficult intubation of 25%, significantly higher than that for the overall population. One in three patients with combined impossible mask ventilation and difficult intubation required an alternative intubation technique to secure the airway, with 10% of such patients requiring a surgical airway. Similarly, one of the significant findings in another study was that difficult mask ventilation conferred a fourfold greater risk for difficult intubation and a 12-fold greater risk of an impossible intubation.[5]

3. Impossible Mask Ventilation and Intubation

The incidence of CICV has been estimated to range from 0.01 to 2.0 cases per 10,000 patients.[17-20] In a recent study of 50,000 patients, Kheterpal and colleagues described the incidence as 3.75 per 10,000 patients.[7] Despite recent advances in airway devices and techniques, most busy hospitals encounter several such events every year, making it imperative to ensure that DA recognition and management remains a central tenet of anesthesiology education and training.

4. Variability in Incidence of Difficult Laryngoscopy and Difficult Intubation

Difficult direct laryngoscopy (a grade 3 or 4 laryngeal view) is synonymous with difficult intubation in most patients.[12] However, tracheal intubation and laryngoscopy have slightly differing skill requirements, which may contribute to variability in the occurrence of difficult laryngoscopy and difficult intubation. In one prospective study examining respiratory complications in 1005 patients whose tracheas were intubated, 3 patients had grade 4 laryngeal views. One of these patients was easy to intubate, one was "moderately difficult" to intubate, and one was "difficult" to intubate.[8] In the same study, among 68 patients with a grade 3 laryngoscopic view, 5 (7%) were difficult to intubate, 50 (74%) were moderately difficult, and 13 (19%) were easy to intubate.

Four relatively uncommon scenarios explain some of the discordance between difficult laryngoscopy and difficult intubation. First, some patients with a grade 3 view have a trachea that can be intubated on the first or second attempt if the distal end of the endotracheal tube is appropriately curved by a malleable stylet (hockey-stick shape) or if a small curved introducer is used (e.g., a gum elastic bougie). Second, grade 3 laryngoscopic views have been variously described as seeing only the palate and all of the epiglottis or as seeing only the palate and just the tip of the epiglottis.[21] The different attributes of grade 3 may respond differently to adjustments such as optimal external laryngeal pressure, and therefore they may differ initially and subsequently with respect to difficulty of tracheal intubation. Third, a grade 3 view with a curved blade placed in the vallecula (because of a long, floppy epiglottis) may become a grade 1 or 2 view if either a curved or straight blade is placed posterior to the epiglottis and lifted anteriorly.[22] Fourth, pathologic conditions

TABLE 8-3
Success Rates of Intubation with Video-Enabled Laryngoscopes in Patients with Non-difficult Airways

Device	Intubations	No. Patients	% Success	References
Storz VMac	1395	1400	99.6	29, 30, 45, 47, 49
Glidescope	1452	1495	97.1	26, 27, 28, 37, 38, 40, 41, 43, 45, 46, 47, 50
McGrath	432	440	98.2	31, 45, 47, 48, 51
Pentax AWS	1663	1669	99.6	32, 33, 34, 35, 36, 39, 40, 42, 43, 44, 46, 52

such as laryngeal web, laryngeal tumors, or tracheal stenosis may disassociate ease of laryngoscopy from difficulty of tracheal intubation.

5. Complications of Difficult Laryngoscopy and Difficult Intubation

Anesthesia in a patient with a DA can lead to direct airway trauma and morbidity from hypoxia and hypercarbia. Incidence of brain damage, cardiac arrest, and death related to airway disasters appears to be decreasing.[2,19,23] Directly mediated laryngovagal reflexes (airway spasm, apnea, bradycardia, arrhythmia, or hypotension) and laryngospinal reflexes (coughing, vomiting, or bucking) are the source of some morbidity. In general, DA management is more likely to be associated with use of physical force during laryngoscopy and more attempts to secure the airway; together, these increase the incidence of complications. Airway complications can range from minor (trivial or nuisance value) to major (life-threatening or fatal).

In a recent study on emergent tracheal intubations with a 10.8% incidence of difficult intubation, the complications seen in 4.2% of cases were aspiration, esophageal intubation, dental injury, and pneumothorax.[16] The independent predictors of complications in this study were multiple intubation attempts (odds ratio [OR], 6.7; 95% confidence interval [CI], 3.2 to 14.2), grade 3 or 4 laryngeal view (OR, 1.9; 95% CI, 1.1 to 3.5), general care floor location (OR, 1.9; 95% CI, 1.2 to 3.0), and emergency department location (OR, 4.7; 95% CI, 1.1 to 20.4).

In an earlier study, a 5% incidence of relatively minor upper airway complications (posterior pharyngeal and lip lacerations and bruises) was demonstrated with laryngoscopy and intubation in patients with normal airways. In patients with anticipated difficult intubation, the incidence of minor trauma increased to 17%.[24] In patients in whom tracheal intubation was actually found to be difficult (i.e., multiple attempts at laryngoscopy but ultimately successful), the incidence of upper airway complications was 63%.[24]

In previous studies of anesthetic cardiac arrests, the incidence of inability to ventilate after induction was 0.12 per 10,000 anesthesias, accounting for 12% of the preventable causes. However, in a large contemporary study of 50,000 patients undergoing anesthesia for surgery, no incidence of brain damage or death was noted.[7] This result validates the view that modern advances in preoperative airway assessment, patient monitoring, airway equipment, and techniques have significantly reduced severe morbidity due to a DA.

E. Difficult Video Laryngoscopy

Video laryngoscopes and optical laryngoscopes have been increasingly used in routine and DA management. In general, these devices provide a better laryngoscopic view than does direct laryngoscopy. It is important to note that an improved Cormack-Lehane laryngoscopic grade does not always guarantee successful intubation of the trachea.[25] Many of these devices use a highly angulated blade with a camera positioned to allow the user to "see around the corner" of the tongue. Whereas direct laryngoscopy creates a straight line between the operator's eye and the vocal cords, allowing straightforward intubation, highly curved video laryngoscopes maintain the natural curvature of the airway and require special techniques to pass a tube into the trachea.

An excellent review of video laryngoscope use in adult airway management has been published.[25] It pooled data from 27 studies in adult patients (Tables 8-3 and 8-4). The operators using the devices were different, and the criteria for successful intubation as well as the definition of a DA were inconsistently applied from study to study, so the reader should not make direct comparisons between the devices listed in these two tables. The tracheas of patients with normal airways were intubated between 97.1% and 99.6% of the time with these devices. There are fewer data for patients with DAs, but the rate of successful intubation varied from 95.8% to 100% with video-enabled devices.

F. Difficult Flexible Bronchoscopic Intubation

1. Definition of Difficult Flexible Bronchoscopic Intubation

Flexible bronchoscopic intubation skills are now considered essential for all practicing anesthesia providers. Although flexible bronchoscopic devices have enhanced patient safety, especially when DA management is

TABLE 8-4
Success Rates of Intubation with Video-Enabled Laryngoscopes in Patients with Predicted Difficult Airways

Device	Intubations	No. Patients	% Success	References
Storz Vmac	198	201	98.5	30, 31, 45, 49
Glidescope	113	118	95.8	26, 28, 38, 41, 45
McGrath	32	32	100	31, 45

anticipated, they are by no means fail-safe. A difficult or impossible flexible bronchoscopic intubation can broadly be described as inadequate laryngeal visualization with or without difficulty in advancing an endotracheal tube. The ease of laryngeal exposure was defined by Ovassapian as not difficult, moderately difficult (needing some manipulation of the fiberscope in all directions), or difficult (needing extensive manipulation of the bronchoscope in all directions with or without change in position).[53]

2. Incidence of Difficult or Failed Flexible Bronchoscopic Intubation

Inadequate laryngeal visualization is a result of several factors acting individually or in tandem: inexperienced operators, presence of blood or secretions, inadequate topical anesthesia, distorted airway anatomy, and equipment failure. Factors typically unaffected by direct laryngoscopy, such as the presence of a large, floppy epiglottis or small amounts of pharyngeal blood, could pose significant hurdles to successful flexible bronchoscopic intubation. The incidence of difficult laryngeal visualization has been reported to be 6.7% with orotracheal and 4.4% with nasotracheal awake flexible bronchoscopic intubation.[53] The incidence of difficult laryngeal visualization using orotracheal approach under general anesthesia was only 4.4%, reflecting differences in patient types, with distorted upper airway anatomy or a severely compromised airway typically being managed in an awake patient. The incidence of difficult flexible bronchoscopic intubation using an orotracheal approach was 29.1% in awake and 24.1% in anesthetized patients. In contrast, the incidence during nasotracheal intubation was markedly lower, at 6.0% in awake and 11.0% in anesthetized patients, reflecting important technical differences between the two approaches. Flexible bronchoscopic intubation failed in 1.4% of awake and 2.1% of anesthetized patients, with equal distribution of difficult visualization and inability to advance the endotracheal tube.[53]

III. CONCLUSIONS

Inability to adequately ventilate or oxygenate patients remains an important cause of anesthesia-related morbidity and mortality. It is incumbent on an anesthesia provider to ensure adequate gas exchange and oxygenation for his or her patient.

Difficult mask ventilation has been reported at a rate of 1 or 2 per 100 anesthesias, and impossible mask ventilation can be expected at a rate of 1 or 2 per 1000 anesthesias. The failure rate for SGA devices is approximately 2% for the classic and flexible LMAs and 1% for the intubating and ProSeal LMAs.

Fewer data exist regarding failure of video and optical laryngoscopy than for direct laryngoscopy, but the incidence of failed intubation with these devices ranges from 0.4% to 2.9% in patients with a normal airway and from 0% to 4.2% for patients with a DA.

Difficult laryngoscopy occurs at a rate of 1% to 18% of surgical cases, but most of these patients are successfully intubated. Unsuccessful intubation with direct laryngoscopy occurs at a rate of 5 to 35 per 10,000 anesthesias and the CICV scenario occurs at a rate of 0.01 to 2 per 10,000 anesthesias.

Because the incidence of serious airway problems occurs at a low rate, large populations must be examined to improve understanding of the causes and incidence of these events. Understanding of DA management will improve as data are collected from multicenter trials. If electronic medical and anesthesia records use common language and definitions, data can be pooled from multiple institutions, providing the resources for effective analysis of the serious problem of DA management. This will become increasingly important as advances in technology and techniques reduce the rate of DA management.

IV. CLINICAL PEARLS

- The inability to manage a difficult airway (DA) is responsible for a large proportion of deaths and morbidity directly attributable to anesthesia.
- Although it is important to have common definitions for common problems, the literature continues to report variable nomenclature related to DA management. It is important to have an understanding of the incidence of significant airway problems for the specialty to make advances in this area.
- Difficult mask ventilation has been reported at a rate of 1 to 2 per 100 anesthesias, and impossible mask ventilation can be expected at a rate of 1 to 2 per 1000 anesthesias.
- The failure rate for supraglottic airway (SGA) devices is approximately 2% for the classic and flexible laryngeal mask airways (LMAs) and 1% for the intubating and ProSeal LMAs.
- Fewer data exist regarding failure of video and optical laryngoscopes than for direct laryngoscopy, but the incidence of failed intubation with these devices ranges from 0.4% to 2.9% in patients with a normal airway and from 0% to 4.2% for patients with a DA.
- When difficult laryngoscopy is defined as a Cormack-Lehane grade 2 or 3 view requiring multiple attempts or blades, the reported incidence varies from 1% to 18% of surgical cases; however, most of these patients are successfully intubated.
- Unsuccessful intubation with direct laryngoscopy occurs at a rate of 5 to 35 per 10,000 anesthesias, and the "cannot intubate, cannot ventilate" (CICV) scenario occurs at a rate of 0.01 to 2 per 10,000 anesthesias.
- Large multicenter studies will be required to refine understanding of the incidence of serious airway problems.

VIII. Clinical Pearls

I. INTRODUCTION

The quest to forecast difficult airway (DA) management has spanned more than a half century. In that time, a plethora of scientific investigations, book chapters, editorials, lectures, and workshops have been devoted to this essential issue. In 1956, Cass and colleagues underscored the point and began the search for a simple beside test to determine whose airway will be difficult to manage.[1] As of this writing, such a test does not exist.[2] Practitioners apply multiple tests, none of which are accurate. Absent reliable data, airway managers depend on case reports and personal experience to formulate critically important airway management plans.[3]

The medical literature boasts an abundance of articles discussing predictors of difficult intubation (DI) but relatively few explaining predictors of difficult mask ventilation (DMV). Among all of them, practitioners seek to determine which criteria are dependable and which are not.[4] Having established a basis on which to predict DMV or DI or both, it becomes possible to select modes of airway management that optimize patients' safety and comfort.

Generally, failed endotracheal intubation occurs once in every 2230 attempts.[5] The average anesthesiologist in the United States has one failed intubation every other year. The incidence is small, but the potential consequences of DA management are of major importance. Failed ventilation accounted for 44% of intraoperative cardiac arrests reported by Keenan and Boyan.[6] Thirty-four percent of liability claims identified by Caplan and coauthors were based on adverse respiratory events,[7] of which three quarters were judged to be preventable.[8]

Radiographs and other imaging techniques have been advocated to predict DI but are too expensive and inconvenient to serve as routine screening tests. Highly specialized techniques such as acoustic reflectometry are of dubious reliability.[9] More quantitative, noninvasive measurements, such as those with the laryngeal indices caliper,[10] bubble inclinometer,[11] and goniometer, offer the potential for accurate measurements but have never found their way into clinical practice.

This chapter reviews the current state of the art regarding predictability of difficult mask airway management and difficult traditional laryngoscopy (DL). Historically, these procedures were performed with anesthesia face masks in the case of mask ventilation and with Macintosh or Miller blades in the case of laryngoscopy.

The ensuing discussion observes these limitations. The application of supralaryngeal airway devices and alternative intubation techniques are addressed in other chapters.

A history of DA is a strong predictor of future problems[12]; in my opinion, it is the single most reliable predictor of a DA. The contrapositive is not necessarily true, however. A history of problem-free airway management is suggestive of future ease but not a guarantee. Many factors that contribute to difficulty are progressive with time. Examples of such problems include rheumatoid arthritis and obesity. An airway history should be elicited from all patients. Review of prior anesthesia records is frequently helpful; they may describe previously encountered problems, failed therapies, and successful solutions.[13]

II. PROBLEMATIC VENTILATION BY TRADITIONAL FACE MASK

DMV occurs when a practitioner cannot provide sufficient gas exchange because of inadequate mask seal, large volume leaks, or excessive resistance to the ingress or egress of gas.[13] The incidence of DMV varies between 0.08% and 5%.[14,15] This wide range is probably related to conflicting definitions of DMV.[16] Impossible mask ventilation occurs in 0.07% to 0.16% of patients.[15,17] Risk factors for DMV include full beard, massive jaw, edentulous state, skin sensitivity (e.g., burns, epidermolysis bullosa, fresh skin grafts), facial dressings, obesity, age older than 55 years, and a history of snoring.[15] Other criteria that suggest the possibility of DMV include large tongue, heavy jaw muscles, history of obstructive sleep apnea (OSA), poor atlanto-occipital extension, some types of pharyngeal pathology, facial burns, and facial deformities[18] (Box 9-1).

Many types of pharyngeal problems can produce DMV, including lingual tonsil hypertrophy,[19] lingual tonsillar abscess, lingual thyroid,[20] and thyroglossal cyst.[21-24] Many abnormalities cannot be diagnosed by classic airway examination techniques. The presence of any one factor is suggestive of DMV, and as factors increase in number, the likelihood of difficulty increases. A greater than normal mandibulohyoid distance has been associated with OSA, the pathophysiology of which may be related to DMV.[25–27] Anesthetic technique could contribute to DMV. El-Orbany and Woehlck suggested that high-dose opioid–induced vocal cord adduction produces DMV.[28]

Traditional face mask airway management is generally safe and effective. In the unusual instances in which it is not, endotracheal intubation remains one fallback option. Although this scheme works well in most cases, approximately 15% of all DIs are also DMVs.[29] Some factors that predispose to DMV also contribute to DI; they include OSA, history of snoring, obese neck, and poor mandibular translation. Some 25% of impossible mask ventilation patients are also difficult to intubate. The overall incidence of impossible mask ventilation and DI is 1 in every 2800 patients.[30] Proposed predictors of impossible mask ventilation are listed in Box 9-2.

BOX 9-1 Risk Factors for Difficult Mask Ventilation

- Obesity
- Beards
- Edentulousness
- History of snoring
- History of obstructive sleep apnea
- Age older than 55 years
- Large tongue
- Poor temporomandibular joint translation
- Skin sensitivity (burns, epidermolysis bullosa, fresh skin grafts)
- Massive jaw
- Heavy jaw muscles
- Poor atlanto-occipital extension
- Pharyngeal pathology
- Lingual tonsil hypertrophy
- Lingual tonsil abscess
- Lingual thyroid
- Thyroglossal cyst
- Facial dressings
- Facial burns
- Facial deformities

III. PROBLEMATIC INTUBATION BY TRADITIONAL LARYNGOSCOPY

A. Sniffing Position

DI occurs when multiple attempts at endotracheal intubation are required.[13] The presence or absence of airway pathology does not influence its definition. Traditional laryngoscopy is performed to visualize the laryngeal opening. The observing laryngoscopist is situated outside the airway, above the patient's head. To see through the airway, light must travel from the glottic opening to the laryngoscopist's eye. Because light travels in straight lines, the technique requires an uninterrupted linear path between larynx and observer. Most of the manipulations performed attempt to satisfy this criterion.

The airway contains three visual axes. They are the long axes of the mouth, oropharynx, and larynx. In the neutral position, these axes form acute and obtuse angles with one another (Fig. 9-1). Light cannot bend around these angles under normal circumstances. To bring all three axes into better alignment, McGill suggested the "sniffing the morning air" position.[31] The true sniffing position has two components: cervical flexion and atlanto-occipital extension. Cervical flexion approximates the pharyngeal and laryngeal axes, and atlanto-occipital extension brings the oral axis into better alignment with the other two. Normal atlanto-occipital extension

BOX 9-2 Proposed Predictors of Impossible Mask Ventilation

- Neck radiation changes
- Beard
- Male gender
- Sleep apnea
- Mallampati class III or IV

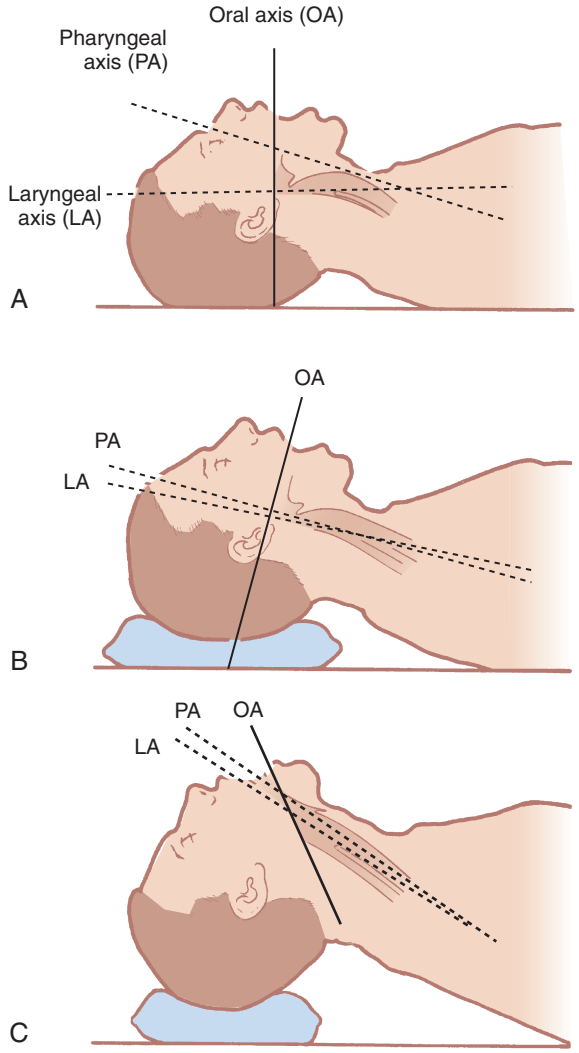

Figure 9-1 Visual axis diagram. **A,** Head in neutral position. None of the three visual axes align. **B,** Elevation of the head approximates the laryngeal and pharyngeal axes. **C,** Extension at the atlanto-occipital joint brings the visual axis of the mouth into better alignment with those of the larynx and pharynx. (From Stone DJ, Gal TJ: Airway management. In Miller RJ, editor: *Anesthesia*, ed 5, Philadelphia, 2000, Churchill Livingstone, p 1419.)

measures 35 degrees.[32] With optimal alignment of the airway's visual axes, it becomes possible to look through the airway into the laryngeal opening. A reduced atlanto-occipital gap or a prominent C1 spinous process impairs laryngoscopy[33,34] if vigorous attempts at extension are performed, because the trachea bows and the larynx is forced anteriorly.[33]

Inability to assume the sniffing position is a predictor of DI. Examples of problems that prevent the sniffing position are cervical vertebral arthritis, cervical ankylosing spondylitis, unstable cervical fractures, protruding cervical discs, atlantoaxial subluxation, cervical fusions, cervical collars, and halo frames. Morbidly obese patients sometimes have posterior neck fat pads that prevent atlanto-occipital extension.

The ability to achieve the sniffing position is easily tested. One simply has the patient flex the lower cervical vertebrae and extend at the atlanto-occipital joint. Pain, tingling, numbness, or inability to achieve these maneuvers predicts DI.[35] The benefits of the sniffing position have been dogma for more than 70 years, but Adnet and colleagues and Chou and Wu have questioned its utility.[36,37]

B. Mouth Opening

Mouth opening is important because it determines the available space for placing and manipulating laryngoscopes as well as endotracheal tubes.[38,39] A small mouth opening may not accommodate either. Mouth opening also provides room to see through the uppermost part of the airway. Mouth opening relies on the temporomandibular joint (TMJ), which has both a hingelike movement and a gliding motion. The gliding motion is known as *translation*. The hingelike movement allows the mandible to pivot on the maxilla. The more the mandible swings away from the maxilla, the bigger the mouth opening.

The adequacy of mouth opening is assessed by measuring the interincisor distance. An interincisor distance of 3 cm provides sufficient space for intubation, absent other complicating factors. This corresponds approximately to two finger breadths.[40] The two finger breadth test is performed by placing the examiner's second and third digits between the patient's central incisors. If they fit, there should be adequate room to perform laryngoscopy; if they do not fit, laryngoscopy may be difficult. Factors that interfere with mouth opening include masseter muscle spasm, TMJ dysfunction, and various integumentary aliments. Skin problems that adversely effect mouth opening include burn scar contractures and progressive systemic sclerosis. Masseter muscle spasm can be relieved by induction of anesthesia and administration of muscle relaxants. Mechanical problems at the TMJ remain unaltered by medications. Some patients demonstrate adequate mouth opening when awake but not after anesthesia induction.[41] The problem can often be relieved by pulling the mandible forward. A mouth opening that was sufficient for a previous anesthetic may not be so after temporal neurosurgical procedures.[42]

C. Dentition

Instrumentation of the airway places teeth at risk for damage. Multiple problems result from dental injury. Teeth may be dislodged or broken, leading to inability to chew, pain, and costly repair. Moreover, broken teeth can fall into the trachea, migrate to the lung, and predispose to abscesses. Poor dentition is at risk for damage as the mouth is opened and as the laryngoscope blade is employed. Teeth that can be extracted easily with digital pressure should probably be removed. During laryngoscopy in the presence of poor dentition, extra efforts are made to avoid placing pressure on maxillary incisors. This causes laryngoscopes to be manipulated into less than ideal positions for visualizing the larynx, resulting in poor visualization of the glottis.

Prominent maxillary incisors complicate laryngoscopy in another way. They protrude into the mouth and block the line of sight to the larynx. To overcome this problem,

laryngoscopists must adjust their line of sight. This is done by bringing the observer's eye into a new position that is higher than the original one, so that the laryngoscopist looks tangentially over the protruding maxillary incisor. Two new points of observation exist in the adjusted line of sight and determine a new line of sight, one that brings the laryngoscopist's view to a more posterior laryngopharyngeal position. The result is a view that is posterior to the larynx. Consequently, the larynx is not visualized and a DL is produced. In much the same way, edentulous patients tend to be easy to intubate because the laryngoscopist can adjust the line of sight to a more advantageous angle.

D. Tongue

The tongue occupies space in the mouth and oropharynx. The base of the tongue lies close to the glottic aperture. During traditional direct laryngoscopy, the base of the tongue falls posteriorly, obstructing the line of sight into the glottis. Visualization of the larynx requires displacing the tongue base anteriorly so that the line of sight to the glottis is restored. The tongue is frequently displaced with a handheld rigid laryngoscope to which a Macintosh or Miller blade has been attached. These laryngoscopes push the tongue anteriorly, moving it from a posterior, obstructing position to a new anterior, nonobstructing position. The new position is within the *mandibular space*, the area between the two rami of the mandible. Even with the tongue maximally displaced into the mandibular space, visualization of the larynx is sometimes inadequate.

A normal-size tongue usually fits easily into a normal-size mandibular space. A large tongue fits poorly into a normal-size mandibular space. After filling the space, a large tongue still occupies some of the oropharyngeal airway and obstructs it. For this reason, a large tongue (macroglossia) is a predictor of DI. Similarly, a normal-size tongue fits poorly into a small mandibular space.[43] It, too, occupies some of the oropharyngeal airway, thereby obstructing the line of sight. Consequently, a small mandible (micrognathia) is a predictor of DI. In essence, a tongue that is large compared with the size of the mouth (oropharynx) and mandible takes up excessive space in the oropharynx and interferes with visualization.

The base of the tongue is located so close to the larynx that inability to adequately displace it anteriorly creates another problem. Because the base of the tongue hangs down over the larynx, the glottis is hidden from view. The glottic aperture is then anatomically anterior to the base of tongue—hence, the term *anterior larynx*. Under such circumstances, the larynx is anterior to the base of the tongue and cannot be seen because the tongue hides it. In this manner, glottic and supraglottic masses can create DI if they force the base of the tongue posteriorly. Some of the masses that may be encountered are lingual tonsils,[19,44] epiglottic cysts,[23] and thyroglossal duct cysts.

After the mandibular space is filled with the tongue, additional pressure on the laryngoscope blade lifts the mandible anteriorly. In this setting, mandibular displacement depends on the TMJ. In addition to its hingelike motion, the TMJ works in a gliding (translational) movement. It is the gliding motion that allows the mandible to slide anteriorly across the maxilla. If the joint does not translate, the mandible cannot be displaced anteriorly, and the tongue cannot be moved out of the line of sight.

Recognizing the implications of tongue size for successful laryngoscopy, Mallampati and colleagues[45] in 1985 and Samsoon and Young[5] in 1987 devised classification systems to predict DL utilizing this concept. Mallampati and Samsoon reasoned that a large tongue could be identified on visual inspection of the open mouth. Both classification systems relate the size of the tongue to the oropharyngeal structures identified. A normal-size tongue allows visualization of certain oropharyngeal structures. As the tongue size increases, some structures become hidden from view. Both investigators proposed systems that reasoned backward from this premise.

Application of the Mallampati or the Samsoon classification system is easy and painless. The patient is seated in the neutral position. The mouth is opened as wide as possible, and the tongue is protruded as far as possible. Phonation is discouraged because it raises the soft palate and allows visualization of additional structures.[46] The observer looks for specific anatomic landmarks: the fauces, pillars, uvula, and soft palate. The Mallampati classification system uses three groups and the Samsoon system uses four (Fig. 9-2). Both systems suggest that as tongue size increases, fewer structures are visualized and laryngoscopy becomes more difficult. Mallampati class tends to be higher in pregnant patients than in nonpregnant ones.[47]

Just as the size of tongue can be estimated, so too can the size of the mandible. The patient's head is extended at the atlanto-occipital joint. The mentum of the mandible and the thyroid cartilage are identified. The "Adam's apple" (thyroid notch) is the most superficial structure in the neck and serves as a good landmark for the thyroid cartilage. The vocal cords lie just caudad to the thyroid notch. The distance between the thyroid cartilage and the mentum (thyromental distance, or TMD) is measured in one of three ways: with a set of spacers, with a small pocket ruler, or with the observer's fingers. The normal TMD is 6.5 cm. A TMD greater than 6 cm is predictive of easy intubation, and a TMD of less than 6 cm is suggestive of DI.[48] If a ruler is not present at the bedside, practitioners can judge the TMD with their own fingers. The width of one's middle three fingers frequently approximates 6 cm, and the TMD can be compared with the fingers' span. In that way, clinically relevant approximations can be taken into account when examining patients for the purpose of predicting DI.

The ability to translate the TMJ is easily assessed before induction. The patient is simply asked to place the mandibular incisors (bottom teeth) in front of the maxillary incisors (upper teeth). Inability to perform this simple task usually results from one of two sources. First, the TMJ may not glide, predicting DI.[49] Second, some patients find it difficult to coordinate the maneuver, in which case there is no implication for DI.

The upper lip bite test was proposed as a modification of the TMJ displacement test.[50] The upper lip bite

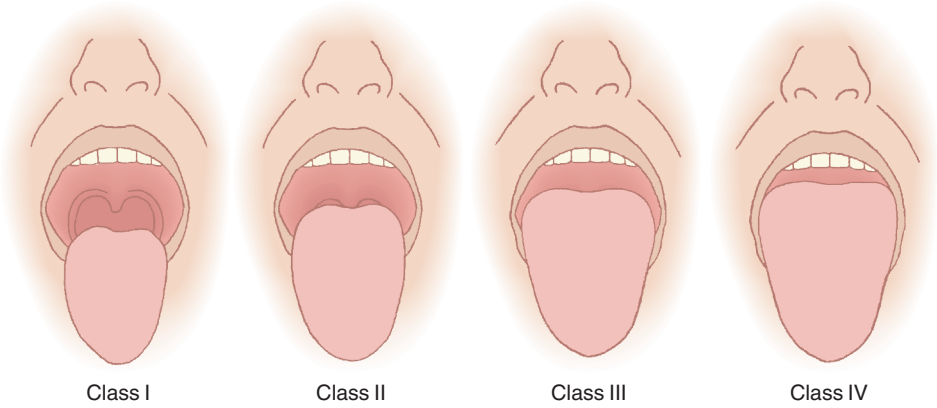

Figure 9-2 Samsoon classification system. The oropharynx is divided into four classes on the basis of the structures visualized: *class I*—soft palate, fauces, uvula, pillars; *class II*—soft palate, fauces, uvula; *class III*—soft palate, base of uvula; *class IV*—soft palate not visible. (From Mallampati SR: Recognition of the difficult airway. In Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 132.)

test is performed by asking the patient to move the mandibular incisors as high on the upper lip as possible. The maneuver is similar to biting the lip. Contact of the teeth above or on the vermilion border is thought to predict adequate laryngoscopic views. Inability to touch the vermilion boarder with the mandibular teeth is thought to predict poor laryngoscopic views. Both the TMJ translation test and the upper lip bite test assess TMJ glide, which is an important consideration during laryngoscopy. Khan and coworkers confirmed the predictive importance of this maneuver.[51] Table 9-1 summarizes a quick, easy, bedside scheme for predicting DI.

IV. SPECIAL SITUATIONS

A. Morbid Obesity

The Centers for Disease Control and Prevention (CDC) defines morbid obesity (MO) in terms of body mass index (BMI). BMI is calculated as a ratio between weight in kilograms and height in meters squared:

$$\text{BMI} = \text{Weight in kg}/(\text{Height in m})^2$$

A BMI of 20 to 25 kg/m^2 is normal, 25 to 30 kg/m^2 is overweight, 30 to 40 kg/m^2 is obese, and greater than 40 kg/m^2 indicates MO. Other definitions of MO have fallen into disfavor.

Patients with MO frequently develop upper airway obstruction, which may present as OSA. During normal inspiration, the diaphragm descends and the chest wall expands, resulting in creation of negative intrathoracic pressure (subatmospheric pressure). Negative intrathoracic pressure is transmitted along the entire airway, including the upper airway. Soft tissues are drawn into the airway as if it were imploding. Under normal circumstances, obstruction is prevented by contraction of three sets of dilator muscles. The tensor palatini prevents airway obstruction by the soft palate at the nasopharynx. The genioglossus pulls the tongue anteriorly to open the oropharynx. The hyoid muscles pull the epiglottis forward and upward to prevent obstruction at the laryngopharynx. In healthy young patients, these muscles prevent obstruction during sleep. As patients age, the dilator muscles become less efficacious and there is a tendency for partial obstruction to occur.

In patients with MO, adipose tissue deposits in the lateral pharyngeal walls. These deposits are not fixed to bone and are highly mobile. They protrude into the airway, narrowing it, and are drawn farther into the airway during periods of negative airway pressure, such as during inspiration. In these ways, reduced dilator

TABLE 9-1
Generally Accepted Predictors of Difficult Intubation

Criterion	Suggestion of Difficult Intubation
History of difficult intubation	Positive history
Length of upper incisors	Relatively long
Interincisor distance	Less than two finger breadths (<3 cm)
Overbite	Maxillary incisors override mandibular incisors
Temporomandibular joint translation	Inability to extend mandibular incisors anterior to maxillary incisors
Mandibular space	Small, indurated, encroached upon by mass
Cervical vertebral range of motion	Cannot touch chin to chest or cannot extend neck
Thyromental distance	Less than three finger breadths (<6 cm)
Mallampati-Samsoon classification	Mallampati III/Samsoon IV—relatively large tongue: uvula not visible
Neck	Short, thick

Adapted from American Society of Anesthesiologists Task Force on Difficult Airway Management: Practice guidelines for management of the difficult airway: An updated report. *Anesthesiology* 98:1269, 2003.

muscle function or pharyngeal adipose depositions predispose to OSA. (See Chapter 43 for further details.)

Clinically, OSA is implied by a history of heavy snoring, daytime somnolence, impaired memory, inability to concentrate, and frequent accidents. Associated findings include hypoxemia, polycythemia, systemic hypertension, pulmonary hypertension, and hypercarbia. Definitive diagnosis is made by polysomnography in sleep laboratories. During sleep, patients with OSA experience at least five episodes per hour of apnea lasting 10 seconds or longer or at least 15 episodes per hour of hypopnea (50% decrease in airflow). Both hypopnea and apnea are frequently associated with decreases in pulse oximetry of 4% or more. Risk factors for OSA are male gender, middle age or older, obesity, evening alcohol consumption, and drug-induced sleep.

Hypopnea or apnea occurs as the pharynx is obstructed. Partial obstruction leads to hypopnea and total obstruction produces apnea. Normally, dilator muscles prevent obstruction, but they do so less successfully with increasing age and obesity. As airflow to the alveoli diminishes, hypoxemia and possibly hypercarbia develop. Both result in enhanced sympathetic outflow, causing patients to awaken. In the awake state, dilator activity increases and airway patency is restored. Patients then fall asleep, and the cycle is repeated numerous times. Rapid-eye-movement sleep is achieved poorly, and patients remain tired during the day. Treatment frequently centers on application of continuous positive airway pressure (CPAP) during sleep, but not all patients tolerate the mask. Alternative therapies include oral appliances to move the tongue anteriorly and nocturnal administration of oxygen. Surgical options also exist, such as uvulopalatopharyngoplasty, genioglossus advancement, maxillomandibular advancement, and tracheostomy.

Although time to oxyhemoglobin desaturation is not a predictor of DI, it is an important consideration. The longer the time available to perform laryngoscopy, the greater the likelihood of success. Rapid hemoglobin desaturation limits that time and thereby reduces the chance of endotracheal intubation. A patient with MO and a BMI of 40 kg/m^2, breathing room air, who becomes apneic desaturates to an oxygen saturation in arterial blood (Sa_{O_2}) of 90% in approximately 1 minute, and to 60% in the next minute. In contrast, if the same patient is breathing 100% O_2 before induction of anesthesia, the Sa_{O_2} takes approximately $2^1/_2$ minutes to fall to 90% and does not reach 60% for an additional $1^1/_2$ minutes.[51,52] The data show that successful oxygenation before induction of anesthesia extends the period of time until oxyhemoglobin desaturation takes place. Consequently, preoxygenation provides a longer period for laryngoscopy, which should increase the chances of successful intubation.

Preoxygenation may be thought of as denitrogenation. During preoxygenation, patients breathe 100% O_2. Air, which is mostly nitrogen, is washed out of alveoli and replaced with O_2. This process stores O_2 in all open alveoli, including those constituting the functional residual capacity (FRC). The more O_2 contained in the FRC, the more time before oxyhemoglobin desaturation and the greater the period for laryngoscopy. Because the FRC in patients with MO is reduced, less O_2 is stored. After induction of anesthesia in a preoxygenated 70-kg adult, it takes approximately 8 minutes for the Sa_{O_2} to fall to 90%, and almost 10 minutes to fall to 60%. For the patient weighing 127 kg, however, the comparable times are $2^1/_2$ minutes and almost 4 minutes.

Evaluation before airway manipulation requires a history and physical examination. Important aspects of the history include previous airway difficulties and the patient's weight at that time. A present-day airway examination is also necessary.

Although OSA pathology and pathophysiology predispose to DMV and DI, the true incidence of problems resulting from MO is undefined. The popularity of bariatric surgery has brought numerous patients with MO to the operating room. Because these patients receive face mask ventilation infrequently, there is little practical experience to refute classic teachings about such ventilation. It is reasonable to expect fat cheeks, a short immobile neck, a large tongue, and pharyngeal adipose deposits to complicate face mask ventilation.[53] Nevertheless, Brodsky and colleagues reported on a morbidly obese patient with a BMI of 43 kg/m^2 and OSA who was ventilated easily by face mask.[54] This experience serves to document the clinical findings of many practitioners. Along the same lines, considerable experience with laryngoscopy in patients with MO has developed. Absent findings to the contrary, most of these patients are easy to intubate. In other words, MO does not appear to be a strong independent predictor of DI.[54–57] The presence of other DI predictors implies potential problems.[58] Gonzalez and colleagues suggested that a neck circumference greater than 43 cm (19 inches) is such a predictor.[59] Pretracheal fat accumulation has been investigated as a predictor of DI, but the results have been conflicting.[60,61]

B. Pregnancy

Airway management is one of the most important factors contributing to maternal mortality.[62,63] (See Chapter 37 for further details.) Airway difficulties pose a risk of pulmonary aspiration and hypoxic cardiopulmonary arrest. Rocke and associates reported some degree of difficulty during intubation in almost 8% of full-term pregnant patients undergoing cesarean section.[55]

Pregnant patients usually are young and have full dentition. Prominent maxillary incisors obstruct the line of sight, as discussed previously, and many pregnant women present with reduced interincisor distances because of TMJ dysfunction or other etiologies. Reduced interincisor distances limit the space available for visualization and manipulation of instruments in the mouth.

Pregnant patients suffer from generalized soft tissue swelling. They all gain weight and often reach MO proportions. Short, fat necks tend to prevent achievement of the proper sniffing position, which impairs aligning the visual axes of the mouth, pharynx, and larynx. Redundant pharyngeal tissues may fall into the airway during traditional laryngoscopy, obstructing the line of sight. Tissue edema can produce so much mucosal swelling that

landmarks, such as epiglottis and arytenoids, are hard to distinguish. The breasts may be so engorged that they interfere with placement of a laryngoscope handle.[64] As the space between mandible and chest diminishes, less room is available for the assistant's hand to provide cricoid pressure. In fact, the assistant's hand may take up space needed to open the mouth, thereby preventing adequate mouth opening. Sufficient mouth opening is required to see through the airway as well as to insert and manipulate equipment.

Tongue swelling produces macroglossia. Macroglossia prevents sufficient displacement into the mandibular space, so the line of sight is obstructed. It has been suggested that straining can exacerbate the Mallampati-Samsoon classification.[65]

Overzealous left lateral uterine displacement can tilt the torso and neck, altering the airway position in relation to the cervical spine. Cricoid pressure may exacerbate this problem by displacing the airway laterally, occluding it,[66] or angulating the larynx.

Swelling of the supraglottic airway interferes with face mask ventilation and complicates laryngoscopy and intubation. As the upper airway becomes edematous, it also becomes more friable. Instrumentation of such airways frequently leads to bleeding, which further complicates face mask ventilation and endotracheal intubation.[67]

Parturients, especially obese parturients, have reduced FRC.[68,69] All pregnant women experience an increase in O_2 consumption of approximately 20%. Consequently, periods of apnea, such as during laryngoscopy under general anesthesia, predispose to desaturation in these patients much more quickly than in their nonpregnant and nonobese counterparts.[70,71] Rapid oxyhemoglobin desaturation reduces the time available for laryngoscopy and detracts from the successful completion of intubation.

Other factors tend to impair successful laryngoscopy. Anxiety on the part of inexperienced physicians has led to intubation attempts before adequate conditions are achieved. Laryngoscopy under general anesthesia requires sufficient depth of anesthesia and profound muscle relaxation.[72,73] Absent one or both of these conditions, the chances of success are markedly reduced. The result is poor mouth opening, reduced interincisor distance, retching, vomiting, and aspiration. Well-intentioned, novice assistants degrade intubating conditions or fail to enhance them.[73] The *Report on Confidential Enquiries into Maternal Deaths in England and Wales* pointed to failure to provide cricoid pressure, poorly applied cricoid pressure, or release of cricoid pressure during a vomiting episode as major contributors to maternal morbidity and mortality.[62]

The application of cricoid pressure during active vomiting has been controversial. Sellick's original description of cricoid pressure called for release of the maneuver during vomiting episodes.[74] A single case report described an elderly woman who vomited during application of cricoid pressure and suffered an esophageal rupture.[75] Although other factors could have contributed to or caused the rupture in this patient, some have recommended relinquishing cricoid pressure during vomiting episodes on the basis of this occurrence. Sellick retracted his initial recommendation, and others have supported the maintenance of cricoid pressure during active vomiting,[76–78] believing that the risk of aspiration pneumonia is greater than the risk of esophageal rupture.[77,78] Furthermore, cricoid pressure sometimes pushes the entire neck posteriorly, resulting in forward flexion of the head on the neck. As a result, the advantages of the sniffing position are lost and laryngoscopy becomes more difficult. To correct this problem, bimanual cricoid pressure was suggested by Crowley and Giesecke.[79] To accomplish this maneuver, the assistant's left hand supports the patient's neck from underneath as the assistant's right hand places pressure on the cricoid cartilage.

C. Lingual Tonsil Hypertrophy

Over $11^1/_2$ years, Ovassapian and colleagues analyzed 33 cases of unanticipated DI. Before induction of anesthesia,[19] none of these patients was thought to pose a significant likelihood of difficulty on the basis of careful preanesthetic airway examinations. Of the 33 patients, 15 had normal airway examinations; 3 of those patients had BMIs of 31 to 40 kg/m^2. The remaining 18 patients presented with varying predictors of DI but were judged to be at low risk for poor laryngoscopic views. After induction, intubation turned out to be difficult in the hands of experienced attending anesthesiologists. All 33 patients subsequently underwent flexible fiberoptic pharyngoscopy for pharyngeal assessments, and all demonstrated lingual tonsil hypertrophy.

Lingual tonsils are lymph tissues located at the base of the tongue. They usually exhibit hypertrophy bilaterally but may do so unilaterally. Enlarged lingual tonsils can push the epiglottis posteriorly, obstructing the line of sight and preventing anterior displacement of the base of the tongue. They sometimes encroach on the vallecula, preventing optimal location of curved laryngoscope blades. They can distort the epiglottis so that it covers the glottic opening or is difficult to recognize. Not only do hypertrophied lingual tonsils prevent elevation of the base of the tongue from the line of sight, but they also have a tendency to bleed, complicating intubation even further.[80,81]

Lingual tonsil hypertrophy cannot be identified by classic airway examinations to predict DI. It is often asymptomatic, and its suggestive symptoms are nonspecific. They include sore throat, dysphagia, snoring, OSA, and sensations of fullness or lumps in the throat. Most patients have a history of palatine tonsillectomy or adenoidectomy.[44] Lingual tonsil hypertrophy has been associated with airway obstruction and OSA.[82–85] Other pharyngeal problems that can complicate laryngoscopy include acute lingual tonsillitis,[82] lingual tonsillar abscesses, lingual thyroids,[20] and thyroglossal cysts.[21–23] These structures reside at the base of the tongue, a location that is hidden from view during routine physical examination.

D. Burns

Thermal burns of the head and neck complicate airway management in several ways. (See Chapter 44 for further

details.) Burn patients with coexisting airway problems experience approximately 50% greater mortality than burn patients without airway issues. Thermal damage to the upper airway results in massive swelling within 2 to 24 hours. Edematous mucosa encroaches on the airway lumen to create severe narrowing or even occlusion. A narrowed upper airway reduces the amount of air drawn into the lungs. An occluded upper airway prevents any O_2 from reaching the alveoli. Both effects result in hypoxia. As the mucosa swells, traditional laryngoscopy becomes difficult or impossible. So much edema can collect in the mucosa that landmarks may be unrecognizable. For these reasons, it is sometimes best to perform endotracheal intubation early in the care of burn patients, before swelling creates hypoxia and DI.[86]

Airway burns are suggested by the occurrence of fire in a closed space, stridor, hoarseness, dyspnea, singed nasal hairs, and carbonaceous material in the mouth, nares, or pharynx. The risk of airway compromise and DI in the near future is significant. Elective prophylactic intubation is indicated for such patients.

For those who survive the acute burn period, chronic airway problems occur frequently. Burn tissue heals by formation of scar, which is nonelastic. Scars over the face and neck limit mobility of the TMJ and cervical vertebrae. The result is a small mouth opening and inability to achieve the sniffing position. Scar release under local anesthesia may be helpful to restore mobility to these important joints and allow improved intubating conditions.

E. Acromegaly

The incidence of DI in acromegaly is four to five times higher than in the general population.[87] Acromegaly results from excess growth hormone, which is frequently produced by pituitary tumors. One screening test for acromegaly involves administration of 75 to 100 g of glucose. If plasma growth hormone concentrations do not fall after 1 to 2 hours, acromegaly is suspected. High plasma growth hormone levels may indicate acromegaly. Skull radiographs and computed tomographic scans showing an enlarged sella turcica suggest anterior pituitary adenoma.

Typical acromegalic features include enlarged nose, big tongue, thick mandible, full lips, elevated nasolabial folds, and prominent frontal sinuses. These patients appear to experience overgrowth of mucosa and soft tissues of the pharynx, larynx, and vocal cords.[88,89] Many experience OSA.[90,91] Early in the disease process, joint spaces may be widened, but later on arthritis develops and limits range of motion. This frequently occurs at the TMJ, resulting in a small mouth opening, and it may occur in cricoarytenoid joints. Overgrowth of tissues can produce vocal cord abnormalities, resulting in hoarseness or recurrent laryngeal nerve paralysis.

These features predispose to DMV and DL. Large tongues and epiglottides produce upper airway obstruction and make laryngoscopy difficult. Big mandibles increase the distance between teeth and vocal cords, necessitating longer laryngoscope blades. Thickened vocal cords and subglottic narrowing may require smaller tracheal tubes than would otherwise be selected. Nasal turbinate enlargement may obstruct the nasal airway and prevent passage of tubes. Dyspnea on exertion, stridor, or hoarseness may suggest laryngeal abnormalities that can complicate intubation. In addition to thick mandibles, acromegalics frequently present with long mandibles. Nonetheless, the resulting increased TMD has not been found to be associated with DL.[87]

F. Epiglottitis

Epiglottitis (supraglottitis) is caused by a potentially life-threatening infection that produces upper airway swelling and obstruction. Formerly, the most common etiology was *Haemophilus influenza* type B (HIB), and the disease usually occurred in children 2 to 8 years of age. Since the widespread use of HIB vaccine, epiglottitis is an unusual finding in the pediatric population, but it still occurs in immunosuppressed adults. Common presenting signs are sore throat and dysphagia. Other signs and symptoms include drooling, inspiratory stridor, high fever, rapid deterioration to respiratory distress, pharyngitis, tachypnea, cyanosis, lethargy, and tripod positioning. These patients are most comfortable sitting up, extending the neck, and leaning forward. The "muffled voice" is an infrequent finding.[92] Lateral radiographs of the neck classically demonstrate a swollen epiglottis. Mild adult forms may be treated with observation for exacerbation of respiratory function.[93–95] Severe cases with respiratory compromise require airway management, which usually means tracheal intubation and antibiotics.

Instrumentation of the airway in these cases can result in total airway obstruction and is contraindicated in the awake patient. Only deep general anesthesia is likely to protect against exacerbation of airway obstruction during intubation. Before induction of anesthesia, preparations are made for immediate tracheostomy if required. Intravenous access is obtained before or just after induction of anesthesia. Despite the fever, glycopyrrolate is administered to dry secretions, which are usually copious and hinder laryngoscopy. Inhalation induction with sevoflurane is begun in the sitting position. After loss of consciousness, patients are placed supine to deepen the level of anesthesia. Assisted ventilation by bag and mask is frequently necessary to maintain airway patency. Supraglottic swelling, copious secretions, and reactive upper airway combine to make mask ventilation and laryngoscopy difficult. Deep inhalation anesthesia allows high concentrations of inspired O_2. When appropriate, laryngoscopy and intubation are performed. Elective extubation usually takes place 2 to 4 days later.

G. Acute Submandibular Space Cellulitis

Acute cellulitis of the submandibular space (Ludwig's angina) can progress rapidly to a life-threatening situation. It generally begins as a mixed-flora infection around the mandibular molars. Aerobic and anaerobic pathogens are involved. The floor of the mouth swells and forces the tongue into the airway, creating upper airway obstruction. Extension to sublingual and hypopharyngeal

areas produces tongue and pharyngeal swelling.[96,97] This mechanism is exacerbated in the supine position, and patients often cannot tolerate lying flat. Inability to assume the supine position precludes computed tomography, but the diagnosis can be confirmed with lateral neck soft tissue radiographs. Potential exists for infection to track down the airway and into the mediastinum, creating significant edema and swelling throughout the airway.

Submandibular cellulitis brings infection and edema fluid into the submandibular space, effectively reducing the area into which the tongue can be displaced during laryngoscopy. The swollen tongue fits poorly into the already reduced submandibular space, so that it cannot be elevated out of the line of sight during laryngoscopy. Swelling throughout the airway reduces space for visualization. It also distorts and hides landmarks needed for successful intubation. Many patients require awake tracheostomy under local anesthesia because traditional laryngoscopy fails to expose the larynx. Awake fiberoptic intubation may also be considered appropriate in these patients.

H. Rheumatoid Arthritis

Synovitis of the TMJ leads to reduced mandibular motion. Consequently, the mouth opening is small. This hampers laryngoscopy by limiting the amount of space available to insert a laryngoscope and endotracheal tube and impairing the manipulation of these devices once they are placed. Severe forms of Still's disease (juvenile rheumatoid arthritis) can involve the TMJ, leading to poor mandibular development (micrognathia). Micrognathia is probably related to a small mandibular space. The small mandibular space does not accommodate a normal size tongue during laryngoscopy. Consequently, the tongue is not displaced anteriorly out of the line of sight. It hangs down into the airway and obstructs visualization of the larynx.

Cervical spine arthritis limits the neck's range of motion. Consequently, patients can neither flex the lower cervical vertebrae nor extend the atlanto-occipital joint (sniffing position). Inability to perform these maneuvers prevents visual axis alignment of the mouth, pharynx, and larynx. Consequently, laryngoscopy may be difficult, and fiberoptic intubation may be considered. In addition, atlantoaxial subluxation and separation of the atlanto-odontoid articulation can result. The diagnosis is made by obtaining lateral neck radiographs. When separation occurs, the odontoid process is free to enter the foramen magnum and impinge on the spinal cord or vertebral arteries. Often the odontoid process is eroded, reducing the risk of spinal cord or vertebral artery compression. Cervical flexion deformities can render the neck totally immobile, impairing mask ventilation and laryngoscopy.

Cricoarytenoid arthritis may arise with hoarseness, pain on swallowing, dyspnea, stridor, and tenderness over the larynx. The arytenoids are edematous and fixed in adduction. Swelling may be so severe that the glottis is obscured.[98] The vocal cords move poorly,[99] which makes the larynx much more difficult to identify.[98]

V. RELIABILITY OF PREDICTION CRITERIA

Although intuitively it makes sense to perform and is consistent with best medical practices, airway evaluation frequently falls short of its intended goal.[13] Numerous rating systems based on recognized prediction criteria have been investigated. Most suffer from recurrent problems.[100]

The first problem is nomenclature. A standardized definition of the DA did not exist until 1993.[101] At that time, it was explained as a situation in which a conventionally trained anesthesiologist experienced difficulty with mask ventilation, difficulty with endotracheal intubation, or both. For years, individual investigators needed to establish their own definition of DI each time studies were conducted. Consequently, the end points of their work were not necessarily comparable to those of other investigations in the field. Multiple meanings of the term *DI* prevented comparative analysis of studies.

In 1993, the American Society of Anesthesiologists (ASA) Committee on Practice Guidelines for Management of the Difficult Airway offered a generally acceptable definition.[101] Ten years later, the definition was altered slightly, and DI now refers to any intubation that requires multiple attempts.[13] This is a good clinical definition, but it lacks the precision required for scientific investigation. For example, some practitioners may perform a single laryngoscopy and, on the basis of the view obtained, elect to forgo further attempts at laryngoscopy. Such cases may be handled with supraglottic ventilatory devices, regional anesthesia, or other techniques. This situation does not meet the definition of DI even though it would have if one more attempt at intubation had been made. *Failed intubation* may be an easier term to understand. A failed intubation exists when laryngoscopists give up and admit that traditional intubation will not be successful. The end point is clear and occurs with an incidence of 1 in 280 obstetric patients and 1 in 2230 among the general surgical population.[5]

The second problem is identifying features that predict DI. This is frequently accomplished by attempting to recognize characteristics found in patients who have proved to have DI. The problem with such an approach is the lack of information about the same characteristics in patients who have easy intubations. As Turkan and colleagues pointed out, we do not even know the normal values for many prediction criteria.[102] A better method is to apply multivariate analysis to populations of patients in a prospective manner. In that way, a single factor can be compared in difficult and easy intubations. Various rating systems have attempted to combine multiple predictors into a formula, but to date, none have been satisfactory.

The third problem is validating the tests once they are promulgated. Validation tests performed on the same population of patients used to identify them are misleading. Different sample populations are needed.

The fourth problem is experimental methods. Individual practitioners differ in many ways. Any given patient, on any given day, may be difficult to intubate for one laryngoscopist and not for another. Clinical practice

has shown that a particular patient who is difficult to intubate in the hands of one laryngoscopist may be successfully intubated by another laryngoscopist. For this reason, experimental designs involving more than one laryngoscopist introduce a source of variation, which detracts from attempts to control experimental conditions. Relying on a single laryngoscopist obviates this problem but limits the number of patients who can be enrolled into a single study. Another source of experimental error is observer variation. Just as laryngoscopists differ, so do observers.[103,104] Observations performed by different experimenters are subject to variations and introduce another source of erroneous data. The best way to prevent this problem is to have all observations performed by a single experimenter. This, too, may limit the number of patients enrolled in a single study.

Statistical tests for assessing the usefulness of criteria involve sensitivity and positive predictive value. Sensitivity is the ratio of DI patients correctly identified compared with all the DI patients within the entire population of patients. For example, consider a population of patients in which five people are difficult to intubate. If a particular predictor of DI correctly identifies all five patients, its sensitivity is 100%. A sensitivity of 100% means that all the DI patients are identified by the test. If the test correctly identifies only two of the five patients, its sensitivity is 2/5, or 40%. Positive predictive value is the probability that DI patients identified by the test are, in fact, difficult to intubate. If the test predicts that five patients will be difficult to intubate and all five of those patients are difficult to intubate, the positive predictive value of the test is 100%. A positive predictive value of 100% means that if the test says that any particular patient will be difficult to intubate, that patient will be difficult to intubate. If the test predicts that 10 patients will be difficult to intubate but only 5 of them are in fact difficult to intubate, its predictive value is 5/10, 50%. Unfortunately, statistical tests such as sensitivity and positive predictive value, when applied to classic prediction criteria, have yielded disappointing results.[14,100]

In 1984, Cormack and Lehane described a grading system for comparing laryngoscopic views (Fig. 9-3).[105] Cormack-Lehane grade 1 views demonstrate the entire glottic opening. Grade 2 views show the posterior laryngeal aperture but not the anterior portion. Grade 3 views allow visualization of the epiglottis but not any part of the larynx. Grade 4 views allow the laryngoscopist to see the soft palate but not the epiglottis. Early evidence indicated a good correlation between Mallampati-Samsoon classes and laryngoscopic grades[5,45] (i.e., a higher Mallampati-Samsoon class predicted a correspondingly higher laryngoscopic grade for any given patient). This concept formed the basis for using Mallampati-Samsoon classes to predict DI. In 1992, Rocke and coworkers disproved that relationship.[55] They investigated several classic predictors of DI and demonstrated that none of them was a reliable predictor of DI (Fig. 9-4).

Classic prediction criteria essentially deal with surface anatomy. They screen for some factors that are associated with DI but fail to address others. Moreover, some potential problems are hidden from surface anatomy examinations. Glottic and supraglottic abnormalities such as lingual tonsil hypertrophy or epiglottic prolapse into the glottic opening cannot be diagnosed by standard physical examinations for predicting DI.[19,106,107] Pathophysiologic factors such as mobile TMJ discs or disc fragments can produce severely limited mouth opening after induction of anesthesia when none existed before.[106] Precise measurements of atlantoaxial motion sometimes fail to predict DI.[108] Supraglottic, glottic, or subglottic pathology may be unrecognized by standard tests but complicate intubation nonetheless.[109] As of this writing, no single factor reliably predicts DI. As more and more

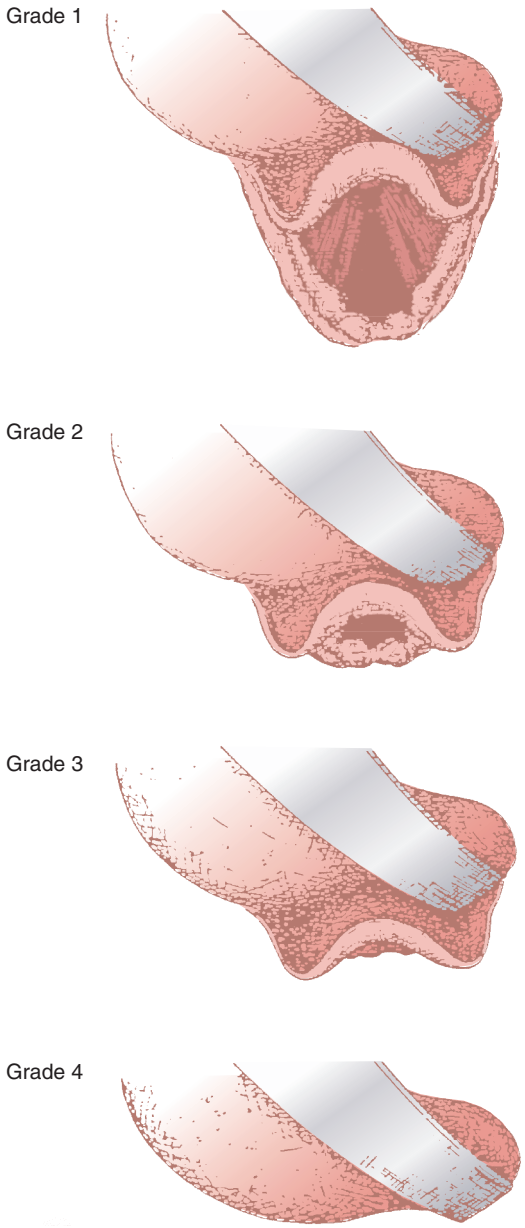

Figure 9-3 Cormack-Lehane grading system. Four laryngoscopic grades are identified: *grade 1,* most of the glottis is visible; *grade 2,* only the posterior extremity of the glottis is visible; *grade 3,* only the epiglottis is seen; *grade 4,* the epiglottis is not seen. (From Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics. *Anaesthesia* 39:1105, 1984.)

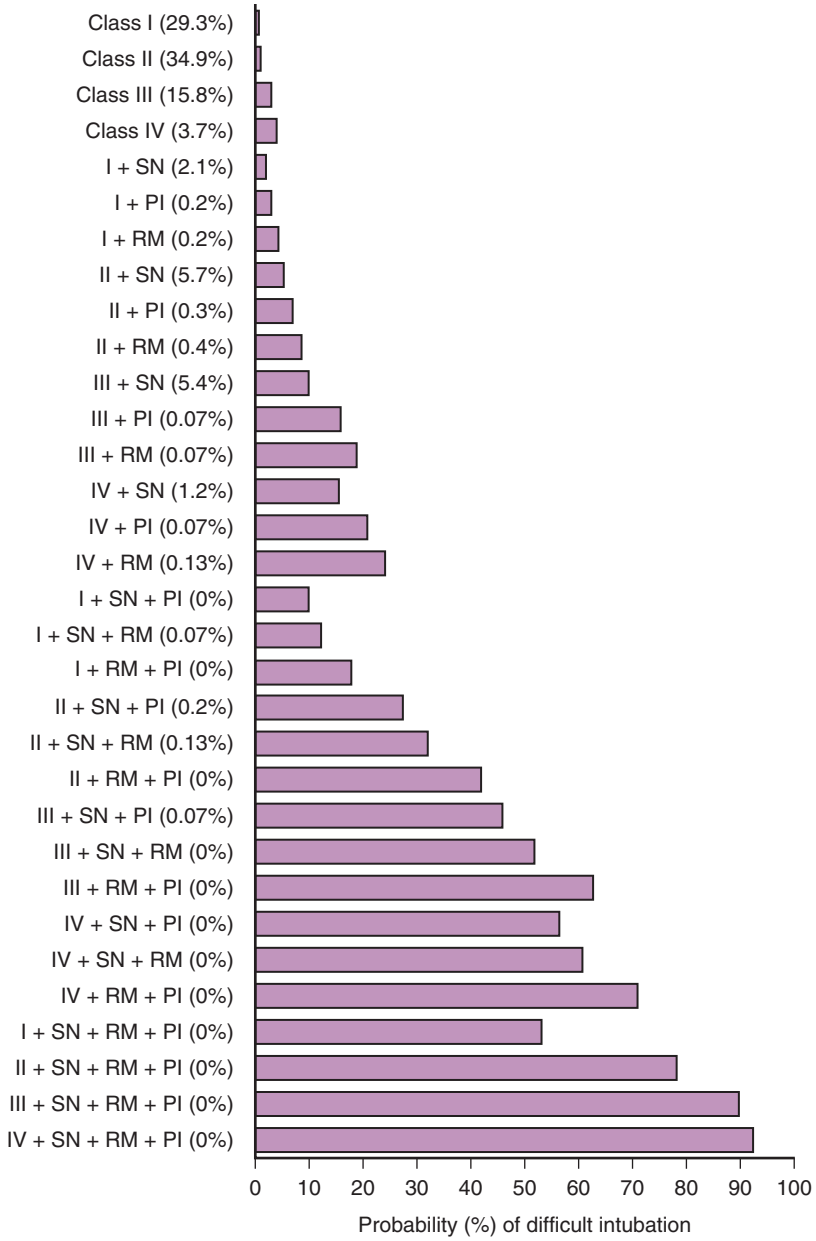

Figure 9-4 Probability of difficult intubation. Classes I-IV are mallampati-Samsoon classifications. *PI,* Protruding incisors; *RM,* receding mandible; *SN,* short neck. (From Rocke DA, Murray WB, Rout CC, Gouws E: Relative risk analysis of factors associated with difficult intubation in obstetric anesthesia. *Anesthesiology* 77:67, 1992.)

predictors of DI are found in the same patient at the same time, the likelihood of DI increases.[35,104,110–112]

VI. NONTRADITIONAL CONSIDERATIONS IN DIFFICULT AIRWAY PREDICTION

A. Imaging

Attempts at predicting DA management by imaging are not new. Standard radiographic films have been used to assess bony structures in an attempt to predict airway problems. However, they have been only minimally helpful. Charters took this concept to the next level; he advocated mathematical modeling, looking at relationships between bony structures.[113] One example is the minimal residual volume[114]: Insufficient volume between the rami of the mandible (i.e., the mandibular space) prevents sufficient anterior tongue displacement and forces the tongue inferiorly, where it drives the epiglottis against the posterior pharyngeal wall and prevents visualization of the larynx. Another example is lateral neck radiographs from which geometric calculations are made.[115] Radiography requires the use of large machines, specialty consultation by radiologists, moving patients to radiology suites, and considerable expense. These constraints are certainly not adaptable to screening large numbers of patients.

Other types of mathematical modeling include airway indices. Numerous indices have been promulgated. Despite the appeal of attaching numbers to criteria and performing calculations with these numbers, airway indices, such as those postulated by Wilson and Arne, have failed to accurately predict DI.[116] Newly created risk scores, such as the one offered by Eberhart and colleagues,[117] await independent validation. Interest in airway indices continues, in the hope that reliable predictions can be formulated based on bedside observations.

Among the most interesting of all mathematical models is computerized facial analysis.[118,119] Connor and Segal[119] are developing programs to assess facial images and predict difficulty of intubation. At present, they require high speed computers, substantial computing power, and network access. As impressive as this program appears, there are likely to be predictors of DI that are not included in their analysis.

B. Supraglottic and Glottic Tumors

Various types of imaging can diagnose supraglottic and glottic tumors. However, relatively few patients benefit from such studies. Most patients present for airway management without imaging. Airway assessment relies on the history and examination of surface anatomy. A history of voice changes, respiratory distress, snoring, and swallowing issues is nondescript and frequently absent when airway tumors are present. Traditionally, a high index of suspicion has prompted otolaryngologic consultation, but otherwise many of these tumors go undiagnosed. These masses can directly obstruct visualization of the larynx. They can occupy space in the vallecula, preventing optimal placement of Macintosh blades, and can interfere with displacement of the epiglottis by Miller blades.[23] Many supraglottic and glottic tumors remain undiagnosed and interfere with mask ventilation and intubation. The classic example is lingual tonsil hypertrophy. Enlarged lingual tonsils push the epiglottis posteriorly, preventing visualization of the glottis and obstructing mask ventilation.[120]

C. Radiation Changes

Traditional laryngoscopy relies on supple elastic laryngeal structures. After head and neck radiation, tissues sometimes become immobile and rigid. These postradiation changes can complicate laryngoscopy.

D. Arthritis

Arthritis is usually associated with joints in the extremities. It also affects laryngeal joints. Cricoarytenoid arthritis can impair Cormack-Lehane views. A related issue is ligament calcification. Stylohyoid ligament calcification can limit forward movement of the hyoid bone, thereby interfering with epiglottic displacement.[114]

E. Cancerous Goiter

In modern practice, thyroid goiters are usually removed before they grow very large. Goiters that bow the trachea generally leave the larynx in the midline. Even tracheomalacia rarely interferes with airway management. Nevertheless, cancerous goiter increases the risk of DI. It is postulated that laryngeal fibrosis extends from the cancer, diminishing soft tissue mobility.[121]

F. Offsetting Features

Individual predictors of DA management carry varying importance in different patients. In some circumstances, a given predictor may produce substantial difficulty, whereas in other situations, it may contribute little. Practitioners have observed this repeatedly. One reason may be offsetting features. One or more factors that contribute to DA management can be offset by others. Perhaps the best recognized example of this point is the edentulous maxilla.[122] Absence of upper teeth allows for such an advantageous line of sight that coexisting confounding issues may well be rendered clinically unimportant.

G. Interobserver Variation

In order to investigate factors that predict DA management and to apply that information clinically, it becomes important to agree on nomenclature and to standardize tests. If different investigators use varying definitions of terms, their findings cannot be compared. Once agreement has been reached among investigators, they must use the same end points in order to apply their findings. The wide range of reported sensitivity and specificity values among tests could relate to this fundamental issue. Interobserver variability confounds establishing specific tests as worthwhile and adversely affects their clinical use. Interobserver variability is especially well recognized for Mallampatti-Samsoon classification systems,[123] and it adversely affects other tests as well.

H. Anesthetic Technique

Optimal conditions for airway management are often dependent on adequate depth of anesthesia and sufficient muscle relaxation. If depth of anesthesia is inadequate for the level of stimulation or muscle relaxation is insufficient, airway management is frequently compromised. The combination of deep anesthesia and profound muscle relaxation provides the best conditions for manipulating the airway.

Patients with myasthenia gravis have undergone laryngoscopy and intubation without muscle relaxants, and this experience has been expanded into other realms, prompting more liberal avoidance of muscle paralysis during airway management. For very short periods of anesthesia, some practitioners are administering small induction doses of a hypnotic and large doses of short-acting opioid, while eliminating muscle relaxants. Such formulas allow for successful airway manipulation in most patients but risk problems.

During mask ventilation, partial or complete vocal cord adduction produces upper airway obstruction and interferes with ventilation as well as oxygenation. During laryngoscopy, passage of a tracheal tube between partially

or completely adducted vocal cords may lead to problems, including vocal cord hematoma and laceration. These conditions can lead to hoarseness and altered voice quality on a temporary basis, and occasionally the changes can be permanent. For most patients, temporary voice changes are a nuisance, but for those who use their voice professionally, this complication becomes a major problem. For patients who experience permanent aphonia, these complications are major setbacks. More acutely, eliminating neuromuscular blockers from anesthetic induction and laryngoscopy increases the risk of DI or failed endotracheal intubation.[124]

VII. CONCLUSIONS

The first consideration in caring for patients is maintaining airway patency. In many cases, that is a hard goal to achieve. Predicting the DA is important because it allows appropriate management planning. It is hoped that heightened awareness and altered treatment strategies will prevent some of the untoward events associated with treatment in patients with DA.

At present, no single factor reliably predicts DI. Consequently, prediction of DI relies on various tests, the results of which are taken into account. After assimilating the data, practitioners assess the information and compare it with similar situations that have been encountered previously. In other words, clinical judgments are made on the basis of previous experience.

New tests are sorely needed. They should be painless to perform; patients do not tolerate discomfort for the sake of DA screening. The tests should be quick, should be simple to apply, and should require little or no equipment. Practitioners need to perform these tests on each patient. Complex procedures, cumbersome equipment, and difficult calculations will dissuade many physicians and nurses from using tests. They should be bedside procedures; it is impractical to send ambulatory surgery patients, day-of-admission surgery patients, or emergency patients to distant places for high-technology, expensive imaging studies. The tests should be objective, with little interexaminer variation,[16,103] and reproducible. They should be reliable.[14,112] High degrees of sensitivity and positive predictive value are crucial.

Classic prediction criteria deal primarily with surface anatomy and fail to address issues such as lingual tonsils, epiglottic cysts, and other soft tissue pathology. For this reason, despite outward appearances, a history of DI may be the most reliable predictor of future DIs. A history of prior DI is typically elicited in one of two ways—orally or in writing. Frequently, patients discuss prior intubation difficulties during the preanesthetic interview. Alternatively, this information may be discovered in old records of patients, in written letters, or through the Medic Alert National Registry (see Chapter 54). The Medic Alert Registry provides patients with bracelets and cards that identify their basic medical problem; more information is available through an emergency phone number provided to each registrant.

Until the ideal predictive criteria are discovered, practitioners will continue to rely on imperfect tests and identification of circumstances that are recognized as associated with DAs.

VIII. CLINICAL PEARLS

- No single test reliably predicts DMV or DL.
- Generally accepted predictors of DA management tend to have poor sensitivity and low positive predictive value.
- Proposed predictors of impossible facemask ventilation include neck radiation changes, beard, male gender, OSA, and Mallampati-Samsoon class III or IV.
- Recommended tests to predict DI include history of DI, protruding upper incisors, interincisor distance <3 cm, failed TMJ translation, small indurated mandibular space, limited cervical vertebral range of motion, TMD <6 cm, Mallampati-Samsoon Class III or IV, and short thick neck.
- The Cormack-Lehane views are as follows: grade I, entire glottic aperture visualized; grade II, posterior glottis visualized, but not the anterior portion; grade III, epiglottis visualized, but no part of the glottis; grade IV, soft palate visualized, but not the epiglottis.
- High-dose opioids sometimes produce vocal cord adduction leading to DMV and DI.

I. INTRODUCTION

There is strong evidence that successful airway management in the perioperative environment depends on specific strategies. Suggested strategies from various subfields of medicine are now being linked together to form more comprehensive treatment plans or algorithms. The classic flow charts of this nature are the resuscitation algorithms that provide evidence-based guidance during cardiopulmonary resuscitation worldwide.

The purpose of the Algorithm on the Management of the Difficult Airway (DAA), published by the American Society of Anesthesiologists (ASA), is to facilitate management of the difficult airway (DA) and to reduce the likelihood of adverse outcomes. The principal adverse outcomes associated with the DA include (but are not limited to) death, brain injury, cardiopulmonary arrest, unnecessary tracheostomy, airway trauma, and damage to teeth.

The original ASA DAA was developed over a 2-year period by the ASA Task Force on Guidelines for Management of the Difficult Airway.[1] The task force included academicians, private practitioners, airway experts, adult and pediatric anesthesia generalists, and a statistical methodologist. The algorithm was introduced by ASA as a practice guideline in 1993. In 2003, the ASA task force presented a revised algorithm that essentially retained the same concept but recommended a wider range of airway management techniques than was previously included, based on more recent scientific evidence and the advent of new technology.

This chapter presents and explains the ASA DAA and then provides a critical appraisal of the ASA algorithm based on recent evidence from the literature. This is followed by the presentation of a new, comprehensive

*Parts of this chapter are adapted and modified from a previous publication on a similar topic: Hagberg C, Lam N, Brambrink AM: Current concepts in airway management in the operating room: A new approach to the management of both complicated and uncomplicated airways. *Curr Rev Clin Anesth* 28:73–88, 2007.

airway management algorithm that provides an innovative and highly structured approach resembling the guidelines for cardiopulmonary resuscitation.

Both algorithms are concerned with the maintenance of airway patency at all times. Special emphasis is placed on an operating room setting, although the algorithm can be extrapolated to the intensive care unit, the ward, and the entire perioperative environment and beyond. Both algorithms are primarily intended for use by anesthesiologists or by individuals who deliver anesthetic care and airway management under the direct supervision of an anesthesiologist. The guidelines apply to airway management during all types of anesthetic care and anesthetizing locations, and to patients of all ages.

Both airway algorithms focus primarily on further improving patient safety during the perioperative period. Adherence to the principles of an airway management algorithm and widespread adoption of such a structured plan should result in a reduction of respiratory catastrophes and a decrease in perioperative morbidity and mortality.

II. THE ASA DIFFICULT AIRWAY ALGORITHM

A side-by-side comparison of the original (1993) and the updated (2003) versions of the ASA DAA is presented in Figure 10-1. The differences between the two algorithms are listed in Box 10-1. Certain aspects of the algorithm require further explanation.

A. Patient Evaluation and Risk Assessment

The ASA DAA begins with the most basic question of whether or not the presence of a DA is recognized (see Chapter 9). Recognizing the potential for difficulty leads to proper mental and physical preparation and an increased chance of a good outcome. In contrast, failure to recognize this potential results in unexpected difficulty in the absence of proper mental and, likely, physical preparation, with an increased chance for a catastrophic outcome.

Airway evaluation should take into account any characteristics of the patient that could lead to difficulty in the performance of (1) bag-mask or supraglottic airway ventilation, (2) laryngoscopy, (3) intubation, or (4) a surgical airway. Routine patient evaluation can be best structured as follows (see Chapter 9 for details):

1. Obtain an airway history to identify medical, surgical, and anesthetic factors that may indicate the presence of a DA.
2. Evaluate for systemic diseases (e.g., respiratory failure, coronary artery disease) that might place limits on awake intubation, such as increased fraction of inspired oxygen (F_{IO_2}), or require special attention, such as prevention of sympathetic nervous system stimulation.
3. Examine previous anesthetic records, which can yield useful information about previous airway management.
4. Conduct a physical examination of the airway to detect physical characteristics that might indicate the presence of a DA (Table 10-1):
   - Maximal mouth opening with tongue extension and pharyngeal anatomy (e.g., uvula, tonsillar pillars)
   - Length of the submental space (mandible to hyoid) and the thyromental distance (mandible to thyroid notch)

Box 10-1 Differences between 1993 and 2003 ASA Management of the Difficult Airway Algorithms

1. *Difficult ventilation* is now listed first under item 1, "Assess the Likelihood and Clinical Impact of Basic Management Problems." Also, in the same category, *Difficult tracheostomy* was added.
2. A new item 2 was inserted: "Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management."
3. When considering the relative merits and feasibility of basic management choices (item 3), awake intubation versus intubation attempts after induction of anesthesia should now be considered first, before noninvasive versus invasive techniques as the initial approach to intubation.
4. Use of the laryngeal mask airway (LMA) was incorporated into the algorithm in the awake induction limb and in both the nonemergency and emergency pathways for induction after general anesthesia (either as a ventilatory device or as a conduit for tracheal intubation).
5. The option for "One more intubation attempt" was removed.
6. Use of the rigid bronchoscope was added as an option for emergency noninvasive ventilation.

TABLE 10-1
Components of the Preoperative Airway Physical Examination

Airway Examination Component	Nonreassuring Findings
Length of upper incisors	Relatively long
Relation of maxillary and mandibular incisors during normal jaw closure	Prominent "overbite" (maxillary incisors anterior to mandibular incisors)
Relation of maxillary and mandibular incisors during voluntary protrusion of the jaw	Patient's mandibular incisors anterior to (in front of) mandibular incisors
Interincisor distance	<3 cm
Visibility of uvula	Not visible when tongue is protruded with patient in sitting position (e.g., Mallampati class III or IV)
Shape of palate	Highly arched or very narrow
Compliance of mandibular space	Stiff, indurated, occupied by mass, or nonresilient
Thyromental distance	<3 ordinary finger breadths
Length of neck	Short
Thickness of neck	Thick
Range of motion of head and neck	Patient cannot touch tip of chin to chest or cannot extend neck

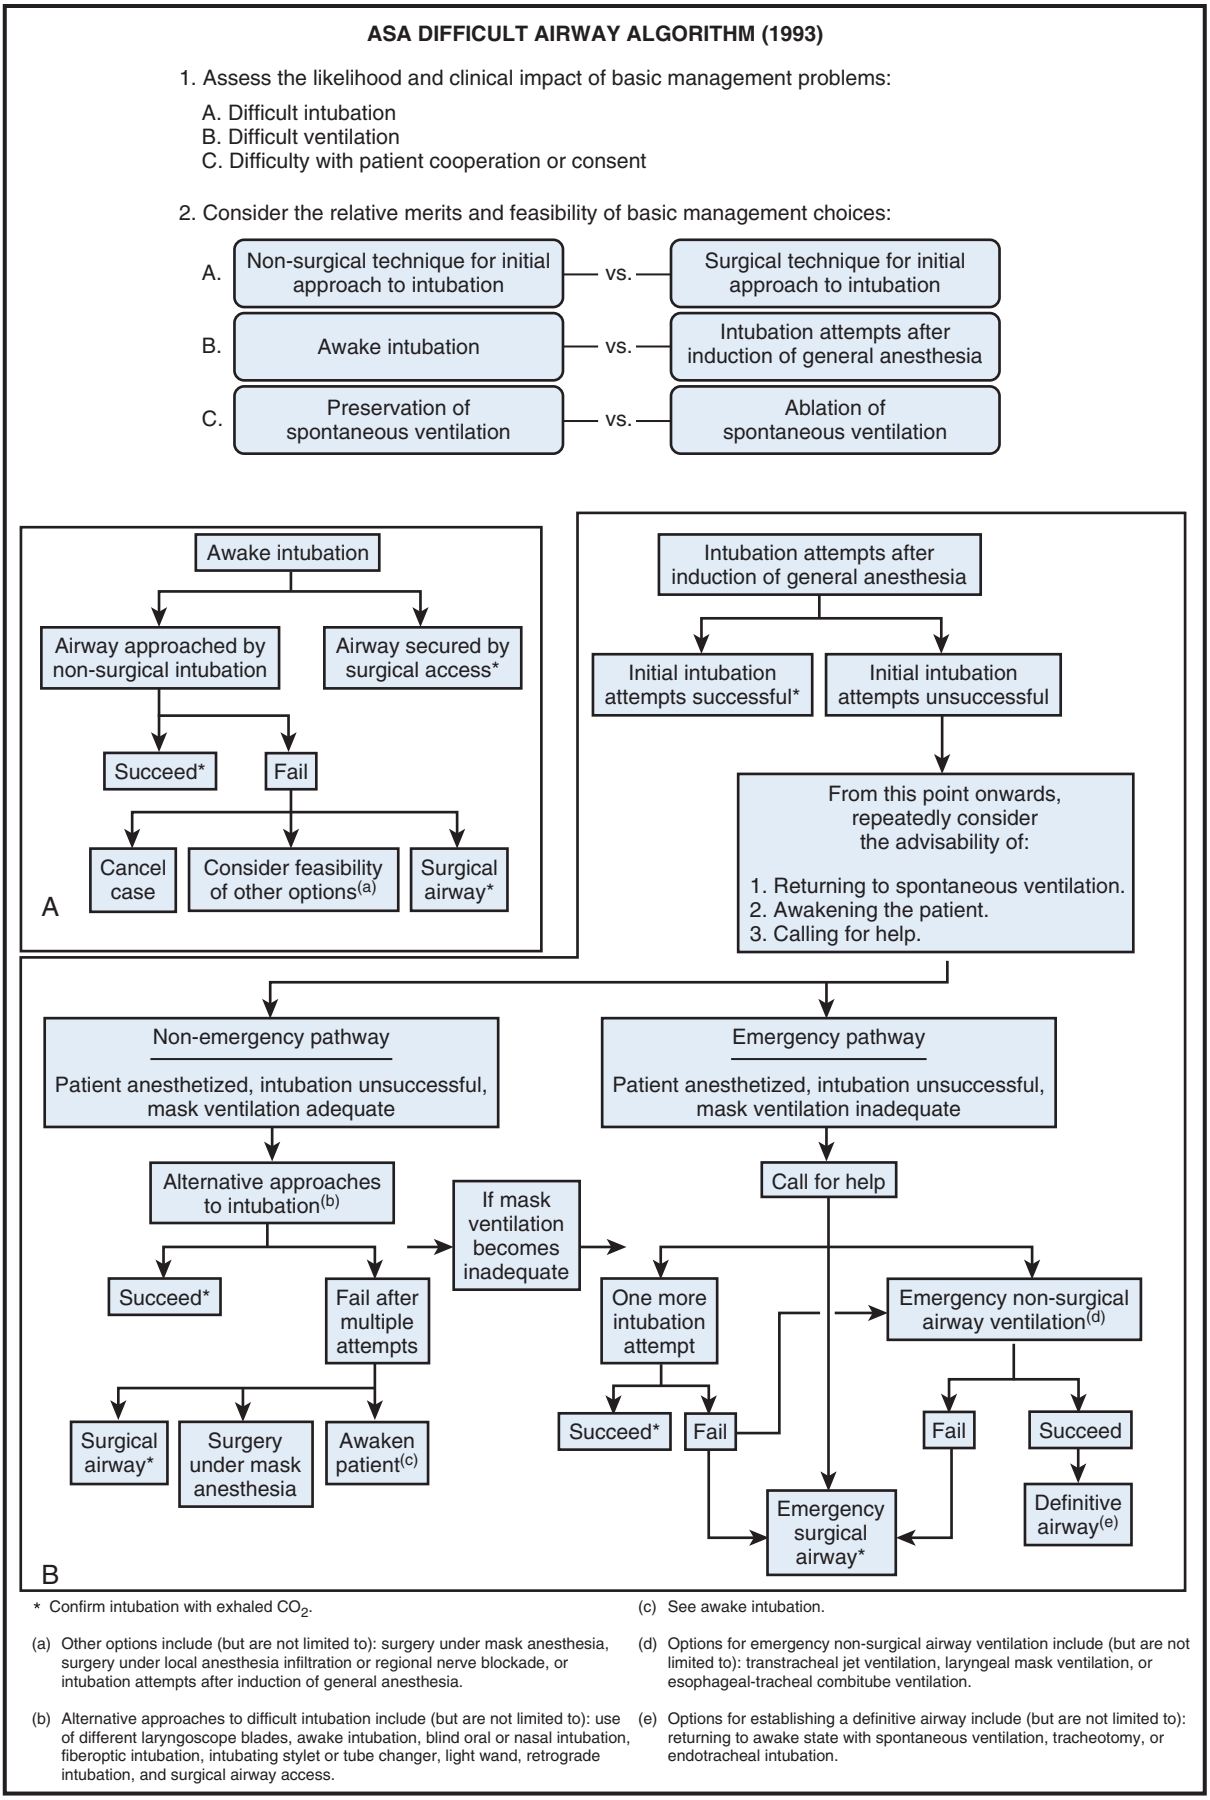

Figure 10-1 **A,** The American Society of Anesthesiologists' difficult airway algorithm (ASA DAA), published in 1993.

ASA DIFFICULT AIRWAY ALGORITHM (2003)

1. Assess the likelihood and clinical impact of basic management problems:

   A. Difficult ventilation
   B. Difficult intubation
   C. Difficulty with patient cooperation or consent
   D. Difficult tracheostomy

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management

3. Consider the relative merits and feasibility of basic management choices:

A.	Awake intubation	vs.	Intubation attempts after induction of general anesthesia
B.	Non-invasive technique for initial approach to intubation	vs.	Invasive technique for initial approach to intubation
C.	Preservation of spontaneous ventilation	vs.	Ablation of spontaneous ventilation

4. Develop primary and alternative strategies:

*Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2.

(a) Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

(b) Invasive airway access includes surgical or precutaneous tracheostomy or cricothyrotomy.

(c) Alternative noninvasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

(d) Consider re-preparation of the patient for awake intubation or canceling surgery.

(e) Options for emergency noninvasive airway ventulation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

B

Figure 10-1, cont'd B, The revised (2003) ASA DAA. (**A** from American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for management of the difficult airway: A report. *Anesthesiology* 78:597–602, 1993; **B** from Practice Guidelines for the Management of the Difficult Airway: An updated report by the American Society of Anesthesiologists Task Force on the Management of the Difficult Airway. *Anesthesiology* 98:1269–1277, 2003.)

- Side view to determine the ability to assume the "sniffing" position (flexion of the neck on the chest and extension of the head on the neck) and to identify maxillary overbite
- Nostril patency
- Length and thickness of the neck

Although each risk factor individually has a rather low positive predictive value for difficult intubation, when combined these factors can provide a gestalt for DA management.

The findings of the airway history and physical examination may be useful in guiding the selection of specific diagnostic tests and consultation to further characterize the likelihood or nature of the anticipated airway difficulty.[2]

An "awake look" using direct laryngoscopy (after adequate preparation) may be performed to assess intubation difficulty further. If an adequate view is obtained, endotracheal intubation may be performed, followed immediately by administration of an intravenous induction agent.

Presence of a pathologic factor or a combination of anatomic factors (large tongue size, small mandibular space, or restricted atlanto-occipital extension) indicates that the airway should be secured while the patient remains awake (awake techniques).

B. Difficult Bag-Mask Ventilation

The risk for difficult mask ventilation (DMV) is the first issue addressed in the most recent version of the DAA. Evidence from the literature[3] suggests that the incidence of DMV is 5% in the general adult population, that the presence of DMV is associated with difficult intubation, and that DMV is not accurately predicted by anesthesiologists.

Five independent criteria predict DMV (age >55 years, body mass index >26 kg/m^2, lack of teeth, presence of mustache or beard, and history of snoring), and the presence of two such risk factors indicates a high likelihood of DMV.[3] It is important to keep these risk factors in mind, because some of them can be reversed. For example, DMV may possibly be preventable by shaving a patient's beard, leaving dentures in place during bag-mask ventilation (BMV), and performing a workup and treating for possible obstructive sleep apnea.

C. Awake Tracheal Intubation

Awake intubation is generally more time-consuming for the anesthesiologist and a more unpleasant experience for the patient. However, if a difficult intubation is anticipated, awake endotracheal intubation is indicated for three reasons: (1) the natural airway is better maintained in most patients when they are awake (i.e., "no bridges are burned"); (2) the orientation of upper airway structures is easier to identify in the awake patient (i.e., muscle tone is maintained to keep the base of the tongue, vallecula, epiglottis, larynx, esophagus, and posterior pharyngeal wall separated from one another)[4,5]; and (3) the larynx moves to a more anterior position with the induction of anesthesia and paralysis, which makes conventional intubation more difficult.[6]

Crucial to the success of endotracheal intubation while the patient is awake is proper preparation (see Chapter 11 for further details). Most intubation techniques work well in patients who are cooperative and whose larynx is nonreactive to physical stimuli. In general, the components of proper preparation for an awake intubation are the following:

- Psychological preparation (awake intubation proceeds more easily when the patient knows and agrees with what is going to happen)
- Appropriate monitoring (i.e., electrocardiography, noninvasive blood pressure monitoring, pulse oximetry, and capnography)
- Oxygen supplementation (e.g., nasal prongs, nasal cannula, suction channel of a fiberoptic bronchoscope [FOB], transtracheal catheter)[7-10]
- Vasoconstriction of the nasal mucous membranes (if performing nasal intubation)
- Administration of a drying agent
- Judicious sedation (keeping the patient in meaningful contact with the environment)
- Adequate airway topicalization (consider performance of bilateral laryngeal nerve blocks, blocking the lingual branch of the glossopharyngeal nerve and the superior laryngeal nerve)
- Aspiration prevention (see Chapter 12)
- Availability of appropriate airway equipment

Box 10-2 lists the suggested ASA guidelines for contents of a portable airway management cart.[11]

Box 10-2 Suggested Contents of the Portable Storage Unit for Difficult Airway Management

Important: The items listed here represent suggestions. The contents of the portable DA management cart should be customized to meet the specific needs, preferences, and skills of the practitioner and health care facility.

1. Rigid laryngoscope blades of alternative design and size from those routinely used; may include a rigid fiberoptic laryngoscope
2. Endotracheal tubes of assorted sizes
3. Endotracheal tube guides, such as semirigid stylets, ventilating tube changer, light wands, and forceps designed to manipulate the distal portion of the endotracheal tube
4. Laryngeal mask airways (LMAs) of assorted sizes; may include the Fastrach intubation LMA and the ProSeal LMA (LMA North America, San Diego, CA).
5. Fiberoptic intubation equipment
6. Retrograde intubation equipment
7. At least one device suitable for emergency nonsurgical airway ventilation, such as the esophageal-tracheal Combitube (Tyco Healthcare, Mansfield, MA), a hollow jet ventilation stylet, and a transtracheal jet ventilator
8. Equipment suitable for emergency surgical airway access (e.g., cricothyrotomy)
9. An exhaled carbon dioxide detector
10. A rigid ventilating bronchoscope

Box 10-3 Techniques for Difficult Airway Management

Important: This box lists commonly cited techniques in alphabetic order. It is not a comprehensive list, and no preference for a given technique or sequence of use is implied. Combinations of techniques may be employed. The techniques chosen by the practitioner depend on the specific needs, preferences, skills, and clinical constraints in the particular case.

Techniques for Difficult Intubation

Alternative laryngoscope blades
Awake intubation
Blind intubation (oral or nasal)
Fiberoptic intubation
Intubating stylet or tube changer
Invasive airway access
Laryngeal mask airway as an intubating conduit
Light wand
Retrograde intubation

Techniques for Difficult Ventilation

Esophageal-tracheal Combitube
Intratracheal jet stylet
Invasive airway access
Laryngeal mask airway
Oral and nasopharyngeal airways
Rigid ventilating bronchoscope
Transtracheal jet ventilation
Two-person mask ventilation

There are numerous methods to intubate the trachea or ventilate a patient (see Part Four of this text). Box 10-3 shows a list of the techniques contained within the ASA guidelines. The techniques chosen depend, in part, on the anticipated surgery, the condition of the patient, and the skills and preferences of the anesthesiologist. Based on recent evidence from the literature[12-14] considerations should also include the use of video laryngoscopy, despite the fact that this technique is not mentioned in the recent ASA algorithm, but likely will be included in future revisions of the guidelines.

Occasionally, awake intubation may fail owing to a lack of patient cooperation, equipment or operator limitations, or any combination thereof. An alternative route is chosen according to the precise cause of the failure:

- Surgery may be canceled (e.g., the patient needs further counseling, airway edema or trauma has resulted, different equipment or personnel is necessary).
- General anesthesia may be induced (the fundamental problem must be considered to be a lack of cooperation, and mask ventilation must be considered nonproblematic).
- Regional anesthesia may be considered (careful clinical judgment is required to balance risks and benefits; see Chapter 45).
- A surgical airway may be created (if the surgery is essential and general anesthesia is considered to be inappropriate until intubation is accomplished); this may be the best choice to secure the airway in patients with laryngeal or tracheal fracture or disruption, upper airway abscess, or combined mandibular-maxillary fractures.

D. Difficult Intubation in the Unconscious or Anesthetized Patient

Three typical scenarios require the anesthesiologist to manage a DA in an unconscious patient with a DA: (1) a comatose patient (e.g., secondary to trauma or intoxication); (2) a patient who absolutely refuses or cannot tolerate awake intubation (e.g., a child, a mentally retarded patient, an intoxicated and combative patient); and perhaps most commonly, (3) failure to recognize intubation difficulty on the preoperative evaluation. Of course, the preoperative airway evaluation is important even in the first and second situations, because the findings may dictate the choice of intubation technique. In all three of these situations, the patient may also have a full stomach.

All of the intubation techniques that are described for the awake patient[1,15] can be used in the unconscious or anesthetized patient without modification. However, direct laryngoscopy and fiberoptic laryngoscopy are likely to be more difficult in the paralyzed, anesthetized patient compared with the awake patient, because the larynx may move to a more anterior position, relative to other structures, as a result of relaxation of oral and pharyngeal muscles.[6] In addition and more importantly, orientation may be impaired because the upper airway structures can coalesce into a horizontal plane instead of separating out in a vertical plane.[4,5]

In the anesthetized patient whose trachea has proved difficult to intubate even with a video laryngoscope it is necessary to try to maintain gas exchange between intubation attempts (by mask ventilation) and, whenever possible, during intubation attempts through the use of (1) supplemental oxygen[11]; (2) positive-pressure ventilation via an anesthesia mask that incorporates a self-sealing diaphragm for entry of the FOB airway intubator (instead of the standard oropharyngeal airway)[5,16]; or (3) a laryngeal mask airway (LMA; LMA North America, Inc., San Diego, CA) as a conduit for the FOB (see Chapters 19 and 22).[17]

One must not continue with the same technique that did not work before. The amount of laryngeal edema and bleeding is likely to increase after every intubation attempt, particularly with the use of a laryngoscope or retraction blade. The most common scenario in the respiratory catastrophes in the ASA closed claims study was the development of progressive difficulty in ventilating by mask between persistent and prolonged failed intubation attempts. The final result was inability to ventilate by mask and provide gas exchange (see Chapter 55).[18]

For each additional attempt, consider modifications, such as improved sniffing position, external laryngeal manipulation, a new blade or new technique, or involvement of a much more experienced laryngoscopist. However, the number of intubation attempts should be limited and the following options should be considered: (1) awaken the patient and do the procedure another day; (2) continue anesthesia by mask or LMA ventilation; (3) perform a surgical airway (tracheostomy or cricothyrotomy) before the ability to ventilate the lungs by mask is lost (see Fig. 10-1).

If awakening the patient is not an option, for instance because surgery is emergent (e.g., cesarean section), and

ventilation can be maintained via mask or LMA, surgery may be conducted as needed. Nevertheless, in some cases, the airway must be secured by a surgical airway (e.g., thoracotomy, intracranial-head-neck cases, cases in which the patient is in the prone position). If regurgitation or vomiting occurs at any time during attempts at endotracheal intubation in an anesthetized patient,

- Immediately apply Trendelenburg position.
- Turn the head, and perhaps the body, to the left.
- Suction the mouth and pharynx with a large-bore suction device.
- Try endotracheal intubation while the patient is in the lateral position (the tongue may be more out of the way, but this position is unfamiliar to most anesthesiologists).
- If the endotracheal tube (ETT) has been passed into the esophagus, it may be left there; this may allow decompression of the stomach, and it identifies the esophagus during subsequent intubation attempts (the disadvantage is that it interferes with satisfactory mask seal).
- After securing the airway, consider tracheal suctioning, mechanical ventilation, positive end-expiratory pressure, fiberoptically guided saline lavage, steroids, antibiotics (see Chapter 35).

E. The "Cannot Intubate, Cannot Ventilate" Scenario

In rare cases, it is impossible either to ventilate the lungs of a patient by mask or to intubate the trachea. This "cannot intubate, cannot ventilate" (CICV) scenario is an immediately life-threatening situation, and an alternative ventilation procedure must be performed. Established rescue methods are the LMA, Combitube (Tyco Healthcare, Mansfield, MA), transtracheal jet ventilation (TTJV), rigid bronchoscope, and, ultimately, cricothyrotomy.

The development of the LMA was a major advance in the management of difficult intubation and difficult ventilation scenarios. The LMA is suggested as a ventilation device or a conduit for a flexible FOB,[19,20] and the Fastrach intubating LMA (ILMA) may also be utilized.[10,17,21] The LMA and the Combitube are supraglottic ventilatory devices and are not helpful if the airway obstruction is located at or below the glottic opening.[22] Use of the rigid bronchoscope may be required to establish a patent airway because it allows ventilation even past an obstruction at these levels. If immediately available, TTJV is relatively easy to perform and can be life-saving.[23] However, it carries significant risks such as subcutaneous emphysema (if the upper airway is not patent or the catheter is not entirely tracheal) and barotrauma (too forced ventilation or proximal airway obstruction)[24] The techniques mentioned can provide time until definitive airway management by tracheal intubation (via direct, fiberoptic, or retrograde technique) or by formal tracheostomy can be performed.[25,26] Future research will determine the role of the new rigid video laryngoscopes in the rescue of the "cannot intubate, cannot ventilate" scenario.

Ultimately, a cricothyrotomy may be necessary, but fewer than 50% of anesthesiologists feel competent to perform one.[27] Nevertheless, when one is faced with a failed airway, preparations for a surgical airway must begin immediately, and once the decision is made, it is essential to use an effective technique (see Chapters 30 and 31). Despite limited familiarity with the procedure, the risks of an invasive rescue technique must be weighed against the risks of hypoxic brain injury or death.[28]

F. Extubation of a Patient with a Difficult Airway

Extubation of the patient with a DA should be carefully assessed and performed. The anesthesiologist should develop a strategy for safe extubation of these patients, depending on the type of surgery, the condition of the patient, and the skills and preferences of the anesthesiologist. Additional considerations include the following:

- Awake extubation versus extubation before return of consciousness
- Clinical symptoms with the potential to impair ventilation (e.g., altered mental status, abnormal gas exchange, airway edema, inability to clear secretions, inadequate return of neuromuscular functions)
- Airway management plan if the patient is not able to maintain adequate ventilation
- Short-term use of a ventilating tube exchanger (TE) or jet stylet (can be used for ventilation and guided reintubation)

The ideal method of extubation of a patient with a DA is gradual, step by step, and reversible at any time. Extubation over a ventilating TE or jet stylet closely approximates this ideal.[16] The equipment that should be immediately available for the extubation of a DA includes that necessary for intubation of the DA (see Chapter 50).[29]

G. Follow-up Care of a Patient with a Difficult Airway

The presence and nature of the airway difficulty should be documented in the medical record. The intent of this documentation is to guide and facilitate the delivery of future care. Aspects of documentation that may prove helpful include the following:

- Description of the airway difficulties, which should distinguish between difficulties with mask ventilation and those with tracheal intubation
- Description of the airway management techniques used, which should indicate the beneficial or detrimental role of each technique in management of the DA
- Information given the patient (or responsible person) concerning the airway difficulty that was encountered. The intent of this communication is to assist the patient (or responsible person) in guiding and facilitating the delivery of future care. The information conveyed may include, for instance, the presence of a DA, the apparent reasons for the difficulty, and implications for future care.

The provider should also strongly consider dispensing or advising a Medic-Alert bracelet for the patient (see

Chapter 54). Finally, the anesthesiologist should evaluate and observe the patient for potential complications of DA management, such as airway edema, bleeding, tracheal or esophageal perforation, pneumothorax, and aspiration.

III. SUMMARY OF THE ASA ALGORITHM

Difficulty in managing the airway is the single most important cause of major anesthesia-related morbidity and mortality.

Successful management of a DA begins with recognition of the potential problem. All patients should be examined for their ability to open their mouth widely, the structures visible on mouth opening, the size of the mandibular space, and the ability to assume the sniffing position.

If there is a good possibility that intubation or ventilation by mask, or both, will be difficult, the airway should be secured while the patient is still awake rather than after induction of general anesthesia. For a successful awake intubation, it is essential that the patient and the provider be properly prepared.

When the patient is properly prepared, any one of a number of intubation techniques is likely to be successful. If the patient is already anesthetized or paralyzed and intubation is found to be difficult, many repeated forceful attempts at intubation should be avoided, because laryngeal edema and hemorrhage will progressively develop, and the ability to ventilate the lungs by mask may consequently be lost.

After several unsuccessful attempts at intubation, it may be best to awaken the patient; administer regional anesthesia, if appropriate (see Chapter 45); proceed with the case using mask or LMA ventilation; or perform a semielective tracheostomy. If the ability to ventilate by mask is lost and the patient's lungs cannot be ventilated, LMA ventilation should be instituted immediately. If LMA ventilation does not provide adequate gas exchange, either TTJV or a surgical airway should be instituted immediately.

Tracheal extubation of a patient with a DA over a jet stylet permits a controlled, gradual, withdrawal from the airway that is reversible in that ventilation and reintubation are possible at any time.

Four concepts emerge from the preceding discussion—four very important, take-home messages on the ASA DAA. These are presented in Box 10-4.

Box 10-4 ASA Difficult Airway Algorithm Take-Home Messages

1. If suspicious of trouble → Secure the airway awake
2. If you get into trouble → Awaken the patient
3. Have plans B and C immediately available and in place = think ahead
4. Intubation choices → Do what you do best

IV. PROBLEMS WITH THE ASA ALGORITHM AND LIKELY FUTURE DIRECTIONS

The strength of the ASA DAA is twofold. First, it is very thorough and complete with respect to the options available when an anesthesiologist encounters a DA. Second, it emphasizes the need for and importance of an organized approach to airway management.[30]

On the other hand, the algorithm has several deficiencies that diminish its application in clinical practice.

- Although it is intended to apply to all patients of all ages, there are certain populations of patients in which further considerations are necessary. Examples include pediatric patients (see Chapter 36), obstetric patients (see Chapter 37), nonfasted patients, and patients with obstruction at or below the level of the vocal cords.[31]
- The algorithm's clinical end point is successful intubation, but endotracheal intubation may not be necessary, and successful ventilation may suffice.
- The algorithm is fairly complex, allowing a wide choice of techniques at each stage, and its multiplicity of pathways may limit its clinical usefulness in guiding day-to-day practice.[32] Unlike the algorithm used in advanced life support (ACLS) guidelines, for example, the ASA DAA is not binary in nature.[33]
- Somewhat vague terminology is used in its definitions of difficult tracheal intubation and difficult laryngoscopy. Definitions of optimal-best attempts at conventional laryngoscopy, mask ventilation, and difficult laryngoscopy or intubation are important because they provide an end point at which the practitioner should stop using a particular approach (limiting risk) and move on to something that has a better chance of working (gaining benefit).
- The algorithm mentions ablation of spontaneous ventilation with muscle relaxants but does not discuss the great clinical management implications of muscle relaxants that have different durations of action.
- Although the algorithm advises confirmation of endotracheal intubation, the usefulness of capnography for this purpose is limited during cardiac arrest, which is not an uncommon consequence of the CICV scenario; the esophageal detector device is not similarly limited (see Chapter 32).
- The algorithm does not provide a definitive flow chart for extubation of the DA that incorporates the use of a device that can serve as a guide for expedited reintubation or ventilation, if necessary.
- The role of regional anesthesia in patients with a DA requires further clarification (see Chapter 45).
- The algorithm does not include the use of rigid video laryngoscopy which has dramatically changed the day-to-day clinical practice in recent years and has been shown to be able to rescue failed direct laryngoscopy, particularly in the DA.[12,13]

Several of the issues mentioned need more in-depth discussion, including the definition of difficult endotracheal intubation, the optimal-best attempt at laryngoscopy, the optimal-best attempt at mask ventilation, and the best muscle relaxant to use.

A. Terminology in the ASA Difficult Airway Algorithm

The original publications that introduced the ASA algorithm and provided basic terms that define a DA were relatively vague in their terminology[1]:

- *Difficult mask ventilation*: "It is *not* possible for the anesthesiologist to provide adequate face mask ventilation due to one or more of the following problems: inadequate mask seal, excessive gas leak or excessive resistance to the ingress or egress of gas."
- *Difficult laryngoscopy*: "Not being able to visualize any portion of the vocal cords after multiple attempts at conventional laryngoscopy."
- *Difficult intubation*: "When tracheal intubation requires multiple attempts in the presence or absence of tracheal pathology."
- *Failed intubation*: "Placement of the tracheal tube fails after multiple intubation attempts" (0.05% of surgical patients and 0.13% to 0.35% in obstetric patients).

These definitions do not identify a specific Cormack-Lehane grade to characterize larynx visibility, and they do not state a specific number of attempts; therefore, on both counts, they can be interpreted differently by individual practitioners. Also, there is no mention of adjuvants such as positioning and use of appropriate equipment to aid laryngoscopy, ventilation, and intubation. Such information would allow the anesthesiologist to proceed in a new direction at certain junctures, knowing that continuing the same maneuvers would accomplish diminishing returns.

In the same vein, it is important to define "attempt" in an airway management algorithm——for example, as physical placement and removal of the laryngoscope blade. Moreover, an ideal airway management algorithm should define and use the "optimal-best attempt" as the unit, because optimizing the conditions for the various maneuvers has clearly been shown to have a profound effect on successful intubation.

B. Definition of Optimal-Best Attempt at Conventional Laryngoscopy

Difficulty in performing endotracheal intubation is the end result of the difficulties that occurred during laryngoscopy, which depends on the operator's level of expertise, the patient's characteristics, and circumstances. The problem with multiple repeated attempts at conventional laryngoscopy is the creation of laryngeal edema and bleeding, which impair mask ventilation and subsequent endotracheal intubation attempts, thereby creating a CICV situation. Therefore, it is imperative that the anesthesiologist makes his or her optimal-best attempt at laryngoscopy as early as possible, under the best circumstances, which is usually the first or second attempt. If the optimal-best attempt fails twice, an alternative plan should be activated as the next step, so that no further risk is incurred from additional attempts without likely benefit.

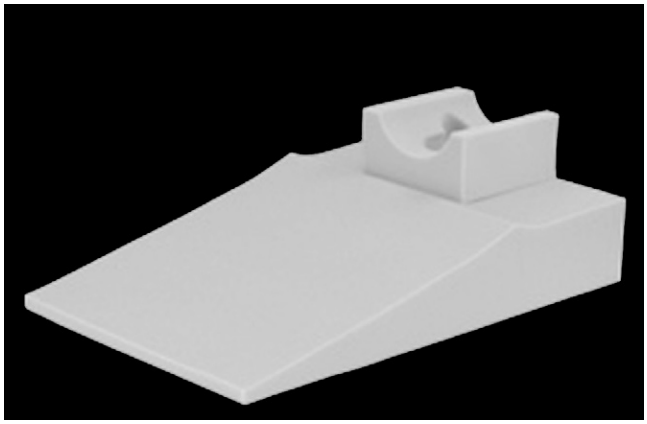

Figure 10-2 Troop Elevation Pillow with additional foam head rest. (Courtesy of Mercury Medical, Clearwater, FL.)

An *optimal-best attempt at conventional laryngoscopy* is defined as having the following characteristics[34,35]:

1. Performed by a reasonably proficient anesthesiologist with at least 3 years of experience (*Rationale:* If such an experienced anesthesiologist is having difficulty in visualizing the glottis, no other anesthesiologist or surgeon needs to or should attempt the same maneuver)
2. With the patient in the optimal "sniffing" position (*Rationale:* No attempt is wasted because the position was suboptimal; slight flexion of the neck on the head and severe extension of the head on the neck aligns the oral, pharyngeal, and laryngeal axes into a straight line; positioning devices are necessary in the obese patient [Fig. 10-2])
3. Using the appropriate type and length of blade (*Rationale:* Macintosh-type blades work best in patients with little upper airway room, and Miller-type blades are ideal for patients who have small mandibular space, anterior larynx, large incisors, or a long, floppy epiglottis). Based on most recent literature, a rigid video laryngoscope should be considered at least for the second attempt, if immediately available.
4. Using the appropriate blade length (*Rationale:* Patients' airways vary in size, and optimal fit of the blade to the airway allows the best possible pressure application to lift the epiglottis directly or indirectly)
5. Having a low threshold for using optimal external laryngeal manipulation (OELM) or backward upward rightward pressure (BURP) (Fig. 10-3) (*Rationale:* Both maneuvers can frequently improve the laryngoscopic view by at least one entire grade and should be an inherent part of laryngoscopy and an instinctive reflex response to a poor laryngoscopic view)

With this definition and no other confounding factors, an optimal-best attempt at laryngoscopy may be achieved on the first attempt, and no more than three attempts should be required (e.g., wrong blade, wrong length).

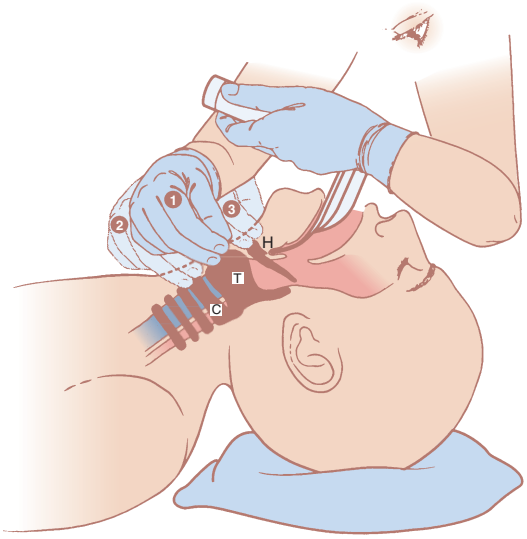

Figure 10-3 Determining optimal external manipulation (OELM) with the free (right) hand. OELM should be an inherent part of laryngoscopy and is performed when the laryngoscopic view is poor. Ninety percent of the time, the best view is obtained by pressing over the thyroid cartilage (*T,* hand position 1) or the cricoid cartilage (*C,* position 2); pressing over the hyoid bone (*H,* position 3) may also be effective.

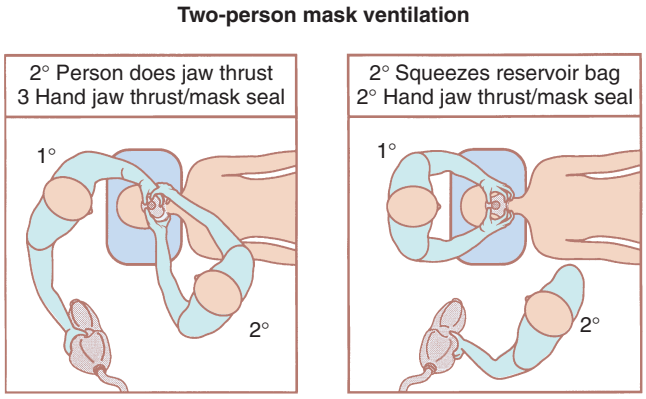

Figure 10-4 Optimal mask ventilation. *Left,* Two-person effort when second person knows how to perform jaw thrust; *right,* two-person effort when second person can only squeeze the reservoir bag.

C. Definition of Optimal-Best Attempt at Conventional Mask Ventilation

If the patient cannot be intubated, gas exchange is dependent on mask ventilation. If the patient cannot be ventilated by mask, a CICV situation exists, and immediate resuscitation maneuvers must be instituted. Because each of the acceptable responses to a CICV situation has its own risks, the decision to abandon mask ventilation should be made after the anesthesiologist has made an optimal-best attempt at mask ventilation.

An *optimal-best attempt at conventional mask ventilation* is defined as having the following characteristics[34,35]:

1. Performed by a reasonably proficient anesthesiologist with at least 3 years of experience (*Rationale:* as above)
2. With the patient in the optimal sniffing position (*Rationale:* as above)
3. Using two-person BMV with the most proficient anesthesiologist holding the mask and the less proficient anesthesiologist squeezing the bag (Fig. 10-4) (*Rationale:* Usually this leads to a far better mask seal, better jaw thrust, and therefore higher tidal volume than can be achieved with one person in a difficult-to-mask patient)
4. Using appropriately sized oropharyngeal or nasopharyngeal airway devices that have been inserted correctly (*Rationale:* This provides a canal for airflow through the soft tissue of the upper airway; establishes and improves tidal volume)

If mask ventilation is very poor or nonexistent, even with a vigorous two-person effort in the presence of large artificial airways, this constitutes a classic CICV scenario, and the team needs to start potentially life-saving plan B (see Fig. 10-1).

D. Options for the CICV Scenario

Both the LMA and the Combitube have been shown to work well to rescue airway emergencies.[17,36,37] The ASA DAA does not dictate the order of preference of these devices in the CICV situation, but the following considerations must be taken into account: (1) the anesthesiologist's own experience and level of comfort in the use of these methods, (2) the availability of these devices, (3) the type of airway obstruction (upper versus lower), and (4) the benefits and risks involved.

The ProSeal LMA usually forms a better seal than the LMA-Classic and provides improved protection against aspiration.[38-48] When properly positioned, the Combitube allows ventilation with a higher seal pressure than the LMA-Classic, protects against regurgitation,[49] and allows further attempts at intubation while the esophageal cuff protects the airway.[50] The Combitube has been successfully used in difficult intubation and CICV situations,[49,51-55] including ventilation failure with an LMA.[56]

Both the LMA and the Combitube are supraglottic ventilatory devices (Fig. 10-5). They cannot solve a truly glottic problem (e.g., spasm, massive edema, tumor, abscess) or a subglottic problem.[37] If an obstacle is suspected to exist in the glottic or subglottic area, the ventilatory mechanism (e.g., ETT, TTJV, rigid ventilating bronchoscope, surgical airway) needs to be positioned below the level of the lesion. The ASA DAA does not discriminate between the obstructed and the unobstructed airway, and this is a critical weakness of the algorithm.

E. Determinants of the Use of Muscle Relaxants for Difficult Airway Management

Muscle relaxants have different characteristics regarding time of onset and duration that significantly determine their advantages and disadvantages in the context of airway management (Table 10-2). The key elements in the choice of a nondepolarizing muscle relaxant are whether mask ventilation will be adequate and what rescue plan has been determined. For instance, with the induction of general anesthesia in an uncooperative

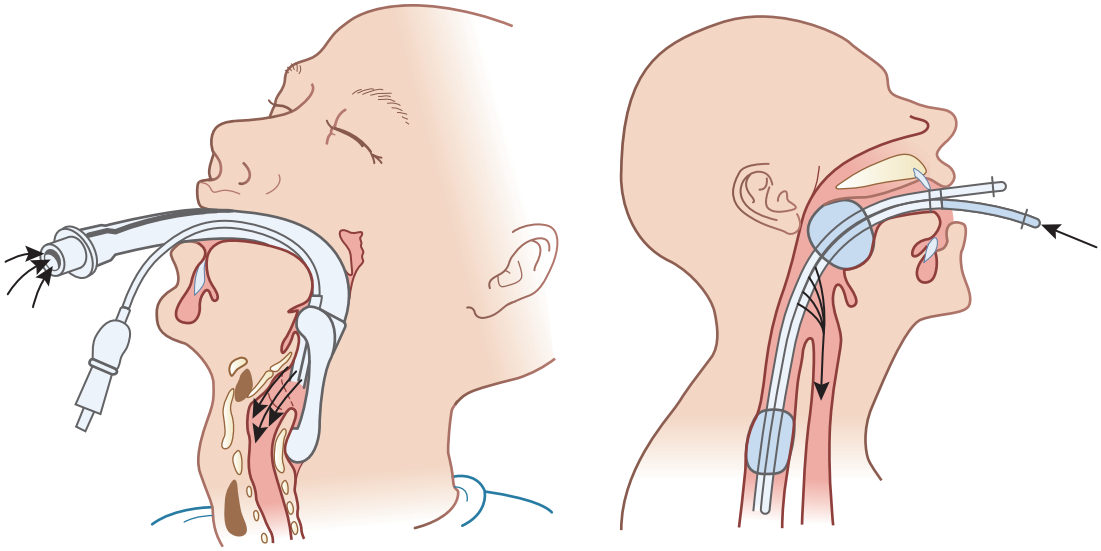

Figure 10-5 The laryngeal mask airway *(left)* and the Combitube *(right)* are supraglottic ventilatory devices.

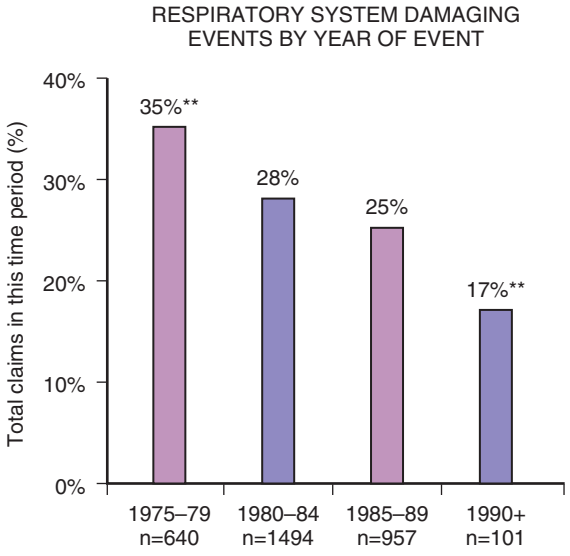
patient who has a DA, the anesthesiologist should consider the relative merits of preservation of spontaneous ventilation versus use of muscle relaxants. Alternatively, if a small dose of succinylcholine (0.5 to 0.75 mg/kg) is used, good intubating conditions can be achieved within 75 seconds for about 60 seconds, allowing an early-awaken option if the ETT cannot be placed. In contrast, use of succinylcholine during DA management may not be the best choice if mask ventilation is considered possible and the alternative plan of action is FOB.[5]

Moreover, endotracheal intubation can be successfully accomplished without the use of any muscle relaxant, and this option should be considered in certain situations.[57,58] Another consideration is that in most patients, prior administration of a small dose of a nondepolarizing neuromuscular blocker may slightly diminish the duration of action of succinylcholine,[59] and therefore the time to spontaneous recovery of airway reflexes may be shortened.

Experts are debating whether a second dose of succinylcholine should be provided during a cannot-intubate situation when the patient resumes spontaneous ventilation. We believe that this practice is appropriate if the chance of successful endotracheal intubation is high (i.e., a fairly good laryngoscopic grade at the initial attempt) and laryngoscopy is difficult because of incomplete paralysis. A second dose of succinylcholine may also be appropriate when mask ventilation is possible, the laryngoscopist is highly skilled, and a simple change in either the patient's position or the type of laryngoscope is necessary for final success. Glycopyrrolate at a dose of 0.2 to 0.4 mg should be administered in conjunction with the repeated dose of succinylcholine in order to prevent a bradycardic response.

F. Summary

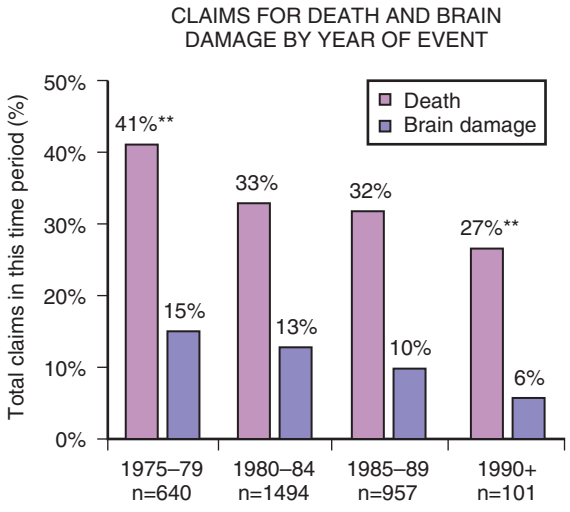
In summary, the ASA DAA has worked well over the past decade. In fact, there has been a very dramatic decrease (30% to 40%) in the number of respiratory-related malpractice lawsuits, brain damage, and deaths attributable to anesthesia since 1990 (Fig. 10-6).[60] However, a number of issues have emerged that indicate that the algorithm can be improved, as discussed earlier. Consideration of these issues should make the algorithm still more clinically specific and functional. Nonetheless, the DAA provides excellent guidelines for anesthesiologists in their clinical decision-making for patients with DAs. Successful management in these cases is key to reducing the risk of anesthesia-related morbidity and mortality.



V. INTRODUCTION OF A NEW COMPREHENSIVE AIRWAY ALGORITHM

Based on the reasoning presented to this point, currently available evidence from the literature, and a plethora of clinical experience, we created a new and comprehensive algorithm for airway management with the intent of

TABLE 10-2



Advantages and Disadvantages of Muscle Relaxants with Different Durations of Action

Muscle Relaxant	Advantages	Disadvantages
Succinylcholine	Permits the awaken option at the earliest time possible	A period of poor ventilation (spontaneous or with positive pressure) may occur as the drug wears off Does not permit a smooth transition to plan B (e.g., use of a fiberoptic bronchoscope) and so on
Nondepolarizing	Permits a smooth transition to plan B and so on, provided mask ventilation is adequate	Does not allow awaken option at an early time

** $P \leq .01$ between 1975 and 1990+ time periods; N = 3282
Claims for respiratory system damaging events as a proportion of all claims in the database for each 5-year time period.
Note: N does not equal the sum of n as there are some claims in the database prior to 1975 or no date is known.

A

**$P \leq .01$ between 1975 and 1990+ time periods; N = 3282
Claims for death and brain damage as a proportion of all claims in the database for each 5-year time period.

B

Figure 10-6 **A,** The incidence of respiratory system damaging events as a proportion of all claims in the database for each 5-year period ($N = 3282$). **$P \leq 0.01$ between 1975 and 1990+ time periods. **B,** Claims for death and brain damage as a proportion of all claims in the database for each 5-year time period ($N = 3282$). **$P \leq 0.01$. (In both **A** and **B,** N does not equal the sum of n because there are some claims in the database for which the date is before 1975 or unknown.) (From Cheney FW: Committee on Professional Liability: Overview. *ASA Newsletter* 58:7–10, 1994.)

improving patient safety during the perioperative period. This new airway algorithm includes several subalgorithms that address the various potential clinical scenarios and suggest clear procedures and readily available equipment to solve the problem.

Most recently we incorporated the use of video laryngoscopy into the new comprehensive airway algorithm based on new evidence that strongly supports its role either as primary device or as first rescue device during the management of a difficult airway.[12,13]

The *main algorithm* comprises all the necessary information for routine airway management. It is supplemented with four subalgorithms (A through D) that describe maneuvers and instruments necessary to solve various DA scenarios and are organized in an escalating manner according to the immediate threat of the respective scenario. In addition, a fifth subalgorithm (E) suggests a standardized approach for extubation of these patients.

- *Subalgorithm A* = cannot ventilate, cannot intubate (CICV)
- *Subalgorithm B* = can ventilate but cannot intubate via laryngoscopy
- *Subalgorithm* C = ventilation established through a subglottic airway, further management options
- *Subalgorithm D* = surgical airway management
- *Subalgorithm E* = extubation of a patient with a known or suspected DA

Extubation of these patients carries significant risks and requires a systematic approach. To our knowledge, this new airway algorithm is the only algorithm that provides a specific paradigm to address extubation of the patient with a DA.

A. The Main Algorithm

This algorithm (Fig. 10-7) is intended for and limited to elective surgery in the operating room and does not include airway trauma and crash intubations. As with the ASA algorithm, the crux of management of the DA lies in its recognition (Box 10-5). If difficulties are anticipated, surgery under regional anesthesia may be considered. However, there are anesthetic, surgical, and patient factors that may render the option of regional anesthesia for surgery inappropriate (Box 10-6). If regional anesthesia is considered appropriate and successful anesthesia is achieved, then surgery may proceed. However, if regional anesthesia fails, then the option for an awake airway technique or inhalation induction should be considered. Similarly, if regional anesthesia is not an appropriate option for surgery, then the performance of an awake intubation or inhalation induction is recommended.

The choice of awake versus asleep spontaneous ventilation depends on the experience of the anesthesiologist and the patient's level of cooperation. In general, the awake technique is the safest technique. However, in some patients (e.g., children; mentally retarded or incapacitated patients; aggressive, intoxicated, or delirious patients), an awake technique may not be possible. Additionally, in patients with cervical spine pathology who are at risk for neurologic injury, extreme caution should be exercised during an awake technique, and precautions should be undertaken to prevent any cervical movement.

Box 10-5 Individual Predictors of Difficult Airway Management*

History

Congenital/acquired syndromes, malignancy, trauma, or disease states affecting the airway (e.g., diabetes, obstructive sleep apnea)
Recent difficult intubation
Prior surgery involving the larynx or neck

Physical

Facial hair (beard or mustache)
Prominent protruding teeth or dentures
Micrognathia
Limited mouth opening <4 cm
Inability to protrude mandible
Mallampati class III or IV
Thyromental distance <6 cm
Hyomental distance <4 cm
Sternomental distance <12 cm
Limited range of motion of neck <80°
Neck circumference >60 cm
Body mass index (BMI) >30 kg/m^2
Upper airway obstruction
Presence of blood or vomitus in oropharynx
Tracheal deviation

*Includes predictors of difficult mask ventilation, difficult laryngoscopy, difficult intubation, and surgical airway.

Failure of an awake technique usually falls into three categories: oversedation, obscuration of vision (by blood or secretions), and technical difficulties. If the patient is oversedated, airway issues may become complicated. If optimal attempts at BMV are successful, then Pathway B may be followed. However, if optimal attempts at BMV fail, the anesthesiologist should quickly proceed to Pathway A. If difficulty occurs with any of the awake fiberoptic techniques as a result of blood, mucus, or secretions such that adequate visualization is not possible, a blind technique may be considered (see "Bloody Airways.") Additionally, more invasive techniques, such as a surgical airway or retrograde intubation may be performed.

1. The Nonpredicted Difficult Airway

Although projected difficulties with airway management may not be present, making an optimal-best attempt at ventilation and intubation is paramount. First, even the best airway assessment will not detect 100% of DAs, as is evident from the literature. Second, the optimal-best attempt allows the anesthesiologist to follow the algorithm quickly and appropriately. Third, when the first attempt is the optimal-best attempt, this allows a greater margin of safety before patient decompensation begins. Fourth, making the first attempt the optimal-best attempt minimizes repeated attempts at airway manipulation,

Box 10-6 Factors Influencing the Choice of Regional Anesthesia (RA) in Patients with a Difficult Airway (DA)

Anesthesiologist

Expertise in both RA and DA management
Enough preoperative time to perform RA technique
Appropriate RA technique for surgical procedure
Prepared for alternative plans for DA management

Patient

Informed consent
Cooperative and calm
Adequate intravenous access
Hemodynamically stable
Ability to tolerate sedation, if required
Ability to communicate with anesthesiologist throughout procedure
No history of claustrophobia
Dependable and reliable
Willing and able to supplement RA with local anesthetics
Cooperative with primary and alternative plans for DA management

Surgical Procedure

Nonemergent
Appropriate duration
Patient position allows airway access during surgery
Procedure can be interrupted
Limited or moderate blood loss

Support

Equipment, including a DA cart with specialized devices and airway adjuncts
Staff (additional experienced anesthesiologists and operating room nurses)

which may lead to greater morbidity. Therefore, the algorithm emphasizes proper positioning and the use of external laryngeal pressure even in patients without predicted airway difficulty.

After proper positioning, preoxygenation, and induction of general anesthesia, adequacy of BMV should be assessed. (An exception may be made for patients who undergo a rapid-sequence induction). If BMV is deemed adequate, intermediate- or long-acting muscle relaxants can be given to aid direct laryngoscopy. Liberal use of external laryngeal manipulation to optimize the laryngoscopist's view of the glottic opening is recommended. If BMV is inadequate despite optimal positioning and placement of an oropharyngeal or nasopharyngeal airway, then the "emergency situation," Pathway A, should be followed.

If direct laryngoscopy is successful, then surgery may proceed. However, if direct laryngoscopy is unsuccessful and BMV is adequate, then the "elective measures," Pathway B, should be followed. In performing a rapid-sequence induction, a short-acting muscle relaxant is usually given after induction of general anesthesia without checking BMV adequacy; therefore, if the anesthesiologist fails to intubate after induction, he or she should proceed directly to Pathway B and continue along the algorithm based on the initial laryngoscopic view.

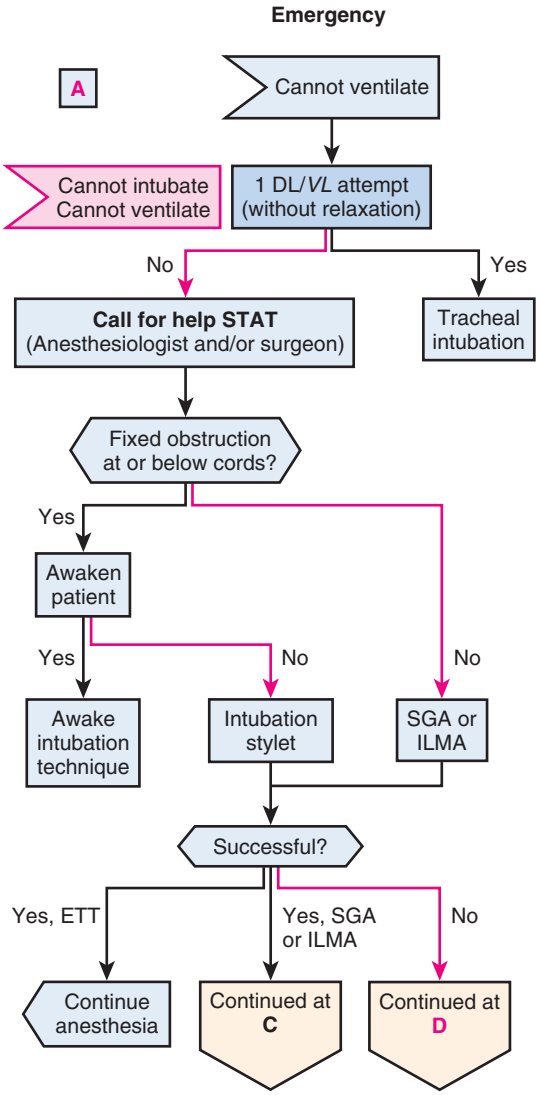

Figure 10-8 Pathway A: cannot ventilate, cannot intubate. *DL,* Direct laryngoscopy; *ETT,* endotracheal tube; *ILMA,* intubating laryngeal mask airway; *SGA,* supraglottic airway; *VL,* video laryngoscopy.

2. New Algorithm Pathways

a. PATHWAY A

The CICV scenario is an emergency situation in which the optimal-best attempt at ventilation and intubation has failed (Fig. 10-8). If muscle relaxants have not been administered, then one further laryngoscopy attempt, preferably using a video laryngoscope if available, or a conventional direct laryngoscope.[12,13] without muscle relaxation can be made (preferably by another experienced anesthesiologist). If tracheal intubation fails, assistance should be summoned. Thereafter, the algorithm alerts the anesthesiologist to the difference in airway management with respect to the possibility of a fixed obstruction (e.g., tumor, vocal cord paralysis) at or below the cords.

If the patient has no known obstruction at or below the cords, a supraglottic airway (SGA) may help establish ventilation. If ventilation is inadequate via an SGA, then a surgical airway (Pathway D) should be performed. If an

SGA does establish adequate ventilation, then Pathway C is recommended, in which endotracheal intubation is performed with an SGA in place.

If the patient has a known fixed obstruction at or below the cords, then use of an SGA would be inappropriate. Ventilation attempts with an SGA would most likely be unsuccessful. If awakening the patient is a valid option, an awake intubation technique should be performed. If awakening the patient is not an option, an intubating stylet in combination with a video laryngoscope or a rigid bronchoscope should be used. These devices, unlike an SGA, allow the provider to establish a conduit beyond the obstructed area. Again, if these approaches are unsuccessful, rapid progression to a surgical airway via Pathway D is advised.

b. PATHWAY B

Pathway B (Fig. 10-9) is derived from a situation where oxygenation and ventilation are adequate but a definitive airway has not been established. After calling for assistance and repeating laryngoscopy, using a video laryngoscope, if available, the management is divided based on the grade of glottic view. If a Cormack-Lehane grade 2B or 3 laryngoscopic view is visualized, an intubating stylet, or special laryngoscopic blade or video laryngoscope can be helpful. If this is successful, surgery may proceed. However, if the attempt is not successful, then adequacy of BMV must be reassessed, especially if BMV has not been attempted previously (i.e., rapid-sequence induction). If BMV is adequate, then further elective measures may be considered. If a grade 4 laryngoscopic view is observed, a retrograde technique may be considered or the anesthesiologist may proceed directly to SGA or ILMA, depending on the availability of equipment and the expertise of the anesthesiologist. However, if BMV is inadequate, then it is likely inappropriate to perform a fiberoptic intubation (FOI) or retrograde intubation. Instead, the anesthesiologist should recognize this as an emergent situation and immediately attempt SGA or ILMA.

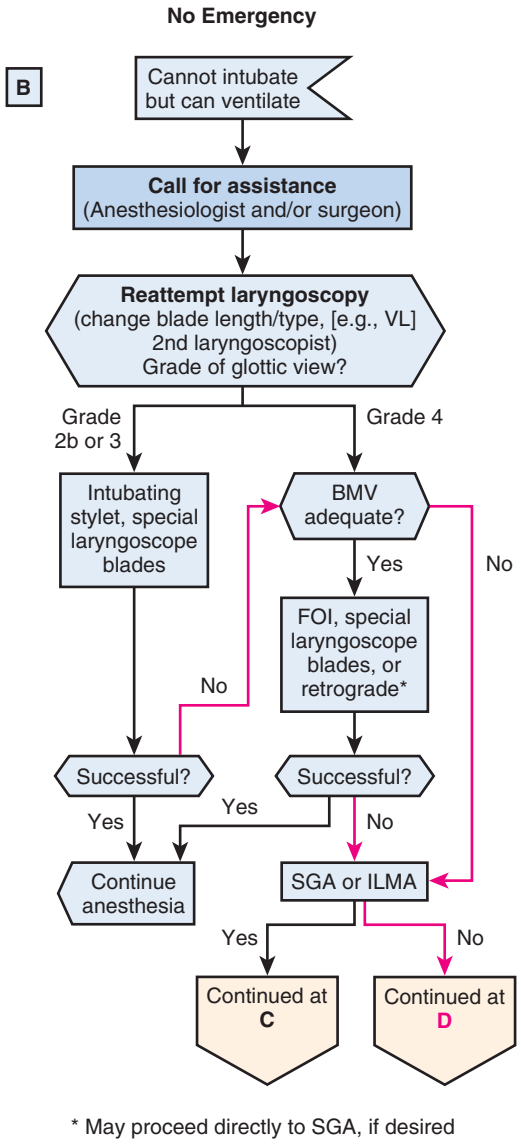

Figure 10-9 Pathway B: can ventilate, but cannot intubate via laryngoscopy. *FOI,* Fiberoptic intubation; *ILMA,* intubating laryngeal mask airway; *SGA,* supraglottic airway; *VL,* video laryngoscopy.

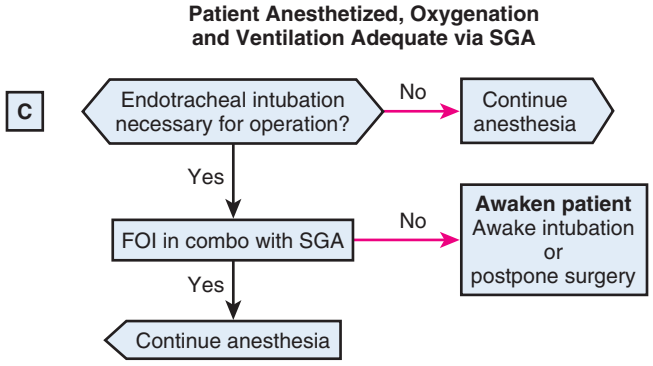
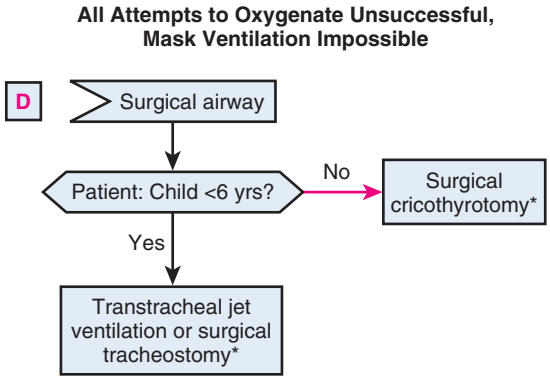
c. PATHWAY C

Pathway C (Fig. 10-10) represents a situation in which the patient is anesthetized and oxygenation and ventilation are adequate via an SGA. The decision to intubate depends on the answer to the question, "Is endotracheal intubation necessary for the surgical procedure?" If the answer is "No," surgery may continue with an SGA. If the answer is "Yes," FOI through the SGA with an Aintree Intubation Catheter (Cook Critical Care, Bloomington, IN) may be performed. Alternatively, if an ILMA or CTrach (LMA International, Singapore) was inserted as the SGA, intubation via these devices is appropriate. However, if intubation attempts fail, it would be appropriate to awaken the patient and perform an awake intubation.

d. PATHWAY D

In Pathway D (Fig. 10-11), all attempts to oxygenate and ventilate the patient have been unsuccessful. A surgical airway is crucial, and in patients older than 6 years of age, the cricothyroid membrane (CTM) remains the window to the airway. However, if the patient is younger than 6 years old, the CTM is not well developed, and TTJV or the performance of a surgical tracheostomy is advised.





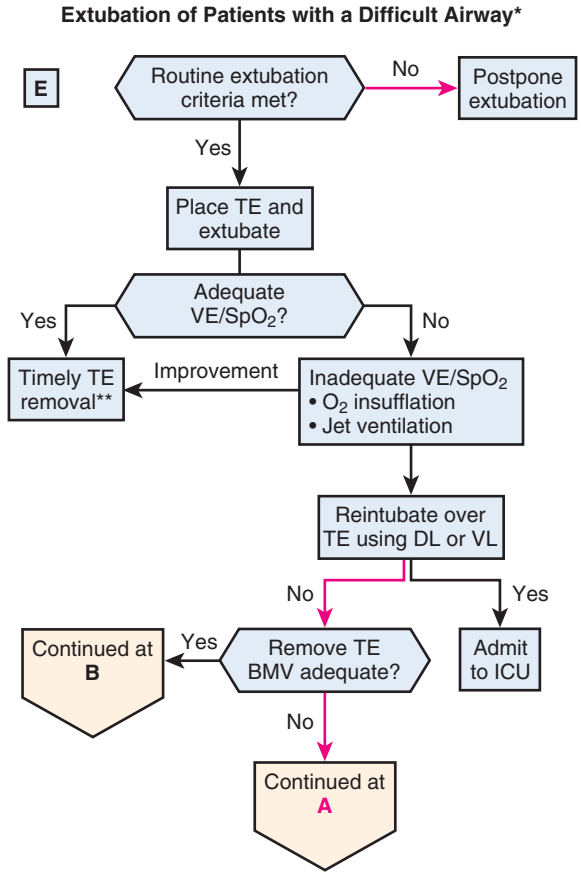


Figure 10-10 Pathway C: ventilation established through a subglottic airway, further management options. *FOI,* Fiberoptic intubation; *SGA,* supraglottic airway.

* Obtain surgeon's assistance, but without unnecessary delay, if possible

Figure 10-11 Pathway D: surgical airway management.

* Multiple attempts at DL or use of alternative device because of expected difficulty performing DL

**If there is no evidence of laryngeal edema or respiratory difficulty

Figure 10-12 Pathway E: a standardized approach for extubation of a patient with a known or suspected difficult airway. *BMV,* Bag-mask ventilation; *DL,* direct laryngoscopy; *ICU,* intensive care unit; *SpO_2,* peripheral oxygen saturation by pulse oximetry; *TE,* tube exchanger; *VE,* ventilation; *VL,* video laryngoscopy.

e. PATHWAY E

After a secure airway has been established, there will come a time when extubation is necessary. Consultants of the ASA Task Force on Management of the Difficult Airway,[5] as well as the Canadian Airway Focus Group, recommended a preformulated strategy for extubation of the DA.[61] Extubation strategies are discussed in detail in Chapter 50. Extubation strategies for the DA include, but are not limited to, bronchoscopic examination under general anesthesia through an SGA, substitution of an ETT with an SGA, and extubation over a TE.

Pathway E (Fig. 10-12) is an extubation algorithm in which a TE used is for patients who underwent multiple attempts at direct laryngoscopy or for whom alternative rescue devices were used. It should also be used for patients with a known or suspected DA who have undergone successful intubation. If the patient has met the extubation criteria (Box 10-7), one of the aforementioned extubation strategies can be used. A TE may be placed and the ETT removed over it, leaving the TE in the trachea. If ventilatory parameters and oxygenation are adequate, the TE can then be removed, provided there is no evidence of laryngeal edema or respiratory difficulty. The length of time for which these catheters are left in place is most commonly 30 to 60 minutes, although durations as long as 72 hours have been reported in the literature. Clinical judgment should be used according to the particular situation.

If minute ventilation, tidal volume, or oxygen saturation is inadequate, passive insufflation of oxygen or jet ventilation may improve the situation. If improvement does not occur or fails to be persistent, reintubation over a TE using direct laryngoscopy or video laryngoscopy is necessary. However, reintubation over the TE may not be successful for various reasons (e.g., kinked TE, wrong size TE, accidental TE removal, ETT catching at the arytenoids). If reintubation is unsuccessful, the TE should be removed and BMV adequacy ascertained. If BMV is adequate, the provider can attempt to establish an airway via Pathway B in a semielective fashion. If BMV is inadequate, the situation has become emergent, and one should continue rapidly down Pathway A.

B. Shortcomings of the New Airway Algorithm

This new comprehensive algorithm is designed for use by anesthesiologists dealing with patients who are to undergo surgery. It is not designed for crash intubations or disrupted airways. It is not an attempt to encompass all airway situations. Rather, it focuses on airway issues in the operating room and guides the practitioner more thoroughly than other algorithms do in that setting.

To simplify the flow of decision making, the situations of failed awake technique and bloody airways are covered in this chapter text rather than in the actual algorithm. Also, a bloody airway can occur at any time in any pathway.

Some airway management algorithms attempt to cover all airway scenarios. They may mention several devices (e.g., Combitube, lighted stylets, ILMA, fiberoptic techniques) without clarification as to their limitations and, more importantly, when they are not appropriate or contraindicated. Blind nasal intubation may be promoted without consideration of disrupted airways and the

Box 10-7 Routine Extubation Criteria

Awake, alert, able to follow commands
- Sustained eye opening for pediatric patients or patients unable to understand commands

Vital signs stable
- Blood pressure, pulse rate, temperature
- Respiratory rate ≤30 breaths/min
- O_2 saturation

Protective reflexes returned
- Gag
- Swallow
- Cough

Adequate reversal of neuromuscular blockade
- TOF 4/4, sustained tetany at 50 Hz
- Strong hand grip
- Unassisted head lift (>5 sec)

Arterial blood gases reasonable with Fio_2 40%
- pH > 7.30
- $Pao_2 \geq 60$ mm Hg
- $Paco_2 < 50$ mm Hg

Respiratory mechanics adequate
- Tidal volume > 5 mL/kg
- Vital capacity > 15 mL/kg
- NIF > –20 cm H_2O

For patients at risk for laryngeal edema, consider cuff leak test and airway inspection
- FOB evaluation

Fio_2, Fraction of inspired oxygen; *FOB,* fiberoptic bronchoscopy; *NIF,* negative inspiratory force; *$Paco_2$,* carbon dioxide tension; *Pao_2,* oxygen tension; *TOF,* train-of-four stimulation.

possibility of converting a clean airway to a bloody airway. Airway trauma may not be covered (and is also not covered in this algorithm). Finally, in other airway algorithms, the rapidly emerging and highly promising technology of video laryngoscopy is not considered and there is a lack of guidelines for using the SGA as a conduit for intubation.

C. Bloody Airways

If blood appears in the airway as a result of awake or asleep intubation techniques, direct visualization through a FOB may be technically challenging. In these cases, a video laryngoscopy plus high-volume oral-pharyngeal suction or a "blind" technique may be more useful. Three commonly used "blind" techniques are lightwand intubation, ILMA, and retrograde intubation.

D. Summary

The new comprehensive algorithm presented here streamlines the various airway management decisions, allowing the airway provider to focus on using rather than choosing airway devices. It emphasizes that the first attempt should be the best attempt and distinguishes supraglottic from nfraglottic obstruction. Also, it provides for the first time a systematic and evidence-based role for video laryngoscopy in management of the difficult airway. Additionally, it clearly delineates pathways for intubation via an SGA, for airway issues encountered during awake fiberoptic intubations, and for extubation. Furthermore, these guidelines address issues such as bloody airways, as well as exclusion criteria for regional and awake techniques. Although this algorithm does not include crash intubations and disrupted airways, it focuses on airway issues in the operating room in great detail.

VI. CONCLUSIONS

Specific strategies can be linked together to form more comprehensive treatment plans or algorithms. The first comprehensive airway algorithm was introduced by the ASA in 1993, and after two revisions this algorithm has now provided guidance for more than 15 years. Yet, several shortcomings of the ASA algorithm can be identified. In this chapter, we present a new comprehensive airway management algorithm that eliminates some of the critical weaknesses of the predecessor ASA DAA. Based on its binary character, similar to that of ACLS algorithms, this new airway algorithm provides immediate direction in critical situations.

As the practice of airway management becomes more advanced, anesthesiologists must become both knowledgeable and proficient in the use of various airway devices and techniques. Although no airway algorithm can be practiced in its entirety on a regular basis, anesthesiologists need to incorporate alternative devices and techniques into their daily practice so that they can develop the confidence and skill required for their successful use in the emergent setting. All of the equipment described should be available for regular practice, and a DA cart or portable unit should be located near every anesthetizing location. Finally, appropriate follow-up and communication should be performed so that future caretakers will not unwittingly reproduce the same experience and risk.

VII. CLINICAL PEARLS

- There is strong evidence demonstrating that successful airway management in the perioperative environment depends on the specific strategies used. The purpose of the American Society of Anesthesiologists Algorithm on the Management of the Difficult Airway (ASA DAA) is to facilitate management of the difficult airway (DA) and to reduce the likelihood of adverse outcomes.
- We are presenting a new comprehensive airway management algorithm that is organized like the BLS/ACLS algorithms in a binary fashion and eliminates some of the weaknesses of the ASA DAA.
- Based on most recent evidence, video laryngoscopy emerges as a superior alternative for primary management of the difficult airway and as an excellent rescue device for failed DL in such circumstance.
- Recognizing the potential for difficulty leads to proper mental and physical preparation and increases the chance of a good outcome.

- Airway evaluation should take into account any characteristics of the patient that could lead to difficulty in the performance of (1) bag-mask or supraglottic airway ventilation, (2) laryngoscopy, (3) intubation, or (4) a surgical airway.
- In the anesthetized patient whose trachea has proved to be difficult to intubate, it is necessary to try to maintain gas exchange by mask ventilation between intubation attempts and also during intubation attempts, whenever possible.
- The most common scenario in the respiratory catastrophes reported in the ASA closed claims study was the development of progressive difficulty in ventilating by mask between persistent and prolonged failed intubation attempts; the final result was inability to ventilate by mask or to provide gas exchange.
- The Laryngeal Mask Airway (LMA) and the Combitube are supraglottic ventilatory devices and are not helpful if the airway obstruction is located at or below the glottic opening.
- Extubation of the patient with a DA should be carefully assessed and performed, and the anesthesiologist should develop a strategy for safe extubation of these patients (depending on the type of surgery, the condition of the patient, and the skills and preferences of the anesthesiologist).
- The presence and nature of the airway difficulty should be documented in the medical record.
- If blood appears in the airway as a result of awake or asleep intubation techniques, direct visualization through a fiberoptic bronchoscope may be technically challenging. In such situations, a blind technique may be more useful.
- Although no airway algorithm can be practiced in its entirety on a regular basis, anesthesiologists need to incorporate alternative devices and techniques into their daily practice so that they can develop the confidence and skill required for their successful use in the emergent setting.

VIII. Clinical Pearls

I. BACKGROUND

A. History

He sat in bed supporting himself with stiffened arms; his head was thrown forward, and he had the distressed anxiety so characteristic of impending suffocation depicted on his countenance. His inspirations were crowing and laboured.… He complained of intense pain … and begged that something should be done for his relief.

The preceding quotation is from Dr. Macewen's 1880 account in the *British Medical Journal* of the first awake endotracheal intubation and describes a patient suffering from glottic edema. The patient underwent an awake manual endotracheal intubation using a metallic endotracheal tube (ETT). This technique was performed without benefit of anesthesia and without topical or regional blocks, sedatives, or analgesics. The ETT was kept in place with the patient in an awake state for 36 hours.[1] Although one may perceive this as brutal, Dr. Macewen was aware, more than 130 years ago, that despite the patient's discomfort, the safest method for securing the airway was to perform an awake intubation (AI) rather than to provide comfort at the risk of further compromising the airway. Since that time, there have been countless reports of successful AI for management of the difficult airway (DA).[2-5]

B. Awake Intubation in Management of the Difficult Airway

The DA is defined as "the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with mask ventilation, difficulty with endotracheal intubation, or both."[6,7] The American Society of Anesthesiologists (ASA) Closed Claims Study in 1990 found that 34% of injury cases in the Closed Claims database involved respiratory events.[8] The ASA formed the Task Force on Management of the Difficult Airway (TFMDA) in 1992 and sought to establish guidelines to facilitate the management of the DA and reduce the likelihood of adverse outcomes.[6] The task force constructed an algorithm to assist the anesthesiologist in devising a strategy for management of the DA (see Chapter 10). In this algorithm, one of the primary management choices for the anesthesiologist is the decision whether to perform AI or to attempt intubation after induction of general anesthesia.[6] In 2002, the practice guidelines were updated and the choice of AI remained an important component of the recommendations.[7]

C. Indications for Awake Intubation

The ASA algorithm stresses the concept that formulation of a strategy for intubation should include the feasibility of three basic options: (1) AI versus intubation after induction of general anesthesia, (2) noninvasive versus invasive (surgical) techniques, and (3) preservation versus ablation of spontaneous ventilation.[7] It is the opinion of most of the consultants of the TFMDA, and has been expressed in the literature,[2,3,5-7,9-11] that the safest method for a patient who requires endotracheal intubation and has a DA is for that patient to undergo AI for the following reasons:

1. Patency of the airway is maintained by upper pharyngeal muscle tone.
2. Spontaneous ventilation is maintained.
3. A patient who is awake and well topicalized is easier to intubate, because the larynx moves to a more anterior position after induction of anesthesia compared with the awake state.
4. The patient can still protect his or her airway from aspiration.
5. The patient is able to monitor his or her own neurologic symptoms (e.g., the patient with potential cervical pathology).[2,5,9]

General indications for AI are compiled in Box 11-1. There are no absolute contraindications to AI other than patient refusal, a patient who is unable to cooperate (such as a child, a mentally retarded patient, or an intoxicated, combative patient), or a patient with a documented true allergy to all local anesthetics.[9]

BOX 11-1 Indications for Awake Intubation

1. Previous history of difficult intubation
2. Anticipated difficult airway based on physical examination:
   - Small mouth opening
   - Receding mandible/micrognathia
   - Macroglossia
   - Short, muscular neck
   - Limited range of motion of the neck (rheumatoid arthritis, ankylosing spondylitis, prior cervical fusion)
   - Congenital airway anomalies
   - Morbid obesity
   - Pathology involving the airway (tracheomalacia)
   - Airway masses (malignancy of the tongue, tonsils, or larynx; large goiter; mediastinal mass)
   - Upper airway obstruction
3. Unstable cervical spine
4. Trauma to the face or upper airway
5. Anticipated difficult mask ventilation
6. Severe risk of aspiration
7. Severe hemodynamic instability
8. Respiratory failure

From Kopman AF, Wollman SB, Ross K, et al: Awake endotracheal intubation: A review of 267 cases. *Anesth Analg* 54:323–327, 1975; Thomas JL: Awake intubation: Indications, techniques and a review of 25 patients. *Anaesthesia* 24:28–35, 1969; Bailenson G, Turbin J, Berman R: Awake intubation: Indications and technique. *Anesth Prog* 14:272–278, 1967.

II. THE PREOPERATIVE VISIT

In this section, the focus is placed on elective patients, for whom there is time for airway evaluation and meaningful communication. In the setting of an emergency—which in itself should increase the probability of airway difficulty, especially with a patient in extremis[9]—the physician may not have time, nor can he or she be expected to be able to perform the detailed investigation of the airway described here.

A. Reviewing Old Charts

Whenever possible, previous anesthesia records should be examined because they may provide useful information.[7,12] Obviously, the most important records are those involving intubation, especially the most recent ones. Other records documenting ease of mask ventilation and tolerance of drugs are also valuable. One should be alert for evidence of reactions to local anesthetics and of apnea with minimal doses of opioids. Another reason for checking as many anesthesia records as possible, including the surgical procedure involved, is that the last intubation may have been routine but the three previous ones may have been difficult, or the last intubation may have been routine but the operation then performed may have rendered the airway difficult.

When reading through a chart, one should focus on four important features:

1. Degree of difficulty of the endotracheal intubation (the difficulty encountered and the method used)
2. Positioning of the patient during laryngoscopy (sniffing position, use of a ramp)
3. Equipment used (even if the intubation was performed routinely in one attempt, a Bullard blade or a fiberoptic bronchoscope [FOB], neither of which requires alignment of the three axes, may have been used)

TABLE 11-1
Incidence of Recall among Patients Undergoing Awake Intubation (AI)

Reference	Number of AIs	Complete Amnesia	Partial Recall	Unpleasant Memories
Kopman, et al[2]	249	213	19	17
Thomas[5]	25	6	14	5
Mongan & Culling[17]	40	25	5	0
Ovassapian, et al[18]	129	89	37	3
Total	443	343 (77%)	75 (17%)	25 (6%)

4. Whether the technique that was used previously is a familiar one (one should not attempt to learn a new technique on a DA)

After the medical records have been reviewed, the preoperative interview should address the possibility of events that may have occurred since the last anesthesia, such as weight gain, laryngeal stenosis from previous airway intervention, facial cosmetic surgery (e.g., chin implants), worsening temporomandibular joint disorder, or worsening rheumatoid arthritis.

B. The Patient Interview

Dorland's Medical Dictionary defines "empathy" as the intellectual and emotional awareness and understanding of another person's thoughts, feelings, and behaviors, even those that are distressing and disturbing. Although the anesthesiologist may participate in 1000 operations per year, few patients undergo more than five in a lifetime.[13] The patient's perception of empathy from the physician is the cornerstone of the patient's acceptance of an AI. Empathy helps the interviewer establish effective communication, which is important for accurate diagnosis and management.[14] Two facets of medical education limit the clinician's development of empathy: the traditional format of interviewing training and the social ethos of medical training and medical practice, which stresses clinical detachment.[14,15] With empathy and the ability to communicate it, the physician can perform the interview in a more patient-oriented rather than disease-oriented fashion, resulting in better data gathering and better patient compliance.[16]

After the anesthesia practitioner has made the decision that AI is necessary, communication with the patient and psychological preparation is of the utmost importance to maximize the odds for a successful AI.[9] One should in a careful, unhurried manner describe to the patient conventional intubation contrasted with AI. Focusing on the fact that the former is easier and less time-consuming but that the latter is safer in light of the patient's own anatomy or condition, one must communicate to the patient that the knowledgeable, caring physician is willing to take extra measures to ensure the patient's safety. Recommendations should be presented to the patient with conviction but at the same time allowing the patient the option of the conventional method of intubation as a last resort.[10]

Complications of AI should also be presented, including local anesthetic toxicity, airway trauma, discomfort, recall, and failure to secure the airway. Patients' recall after AI using different methods of sedation, analgesia, or local anesthetics has not been studied in a controlled fashion. Although episodes of explicit awareness during general anesthesia are rare, the incidence of recall during AI with minimal levels of sedation is likely to be higher.[13] In a review of 443 cases of AI (four studies) in which various combinations of sedation and analgesia were used (Table 11-1), a mean of 17% of the patients had partial recall and 6% had recall with unpleasant memories.[2,5,17,18]

If a patient refuses AI, the anesthesiologist may discuss the case with the primary care physician or the surgeon, or both, in order to recruit their help to convince the patient of the importance of cooperation. If this and subsequent discussion with the patient are unsuccessful, the anesthesiologist should document these efforts in the chart.

III. PREOPERATIVE PREPARATIONS

The preparation of the patient for AI begins, as discussed, with the patient interview, followed by appropriate premedication (discussed later). Additional preparation for AI includes assembling the necessary equipment and arranging in advance for needed assistance.

A. Transport

The acuteness and urgency of the case must be considered when arranging transport to the operating room (OR). In some cases, the airway needs to be secured at once (e.g., the patient in extremis who warrants a bedside emergency airway procedure). In other cases, there is an urgent need for intubation but with sufficient time to transport the patient to the OR with supplemental oxygen (O_2) and appropriate monitors (electrocardiogram [ECG], pulse oximeter, and noninvasive blood pressure monitoring), accompanied by the anesthesiologist, surgeon, or both. Finally, there may be no requirement for immediate attention, and the patient can be transported routinely to the OR. In the elective scenario, supplemental O_2 should be provided, if appropriate (high-dose O_2 may be detrimental in some patients, such as those who rely on hypoxic respiratory drive),[13] and position should be considered (e.g., the patient who is morbidly obese may experience dramatic physiologic changes when supine and should be transported in a wheelchair or on a gurney in a semirecumbent position.).[19,20]

B. Staff

According to the TFMDA guidelines, there should be "at least one additional individual who is immediately available to serve as an assistant in difficult airway management."[7] Whenever possible, it is preferable to have a second member of the anesthesia care team who can assist in the monitoring, ventilation, and pharmacotherapy of the patient, as well as providing an extra set of hands during fiberoptic intubation (FOI). For patients in extremis and those who refuse AI, a surgeon trained in performing a surgical airway should be available with a tracheostomy/cricothyrotomy tray, ready to perform an emergency surgical airway, if necessary.

C. Monitors

During AI, the routine use of ECG, pulse oximetry, noninvasive blood pressure monitoring, and capnography is required as part of standard basic intraoperative monitoring. Depending on the complexity of the surgery and the patient's condition, invasive hemodynamic monitoring (i.e., arterial line) may need to be placed before AI. Indications for this procedure include hemodynamic instability, severe ischemic or valvular heart disease, and a patient for whom hypertension and tachycardia are potentially dangerous (e.g., the patient with aortic dissection or intracerebral aneurysm).

D. Supplemental Oxygen

Administration of supplemental O_2 should be considered throughout the process of DA management.[7] Arterial hypoxemia has been well documented during bronchoscopy, with an average decrease in arterial oxygen tension (PaO_2) of 20 to 30 mm Hg in patients breathing room air, and has been associated with cardiac dysrhythmias.[21] In addition, sedation administered to supplement topicalization for AI may result in unintended respiratory depression or apnea.

Studies have shown that either traditional preoxygenation (≥3 minutes of tidal volume [V_T] ventilation) or fast-track preoxygenation (i.e., four vital-capacity breaths in 30 seconds) is effective in delaying arterial desaturation during subsequent apnea.[7] Daos and colleagues showed that the use of supplemental O_2 delayed circulatory arrest resulting from local anesthetic toxic effects in animals.[22]

In the interest of improving patient safety, therefore, adequate preoxygenation and the use of supplemental O_2 throughout airway management (including sedation, topicalization, intubation, and extubation) is encouraged in all patients undergoing AI.[7]

In addition to the standard methods of supplemental O_2 delivery (nasal cannula or face mask), other opportunities include, but are not limited to, delivering O_2 through the suction port of a flexible fiberoptic bronchoscope (FFB),[9] delivering O_2 through an atomizer or nebulizer during topicalization, and elective transtracheal jet ventilation (TTJV) in a patient in extremis.[9,23,24]

BOX 11-2 Suggested Contents of the Portable Unit for Difficult Airway Management

1. Rigid laryngoscope blades of alternative designs and sizes from those routinely used; this may include a rigid fiberoptic laryngoscope
2. Endotracheal tubes (ETTs) of assorted sizes and styles, such as the Parker FlexTip tube (Parker Medical, Highlands Ranch, CO) or the Endotrol tube (Covidien-Nellcor, Boulder, CO)
3. ETT guides, such as semirigid stylets, ventilating tube changer, light wands, and forceps designed to manipulate the distal portion of the ETT
4. Laryngeal mask airways of assorted sizes and styles, such as the intubating laryngeal mask airway and the LMA-Proseal (LMA North America, Inc., San Diego, CA)
5. Fiberoptic intubation equipment
6. Retrograde intubation equipment
7. At least one device for emergency nonsurgical airway ventilation, such as a transtracheal jet ventilation stylet or the esophageal-tracheal Combitube (Kendall-Sheridan Catheter Corporation, Argyle, NY)
8. Equipment suitable for emergency surgical airway access (e.g., cricothyrotomy)
9. An exhaled CO_2 detector
10. Pulse oximetry unit

The items listed in this table represent suggestions. The contents of the portable storage unit should be customized to meet the specific needs, preferences, and skills of the practitioner and the health care facility.

Modified from Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for management of the difficult airway. *Anesthesiology* 98:1269–1277, 2003.

E. Airway Equipment

Consultants of the TFMDA strongly agreed that "preparatory efforts enhance success and minimize risk to the patient" (i.e., lead to fewer adverse outcomes).[7] The concept of preassembled carts for emergency situations is not new; examples include "crash carts" for cardiac arrest and malignant hyperthermia carts. The task force recommends that every anesthetizing location should have readily available a portable storage unit that contains specialized equipment for DA management. Suggested contents of this portable unit are listed in Box 11-2.

There are many techniques that can be used to secure the airway in the awake patient. Direct laryngoscopy, video laryngoscopy, intubating laryngeal mask airways (iLMAs), FFB, rigid fiberoptic laryngoscopy, retrograde intubation, lighted stylets, and blind nasal intubation have all been used successfully to perform AI.[2,25-30] No matter which technique is selected, all of the necessary equipment should be prepared ahead of time and readily available when needed. The practitioner should also have several backup modalities in mind, and the required equipment available, in case the initial technique used is ineffective.

TABLE 11-2
Pharmacologic Characteristics of Anticholinergic Drugs

Drug	Tachycardia	Antisialagogue Effect	Sedation
Atropine	+++	++	+
Glycopyrrolate	++	+++	0
Scopolamine	+	+++	+++

0, No effect; +, minimal effect; ++, moderate effect; +++, marked effect.

IV. PREMEDICATION AND SEDATION

Once the preoperative visit is concluded and the patient has agreed to proceed with AI, premedication is commonly employed to alleviate anxiety, provide a clear and dry airway, protect against the risk of aspiration, and enable adequate topicalization of the airway. The agents most commonly used in the preparation for AI include antisialagogues, mucosal vasoconstrictors, aspiration prophylaxis agents, and sedatives/hypnotics.

A. Antisialagogues

One of the most important goals of premedication for AI is drying of the airway. Secretions can obscure the view of the glottis, especially when FFB is used. In addition, secretions can prevent local anesthetics from reaching intended areas, resulting in failed sensory blockade, or they can wash away and dilute local anesthetics, diminishing their potency and duration of action.

The medications most often used for their antisialagogic properties are the anticholinergics.[31] These drugs inhibit salivary and bronchial secretions by their antimuscarinic effects. Because they only prevent formation of new secretions and do not eliminate secretions that are already present, anticholinergics should be administered at least 30 minutes before topicalization. The anticholinergics used in clinical practice are atropine, glycopyrrolate, and scopolamine. A summary of their pharmacologic properties is presented in Table 11-2.

1. Atropine

Atropine (0.4 to 0.6 mg IV or IM) has a rapid onset after intravenous (IV) administration of 1 minute; the onset after intramuscular (IM) dosing is 15 to 20 minutes. Atropine produces only a mild antisialagogic effect, but it causes significant tachycardia because of its potent vagolytic effects. As such, it is not an ideal drug for use in drying the airway. As a tertiary amine, it easily crosses the blood-brain barrier and causes mild sedation. It may occasionally cause delirium, especially in elderly patients.

2. Glycopyrrolate

Glycopyrrolate (0.2 to 0.3 mg IV or IM) has an onset after IV dosing of 1 to 2 minutes; the onset after IM dosing is 20 to 30 minutes. The duration of its vagolytic effect after IV dosing is 2 to 4 hours; its antisialagogic effect lasts longer. Glycopyrrolate is devoid of central nervous system effects because its quaternary amine structure prevents passage through the blood-brain barrier. Its pharmacologic profile makes it the drug of choice as a premedicant for AI.

3. Scopolamine

Scopolamine (0.4 mg IV or IM) has an onset of 5 to 10 minutes after IV dosing and 30 to 60 minutes after IM. The duration of action is about 2 hours after IV dosing and 4 to 6 hours after IM dosing. In addition to being a very effective antisialagogue, scopolamine has very potent central nervous system effects, with sedative and amnestic properties. In some patients, however, this may lead to restlessness, delirium, and difficulty waking after short procedures. Because it is the least vagolytic of the anticholinergics in clinical use, it may be the drug of choice for patients in whom tachycardia is contraindicated.

B. Nasal Mucosal Vasoconstrictors

The nasal mucosa and nasopharynx are highly vascular. When a patient requires nasal AI, adequate vasoconstriction is essential, because bleeding can make FOI extremely difficult. One agent commonly used for this purpose is 4% cocaine, which has vasoconstrictive as well as local anesthetic effects (see later discussion). An alternative to cocaine is a 3:1 mixture of 4% lidocaine and 1% phenylephrine, which yields a solution of 3% lidocaine with 0.25% phenylephrine.[32] When these agents are applied with cotton swabs or pledgets to the nasal area, adequate anesthesia and vasoconstriction can be achieved in 10 to 15 minutes, facilitating nasal AI. Alternatively, vasoconstrictive nose sprays may be administered to the patient before local anesthetic topicalization. Phenylephrine 0.5% and oxymetazoline 0.05% sprays are available. They should be administered 15 minutes before attempted nasal intubation.

C. Aspiration Prophylaxis

A percentage of patients requiring AI may need prophylaxis against aspiration pneumonitis because of the presence of risk factors such as a full stomach, symptomatic gastroesophageal reflux disease, hiatal hernia, presence of a nasogastric tube, morbid obesity, diabetic gastroparesis, or pregnancy.[33,34]

Preoperative administration of a nonparticulate antacid, such as sodium citrate, provides effective buffering of gastric acid pH.[35] Total gastric volume is increased, but this effect is offset by an increase in the pH of gastric fluid so that, if aspiration occurs, morbidity and mortality are significantly lower.[36] One disadvantage of sodium citrate is the potential to cause emesis due to its unpleasant taste.

1. Histamine Receptor Blockers

Histamine (H_2) receptor blockers are selective and competitive antagonists that block secretion of hydrogen ion

(H^+) by gastric parietal cells and also decrease the secretion of gastric fluid. With IV administration of cimetidine 300 mg, famotidine 20 mg, or ranitidine 50 mg, peak effects are achieved within 30 to 60 minutes, increasing gastric pH and decreasing gastric volume.[37,38] Of the three, ranitidine is probably the drug of choice because it has fewer adverse effects, greater efficacy, and a longer duration of action.[39,40]

2. Proton Pump Inhibitors

Proton pump inhibitors (PPIs), such as pantoprazole and omeprazole, have not been shown to be as effective as H_2 blockers at increasing gastric pH and decreasing gastric volume.[41,42] PPIs may have a role in aspiration prophylaxis for the patient on chronic H_2 blocker therapy.[43]

3. Metoclopramide

Metoclopramide is a dopamine antagonist that stimulates motility of the upper gastrointestinal tract and increases lower esophageal sphincter tone. The net effect is accelerated gastric emptying with no effect on gastric pH. The standard adult dose is 10 mg IV. Metoclopramide can precipitate extrapyramidal symptoms and should be avoided in patients with Parkinson's disease.[34] For patients at high risk for aspiration, antacids, H_2 blockers, and metoclopramide may be used alone or in combination.

D. Sedatives/Hypnotics

Depending on the clinical circumstance, IV sedation may be useful in allowing the patient to tolerate AI by providing anxiolysis, amnesia, and analgesia. Benzodiazepines, opioids, hypnotics, α_2-agonists, and neuroleptics can be used alone or in combination.[25] It is important that these agents be carefully titrated to effect, because oversedation can render a patient uncooperative and make AI more difficult.[9] Spontaneous respiration with adequate oxygenation and ventilation should always be maintained.[25] Care should be taken in the presence of critical airway obstruction, because awake muscle tone is sometimes necessary in these patients to maintain airway patency.[44] Avoidance of oversedation is also important in the patient with a full stomach, because an awake patient can protect his or her own airway in the chance of regurgitation.[9]

1. Benzodiazepines

Benzodiazepines, via their action at the γ-aminobutyric acid (GABA)–benzodiazepine receptor complex, have hypnotic, sedative, anxiolytic, and amnestic properties.[45] They have also been shown to depress upper airway reflex sensitivity,[46] a property that is desirable for AI. Benzodiazepines are frequently used to achieve sedation for AI in combination with opioids,[47] and they are used for their amnestic and anxiolytic effects when other sedatives (e.g., dexmedetomidine, ketamine, remifentanil) are chosen as the primary agent.[48,49] Three benzodiazepine receptor agonists are commonly used in anesthesia practice: midazolam, diazepam, and lorazepam.[45]

a. MIDAZOLAM

Because of its more rapid onset and relatively short duration, midazolam is the most commonly used agent. Sedation with midazolam is achieved with doses of 0.5 to 1 mg IV repeated until the desired level of sedation is achieved. The IM dose is 0.07 to 0.1 mg/kg. Onset is rapid, with peak effect usually achieved within 2 to 3 minutes of IV administration. The duration of action is 20 to 30 minutes, with termination of effect primarily a result of redistribution. Although recovery is rapid, the elimination half-life is 1.7 to 3.6 hours, with increases noted in patients with cirrhosis, congestive heart failure, or morbid obesity; in the elderly; and in patients with renal failure. It is extensively metabolized by the liver and renally eliminated as glucuronide conjugates.[45,50]

b. DIAZEPAM AND LORAZEPAM

Diazepam has a slightly slower onset and longer duration of action than midazolam and has been shown to be a less potent amnestic.[45,50,51] It can cause pain on IV injection and has the added risk of thrombophlebitis.[25] Lorazepam provides the most profound sedating and amnestic properties; however, it is more difficult to use, because these effects are slower in onset and longer lasting than with either midazolam or diazepam.[25,45]

c. PRECAUTIONS

Care must be used when using benzodiazepines in combination with other sedative drugs. The pharmacologic effects of benzodiazepines are augmented synergistically by other medications used for sedation, including opioids and α_2-agonists.[52] Propofol has been shown to increase the plasma concentration of midazolam by decreasing distribution and clearance.[53] Systemic absorption of local anesthetics used for airway topicalization may also lead to potentiation of the sedative/hypnotic effects of midazolam.[54]

The primary adverse effect of oversedation with benzodiazepines is respiratory depression, which may lead to hypoxemia or apnea.[45] Flumazenil, a specific benzodiazepine antagonist, may be used to reverse the sedative and respiratory effects of benzodiazepines if a patient becomes too heavily sedated. It is given in incremental IV doses of 0.2 mg, repeated as needed to a maximum dose of 3 mg. Because it has a half-life of 0.7 to 1.8 hours, resedation can be a problem if flumazenil is being used to reverse high doses or longer-acting benzodiazepines, and patients should be monitored carefully in those circumstances. Flumazenil is generally safe and devoid of major side effects.[55,56]

2. Opioids

Opioids, by way of their agonist effect on opioid receptors in the brain and spinal cord, provide analgesia, depress airway reflexes, and prevent hyperventilation associated with pain or anxiety. These properties make them a useful addition to the sedating regimen for AI. Although any opioid receptor agonist could theoretically be used for this purpose, the synthetic phenylpiperidine class of opioids—fentanyl, sufentanil, alfentanil, and remifentanil—are best suited to the task. These drugs are particularly useful due to their rapid onset, relatively short duration of action, and ease of titration.[57]

a. FENTANYL

Analgesic doses range from 0.5 to 2 μg/kg IV. Onset is rapid, within 2 to 3 minutes. Duration of a single bolus dose is roughly 30 to 60 minutes. The duration is relatively short because fentanyl is redistributed to a large peripheral compartment rather than rapidly eliminated. Hence, the duration of effect after cessation of a prolonged infusion is markedly longer, due to redistribution to the central compartment from the peripheral compartment. Fentanyl is widely used in anesthesia practice, and it seems to be the most commonly used opioid for AI.[47,58]

b. SUFENTANIL

Sufentanil is 7 to 10 times more potent than fentanyl and has a similar pharmacokinetic profile after a single bolus dose. The primary difference is a significantly faster recovery, compared with fentanyl, after prolonged infusion.[59] Sedative doses are 5 to 20 μg IV in adult patients. Its use in combination with midazolam and droperidol for AI has been reported.[60]

c. ALFENTANIL

Compared with fentanyl and sufentanil, alfentanil has an even quicker onset (1.5 to 2 minutes). It is approximately 1/70 as potent as fentanyl; however, because of rapid plasma to effect-site equilibration, comparatively smaller doses are needed to achieve a similar peak effect. Because smaller doses are needed relative to its potency, recovery from a single bolus of alfentanil is faster than with the other agents of this class, potentially making alfentanil the drug of choice when a transient peak effect after a single bolus is desired, as in AI.[59] Sedative doses range from 10 to 30 μg/kg IV.[57] In patients premedicated with oral diazepam, alfentanil 20 μg/kg IV significantly improved fiberoscopic conditions and attenuated the hemodynamic effects of awake nasal FOI. Moderate respiratory depression was noted without overt apnea or hypoxia.[61]

d. REMIFENTANIL

Remifentanil is an ultrashort-acting opioid that is unique compared with the other short-acting agents in that it is metabolized by nonspecific plasma esterases, with a half-life of 3 minutes. It undergoes no redistribution and therefore has no context sensitivity. Its potency approximates that of fentanyl.[62] Several studies have shown the effectiveness and safety of remifentanil sedation for AI as a single agent,[48,49,63] as well as in combination with midazolam or propofol.[64-68] Dosing is usually weight-based.

Several different remifentanil dosing strategies have been described in the literature for AI, with infusion rates ranging between 0.06 and 0.5 μg/kg/min, with or without an initial bolus of 0.5 to 1.5 μg/kg.[48,63,64,67] Studies using target-controlled infusions for AI have shown that the mean effect-site concentration of remifentanil needed for AI is 2 to 3 ng/mL.[49,65,66,68] The dosing strategy described by Atkins and Mirza,[62] a bolus of 0.5 μg/kg followed by an infusion of 0.1 μg/kg/min, uses the Minto pharmacokinetic model and rapidly achieves a target site concentration of 2 to 2.5 ng/mL. The infusion can subsequently be titrated by 0.025 to 0.05 μg/kg/min in 5-minute intervals to achieve adequate sedation.

e. PRECAUTIONS

The most serious adverse effect of opioids is respiratory depression leading to overt apnea. Opioids reduce the stimulatory effect of carbon dioxide (CO_2) on ventilation while increasing the apneic threshold and the resting end-tidal CO_2. Factors that increase susceptibility to opioid-induced respiratory depression include old age, obstructive sleep apnea, and concomitant administration of central nervous system depressants.

Naloxone, an opioid antagonist, can be used to restore spontaneous ventilation in patients after an opioid overdose. Onset after IV administration is rapid, within 1 to 2 minutes, and the duration of action is 30 to 60 minutes. Naloxone should be administered in boluses of 0.04 to 0.08 μg IV boluses every 2 to 3 minutes. Doses of 1 to 2 μg/kg will restore adequate spontaneous ventilation in most cases while preserving adequate analgesia. Potential complications of naloxone administration are reversal of analgesia, tachycardia, hypertension, and, in severe cases, pulmonary edema or myocardial ischemia. Because of the relatively short duration of action of naloxone, one should carefully monitor for recurrence of respiratory depression, especially when it is used to reverse longer-acting opioids such as morphine or hydromorphone. In those situations, an intramuscular dose of 2 times the required IV dose or a continuous IV infusion (2.5 to 5 μg/kg/hr) should be considered.[57]

Chest wall rigidity leading to ineffectual bag-mask ventilation is commonly cited as a potential adverse effect of opioids, particularly fentanyl, sufentanil, alfentanil, and remifentanil. Opioids do have the potential to cause muscle rigidity, but clinically significant rigidity usually occurs only after an opioid dose sufficient to cause apnea, because the patient loses consciousness.[57] Studies in intubated patients and patients with tracheostomies have shown that decreases in pulmonary compliance due to chest wall rigidity are not sufficient to explain an inability to maintain bag-mask ventilation after a large dose of opioid,[69,70] and fiberoscopic examination of the vocal cords during induction with sufentanil has shown that vocal cord closure is the primary cause of difficult ventilation after opioid-induced anesthesia.[71] Careful titration to prevent overdose is perhaps the best way to prevent rigidity-associated difficult ventilation. Should it occur, treatment with naloxone or neuromuscular blocking agents is effective.[72,73]

3. Intravenous Anesthetics

a. PROPOFOL

Propofol (2,6-diisopropylphenol) is the most frequently used IV anesthetic today.[45] Its primary effect is hypnosis, which results from an unclear mechanism; however, there is evidence that a significant portion of this hypnotic effect is mediated by interaction with GABA receptors. Propofol has a rapid onset of approximately 90 seconds, with rapid recovery (4 to 5 minutes after an induction dose) as a result of both elimination and redistribution. It attenuates airway responses in induction

doses via an unclear mechanism and provides a smooth induction with few excitatory effects. Although it is frequently used as an induction agent in doses of 1.5 to 2.5 mg/kg IV, intermittent doses of approximately 0.25 mg/kg IV or a continuous IV infusion of 25 to 75 µg/kg/min provides an easily titratable level of sedation with rapid recovery.

The use of propofol in AI is well described both as a single agent and in combination with remifentanil.[26,65,68] Target-controlled infusion studies have shown that the effective plasma concentration of propofol to facilitate AI is 1 to 2 µg/mL.[26,65,68] Care should be taken if the patient has a critical airway, because propofol causes reduction of V_t and an increase in respiratory frequency at sedative doses. At sufficiently elevated plasma concentrations, propofol can lead to apnea. Other common adverse effects are a decrease in arterial blood pressure and pain on injection. An additional benefit of propofol is its antiemetic properties.

b. DEXMEDETOMIDINE

Dexmedetomidine is a centrally acting, highly selective α_2-adrenoreceptor agonist with several properties that make it well suited for use in AI.[74-77] It has sedative, analgesic, anxiolytic, antitussive, and antisialagogue effects while causing minimal respiratory impairment, even at high doses. Compared with clonidine, it is 8 to 10 times more specific for the α_2- versus the α_1-adrenergic receptor and has a shorter half-life (2 to 3 hours). Dexmedetomidine sedation provides unique conditions in which the patient is asleep but is easily arousable and cooperative when stimulated. It is approved for continuous IV sedation in intubated and mechanically ventilated patients and for sedation in nonintubated patients undergoing surgical or other procedures.

There are several reports of dexmedetomidine sedation in awake FOI,[77-80] including a phase IIIb Food and Drug Administration (FDA) study specifically for this indication.[81] Dosing for AI is a 1 µg/kg load over 10 minutes, followed by a continuous infusion of 0.2 to 0.7 µg/kg/hr. Some patients may require higher maintenance doses.[82,83] A reduced loading dose of 0.5 µg/kg and a reduction in the maintenance infusion should be considered in elderly patients (age >65 years) and in those with hepatic or renal impairment.[84] For AI, dexmedetomidine is usually combined with airway topicalization, although its successful use as a sole agent without local anesthetics has been reported.[78] Although lowering of bispectral index scores (BIS) and partial amnesia have been reported with its use,[85,86] dexmedetomidine is not a reliable amnestic and is frequently combined with midazolam to decrease the incidence of recall.[79,87]

Dexmedetomidine can cause adverse hemodynamic effects including bradycardia, hypotension, and hypertension. During the loading dose, hypertension and bradycardia can occur due to stimulation of peripheral postsynaptic α_{2B}-adrenergic receptors, resulting in vasoconstriction. Central α_{2A}-mediated sympatholysis eventually leads to bradycardia, hypotension, and decreased cardiac output.[88] The bradycardic effect can be mitigated by pretreatment with an anticholinergic (e.g., glycopyrrolate) or by combining the dexmedetomidine with ketamine for its cardiostimulatory properties.[79,89] Caution should be used in patients with depressed systolic function.[84]

c. KETAMINE

Ketamine[45]is a phencyclidine derivative and *N*-methyl-D-aspartate (NMDA) antagonist that produces *dissociative anesthesia*, which manifests clinically as a cataleptic state with eyes open and many reflexes intact, including the corneal, cough, and swallow reflexes. Ketamine-induced anesthesia is associated with amnesia, nystagmus, and the potential for hallucinations and other undesirable psychological reactions. Benzodiazepines are commonly administered to attenuate or treat these reactions; dexmedetomidine has also been shown to reduce the incidence and severity of ketamine-induced postanesthesia delirium.[90] Ketamine has an opioid-sparing effect and produces analgesia that extends well into the postoperative period, because plasma levels required for analgesia are considerably lower than those required for loss of consciousness. Usual doses for sedation range from 0.2 to 0.8 mg/kg IV, with peak plasma levels occurring after less than 1 minute and a duration of hypnosis of 5 to 10 minutes. At these doses, minute ventilation, V_t, FRC, and the minute ventilation response to CO_2 are maintained. Although airway reflexes and upper airway skeletal muscle tone are preserved, airway protection remains necessary in patients who are at risk for aspiration.

Ketamine increases blood pressure, heart rate, cardiac output, and myocardial O_2 consumption via a centrally mediated stimulation of the sympathetic nervous system. Ketamine is a direct myocardial depressant, however, and in patients with depleted catecholamine stores (e.g., the patient in shock), it may cause hypotension.[91] Its use in AI has been described in combination with benzodiazepines and dexmedetomidine.[2,89,92] Patients receiving ketamine sedation should always be pretreated with an antisialagogue, because ketamine causes increased airway secretions that can lead to upper airway obstruction or make FOI difficult.

d. DROPERIDOL

Droperidol, a butyrophenone, is a neuroleptic medication occasionally used in anesthesia practice for its sedative and antiemetic properties.[10,45] Its mechanism of action is antagonism of dopamine receptors in the central nervous system; it also interferes with GABA-, norepinephrine-, and serotonin-mediated neuronal activity. In combination with fentanyl, it produces a state of hypnosis, analgesia, and immobility classically referred to as *neuroleptanalgesia*. In combination with a hypnotic or nitrous oxide, droperidol and fentanyl produce general anesthesia (*neuroleptanesthesia*), not unlike the dissociative state produced by ketamine. Neuroleptanalgesia has been used for AI with favorable results.[2,93,94] In this state, patients may experience extreme fear and apprehension despite appearing outwardly calm; droperidol is also a poor amnestic. For this reason, benzodiazepines should be administered for anxiolysis and amnesia.

Doses for neuroleptanalgesia range from 2.5 to 5 mg IV; the antiemetic dose is 0.625 to 1.25 mg. Onset is in 20 minutes, with a half-life of about 2 hours. Side effects

include mild hypotension due to peripheral α-adrenergic blockade, dysphoria, and extrapyramidal symptoms. Droperidol can also cause QT prolongation, especially in larger doses. This has led to an FDA "black box" warning concerning the risk for potentially fatal torsades de pointes. As a result, droperidol should not be administered to patients with a prolonged QT interval (>440 msec for males, >450 msec for females), and ECG monitoring should be performed during and for 2 to 3 hours after treatment.[95]

V. TOPICALIZATION

Topicalization of the airway with local anesthetics should, in most cases, be the primary anesthetic for AI; many times, it is all that is needed.[9] When using local anesthetics, it is important to be familiar with the speed of onset, duration of action, optimal concentration, signs and symptoms of toxicity, and maximum recommended dosage of the drug chosen.[96] The rate and amount of topical local anesthetic absorption vary depending on the site of application, the concentration and total dose of local anesthetic applied, the hemodynamic status of the patient, and individual patient variation.[97] Local anesthetic absorption is more rapid from the alveoli than from the tracheobronchial tree, and more rapid from the tracheobronchial tree than from the pharynx. The most commonly used agents for topical anesthesia of the airway are lidocaine and cocaine.

Although AI with airway topicalization is considered the safest method of airway management for the patient with a DA, it is not without risk. Local anesthetic toxicity is a real concern; death due to lidocaine toxicity of a healthy volunteer undergoing bronchoscopy has occurred.[98,99] In addition, total airway obstruction during topical anesthesia in a nonsedated patient with a critical airway has been reported. This was postulated to have been caused by dynamic airway obstruction related to loss of upper airway tone as a result of topicalization.[100]

A. Lidocaine

Lidocaine, an amide local anesthetic, is the most commonly used agent for airway topicalization.[101,102] It is available in various concentrations (1% to 10%) and in preparations including aqueous and viscous solutions, ointments, gels, and creams. For infiltration and minor nerve blocks, 1% to 2% lidocaine is commonly used; for topical anesthesia, the concentration used is 2% to 4%. Lidocaine is an excellent choice for airway anesthesia because of its reasonably rapid onset of 2 to 5 minutes and its high therapeutic index. Its duration of action is 30 to 60 minutes after topical application or infiltration; addition of epinephrine extends the duration to 2 to 3 hours when used for infiltration. It is hepatically metabolized with a half-life of 90 minutes; care should be taken in patients with hepatic failure.

The maximum recommended dosage for infiltration of lidocaine without epinephrine is 5 mg/kg of lean body mass. For topicalization of the airway, the maximum dose is less well established. The British Thoracic Society recommends a maximum dose of 8.2 mg/kg,[103] based on a study by Langmack and associates.[104] Studies of plasma concentration after nebulization of 6 mg/kg of lidocaine showed peak plasma levels an order of magnitude lower than the toxic plasma level of 5 μg/mL.[105] Other studies using total doses as high as 10.5 mg/kg in obese patients failed to demonstrate signs or symptoms of lidocaine toxicity.[106] Early symptoms of lidocaine toxicity include euphoria, dizziness, tinnitus, confusion, and a metallic taste in the mouth. Signs of severe lidocaine toxicity include seizures, respiratory failure, loss of consciousness, and circulatory collapse. In asthmatics, lidocaine has been reported to precipitate bronchoconstriction by a nonhistamine-mediated mechanism.[107]

B. Cocaine

Cocaine, a naturally occurring ester anesthetic, is used primarily for anesthesia of the nasal mucosa when the nasal route is planned for AI.[108] It has a vasoconstrictor property that makes it particularly useful for this application, because the nose is highly vascularized and bleeding can make FOI impossible. It is available commercially as a 4% solution (each drop containing 3 mg), and can be applied to the nasal mucosa using cotton pledgets or cotton-tipped swabs. The maximum recommended dosage for intranasal application is 1.5 mg/kg. After topical application of cocaine to the nasal mucosa, peak plasma levels are achieved in 30 to 45 minutes, and the drug persists in the plasma for 5 to 6 hours.

Cocaine is primarily metabolized by plasma pseudocholinesterase; it also undergoes slow hepatic metabolism and is excreted unchanged by the kidney. The signs and symptoms of cocaine toxicity include tachycardia, cardiac dysrhythmia, hypertension, and fever. Severe complications include convulsions, respiratory failure, coronary spasm, cardiac arrest, stroke, and death. It must be used with caution in patients with hypertension, coronary artery disease, hyperthyroidism, pseudocholinesterase deficiency, or preeclampsia, and in those patients taking monoamine oxidase inhibitors.

C. Other Local Anesthetics

Benzocaine is a water-insoluble ester-type local anesthetic agent that is mainly useful for topical application. The onset of action is rapid (<1 minute), and the effective duration is 5 to 10 minutes. Benzocaine is most commonly available as a 20% aerosol spray that is easily applied to the oropharyngeal mucosa. The limiting factor in benzocaine use is the potential development of clinically significant methemoglobinemia. In some patients, this can occur with as little as 1 to 2 seconds of spraying.[109] The risk increases by almost 20-fold when benzocaine exposure is repeated within 1 week. Although most patients tolerate benzocaine airway topicalization without any adverse effects, it is not possible to identify in advance those patients who are at risk for significant methemoglobinemia. Some have advocated for the cessation of benzocaine use across the board.[110] Symptoms of early methemoglobinemia toxicity can be seen with methemoglobin levels of 5% and include cyanosis, tachycardia, and tachypnea. As levels increase to 20% to 30%, patients

may develop chest pain, ischemic changes on ECG, hypotension, altered mental status, syncope, or coma. The most severe cases have led to neurologic hypoxic injury, myocardial infarction, and death. Should symptomatic methemoglobin occur, treatment is with methylene blue 1 to 2 mg/kg IV given over 5 minutes.[110,111]

Tetracaine is an amide local anesthetic agent with a longer duration of action than lidocaine or cocaine. It is available as 0.5% to 1% solutions for local use. It is metabolized through hydrolysis by plasma cholinesterase. Tetracaine is rapidly absorbed from the respiratory and gastrointestinal tract when used to anesthetize the airway, and aerosol doses as small as 20 mg have been shown to precipitate toxicity.[112] Severe toxic reactions after tetracaine overdose include convulsions, respiratory arrest, and circulatory collapse.[113] Fatalities have been reported with topical application of tetracaine 100 mg used to anesthetize mucous membrane.[114] These issues have limited its use as a primary local anesthetic for airway topicalization.

Cetacaine is a topical application spray containing 14% benzocaine, 2% tetracaine, and 2% butyl aminobenzoate (a local anesthetic similar to benzocaine). Like 20% benzocaine spray, this combination produces rapid airway anesthesia, but with a prolonged duration of action compared to benzocaine alone. The risk of methemoglobinemia is still a consideration, and cases of severe toxicity have been reported.[115,116]

EMLA cream (eutectic mixture of local anesthetic) contains 2.5% lidocaine and 2.5% prilocaine and is considered a topical anesthetic for use on intact skin. Although the manufacturer does not recommend its use on mucosal surfaces because of faster systemic absorption, it has been employed safely as a topical anesthetic for AI. Larijani and colleagues described 20 adult patients who underwent awake FOI using 4 g of EMLA applied over the upper airway. The measured peak plasma concentrations of lidocaine or prilocaine did not reach toxic levels, and methemoglobin levels did not exceed normal values (1.5%).[117]

Benzonatate, an oral antitussive chemically similar to ester-type local anesthetics, has also been used for airway topicalization. The dose used is 200 mg; the capsules are pierced with a needle, and the patient is instructed to crush the capsules with the teeth or to hold the capsules in the back of the mouth. Oropharyngeal anesthesia is quickly obtained. In a study by Mongan and Culling, intubating conditions using benzonatate were comparable to those achieved with topical benzocaine and superior laryngeal nerve blocks, with no adverse effects noted.[17]

D. Application Techniques

1. Atomizers

A common method for applying local anesthetic to the airway is with an atomizer. One system for local anesthetic atomization involves the use of a standard DeVilbiss atomizer with the bulb removed. The atomizer reservoir is filled with 2% to 4% lidocaine. O_2 tubing is connected from the atomizer to an O_2 cylinder with a flow rate of 8 to 10 L/min. A bleed hole is cut in the O_2 tubing; this allows for intermittent application of the local anesthetic when a thumb is placed over the hole in the tubing. The atomizer spray is directed toward the soft palate and posterior pharynx to topicalize the mucosa (Fig. 11-1). Any residual anesthetic agent in the oropharynx should be suctioned out to reduce absorption from the gastrointestinal tract. Disposable plastic atomizers are available for this purpose as well (Fig. 11-2). The device is attached to an O_2 tank, and the phalange is depressed to deliver the local anesthetic solution to the oropharyngeal mucosa. A disadvantage with these methods is the difficulty of controlling the exact amount of local anesthetic administered.

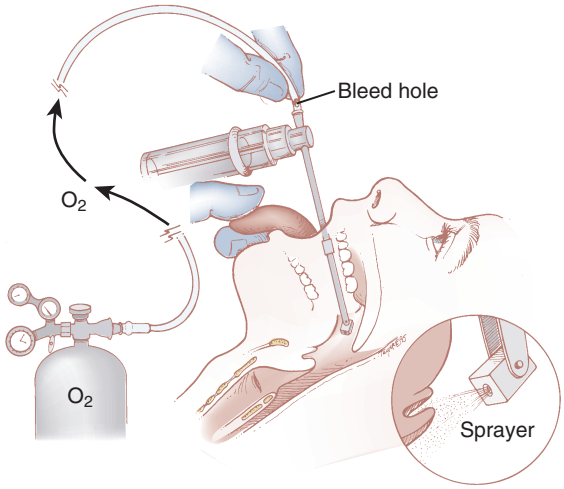

Figure 11-1 Atomizer connected to an oxygen tank. A bleed hole is made near the operator's hand to allow intermittent spraying. Inset shows the tip of the atomizer as it is angulated to spray toward the glottic opening. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

Alternatively, the MADjic Mucosal Atomization Device (Wolfe Tory Medical, Inc., Salt Lake City, UT) is an inexpensive, disposable, latex-free device that, when attached to a Luer fitted syringe containing local anesthetic, can be used to dispense a fine mist to the oropharyngeal or nasal mucosa (Fig. 11-3). The tubing is

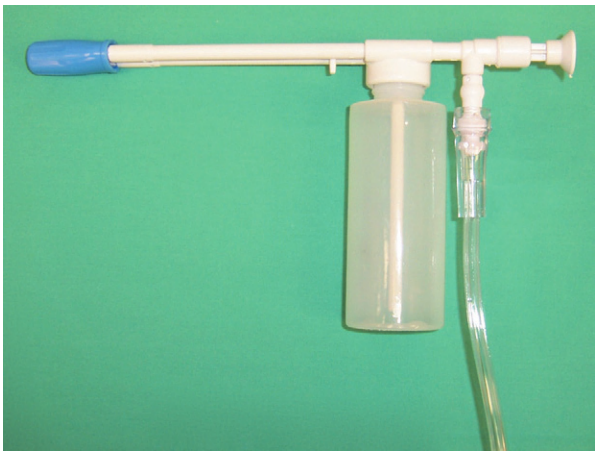

Figure 11-2 Typical disposable atomizer.

malleable, allowing for delivery of local anesthetic to deeper pharyngeal structures and to the glottis. Because a syringe is used, a known amount of local anesthetic can be administered.

2. Nebulizers

Nebulizers may be used to apply local anesthetic to the airway. The advantages of this technique include ease of application and safety. A standard mouthpiece-type nebulizer (Fig. 11-4) can topicalize the oropharynx and trachea. If nasal cavity anesthesia is needed, a facemask-type nebulizer (Fig. 11-5) can be used; the patient is instructed to breathe in through the nose. This approach is especially advantageous for patients with increased intracranial pressure (ICP), open eye injury, or severe coronary artery disease.[118] Foster and Hurewitz compared the administration of lidocaine using two different modalities (nebulizer-atomizer combination and atomizer alone) in patients undergoing bronchoscopy.[119] They found that the nebulizer-atomizer combination was more efficacious, resulting in a reduction of the dose required to anesthetize the upper airway. A typical dose of lidocaine used in a standard nebulizer is 4 mL of 4% lidocaine. This results in a total dose of 160 mg of lidocaine, which is well within the safe dosage range. Studies using

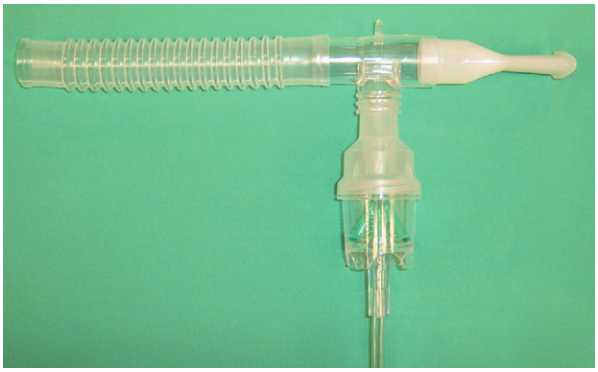

Figure 11-4 Typical mouthpiece-type nebulizer.

Figure 11-5 Typical facemask-type nebulizer.

6 mg/kg of 10% lidocaine showed that peak plasma concentrations are much lower than would be expected if all the lidocaine had been absorbed—evidence that some of the local anesthetic is lost during exhalation.[105]

3. "Spray-As-You-Go"

In addition to using a nebulizer or an atomizer to anesthetize the vocal cords and trachea, a technique termed "spray-as-you-go" through the FFB can be performed. The technique is noninvasive and involves injecting local anesthetics through the suction port of the FOB. Two methods have been described. The first requires attaching a triple stopcock (Fig. 11-6) to the proximal portion of

Figure 11-6 "Spray-as-you-go" technique. An oxygen hose and a triple stopcock are attached to the suction port of a flexible fiberoptic bronchoscope with syringe attached containing local anesthetic.

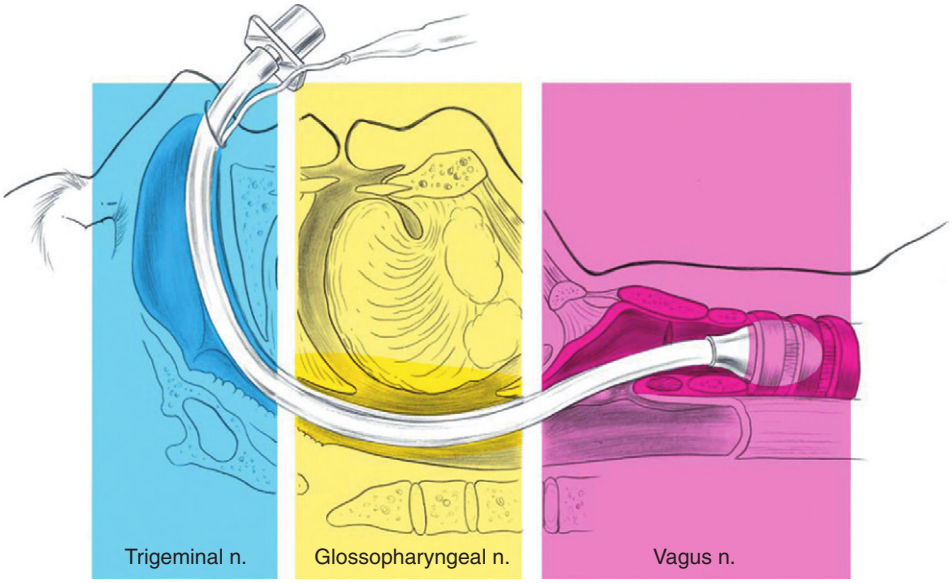

Figure 11-7 Innervation of the upper airway. (From Brown D, editor: *Atlas of regional anesthesia*, ed 2, Philadelphia, 1999, Saunders.)

the suction port to connect O_2 tubing from a regulated O_2 tank set to flow at 2 to 4 L/min. Under direct vision through the bronchoscope, targeted areas are sprayed with aliquots of 0.2 to 1.0 mL of 2% to 4% lidocaine. The physician then waits 30 to 60 seconds before advancing to deeper structures and repeating the maneuver. The flow of O_2 allows higher delivery of a higher fraction of inspired oxygen (F_{IO_2}), keeps the FOB lens clean, disperses mucous secretions away from the lens, and aids in nebulizing the local anesthetic. The second method involves passing a multiorifice epidural catheter (0.5- to 1.0-mm inner diameter [ID]) through the suction port of an adult FOB.[120] These techniques are especially useful in patients who are at risk for aspirating gastric contents because the topical anesthetic is applied only seconds before the intubation is accomplished, allowing the patient to maintain airway reflexes as long as possible.

VI. NERVE BLOCKS

Because of the multitude of nerves innervating the airway (Fig. 11-7), there is no single anatomic site where a physician can perform a nerve block and anesthetize the entire airway. Even though topicalization of the mucosa serves to anesthetize the entire airway adequately in most patients, some require supplementation to ablate sensation in the nerve endings that run deep to the mucosal surface, such as the periosteal nerve endings of the nasal turbinates and the stretch receptors at the base of the tongue, which are involved in the gag reflex. Some studies have shown superior patient comfort and hemodynamic stability when a combined regional block technique was used rather than nebulized local anesthetic.[121] The following nerve blocks are remarkable for their ease of performance, their minimal risk to the patient, and their speed of onset. Nerve blocks are applied to the nasal cavity and nasopharynx,[4,12,102,122-127] the oropharynx,[12,102,122,128-134] the larynx,[9,12,25,102,113,122,128,135-140] and the trachea and vocal cords.[12,25,102,113,122,141]

A. Nasal Cavity and Nasopharynx

1. Anatomy

Most of the sensory innervation of the nasal cavity is derived from two sources: the sphenopalatine ganglion and the anterior ethmoidal nerve. The sphenopalatine ganglion (pterygopalatine, nasal, or Meckel's ganglion) is a parasympathetic ganglion that is located in the pterygopalatine fossa (Fig. 11-8A), posterior to the middle turbinate. Its sensory root is derived from sphenopalatine branches of the maxillary nerve, cranial nerve (CN) V_2. As they pass through the sphenopalatine ganglion, these sensory branches form the greater and lesser palatine nerves, which provide sensory innervation to the nasal cavity as well as the roof of the mouth, soft palate, and tonsils. The anterior ethmoidal nerve (see Fig. 11-8B) is one of the sensory branches of the ciliary ganglion, which is located within the orbital cavity and inaccessible to nerve blocks. It provides sensory innervation to the anterior portion of the nasal cavity.

2. Nasal Pledgets or Nasopharyngeal Airways

Regardless of which technique is used to anesthetize the nasal cavity, the nares should first be inspected for a deviated septum by using a nasal speculum and asking the patient to breathe deeply through each individual naris while the opposite naris is occluded. Patency can also be determined by using bayonet forceps to place cotton pledgets soaked in either 4% cocaine or 4% lidocaine with epinephrine 1:200,000 along the floor of the nasal cavity. The pledgets are advanced posteriorly to the level of the posterior nasopharyngeal wall. The benefits of this technique are that initial topicalization of the nasal cavity is achieved, the angle of ETT insertion can be predicted, and dilation of the nasal cavity is initiated. The pledgets are then followed by placement of nasopharyngeal airway (nasal trumpet) coated in 2% to 4% viscous lidocaine (a 34-F nasal trumpet predicts easy passage of a 7.0-mm ID ETT).[4,102]

V_2 is the major contributor to the sphenopalatine (pterygopalatine) ganglion, shown as it sits in the pterygopalatine fossa. **B,** Left lateral view of the right nasal cavity depicting the anterior ethmoidal nerve, olfactory nerve, and the trigeminal nerve (V_1 to V_3). The pterygopalatine ganglion lies just beneath the mucosal surface on the caudad surface of the sphenoid sinus and forms the roof of the pterygopalatine fossa. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

3. Sphenopalatine Nerve Block

a. ORAL APPROACH

With the patient in the supine position, the physician stands facing the patient on the contralateral side of the nerve to be blocked. Using the nondominant index finger, the physician identifies the greater palatine foramen. It is located on either side of the roof of the mouth between the second and third maxillary molars, approximately 1 cm medial to the palatogingival margin, and can usually be palpated as a small depression near the posterior edge of the hard palate. In approximately 15% of the population, the foramen is closed and inaccessible. A 25-G spinal needle, bent 2 to 3 cm proximal to the tip to an angle of 120 degrees, is inserted through the foramen in a superior and slightly posterior direction to a depth of 2 to 3 cm. An aspiration test is performed to ascertain that the sphenopalatine artery has not been cannulated, and 1 to 2 mL of 2% lidocaine with epinephrine 1:100,000 is injected. The epinephrine is used as a vasoconstrictor for the sphenopalatine artery, which runs parallel to the nerves, to decrease the incidence of epistaxis. The injection of the local anesthetic should be performed in a slow, continuous fashion (preventing acute increases in pressure within the fossa) to decrease sympathetic stimulation.[123-125,127]

This block anesthetizes the greater and lesser palatine nerves as well as the nasociliary and nasopalatine nerves, which also contribute to the sensory innervation of the nasal cavity. Complications include bleeding, infection, nerve trauma, intravascular injection of local anesthetic, and hypertension. Pain on insertion of the needle can be avoided by application of 2% viscous lidocaine with a cotton-tipped applicator for 1 to 2 minutes before the block is applied. See Figures 11-9 and 11-10.

b. NASAL APPROACH

Two noninvasive nasal approaches to the sphenopalatine ganglion have been described, both of which take advantage of the ganglion's shallow position beneath the nasal mucosa. The first involves the application of long cotton-tipped applicators soaked in either 4% cocaine or 4% lidocaine with epinephrine 1:200,000 over the mucosal surface overlying the ganglion (Fig. 11-11A). The applicator is passed along the upper border of the middle turbinate at an angle of approximately 45 degrees to the hard palate and directed posteriorly until the upper posterior

wall of the nasopharynx (sphenoid bone) is reached. The applicator is then left in place for 5 to 10 minutes. The second method involves using the plastic sheath of a 20-G angiocatheter placed along the same path (Fig. 11-12). An anesthetic solution (4 mL of 3% lidocaine/0.25% phenylephrine) is then rapidly injected. About 2 minutes should be allowed for the anesthetic to take effect.[4,122,123,126]

4. Anterior Ethmoidal Nerve Block

The anterior ethmoidal nerve is blocked by insertion of a long cotton-tipped applicator, soaked in either 4% cocaine or 4% lidocaine with epinephrine 1:200,000, parallel to the dorsal surface of the nose until it meets the anterior surface of the cribriform plate (see Fig. 11-11B). The applicator is held in position for 5 to 10 minutes.[126]

(From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

B. Oropharynx

1. Anatomy

The somatic and visceral afferent sensory fibers of the oropharynx are supplied by a plexus derived from the vagus (CN X), facial (CN VII), and glossopharyngeal (CN IX) nerves. The glossopharyngeal nerve (GPN) emerges from the skull through the jugular foramen and passes anteriorly between the internal jugular and carotid vessels, traveling along the lateral wall of the pharynx. It supplies sensory innervation to the posterior third of the tongue via the lingual branch and to the vallecula, the anterior surface of the epiglottis, the posterior and lateral walls of the pharynx, and the tonsillar pillars. Its only motor innervation in the pharynx is to the stylopharyngeus muscle, one of the muscles of deglutition.

In most patients, topicalization of the mucosa of the oropharynx is sufficient to allow instrumentation of the airway. In some, however, the gag reflex is so pronounced that topicalization alone may be insufficient for AI. The afferent limb of the gag reflex arises from stimulation of deep pressure receptors found in the posterior third of the tongue, which cannot be reached by the diffusion of local anesthetics through the mucosa. There are various measures for minimizing this problem: instructing the patient to breathe in a nonstop panting fashion, avoiding pressure on the base of the tongue by performing a nasal intubation, administering opioids, and performing blockade of the GPN. The GPN block is easy to perform and is highly effective in abolishing the gag reflex and decreasing the hemodynamic response to laryngoscopy, including awake laryngoscopy. Several different approaches have been described.

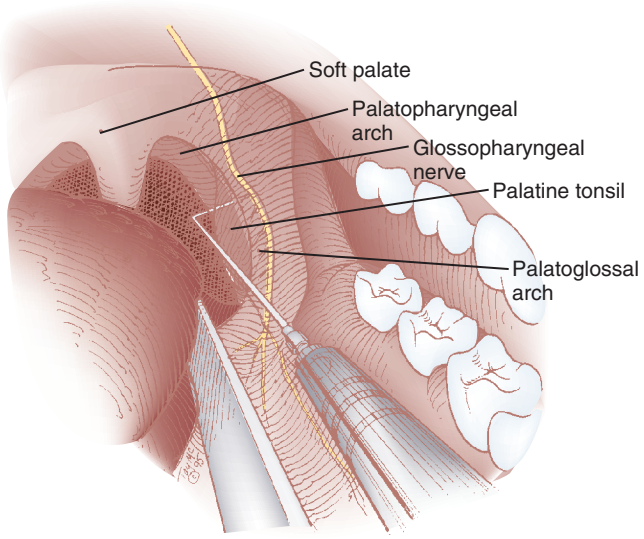

Figure 11-13 Left glossopharyngeal nerve block, posterior approach. A 25-G spinal needle bent at a right angle (or a tonsillar needle) is placed behind the midportion of the palatopharyngeal fold. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

2. Glossopharyngeal Nerve Block

a. POSTERIOR APPROACH (PALATOPHARYNGEAL FOLD)

The classic intraoral approach to the GPN block involves injecting local anesthetic at the base of the posterior tonsillar pillar (palatopharyngeal fold).[102,128,129] Because of the proximal location of the nerve targeted, this technique has the potential to block both the sensory fibers (pharyngeal, lingual, and tonsillar branches) and the motor branch innervating the stylopharyngeus muscle.

After adequate topicalization of the oropharynx, the patient is placed in a semireclined position with the physician facing the patient on the ipsilateral side of the nerve to be blocked. The patient's mouth is opened wide. With a tongue depressor held in the nondominant hand, the tongue is displaced caudad and medially, exposing the soft palate, uvula, palatoglossal arch, tonsillar bed, and palatopharyngeal arch (Figs. 11-13 and 11-14). This maneuver stretches both the palatopharyngeal arch and the palatoglossal arch, making them more accessible. A Macintosh size 3 laryngoscope blade may also be useful for retraction, because it provides additional light. The dominant hand holds a 23-G tonsillar needle attached to a syringe. Alternatively, a 22-G, 9-cm spinal needle with the distal 1 cm of the needle bent at a 90-degree angle may be used. The needle is inserted submucosally into the caudad portion of the posterior tonsillar pillar. After an attempt to aspirate blood, 5 mL of 0.5% to 1% lidocaine is slowly injected. If blood is aspirated or the patient complains of headache during injection, the needle should be removed and repositioned. The procedure is repeated on the contralateral side.

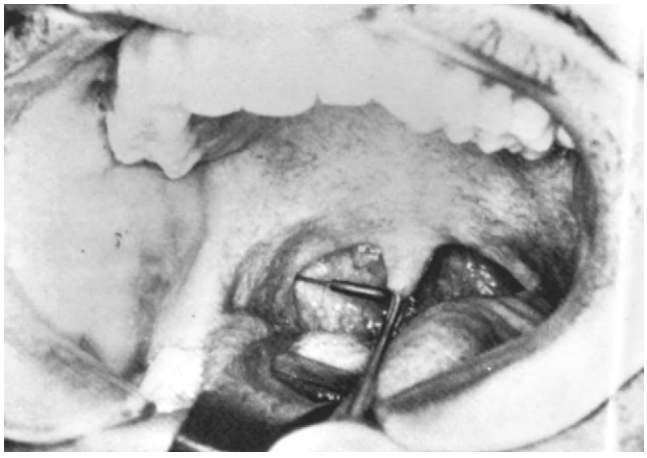

Figure 11-14 Right glossopharyngeal nerve block, posterior approach.

Because of the proximity of the GPN at this location to the internal carotid artery, care must taken to avoid intra-arterial injection, which could result in headache or seizure. Hypopharyngeal swelling and mucosal bleeding may occur. Tachycardia may also result from blockade of the afferent nerve fibers of the GPN that arise from the carotid sinus.[133]

b. ANTERIOR APPROACH (PALATOGLOSSAL FOLD)

The lingual branch of the GPN provides sensory innervation to the posterior third of the tongue and is the afferent limb of the gag reflex. The anterior approach, which isolates this branch as it passes medial to the base of the anterior tonsillar pillar, is easier and is better tolerated by the patient because it requires less exposure.[9,130-132]

The patient is placed in the sitting position with the physician facing the patient on the contralateral side of the nerve to be blocked. The patient's mouth is opened wide with the tongue protruded. With the nondominant hand, the physician uses a tongue blade or a Macintosh size 3 laryngoscope blade to displace the tongue medially, forming a gutter or trough along the floor of the mouth between the tongue and the teeth. The gutter ends in a cul-de-sac formed by the base of the palatoglossal arch (also known as the anterior tonsillar pillar), which is a U- or J-shaped structure that starts at the soft palate and runs along the lateral aspect of the pharynx. A 25-G spinal needle is inserted 0.25 to 0.5 cm deep at the base of the palatoglossal arch, just lateral to the base of the tongue, and an aspiration test is performed (Figs. 11-15 and 11-16). If air is aspirated, the needle has been advanced too deeply (i.e., the tip has advanced all the way through the palatoglossal arch) and should be withdrawn until no air can be aspirated; if blood is aspirated, the needle should be redirected more medially. Two mL of 1% to 2% lidocaine is injected, and the procedure is repeated on the contralateral side.

Although this block is targeted at the lingual branch of the GPN, studies using methylene blue dye have shown that, in some cases, retrograde submucosal tracking of local anesthetic occurs, blocking more proximal branches of the GPN (i.e., pharyngeal and tonsillar branches). Serious complications are rare for this approach, although one study reported that 91% of patients undergoing this procedure experienced oropharyngeal discomfort for at least 24 hours after the procedure.[134]

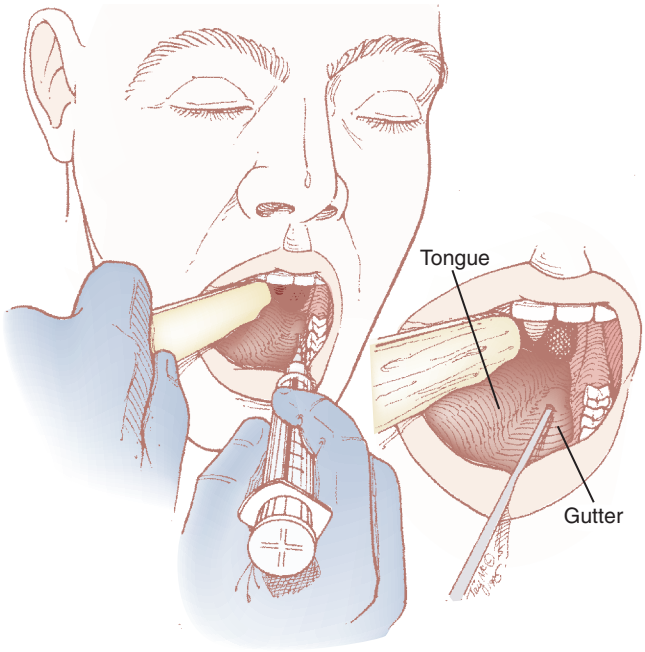

Figure 11-15 Left glossopharyngeal nerve block, anterior approach. The tongue is displaced medially, forming a gutter (glossogingival groove), which ends distally in a cul-de-sac. A 25-G spinal needle is placed at the base of the palatoglossal fold. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

c. EXTERNAL APPROACH (PERISTYLOID)

The external approach is most useful when the patient's mouth opening is insufficient to allow adequate visualization to perform one of the intraoral blocks.[102,129] The patient is placed supine with the head in a neutral position. The styloid process is located by identifying the midpoint of the line between the mastoid process and the angle of the jaw. A skin wheal with local anesthetic is made at this location, and a 22-G spinal needle is advanced perpendicularly to the skin until the styloid process is contacted. Depending on the patient's habitus, this should occur at a depth of 1 to 2 cm. The needle is then redirected posteriorly, and as soon as contact is lost

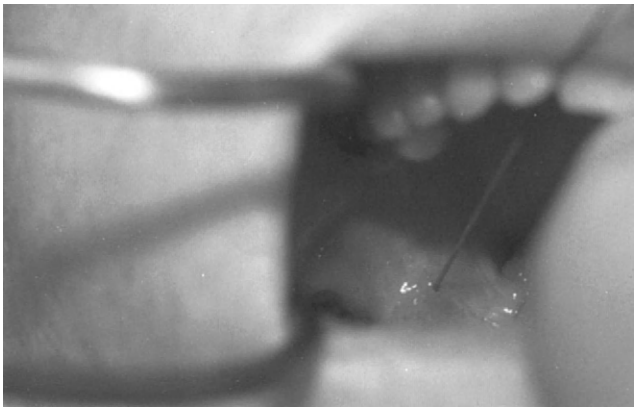

Figure 11-16 Right glossopharyngeal nerve block, anterior approach. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

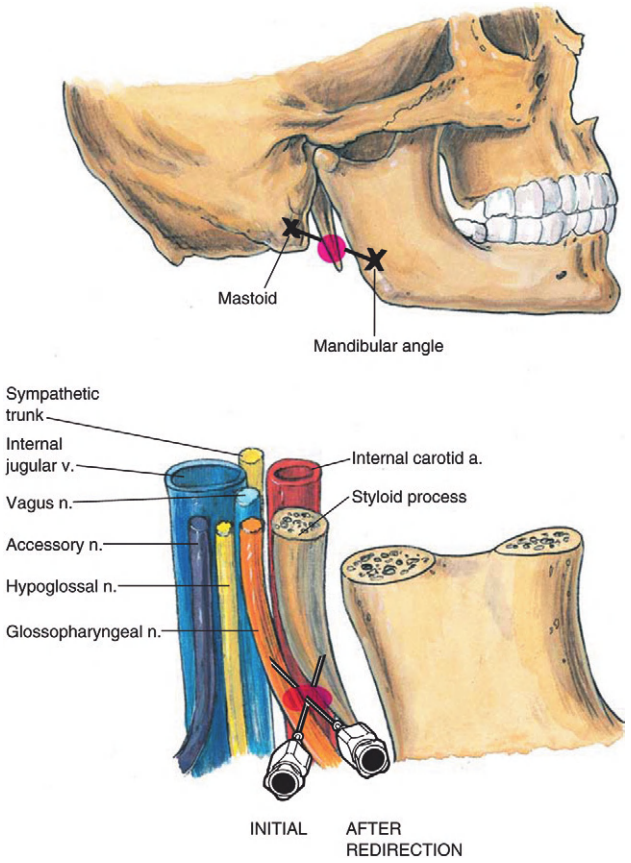

Figure 11-17 Glossopharyngeal nerve block, peristyloid approach. A 22-G spinal needle is inserted to contact the styloid process. It is then redirected posteriorly, putting the tip of the needle near the glossopharyngeal nerve. (From Brown D, editor: *Atlas of regional anesthesia*, ed 2, Philadelphia, 1999, Saunders.)

with the styloid process, 5 to 7 mL of 0.5% to 1% lidocaine is injected after a negative aspiration for blood (Fig. 11-17). The procedure is then repeated on the opposite side. Similar precautions should be taken for the peristyloid approach as for the posterior approach because of the proximity of the GPN at this anatomic location to both the internal carotid artery and the internal jugular vein.

C. Larynx

1. Anatomy

Sensory innervation of the larynx is supplied by the superior laryngeal nerve (SLN), a branch of the vagus nerve. The SLN originates from the ganglion nodosum and descends deep to the carotid artery. It then courses anteriorly, and at the level of the cornu of the hyoid bone it branches into the external and internal branches. The external branch supplies motor innervation to the cricothyroid muscle, which functions to tighten and elongate the vocal cords. The internal branch of the SLN contains sensory fibers that are distributed to the base of the tongue, vallecula, epiglottis, aryepiglottic folds, arytenoids, and glottis down to the level of the vocal cords. It passes medially between the greater cornu of the hyoid bone and the superior cornu of the thyroid cartilage and

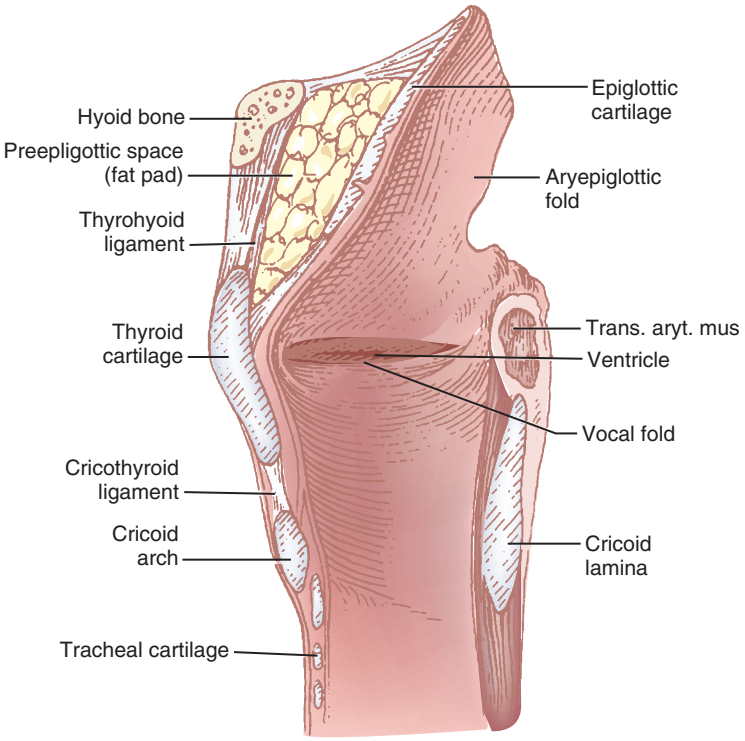

Figure 11-18 Midsagittal view of the larynx showing the pre-epiglottic space containing fat pad and thyrohyoid ligament (see Fig. 11-19).

pierces the thyrohyoid membrane along with the superior laryngeal artery and vein. The nerve then lies in the paraglottic space, a closed space bounded by the thyrohyoid membrane laterally and the laryngeal mucosa medially, where it ramifies (Figs. 11-18 and 11-19).

Blockade of the SLN produces dense anesthesia of the hypopharynx and upper glottis, including the vallecula and the laryngeal surface of the epiglottis. In combination with oropharyngeal topical anesthesia with or without a GPN block, this allows adequate airway anesthesia for a variety of AI techniques, including direct laryngoscopy. In the external approach, local anesthetic is injected into the paraglottic or pre-epiglottic space, targeting the nerve soon after it pierces the thyrohyoid ligament. The internal approach targets the nerve as it courses submucosally in the region of the pyriform recess.

2. Superior Laryngeal Nerve Block

a. EXTERNAL APPROACH

In the external approach,[5,102,113,128,135,136] the patient is placed in the supine position, head slightly extended, with the physician standing on the side to be blocked. The two main anatomic structures that are useful to identify are the hyoid bone and the superior cornu of the thyroid cartilage. The hyoid bone lies above the thyroid cartilage. It is identified by deep palpation; this can be uncomfortable to the patient and is difficult in patients who have a short or thick neck. Because it does not articulate with any other bones, the hyoid is freely movable, which helps in its identification. The greater cornu of the hyoid is the most lateral aspect of the bone that can be palpated. One side can be made more prominent by displacing the contralateral side toward the side

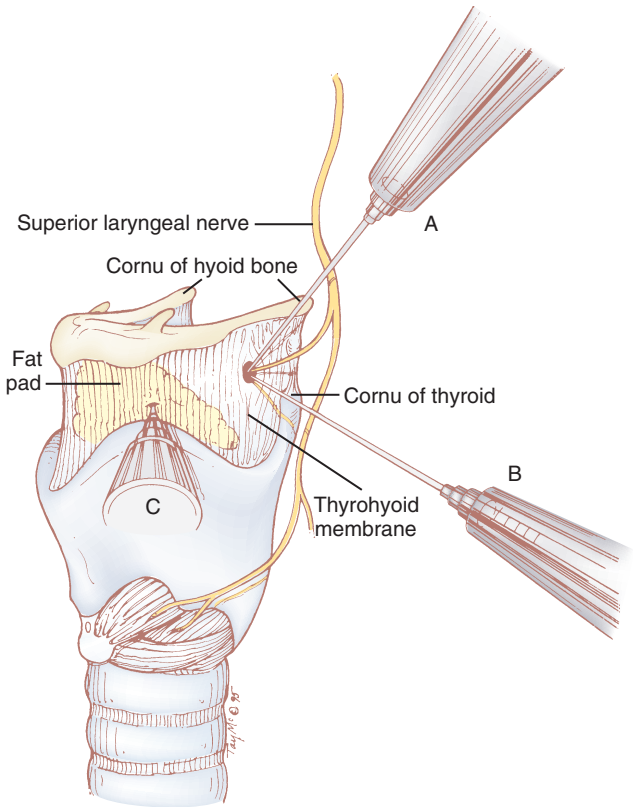

Figure 11-19 Superior laryngeal nerve block, external approach using as a landmark the greater cornu of the hyoid bone *(A)*, the superior cornu of the thyroid cartilage *(B)*, or the thyroid notch *(C)*. (From Difficult Airway Teaching Aids. Irvine, University of California, Department of Anesthesia.)

being blocked. The superior lateral cornu of the thyroid cartilage can be identified by palpating the superior thyroid notch ("Adam's apple") and tracing the upper edge of the thyroid cartilage laterally until the most lateral aspect is identified. Three techniques using different landmarks have been described (see Fig. 11-19). Using 1% to 2% lidocaine, satisfactory sensory blockade is achieved within 5 minutes, with a success rate of 92% to 100%.[136]

GREATER CORNU OF THE HYOID. After identifying the greater cornu of the hyoid, the physician uses the nondominant index finger to depress the carotid artery laterally and posteriorly. With the dominant hand, a 25-G needle is "walked off" the cornu of the hyoid bone (see *A* in Fig. 11-19) in an anterior-inferior direction, aiming toward the middle of the thyrohyoid membrane. A slight resistance is felt as the needle is advanced through the membrane, usually at a depth of 1 to 2 cm (2 to 3 mm deep to the hyoid bone). The needle at this point has entered the pre-epiglottic space. Aspiration through the needle should be attempted. If air is aspirated, the needle has gone too deep and may have entered the pharynx; it should be withdrawn until no air can be aspirated. If blood is aspirated, the needle has cannulated the superior laryngeal artery or vein or the carotid artery; the needle should be directed more anteriorly. After satisfactory needle placement is achieved, 2 to 3 mL of local anesthetic is injected as the needle is withdrawn. The block is repeated on the opposite side. An ultrasound-guided technique for this approach has been described and may be beneficial for patients with abnormal neck anatomy.[138]

SUPERIOR CORNU OF THE THYROID. A similar technique to the one previously described uses the superior lateral cornu of the thyroid as the landmark. The benefit of this technique is that, in many patients, this structure is easier and less painful to palpation than the hyoid bone. A 25-G needle is walked off the cornu of the thyroid cartilage (see *B* in Fig. 11-19) in a superior-anterior direction, aiming toward the lower third of the thyroid membrane. The same precautions as before are taken, and the local anesthetic solution is injected as the needle is withdrawn. The block is repeated on the opposite side.

THYROID NOTCH. The easiest landmark to identify in many patients, especially in the morbidly obese, is the thyroid notch (Adam's apple), the most medial and superficial aspect of the thyroid cartilage. The thyroid notch is palpated, and the upper border of the thyroid cartilage is traced laterally for approximately 2 cm (see C in Fig. 11-19). With a 25-G needle, the thyrohyoid ligament is pierced just above the thyroid cartilage at this location, and the needle is advanced in a posterior and cephalad direction to a depth of 1 to 2 cm from the skin. The tip of the needle is then in the pre-epiglottic space, which normally contains the terminal branches of the internal branch of the SLN imbedded in a fat pad (see Fig. 11-18). After an aspiration test, the entire volume of local anesthetic is injected into the pre-epiglottic space, and the needle is withdrawn. The block is repeated on the opposite side. An added benefit of this approach is the decreased likelihood of blocking the motor branch of the SLN.

b. INTERNAL APPROACH

A noninvasive SLN block can be performed by applying local anesthetic to the pyriform recess. At this anatomic location, the internal branch of the SLN lies submucosally, and blockade is possible by diffusion of concentrated local anesthetic.[25,113] After adequate topicalization of the oropharynx, the patient is placed in the sitting position with the physician standing on the contralateral side of the nerve to be blocked. The patient's mouth is opened widely with the tongue protruded. The tongue is grasped with the nondominant hand using a gauze pad and gently pulled anteriorly, or it is depressed with a tongue blade. With the dominant hand, a Krause forceps holding a sponge soaked in 4% lidocaine is advanced over the lateral posterior curvature of the tongue along the downward continuation of the tonsillar fossa (Fig. 11-20). The tip of the forceps is advanced until it cannot be advanced any farther (Fig. 11-21); at that point, the handle of the forceps should be in a horizontal position and the tip should be resting in the pyriform recess. The position of the tip of the forceps may be checked by palpating the neck lateral to the posterior-superior aspect of the thyroid cartilage. The forceps are kept in this position for 5 minutes or longer, and then the process is repeated on the opposite side. This approach requires a considerable length of time and is limited to those patients who can open their mouths sufficiently wide.

3. Cautions, Complications, and Contraindications

When performing a SLN block from an external approach, care should be taken to avoid insertion of the needle into the thyroid cartilage, to preclude the possibility of injecting the local anesthetic at the level of the vocal cords, which could cause laryngeal edema and airway

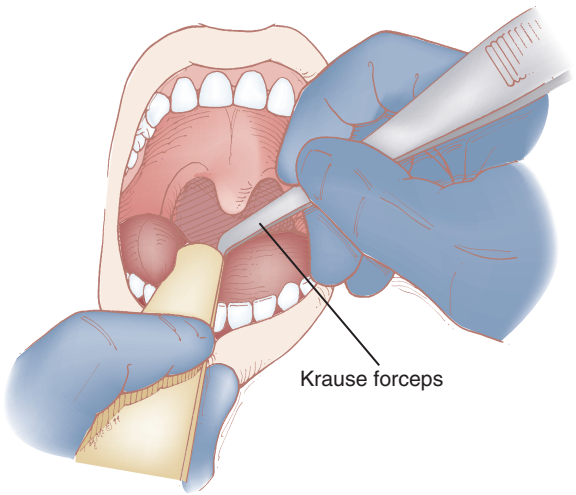

Figure 11-20 Superior laryngeal nerve block, internal approach. A Krause forceps is advanced over the tongue toward the pyriform sinus. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

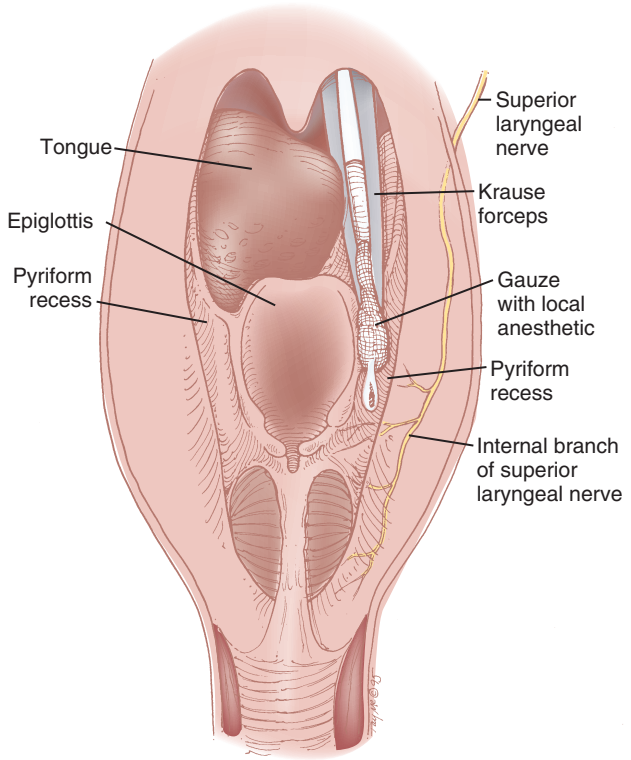

Figure 11-21 Superior laryngeal nerve block, internal approach. Posterior view of the larynx showing tip of Krause forceps at the level of the pyriform sinus. (From Difficult Airway: Teaching Aids. Irvine, University of California, Department of Anesthesia.)

obstruction. The carotid artery should be identified and displaced posteriorly to minimize the risk of intravascular injection; even small amounts (0.25 to 0.5 mL) of local anesthetic injected into the carotid artery can induce seizures.

Hypotension and bradycardia have also been associated with SLN blockade. A number of possible causes of this reaction have been postulated, including (1) vasovagal reaction related to painful stimulation, (2) digital pressure on the carotid sinus, (3) excessive manipulation of the larynx causing vasovagal reaction, (4) large doses of or accidental intravascular administration of local anesthetic drugs, and (5) direct neural stimulation of the branch of the vagus nerve by the needle.[139] It is recommended that anticholinergics be administered before the block is performed.

Complications of the external approach also include hematoma and rupture of the ETT cuff in patients already intubated. Pharyngeal puncture and subsequent aspiration of air may occur and is generally a benign occurrence; the needle should be withdrawn until no more air is aspirated before local anesthetic is injected.

Contraindications to the external approach include local infection, local tumor growth, and coagulopathy. Although the position is not universally accepted, some have advocated avoidance of SLN anesthesia in patients who are at high risk for aspiration.[140]

D. Trachea and Vocal Cords

1. Anatomy

The sensory innervation of the trachea, inferior larynx, and vocal cords is supplied by the recurrent (inferior) laryngeal nerves, branches of the vagus nerve. The right recurrent laryngeal nerve (RLN) originates at the level of the right subclavian artery; the left originates at the level of the aortic arch, distal to the ligamentum arteriosum. Both ascend along the tracheoesophageal groove to supply sensory innervation to the tracheobronchial tree up to and including the vocal cords, as well as supplying motor nerve fibers to the intrinsic muscles of the larynx (except the cricothyroid muscle). Because the sensory and motor fibers run together, nerve blocks cannot be performed because they would result in bilateral vocal cord paralysis and complete airway obstruction.

The alternative is topicalization of the mucosa. In addition to the use of a nebulizer, atomizer, or "spray-as-you-go" technique, topicalization of the trachea may be achieved by translaryngeal (transtracheal) injection. Although this technique does not provide a nerve block in the strictest sense, it is invasive and bears risks similar to those of other airway nerve blocks. In one study comparing transtracheal injection, "spray-as-you-go" topicalization through an FFB, and nebulization, transtracheal injection was most preferred by patients and bronchoscopists.[142] Tracheal topicalization is also of particular benefit in cases in which a neurologic examination is required after intubation, because it makes the presence of an ETT more comfortable.

2. Translaryngeal (Transtracheal) Anesthesia

a. POSITIONING AND LANDMARKS

The ideal position for translaryngeal anesthesia is the supine position with the neck in extension. In this position, the cervical vertebrae push the trachea and cricoid cartilage anteriorly and displace the strap muscles of the neck laterally. As a result, the cricoid cartilage and the structures above and below it are easier to palpate. The thyroid cartilage (Adam's apple) is palpated at midline and followed caudally until a depression and a firm ring of tissue are identified. These are the cricothyroid groove and the cricoid cartilage, respectively. Overlying the cricoid groove is the cricothyroid membrane.

b. TECHNIQUE

The physician should stand at the side of the patient with the dominant hand closest to the patient. The patient is asked not to talk, swallow, or cough until instructed. The midline of the cricothyroid membrane is identified as the needle insertion site. The index and middle finger of the nondominant hand can be used to mark this spot and stabilize the trachea (Fig. 11-22). Using a tuberculin syringe or a 25-G needle, the physician raises a small skin wheal. A 20-G angiocatheter attached to a 5- to 10-mL syringe containing 3 to 5 mL saline is used. The needle is advanced through the skin perpendicularly or slightly caudally while aspirating. When air is freely aspirated, the sheath of the angiocatheter is advanced slightly, the needle is removed, and a syringe containing 3 to 5 mL of

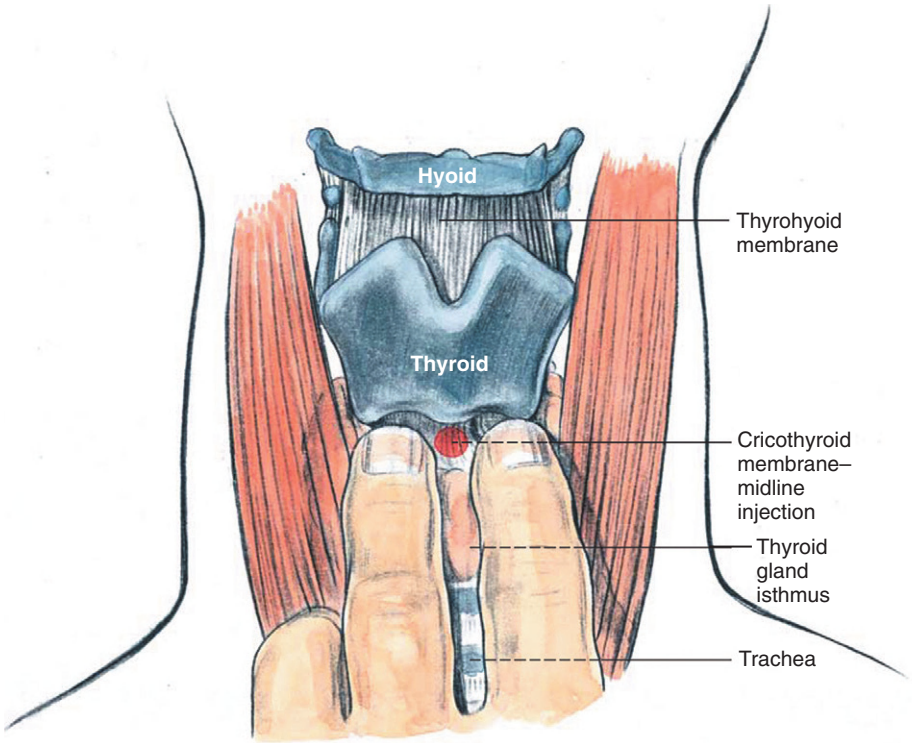

Figure 11-22 Translaryngeal anesthesia, anatomic landmarks. (From Brown D, editor: *Atlas of regional anesthesia*, ed 2, Philadelphia, 1999, Saunders.)

2% to 4% lidocaine is carefully attached to the catheter sheath that has been left in place. Aspiration of air is reconfirmed, the patient is warned to expect vigorous coughing, and the local anesthetic is injected rapidly during inspiration (Fig. 11-23). The sheath of the angiocatheter may be left in place until the intubation is complete in case more local anesthetic is needed and to decrease the likelihood of subcutaneous emphysema. Coughing helps to nebulize the local anesthetic so that the inferior and superior surfaces of the vocal cords can be anesthetized along with the tracheobronchial tree and inferior larynx. Anesthesia of the epiglottis, vallecula, tongue, and posterior pharyngeal wall are possible but unreliable. The success of translaryngeal anesthesia has been found to be as high as 95% and is attributed to both topicalization of the airway and systemic absorption.

This technique may be performed using a standard 20- or 22-G needle. This may, however, increase the risk of airway injury from the sharp metal bevel as the patient coughs. If this technique is used, care should be taken to remove the needle immediately after injection of the local anesthetic. This technique has also been described using a 25-G needle, but this is not recommended, because it introduces the risk of needle breakage as a result of movement of the cricoid cartilage cephalad when the patient coughs.[141]

c. CAUTIONS, COMPLICATIONS, CONTRAINDICATIONS

The tip of the needle should never be aimed in a cephalad direction, to avoid laryngeal trauma and to ensure adequate spread of local anesthetic below the vocal cords. Because this procedure eliminates the patient's ability to protect the airway from aspiration, it should not be performed in patients who are at high risk for aspiration. Coughing elicited by this block may result in increased heart rate, mean arterial blood pressure, ICP, and intraocular pressure. As a result, it is contraindicated in patients with elevated ICP or open globe, and care should be taken in patients with significant cardiac disease. It is also relatively contraindicated in patients with cervical instability, although its routine use in these patients has been described without complications.[143] Transtracheal injection should be avoided in patients with local tumor or large goiter.

Potential complications are similar to those described for retrograde intubation (see Chapter 20). They include subcutaneous and intratracheal bleeding, infection, subcutaneous emphysema,[144] pneumomediastinum, pneumothorax, vocal cord trauma, and esophageal perforation. These complications are rare, as was illustrated by a review of 17,500 cases of translaryngeal puncture that showed an incidence of complications of less than 0.01%.[141]

VII. CONCLUSIONS

Once the decision to perform an AI has been made, the physician has many choices to make regarding the mode of preparation and the technique to be used. Regardless of the indication for AI, these clinical situations involve greater risk than a standard anesthetic technique. Safety should be the primary concern. Sedation should generally be a supplement to, rather than a substitute for, topical anesthesia of the airway. As long as the patient is awake,

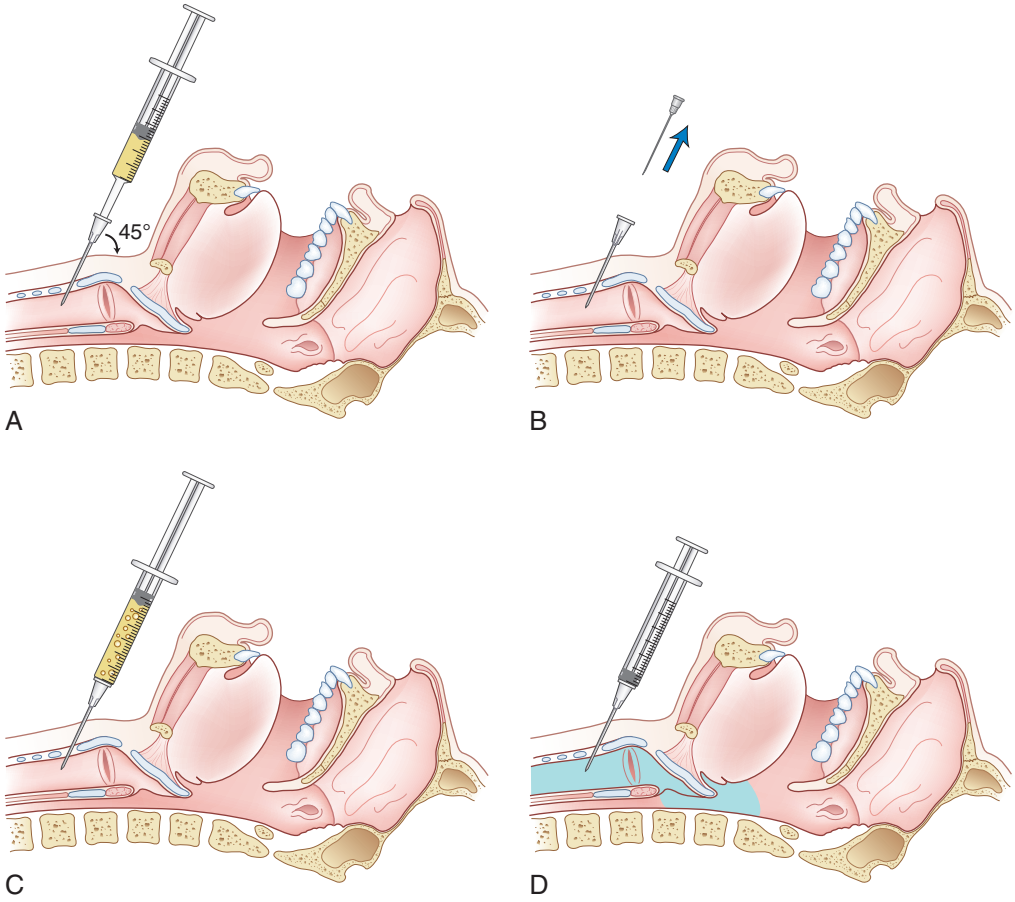

Figure 11-23 Translaryngeal anesthesia (midsagittal view of the head and neck). **A,** The angiocatheter is inserted at the cricothyroid membrane, aimed caudally. An aspiration test is performed to verify the position of the tip of the needle in the tracheal lumen. **B,** The needle is removed from the angiocatheter. **C,** The syringe containing local anesthetic attached, the aspiration test is repeated. **D,** Local anesthetic is injected, resulting in coughing and nebulization of the local anesthetic (*shaded area*). (From The Retrograde Cookbook. Irvine, University of California, Department of Anesthesia.)

cooperative, maintaining the airway, and spontaneously ventilating, no bridges have been burned. It is important that the physician be comfortable with the techniques used for topicalization and intubation; during management of a critical airway is not the time to learn a new technique. There should be a detailed backup plan in place in the event that the primary technique planned is unsuccessful. With the proper planning, patient preparation, and technique, AI is an invaluable tool for management of the DA.

VIII. CLINICAL PEARLS

- When faced with a difficult airway (DA), awake intubation (AI) is the gold standard for airway management.
- Preparation begins with a careful history and physical examination and a detailed discussion of the procedure with the patient.
- The goals of premedication are to alleviate anxiety, provide a clear and dry airway, protect against the risk of aspiration, and enable adequate topicalization.
- Sedation may be accomplished with benzodiazepines, opioids, or intravenous hypnotics, either alone or in combination; these agents must be titrated carefully to maintain cooperation and adequate ventilation.
- Adequate topicalization of the airway with local anesthetics is the key to a successful AI.
- If airway topicalization is insufficient, airway nerve blocks may be employed to supplement airway anesthesia.
- There are many choices involved when preparing for AI. Safety should be the primary consideration.

IV. Conclusions

V. Clinical Pearls

I. PERIOPERATIVE ASPIRATION

The pulmonary aspiration of gastric contents has generated a body of research and recrimination that might seem disproportionate to its reported incidence. Aspiration pneumonitis is an anesthetic complication whose consequences can be formidable but whose prevention would seem, at least in theory, to be readily attainable. The desire to minimize risks long ago led to rituals of fasting that were later challenged, at least with respect to fluids. Any experience with aspiration and its dire sequelae may, however, inspire rigid adherence to conservative nil per os (NPO) standards and avid administration of prophylactic preoperative medications.

A. Incidence

The statistical incidence of perioperative aspiration has been examined in long-term case reviews. A multicenter, prospective study of almost 200,000 operations performed in France found the overall incidence of clinically apparent aspiration to be 1.4 per 10,000 anesthesias.[1] Leigh and Tytler's 5-year survey of almost 110,000 anesthesias found 6 cases of aspiration requiring unplanned critical care.[2] Warner and colleagues retrospectively reviewed more than 215,000 general anesthesias and found an incidence of aspiration of 3.1 per 10,000 cases.[3] Olsson and associates examined the records of more than 175,000 anesthesias administered at one hospital over more than 13 years and reported an incidence of aspiration of 4.7 per 10,000.[4] Kallar and Everett's multicenter survey of more than 500,000 outpatient anesthesias found the incidence of aspiration to be 1.7 per 10,000.[1]

In their 1999 review of 133 Australian cases, Kluger and Short reported that the incidence of passive regurgitation was three times that of active vomiting and that a majority of aspiration episodes accompanied anesthesias delivered by face mask or laryngeal mask airway (LMA). Thirty-eight percent of those who aspirated developed radiographic infiltrates, more often in the right lung than in the left. The authors also noted that "a recurring theme in many incidents was one of inadequate anaesthesia leading to coughing/straining and subsequent regurgitation/vomiting."[5] In their 1999 survey of pediatric aspiration, Warner and coauthors also wrote that "nearly all cases of pulmonary aspiration … occurred in patients who gagged or coughed during airway manipulation or during induction of anesthesia."[6]

Several authors have observed that only about 50% or fewer of the episodes of perioperative aspiration occur during anesthetic induction and intubation, perhaps because concern is less heightened at other times.[1–9] These potentially catastrophic events also take place before induction (when the unguarded patient may be

excessively sedated), during anesthesia maintenance, and during or after emergence and extubation.

B. Consequences

When aspiration does occur, the subsequent clinical course can range from benign to fatal. Olsson and colleagues reported that 18% of patients who aspirated perioperatively required mechanical ventilatory support, and 5% died. All those who died had a poor preoperative physical status.[4] Warner and coworkers reported that 64% of patients did *not* manifest coughing, wheezing, radiographic abnormalities, or a 10% decrease in arterial oxygen saturation (Sao_2) from preoperative room air values during the first 2 hours after aspiration. Such patients who remained asymptomatic for 2 hours developed no respiratory sequelae. Of the patients who did manifest signs or symptoms of pulmonary aspiration within 2 hours after the event, 54% required mechanical ventilatory support for 6 hours or longer, and 25% were ventilated for more than 24 hours. Approximately 50% of those ventilated for 24 hours or longer died, generating an overall mortality rate of less than 5% of all aspirations.[3]

Mortality rates resulting from perioperative pulmonary aspiration have ranged from less than 5% to more than 80% in other reports.[10,11] In the studies of Warner and Olsson and their coworkers, there were no deaths in healthy patients undergoing elective surgery.[3,4] In their 1999 survey of 133 perioperative aspirations in Australia, Kluger and Short wrote that "the deaths following aspiration events occurred in sicker patients … although mortality can occur in healthy, younger patients."[5] Reviewing more than 85,000 Scandinavian anesthesias, Mellin-Olsen and associates noted that only 3 of 25 patients who aspirated developed serious morbidity, 2 of whom endured a prolonged course of illness but all of whom survived.[8] In general, most healthy patients who aspirate only gastric fluid can expect to survive without residual respiratory impairment, albeit sometimes after a stormy postoperative course.

C. Risk Factors

1. Demographic

Published surveys have associated some characteristics of patients or circumstances with an increased incidence of aspiration. Warner and colleagues noted that the relative risk of aspiration was more than four times higher for emergency surgeries compared with elective surgeries. A higher American Society of Anesthesiologists (ASA) physical status classification was also associated with a higher risk of aspiration. The incidence of aspiration increased from 1.1 per 10,000 elective anesthesias in ASA class I patients to 29.2 per 10,000 emergency anesthesias in ASA class IV and V patients. Contrary to conventional wisdom, "Age, gender, pregnancy … concurrent administration of opioids, obesity … experience … of anesthesia provider, and types of surgical procedure were not independent risk factors for pulmonary aspiration. … The most common predisposing condition in all patients was gastrointestinal obstruction."[3] Borland and coauthors also wrote that "aspiration occurred significantly more often in patients with greater severity of underlying illness."[12]

Olsson and colleagues found that children and elderly persons were more likely than patients of intermediate ages to aspirate perioperatively.[4] Statistically, the risk of aspiration was more than three times higher in emergency surgeries than in elective operations. The incidence of aspiration was increased more than sixfold when surgery was performed at night rather than during daylight hours. More recent studies of both adult and pediatric cases have confirmed an impressive increase in the incidence of perioperative aspiration in emergency operations,[6,8] but Borland and coauthors found this increase to be only "marginally significant."[12]

In Kallar and Everett's outpatient survey,[1] aspiration occurred most frequently in patients younger than 10 years of age. They also reported, "In patients with no other identifiable risk factors, 67% of aspirations occurred after difficulties in airway management or intubation."[1] In the study of Olsson and colleagues, 15 of 83 aspirations occurred in patients with no known risk factors.[4] In 67% (10/15) of these cases, aspiration accompanied airway problems. In contrast to Kluger and Short's findings,[5] no patient aspirated while intubated. Although regional techniques are often favored for patients at increased risk for aspiration, elderly patients, in particular, have been reported to vomit and aspirate during subarachnoid anesthesia. Hypotension resulting from neuraxial sympathectomy can induce nausea and vomiting, and supplemental analgesics and sedatives given during lengthy operations can seriously obtund protective airway reflexes.[4,13,14]

Patients who are likely to have gastric contents of increased volume or acidity, elevated intragastric pressure, or decreased tone of the lower esophageal sphincter (LES) are traditionally considered to be at increased risk for perioperative pulmonary aspiration (Boxes 12-1 and 12-2).[10,15] As discussed later, pregnancy combines several of these likely risk factors. Although a lengthy NPO period before elective surgery is intended to minimize the volume of gastric contents, up to 90% of fasted patients have a gastric fluid pH level lower than 2.5.[11] Recent ethanol ingestion or hypoglycemic episodes stimulate gastric acid secretion, whereas tobacco inhalation temporarily lowers LES tone. LES tone has also been found to be reduced by gastric fluid acidity, caffeine, chocolate, and fatty foods.[11]

BOX 12-1 Risk Factors for Aspiration of Gastric Contents

Regurgitation or vomiting
Hypotension in awake patient
Opioids in awake patient
Increased intragastric volume and pressure
Decreased lower esophageal barrier pressure
Incompetent laryngeal protective reflexes
Neurologic disease
Neuromuscular disease
Central nervous system depressants
Advanced age or debility

BOX 12-2 Factors That Increase Intragastric Volume and Pressure

Increased gastric filling
Air inflation during mask ventilation
Increased gastric acid production
Gastrin
Histamine$_2$ (H_2) receptor stimulation
Recent ethanol ingestion
Recent hypoglycemic episode
Decreased gastric emptying
Intestinal obstruction
Diabetic gastroparesis
Opioids
Anticholinergics
Sympathetic stimulation (pain and anxiety)

Surgical outpatients have traditionally been thought to carry gastric contents of expanded volume and reduced pH, possibly because of preoperative anxiety. Clinical studies, however, have not consistently confirmed this expectation.[1] Furthermore, Hardy and associates contradicted several conventional notions by finding that neither gastric content volume nor pH correlated with preoperative anxiety, body mass index (BMI), ethanol or tobacco intake, or reflux history.[15]

2. Obesity

Obese patients were traditionally thought to pose a relatively high risk for aspiration because of their greater gastric fluid volume and acidity, intragastric pressure, and incidence of gastroesophageal reflux (GER).[16] This assumption has been challenged. In 1998, Harter and colleagues studied 232 fasted, nondiabetic surgical patients who had received no relevant preoperative medication. Using conventional arbitrary criteria, they found that only 27% of obese patients, compared with 42% of the nonobese, had gastric contents of high volume and acidity. Grading obesity by BMI, they also found no association between degree of obesity and gastric fluid volume or pH.[16] The presumed sluggishness of gastric emptying in obese patients has also been denied. Verdich and coworkers reported that obese and lean patients did not differ in rate of gastric emptying during the first 3 hours after a test meal.[17] Lower esophageal pressure has also been shown not to differ significantly between obese and nonobese patients.[16]

On the other hand, the laryngoscopic challenges that arise with corpulence, along with the association between airway difficulties and aspiration episodes, appear to increase the risk of aspiration in obese patients regardless of their gastrointestinal motility. Clinical studies have both confirmed and denied a demonstrable increase in the incidence of difficult intubation (DI) in the obese.[18–21] In a review of the topic, Freid noted that "obese patients … develop oxygen desaturation faster than the nonobese, and the safe apneic period is reduced from more than five minutes to less than two to three minutes in the preoxygenated state." Importantly, he observed that "far more morbidity occurs owing to hypoxemia during difficult or failed intubation than from aspiration."[7]

3. Systemic Diseases

Patients with connective tissue, neurologic, metabolic, or neuromuscular disease may be imperiled by esophageal dysfunction or laryngeal incompetence. Progressive systemic sclerosis and myotonia dystrophica have been specifically mentioned in case reports.[22–24] Hardoff and coworkers found that "gastric emptying time in patients with Parkinson's disease was delayed compared with control volunteers [and] was even slower in patients treated with levodopa."[25] Advanced age may be associated with attenuated cough or gag reflexes.

Long-standing diabetes mellitus is commonly considered to delay gastric emptying and may also compromise LES function.[26] Several authors have reported a high incidence of gastroparesis and prolonged mean gastric emptying times, at least for solid foods, in diabetic patients compared with control subjects.[27–30] Impairment of gastric motility was usually found to correlate with findings of autonomic neuropathy but not with peripheral neuropathy or with indices of glycemic stability.

4. Pregnancy

Pregnancy imposes a constellation of potential risk factors. The enlarging uterus increases intragastric pressure by compressing the stomach, physically delays gastric emptying by pushing the pylorus cephalad and posteriorly, and promotes GER by altering the angle of the gastroesophageal junction. Progesterone decreases the tone of the LES, and excess gastrin, produced by the placenta, promotes gastric acid secretion.[26,31,32] The alterations in physique that are typical of late pregnancy can interfere with laryngoscopy and endotracheal intubation. Laryngeal and upper airway edema is also common in the parturient and can be exaggerated by preeclampsia.[33]

Studies of gastric emptying in pregnancy have produced somewhat inconsistent results. Wong and colleagues found that water was readily cleared from the stomachs of nonobese, nonlaboring parturients at term and wrote that "recent studies of gastric emptying in nonlaboring term women … suggest that gastric emptying is not delayed during pregnancy."[34] Chiloiro and coworkers found that gastric emptying time did not become slower with the progress of gestation but that total orocecal transit time did.[35] A more common clinical concern is the parturient in labor. Scrutton and associates reported that laboring patients who consumed a light solid meal had significantly greater gastric volumes than those allowed only water.[36] Although pain, in any circumstance, is thought to delay gastric emptying, Porter and coauthors stated that "pain does not appear to be the sole cause of gastric slowing in late labour since [there was] a similar delay in women in late labour who had received either epidural local anesthetic alone or no analgesia."[37]

5. Pain and Analgesics

Pain and its treatment are considered to be risk factors for aspiration, notably in patients presenting with trauma. As stated by Crighton and colleagues, "circulating catecholamines have an inhibitory effect on gastric emptying, and noradrenaline release in response to painful stimuli may cause inhibition of gastric tone and emptying."[38]

Patients with spinal cord or brain injuries have also been shown to manifest delayed gastric emptying of both liquid and solid contents.[39–41]

Administration of opioids to alleviate pain is an essential act of kindness but may further impair gastrointestinal function. Opioid receptors can be found throughout the gastrointestinal tract; human and animal studies suggest that there are central and peripheral mechanisms by which these drugs retard gastric emptying.[42] Even modest intravenous doses of morphine demonstrably prolong gastric transit times in clinical studies.[38,43–45]

Neuraxial opioids can also prolong gastric emptying. In obstetric anesthesia, Kelly and associates "conclude[d] that the administration of fentanyl 25 mg intrathecally delays gastric emptying in labor compared with both extradural fentanyl 50 mg with bupivacaine and extradural bupivacaine alone."[46] Older reports indicated that epidural fentanyl boluses of 50 or 100 mg would retard gastric emptying. On the other hand, the addition of fentanyl (2 or 2.5 mg/mL) to dilute bupivacaine for epidural infusion during labor was not found to affect gastric motility.[37,47]

6. Positioning

Agnew and colleagues continuously monitored esophageal and tracheal pH in thoracotomy patients "considered to be at low risk of GER." Twenty-eight percent of their patients not treated with a histamine$_2$ (H_2)-receptor antagonist were found to have acid reflux into the esophagus while in the lateral decubitus position, and almost 8% had acid in the trachea. Although the authors did not correlate clinical outcomes with their findings, they did advise that patients undergoing thoracotomy be considered for routine preoperative aspiration chemoprophylaxis.[48]

D. Pathophysiology

When gastric contents enter the lungs, the resultant pulmonary pathology depends on the nature of the material aspirated (Box 12-3). Food particles small enough to enter the distal airways induce a foreign body reaction of inflammation and eventual granuloma formation. The aspiration of particulate antacids produces the same adverse response.[32,49] Acid aspiration induces an inflammatory response that begins within minutes and progresses over 24 to 36 hours.[49,50] In 1940, Irons and Apfelbach wrote that the "characteristic microscopic changes are intense engorgement of the alveolar capillaries, … edema, and hemorrhage into the alveolar spaces.… Another outstanding characteristic is the extensive desquamation of the lining of the bronchial tree."[51] Other authors have also described hemorrhagic pulmonary edema, intense inflammation, and derangement of the pulmonary epithelium.[50,52] The membranous epithelial cells that produce surfactant are damaged or destroyed by the acid and replaced by granular epithelial cells.[14] As surfactant production fails, lung units progressively collapse. Fibrin and plasma leak from the capillaries into the pulmonary interstitium and alveoli, producing the noncardiogenic pulmonary edema often referred to as adult (or acute) respiratory distress syndrome (ARDS).[14,50,53,54] With effective supportive care, the acute inflammation can diminish, and epithelial regeneration can begin, within 72 hours.

The clinical features of aspiration pneumonitis have been well described for more than 60 years. Even earlier, in 1887, Becker referred to bronchopneumonia as a postoperative complication related to the inhalation of gastric contents.[51] Hall, in 1940, published the first description of gastric fluid inhalation in obstetric patients. He distinguished between the aspiration of solid material, which could quickly kill by suffocation, and the aspiration syndrome produced by gastric fluid, for which he coined the term *chemical pneumonitis*.[55] Mendelson, in 1946, described the clinical features of 66 cases of peripartum aspiration observed from 1932 to 1945. Solid food produced airway obstruction, which was quickly fatal in two instances. Otherwise, wheezing, rales, rhonchi, tachypnea, and tachycardia were prominent.[56] (Subsequent reports have not found wheezing to be so universal a manifestation, occurring in about one third of aspirations.) When present, wheezing is thought to result from bronchial mucosal edema and from a reflex response to acidic airway irritation.[11,50,57]

Refractory hypoxemia can ensue almost immediately as bronchospasm, airway edema or obstruction, and alveolar collapse or flooding increase the effective intrapulmonary shunt fraction (Box 12-4). The awake patient may experience intense dyspnea and may cough up the pink, frothy sputum characteristic of pulmonary edema.[11,32,50] More modest aspirations may not become clinically evident for several hours.[32,58,59]

Hemodynamic derangements can also demand therapeutic attention. As the alveolar-capillary membrane loses its integrity, plasma leaks out of the pulmonary vasculature. If the leak becomes a flood, the loss of circulating fluid volume can produce hemoconcentration,

BOX 12-3 Pathophysiology of Aspiration

Particulate aspiration
Airway obstruction
Granulomatous inflammation
Acid aspiration
Neutrophilic inflammation
Hemorrhagic pulmonary edema
Destruction of airway epithelium
Loss of type I alveolar cells
Loss of surfactant
Alveolar instability and collapse
Disruption of alveolar-capillary membrane
Plasma leakage from pulmonary capillaries
Noncardiogenic pulmonary edema
Hypovolemia

BOX 12-4 Aspiration and Hypoxemia

Upper airway obstruction
Increased lower airway resistance
Obstruction by airway debris
Airway edema
Reflex bronchospasm
Alveolar collapse and flooding

hypotension, tachycardia, and even shock.[11,32] Pulmonary vasospasm may also contribute to right ventricular dysfunction.[11]

The radiographic evidence of pulmonary aspiration may become evident promptly, if aspiration is massive, or after a delay of several hours. There is no pattern on the chest roentgenogram that is specific for aspiration. The distribution of infiltrates depends on the volume of material inhaled and the patient's position at the time of the event. Because of bronchial anatomy, aspiration occurring in the supine patient affects the right lower lobe most commonly, the left upper lobe least often.[11,32] If pulmonary aspiration is not complicated by secondary events, improvement in symptoms can be anticipated within 24 hours, although the radiographic picture may continue to worsen for another day.[32]

E. Determinants of Morbidity

1. pH and Volume of Aspirate

In his 1946 report, Mendelson undertook to determine the relationship between gastric fluid acidity and pulmonary morbidity. When liquid containing hydrochloric acid (HCl) was instilled into rabbits' tracheas, the animals developed a syndrome "similar in many respects to that observed in the human following liquid aspiration,"[56] with cyanosis, dyspnea, and pink, frothy sputum. On the other hand, when neutral liquid was instilled into the trachea, the rabbits endured a brief symptomatic period, "but within a few hours they [were] apparently back to normal, able to carry on rabbit activities uninhibited."[56] (Mendelson maintained a discreet silence about the nature of these uninhibited rabbit activities.)

Since Mendelson's report, numerous attempts (and assumptions) have been made to define the "critical" volume and pH of gastric contents required to inflict significant damage on the lungs. Such neatly defined threshold values may be illusory objects of desire rather than features of clinical reality. Nonetheless, almost all researchers in the field of aspiration pneumonitis have made some use of critical values to define the success or failure of drug therapies in the modification of gastric contents.

In 1952, Teabeaut injected HCl solutions of different volumes and acidities into rabbits' tracheas. He found that solutions with a pH higher than 2.4 caused a relatively benign tissue response similar to that induced by the intratracheal injection of water. As the pH of the injectate was reduced from 2.4 to 1.5, a progressively more severe tissue reaction was elicited. At pH 1.5, the damage was maximal and equal to that found at lower pH values.[60] From this study stemmed the popular concept of the pH value of 2.5 as a threshold for chemical pneumonitis.

The determination of a critical volume of gastric contents required to produce severe aspiration pneumonitis has been even more contentious than that of a critical pH. Two teams of investigators each found that, in dogs, pulmonary injury became independent of pH as the volume of aspirate was increased from 0.5 to 4.0 mL/kg.[11] A preliminary experiment by Roberts and Shirley, involving gastric fluid instillation into the right main stem bronchus of a single monkey, long ago led to the acceptance, in some quarters, of 0.4 mL/kg as the volume of gastric fluid that places a subject at risk for development of aspiration pneumonitis.[61–63] Subsequent researchers challenged this number. James and colleagues demonstrated that aspirate volumes as low as 0.2 mL/kg could induce pulmonary injury if the pH of the aspirate were reduced to 1.09.[64] On the other hand, Raidoo and coworkers, also studying monkeys, found that the aspiration of 0.4 to 0.6 mL/kg of fluid with a pH of 1.0 produced mild or moderate pulmonary injury, and 0.8 to 1.0 mL/kg at pH 1.0 produced severe pneumonitis, with a 50% mortality rate (3/6) at 1.0 mL/kg.[61]

Clearly, the volume of aspirate that is considered hazardous depends on how much morbidity or pathology must be produced to be considered significant. Arguments have also been made concerning the experimental instillation of gastric fluid into one lung versus both lungs and the reliability of gastric fluid volume measurements. In addition, even if a critical volume for aspiration pneumonitis could be reliably determined, it cannot be known how much fluid must be present in the stomach in order to deposit this critical volume into the lung or lungs.[61,65] However, studies of therapeutic interventions must have criteria for defining success or failure, and threshold values for gastric fluid volume and pH are typically employed, regardless of their validity.

2. Particulate Matter

Volume and acidity are not, of course, the only determinants of sequelae when gastric contents enter the lungs. Since the report of Bond and coworkers in 1979, it has been appreciated that gastric fluid containing particulate antacids can produce severe aspiration pneumonitis, even at near-neutral pH, with wheezing, pulmonary edema, and hypoxemia requiring mechanical ventilatory support.[66] Animal studies confirmed that nonparticulate gastric acid and particulate antacid solutions have similar potentials for pulmonary mischief if aspirated.[58] Although blood and digestive enzymes do not appear to induce chemical pneumonitis, feculent gastric contents with a high bacterial density readily produce pneumonitis and death in animals. (Acidic gastric contents are normally sterile.) Another study demonstrated that the mucus present in the gastric fluid of dogs with intestinal obstruction produced diffuse small airway obstruction and pulmonary injury when aspirated.[11]

II. PREVENTION OF ASPIRATION

The clinical challenges of perioperative pulmonary aspiration are prevention, prophylaxis, and treatment. Ideally, gastric contents can be physically prevented from entering the lungs in the first place. Should prevention fail, pharmacologic prophylaxis may modify the volume and character of gastric contents so that they inflict minimal damage on the lungs. Least desirably, aspiration pneumonitis can require intensive medical treatment and ventilatory support.

The nonpharmacologic means of keeping gastric contents out of the lungs are preoperative fasting, gastric decompression, and optimal airway management.

A. Preoperative Fasting

The most common means of keeping gastric contents out of the lungs is to minimize the volume of such contents through preoperative fasting. However, both the utility and the necessity of adhering to traditional NPO regimens for clear liquids have been challenged. As noted by Sethi and coauthors, "the stomach can never be completely empty even after a midnight fast since it continues to secrete gastric juices."[67] The issue has been studied in both pediatric and adult surgical patients and has become particularly contentious and emotional regarding obstetric anesthesia.

1. Pediatric Patients

Conventional preoperative fasting can impose physical and emotional discomfort on children and their parents and may be difficult to enforce reliably in outpatients. Dehydration in infants and hypoglycemia in neonates may also result from prolonged NPO times.[1,10] The normal stomach can empty 80% of a clear liquid load within 1 hour after ingestion. Whereas the stomach continues to secrete and reabsorb fluid throughout NPO time, ingested clear liquids are completely passed into the duodenum within 2.25 hours.[68] Several researchers have therefore sought to demonstrate that children may safely be allowed to drink clear liquids until just 2 to 3 hours before elective surgery.

Van der Walt and Carter, as well as other groups, determined that healthy infants could drink limited volumes of clear liquids 3 to 4 hours before surgery with no effect on gastric content volumes.[69] Splinter and colleagues found that healthy infants could drink clear liquids ad libitum until 2 hours before anesthetic induction without altering gastric fluid volume or pH. (Gastric fluid pH was quite variable, and mean pH was less than 2.5 in all groups of patients studied, regardless of NPO time.) On the other hand, milk or formula intake on the morning of surgery (4 to 6 hours before induction) was associated with the presence of curds in many of the gastric aspirates. This was considered to represent an unacceptable risk of particulate aspiration. The authors therefore concurred with previous recommendations that infants not be allowed milk or formula on the morning of surgery.[70]

More recently, Cook-Sather and associates studied 97 healthy infants undergoing elective surgery and found that gastric fluid volume was not increased when the fasting time for formula was reduced from 8 hours to either 6 or 4 hours.[71] Schreiner and colleagues compared the gastric contents of children subjected to conventional preoperative fasting (mean NPO time, 13.5 hours) with those of children permitted clear liquids until 2 hours before anesthetic induction (mean NPO time, 2.6 hours). Gastric fluid volumes actually tended to be somewhat smaller in the children allowed to drink clear liquids up to 2 hours preoperatively, and almost all children in both groups had gastric content pH values of 2.5 or less.[72] Sandhar and coauthors, studying children 1 to 14 years old, also found that clear liquid ingestion 2 to 3 hours preoperatively did not significantly increase the mean volume of gastric contents and did not increase the number of patients with gastric contents more voluminous than 0.4 mL/kg.[68] Reports by Splinter, Moyao-Garcia, Maekawa, and Gombar and their colleagues all concluded that permitting children to drink nonparticulate fluids 2 to 3 hours before surgery had either no effect or a small beneficial influence on the quantity and acidity of their gastric contents.[73–76]

Ingestion of clear liquids alone therefore appears to pose no demonstrable hazard if taken no later than 2 hours before anesthesia by children without gastrointestinal pathology. However, solid or semisolid foods are not cleared from the stomach as rapidly as clear liquids. Meakin and associates found that a light breakfast of biscuits or orange juice with pulp, taken 2 to 4 hours before induction, did increase the volume of gastric aspirate in healthy children compared with those who had fasted for 4 hours or longer. In all fasted children, and in almost all of the fed children, the gastric content pH was 2.5 or less.[77] Hyperosmolar glucose solutions are also associated with delayed gastric emptying.[68]

In 1999, the ASA issued the report of its Task Force on Preoperative Fasting, which included practice guidelines. These guidelines were intended to apply to healthy patients who have no known relevant risk factors or injuries and are scheduled for elective surgery. Within these limitations, the ASA Task Force "support[ed] a fasting period for clear liquids of two hours for all patients [and] a fasting period for breast milk of four hours for both neonates and infants" while considering it "appropriate to fast from intake of infant formula for six or more hours."[78]

2. Adult Patients

In adult surgical patients, too, considerable evidence has demonstrated that clear liquid intake within 2 to 3 hours of anesthetic induction does not increase the risk of gastric acid aspiration. It is important to note that these studies typically involved healthy, nonpregnant, nonobese patients who were free of known gastrointestinal pathology, were not receiving opioids or other medications known to interfere with gastric emptying, and were undergoing elective surgery. The results of such studies cannot, therefore, be reliably applied to any other groups of patients.[79–82]

With adults, as with children, the basic arguments favoring relaxed NPO regimens for clear liquids involve their normally rapid gastric clearance. More than 90% of a 750-mL bolus of isotonic saline was found to pass from the normal stomach within 30 minutes.[83] After 2 hours of fasting, the fluid in the stomach primarily represents the acid secreted by the stomach itself. Exogenous clear liquids tend to dilute endogenous gastric acid and may even accelerate gastric emptying.[65,72,81] Solids, lipids, and hyperosmotic liquids are thought to delay gastric emptying, and their intake would therefore be considered ill advised before anesthetic induction.[65]

Several researchers have sought to correlate these theoretical considerations with clinical situations. Maltby and colleagues studied outpatients who were either kept NPO from the previous midnight or given 150 mL of water 2.5 hours before anesthetic induction. Although the mean gastric pH did not differ significantly between the two groups, the mean gastric volume was significantly

less in the patients who drank than in those who fasted.[83] Read and Vaughan similarly found that permitting patients to drink water ad libitum until 2 hours before surgery had no impact on gastric volume or pH but did decrease preanesthetic anxiety. Many patients had gastric pH values less than or equal to than 2.5, regardless of the time elapsed since fluid intake.[84]

Phillips and colleagues also determined that patients who were allowed to drink clear liquids until 2 hours before surgery had gastric volume and pH values similar to those of patients who fasted for 6 hours. Other studies have also confirmed that the ingestion of 150 mL of (pulp-free) orange juice, coffee, tea, or apple juice 2 to 3 hours before surgery has no detrimental effect on gastric pH or volume in surgical outpatients.[81] (Since the publication of these reports, one can only wonder how many hours of presurgical time have been consumed in speculation regarding the pulp content of orange juice that patients have admitted to consuming.)

The safety of clear liquid ingestion before surgery does not, of course, imply that solid food may also be taken with impunity. In an early study, Miller and coworkers compared 22 adults kept NPO overnight before surgery with 23 adults permitted a light breakfast (one slice of buttered toast and tea or coffee with milk) on the morning of surgery (mean NPO time, 3.8 hours). The two groups were found not to differ significantly in mean volume or median pH of gastric contents or in the percentage of patients with a gastric pH lower than 3.0.[80] Soreide and coauthors reported that the particulate elements of a light breakfast had not completely exited after 4 hours.[85] Reflecting a consensus of clinical comfort, the aforementioned ASA Task Force recommended a 6-hour preoperative fast following a "light meal" and a fast of 8 hours or longer "for a meal that included fried or fatty foods or meat."[78]

3. Pregnant Patients

As preoperative NPO standards became more relaxed, strenuous debate arose over the necessity of adhering to conventional NPO regimens for patients in labor. Obstetricians, nurse-midwives, and psychologists joined the fray. On the one hand, anesthesiologists have long recognized that advanced gestation increases the risk of gastric content aspiration. On the other hand, proponents of liberalizing oral intake for parturients cited the infrequency of aspiration pneumonitis in modern practice, the futility of fasting in ensuring an empty stomach, and the detrimental effects of fasting on maternal and fetal well-being. The fashionable battle cry of "patient autonomy" was also heard.

Elkington cited a Washington state survey (1977-1981) in which none of 36 maternal deaths resulted from anesthetic complications and a North Carolina survey (1981-1985) in which only 1 of 40 maternal deaths resulted from aspiration. He did not advocate uninhibited feeding of patients in labor but rather recommended that, "For otherwise uncomplicated parturients, a nonparticulate diet should be allowed as desired."[86]

Ludka and Roberts referred to a Michigan survey (1972-1984) showing that only 1 of 15 maternal deaths (0.82 per 100,000 live births) resulted from the aspiration of gastric contents, that no deaths were related to regional anesthesia, and that "failure to secure a patent airway was the primary cause of anesthesia-related maternal deaths."[87] They cited other studies indicating that women who ate during labor were less ketotic, required less analgesic medication and oxytocin, and had more active fetuses and neonates with higher Apgar scores than women who fasted during labor. They also "found that laboring women self-regulated intake. Once active labor began, women usually preferred liquids."[87]

Regarding the inevitability of a full stomach in the parturient, Kallar and Everett referred to an ultrasound study in which almost two thirds of patients in labor had solid food in the stomach, regardless of how long they had fasted.[1] Elkington cited a report that approximately 25% of parturients were "at risk" for aspiration pneumonitis, regardless of the duration of fasting, and that prolonged fasting was actually associated with increased gastric fluid volume at a lower pH.[86] Broach and Newton contended that "administration of narcotics, not labor itself, appears to be the major factor in delaying stomach emptying."[88] In a recent review, de Souza and associates wrote the following: "It has now been proven that pregnancy by itself does not delay gastric emptying. Many investigators using different modalities have confirmed this finding. Obese term pregnant patients have also been found to have normal gastric emptying. We emphasize that these findings apply only to patients who are not in labor."[89]

McKay and Mahan stated that, "among many factors that can be linked to the occurrence of aspiration, the most important appears to be faulty administration of obstetric anesthesia." They questioned "whether parturients should be kept … on restricted liquid intake to protect them from what appears to be the basic problem: inadequate anesthesia practices."[90] The apparent implication was that the parturient should eat, drink, and be merry, for if she should aspirate, only poor anesthetic care would be to blame.

On the other hand, Chestnut and Cohen cited the Report on Confidential Enquiries into Maternal Deaths in England and Wales 1982-1984, which found that 7 of 19 anesthesia-associated maternal deaths resulted from aspiration of gastric contents into the lungs, and an ASA review of closed malpractice claims in which "maternal aspiration was the primary reason for 8% of all claims against anesthesiologists for obstetric cases." The authors argued that "These data hardly suggest that the risk of maternal aspiration is remote."[91]

In his reply to McKay and Mahan, Crawford observed that "most of the deaths from aspiration prior to the mid-1950s … were due to asphyxia, caused by respiratory obstruction with solid or semisolid material—since that time, with introduction of a firm dietary regimen for labor, only 2 of the 146 deaths noted have been in that category." Furthermore, he contended, "There is inevitably an incidence of cesarean section and of general anesthesia in every obstetric population.… In an obstetric population the incidence of failed or difficult intubation is roughly one in 300."[92]

In the work of Scrutton and colleagues, permitting parturients a "light diet" (as opposed to water only) had

no effect on the course of labor or the neonatal Apgar scores but did increase the volume of gastric contents and of vomitus. They stated that "the presence of undigested food particles in the vomitus is probably of greater importance [than low pH] as a cause of mortality [and] would not support the policy of encouraging women to eat any solid food once in labour particularly when isotonic drinks appear to offer an adequate calorific alternative."[36] In their review, Ng and Smith concluded that "there is insufficient evidence to clarify changes in risk in the first 24 hours of the postpartum period, when operative procedures are common."[93]

Obviously, the pregnant patient with a difficult airway cannot always be avoided, nor can general anesthesia for cesarean section, no matter how aggressively regional anesthesia is promoted. Regardless of gastric fluid volume or acidity, the presence of solid food imparts the immediate hazard of asphyxiation. Mendelson warned that "misinformed friends and relatives often urge the patient to ingest a heavy meal early in labor before going to the hospital."[56] Crawford concluded, "Grafting good anesthetic technique upon poor preparation of a patient for anesthesia is unjustifiable—there is an essential symbiosis between the two if safety is to be ensured."[92]

B. Preinduction Gastric Emptying

When a patient who is at increased risk for aspiration presents for surgery, the stomach can be emptied, at least in part, by an orogastric or a nasogastric (NG) tube. Some patients, of course, already have such tube placed for gastric decompression, particularly if intestinal obstruction has been diagnosed. In such cases, the anesthesiologist must decide whether to remove the gastric tube before induction. If gastric decompression has not been attempted, the anesthesiologist may wish to do so while the patient's protective airway reflexes remain intact.

It has long been argued that the presence of a gastric tube interferes with the sphincter function of the gastroesophageal junction and promotes GER by acting as a "wick."[94] The presence of a foreign body in the pharynx could also interfere with laryngoscopy. These considerations would favor removal of the gastric tube before induction. However, in an early study by Satiani and colleagues, the incidence of "silent" GER was found to be 12% in anesthetized patients without an NG tube and 6% in patients with an NG tube in place (a statistically insignificant difference).[95] Hardy wrote that "a nasogastric tube need not be withdrawn before induction of anesthesia. The tube can act as an overflow valve" and provide "a venting mechanism whereby pressure cannot build up in the stomach."[96]

Dotson and associates prospectively studied the effect of NG tube size on GER in normal subjects. Attempts were made to provoke GER with a device that elevated abdominal pressure stepwise to 100 mm Hg. In this report, GER "was not detected at any level of abdominal pressure regardless of the presence or size of a nasogastric tube."[97] Salem and colleagues had previously demonstrated that "cricoid pressure is effective in sealing the esophagus around an esophageal tube against an intraesophageal pressure up to 100 cm H_2O."[98] They also advocated the utility of an NG tube as a "blow-off valve" for increased intragastric pressure during induction.[98] The presence of an NG tube, while allowing gastric decompression, may also hold open the LES.[11,99]

Vanner and Asai advised that an NG tube already inserted "should be [suctioned and] left in place [for anesthetic induction], since its presence does not reduce the efficacy of cricoid pressure."[9] On the other hand, Brock-Utne contended that "the recommendation that a nasogastric tube should be left *in situ* during a rapid sequence technique induction is not supported by the evidence. Clinicians who have seen aspiration of gastric contents with an nasogastric tube *in situ* will, no doubt, remove the nasogastric tube before anesthetic induction."[100] None of these writings addressed the usually surgical decision concerning which patients should have NG tubes placed before entering the operating room.

Some of the studies just cited would seem to indicate that an NG tube, already inserted, can be safely left in place during induction and may even have a protective benefit. Gastric decompression during surgery could also reduce the risk of regurgitation and aspiration in the postanesthetic period.[96] The necessity and the utility of NG tube insertion just before induction are not so well defined. The benefits of awake gastric decompression depend, in part, on how completely the stomach can thereby be emptied. The primary drawback is patient discomfort.

Several authors have studied the thoroughness of gastric emptying attainable by gastric tube suctioning, usually in the context of comparing different methods for estimating gastric residual volume. Ong and coauthors reported, as early as 1978, that the volume of fluid obtained by orogastric suctioning correlated poorly with the gastric residual volume calculated by a dilution method, "the volume aspirated being frequently much less than the volume calculated."[101] They concluded that "aspiration through a gastric tube will not empty the stomach completely." Mechanical decompression of the stomach before induction might therefore be of limited reliability and thus provide a false sense of security.[101] Taylor and associates studied 10 obese patients in whom gastric contents were first aspirated through a 16-F multiorificed Salem Sump tube, then "completely" removed by a gastroscope. "The blind aspirated volume underestimated true total gastric volume by an average of 14.7 mL, [which] was statistically significant.… The residual content volume left in the stomach after blind aspiration varied from 4 mL to 23 mL,"[102] a maximal discrepancy far less than that found by Ong and coworkers in 42 patients.[101]

Hardy and colleagues measured the volume of gastric fluid aspirated through an 18-F Salem Sump tube in 24 patients, then directly inspected the stomach and measured the volume of fluid remaining. The residual volume that eluded orogastric suctioning ranged from 0 to 13 mL. The authors concluded "that the volume of aspirated gastric fluid … is a very good estimate of the volume present in the stomach at the time of induction" and that gastric tube suctioning "could also be suitable to empty the stomach of its liquid contents prior to anaesthesia."[103]

It can be argued that any reduction in intragastric volume and pressure before anesthetic induction is desirable and should therefore be attempted. On the other hand, as Satiani and colleagues conceded, "particulate matter [is] impossible to evacuate through the lumen of an ordinary nasogastric tube."[95] Salem and associates concluded that "placement of a nasogastric tube before anesthetic induction seems to be indicated only in patients with overdistention of the stomach."[98] Although obvious enteric obstruction is conventionally treated with gastric decompression before anesthetic induction, not every emergency or at-risk patient is subjected to NG tube insertion while awake. There is currently no consensus to dictate preinduction placement of a gastric tube in any set of patients without intestinal obstruction. In any case, gastric decompression in no way substitutes for proper perioperative management of the airway.

C. Rapid-Sequence Induction and Cricoid Pressure

For the patient whose stomach is assumed to be full, the anesthesiologist must first decide whether to secure the airway before or after anesthetic induction. Awake intubation with topical anesthesia of the airway and varying degrees of sedation can always be considered. Without meticulous explanation and preparation, the patient's enthusiasm for this technique is unlikely to match the practitioner's.

If anesthetic induction is to precede endotracheal intubation, the standard protective maneuver for 5 decades has been rapid-sequence induction (RSI) with cricoid pressure. The traditional components of this technique include preoxygenation and denitrogenation of the lungs, rapid administration of anesthetic induction and neuromuscular blocking agents with brief onset times, cricoid pressure, no manual ventilation by mask, and (one hopes) endotracheal intubation immediately after consciousness and neuromuscular transmission have been obtunded. As El-Orbany and Connolly wrote, this sequence "has achieved a status close to being a standard of care for anesthesia induction in patients with full stomachs. Despite the technique's widespread use, there is still no agreement on how it should best be performed."[104] The practice of RSI has generated contention regarding both cricoid pressure and obligatory apnea between induction and intubation.

Abstention from positive-pressure ventilation (PPV) during RSI rests on the fear that the resulting gastric insufflation will increase the likelihood of regurgitation and aspiration of gastric contents before endotracheal intubation. The preservation of adequate oxygenation despite apnea is, of course, crucial. As noted by El-Orbany and Connolly, "Currently, some experts strongly recommend the routine use of PPV … in certain [RSI] situations. Hypoxemia can develop in obese, pregnant, pediatric, and critically ill patients … even after adequate administration of oxygen … because of their low functional residual capacity."[104] Fifty years ago, Ruben and colleagues demonstrated that "manual … ventilation did not result in gastric insufflation when airway pressures were kept <15 cm H_2O. … With the application of cricoid pressure, no gastric insufflation occurred even when the inflating pressure was increased to 45 cm H_2O."[105] Of course, if the patient becomes hypoxemic, manual ventilation becomes mandatory.

The utility of cricoid pressure has been challenged on many fronts. As described by Sellick in 1961, "The manoeuver consists in temporary occlusion of the upper end of the oesophagus by backward pressure of the cricoid cartilage against the bodies of the cervical vertebrae.… Extension of the neck and application of pressure on the cricoid cartilage obliterates the oesophageal lumen at the level of the body of the fifth cervical vertebra.… Pressure is maintained until intubation and inflation of the cuff of the endotracheal tube is completed."[106] Kopka, Herman, and colleagues noted that cricoid pressure was used as early as 1774 to avert regurgitation related to gastric distention with air during resuscitation from drowning.[107,108] In Sellick's original report of 26 high-risk cases, 23 patients neither vomited nor regurgitated at any time near induction, and in the other 3 cases the "release of cricoid pressure after intubation was followed immediately by reflux into the pharynx of gastric or oesophageal contents, suggesting that in these three cases cricoid pressure had been effective."[106]

Although the LES has received considerable attention with regard to the pharmacology and pathophysiology of GER, there is also effective sphincter tone at the upper end of the esophagus. As described by Vanner and colleagues, "The upper oesophageal sphincter is formed mainly by the cricopharyngeus, a striated muscle situated behind the cricoid cartilage. The muscle tone of the cricopharyngeus creates a sphincter pressure which prevents regurgitation in the awake state."[109] These authors found that general anesthesia with neuromuscular blockade reduced the upper esophageal sphincter pressure from 38 mm Hg (while awake) to 6 mm Hg, a pressure that would typically permit passive regurgitation. Although cricoid pressure could exceed the normal awake level of upper esophageal sphincter pressure, in only half of their study patients was it applied firmly enough to do so.[109]

Other authors have noted the inconsistency with which Sellick's maneuver is applied. As Stept and Safar wrote in 1970, "The attempt to close the esophagus by pressing the cricoid cartilage against the cervical vertebrae is rarely applied with proper timing, namely, starting with the onset of unconsciousness and continuing until the tracheal cuff is inflated."[110] In their study of simulated cricoid pressure, Meek and coauthors reported that target pressures could be sustained with a flexed arm for a mean of only 3.7 to 6.4 minutes and with an extended arm for 7.6 to 10.8 minutes.[111]

A rising chorus of skepticism concerning the efficacy of cricoid pressure has been heard. In their reviews, Kluger and Short[5] and Thwaites and colleagues[112] cited reports of lethal aspiration occurring despite Sellick's maneuver. The former authors specifically questioned the "almost unerring faith in the efficacy of this manoeuvre."[5] In their prospective investigation of emergency intubations in critically ill patients, Schwartz and associates reported that "twelve patients had an unexplained infiltrate that probably resulted from aspiration.… Nine of

the twelve patients had cricoid pressure applied during airway management."[113] Specifically addressing medicolegal arguments, Jackson contended that "there is no scientific validation for the commonly held belief that 'improper application of cricoid pressure might explain any failures' to prevent aspiration."[114]

Although it is largely accepted that cricoid pressure limits the incidence of passive regurgitation, "it cannot be expected to prevent regurgitation during coughing, straining, or retching."[9] Sellick himself warned against applying cricoid pressure to a patient who is actively vomiting, lest the resulting increased pressure injure the esophagus.[106] In addition, the maneuver itself can induce gagging and even vomiting in the awake patient.[9] Ralph and Wareham reported a case in which "rupture of the oesophagus occurred during the application of cricoid pressure at induction of anaesthesia when the patient vomited." Fatal mediastinitis ensued.[115]

It has also become more widely acknowledged that cricoid pressure can interfere with both pulmonary ventilation and endotracheal intubation. Hocking and associates reported that "cricoid pressure produced a reduction in tidal volume (V_T) and an increase in peak inspiratory pressure" in 50 female patients given mechanical ventilation by mask with an oral airway. Although the changes in pressure and volume were not large, "Complete airway obstruction resulted on three occasions, all with cricoid pressure applied."[116] Saghaei and Masoodifar, in their study of 80 healthy anesthetized adults, found that bimanual cricoid pressure induced decreases in V_T with significant increases in peak inspiratory pressure, blood pressure, and heart rate.[117] Hartsilver and Vanner reported similar findings, concluding that "the degree of airway obstruction is related to the force applied to the cricoid cartilage. Therefore, if it is difficult to ventilate via a facemask, the amount of cricoid pressure should be reduced."[118]

Cricoid pressure can also impede ventilation through an LMA. Asai and colleagues reported that standardized cricoid pressure reduced the success rate of LMA ventilation from 100% (22/22) to 14% (3/22). Under fiberoptic visualization, the 18 LMAs that had been properly positioned became displaced when cricoid pressure was applied.[119] Similarly, Harry and Nolan stated that cricoid pressure reduced the success rate of endotracheal intubation through an intubating LMA from 84% to 52%.[120] Using fiberoptic visualization by LMA, MacG Palmer and Ball noted that cricoid pressure commonly caused cricoid deformation or occlusion, vocal cord closure, and impairment of ventilation, especially in women.[121]

The application of cricoid pressure may either improve or impede conventional laryngoscopy. According to Vanner and coauthors, standard cricoid pressure usually facilitated the exposure of the glottis, and "cricoid pressure in an upward (cephalad) and backward direction was more likely to give a better view at laryngoscopy than the standard technique."[122] In a substantial minority of their patients, however, cricoid pressure had either no impact or a detrimental effect on laryngoscopy. Hillman and colleagues reported that "the change in laryngoscopic view with increasing cricoid pressure fell into one of four broad patterns: little change (11/40), gradual deterioration (10/40), improvement at low force followed by deterioration [at high force] (9/40), [and] improvement at high force (10/40).... [I]n some individuals, a force close to that currently recommended may cause a complete loss of the glottic view."[123] Other authors have contended that cricoid pressure tends to interfere with intubation with lightwand or fiberoptic techniques.[124,125] On the other hand, Riad and Ansari found that "application of cricoid pressure during induction of anaesthesia for elective caesarean section neither prolongs the time nor interferes with ease of endotracheal intubation using Airtraq [a disposable optical laryngoscope]."[126] In a randomized study of 700 adult surgical patients, Turgeon and colleagues concluded that "cricoid pressure applied by trained personnel does not increase the rate of failed intubation."[127]

MacG Palmer and Ball concluded that "Orthodox application of cricoid pressure may … be directly implicated in the 'can't intubate, can't ventilate' scenario."[121] In their review of the current practice of RSI, Thwaites and coworkers sharpened the point of their critique by reminding us "that hypoxia can kill rapidly, while aspiration only might occur and only might kill."[112] Although Sellick's maneuver remains a conventional element of aspiration prevention, many authors now assert that it should not be slavishly pursued to the detriment of gas exchange and airway securement.

III. MEDICAL PROPHYLAXIS OF ASPIRATION

A. Gastroesophageal Motility

Although preparation of the patient (rational NPO strategy and perhaps gastric suctioning) and airway management are the twin pillars of aspiration prevention, pharmacologic prophylaxis has been promoted as adjunctive to patients' safety. Because gastric contents must first pass through the esophagus before entering the pharynx and trachea, the LES has become a locus of attention. As described by Ciresi, the LES "consists of functionally but not anatomically specialized smooth muscle, about 2-4 cm in length, just proximal to the stomach. The sphincteric muscle maintains closure of the distal esophagus through a mechanism of tonic contraction … accompanied by a zone of intraluminal high pressure."[128] Normally, a cholinergic reflex loop acts to increase LES pressure when intragastric or intra-abdominal pressure rises.[4] The pressure gradient between the LES and the stomach, referred to as the *barrier pressure*, is responsible for preventing GER (Boxes 12-5 and 12-6).[13,129,130]

LES function is modulated by neurohumoral influences. Cholinergic stimulation increases LES tone, whereas dopaminergic and adrenergic stimulations reduce it.[13,24,129] β-Adrenergic agents and theophylline reduce LES pressure and promote GER, often with symptomatic heartburn in awake patients. β-Adrenergic blockade elevates LES pressure.[131] Anticholinergics attenuate LES tone and impair the efficacy of medications given to increase LES barrier pressure.[1,26,58,132,133] Although prochlorperazine raises LES pressure (presumably by an antidopaminergic effect), promethazine lowers LES

BOX 12-5 Factors That Decrease Lower Esophageal Barrier Pressure

Anticholinergics
Opioids

pressure because of its anticholinergic properties.[13] Among the wide variety of other drugs that may reduce LES tone are benzodiazepines, opioids, barbiturates, dopamine, tricyclic antidepressants, calcium channel blockers, nitroglycerin, and nitroprusside.[1,26] Although succinylcholine-induced fasciculations can elevate intra-abdominal pressure, LES tone concurrently rises, and the barrier pressure is maintained or increased.[1,13] Apart from pharmacologic influences, Rabey and colleagues demonstrated that "barrier pressure may be reduced after insertion of an LMA during anesthesia with spontaneous ventilation."[130]

In many cases, agents that increase LES contractility also promote forward passage of gastric contents, and the factors that attenuate LES tone also retard gastric emptying. This correlation compounds pharmacologic opportunities for either protection or mischief. Opioids and anticholinergics inhibit gastrointestinal motility, increasing the volume of gastric contents available for vomiting or regurgitation.[133,134] Although pain and anxiety delay gastric emptying through sympathetic stimulation, the administration of an opioid for analgesia can further retard the propulsion of gastric contents into the duodenum.[26,129]

1. Metoclopramide

Gastroprokinetic drugs are now available to promote gastric emptying while simultaneously enhancing LES barrier pressure. Metoclopramide is the prototypical agent in this category. The mechanisms of action proposed for metoclopramide include central antidopaminergic activity and prolactin stimulation as well as peripheral blockade of dopamine receptors and stimulation of cholinergic function in the upper gastrointestinal tract. Although metoclopramide retains its gastrokinetic effect in vagotomized subjects, atropine has been shown to interfere with this activity.[128,135] Metoclopramide both raises LES contractility and barrier pressure and accelerates gastric emptying. The latter effect is achieved by intensifying gastric longitudinal muscle contraction while relaxing the gastroduodenal sphincter and increasing the coordination of gastrointestinal peristalsis. Metoclopramide has no effect on gastric acid secretion.[58,128]

Dopaminergic antagonists
  Metoclopramide
β-Adrenergic antagonists
Gastrointestinal cholinergic agonists
  Metoclopramide

Metoclopramide has been extensively investigated as a chemoprophylactic agent for aspiration pneumonitis in children and in adults. Several original studies of patients given metoclopramide, in a dose of 10 or 20 mg either orally (PO) or intravenously (IV), demonstrated the drug's utility in reducing gastric residual volume.[58,136,137] Gonzalez and Kallar wrote that "metoclopramide 10 mg PO or IV, in combination with Bicitra or an H_2-receptor antagonist, provides the most effective control of gastric volume and pH."[58] Given PO, metoclopramide has an onset of action that reportedly varies from 30 to 60 minutes, with a duration of action of 2 to 3 hours.[58] Ciresi found that metoclopramide at either 10 or 20 mg IV could reliably empty the stomach within 10 to 20 minutes.[128] Manchikanti and coworkers reported that metoclopramide 10 mg IV reduced the increase in gastric volume that followed ingestion of sodium citrate and citric acid (Bicitra) but did not interfere with Bicitra's antacid activity.[136] Metoclopramide was also found to reduce the volume of gastric contents in pediatric trauma patients.[138]

Other researchers found metoclopramide to be less uniformly effective, especially in the context of opioid coadministration or the recent ingestion of a solid meal.[132] Christensen and colleagues demonstrated no influence of metoclopramide 0.1 mg/kg on the gastric pH or volume of healthy pediatric patients.[139] As a perioperative antiemetic, metoclopramide was shown to be inconsistently useful.[132] Side effects attributed to metoclopramide have included somnolence, dizziness, and faintness. These problems may surface more frequently in elderly or severely ill patients.[58,128] Extrapyramidal reactions are a more serious problem but reportedly occur in only 1% of subjects.[128] Deehan and Dobb reported on a patient with traumatic brain injury in whom metoclopramide 10 mg IV twice induced a severe rise in intracranial pressure associated with increased cerebral blood flow.[140]

Metoclopramide has also been investigated in obstetric anesthesia. The drug has been shown to increase LES tone in pregnant women and therefore may be a useful prophylactic agent before cesarean section.[132,135] However, studies of gastric emptying in parturient women have provided less consistent results. Metoclopramide was shown to accelerate gastric emptying in patients undergoing scheduled or urgent cesarean section.[135,137] On the other hand, Cohen and associates examined 58 healthy parturients after an overnight fast and found that metoclopramide, 10 mg IV, had no significant effect on mean gastric volume or pH or on the proportion of patients with a gastric content volume exceeding 25 mL. They suggested that the drug might be more useful in the emergency setting for patients with active labor, recent food intake, pain, and anxiety.[135] Maternal metoclopramide administration does produce detectable and variable neonatal blood levels of the drug but without reported effects on Apgar scores or neurobehavioral test results.[135,141]

2. Erythromycin

Erythromycin is a macrolide antibiotic that has been in common use for more than 50 years. Given intravenously, it has been shown to improve gastric motility in patients with diabetic gastroparesis. Enteral feedings with erythromycin also pass more quickly through the stomach than control feedings. This action is thought to arise from the stimulation of motilin receptors in gastric smooth muscle.[142] Boivin and associates demonstrated that intravenous "erythromycin increased gastric emptying in a dose-response manner.… [N]ausea and stomach cramping were associated with the 3.0 mg/kg dose of erythromycin; drowsiness was associated with metoclopramide [10 mg]."[143] The potential applicability of these findings to perioperative aspiration prophylaxis is interesting but unproved.

B. Reduction of Gastric Acid Content

Chemoprophylaxis of aspiration pneumonitis can also include the inhibition of gastric acid secretion or the neutralization of HCl already in the stomach. The former should eventually increase the pH and reduce the volume of gastric contents but has no effect on acidic fluid already in place. The latter should elevate gastric fluid pH but may also increase gastric fluid volume. The aspiration of particulate antacids can pose hazards equivalent to those of gastric acid inhalation, as previously described. In 1982, Eyler and colleagues demonstrated severe pulmonary pathology in rabbits resulting from aspiration of a commercial particulate antacid.[144] Oral antacid prophylaxis should therefore include only soluble, nonparticulate agents.

1. Neutralization of Gastric Acid

The clear antacid solutions most commonly studied are sodium citrate (0.3 molar solution) and Bicitra. The pH of sodium citrate solutions typically exceeds 7.0, whereas that of Bicitra is 4.3.[136] Manchikanti and associates compared surgical outpatients given Bicitra 15 or 30 mL PO with a matched control group. All patients studied were nonobese and NPO for at least 8 hours. Of the control patients, 88% had a gastric content pH of 2.5 or less, in contrast to 32% of those given Bicitra 15 mL and only 16% of those given Bicitra 30 mL.[136]

Sodium citrate has been evaluated as a sole prophylactic agent in a variety of surgical settings, with inconsistent results. Kuster and colleagues found that sodium citrate 30 mL, taken shortly before elective surgery, resulted in gastric fluid pH values greater than 3.5 in 95% of patients.[145] Colman and coworkers administered 15 or 30 mL of sodium citrate to 30 parturient women before emergency cesarean section. All 15 patients given 30 mL sodium citrate and 14 of 15 given 15 mL had gastric pH values of 2.5 or higher.[146] In other reports, however, sodium citrate failed to alter gastric fluid pH in surgical patients. In a 0.3 molar solution, 30 mL may be more consistently effective than 15 mL, but it may still not have prolonged effects in patients with rapid gastric emptying.[13,147,148] Antacid prophylaxis may therefore be adequate at the induction of anesthesia but inadequate at the time of awakening. Larger volumes of sodium citrate can induce nausea and vomiting or diarrhea.[136]

2. Inhibition of Gastric Acid Secretion

a. H_2-RECEPTOR BLOCKADE

Gastric acid production is strongly modulated by the action of H_2 receptors. H_2-receptor blockade inhibits basal acid secretion as well as that stimulated by the presence of gastrin or food. Both H_2 antagonists and anticholinergic agents block the neural stimulation of gastric acid secretion.[128] However, this beneficial anticholinergic effect is overridden by the inhibition of gastrointestinal motility, so that gastric volume is not reduced and gastric pH is elevated only inconsistently.[58] Although H_2 antagonists do not delay gastric emptying, their inhibition of acid secretion tends to correlate inconsistently with both the timing and the magnitude of maximal drug concentration in the plasma.[93] Various H_2 antagonists have been evaluated in both surgical and obstetric settings, with different doses and routes of administration, and with and without other prophylactic medications, to produce an expansive volume of findings.

CIMETIDINE. Given before elective surgery, a variety of cimetidine regimens can ensure that most patients have gastric fluid volume or pH values, or both, in the safe range, as defined by the investigators. These usually effective regimens include cimetidine 300 mg PO at bedtime followed by 300 mg PO or intramuscularly (IM) on the morning of surgery; cimetidine 300 to 600 mg PO given 1.5 to 2 hours preoperatively; and cimetidine 200 mg IV given 1 hour before surgery. In one study, cimetidine most reliably produced gastric content safety when combined with preoperative metoclopramide.[1] The reliability of oral cimetidine is generally improved if the drug is administered both the night before and on the morning of anesthesia.[11]

A gastric fluid pH of 2.5 or lower has been found in 5% to 35% of patients treated with single 300-mg doses of cimetidine given PO, IM, or IV in different studies. Significant elevation of gastric pH requires 30 to 60 minutes to become evident after the IV administration of cimetidine and 60 to 90 minutes after IM or PO dosing. Effective inhibition of gastric acid secretion persists for 4 to 6 hours.[58,132] Papadimitriou and colleagues administered cimetidine 400 mg IV to 20 patients facing emergency surgery. Compared with 10 such patients given placebo treatment, those receiving cimetidine were found to have significantly lower mean gastric acidity, but the range of pH values was 1.6 to 7.2.[149]

Cimetidine chemoprophylaxis has also been evaluated in obstetric anesthesia. In a study of 100 patients undergoing emergency cesarean section, cimetidine 200 mg IM was administered when surgical delivery was decided upon, followed by oral intake of a 0.3-molar solution of sodium citrate 30 mL just before induction. None of these patients had a gastric fluid pH lower than 2.7, and only 1 of 100 had a gastric fluid pH lower than 3.0.[90] Cimetidine administered in this fashion would most likely reduce gastric acidity by the time of extubation,

whereas sodium citrate would be required to neutralize the acid already present.

Although cimetidine has a well-established record of safety when administered for perioperative aspiration prophylaxis, there are potential and observed side effects. The rapid IV infusion of large doses (e.g., 400 to 600 mg) has reportedly induced both hypotension and dangerous ventricular dysrhythmias.[129,132] Smith and colleagues advised that IV cimetidine be infused over at least a 10-minute period.[150] Other side effects sporadically associated with cimetidine include confusion, dizziness, headaches, and diarrhea, although these have not been reported to occur with single-dose preoperative administration.[128,129,132]

Cimetidine competitively inhibits the hepatic mixed-function oxidase system (cytochrome P450 enzyme) and also reduces hepatic perfusion.[129,131,132] As a result, cimetidine may elevate the blood concentrations of other drugs that are cleared by the liver, including warfarin, propranolol, diazepam, theophylline, phenytoin, meperidine, bupivacaine, and lidocaine. Clinically, this seems to be a greater concern with long-term use than with one- or two-dose administration.[128,132,146]

RANITIDINE. After cimetidine, ranitidine emerged as the next option for H_2 blockade. Ranitidine is considered to exert little or no inhibition of hepatic enzymes, has a longer duration of action (6 to 8 hours) than cimetidine, and has an efficacy greater than or equal to that of the original H_2 blocker. Effective onset times for the two drugs appear to be similar.[1,58,132,146,151] Smith and coauthors reported that ranitidine 50 mg, given IV over 2 minutes to 20 critically ill patients, led to variable, transient reductions in mean arterial pressure and systemic vascular resistance. These hemodynamic effects occurred less frequently and were of lesser degree and duration than those resulting from cimetidine 200 mg, similarly administered. Previous sporadic case reports associated significant bradycardia with the IV administration of either cimetidine or ranitidine.[150]

In the study of adult surgical outpatients by Maltby and colleagues, ranitidine 150 mg PO, given 2.5 hours before anesthetic induction, significantly decreased gastric residual volume and significantly increased gastric fluid pH compared with placebo. In no patient was there the conventional (but arbitrary) at-risk combination of gastric pH lower than 2.5 and gastric volume greater than 25 mL.[83] McAllister and associates treated adult patients with a single oral dose of ranitidine 300 mg, given 2 hours before surgery, and found both a significant increase in mean gastric fluid pH and a significant decrease in mean gastric fluid volume compared with placebo treatment. Noting the occasional patient with gastric fluid pH lower than 2.5, the authors cautioned that "it is unsafe to assume that H_2 antagonists will always eliminate the risk of acid aspiration pneumonitis."[152] Single-dose IV administration of ranitidine, 40 to 100 mg, has also been found to reliably generate gastric fluid pH values greater than 2.5 in adults, manifesting a greater efficacy than that of cimetidine 300 mg IV.[1]

Sandhar and coworkers evaluated the efficacy of a single oral dose of ranitidine, 2 mg/kg, given 2 to 3 hours before surgery to patients aged 1 to 14 years. Although ranitidine significantly reduced both the volume and the acidity of gastric contents compared with placebo, 6 of 44 children receiving ranitidine did have gastric fluid pH values of 2.5 or lower.[68] These findings confirmed those of a similar study of Goudsouzian and Young,[153] although other authors have not demonstrated such a consistent reduction in gastric fluid volume.[1,83]

Papadimitriou and associates compared ranitidine 150 mg IV with cimetidine 400 mg IV and with placebo given 1 hour before anesthetic induction to emergency surgical patients. Ranitidine and cimetidine caused similar reductions in gastric volume and acidity; only the reductions in acidity were statistically significant. Although the mean pH values in the cimetidine and ranitidine groups were similar, only ranitidine consistently produced safe gastric pH values (all of which were 5.0 or higher).[149] Vila and colleagues, evaluating H_2 antagonists in morbidly obese surgical patients, concluded that ranitidine was superior to cimetidine in elevating gastric fluid pH.[154] A literature review cited by Gonzalez and Kallar also found that ranitidine more reliably ensured that gastric fluid pH would exceed 2.5 than did cimetidine, although neither agent consistently reduced gastric fluid volume into the range considered safe by study authors.[58]

The effect of PO ranitidine (150 mg, given 2 to 3 hours before the scheduled time of surgery) with or without PO metoclopramide (10 mg, given 1 hour before surgery) and/or sodium citrate (30 mL on call to the operating room) on gastric fluid volume and pH was measured in 196 elective surgical inpatients. Although no combination guaranteed a safe combination of fluid volume and pH, a single oral dose of ranitidine was statistically as effective as triple prophylaxis.[155] In pediatric patients, both Gombar and Maekawa and their colleagues showed that PO ranitidine (either 2 mg/kg or 75 mg) effectively elevated gastric fluid pH with no appreciable effect on gastric volume.[76,156] In his study of the IV administration of these drugs 15 minutes before anesthetic induction, Hong concluded that "prophylactic ranitidine (50 mg IV) and metoclopramide (10 mg IV) may be an easy and useful method to decrease the volume while increasing the pH of gastric contents."[157]

Ranitidine has also been evaluated for prophylactic use in obstetric anesthesia. Rout and colleagues evaluated the efficacy of ranitidine 50 mg IV given to laboring patients when cesarean section was decided upon. A control group received no H_2-antagonist therapy, but all patients were given 30 mL of 0.3-molar sodium citrate shortly before induction. At the time of induction, 4% of those given only sodium citrate had a gastric fluid volume greater than 25 mL along with a pH lower than 3.5, compared with 2.3% of those given both citrate and ranitidine ($P = 0.05$).[151] At the time of extubation, 5.6% of those given only sodium citrate were considered to be at risk by the preceding criteria, compared with only 0.3% of those given both citrate and ranitidine ($P < 0.05$). In a recent *Cochrane Database Systems Review*, Paranjothyand coworkers concluded that, although "the quality of the evidence was poor, … the findings suggest that the combination of antacids plus H_2 antagonists is superior to antacids alone in increasing gastric pH [in patients

undergoing caesarean section]. When a single agent is used, antacids alone are superior to H_2 antagonists."[158]

OTHERS. A voluminous body of evidence thus documents the general safety and efficacy of preoperative cimetidine and ranitidine in ameliorating the acidity and volume of gastric contents. Newer agents, such as famotidine (10 mg PO) and nizatidine, have also been evaluated, with generally favorable results.[154,159] Wajima and colleagues reported that nizatidine 300 mg PO was uniformly effective in maintaining gastric content pH above 2.5 and volume below 25 mL when given 2 hours before surgery.[160]

On the basis of the presumably high ratio of benefit to risk, H_2-blocking agents have been recommended for surgical patients who have an increased likelihood of inhaling gastric contents.[1,65] However, given the infrequency of perioperative aspiration pneumonitis, documentation of the actual clinical benefit of such practice has yet to be provided. In the review by Warner and coauthors of more than 215,000 general anesthesias in adults, 35 patients with acknowledged risk factors did aspirate perioperatively. Of these 35, 17 had been given prophylactic medication. In this small sample, aspiration prophylaxis produced no discernible difference in the incidence of pulmonary complications.[3] In general, the routine preoperative use of H_2 antagonists is not considered either essential or cost-effective. As stated by Kallar and Everett, "It has yet to be proven that prophylaxis against acid aspiration changes morbidity or mortality in healthy patients having elective surgery."[1]

b. PROTON PUMP INHIBITION

Proton pump inhibitors (PPIs) constitute a newer class of agents for the suppression of gastric acid production. Acetylcholine, histamine, and gastrin all stimulate HCl secretion by the gastric parietal cell. Although these agonists stimulate different populations of receptors, their mechanisms of action all eventually result in the formation of cyclic adenosine monophosphate (cAMP). cAMP activates the proton pump, H^+,K^+-adenosine triphosphatase (H^+,K^+-ATPase), which exchanges intraluminal potassium ions for intracellular hydrogen ions. Hydrogen ions are thereby secreted from the parietal cell into gastric fluids.[68,152] Omeprazole, the prototype PPI, is actually a pro-drug that is absorbed in the small intestine and is activated in the highly acidic milieu of the gastric parietal cell. Activated omeprazole then remains in the parietal cell for up to 48 hours, inhibiting the proton pump in a prolonged manner.[141,161-163] Inhibition of gastric acid secretion can be nearly complete, with no discernible side effects. A single dose of omeprazole, 20 to 40 mg, reduces gastric acidity for up to 48 hours. On the other hand, PPIs are characterized by variable first-pass metabolism with resulting inconsistencies in the plasma concentration after any given oral dose. As is the case with H_2 antagonists, there is also an unpredictable relationship between peak plasma concentration and peak inhibition of gastric acid production.[93]

Omeprazole has been evaluated as a preoperative agent for the chemoprophylaxis of aspiration pneumonitis. Bouly and colleagues gave omeprazole 40 mg PO to healthy patients either the evening before or 2 hours before elective surgery. Although mean gastric fluid pH was significantly higher with omeprazole treatment than with placebo, 6 of 30 patients receiving omeprazole had gastric fluid pH values lower than 2.5 at the time of induction. Omeprazole significantly reduced gastric fluid volume compared with placebo.[161]

Omeprazole has also been evaluated in obstetric anesthesia. In a study by Orr and associates, all 15 patients who received omeprazole and also metoclopramide 20 mg IM at least 20 minutes before elective cesarean section had gastric fluid pH values greater than 2.5, both on induction and at extubation. When omeprazole 80 mg PO was given only on the morning of elective cesarean section, 2 of 33 patients had a gastric fluid pH lower than 2.5 at induction, 1 of whom also had a gastric fluid volume greater than 40 mL. All gastric fluid pH values were greater than 2.5 at extubation. Of 16 patients who also received metoclopramide 20 mg IM at least 20 minutes before elective cesarean section, 2 still had gastric fluid pH values lower than 2.5 (with gastric fluid volumes less than 25 mL) on induction, but all gastric fluid pH values exceeded 2.5 at extubation.[141]

In general, the PPIs have been found most effective when given in two doses, one on the night before and one on the morning of surgery.[93] Given the dwindling proportion of patients hospitalized before elective surgery, however, two-dose regimens for chemoprophylaxis would seem somewhat impractical. Furthermore, Nishina and coauthors reported that a single preoperative oral dose of ranitidine was more effective in reducing gastric acid content than two-dose regimens of rabeprazole or lansoprazole.[164] On the other hand, Pisegna and colleagues found that "pantoprazole (40 mg IV) decreased gastric acid output and volume, and increased pH within 1 hour of dosing. Effects were sustained for up to 12 hours following single-dose administration."[165]

IV. CONCLUSIONS

It is clearly best to prevent gastric contents of any volume or pH from entering the trachea. Although this ideal may not always be attainable, even by the most skillful of clinicians, its likelihood would appear to be favored by optimal preparation of patients and a carefully executed, well-designed plan for anesthetic induction and airway management. The place of awake induction and gastric emptying in high-risk cases is influenced by patients' characteristics and practitioners' experience and confidence. Although RSI with cricoid pressure remains a standard prophylactic maneuver, it is now recognized that airway management and effective ventilation may mandate its modification, or even discontinuation, in certain circumstances.

An impressive array of pharmacologic agents can now be employed to promote antegrade gastric emptying, inhibit GER, and reduce the acid content of gastric fluids. These drugs have an established record of safety and offer the reasonable expectation of rendering gastric fluid less threatening to the lungs. However, because of the low incidence of clinically significant perioperative aspiration, it may not be possible to demonstrate statistically that

the use of these agents actually improves patients' outcomes. In reference to gastric prokinetic drugs, antacids, and inhibitors of acid secretion, the ASA Task Force concluded that "the routine preoperative use of [such medications] in patients who have no apparent increased risk for pulmonary aspiration is not recommended."[78] Chemoprophylaxis is only an adjunct to and not a substitute for otherwise sound clinical practice. It is, of course, less desirable to have aspirated and survived than never to have aspirated at all.

V. CLINICAL PEARLS

- Regurgitation and aspiration can result from "light" anesthesia, coughing, and gagging in the patient not intubated.
- About half of all cases of perioperative aspiration occur at times other than anesthetic induction.
- Patients manifesting no evidence of respiratory impairment for 2 hours after a known or suspected aspiration episode are highly unlikely to become significantly symptomatic later.
- Delayed gastric emptying in diabetic patients correlates with the presence of autonomic, but not peripheral, neuropathy.
- Both pain and opiates significantly retard gastric emptying.
- Aspiration of particulate antacids can induce a severe granulomatous pneumonitis.
- Ingestion of clear liquids 2 to 3 hours before anesthetic induction does not appear to increase the risk of gastric content aspiration in patients with no gastrointestinal pathology.
- Cricoid pressure can compromise ventilation by either mask or LMA and can either facilitate or interfere with direct laryngoscopy.
- Nonparticulate antacids rapidly raise gastric fluid pH in most patients, with an inconsistent duration of action.
- H_2 antagonists more reliably reduce gastric fluid acidity than gastric fluid volume.
- Metoclopramide reduces gastric fluid volume in most patients without consistently affecting gastric fluid pH.

I. HISTORICAL PERSPECTIVE

In 1948, Fowler and Comroe demonstrated that inhalation of 100% oxygen (O_2) resulted in a very rapid increase of arterial oxyhemoglobin saturation (Sa_{O_2}) to between 98% and 99%, but that attainment of the last 1% to 2% was a much slower process.[1] They also observed that the rate of increase was attenuated in patients with pulmonary emphysema or pulmonary artherosclerosis.[1] In 1955, Hamilton and Eastwood showed that "denitrogenation" was 95% complete within 2 to 3 minutes in subjects breathing normally from a circle anesthesia system with 5 L/min O_2.[2] Dillon and Darsi, in the same year, observed significant arterial oxyhemoglobin desaturation during apnea after anesthetic induction with sodium thiopental and recommended that induction of anesthesia and endoscopy should be preceded by O_2 administration for 5 minutes.[3] Six years later, Heller and Watson found that 3 to 4 minutes of O_2 breathing was necessary in patients before anesthetic induction, whereas adequate oxygenation could be accomplished with the use of manual ventilation in 30 seconds.[4] With the introduction of the rapid-sequence induction and intubation (RSI) technique in the 1950s in patients at risk for aspiration of gastric contents, preoxygenation became a component of the technique.[5,6] Preoxygenation was emphasized by Sellick when he introduced cricoid pressure into clinical practice in 1961,[7] and it was also recommended before RSI in pediatric patients in the 1970s.[8]

Preoxygenation before anesthetic induction and intubation became a widely accepted maneuver designed to increase O_2 reserves and thereby delay the onset of arterial oxyhemoglobin desaturation during apnea. Various techniques and regimens have been advocated to ensure adequate preoxygenation. For many years, tidal volume breathing (TVB) of O_2 for 3 to 5 minutes has been commonly practiced.[2,3] Gold and colleagues challenged the need for 3 minutes of TVB by demonstrating that 4 deep breaths within 0.5 minutes (4 DB/0.5 min) and TVB for 5 minutes using a semiclosed circle absorber system were equally effective in increasing arterial oxygen tension (Pa_{O_2}).[9] Although some investigators corroborated their findings,[10,11] others showed that TVB for 3 minutes provided better preoxygenation and longer protection against hypoxemia during apnea than 4 DB/0.5 min.[12-15] Later investigations suggested that the use of extended deep breathing (8, 12, and 16 deep breaths in 1.0, 1.5, and 2.0 minutes, respectively) could produce maximal preoxygenation comparable to that achieved with TVB for 3 minutes and could also delay the onset of apnea-induced oxyhemoglobin desaturation.[16,17]

Regardless of the technique used, preoxygenation has become an integral component of the RSI technique, and it is particularly important if manual ventilation is not desirable, if difficulty with ventilation or endotracheal intubation is anticipated, and in patients with oxygen transport limitations. Because the "cannot intubate,

cannot ventilate" (CICV) situation is largely unpredictable, the desirability of maximal preoxygenation is theoretically present for all patients.[18]

The original American Society of Anesthesiologists' (ASA) difficult airway (DA) algorithm made no mention of preoxygenation. In an updated report by the ASA Task Force on Management of the DA (2003), the topic of "facemask preoxygenation before initiating management of the difficult airway" was added.[19] "Routine" preoxygenation has become a new "minimum standard" of care, not only during induction of anesthesia, but also during emergence from anesthesia and tracheal extubation.[20-22]

II. BODY OXYGEN STORES

Oxygen is carried in the blood in two forms: the greater portion is in reversible chemical combination with hemoglobin (Hb), and the smaller part is dissolved in plasma.[23] The ability to carry large amounts of O_2 in Hb is important, because without it, the amount carried in the plasma would be so small that the cardiac output would need to be increased more than 20 times to yield an adequate O_2 flux.[23] The amount of chemically bound O_2 is directly related to the concentration of Hb and how saturated the Hb is with O_2. Arterial O_2 content (Cao_2) can be calculated from the following equation:

$$Cao_2 = Hb \times 1.36 \times SaO_2 + PaO_2 \times 0.003$$

where

1.36 = estimated mass volume of O_2 that can be bound by 1 g of normal Hb

Sao_2 = arterial oxyhemoglobin saturation (when fully saturated, Sao_2 = 100%)

Pao_2 = arterial partial pressure of oxygen

0.003 = solubility coefficient of O_2 in human plasma

The Cao_2 with an Hb concentration of 15 g/dL is approximately 20 mL of O_2 per 100 dL of blood. In addition, approximately 0.3 mL of O_2/100 dL blood is in physical solution. This amount of dissolved O_2 normally accounts for only 1.5% of the total O_2, but its contribution increases when Pao_2 is increased (dissolved O_2 is linearly related to Pao_2). The venous O_2 content ($C\bar{v}O_2$) when there is a mixed venous O_2 tension ($P\bar{v}O_2$) of 40 mm Hg and mixed venous oxyhemoglobin saturation ($S\bar{v}O_2$) of 75% can be calculated accordingly.

Hb uptake and release of O_2 are regulated by a pattern demonstrated by the familiar oxyhemoglobin dissociation curve, which is a plot of Sao_2 as a function of Pao_2. The sigmoid shape of the curve reflects the fact that the four binding sites on a given Hb molecule interact with each other.[23] When the first site has bound a molecule of O_2, the binding of the next site is facilitated, and so forth. The result is a curve that is steep up to a Po_2 of 60 mm Hg and becomes more shallow thereafter, approaching 100% saturation asymptotically. At a Po_2 of 100 mm Hg, the normal arterial value, 97% of the hemes have bound O_2; at 40 mm Hg, a typical value for ($P\bar{v}O_2$) in a resting person, the saturation declines to about 75%. The shape of the oxyhemoglobin dissociation curve has important physiologic implications. The flatness of the curve above a Po_2 of 80 mm Hg ensures a relatively constant Sao_2 despite wide variations in alveolar O_2 pressure. The steep portion of the curve between 20 to 60 mm Hg permits unloading of O_2 from Hb at relatively high Po_2 values, which favors the delivery of large amounts of O_2 into the tissues by diffusion.

The O_2-binding properties of Hb are influenced by a number of factors, including pH, Pco_2, and temperature.[23] These factors cause shifts of the oxyhemoglobin dissociation curve to the right or left without changing the slope of the curve. For example, an increase in temperature or a decrease in pH, such as may occur in active tissues, decreases the affinity of Hb for O_2 and shifts the oxyhemoglobin dissociation curve to the right. As a result, a higher Po_2 is required to achieve a given saturation, which facilitates unloading of O_2 at the tissue. To quantify the extent of a shift of the oxyhemoglobin dissociation curve, the so-called P_{50} is used—that is, the Po_2 required for 50% saturation. The P_{50} of normal adult Hb at 37° C and normal pH and Pco_2 is 26 to 27 mm Hg.

Despite its great importance, O_2 is a very difficult gas to store in a biologic system. In subjects breathing air, O_2 stores are small (Table 13-1).[23,24] The relatively steep oxyhemoglobin dissociation curve and the small O_2 stores imply that factors affecting Pao_2 produce their full effects very quickly. This is in contrast to CO_2, for which the large size of the stores buffers the body against rapid changes. Therefore, in a subject breathing air, a pulse oximeter probably gives an earlier indication of hypoventilation than does CO_2 measurement. In contrast, in a subject breathing a high fraction of inspired O_2 (Fio_2), CO_2 measurement gives an earlier indication of hypoventilation.[23]

The amounts of body O_2 in the various storage sites of a person breathing air are increased with breathing 100% of O_2 (Fig. 13-1; see also Table 13-1).[23,24] The maximal increase of O_2 stores occurs in the functional residual capacity (FRC). Storage of O_2 in the tissue is rather difficult to assess, but assuming that Henry's law applies and the partition coefficient for gases approximates the gas-water coefficients, breathing O_2 for 3 minutes significantly increases tissue O_2 stores.[24]

TABLE 13-1

Body O_2 Stores (in mL) during Room Air and 100% O_2 Breathing

Storage Site	Room Air	100% O_2
In the lungs (FRC)	450	3000
In the blood	850	950
Dissolved in tissue fluids	50	100
In combination with myoglobin	200?	200
Total	1550	4250

FRC, Functional residual capacity; *O_2,* oxygen.

III. PHYSIOLOGY OF APNEA AND APNEIC MASS-MOVEMENT OXYGENATION

During apnea, the total body O_2 consumption ($\dot{V}O_2$) remains fairly constant at about 250 mL/min. Consequently, the alveolar O_2 concentration (PAO_2) decreases rapidly as a result of the depletion of the diminishing O_2 stores in the lungs. If the airway becomes obstructed, O_2 removal will generate a substantial and immediate negative pressure, contributing to a further decrease of PaO_2. Although the PaO_2 falls in direct relation to PAO_2, SaO_2 remains greater than 90% as long as the Hb can be reoxygenated in the lungs.[25-28] SaO_2 starts to decrease only after the lung O_2 stores are depleted and the PaO_2 is lower than 60 mm Hg. It is for this reason that oximetry is not the best "physiologic means," compared with PaO_2, for predicting the onset of hypoxemia. However, because it detects decreases in SaO_2 before other clinical signs, oximetry is an invaluable clinical monitor that adds to the safety of anesthetic management.[27] Critical oxyhemoglobin desaturation may be defined as SaO_2 less than or equal to 80%; for patients with SaO_2 less than 80%, the range in the rate of decrease is 20% to 40% per minute during apnea.[29]

Preoxygenation followed by O_2 insufflation during subsequent apnea maintains SaO_2 by apneic diffusion oxygenation.[25,26] In the apneic adult, the $\dot{V}O_2$ averages 230 mL/min, whereas the output of CO_2 to the alveoli is limited to about 21 mL/min and the remaining CO_2 production (approximately 90%) is buffered within the body tissues. The lung volume initially decreases by the net gas exchange ratio of 209 mL/min. Therefore, a pressure gradient is created between the upper airway and the alveoli, and if the airway is patent, this results in a mass movement of O_2 down the trachea into the alveoli. Conversely, CO_2 is not exhaled because of this mass movement of O_2 down the trachea, and the alveolar CO_2 concentration ($PACO_2$) shows an initial rise of about 8 to 16 mm Hg during the first minute and a subsequent fairly linear rise of about 3 mm Hg/min.[30]

Fraioli and colleagues emphasized the importance of the ratio of FRC to body weight during apneic diffusion and demonstrated that patients with a low FRC/body weight ratio could not tolerate apnea for more than 4 minutes, whereas those with a high FRC/body weight ratio (>53.3 ± 7 mL/kg) maintained PaO_2 at 90% of the control value.[25] Some studies demonstrated that with a patent airway and an FIO_2 of 1, SaO_2 can be maintained at greater than 90% for up to 100 minutes with apneic oxygenation.[25,26]

The success of apneic mass-movement oxygenation depends on airway patency to allow O_2 to move into the apneic lungs. In the presence of air obstruction, not only does the lung gas volume decrease rapidly, but the intrathoracic pressure also decreases at a rate that is dependent on $\dot{V}O_2$ and thoracic compliance, subsequently leading to a marked fall in PaO_2. When airway obstruction is relieved, rapid flow of O_2 into the lungs occurs, and with high FIO_2, rapid reoxygenation resumes.[27]

Apneic mass-movement oxygenation can be achieved by preoxygenation followed by insufflation of O_2 through a nasopharyngeal or oropharyngeal cannula or through a needle inserted in the cricothyroid or cricotracheal membrane. This provides at least 10 minutes of adequate oxygenation in healthy apneic patients whose airways are unobstructed and therefore has many practical applications.[31] In patients who are difficult to intubate or ventilate, pharyngeal O_2 insufflation (or tracheal insufflation, in cases of upper airway obstruction) may allow additional time for laryngoscopy and endotracheal intubation.[31-33] This can be advantageous in patients who have decreased O_2 reserves, such as children, pregnant women, obese patients, and patients with adult respiratory distress syndrome (ARDS).[30,32] The combination of preoxygenation and apneic diffusion oxygenation can be used during bronchoscopy and can provide the otolaryngologist with adequate time for glottic surgery unimpeded by the presence of the endotracheal tube (ETT) or by the patient's respiratory movements.[33]

During apneic diffusion oxygenation via an open airway, the increase in time to Hb desaturation achieved by increasing the FIO_2 from 0.9 to 1.0 is greater than that caused by increasing the FIO_2 from 0.21 to 0.9. Increasing the FIO_2 from 0.9 to 1.0 more than doubles the time to desaturation[34] (Fig.13-2).

IV. EFFICACY AND EFFICIENCY OF PREOXYGENATION

Studies of preoxygenation have focused on measurements of indices reflecting its efficacy and efficiency.[18] Measurements of alveolar O_2,[14,35,36] alveolar N_2,[37] or PaO_2 reflect the efficacy of preoxygenation, whereas the decline of SaO_2 during apnea is indicative of its efficiency.[9,16,18,37,38]

The SaO_2 may be misleading as a guide to alveolar denitrogenation. A saturation of 100% measured by pulse oximetry (SpO_2) is most definitely not a reason to stop denitrogenation and may occur well before the lungs are

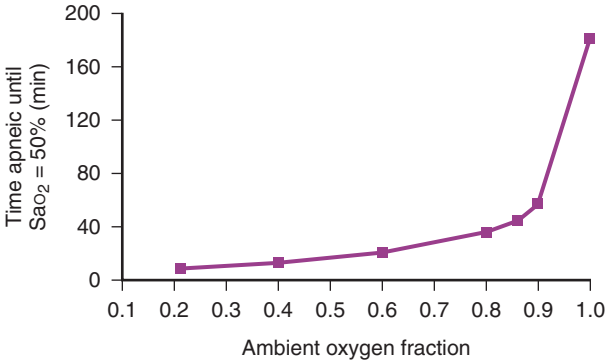

Figure 13-2 The time (duration of apnea) required to reach 50% Sao_2 with an open airway exposed to various ambient O_2 fractions. (From McNamara MJ, Hardman JG: Hypoxaemia during open-airway apnoea: A computational modelling analysis. *Anaesthesia* 60:741–746, 2005.)

adequately denitrogenated. Conversely, failure of SpO_2 to increase substantially during denitrogenation does not necessarily indicate failure of preoxygenation or lack of its value; patients with substantial pulmonary shunting may achieve excellent pulmonary O_2 reservoirs while remaining hypoxemic.[39]

A. Efficacy of Preoxygenation

Preoxygenation increases the alveolar O_2 and decreases the alveolar N_2 in a parallel fashion (Fig. 13-3).[37,40] It is the washout of N_2 from the lungs that is the key to achieving preoxygenation.[37,40] The terms *preoxygenation* and *denitrogenation* have been used synonymously to describe the same process, although a change in focus from preoxygenation to denitrogenation has been suggested.[37]

With normal lung function, the O_2 washin and nitrogen washout (the reverse of the washin) are exponential functions; therefore, the rate of preoxygenation (or denitrogenation) is governed by the time constant (τ) of the exponential curves. This constant is the same for both washin and washout curves and is proportional to the ratio of alveolar ventilation ($\dot{V}A$) to FRC. Because the O_2 flow used for $\dot{V}A$ is delivered via an anesthesia circuit, preoxygenation occurs in two sequential stages according to the time constant, which is the time required for a flow through a container (volume) to equal the capacity. These two stages are

1. Washout of the anesthesia circuit by O_2 flow

$$\tau = \frac{\text{Size of the circuit}}{O_2 \text{ flow}}$$

2. Washout of the FRC by alveolar ventilation

$$\tau = \frac{FRC}{\dot{V}A}$$

After 1 τ, the O_2 concentration of FRC will be increased by approximately 63% of its original value; after 2 τ, to 86%; after 3 τ, to 95%; and after 4 τ, to about 98% of its original value.

In order to hasten denitrogenation, it is advisable to washout (flush) the anesthesia circuit by a high O_2 flow before applying the face mask to the patient. On preoxygenation of the patient, an O_2 flow per minute that eliminates rebreathing should be used. Therefore, three steps are required to enhance preoxygenation:

1. The anesthesia circuit is flushed by a high O_2 flow.
2. A nonleaking face mask is used to avoid air entrainment.
3. An O_2 flow of 5 L/min is required for TVB, and a flow of 10 L/min is necessary for the deep breathing.

It should be noted that the time spent instructing the patient about the procedure, flushing the circuit,

positioning the face mask tightly with or without head straps, and turning on the O_2 flow may prolong the time to achievement of maximal preoxygenation.

The end points of maximal alveolar preoxygenation or denitrogenation have been defined as an end-tidal O_2 concentration (E_{tO_2}) of approximately 90% and an end-tidal nitrogen concentration (E_{tN_2}) of 5%.[15,35,36] In an adult with a normal FRC and V_{O_2}, an E_{tO_2} greater than 90% means that the lungs contain more than 2000 mL of O_2 (8 to 10 times the V_{O_2}).[27] Because of the obligatory presence of CO_2 and water vapor in the alveolar gas, an E_{tO_2} greater than 97% cannot be easily achieved. Factors affecting the efficacy of preoxygenation include F_{IO_2}, duration of breathing, and the $\dot{V}_A$/FRC ratio (Box 13-1).

1. Fraction of Inspired Oxygen

The main reasons for failure to achieve an F_{IO_2} close to 1.0 are a leak under the face mask,[14,18,41-43] rebreathing of exhaled gases, and the use of systems incapable of delivering a high O_2 concentration, such as resuscitation bags.[40] Even the presence of minor leaks may not be fully compensated for by increasing the fresh gas flow (FGF) or by increasing the duration of preoxygenation. Bearded patients, edentulous patients, patients with sunken cheeks, the presence of nasogastric tubes, use of a wrong face mask size, improper use of head straps, and use of systems allowing air entrainment under the face mask are all common factors causing leaks between the face mask and the patient's head resulting in lower F_{IO_2}. Clinical end points indicative of a sealed system are movement of the reservoir bag in and out with inhalation and exhalation, presence of a normal capnogram and end-tidal CO_2, (E_{tCO_2}), and measurements of inspired and E_{tCO_2} values.[18]

There is reluctance among some anesthesiologists to use preoxygenation routinely because the mask presents discomfort to the patient and some patients find preoxygenation objectionable. There is clearly marked overestimation of the patient's discomfort by the anesthesiologist. In fact, patients' discomfort during preoxygenation is not more than the discomfort during other procedures such as the placement of intravenous lines.[44,45] It is our experience that patients accept a tight-fitting mask if the procedure is explained beforehand and they are told that "it is important to fill the tank with oxygen."

Although anesthetic circuits can deliver 100% O_2 concentration, the F_{IO_2} can be influenced by the type of breathing, the level of FGF, and the duration of breathing.[17] In a study involving volunteers that compared preoxygenation techniques using a semiclosed circle absorber with varying FGF in the same subjects, it was found that with TVB, inspired O_2 concentration was 95% with FGF of 5 L/min and increased to 98% with FGFs of 7 and 10 L/min. However, with deep breathing, the inspired O_2 concentration was only 88% at 5 L/min, 91% at 7 L/min, and 95% at 10 L/min FGF (Fig. 13-4).[17] These findings imply that increasing the FGF from 5 to 10 L/min has little impact on increasing F_{IO_2} during TVB but has a noticeable effect during deep breathing.[17] Because of the breathing characteristics of the circle system, the minute ventilation during deep breathing may exceed the FGF, resulting in rebreathing of exhaled gases (N_2) and consequently decreasing the F_{IO_2}; in contrast, during TVB,

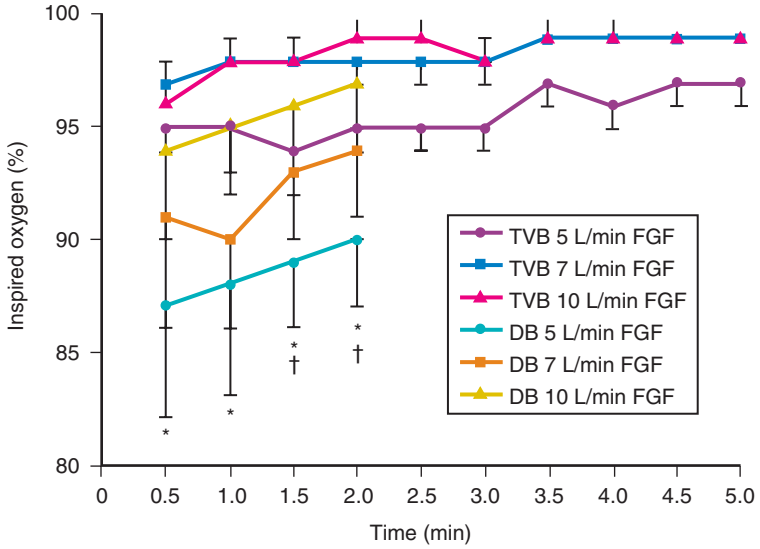

Figure 13-4 Comparison of tidal volume breathing (TVB) and deep breathing (DB) preoxygenation techniques on inspired O_2 using 5, 7, and 10 L/min fresh gas flow (FGF). *Significant difference ($P < .05$) between 5, 7, and 10 L/min FGF; †significant difference ($P < .05$) from deep breaths at 0.5 and 1.0 minute. (From Nimmagadda U, Chiravuri SD, Salem MR, et al: Preoxygenation with tidal volume and deep breathing techniques: The impact of duration of breathing and fresh gas flow. *Anesth Analg* 92:1337–1341, 2001.)

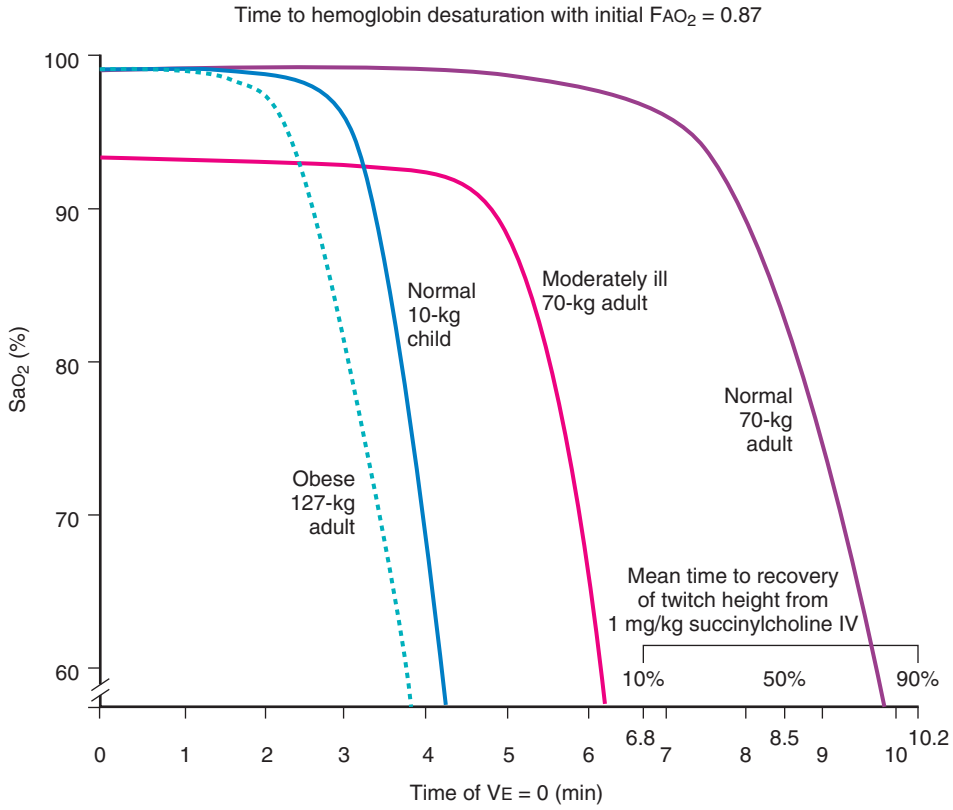

Figure 13-5 Arterial oxyhemoglobin saturation (*Sa_{O_2}*) versus time of apnea in an obese adult, a 10-kg child (low functional residual capacity (FRC) and high oxygen consumption ($\dot{V}O_2$)), and in a moderately ill adult, compared with a healthy adult. *F_{AO_2}*, Fractional alveolar oxygen concentration; *V_E*, expired volume. (From Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to unparalyzed state from 1 mg/kg succinylcholine. *Anesthesiology* 87:979–982, 1997.)

rebreathing of exhaled gases is negligible, and increasing the FGF from 5 to 10 L/min would have only a slight effect on F_{IO_2}.[12,17]

2. Duration of Breathing, Functional Residual Capacity, and Alveolar Ventilation

Sufficient time is needed to accomplish maximal preoxygenation. With an F_{IO_2} close to 1, most healthy adult patients can reach the target level of E_{tO_2} greater than or equal to 90% (or $E_{tN_2} \leq 5\%$) within 3 to 5 minutes of TVB. The half-time for exponential change in fraction of alveolar O_2 concentration (F_{AO_2}) with a step change in F_{IO_2} for a nonrebreathing system is given by the equation, $F_{AO_2} = 0.693 \times V_{FRC}/\dot{V}A$. ($V_{FRC}$ is volume of functional residual capacity). With a V_{FRC} of 2.5 L, the half-times are 26 seconds when $\dot{V}A$ = 4 L/min and 13 seconds when $\dot{V}A$ = 8 L/min.[18] Therefore, most of the O_2 that can be stored in the lungs may be brought in by hyperventilation with an F_{IO_2} of 1.0 for a shorter period of time than that needed with TVB.[18] This is the basis for the deep breathing techniques, which have been introduced as an alternative to TVB.[9,18]

Changes in $\dot{V}A$ and FRC can have a marked effect on the rate of rise in E_{tO_2} (and decrease in E_{tN_2}) during preoxygenation. Because of their increased $\dot{V}A$ and decreased FRC, E_{tO_2} rises faster in pregnant women than in nonpregnant women.[14,46,47] Similarly, preoxygenation can be accomplished faster in infants and children than in adults.[48,49]

B. Efficiency of Preoxygenation

Preoxygenation can markedly delay arterial oxyhemoglobin desaturation during apnea. In healthy individuals breathing air, desaturation to 70% can occur within 1 minute, whereas with adequate preoxygenation, desaturation occurs after 5 minutes. The delay in desaturation during apnea depends on the efficacy of preoxygenation, the capacity for O_2 loading, and $\dot{V}O_2$ (see Box 13-1). Patients with a decreased capacity for O_2 loading (decreased FRC, Pa_{O_2}, Ca_{O_2}, or cardiac output) or with increased $\dot{V}O_2$, or both, desaturate much faster during apnea than healthy patients do.[18,29,42,50-52] The main difference in the rate of apnea-induced oxyhemoglobin desaturation after different preoxygenation techniques is observed between Sa_{O_2} levels of 100% and 99%.[18,27,29,34,50] This range represents the flat portion of the oxyhemoglobin dissociation curve. When O_2 reserves are depleted, rapid desaturation occurs regardless of the technique of preoxygenation and is similar to that observed in patients breathing air.

Farmery and Roe developed a computer model describing the rate of oxyhemoglobin desaturation during apnea.[50] This model was found to agree reasonably well with actual data from patients whose weight and degree of normalcy and preoxygenation were reliably known (Fig. 13-5).[29,50] Because it would be dangerous to obtain data in time to marked oxyhemoglobin desaturation in humans, this model is uniquely useful for analysis of oxyhemoglobin desaturation below 90%.[29,50]

BOX 13-2 Techniques of Preoxygenation

Tidal Volume Breathing

Traditional tidal volume breathing (3-5 min)
One vital capacity breath followed by tidal volume breathing

Deep Breathing

Single vital capacity breath
Four deep breaths (4 inspiratory capacity breaths)
Eight deep breaths (8 inspiratory capacity breaths)
Extended deep breathing (12-16 inspiratory capacity breaths)
One vital capacity breath followed by deep breathing

Preoxygenation and an Additional Maneuver

Preoxygenation and continuous positive airway pressure (CPAP)
Preoxygenation and O_2 insufflation
Preoxygenation and bi-level positive airway pressure (BiPAP)

As the preapnea F_{AO_2} is progressively decreased from 0.87 to 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, and 0.13 (air) in a healthy 70-kg patient, the apnea time to 60% Sa_{O_2} is progressively decreased from 9.9 to 9.31, 8.38, 7.30, 6.37, 5.40, 4.40, 3.55, and 2.8 minutes, respectively.[29,50] Figure 13-5 shows that for a healthy 70-kg adult, a moderately ill 70-kg adult, a healthy 10-kg child, and an obese 127-kg adult, 80% Sa_{O_2} is reached after 8.7, 5.5, 3.7, and 3.1 minutes, respectively, whereas 60% Sa_{O_2} is reached at 9.9, 6.2, 4.23, and 3.8 minutes, respectively.[18,29]

V. TECHNIQUES OF PREOXYGENATION

Two main techniques are used: TVB and deep breathing (Box 13-2).

A. Tidal Volume Breathing

The traditional TVB has proved to be an effective preoxygenation technique. To ensure maximal preoxygenation, the duration of TVB should be 3 minutes or longer in adults, and an F_{IO_2} near 1 should be maintained (see Box 13-2 and Fig. 13-3). Various anesthetic systems (circle absorber,[9-12] Mapleson A,[14,53-55] Mapleson D,[13-15,54,55] and nonrebreathing systems) and FGFs ranging from 5 to 35 L/min have been used successfully.[2,14,15,43,54,55] However, the circle absorber system (the system most commonly used in the operating room) with an FGF as low as 5 L/min is just as effective.[40] Increasing the FGF from 5 to 10 L/min has little effect in enhancing preoxygenation during TVB in normal subjects (Fig. 13-6).[40]

B. Deep Breathing Techniques

Based on the assumption that alveolar denitrogenation can be achieved rapidly by deep breathing, Gold and colleagues introduced the 4 DB/0.5 min method of preoxygenation.[9] They showed that the Pa_{O_2} after 4 DB/0.5 min was no different from the Pa_{O_2} after TVB for 3 minutes. Although a few studies corroborated their findings,[10,11] other investigations showed that 3 minutes of TVB provided better preoxygenation (Fig.13-6) and longer protection against hypoxemia during apnea than the 4 DB/0.5 min method did, particularly in pregnant women, patients with morbid obesity (MO), and elderly patients.[12-15]

There are two main reasons why the 4 DB/0.5 min method is inferior to TVB. First, if the ventilation in 0.5 minutes is much greater than the O_2 inflow rate, rebreathing of exhaled nitrogen must occur, which decreases F_{IO_2}. Nimmagadda and colleagues confirmed that 4 DB/0.5 min provided suboptimal preoxygenation in volunteers; no

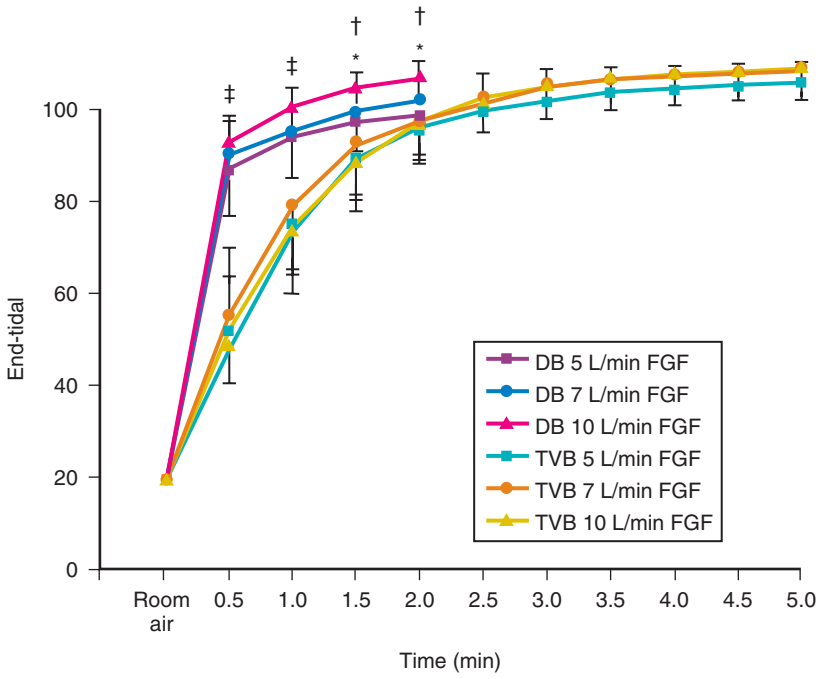

Figure 13-6 Comparison of tidal volume breathing (TVB) and deep breathing (DB) preoxygenation techniques on end-tidal O_2 using 5, 7, and 10 L/min fresh gas flow (FGF). *Significant difference ($P < .05$) from DB at 5 and 7 L/min FGF; †significant difference ($P < .05$) from DB at 0.5 and 1.0 minute; ‡significant difference ($P < .05$) from TVB. Figure 13-8 Effect of the deep breathing technique on end-tidal carbon dioxide tension using 5, 7, and 10 L/min fresh gas flow *(FGF). DB,* Deep breathing; *TVB,* tidal volume breathing. †Significant difference ($P < .05$) from deep breaths at 0.5 and 1.0 minute. (From Nimmagadda U, Chiravuri SD, Salem MR, et al: Preoxygenation with tidal volume and deep breathing techniques: The impact of duration of breathing and fresh gas flow. *Anesth Analg* 92:1337–1341, 2001.)

subject achieved an Et_{O_2} value of 90% or better (see Fig. 13-6).[17] Another possible reason why patients preoxygenated with 4 DB/0.5 min desaturate faster is that the tissue and venous compartments need longer than 0.5 minutes to fill with O_2.[18,24] Probably, these compartments have the capability of storing additional O_2 above that contained while breathing room air.[17,18] Such stored O_2 increases in an exponential fashion. It is possible that the 4 DB/0.5 min technique leads to rapid arterial oxygenation without substantial increase in the tissue O_2 stores and hence results in more rapid desaturation during subsequent apnea than would a longer period of preoxygenation with TVB.[18] Because the 4 DB/0.5 min technique yields submaximal preoxygenation, it should be reserved for emergency situations when time is limited.[17]

To optimize the deep breathing method of preoxygenation, investigators have focused on (1) extending the duration of deep breathing to 1, 1.5, and 2 minutes (to allow 8, 12, and 16 deep breaths, respectively) and (2) using high FGF (≥10 L/min).[16,17] These maneuvers result in maximal preoxygenation (evidenced by higher Et_{O_2}, Pa_{O_2}, and lower Et_{N_2}) and improved efficiency (delayed onset of oxyhemoglobin desaturation during apnea) compared with the original 4 DB/0.5 min method.[16,17] An investigation suggested that preoxygenation using 8 deep breaths in 1.0 minute at an FGF of 10 L/min is associated with slower oxyhemoglobin desaturation than that using 4 DB/0.5 min or TVB for 3 min (Fig. 13-7).[16] Several explanations were given for this finding, including leftward shift of the oxyhemoglobin dissociation curve secondary to hyperventilation-induced reduction in Pa_{CO_2} (Fig. 13-8) and the occurrence of several extra deep breaths during anesthetic induction.[18,56]

The use of maximal exhalation before any preoxygenation maneuver has been suggested.[32,57] In a healthy subject with an FRC of 3 L, forced exhalation to the residual volume decreases the lung volume to approximately 1.5 L. A 50% reduction of the FRC leads to 50% reduction in the time constant of the O_2 washin (N_2 washout) curve.[58] The influence of prior maximal exhalation on preoxygenation using TVB or deep breathing has been studied.[59] TVB after maximal exhalation resulted in a more rapid rise in Et_{O_2} during the first minute than did TVB without prior maximal exhalation. However, the time required to reach maximal preoxygenation (Et_{O_2} ≥90%) was the same (2.5 minutes) with or without maximal exhalation before TVB (Fig. 13-9).[59] During deep breathing, the time courses of preoxygenation with and without prior maximal exhalation were identical. Apparently, the decrease in FRC resulting from maximal exhalation is minor in comparison with the level of $\dot{V}_A$ associated with deep breathing. Regardless of whether prior maximal exhalation was used, 1.5 minutes of deep breathing was still required to reach an Et_{O_2} of 90% or greater. Therefore, prior maximal exhalation confers little or no additional practical benefit to preoxygenation.[59]

It has been demonstrated that preoxygenation using the single vital capacity breath (SVCB) technique can provide within 30 seconds a Pa_{O_2} comparable to that achieved by TVB for 3 minutes (Fig. 13-10).[60] This technique is basically a triphasic process. The first phase consists of forced exhalation to the residual volume, which minimizes lung N_2 content and the subsequent dilution of incoming O_2. The second phase is deep inspiration to expand the lungs to their total capacity, with a consequent maximal increase in Pa_{O_2}. The third phase consists of holding the chest in full inspiratory position, which may allow gas movement from the compliant alveoli to the less compliant alveoli (pendelluft maximization), because the time constants of filling between alveoli are

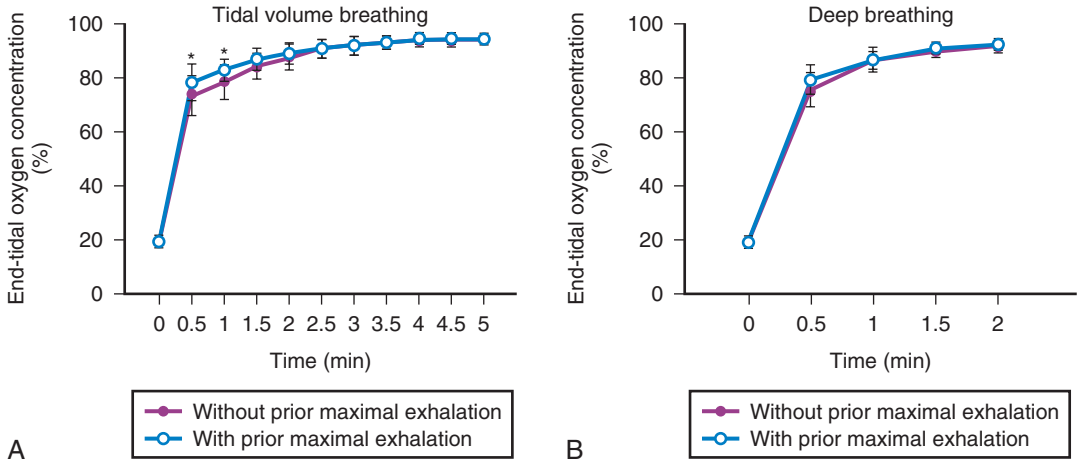

Figure 13-9 **A,** Comparison of end-tidal O_2 concentration values (mean ± SD) over 5-minute periods during simulated preoxygenation using tidal volume breathing (TVB) technique after maximal exhalation (*blue* ○) versus TVB without prior maximal exhalation (*purple* ●). *Statistically significant difference ($P < .05$) between techniques (TVB with or without prior maximal exhalation) at that time period. **B,** Comparison of end-tidal O_2 concentration values (mean ± SD) over 2-minute periods during simulated preoxygenation using deep breathing technique after maximal exhalation (*blue* ○) versus deep breathing without prior maximal exhalation (*purple* ●). not uniform.[60] The SVCB technique can optimize preoxygenation, especially when it is used for fast induction of inhalation anesthesia.[60]

VI. BREATHING SYSTEMS FOR PREOXYGENATION

Mapleson suggested that the degree of rebreathing during spontaneous respiration is less with the Mapleson A system than with the Mapleson D system.[61] Such difference of rebreathing between the anesthesia systems can affect the efficacy of preoxygenation. When using the Mapleson A or the circle system for preoxygenation by TVB, an O_2 flow of 5 L/min can adequately preoxygenate the patient within 3 minutes, whereas an O_2 flow of 10 L/min is required to achieve a similar Et_{O_2} with the Mapleson D system.[54,55] In contrast, when deep breathing is used, an O_2 flow of 10 L/min is required irrespective of the anesthesia circuit.[55]

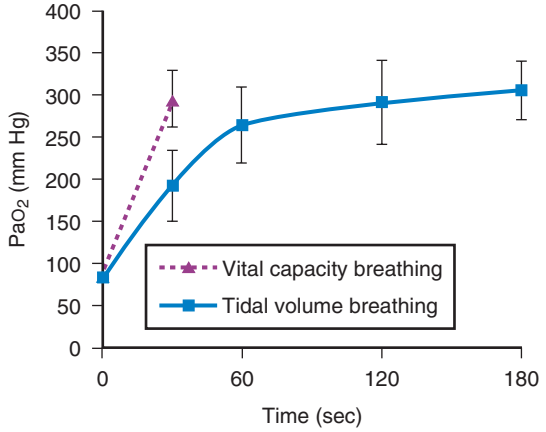

Figure 13-10 The mean arterial O_2 tension (Pa_{O_2}) achieved after preoxygenation by the single vital capacity breath technique (▲) compared with that achieved by the traditional preoxygenation technique (■). (From Baraka A, Haroun-Bizri S, Khoury S, et al: Single vital capacity breath for preoxygenation. *Can J Anaesth* 47:1144–1146, 2000.)

A system designed specifically for preoxygenation has gained some popularity in Europe (NasOral; LogoMed GambH, Windhagen, Germany).[62,63] The NasOral system is a nonrebreathing system that delivers O_2 from a 3.3-L reservoir bag to a small nasal mask, with exhalation occurring by the oral route using a mouthpiece.[40,62,63] One-way valves in the nasal mask and the mouthpiece ensure unidirectional flow (Fig. 13-11). The FGF is adjusted to the individual ventilation to maintain an inflated reservoir bag.[62,63] Investigations have shown that the semiclosed circle absorber and NasOral systems are equally effective in achieving oxygenation despite their different characteristics (see Fig. 13-3).[40] Accordingly, there is little justification for the additional cost of this device for use in the operating room, where the circle absorber can be used for preoxygenation and the administration of anesthesia.[40]

In the critical care setting, resuscitation bags are commonly used for preoxygenation. However, their effectiveness differs markedly during spontaneous respiration.[40] Some, because of their design, cannot deliver high F_{IO_2} despite an FGF of 15 L/min or greater (Fig. 13-12).[40] Resuscitation bags can be categorized into two groups depending on the type of valve mechanism. Disk-type valve systems use single or multiple disks to allow fresh gas to flow to the subject (and seal the exhalation port) during inspiration. The disk returns to its former position and opens the exhalation port during exhalation (Fig. 13-13). Because the disk valve function is not dependent on compression of the reservoir bag, this type of resuscitation bag functions equally well during manual and spontaneous ventilation and therefore can be used for preoxygenation.[40,64,65]

Resuscitation bags using duckbill inspiratory valves function differently during manual and spontaneous

Figure 13-11 The NasOral system uses a small nasal mask for inspiration of O_2 from a reservoir bag. Exhalation occurs through a mouthpiece. One-way valves in the nasal mask and the mouthpiece ensure unidirectional flow. (From Nimmagadda U, Salem MR, Joseph NJ, et al: Efficacy of preoxygenation with tidal volume breathing: Comparison of breathing systems. *Anesthesiology* 93:693–698, 2000.)

ventilation.[40,65] During manual ventilation, gas is forced through the valve base, opening the duckbill valve and delivering fresh gas to the patient's lungs. The force generated also seals the valve base to the exhalation port. During exhalation, the valve base returns to its former position, and exhaled gases are vented to the exhalation port (Fig. 13-14). Mills and colleagues found that duckbill-type resuscitation bags, without one-way exhalation valves to prevent air entrainment, showed variability in delivered O_2 concentration during spontaneous respiration.[65] These findings were confirmed by Nimmagadda and associates, who showed that some duckbill resuscitation bags cannot deliver a high F_{IO_2} during spontaneous ventilation even if a high FGF is used.[40] In the absence of a one-way valve on the exhalation port, generation of sufficient negative pressure to open the duckbill valve becomes impossible. During inspiration, the unsealed valve base allows room air to enter through the exhalation port and mix with O_2 from a partially open duckbill valve (see Fig. 13-14). With the addition of a one-way valve on the exhalation port, duckbill-type resuscitation bags (Laerdal and Kirk) can reliably deliver an F_{IO_2} greater than 0.9 with an FGF of 15 L/min. This valve seals the exhalation port during inspiration and allows the patient to generate sufficient negative pressure to open the duckbill valve, permitting O_2 to flow without dilution[40] (see Fig. 13-14).

The NasOral system has several advantages over resuscitation bags when used for preoxygenation: (1) It provides better preoxygenation than all available resuscitation bags because of a higher F_{IO_2} and reduced apparatus dead space (see Fig. 13-12), (2) It is economical when O_2 tanks are used because it requires an FGF comparable to the subject's minute ventilation; (3) It can provide apneic oxygenation through the nasal mask during laryngoscopy

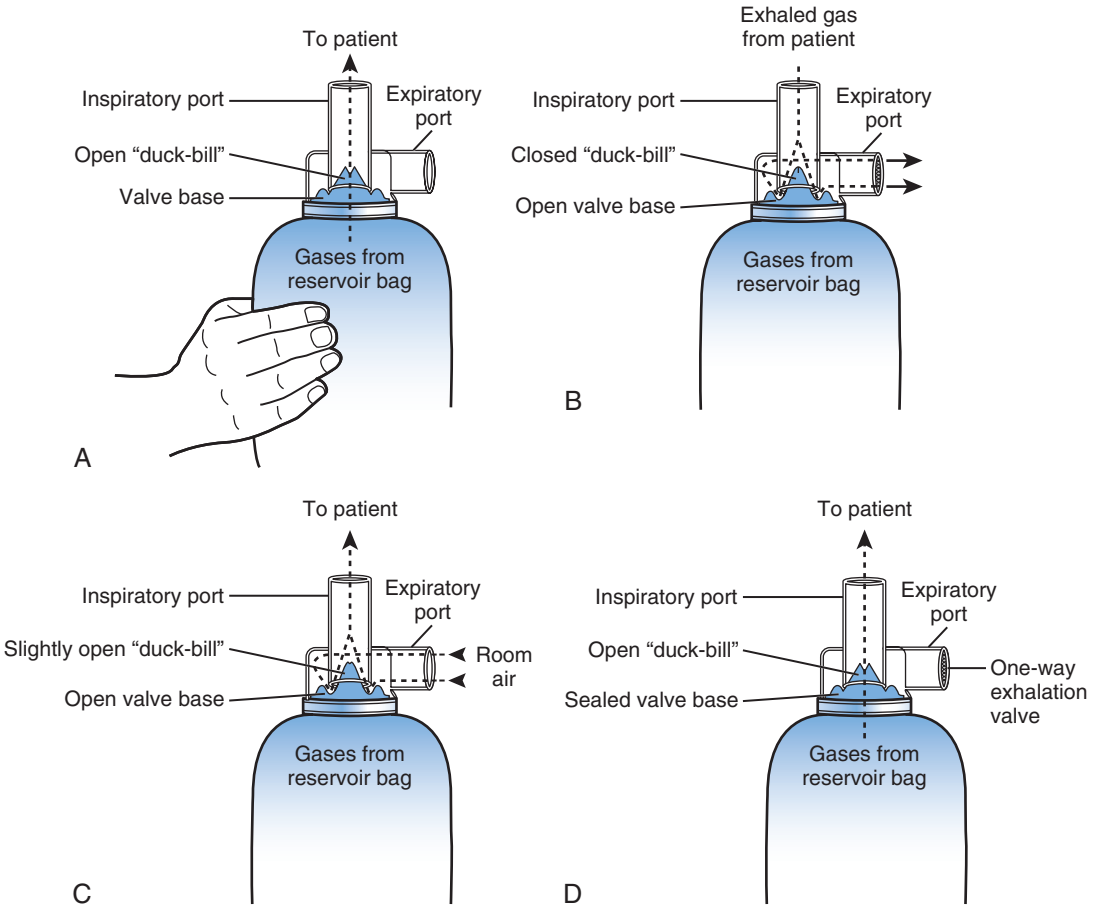

Figure 13-14 Schematic diagrams of a duckbill-type resuscitation bag during inspiration by manual ventilation **(A),** exhalation by manual or spontaneous ventilation **(B),** spontaneous inspiration without a one-way exhalation valve **(C),** and spontaneous inspiration with a one-way exhalation valve **(D).** (From Nimmagadda U, Salem MR, Joseph NJ, et al: Efficacy of preoxygenation with tidal volume breathing: Comparison of breathing systems. *Anesthesiology* 93:693–698, 2000.)

and orotracheal intubation, if needed. Disadvantages of the NasOral system are that it requires the patient's cooperation to use the mouthpiece and that the system cannot be used for positive-pressure ventilation.[40]

The inability of a resuscitation bag to deliver a high F_{IO_2} may have serious consequences during RSI in the critical care setting or during transport of the spontaneously breathing, critically ill patient.[40] Clinicians should ascertain that the resuscitation bags used for preoxygenation in their institutions are capable of delivering a high F_{IO_2} during spontaneous ventilation.[40]

VII. SPECIAL SITUATIONS

Investigations have highlighted risk factors for the rapid development of hypoxemia during apnea. These factors are additive and include a reduced FRC, inadequate denitrogenation, hypoventilation prior to apnea, increased $\dot{V}O_2$, and airway obstruction.[34,39] Patients with a combination of these risk factors should be considered to be at high risk for hypoxemia during apnea.

A. Pregnant Patients

Because pregnant women are at high risk for pulmonary aspiration, RSI is desirable whenever general anesthesia is administered to these patients. Maximal preoxygenation can be achieved faster in pregnant than in nonpregnant women because of the increased $\dot{V}A$ and decreased FRC.[11,14,47] However, during apnea, pregnant women become hypoxemic more rapidly because of the limited O_2 stores in their small FRC and increased $\dot{V}O_2$.[46] This can be further compounded by pregnancy-associated airway changes which can add to delay in securing the airway.[27] From the fifth month of pregnancy, the FRC decreases to 80% of that in the nonpregnant state, while the $\dot{V}O_2$ increases by 30% to 40%. In pregnant women, preoxygenation can be accomplished by TVB for 3 minutes or by deep breathing for 1 minute or longer before anesthetic induction. A combination of both techniques may also be used. Because of the increased $\dot{V}A$ during pregnancy, an O_2 flow of 10 L/min or higher is necessary (using the circle absorber) during TVB or deep breathing.[66] However, the 4 DB/0.5 min technique should be used only in emergency situations when time is limited.

The influence of preoxygenation in the supine position versus the 45-degree head-up position on the duration of apnea leading to a decrease in S_{PO_2} to 95% has been investigated.[46] The average time for S_{PO_2} to reach 95% was shorter in pregnant than in nonpregnant patients (173 versus 243 seconds) in the supine position.[46] Use of

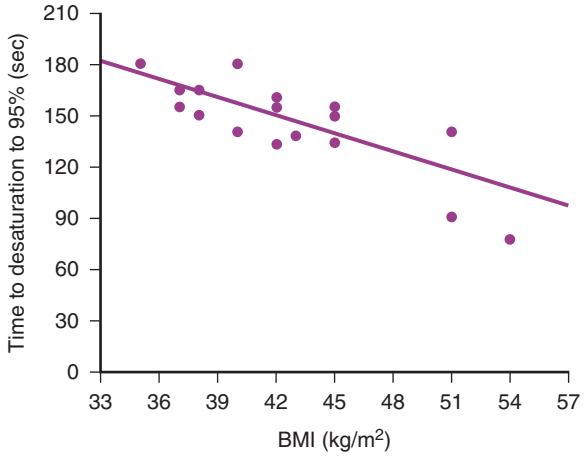

Figure 13-16 Correlation between time required for desaturation to 95% in seconds and body mass index *(BMI)* in $kg \cdot m^{-2}$ during apnea after preoxygenation in morbidly obese patients. The time to desaturation is inversely related to the body mass index: $R^2 = 0.66$ ($P < 0.05$). (From Baraka AS, Taha SK, Siddik SM, et al: Supplementation of preoxygenation in morbidly obese patients using nasopharyngeal O_2 insufflation. *Anaesthesia* 62:769–773, 2007.)

the head-up position resulted in an increase in desaturation time in nonpregnant patients but had no effect in pregnant patients.[46] It is possible that the gravid uterus prevents descent of the diaphragm in the upright position and therefore does not allow the expected increase in FRC.

B. Morbidly Obese Patients

MO is associated with a more rapid decrease in Spo_2 during apnea after induction of anesthesia.[10,53,67-70] This is particularly hazardous because MO complicated by obstructive sleep apnea may be associated with an increased risk of difficult intubation (DI) and difficult mask ventilation (DMV).

The more rapid hemoglobin desaturation in the patient with MO is attributed to increased $\dot{V}O_2$ associated with a decreased FRC (Fig. 13-15). The supine position further decreases the FRC due to the cephalad displacement of the diaphragm by the abdominal contents. Anesthetic induction results in an additional reduction of the FRC. Whereas the FRC of nonobese patients decreases by 20% after induction of anesthesia, it decreases by 50% in MO patients. The tidal volume of the patient with MO may fall within the closing capacity, resulting in atelectasis, with a subsequent increase in intrapulmonary shunting.

In the patient with MO, the time required for Spo_2 to fall to 90% during apnea after preoxygenation with TVB for 3 minutes is significantly reduced compared to the time in nonobese patients (Fig. 13-16).[29,70] In one study, the time to desaturation (Sao_2 = 90%) for patients of normal weight was 6 minutes after preoxygenation, but for those with MO it was 2.7 minutes.[67] A significant negative correlation between body mass index (BMI) and time to oxyhemoglobin desaturation has been described (see Fig. 13-15).[70] The head-up position (25 degrees) during preoxygenation in MO patients has been shown to prolong the time of desaturation by about 50 seconds.[69] The application of continuous positive airway pressure (CPAP) has been suggested to optimize preoxygenation in these patients, based on the assumption that CPAP will increase the FRC. [71] However, clinical observations showed that it did not delay the onset of desaturation, because the FRC returns to pre-CPAP levels once the patient is anesthetized and the CPAP mask is removed.[71]

It has been shown that nasopharyngeal O_2 insufflation after preoxygenation in patients with MO delays the onset of oxyhemoglobin desaturation during the subsequent apnea by apneic diffusion oxygenation.[70] In the critically ill MO patient with respiratory failure, traditional preoxygenation without or even with subsequent nasopharyngeal O_2 insufflation may not increase the FRC O_2 store and improve Sao_2 before, during, or after endotracheal intubation. This may be attributed to atelectasis and decreased FRC with marked intrapulmonary shunting. In this situation, the use of noninvasive bi-level positive airway pressure (BiPAP) can improve alveolar recruitment with a consequent decrease in intrapulmonary shunting.[72] BiPAP preoxygenation can achieve a notable increase in Sao_2 associated with less hypercarbia, compared with the traditional technique of preoxygenation.[72]

C. Elderly Patients

Several changes during aging may influence the period of preoxygenation needed in elderly patients and the subsequent time to oxyhemoglobin desaturation.[13,15,36] On one hand, the basal $\dot{V}O_2$ declines with age (from 143 $mL/min/m^2$ in a male aged 20 years to 124 $mL/min/m^2$ in a male aged 60 years), so the demand for O_2 is less; on the other hand, changes in lung function make O_2 uptake less efficient. The closing volume increases with age, leading to less efficient denitrogenation and a longer period of preoxygenation. The reduction of O_2 demand

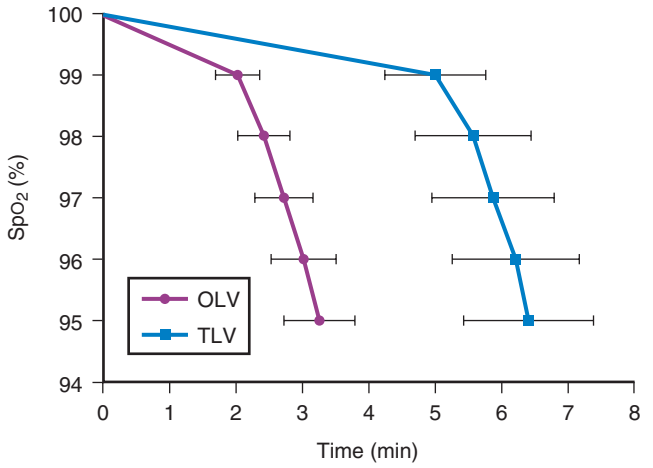

Figure 13-17 Diagram comparing the mean time to apnea-induced oxyhemoglobin desaturation from pulse oximetry O_2 saturation *(Spo$_2$)* of 100% down to 95% after two-lung ventilation *(TLV)* versus one-lung ventilation *(OLV)*. (From Baraka A, Aouad M, Taha S, et al: Apnea-induced hemoglobin desaturation during one-lung vs two-lung ventilation. *Can J Anaesth* 47:58–61, 2000.)

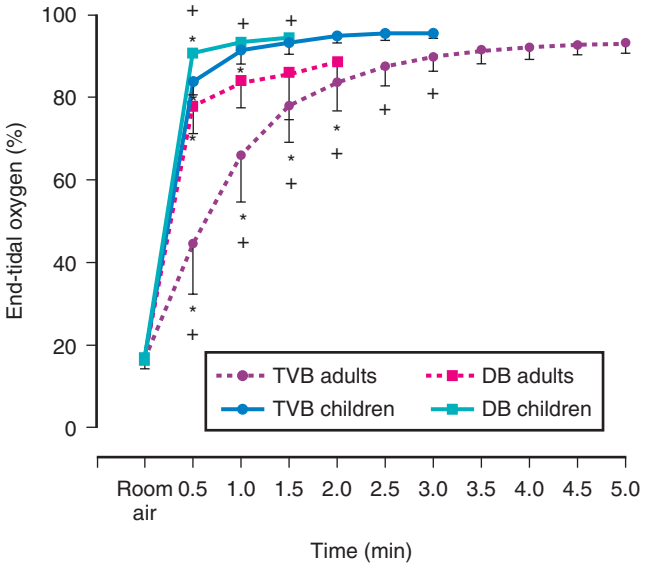

Figure 13-18 Comparison of the effects of tidal volume breathing *(TVB)* and deep breathing *(DB)* preoxygenation techniques on end-tidal O_2 in adults and children. *Significant difference from all other time periods. †significant difference (*P*, < .01) between adults and children. in elderly patients does not compensate fully for the less efficient O_2 uptake, because the mean times to 93% desaturation in elderly patients are approximately one half of those reported for equivalent preoxygenation periods in young patients. Reliable preoxygenation can be achieved with extended TVB (>3 minutes) or deep breathing for longer than 1 minute.

D. Patients with Lung Disease

Patients with ARDS have decreased FRC, increased intrapulmonary shunting, and increased $\dot{V}O_2$; therefore, interruption of ventilation can result in rapid oxyhemoglobin desaturation. During thoracic surgery, the time to desaturation after one-lung ventilation is almost one half the time after two-lung ventilation (Fig. 13-17).[73] This can be attributed to collapse of the nonventilated lung with a consequent decrease of the FRC O_2 store; the rate of oxyhemoglobin desaturation may be further exaggerated by the associated intrapulmonary shunting.[73] A similar decrease of the safety margin may occur in patients with lung disease characterized by decreased FRC or increased intrapulmonary shunting or both. In these patients, maximal preoxygenation should precede interruption of ventilation or tracheobronchial suction.

E. Pediatric Patients

Because of their smaller FRC and increased metabolic requirements, children are at increased risk for developing faster oxyhemoglobin desaturation than in adults whenever there is an interruption of their O_2 delivery.[48,74-80] The younger the child, the faster is the onset of hypoxemia.[45,74-80] With a satisfactory mask fit, the efficacy of preoxygenation depends on the age and the duration and type of breathing.[48,80,81] Studies in children have demonstrated that maximal preoxygenation can be reached faster than in adults. With TVB, an Et_{O_2} of 90% or greater is reached within 60 to 100 seconds in almost all children.[48,49,80] Among those in the first year of life, it is reached in 36 seconds (range, 20 to 60 seconds); between 3 and 5 years age, it is reached in 50 seconds (range, 30 to 90 seconds), and in those older than 5 years, it is reached in 68 seconds (range, 30 to 100 seconds).[80] Deep breathing in children results in faster preoxygenation than TVB and also faster preoxygenation than deep breathing in adults (Fig. 13-18).[49] Optimal preoxygenation can be accomplished in children with the use of deep breathing for 30 seconds.[49]

Several factors affect the onset of apnea-induced oxyhemoglobin desaturation after preoxygenation in children. These include the efficacy of preoxygenation, the child's age (or weight), the presence of disease, and the composition of gases in the lungs. Some studies have examined the time required for Spo_2 to decrease from 100% to 95% (Fig. 13-19)[76,77]; others have targeted a level as low as 90%.[75,78,81] In a comparison of three groups of children who breathed 100% O_2 at TVB for 1, 2, and 3 minutes before apnea, the times needed for Spo_2 to decrease from 100% to 98%, 95%, and 90% were shorter in those who had breathed O_2 for 1 minute.[81] On the basis of these findings, 2 minutes of preoxygenation with TVB in children seems to provide maximum benefit and allows at least 2 minutes of safe apnea.[81] In a 1-month-old infant, the rate of decline in Pa_{O_2} during apnea is three times more rapid than in an adult.[82] The times for Spo_2 to decrease from 100% to 95% and to 90% are shorter in younger children than in older children. Most infants reach an Spo_2 of 90% in 70 to 90 seconds (see Fig. 13-19).[75] This duration is shortened in the presence of upper respiratory infection.[76] The benefit of preoxygenation is greater in the older child than that in the infant.[82]

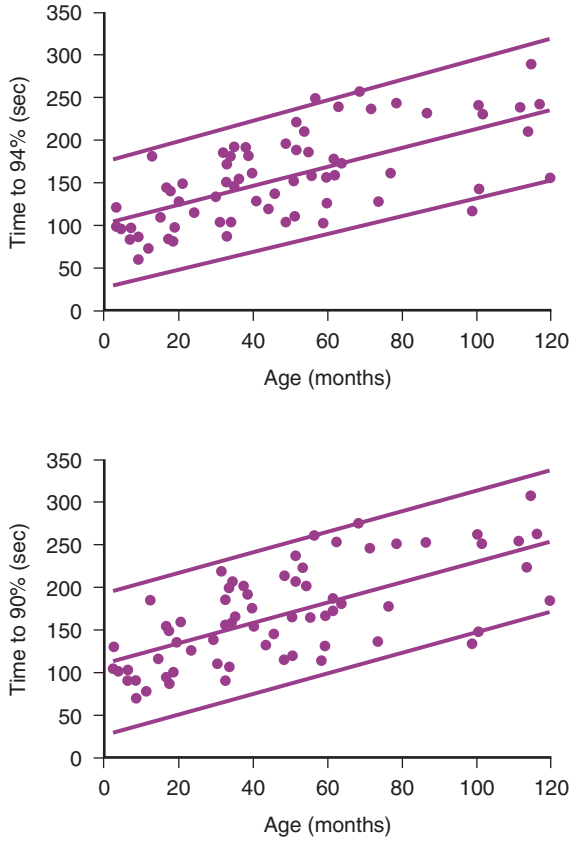

Figure 13-19 Relationship between desaturation times to 94% *(top)* and to 90% *(bottom)* versus age with a prediction interval of 95 ($P < .001$). (From Dupeyrat A, Dubreuil M, Ecoffey C: Preoxygenation in children (letter). *Anesth Analg* 79:1027, 1994.)

In an 8-year-old, the time after the onset of apnea to 90% Sa_{O_2} is 0.47 minutes without preoxygenation but slightly longer than 5 minutes with preoxygenation.[82]

Although the time for desaturation is mainly dependent on the O_2 content of the lungs at the start of apnea, other gas components may play a role. If 60% nitrous oxide (N_2O) in O_2 is used, the time for Sp_{O_2} to decrease to 95% is shortened to approximately one third,[77] but it is still longer than the time observed after air-O_2 breathing and maintains the same delivered O_2 concentration.[77] This can be explained by the second-gas effect. Compared with N_2 in case of air-O_2 breathing, N_2O continues to dissolve into the blood and is carried away from the lungs, resulting in an increase in the Pa_{O_2} and hence delaying the onset of desaturation.[77]

It should be emphasized that the apnea-desaturation studies were performed in healthy children with a patent airway. The presence of cardiac or respiratory disease or airway obstruction could lead to faster desaturation during apnea.[77] Premature infants are usually given a low F_{IO_2} using an air-O_2 mixture because of fear of retinopathy. Oxyhemoglobin desaturation occurs very quickly in these infants even after a short period of apnea. Transiently increasing the F_{IO_2}, limiting apnea to very short periods, and close monitoring are important considerations.[83] The respiratory rate in preterm infants is 30 to 60 breaths/min. Rapid respirations tend to maintain their FRC by not allowing time to complete exhalation. Slow respirations and apnea result in marked decrease of FRC and fast desaturation after apnea.[83]

F. Tracheobronchial Suctioning

Tracheobronchial suctioning to remove secretions is a commonly practiced maneuver in anesthetized and critically ill patients. Although the effects of suctioning are usually mild, they on occasion can have serious consequences.[84-93] Cardiovascular collapse and even death as a consequence of severe hypoxemia associated with suctioning were recognized as early as the 1950s.[84] Traditionally, tracheobronchial suctioning requires disconnection of the ETT from the anesthesia machine or the ventilator. A catheter is then introduced inside the ETT or tracheostomy tube, and suction is performed. This common method is referred to as open endotracheal suctioning (OES).[94] The mechanisms of acute hypoxemia after OES are twofold.[90,92,94] First, disconnection dilutes the F_{IO_2} with air and induces massive loss of FRC, especially in patients with acute lung injury.[90,92,94] Second, the high negative pressure required for removal of secretions contributes to further dilution of F_{IO_2} and decrease in FRC, which results in atelectasis, fall in lung compliance, and intrapulmonary shunting.[86,93]

The effects of OES can be severe in patients with limited O_2 reserves, when large suction catheters are used, with prolonged suctioning, and when selective bronchial suctioning is performed.[86,89-95] Especially vulnerable is the infant, because a suction catheter may occupy a large part of the lumen of a small ETT.[86,95] Studies in infants have consistently demonstrated a sharp fall in pulmonary compliance with prolonged suctioning and when large catheters are used.[86] Infants ventilated at constant volumes had increases in transpulmonary pressure after tracheal suctioning ranging from 15% to 60%, whereas in infants ventilated with pressure-preset ventilators, tidal volumes fell by 25% to 70% (Fig. 13-20).[86] Failure of tidal volumes to return to the pre-suctioning level was observed for periods as long as 30 minutes[86] (Fig. 13-21).

In adult patients with acute lung injury, OES induces an 18% decrease in Pa_{O_2} and an increase in Pa_{CO_2} of 8%[94] (Fig. 13-22). The maximum impairment appears within 1 minute after suctioning is begun and persists for 15 minutes after the end of suctioning. A 70% reduction in Pa_{O_2} has been observed in some patients.[94] Decreases in $S\bar{v}O_2$ are commonly observed during OES in critically ill patients.[91] The rise in Pa_{CO_2} may explain why OES is frequently associated with an increase in intracranial pressure in patients with severe head injury.[94,96] A collapsed lung, as a consequence of suctioning, may remain collapsed for hours or even days, unless high pressures or high volumes are used to reinflate the lungs.[86] Collapsed alveoli begin to open at an airway pressure of 18 to 23 cm H_2O, and frequently an inflation pressure of 25 cm H_2O or higher is desirable.[86] Impairment in oxygenation after OES can be attenuated by prior maximal preoxygenation

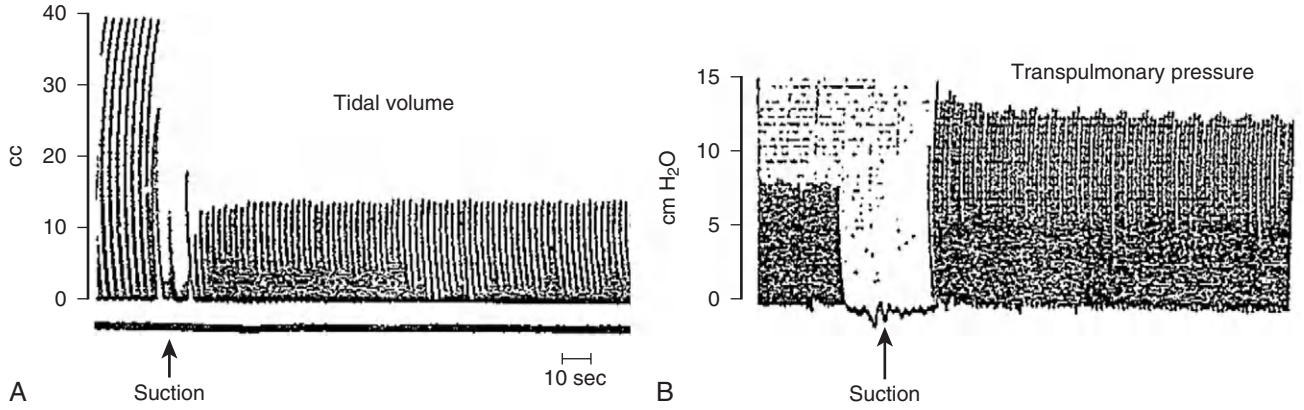

Figure 13-20 **A,** Effect of tracheal suctioning on tidal volume in an infant ventilated with a Bird respirator set to produce a peak transpulmonary inflation limit of 11 cm H_2O. **B,** Effect of tracheal suctioning on transpulmonary pressure in an infant ventilated at a constant tidal volume of 20 mL. Pao_2 and $Paco_2$ were sampled every second in each patient, and the mean curves are presented. *Red lines* represent open suctioning, whereas *blue lines* represent closed-circuit suctioning followed by a recruitment maneuver. Arrows indicate the beginning of the recruitment maneuver. (From Lasocki S, Lu Q, Sartorius A, et al: Open and closed-circuit endotracheal suctioning in acute lung injury: Efficiency and effects on gas exchange. *Anesthesiology* 104:39–47, 2006.)

and by using a postsuctioning maneuver consisting of a multiple number of high tidal volumes.

In the critical care setting, closed-circuit endotracheal suctioning (CES) has been advocated to prevent hypoxemia resulting from ventilator disconnection.[94,97-99] Two methods are used. In one, suctioning is performed via a swivel adapter positioned at the proximal tip of the ETT; and in the other, total CES is done with a catheter continuously placed between the ETT and the Y-piece of the ventilator circuit.[93,94] Because neither method requires disconnection, the loss of lung volume and hypoxemia are much less compared with OES, and the effect of suctioning becomes dependent only on the negative suction pressure.[93]

There is evidence that OES is more efficient than CES for secretion removal.[94] Several mechanisms contribute to this difference. First, during OES, the airway pressure is zero, whereas in CES it is positive, especially if positive end-expiratory pressure (PEEP) is used. Second, during CES, the positive pressure from the ventilator fills the suction catheter with gas and tends to blow secretions distally. Third, disconnection from the ventilator during OES induces a sudden decrease in expiratory lung volume, and bronchial secretions may be entrained proximally with the expiratory gas flow, thereby facilitating secretion removal. The problem of decreased secretion removal with CES can be corrected by increasing the negative suction pressure from –200 cm H_2O to –400 cm H_2O, which enhances suctioning efficiency without further impairment of gas exchange.[94]

1. Guidelines for Suctioning

Suctioning may be divided into three stages: the presuctioning stage, the suctioning procedure, and the postsuctioning maneuvers. The strategies may depend on the method used.

a. OPEN ENDOTRACHEAL SUCTIONING

1. *The Presuctioning Stage*: Before suctioning, the patient's cardiovascular and respiratory status are optimized, and appropriate monitoring is continued. An additional dose of a muscle relaxant, opioid, or intravenous lidocaine may be given. The patient's oxygenation should be maximized by using an F_{IO_2} of 1 for several minutes. An indication of the efficacy of oxygenation is an E_{TO_2} close to 90%. Other respiratory parameters may be adjusted to enhance O_2 delivery. Suction equipment and sterile supplies should be checked. The choice of appropriate suction catheter size is important. The outer diameter (OD) of the catheter should be approximately 60% of the inner diameter (ID) of the ETT (e.g., 16 F for an 8.0-mm ETT, 14 F or for a 7.5-mm ETT). In infants, a slightly larger suction catheter with an OD 70% of the ID of the ETT may be used.
2. *The Suctioning Procedure*: After disconnection from the anesthesia machine or the ventilator, the suction catheter is introduced into the ETT and advanced until resistance is felt and is then withdrawn about 2 cm. Negative pressure of –50 to –200 cm H_2O is applied intermittently for 2 to 4 seconds by occluding the side hole located at the proximal end of the catheter with the operator's thumb. Intermittent suctioning may be continued (up to 20 seconds), during which the catheter is gently rotated and withdrawn. If additional suctioning is required, a recruitment maneuver (with high F_{IO_2}) should be performed before suctioning is repeated.
3. *Postsuctioning Maneuvers*: After suctioning, the patient is reconnected to the ventilator and a recruitment maneuver is performed while administering high F_{IO_2} immediately.[92,94] The most common maneuver is tidal volumes set at twice the baseline value, provided that the airway pressure does not exceed 25 to 50 cm H_2O (depending on the existing lung pathology). The numbers of these high tidal volumes can vary from 2 to 20 breaths. In anesthetized healthy patients, 3 large TVBs are adequate. A study in ARDS patients showed that 2 consecutive sustained inflations lasting 20 seconds with an interval of 1 minute in between reversed the OES-induced decrease in Pa_{O_2} and lung volume.[100]

b. CLOSED-SYSTEM ENDOTRACHEAL SUCTIONING

In CES, the suction catheter is introduced via the swivel adapter or the sealed system. The same suctioning procedure described for OES is used. Negative pressure of –200 cm H_2O may be applied for up to 20 seconds. To enhance removal of secretions, –400 cm H_2O may be used. Although the deterioration in gas exchange is markedly reduced with CES, it is probably beneficial to use a recruitment maneuver immediately after suction.

G. "Routine" Preoxygenation Before Induction, During Recovery from Anesthesia, and in Critically Ill Patients

Preoxygenation is mandatory in the context of RSI, and it is arguably so in an additional range of scenarios. Imperative preoxygenation is indicated in those patients who cannot tolerate a fall in P_{O_2}, such as those with ischemic heart disease, and in patients with low Pa_{O_2}, such as those with lung disease or right-to-left shunt. Because conditions such as the DI-DMV scenarios are unpredictable and many adverse reactions (e.g., drug-induced anaphylaxis, hypotension, hypoventilation) can occur, "routine" preoxygenation offers identifiable safety benefits during anesthetic induction.[20-22] However, "routine" preoxygenation must be used as an adjunct rather than an alternative to a sequence of fundamental preoperative precautions that minimize adverse sequelae.[21]

Recovery from anesthesia and extubation have received limited critical safety measures compared with attention to the identification and management of potential DI, despite the observation that airway complications are more likely to be associated with extubation than intubation.[101-103] The ASA Task Force on Management of the DA recommended that each anesthesiologist must have a preformulated strategy for extubation of the DA and an airway management plan for dealing with postextubation hypoventilation.[19] Even routine

discontinuation of anesthesia and tracheal extubation can be complicated with hypoxemia, hypoventilation, and loss of airway patency because of the residual effects of anesthetics and incomplete reversal of neuromuscular block.[104,105] These effects can result in decreased functional activity of the pharyngeal muscles, leading to upper airway obstruction and a fivefold increase in the risk of aspiration; and they can affect the contractions of the respiratory muscles, resulting in hypoventilation and inability to cough effectively.[104,105] They can also obtund the hypoxic drive by the peripheral chemoreceptors.[105] In addition, adequate oxygenation before reversal of neuromuscular block is essential to ensure safe reversal and to minimize neostigmine-induced cardiac arrhythmias.[106] Accordingly, "routine" preoxygenation before reversal of neuromuscular blockade and extubation is recommended to improve the margin of safety, given the potential of unpredictable airway and ventilation problems.

In critically ill, hemodynamically unstable patients, preoxygenation is less effective in raising Pa_{O_2}. Whereas in a healthy patient, preoxygenation (F_{IO_2} = 1) typically raises the Pa_{O_2} from 80 to 400 mm Hg, the increase in hemodynamically unstable patients is from 67 to 107 mm Hg only.[107] Multiple factors limit the rise in Pa_{O_2}, including inability to provide high F_{IO_2}, increased V_{O_2}, blood loss, anemia, stress, hypoventilation, acidemia, hypermetabolic state, older age, cardiopulmonary disease, and airway obstruction.[107] This limitation implies that the time available to safely perform airway management maneuvers is rather limited in critically ill patients. Nevertheless, preoxygenation enhances the safety of these patients requiring emergency intubation. Findings from a recent swine hemorrhagic shock model confirm that F_{IO_2} does influence the rate of apneic desaturation.[108] A fivefold increase in time until critical desaturation can be achieved with preoxygenation compared with breathing of room air.[108]

VIII. CONCLUSIONS

Oxygenation before anesthetic induction and endotracheal intubation has become an accepted maneuver designed to increase O_2 reserves and thereby delay the onset of arterial oxyhemoglobin desaturation during apnea. It is particularly important when manual mask ventilation is undesirable and when difficulty with ventilation or endotracheal intubation is anticipated. Because the CICV situation is largely unpredictable, maximal preoxygenation is desirable in all patients. It is also essential in patients who have a decreased capacity for O_2 loading (decreased FRC, Pa_{O_2}, or cardiac output) or an increased V_{O_2} or both. Preoxygenation should be considered when maneuvers that deplete the O_2 reserves, such as suctioning, one-lung ventilation, or apneic oxygenation, are performed.

In the operating room, maximal preoxygenation can be accomplished in most patients with the commonly used anesthetic systems—either TVB for 3 to 5 minutes or deep breathing for 1.0 to 1.5 minutes. Elderly patients and patients with pulmonary disease may require longer periods of preoxygenation, whereas pediatric patients may need a shorter time. Except in children, the 4 DB/0.5 min technique provides submaximal preoxygenation and therefore should be reserved for emergency situations when time is limited. When deep breathing is used, an FGF of 10 L/min or greater is necessary; otherwise, rebreathing of exhaled gases occurs, leading to decreased inspired O_2 concentration. During preoxygenation, it is important that a tight-fitting mask be used to prevent air entrainment and that the reservoir bag be fully inflated. Almost all patients accept mask preoxygenation if the procedure and its importance are explained to them beforehand.

Clinical end points indicative of maximal preoxygenation are movement of the reservoir bag in and out with each inspiration and exhalation, presence of a normal capnographic tracing, and a near-normal Et_{CO_2} throughout the period of preoxygenation. Monitoring of O_2 or N_2, or both, to ensure a target level of Et_{O_2} 90% or higher or an E_{NO_2} 5% or lower is desirable, if available.

"Routine" preoxygenation with 100% O_2 is considered a "safety" measure during anesthetic induction and emergence from anesthesia and in critically ill patients requiring emergency airway management. However, it must be used as an adjunct rather than an alternative to a sequence of fundamental precautions that minimize adverse sequelae.

IX. CLINICAL PEARLS

- The principal stores of body O_2 are increased with breathing 100% O_2; the maximal increase occurs in the functional residual capacity (FRC).
- The end points of maximal preoxygenation or denitrogenation have been defined as Et_{O_2} of 90% or higher and Et_{N_2} 5% or lower.
- An O_2 saturation of 100% on pulse oximetry (Sp_{O_2}) should not be a reason to stop preoxygenation; conversely, failure of Sp_{O_2} to increase substantially does not necessarily indicate failure of preoxygenation.
- During apneic diffusion oxygenation via an open airway, the increase in time to hemoglobin desaturation achieved by increasing the fraction of inspired oxygen (F_{IO_2}) from 0.9 to 1.0 is greater than that caused by increasing the F_{IO_2} from 0.21 to 0.9.
- In most patients, maximal preoxygenation can be accomplished by using tidal volume breathing (TVB) for 3 minutes or longer with a fresh gas flow (FGF) of 5 L/min or deep breathing for 1.5 minutes (FGF of 10 L/min) with the circle absorber.
- In the critical care setting, clinicians should ascertain that the resuscitation bags used for preoxygenation before rapid-sequence intubation (RSI) are capable of delivering high F_{IO_2} during spontaneous ventilation.
- Patients with decreased O_2 stores or increased $\dot{V}_{O_2}$ or both—including morbidly obese patients, children, pregnant women, critically ill patients, patients with ARDS, patients undergoing one-lung ventilation, and those patients with airway obstruction—develop faster arterial oxyhemoglobin desaturation during apnea.

- Preoxygenation in the head-up position in morbidly obese patients prolongs the time of oxyhemoglobin desaturation.
- "Routine" preoxygenation is recommended, not only before anesthetic induction, but also before and during reversal of neuromuscular blockade, emergence from anesthesia, and extubation. It is also recommended before interruption of ventilation and tracheobronchial suctioning and before emergency intubation in the critically ill.
- Routine preoxygenation must be used as an adjunct rather than an alternative to a sequence of fundamental precautions that minimize adverse sequelae.

Chapter 14

Oxygen Delivery Systems, Inhalation Therapy, and Respiratory Therapy

ARTHUR J. TOKARCZYK | STEVEN B. GREENBERG | JEFFERY S. VENDER

I. Introduction

II. Oxygen Therapy
- A. Indications
- B. Oxygen Delivery Systems
  - 1. Low-Flow Oxygen Systems
  - 2. High-Flow Oxygen Systems
- C. Oxygen Delivery Devices
  - 1. Low-Flow Devices
  - 2. High-Flow Devices
- D. Humidifiers
- E. Manual Resuscitation Bags
- F. Complications

III. Techniques of Respiratory Care
- A. Suctioning
  - 1. Indications
  - 2. Equipment
  - 3. Technique
  - 4. Complications
- B. Chest Physical Therapy
  - 1. Postural Drainage and Positional Changes
  - 2. Percussion and Vibration Therapy
  - 3. Incentive Spirometry
- C. Intermittent Positive-Pressure Breathing
  - 1. Indications
  - 2. Administration
- D. Noninvasive Ventilation
  - 1. Indications
  - 2. Limitations

IV. Inhalation Therapy
- A. Basic Pharmacologic Principles
- B. Aerosolized Drug Delivery Systems
- C. Pharmacologic Agents
  - 1. Mucokinetic Drugs
  - 2. Bronchodilators and Antiasthmatic Drugs

V. Conclusion

VI. Clinical Pearls

I. INTRODUCTION

Many patients suffer from acute and chronic dysfunction of the pulmonary system. Management of the surgical and critical care patient requires an understanding of pulmonary pathophysiology and the appropriate prophylactic and therapeutic techniques. Oxygen (O_2) therapy is one of the most commonly employed medical interventions. An understanding of O_2 delivery systems and devices is essential for optimal care. Bronchial hygiene has become a cornerstone in prophylactic care of the perioperative surgical patient, and these techniques may restore normal pulmonary physiology in patients with compromised function. Many medications that are specifically intended to treat pulmonary pathophysiology can be delivered by inhalation therapy with greater efficiency and less toxicity than oral or parenteral methods. This chapter reviews the various procedures and techniques used in the respiratory care of patients.

II. OXYGEN THERAPY

A. Indications

O_2 is one of the most common therapeutic substances used in the practice of critical care medicine. O_2 therapy may improve outcomes of patients undergoing surgery. Use of O_2 concentrations greater than 50% F_{IO_2} has reduced the incidence of wound infections in patients undergoing colorectal or spinal surgery.[1-4] This section reviews some of the indications, goals, and modes of O_2 therapy in the adult patient.

BOX 14-1 Calculation of Arterial Oxygen Content

$$Ca_{O_2} = Sa_{O_2} \times Hg \times 1.34 + Pa_{O_2} \times 0.0031$$

Ca_{O_2} = arterial O_2 content (mL/dL)
Hg = hemoglobin (g/dL)
1.34 = O_2-carrying capacity of hemoglobin
Pa_{O_2} = arterial partial pressure of O_2 (mm Hg)
0.0031 = solubility coefficient of O_2 in plasma

Treatment or prevention of hypoxemia is the most common indication for O_2 therapy, and the final goal of effective treatment is avoidance or resolution of tissue hypoxia. Tissue hypoxia exists when delivery of O_2 is inadequate to meet the metabolic demands of the tissues. O_2 content (Box 14-1) depends on the arterial partial pressure of O_2 (Pa_{O_2}), the hemoglobin concentration of arterial blood, and the saturation of hemoglobin with O_2. O_2 delivery (D_{O_2}) is calculated by multiplying cardiac output (liters per minute) by the arterial O_2 content. D_{O_2} is measured in milliliters of O_2 per minute, and for a 70-kg, healthy patient, it is approximately 1000 mL/min (Box 14-2).

Hypoxia may result from a decrement of any of the determinants of D_{O_2}, including anemia, low cardiac output, hypoxemia, or abnormal hemoglobin affinity (e.g., carbon monoxide toxicity) out of proportion to demand. Hypoxia may also arise from a failure of O_2 use at the tissue level (e.g., microvascular perfusion defect of shock) or at the cellular level (e.g., cyanide poisoning).

Aerobic metabolism requires a balance between D_{O_2} and O_2 consumption. Inspiration of enriched concentrations of O_2 may increase the Pa_{O_2}, the percentage of saturation of hemoglobin, and the O_2 content, thereby augmenting D_{O_2} until the underlying cause of the hypoxia can be corrected (e.g., transfusing the anemic patient, reversing cardiac dysfunction). The clinical situation in which O_2 therapy is most effective, however, is in the treatment of hypoxemia.

Hypoxemia may be defined as a deficiency of O_2 tension in the arterial blood, typically defined as a Pa_{O_2} value less than 80 mm Hg. The most common perioperative causes of hypoxemia include decreased alveolar O_2 tension (e.g., ventilation-perfusion mismatch, hypoventilation) and capillary shunt (e.g., atelectasis). Less common causes of perioperative hypoxemia include decreased mixed venous O_2 content ($C\bar{v}_{O_2}$) and diffusion defect.

Mismatch of ventilation and perfusion ($\dot{V}/\dot{Q}$) is essentially an uncoupling of alveolar blood supply and ventilation. In an area of low $\dot{V}/\dot{Q}$, hypoxemia results when mixed venous blood flowing past the alveolar-capillary membrane (ACM) takes away O_2 molecules faster than ventilation to the alveolus can replace them. The resultant partial pressure of O_2 in the alveolus (P_{AO_2}) is too low to oxygenate the blood flowing past it. In a true intrapulmonary shunt, the ventilation decreases to zero, with $\dot{V}/\dot{Q} = 0$. Anatomic shunt occurs when blood flows from the right side of the heart to the left side without traversing the pulmonary capillaries. A small percentage of physiologic shunt results from bronchial and thebesian circulation. True intrapulmonary shunts cause hypoxemia that is poorly responsive to O_2 therapy. Therapy for "oxygen-refractory" hypoxemia is aimed at reducing the shunt. Different levels of shunting, such as low-ventilation areas, often cause blood to flow through capillaries adjacent to alveoli that do not participate in ventilation. Atelectasis is a common cause of this type of shunt. Respiratory therapy, such as tracheobronchial toilet, to remove mucous plugging of a lobar bronchus or adjusting an endotracheal tube (ETT) that has advanced into a main stem bronchus, may be effective at reversing causes of relative shunt. Positive airway pressure therapy can reduce intrapulmonary shunting in certain disease states associated with a diffuse reduction in functional residual capacity.

In a situation that is the opposite of a high $\dot{V}/\dot{Q}$ ratio, a portion of ventilation does not participate in gas exchange. Dead space ventilation occurs when the perfusion becomes zero, and the $\dot{V}/\dot{Q}$ ratio approaches infinity. Anatomic dead space is an area of the lungs that does not participate in gas exchange, such as the larger airways. Physiologic dead space is the total dead space that contributes to elevated $\dot{V}/\dot{Q}$ ratio. Dead space ventilation does not contribute significantly to hypoxemia unless perfusion is significantly disrupted, as occurs in a pulmonary embolus.

Hypoventilation causes hypoxemia when an increase in alveolar carbon dioxide (CO_2) displaces the O_2 molecules and decreases P_{AO_2}, as demonstrated in the alveolar gas equation:

$$P_{AO_2} = F_{IO_2}(P_{atm} - P_{H_2O}) - Pa_{CO_2}/RQ$$

Clinical entities associated with low P_{AO_2} values include chronic obstructive pulmonary disease (COPD), asthma, retained secretions, sedative or narcotic administration, acute lung injury syndrome, and early or mild pulmonary edema. Inspiration of enriched concentrations of O_2 under these circumstances increases P_{AO_2}, which increases the O_2 gradient across the ACM, resulting in faster equilibration of mixed venous blood exposed to the ACM and a higher pulmonary venous, left atrial, left ventricular, and arterial P_{O_2}.

Even small increases in inspired O_2 tension can affect hypoxemia when caused by low PaO_2. Drug-induced

BOX 14-2 Calculation of Oxygen Delivery

$$D_{O_2} = Ca_{O_2} \times CO \times 10$$

Ca_{O_2} = arterial O_2 content per 100 mL of blood mL/dL. This value is approximately 20 mL/dL in the normal adult with a hemoglobin of 15 g/dL.
CO = cardiac output (L/min). This value is approximately 5 L/min in the healthy, 70-kg adult.
D_{O_2} = O_2 delivery (mL/min). This value is approximately 1000 mL/min in the healthy, 70-kg adult.

alveolar hypoventilation resulting in hypoxemia on room air is exquisitely sensitive to increases in inspired O_2 concentration. Appropriate initial management of patients with alterations in mental status includes the use of O_2 therapy as long as ventilatory needs are also monitored.

Cases of hypoxemia caused by true shunt or $\dot{V}/\dot{Q}$ mismatch share a common phenomenon, which is exaggerated by a decreased mixed venous hemoglobin saturation (low $S\bar{v}O_2$). Because hemoglobin saturation is the major determinant of O_2 content in blood, a low $S\bar{v}O_2$ leads to a low venous O_2 content ($C\bar{v}O_2$). Low $C\bar{v}O_2$ causes hypoxemia by worsening the hypoxemic effect of any existing shunt or areas of low $\dot{V}/\dot{Q}$ by presenting more desaturated blood to the left atrium. Decreased $C\bar{v}O_2$ arises from low O_2 delivery (e.g., low cardiac output, anemia, hypoxemia) or increased O_2 consumption (e.g., high fever, increased minute ventilation and work of breathing).

The consequences of untreated hypoxemia include tachycardia, acidosis, and increased myocardial O_2 demand, as well as increased minute volume and work of breathing. By treating hypoxemia, supplemental O_2 restores homeostasis and greatly decreases the stress response and its attendant cardiopulmonary sequelae.

B. Oxygen Delivery Systems

With the exception of anesthetic breathing circuits, virtually all O_2 delivery systems are nonrebreathing. In nonrebreathing circuits, the inspiratory gas is not made up in any part by the exhaled tidal volume (V_T), and the only CO_2 inhaled is that in any entrained room air. To avoid rebreathing, exhaled gases must be sequestered by one-way valves, and inspired gases must be presented in sufficient volume and flow to satisfy the high peak flow rates and minute ventilation demonstrated in critically ill patients. Inspiratory entrainment of room air or the use of inspiratory reservoirs (including the anatomic dead space of the nasopharynx, oropharynx, and non–gas-exchanging portion of the bronchial tree) and one-way valves typifies nonrebreathing systems and defines them as two groups.[5-7] Low-flow systems depend on inspiration of room air to meet inspiratory flow and volume demands. High-flow systems attempt to provide the entire inspiratory demand. High-flow systems use reservoirs or very high flow rates to meet the large peak inspiratory flow demands and the exaggerated minute volumes found in many critically ill patients.

1. Low-Flow Oxygen Systems

A low-flow, variable-performance system depends on room air entrainment to meet the patient's peak inspiratory and minute ventilatory demands that are not met by the inspiratory gas flow or O_2 reservoir alone. Low-flow devices include the nasal cannula, simple face mask, partial rebreathing mask, nonrebreathing mask, and tracheostomy collar. Low-flow systems are characterized by the ability to deliver high and low values of F_{IO_2}. The F_{IO_2} becomes unpredictable and inconsistent when these devices are used for patients with abnormal or changing ventilatory patterns.[8] Low-flow systems produce F_{IO_2} values of 21% to 80%. The F_{IO_2} may vary with the size of the O_2 reservoir, O_2 flow, and the patient's ventilatory pattern (e.g., V_T, peak inspiratory flow, respiratory rate, minute ventilation). With a normal ventilation pattern, these devices can deliver a relatively predictable and consistent F_{IO_2} level.

TABLE 14-1
Example 1: V_T Is Decreased to 500 mL

Cannula	6 L/min	V_T, 500 mL
Mechanical reservoir	None	I/E ratio = 1:2
Anatomic reservoir	50 mL	Rate = 20 breaths/min
100% O_2 provided/sec	100 mL	Inspiratory time = 1 sec
Volume inspired O_2		
Anatomic reservoir	50 mL	
Flow/sec	100 mL	
Inspired room air (0.20 × 350 mL)	70 mL	
O_2 inspired	220 mL	
	$F_{IO_2} = \frac{200\text{mL } O_2}{500\text{mL } V_T} = 0.44$	

F_{IO_2}, Fraction of inspired oxygen; *I/E ratio,* inspiration/expiration ratio; *V_T,* tidal volume.

Low-flow systems do not mean low F_{IO_2} values. With changes in V_T, respiratory rate, O_2 reservoir size, and so on, the F_{IO_2} can vary dramatically at comparable O_2 flow rates. The following examples are theoretical mathematical estimates of an F_{IO_2} produced by a low-flow system (e.g., nasal cannula) in two clinical conditions.

The example for estimation of F_{IO_2} from a low-flow system is based on the standard normal patient and ventilatory pattern. Several assumptions are used for the F_{IO_2} calculation. The anatomic reservoir for a nasal cannula consists of nose, nasopharynx, and oropharynx, and it is about one third of the entire normal anatomic dead space (including trachea). For example, 150 mL ÷ 3 = 50 mL; assume a nasal cannula O_2 flow rate of 6 L/min (100 mL/sec), V_T of 500 mL, respiratory rate of 20 breaths/min, inspiratory (I) time of 1 second, and expiratory (E) time of 2 seconds. If the terminal 0.5 second of the 2-second expiratory time has negligible gas flow, the anatomic reservoir (50 mL) completely fills with 100% O_2, assuming an O_2 flow rate of 100 mL/sec. Using the preceding normal variables, the F_{IO_2} is calculated for a patient with a 500 mL and a 250 mL V_T (Tables 14-1 and 14-2).

TABLE 14-2
Example 2: If V_T Is Decreased to 250 mL

Volume inspired O_2	
Anatomic reservoir	50 mL
Flow/sec	100 mL
Inspired room air (0.20 × 100 mL)	20 mL
O_2 inspired	170 mL
	$F_{IO_2} = \frac{170\text{mL } O_2}{250\text{mL } V_T} = 0.68$

F_{IO_2}, Fraction of inspired oxygen; *V_T,* tidal volume.

The preceding 50% variability in F_{IO_2} at 6 L/min of O_2 flow clearly demonstrates the effects of a variable ventilatory pattern. In general, the larger the V_T or faster the respiratory rate, the lower the F_{IO_2}. The smaller the V_T or lower the respiratory rate, the higher the F_{IO_2}.

Low-flow O_2 devices are the most commonly employed O_2 delivery systems because of simplicity, ease of use, familiarity, economics, availability, and acceptance by patients. In most clinical situations (see "High-Flow Oxygen Systems" and "High-Flow Devices"), these systems should be initially employed.

2. High-Flow Oxygen Systems

High-flow, fixed-performance systems are nonrebreathing systems that provide the entire inspiratory atmosphere needed to meet the peak inspiratory flow and minute ventilatory demands of the patient. The flow rate and reservoir are essential to meet the patient's peak inspiratory flow. Flows of 30 to 40 L/min (or three to four times the measured minute volume) are often necessary. High-flow devices include aerosol masks and T-pieces that are powered by air-entrainment nebulizers or air-O_2 blenders and Venturi masks (see "Oxygen Delivery Devices"). Regardless of the patient's respiratory pattern, high-flow systems are expected to deliver predictable, consistent, and measurable high and low F_{IO_2} values. High-flow systems also can control the humidity and temperature of the delivered gases. The primary limitations of these systems are cost, bulkiness, and patients' tolerance.

There are two primary indications for high-flow O_2 devices:

1. Patients who require a consistent, predictable, minimal F_{IO_2} to reverse hypoxemia but prevent respiratory compromise due to excessive O_2 delivery (see "Complications")
2. The patient with increased minute ventilation and abnormal respiratory pattern who needs predictable and consistent high F_{IO_2} values

C. Oxygen Delivery Devices

1. Low-Flow Devices

a. NASAL CANNULAS

Because of their simplicity and the ease with which patients tolerate them, nasal cannulas are the most frequently used O_2 delivery devices. The nasal cannula consists of two prongs, with one inserted into each naris, that deliver 100% O_2. To be effective, the nasal passages must be patent, but the patient need not breathe through the nose. The flow rate settings range from 0.25 to 6 L/min. The nasopharynx serves as the O_2 reservoir (Fig. 14-1). Gases should be humidified to prevent mucosal drying if the O_2 flow exceeds 4 L/min. For each 1 L/min increase in flow, the F_{IO_2} is assumed to increase by 4% (Table 14-3).

An F_{IO_2} of 0.24 to 0.44 can be delivered predictably if the patient breathes at a normal minute ventilation rate with a normal respiratory pattern. Increasing flows to more than 6 L/min does not significantly increase the F_{IO_2} above 0.44 and is often poorly tolerated by the patient.

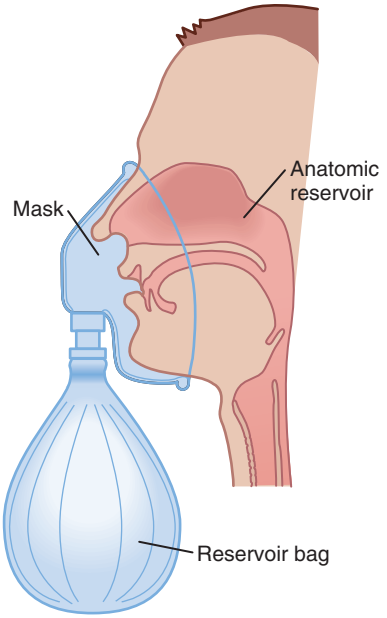

Figure 14-1 The three reservoirs of low-flow oxygen therapy. (From Vender JS, Clemency MV: O_2 delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care*, Philadelphia, 1992, JB Lippincott, pp 63–87.)

The components of a nasal cannula are nasal cannula prongs, delivery tubing, and an adjustable, restraining headband. Additional equipment includes an O_2 flowmeter to provide controlled gas delivery from a wall outlet; a humidification system increases patients' comfort at higher flows (≥4 L/min).

Procedurally, the initiation of O_2 therapy should be preceded by a review of the chart and documentation of the O_2 concentration and device ordered. If a humidifier (typically prefilled, single-use, disposable) is used, it should be filled to the appropriate level with sterile water and connected to the flowmeter. The nasal prong should be secured in the patient's naris and the cannula secured around the patient's head by a restraining strap.

Avoidance of undue cutaneous pressure is essential. Gauze may be needed to pad pressure points around the cheeks and ears during prolonged use. The flowmeter should be adjusted to the prescribed liter flow to attain the desired F_{IO_2} (see Table 14-3).

TABLE 14-3

3	0.32
4	0.36
5	0.40
6	0.44

F_{IO_2}, Fraction of inspired oxygen.
*Based on normal ventilatory patterns.

Although nasal cannulas are simple and safe, several potential hazards and complications exist. O_2 supports combustion, and any type of O_2 therapy is a fire hazard. Nasal trauma from prolonged use of or pressure from the nasal prongs can cause tissue damage. With poorly humidified, high gas flows, the airway mucosal surface can become dehydrated. This mucosal dehydration can result in mucosal irritation, epistaxis, laryngitis, ear tenderness, substernal chest pain, and bronchospasm.[5,7,9] Because this is a low-flow system, the F_{IO_2} can be inaccurate and inconsistent, leading to the potential for underoxygenation or overoxygenation. Overoxygenation may induce respiratory distress in patients with severe COPD by reversing protective hypoxic pulmonary vasoconstriction, depressing ventilation, and minimizing the Haldane effect (see "Complications"). Underoxygenation potentiates any problems associated with hypoxemia.

b. SIMPLE FACE MASK

To provide a higher F_{IO_2} value than that provided by nasal cannula with low-flow systems, the size of the O_2 reservoir must increase (see Fig. 14-1). A simple face mask consists of a mask with two side ports. The mask serves as an additional O_2 reservoir of 100 to 200 mL. The side ports allow room air entrainment and exit for exhaled gases. The mask has no valves. An F_{IO_2} of 0.40 to 0.60 can be achieved predictably when patients exhibit normal respiratory patterns. Gas flows greater than 8 L/min do not significantly increase the F_{IO_2} above 0.60 because the O_2 reservoir is filled. A minimum flow of 5 L/min is necessary to prevent CO_2 accumulation and rebreathing. The delivered O_2 value depends on the ventilatory pattern of the patient, similar to the situation with nasal cannulas.

The equipment needed is identical to that used for nasal cannula O_2 administration. The only difference is the use of a face mask. The predicted F_{IO_2} can be estimated from the O_2 flow rate (Table 14-4). Appropriate mask application is needed with all masks to maximize the F_{IO_2} and the patient's comfort. The mask should be positioned over the nasal bridge and the face, restricting O_2 escape into the patient's eye, which can cause ocular drying and irritation. If F_{IO_2} values above 0.60 are required, a partial rebreathing mask, nonrebreathing mask, or high-flow system should be employed. All O_2 devices that deliver higher values of F_{IO_2} increase the potential of O_2 toxicity (see "Complications").

c. PARTIAL REBREATHING MASK

To deliver an F_{IO_2} level of more than 60% with a low-flow system, the O_2 reservoir system must be increased (see Fig. 14-1).[7] A partial rebreathing mask adds a reservoir bag with a capacity of 600 to 1000 mL. Side ports allow entrainment of room air and the exit of exhaled gases. The distinctive feature of this mask is that the first 33% of the patient's exhaled volume fills the reservoir bag. This volume is derived from the anatomic dead space and contains little CO_2. During inspiration, the bag should not completely collapse. A deflated reservoir bag results in a decreased F_{IO_2} because of entrained room air. With the next breath, the first exhaled gas (which is in the reservoir bag) and fresh gas are inhaled—accounting for the name *partial rebreather*. Fresh gas flows should be 8 L/min or greater, and the reservoir bag must remain inflated during the entire ventilatory cycle to ensure the highest F_{IO_2} and adequate CO_2 evacuation. An F_{IO_2} of 0.60 to 0.80 or more can be delivered with this device if the mask is applied appropriately and the ventilatory pattern is normal (Table 14-5). This mask's rebreathing capacity allows O_2 conservation and may be useful during transportation, when O_2 supply may be limited. Complications with partial rebreathing O_2 delivery systems are similar to those with other mask devices with low-flow systems.

d. NONREBREATHING MASK

A nonrebreathing mask (Fig. 14-2) is similar to a partial rebreathing mask but adds three unidirectional valves. One valve is located on each side of the mask to permit the venting of exhaled gases and to prevent room air entrainment. The third unidirectional valve is situated between the mask and the reservoir bag and prevents exhaled gases from entering the bag.

The bag must be inflated throughout the ventilatory cycle to ensure the highest F_{IO_2} and adequate CO_2 evacuation. Typically, the F_{IO_2} level is 0.80 to 0.90. Fresh gas flow is usually 15 L/min (range, 10 to 15 L/min). If room air is not entrained, an F_{IO_2} value approaching 1.0 can be achieved. If fresh gas flows or reservoir volume do not meet ventilatory needs, many masks have a spring-loaded tension valve that permits room air entrainment if the reservoir is evacuated. This spring valve is often called a *safety valve*. The spring valve tension should be checked periodically. If such a valve is not present, one of the unidirectional valves on the mask should be removed to allow room air entrainment if needed to meet ventilatory demands. This may be required to meet the increased inspiratory drive of critically ill patients. If the total ventilatory needs are met without room air entrainment, the rebreathing mask performs like a high-flow system. The operational application of a nonrebreathing mask is

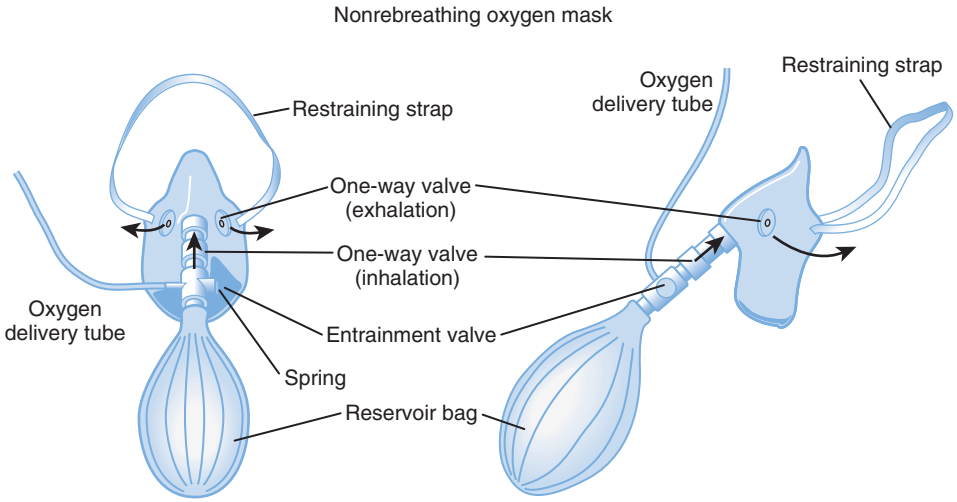

Figure 14-2 A nonrebreathing oxygen mask. In addition to the exhalation valve, the mask has a one-way inhalation valve. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care*, Philadelphia, 1992, JB Lippincott.)

similar to that of other mask devices. To optimize the system, the mask should fit snugly (without excessive pressure) to avoid air entrainment around the mask, which would dilute the delivered gas and lower the F_{IO_2}. If the mask fit is appropriate, the reservoir bag responds to the patient's inspiratory efforts. The high flows often employed increase the potential for several problems. Gastric distention, cutaneous irritation, and distention of the venting valves in the open position allowing room air entrainment can occur with excessive gas flows.

e. TRACHEOSTOMY COLLARS

Tracheostomy collars are used primarily to deliver humidity to patients with artificial airways. O_2 may be delivered with these devices, but as with other low-flow delivery systems, the F_{IO_2} is unpredictable, inconsistent, and dependent on ventilatory pattern due to the limited reservoir volume. The consistency of delivered F_{IO_2} by tracheostomy also depends on the patient breathing entirely through the tracheostomy. Cuff deflation or tube fenestration allows entrainment of air through the upper airways, and this may alter the concentration of delivered O_2.

2. High-Flow Devices

a. VENTURI MASKS

High-flow systems have flow rates and reservoirs large enough to provide the total inspired gases reliably. Most high-flow systems use gas entrainment at some point in the circuit to provide the flow and F_{IO_2} needs. Venturi masks entrain air by the Bernoulli principle and constant pressure-jet mixing.[10] This physical phenomenon is based on a rapid velocity of gas (e.g., O_2) moving through a restricted orifice. This action produces viscous shearing forces that create a decreased pressure gradient (subatmospheric) downstream relative to the surrounding gases. The pressure gradient causes room air to be entrained until the pressures are equalized. Figure 14-3 illustrates the Venturi principle.

Altering the gas orifice or entrainment port size causes the F_{IO_2} value to vary. The O_2 flow rate determines the total volume of gas provided by the device. It provides predictable and reliable F_{IO_2} values of 0.24 to 0.50 that are independent of the patient's respiratory pattern. These masks come in two varieties:

1. A fixed F_{IO_2} model, which requires specific inspiratory attachments that are color coded and have labeled jets that produce a known F_{IO_2} with a given flow
2. A variable F_{IO_2} model (Fig. 14-4), which has a graded adjustment of the air entrainment port that can be set to allow variation in delivered F_{IO_2}

To use any air entrainment device properly to control the F_{IO_2}, the standard air-O_2 entrainment ratios and minimum recommended flows for a given F_{IO_2} level must be used (Table 14-6). The minimum total flow requirement should result from entrained room air added to the fresh O_2 flow and equal three to four times the minute ventilation. This minimal flow is required to meet the patient's peak inspiratory flow demands. As the desired F_{IO_2} increases, the air-O_2 entrainment ratio decreases with a net reduction in total gas flow. The higher the desired F_{IO_2}, the greater the probability of the patient's needs exceeding the total flow capabilities of the device.

Venturi masks are often useful when treating patients with COPD who may develop worsening respiratory distress and dead space ventilation with supplemental increases in O_2 fraction.[11,12] The Venturi mask's ability to deliver a high flow with no particulate H_2O makes it beneficial in treating asthmatics, in whom bronchospasm may be precipitated or exacerbated by aerosolized H_2O administration.

Several specific concerns regarding the application of a Venturi mask must be recognized to provide

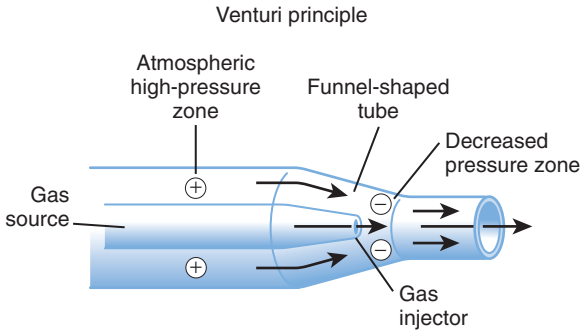

Figure 14-3 Application of the Venturi principle. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care*, Philadelphia, 1992, JB Lippincott.)

TABLE 14-6
Approximate Air Entrainment Ratio and Gas Flow (F_{IO_2})

appropriate function. Obstructions distal to the jet orifice can produce back pressure and an effect referred to as Venturi stall. When this occurs, room air entrainment is compromised, causing a decreased total gas flow and an increased F_{IO_2}. Occlusion or alteration of the exhalation ports can also produce this situation. Aerosol devices should not be used with these devices. Water droplets can occlude the O_2 injector. If humidity is needed, a vapor-type humidity adapter collar should be used.

b. HIGH-FLOW NASAL CANNULAS

High-flow nasal cannulas have been developed that can provide humidified gas flows up to 50 L/min while achieving 72% to 100% F_{IO_2}.[13] Consistent delivery of humidification is also maintained at 72% to 99.9% relative humidity through the use of specialized nasal cannulas,[14] larger tubing, high-flow humidifiers, and O_2 blenders. These high-flow nasal cannulas can generate moderate levels of continuous positive airway pressure (CPAP) in nasal- and mouth-breathing patients.[15] It does not require a face mask, unlike most other high-flow systems, and this affords patients the opportunity to verbally communicate and eat in a normal manner.

Two types of high-flow cannulas are available for adults: the High Flow Adult Cannula (Salter Labs, Arvin, CA) and the Nasal High Flow (Fisher & Paykel Healthcare, New Zealand). Both can achieve high relative humidity and high F_{IO_2} values. The High Flow Adult Cannula appears similar to a regular nasal cannula. Key differences include larger, three-channel tubing that is colored green; an enlarged reservoir at the prongs; and flow rates up to 15 L/min. The Nasal High Flow employs small-diameter corrugated tubing throughout the length of the supply tubing to achieve flow rates up to 50 L/min.

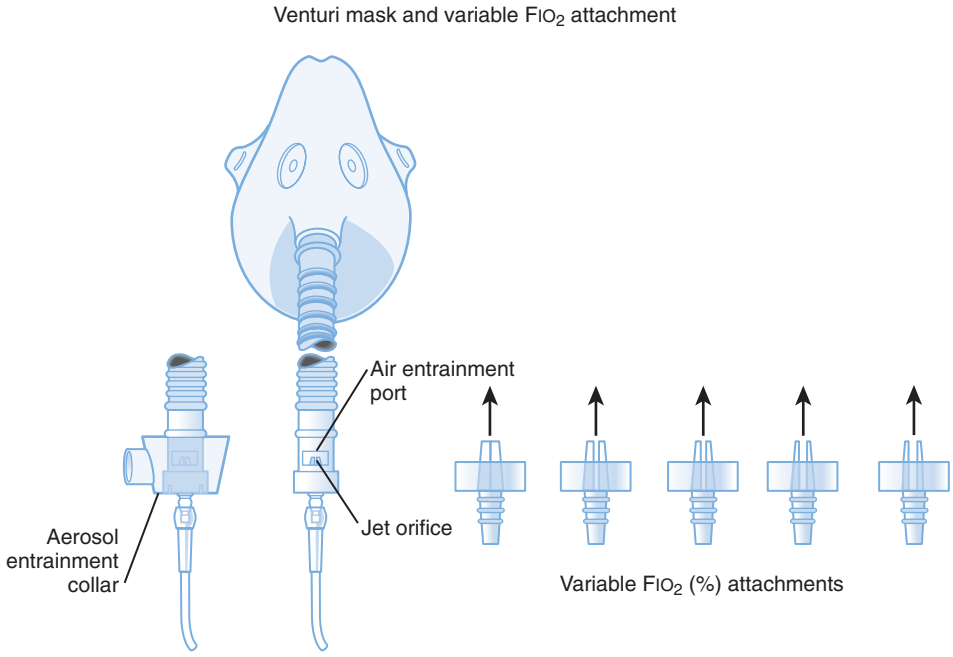

Figure 14-4 Graded air entrainment by the Ventimask provides specific F_{IO_2} levels through the jet orifices. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care*, Philadelphia, 1992, JB Lippincott.)

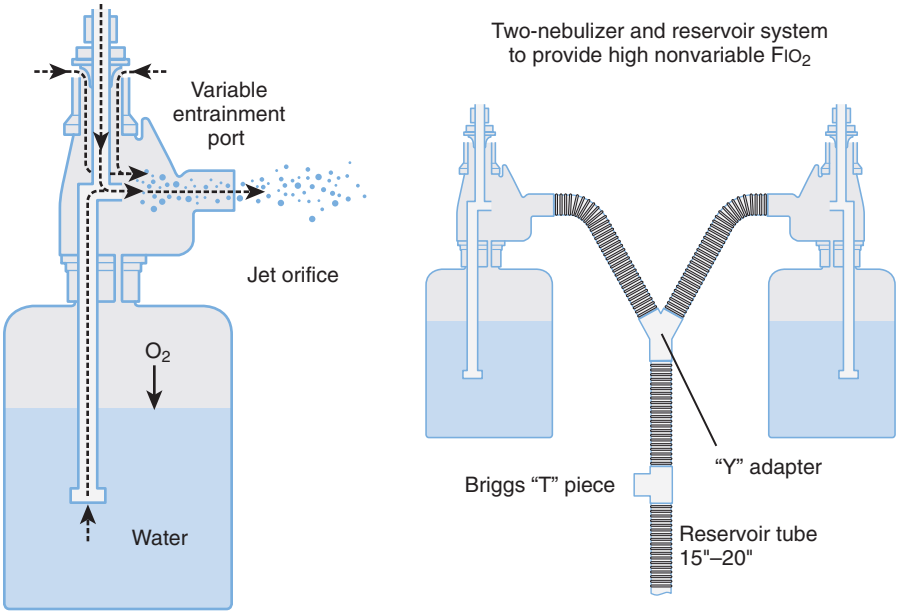

Figure 14-5 Single-unit and double (tandem)-unit mechanical aerosol systems. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care*, Philadelphia, 1992, JB Lippincott.)

c. AEROSOL MASKS AND T-PIECES WITH NEBULIZERS OR AIR-OXYGEN BLENDERS

Large-volume nebulizers and wide-bore tubing are optimal for delivering F_{IO_2} levels greater than 0.40 with a high-flow system. Aerosol masks, in conjunction with air entrainment nebulizers or air-O_2 blenders, deliver consistent and predictable F_{IO_2} levels, regardless of the patient's ventilatory pattern. A T-piece is used in place of an aerosol mask for patients with an artificial airway.

Air entrainment nebulizers can deliver F_{IO_2} of 0.35 to 1.00 and produce an aerosol. The maximum gas flow through the nebulizer is 14 to 16 L/min. As with the Venturi masks, less room air is entrained with higher F_{IO_2} values. As a result, total flow at high F_{IO_2} values is decreased. To meet ventilatory demands, two nebulizers may feed a single mask to increase the total flow, and a short length of corrugated tubing may be added to the aerosol mask side ports to increase the reservoir capacity (Fig. 14-5). If the aerosol mist exiting the mask side ports disappears during inspiration, room air is probably being entrained, and flow should be increased.

Circuit resistance can increase as a result of water accumulation or kinking of the aerosol tubing. The increased pressure at the Venturi device decreases room air entrainment, increases the F_{IO_2} level, and decreases total gas flow. If a predictable F_{IO_2} level of more than 0.40 is desired, an air-O_2 blender should be used. Air-O_2 blenders can deliver consistent and accurate F_{IO_2} values from 0.21 to 1.0 and flows of up to 100 L/min with humidification. The higher flows tend to produce excessive noise through the large-bore tubing. Air-O_2 blenders are recommended for patients with increased minute ventilation who require a high F_{IO_2} level and in whom bronchospasm may be precipitated or worsened by a nebulized H_2O aerosol. With an artificial airway, a 15- to 20-inch reservoir tube should be added to the Briggs T-piece (Hudson, RCI, Temecula, CA) to prevent the potential of entraining air into the system.

D. Humidifiers

Humidity is the water vapor in a gas. When air is 100% saturated at 37° C, it contains 43.8 mg of H_2O/L. The amount of water vapor a volume of gas contains depends on the temperature and water availability. The vapor pressure exerted by the water vapor is equal to 47 mm Hg. Alveolar gases are 100% saturated at 37° C. When the inspired atmosphere contains less than 43.8 mg of H_2O/L or has a vapor pressure of less than 47 mm Hg, a gradient exists between the respiratory mucosa and the inhaled gas. This gradient causes water to leave the mucosa and to humidify the inhaled gas.

Room air that has a relative humidity of 50% at 21° C has a relative humidity of 21% at 37° C. Under normal conditions, the lungs contribute about 250 mL of H_2O per day to maximally saturate inspired air.[7]

The administration of dry O_2 lowers the water content of the inspired air. The upper respiratory tract filters, humidifies, and warms inspired gases. Nasal breathing is more efficient than oral breathing for conditioning inspired gases. The use of an artificial airway bypasses the nasopharynx and oropharynx, where a significant amount of warming and humidification of inspired gases are accomplished. As a result, O_2 administration and the use of artificial airways increase the demand on the lungs to humidify the inspired gases.

The increased demand ultimately leads to mucosal drying, inspissated secretions, and decreased mucociliary clearance, which can eventually result in bacterial infections, mucous plugging, atelectasis, and pneumonia. To prevent these complications, a humidifier or nebulizer should be used to increase the water content of the inspired gases.

Indications for humidity therapy include high-flow therapeutic gas delivery to nonintubated patients, delivery of gases through artificial airways, and reduction of airway resistance in asthma. Low flows (1 to 4 L/min)

usually do not need humidification except in specific individuals, but all O_2 delivered to infants should be humidified.

A humidifier increases the heated or unheated water vapor in a gas. This can be accomplished by passing gas over heated water (heated passover humidifier); by fractionating gas into tiny bubbles as gas passes through water (bubble diffusion or jet humidifiers); by allowing gas to pass through a chamber that contains a heated, water-saturated wick (heated wick humidifier); and by vaporizing water and selectively allowing the vapor to mix with the inspired gases (vapor-phase humidifier). Other variations of humidification systems exist but are beyond the scope of this chapter.[16]

Bubble humidifiers can be used with nasal cannulas, simple face masks, partial and nonrebreathing masks, and air-O_2 blenders. They increase the relative humidity of gas from 0% to 70% at 25° C, which is approximately equal to 34% at 37° C.[17,18] Large-volume bubble-through humidifiers are available for use with ventilator circuits or high-gas-flow delivery systems.

A heated humidifier may be used when delivering dry gases to patients with ETTs because it allows delivery of gases with an increased water content and relative humidity exceeding 65% at 37° C. When heated humidifiers are used, proximal airway temperature should be monitored to ensure a gas temperature that allows maximum moisture-carrying capacity but prevents mucosal burns.

Heat and moisture exchangers (HMEs) are simple, small humidifier systems designed to be attached to an artificial airway. The HMEs are often referred to as an *artificial nose*. The efficiency of these devices is quite variable, depending on the HME design, V_T, and atmospheric conditions. HMEs are typically used for short-term ventilatory support and for humidification during anesthesia. Several contraindications include use in neonatal and small pediatric patients; copious secretions; significant spontaneous breathing, in which the patient's V_T exceeds the HME specifications; and large-volume losses through a bronchopleural fistula or leakage around the ETT.[16]

A nebulizer increases the water content of the inspired gas by generating aerosols (small droplets of particulate water) that become incorporated into the delivered gas stream and then evaporate into the inspired gas as it is warmed in the respiratory tract. There are two basic kinds of nebulizers: pneumatic and electric. Pneumatic nebulizers operate from a pressured gas source and are jet or hydrodynamic. Electric nebulizers are powered by an electrical source and are referred to as *ultrasonic*. There are several varieties of both types of nebulizers, and they depend more on design differences than on the power source. A more in-depth discussion of nebulizers is available elsewhere.[7,9] The resultant humidity ranges from 50% to 100% at 37° C, depending on the device used. If heated, the relative humidity of the gas can exceed 100% at 37° C. Air entrainment nebulizers are used in conjunction with aerosol masks and T-pieces.

Aerosol therapy can be used for three general purposes. First, aerosol therapy increases the particulate and molecular water content of the inspired gases. The aerosol increases the water content of desiccated and retained secretions, enhancing bronchial hygiene. This does not alleviate the need for systemic hydration. Second, delivery of medications is a primary indication for aerosol therapy. For example, β_2-agonists, corticosteroids, anticholinergics, and antiviral-antibacterial agents (see "Inhalation Therapy") may be delivered to patients' airways by aerosol therapy. Third, aerosol therapy can be employed for sputum induction. The success of aerosol therapy depends on appropriate application and proper technique of administration.

The aerosol generated by the nebulizer can precipitate bronchospasm of hyperactive airways.[5,7] Prophylactic bronchodilator therapy should be employed before or during the aerosol treatment. Fluid accumulation and overload have been reported. These problems are more common in treating pediatric patients and with continuous ultrasonic rather than intermittent or jet therapy. Dry secretions are hydrophilic and can swell because of the absorbed water content. If secretions swell, they can obstruct airways. Mobilization of secretions limits this problem. Aerosol therapy for drug delivery has been reported to precipitate the same side effects as systemic drug delivery. Therapeutic aerosols have been implicated in nosocomial infections.[19] Cross-contamination between patients must be avoided.

E. Manual Resuscitation Bags

Manual resuscitation bags are used primarily for resuscitation and manual ventilation of ventilator-dependent patients. These bags can deliver an F_{IO_2} of more than 0.90 and V_T values up to 800 mL when O_2 flows to the bag are 10 to 15 mL/min. Factors that promote the highest F_{IO_2} level include the use of an O_2 reservoir, connection to an O_2 source, and slow rates of ventilation that allow the bag to refill completely. Positive end-expiratory pressure (PEEP) valves should be used for patients who require more than 5 cm H_2O of PEEP. The clinician should be aware of different capabilities among various resuscitation bags in the delivery of maximum F_{IO_2}.[20-22]

F. Complications

Complications related to O_2 delivery can be divided into two groups: complications related to the O_2 delivery systems (see sections that discuss the specific devices) and pathophysiologic complications related to O_2 therapy. Pathophysiologic complications related to O_2 therapy can lead to serious consequences. The three major complications encountered in adults are hypoventilation, absorption atelectasis, and O_2 toxicity.

O_2 therapy must be used appropriately in patients with severe COPD because of a risk of developing respiratory distress. Conventional teaching of hypoxic drive theory and excessive O_2 delivery have not been consistently supported in the literature.[11,23] Disturbances in $\dot{V}/\dot{Q}$ develop in patients with COPD, and through hypoxic pulmonary vasoconstriction, the perfusion is then redistributed to areas of higher O_2 tension. In the presence of low O_2 tension, pulmonary arterioles constrict, resulting in increased vascular resistance. This results in shunting of blood flow to areas of higher O_2 tension. Increasing mixed venous or alveolar O_2

tension can reverse this shunting and worsen $\dot{V}/\dot{Q}$ matching.[12,24]

In addition to regional ventilation disturbances, patients with severe COPD typically have a chronically elevated $PaCO_2$ value, a normal pH, and a PaO_2 level that usually is less than 60 mm Hg. The patient may become desensitized to ventilatory stimulation from changes in $PaCO_2$ because an increased $PaCO_2$ is compensated by an increased bicarbonate ion concentration in the arterial blood and in the cerebral spinal fluid. Instead, the chemoreceptors in the aortic and carotid bodies stimulate ventilation. They are sensitive to PaO_2 values less than 60 mm Hg. When worsening hypoxemia is treated with supplemental O_2, the goal is to raise the PaO_2 to the patient's chronic level. Although many patients will demonstrate an initial decrease in respiratory rate with hyperoxia, the minute ventilation soon normalizes.[24] By means of the Haldane effect, deoxygenated hemoglobin binds to and reduces dissolved CO_2. By displacing the CO_2 from hemoglobin, the elevated O_2 concentration reverses the compensatory mechanism of the Haldane effect.[25]

Absorption atelectasis occurs when high alveolar O_2 concentrations cause alveolar collapse. Nitrogen, already at equilibrium, remains within the alveoli and "splints" alveoli open. When high FIO_2 values are administered, nitrogen is washed out of the alveoli, which are then filled primarily with O_2. In areas of the lungs with reduced $\dot{V}/\dot{Q}$ ratios, O_2 is absorbed into the blood faster than ventilation can replace it. The affected alveoli become smaller and smaller and eventually collapse with increased surface tension. Progressively higher fractions of inspired O_2 greater than 0.50 cause absorption atelectasis in healthy individuals. FIO_2 values of 0.50 or greater may precipitate this phenomenon in patients with decreased $\dot{V}/\dot{Q}$ ratios.

The third pathophysiologic complication of O_2 therapy, O_2 toxicity, becomes clinically important after 8 to 12 hours of exposure to a high FIO_2 level.[26] O_2 toxicity probably results from direct exposure of the alveoli to a high FIO_2 level. Healthy lungs appear to tolerate FIO_2 values of less than 0.6. In damaged lungs, FIO_2 values of more than 0.50 can result in a toxic alveolar O_2 concentration. Because most O_2 therapy is delivered at 1 atm barometric pressure, the FIO_2 and the duration of exposure become the determining factors in the development of most clinically significant O_2 toxicity.

The mechanism of O_2 toxicity is related to the significantly higher production of O_2 free radicals, including superoxide anions (O_2^-), hydroxyl radicals (OH^-), hydrogen peroxide (H_2O_2), and singlet O_2. These radicals affect cell function by inactivating protein sulfhydryl enzymes, disrupting DNA synthesis, and disrupting the cell membrane integrity by lipid peroxidation. Vitamin E, superoxide dismutase, and sulfhydryl compounds promote normal, protective free radical scavenging within the lung. During periods of lung tissue hyperoxia, these protective mechanisms are overwhelmed, and toxicity results.[27]

The classic clinical manifestations of O_2 toxicity include cough, substernal chest pain, dyspnea, rales, pulmonary edema, progressive arterial hypoxemia, bilateral pulmonary infiltrates, decreasing lung compliance, and atelectasis. These signs and symptoms are nonspecific, and O_2 toxicity is frequently difficult to distinguish from severe underlying pulmonary disease. Often, only subtle progression of arterial hypoxemia heralds the onset of pulmonary O_2 toxicity.

Classic O_2 toxicity in animal models occurs in two distinct phases. The early or exudative phase, observed during the first 24 to 48 hours, is characterized by the capillary endothelial thinning and vacuolization,[28] destruction of type I pneumocytes, and development of interstitial and intra-alveolar hemorrhage and edema. The late or proliferative phase, which begins after 72 hours, is characterized by reabsorption of early infiltrates, hyperplasia, proliferation of type II pneumocytes, and increased collagen synthesis. When O_2 toxicity progresses to the proliferative stage, permanent lung damage may result from scarring, fibrosis, and proliferation of type II pneumocytes.[28]

The best treatment for O_2 toxicity is preventing it from occurring altogether. O_2 therapy should be directed at improving oxygenation with the minimum FIO_2 needed to obtain an arterial oxygenation (SaO_2) of more than 90%. Inhalation treatments and raised expiratory airway pressure may be useful adjuncts in improving pulmonary toilet, decreasing $\dot{V}/\dot{Q}$ mismatch, and improving arterial oxygenation. These therapies may be used to maintain adequate oxygenation at an FIO_2 of 0.50 or less.

III. TECHNIQUES OF RESPIRATORY CARE

The provision of adequate pulmonary gas exchange is implicit in our teaching and management of respiratory care. For optimal gas exchange to occur, the airways must be maintained clear of foreign material (e.g., secretions). The various therapeutic techniques available are aimed at the mobilization and removal of pulmonary secretions. Therapies are intended to optimize breathing efficiency.

Respiratory therapy aimed at the patient with impaired pulmonary function can improve several outcome measures. Using common physiotherapy techniques such as postural drainage, vibration, percussion, and suction on critically ill patients can lead to decreases in intrapulmonary shunt. The lining of the lungs secretes a mucous layer that usually moves toward the larynx at a rate of 1 to 2 cm/min by ciliary motion. This mucous layer is responsible for transporting foreign particles from the lungs to the larynx. Critically ill patients have many factors contributing to the presence of increased secretions. Alterations in the mucociliary escalator system related to smoking, stress, high FIO_2 levels, anesthesia, foreign bodies in the trachea (e.g., ETT), tracheobronchial diseases, and abnormalities in mucus production are all recognized contributors to retention of airway secretions. To help compensate for these deficiencies, the patient must be able to generate an adequate cough. Critically ill patients and individuals with an artificial airway often do not have an adequate cough. If any of these problems is present, there is an increased tendency to retain secretions.

Retained secretions promote several potential complications. Occlusion of the airway promotes

ventilation-perfusion inequalities. This produces a progressively worse hypoxemia that is less responsive to O_2 therapy (see indications in "Oxygen Delivery Systems"). Retained secretions and distal airway occlusion promote an increased incidence of postobstructive pneumonia. Retained secretions increase the patient's work of breathing because of an increased airway resistance associated with the airway inflammation and partial airway occlusion. Reduced pulmonary compliance results from atelectasis and reduced lung volumes.

Many of the fundamental practices of respiratory care are aimed at the provision of optimal airway care, tracheobronchial toilet, and the prevention and management of retained secretions. Because dehydration is a common cause of retained secretions, adequate hydration and humidification of gas delivery are essential. Humidity and aerosol therapy are discussed in the Oxygen Delivery Systems section of this chapter. The remainder of this section addresses other techniques commonly employed in respiratory care, including airway suctioning, chest physical therapy, and incentive spirometry. Intermittent positive-pressure breathing (IPPB) is discussed separately because it is used for the promotion of tracheobronchial toilet and the delivery of medications (see "Inhalation Therapy").

A. Suctioning

Airway suctioning is commonly employed in respiratory care to promote optimal tracheobronchial toilet and airway patency in critically ill patients. Because of the perceived simplicity and limited complications, airway suctioning is frequently employed. If proper indications and technique are not appreciated, however, the potential for significant complications exists.

1. Indications

Suctioning of the airway should not be done without appropriate clinical indications. The audible (auscultatory) or visible presence of airway secretions is the most common indication. Increasing peak inspiratory pressures in mechanically ventilated patients are often indicative of retained secretions. Routine prophylactic suctioning is unwarranted except in neonates, in whom the small airway diameters can be acutely obstructed by a small accumulation of secretions.

In addition to removal of secretions, suction catheters are employed as aids in evaluating airway patency. If an artificial airway appears to be occluded, an attempt to pass a suction catheter can help assess airway patency. Causes of artificial airway occlusion include mucous plugging, foreign body obstructions, kinking, and cuff herniations. If the suction catheter cannot be passed and ventilation is obstructed, the artificial airway may require replacement. Bronchoscopic evaluation may assist the clinician in the evaluation of the airway. Provision of airway suctioning depends on an appreciation of the available equipment, the appropriate techniques, and the potential complications.

2. Equipment

Numerous commercial suction catheters exist.[5,7,29] The ideal catheter is one that optimizes secretion removal and minimizes tissue trauma. Specific features of the catheters include the material of construction, frictional resistance, size (length and diameter), shape, and position of the aspirating holes. An opening at the proximal end of the catheter to allow the entrance of room air, neutralizing the vacuum without disconnecting the vacuum apparatus, is ideal. The proximal hole should be larger than the catheter lumen. Tracheal suctioning can occur only with occlusion of this proximal opening. The conventional suction catheter has side holes and end holes (Fig. 14-6).

The length of the typical catheter should pass beyond the distal tip of the artificial airway. The diameter of the suction catheter is very important. The optimal catheter diameter should not exceed one half of the internal diameter of the artificial airway. A catheter that is too large can produce an excessive vacuum and evacuation of gases distal to the tip of the airway, promoting atelectasis because of inadequate space for entrainment of air around the suction catheter. If the catheter is too small, removal of secretions can be compromised.

3. Technique

The technique of suctioning is important for the optimal removal of secretions and limitation of complications. This is a sterile procedure necessitating appropriate care in handling the catheter. Gloves and hand washing are necessary unless a closed system is employed. Other necessary equipment includes a vacuum source, sterile rinsing solution, AMBU O_2 system, and lavage solution. The optimal vacuum pressure should be adjusted for the patient's age.

Before suctioning, the patient should be preoxygenated by increasing the F_{IO_2} to 100% or by manual ventilatory assistance. Preoxygenation minimizes the hypoxemia

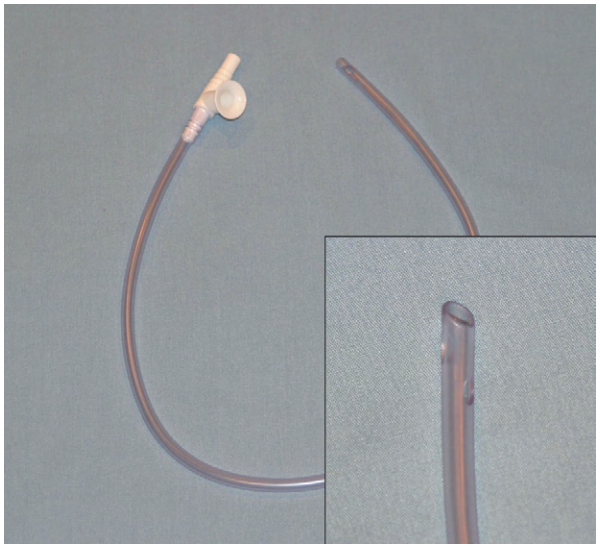

Figure 14-6 A conventional suction catheter has side and end holes. *Inset,* Enlarged view of the beveled tip and dual side holes.

induced by circuit disconnection and application of the suction vacuum. After preoxygenation, the sterile catheter is advanced past the distal tip of the artificial airway without the vacuum. When the catheter can no longer easily advance, it should be slightly withdrawn, and intermittent vacuum pressure should be applied while the catheter is removed in a rotating fashion. This technique reportedly reduces mucosal trauma and enhances secretion clearance. The vacuum (suction) time should be limited to 10 to 15 seconds, and discontinuation of ventilation and oxygenation should not exceed 20 seconds. After removal of the catheter, reoxygenation and ventilation are essential. Throughout the procedure, the patient's stability and tolerance should be monitored. If signs of distress or dysrhythmias develop, the procedure should be immediately discontinued and oxygenation and ventilation reestablished. Suctioning is repeated until secretions have been adequately removed. After airway suctioning, oropharyngeal secretions should be suctioned and the catheter should be disposed.

Optimization of secretion removal necessitates adequate hydration and humidification of delivered gases. Occasionally, secretions can become quite viscous. Instillation of 5 to 10 mL of sterile normal saline can aid removal.

In critically ill patients, using a closed system or swivel adapter to allow simultaneous suctioning and ventilation limits the consequences of airway disconnection, minimizes the loss of PEEP, and enhances sterility. These disposable systems are usually more costly but are used for up to 72 hours.

When an artificial airway is absent, nasotracheal suctioning techniques are employed. These techniques are technically less effective and more difficult than oral suctioning without an artificial airway and have the potential for additional complications. After appropriate lubrication, the catheter is inserted into a patient's nasal passage (often through a previously placed nasopharyngeal airway). The catheter is advanced into the larynx. Breath sounds from the proximal end of the catheter are often used as an audible guide. On the catheter's entry into the larynx, the patient often coughs. The vacuum is connected, and suctioning of the trachea is accomplished as previously described.

4. Complications

Complications of suctioning can be significant.[7,30] Although the suction vacuum is used to remove secretions, it also removes O_2-enriched gases from the airway. If inappropriately applied and monitored, suctioning can produce significant hypoxemia. The use of arterial O_2 monitors (e.g., pulse oximetry) can often help detect alterations in Sa_{O_2}, heart rate, and the presence of dysrhythmias.

Cardiovascular alterations are common. Dysrhythmias and hypotension are the most frequent cardiac complications. Arterial hypoxemia (and eventually myocardial hypoxia) and vagal stimulation from tracheal suctioning are recognized precipitory causes of cardiovascular complications. Coughing induced by stimulation of the airway can reduce venous return and ventricular preload. Avoidance of hypoxemia, prolonged suctioning (>10 seconds), and appropriate monitoring and sedation help reduce the incidence and significance of these complications.[31]

Inappropriate suction catheter size can produce excessive evacuation of gas distal to the artificial airway because of inadequate space for proximal air entrainment. This leads to hypoxemia and atelectasis. It is best avoided by reducing the catheter size to less than one half of the internal diameter of the airway. Presuctioning and postsuctioning auscultation of the lungs helps detect significant atelectasis. After suctioning, several hyperinflations of the lungs can help reinflate atelectatic lung segments.

Mucosal irritations and trauma are common with frequent suctioning. The incidence and severity of trauma depend on the frequency of suctioning; technique; catheter design; absence of secretions, allowing more direct mucosal contact; and amount of vacuum pressure applied. Blood in the secretions is usually the first sign of tissue trauma. Meticulous technique is essential to limit this common complication. Airway reflexes can be irritated by direct mechanical stimulation. Wheezing resulting from bronchoconstriction can necessitate bronchodilator therapy. Nasotracheal suctioning can induce several additional complications, such as nasal irritation, epistaxis, and laryngospasm. Laryngospasm can be life-threatening if it is not recognized and appropriately managed.

B. Chest Physical Therapy

Chest physical therapy techniques are an integral part of respiratory care. Chest physical therapy plays an important role in the provision of bronchial hygiene and optimization of ventilation. The mucociliary escalator systems and cough can be aided by adjunctive techniques.

1. Postural Drainage and Positional Changes

The fundamental goal of postural drainage is to move loosened secretions toward the proximal airway for eventual removal. Pulmonary drainage takes advantage of the normal pulmonary anatomy and gravitational flow. Flow of secretions is optimized by liquefaction (see "Humidifiers").

The primary indications for pulmonary drainage are malfunctioning of normal bronchial hygiene mechanisms and excessive or retained secretions.[7,9,32,33] In patients with ineffective lung volumes and cough, pulmonary drainage can be used prophylactically to prevent accumulation of secretions. Clinical conditions that typically benefit from pulmonary drainage include bronchiectasis, cystic fibrosis (CF), COPD, asthma, lung abscess, spinal cord injuries, atelectasis, pneumonia, and healing after thoracic and abdominal surgery.

To administer postural drainage appropriately, the practitioner must be able to understand the location of the involved lung segments and the proper position to optimize drainage into the proximal airway. The lungs are divided into lobes, segments, and subsegments, and fluid drainage is directed centrally to the hilum (Table 14-7).

Precise anatomic descriptions of the various pulmonary subsegments and positions are beyond the scope of this chapter. The large posterior and superior basal

TABLE 14-7

Posterior basal	

segments of the lower lobe are commonly involved in hospital patients with atelectasis and pneumonia. In the typical hospital patient, these segments are most gravity dependent, causing stasis of secretions (Fig. 14-7).

Appropriate positioning of the patient can enhance gravitational flow. This therapy also includes turning or rotating the body around its longitudinal axis. Newer critical care beds have this feature incorporated into their design and function. Commonly employed positions for postural drainage are demonstrated in Figure 14-8.

Postural drainage should be done several times each day. For optimal results, postural drainage should follow humidity treatments and other bronchial hygiene therapies. Postural drainage should precede meals by 30 to 60 minutes, and the duration of treatment continues as long as the patient tolerates the therapy and may last up to 1 hour in certain patient populations (e.g., CF patients).

Postural drainage can produce physiologic and anatomic stresses that are potentially detrimental to specific patients.[34] Alterations in the cardiovascular system from abrupt changes in position are well recognized. Hypotension, dysrhythmias, or congestive heart failure that is due to changes in preload can be induced by positional change. $\dot{V}/\dot{Q}$ relationships are altered by changes in position. When pulmonary drainage occurs in the uppermost position, blood preferentially flows to the gravity-dependent, nondiseased segments, improving the ventilation-perfusion relationships. The head-down position, which is commonly used, is best avoided in patients with intracranial disease. Decreased venous return from the head can increase intracranial pressure.

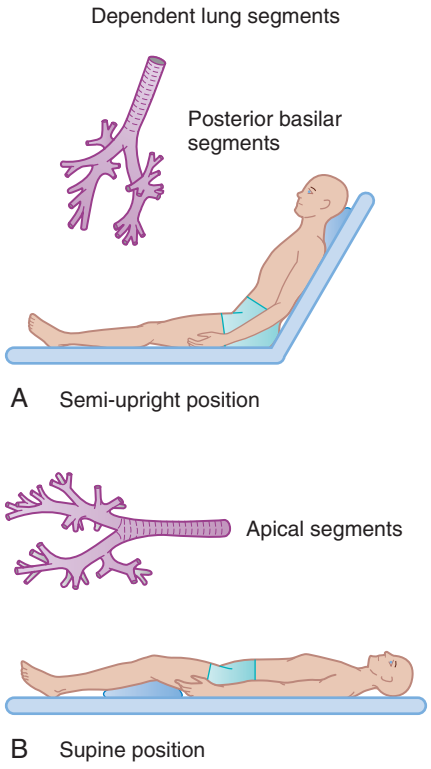

Figure 14-7 Lung segments typically are at risk for retained secretions, atelectasis, and pneumonia due to body position during convalescence. **A,** Posterior basilar segment of the lower lobe. **B,** Apical segment of the lower lobe. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care,* Philadelphia, 1992, JB Lippincott.)

The prone position has been demonstrated to improve oxygenation in patients with acute respiratory distress syndrome. The placement of critically ill patients in the prone position can be done without significant morbidity despite the presence of multiple sites of vascular access and intubation. The improvement in oxygenation probably depends on recruitment of collapsed alveoli, more evenly distributed pleural pressure gradients, and caudad movement of the diaphragm.[35]

Continuous rotational therapy employs dedicated intensive care unit beds that slowly and continuously rotate the patient along a longitudinal axis. The theory is that rotation of patients prevents gravity-dependent airway closure or collapse, worsening of pulmonary compliance and atelectasis, and pooling of secretions and subsequent pulmonary infection caused by long-term immobilization.[36] The use of rotational therapy may lead to a significantly lower incidence of patients diagnosed with pneumonia compared with patients cared for on conventional beds.[37]

Continual assessment of patients' tolerance during the procedure is necessary. Vital signs, oxygenation monitoring, general appearance, level of consciousness, and subjective comments by the patient are all part of the appraisal process.

2. Percussion and Vibration Therapy

Percussion and vibration therapy are used in conjunction with postural drainage to loosen and mobilize secretions that are adherent to the bronchial walls.[7,38] Percussion involves a manually produced, rhythmic vibration of varying intensity and frequency. In a clapping motion (cupped hands), a blow is delivered during inspiration and expiration over the affected area while the patient is in the appropriate position for postural drainage (Fig. 14-9).

Mechanical energy is produced by compression of the air between the cupped hand and the chest wall. Proper percussion should produce a popping sound (similar to striking the bottom of a ketchup bottle). Proper force and rhythm can be accomplished by placing the hands not farther than 5 inches from the chest and then alternating flexing and extending of the wrists (similar to a waving motion). The procedure should last 5 to 7 minutes per affected area.

Like all respiratory care, percussion therapy should not be performed without a medical order. Therapy should not be performed over bare skin, surgical incisions, bone prominences, kidneys, and female breasts or with hard objects. If a stinging sensation or reddening of the skin develops, the technique should be reevaluated. Special care must be given to the fragile patient. Fractured ribs, localized pain, coagulation abnormalities, bone metastases, hemoptysis, and empyemas are relative contraindications to percussion therapy.

Vibration therapy is used to promote bronchial hygiene in a fashion similar to chest percussion. Manually or mechanically (Fig. 14-10) gentle vibrations are transmitted through the chest wall to the affected area during exhalation. Vibration frequencies in excess of 200/min can be achieved if the procedure is done correctly. In patients receiving IPPB, all chest physical therapy procedures should be performed during the IPPB.

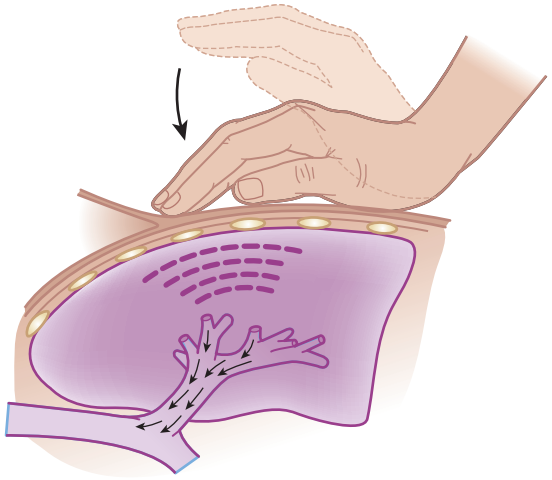

Figure 14-9 Typical hand position for chest percussion therapy. The hand is cupped and positioned about 5 inches from the chest, and the wrist is flexed. The hand strikes the chest in a waving motion. (From Vender JS, Clemency MV: Oxygen delivery systems, inhalation therapy, and respiratory care. In Benumof JL, editor: *Clinical procedures in anesthesia and intensive care,* Philadelphia, 1992, JB Lippincott.)

3. Incentive Spirometry

In the 1970s, alternative methods for prophylactic bronchial hygiene were developed to replace the more costly and controversial use of IPPB. Incentive spirometry (IS) was developed after several techniques using expiratory maneuvers (e.g., blow and glove bottles) and CO_2-induced hyperventilation were found to be clinically ineffective or to cause other risks.[5,7,9]

IS was developed with an emphasis on sustained maximal inspiration (SMI). IS provides a visual goal or incentive for the patient to achieve SMI. Normal, spontaneous breathing patterns have periodic hyperinflations

Figure 14-10 The pneumatic chest percussion device uses Newton's third law of motion to assist the respiratory therapist in controlling percussion intensity. Therapists control the pulse intensity by how firmly they press the device. The device provides percussion without the need for clapping. It is less fatiguing for the therapist and may be more comfortable for the patient than manual percussion.

that prevent the alveolar collapse associated with shallow tidal ventilation breathing patterns. Narcotics, sedative drugs, general anesthesia, cerebral trauma, immobilization, and abdominal or thoracic surgery can promote shallow tidal ventilation breathing patterns. Complications from this breathing pattern include atelectasis, retained secretions, and pneumonia.

The physiologic principle of SMI is to produce a maximal transpulmonary pressure gradient by generating a more negative intrapleural pressure. This pressure gradient produces alveolar hyperinflation with maximal airflow during the inspiratory phase.[39]

The indications for IS and SMI are primarily related to bronchial hygiene. These techniques should be employed perioperatively in surgical patients at an increased risk for pulmonary complications. IS involves the patient in his or her care and recovery, which can be psychologically beneficial while also being cost advantageous relative to the equipment and personal costs associated with other forms of respiratory care (e.g., IPPB).

The goals of IS and SMI therapy are to optimize lung inflation to prevent atelectasis, to optimize the cough mechanism by providing larger lung volumes, and to provide a baseline standard to assess the effectiveness of therapy or detect the onset of acute pulmonary disease (indicated by a deteriorating performance). To achieve these goals, patient instruction and supervision are preferred. Preoperative education enhances the effectiveness of postoperative bronchial hygiene therapy (e.g., IS, SMI). Appropriate instruction for proper breathing techniques can help produce an effective cough mechanism.

Various clinical models of incentive spirometers are available.[9] The devices vary in how they function, guide the therapy, or recognize the achievements. Each manufacturer provides instructions for use that should be followed. The devices are aimed at generating the largest inspiratory volumes during 5 to 15 seconds. The actual device used or rate of flow is not as important as the frequency of use and the attainment of maximal inspiratory volumes and sustained inspiration. Maximal benefit with most devices can be achieved only with user education.

The administration of IS and SMI therapy necessitates a physiologically and psychologically stable patient. The patient's cooperation and motivation are very important. For the therapy to be optimally effective, the patient should be free of acute pulmonary distress, have a forced vital capacity of more than 15 mL/kg, and have a spontaneous respiratory rate of less than 25 beats/min. Ideally, the patient should not require a high F_{IO_2} level. Therapy should be done hourly while the patient is awake. Typically, the patient should do four or five SMIs at a 30- to 60-second interval to prevent fatigue or hyperventilation. The patient should be coached to inspire slowly while attaining maximal inspiratory volumes.

Significant complications are not associated with IS and SMI therapy. The only relative contraindications are patients who are uncooperative, physically disabled with acute pulmonary disease, or unable to generate minimum volumes for lung inflation (e.g., 12 to 15 mL/kg).

Although the use of IS is widespread throughout the United States, many reviews cast doubts on the superiority of IS in reducing postoperative pulmonary complications over other methods of postoperative respiratory care.[40] Meta-analyses suggest that IS does not prevent pulmonary complications in patients undergoing coronary artery bypass grafting (CABG) or upper abdominal surgery.[41-43]

C. Intermittent Positive-Pressure Breathing

In the past 40 years, few respiratory care therapies have been as controversial as IPPB.[5,7,9] Objective data assessing therapeutic benefit relative to cost and alternative therapies have been less than confirmatory.[44,45] Numerous conferences have been sponsored by medical organizations to evaluate literature supporting and opposing IPPB. The inconclusive result of these efforts has significantly reduced the use of IPPB in contemporary clinical practice. IPPB has been largely replaced with other forms of noninvasive positive-pressure ventilation (PPV), such as CPAP and bi-level positive airway pressure (BiPAP). This section is intended to define IPPB, discuss its indications, and describe the technique of administration and potential side effects and complications. An extensive historical and in-depth analysis of IPPB controversies is beyond the scope of this section.

1. Indications

IPPB is the therapeutic application of inspiratory positive pressure to the airway and is distinctly different from intermittent PPV or other means of prolonged, continuous ventilation. The clinical indications for IPPB have evolved over the lifetime of this therapy and include the need to provide a large V_T with resultant lung expansion, provide for short-term ventilatory support (although this has been replaced with noninvasive PPV), and administer aerosol therapy.[46] The fundamental basis and primary goal of IPPB is to provide a larger V_T to the spontaneously breathing patient in a physiologically tolerable manner. If this goal is achieved, IPPB could be employed to improve and promote the cough mechanism, to improve distribution of ventilation, and to enhance delivery of inhaled medications.

Bronchial hygiene can be compromised in patients with a reduced or inadequate cough mechanism. An adequate vital capacity (VC; 15 mL/kg) is necessary to generate the volume and expiratory flow needed to produce an effective cough. Although IPPB can increase V_T significantly, effectiveness still depends on the pressure and flow patterns generated and on an understanding of cough technique. If cough is improved, the clinician can indirectly see the benefit of IPPB for removal of secretions and for limiting complications associated with this problem.

The increased V_T produced by IPPB can be used to improve the distribution of ventilation. As in most respiratory care therapies, the efficacy depends on the patient's underlying condition, selection of patients, optimal technique, and frequency of application. Continual assessment of the therapy is mandatory. Theoretically, if ventilation increases, atelectasis can be prevented or treated.

In patients who are unable to provide an adequate inspiratory volume, IPPB can enhance drug delivery and

distribution. When the patient is capable of an adequate cough and spontaneous deep breath, a hand nebulizer should be as efficacious as IPPB. IPPB is rarely used solely for delivery of medication.

2. Administration

The effectiveness of IPPB depends on the individual administering the therapy.[9] It is incumbent for that individual to understand the appropriate operation, maintenance, and clinical application of the mechanical device employed; to select the appropriate patient; to provide the necessary education to the patient to optimize the effort; to assess the effectiveness relative to goals and indications; and to identify complications or side effects associated with the therapy.

The generic device uses a gas pressure source, a main control valve, a breathing circuit, and an automatic cycling control. Typically, IPPB is delivered by a pressure-cycled ventilator. Positive pressure (e.g., 20 to 30 cm H_2O) is used to expand the lungs. To be effective, the increase in V_T from the IPPB treatment must exceed the patient's limited spontaneous VC by 100%. A prolonged inspiratory effort to the preset pressure limit should be emphasized. Therapy is typically 6 to 8 breaths/min, lasting 10 minutes.

Keys to successful therapy include machine sensitivity to the patient's inspiratory effort; a tight seal between the machine and patient because these are pressure-limited devices; a progressive increase in the inspiratory pressure as tolerated by the patient in an effort to achieve a desired exhaled volume; and a cooperative, relaxed, and well-educated patient.

The physiologic side effects and complications associated with IPPB are well described in the literature.[9] Hyperventilation and variable oxygenation can result from IPPB therapy. Hypocarbia (resulting in a respiratory alkalosis) due to an increased V_T and respiratory frequency can produce altered electrolyte concentrations (e.g., K^+), dizziness, muscle tremors, and tingling and numbness of the extremities. Proper instruction to the patient and a 5 to 10 minute rest period after therapy can minimize this problem. Hypoxemia and hyperoxia caused by inaccurately delivered F_{IO_2} can be a concern in patients with severe COPD.

The use of IPPB can increase mean intrathoracic pressure, resulting in a decreased venous return. As with other forms of PPV, a decreased venous return (preload) can produce a decreased cardiac output and subsequent vital sign changes (hypotension or tachycardia). The patient may be unable to coordinate breathing patterns with IPPB and therefore develop auto-PEEP with resultant increase in work of breathing and elevation of intrathoracic pressures. In addition to cardiovascular changes, IPPB can impede venous drainage from the head. This is a potential but limited concern in patients with increased intracranial pressure if IPPB is appropriately administered in the sitting position.

Barotrauma is a concern with all forms of PPV. The exact etiologic mechanism of PPV in the development of pneumothorax and ruptured lobes is unclear. PPV results in increased intrapulmonary volume and pressure, but the same conditions tend to promote a better cough mechanism that causes sudden marked changes in pressure and lobe rupture. Before proceeding with an IPPB treatment, any chest pain complaints must be evaluated to rule out barotrauma.

Other reported complications include gastric insufflation and secondary nausea and vomiting, psychological dependency, nosocomial infections, altered airway resistance, and adverse reactions to medications administered through the IPPB system. The incidence and significance of these adverse effects are often the result of inappropriate administration, noncompliance by the patient, selection of inappropriate patients, and simple lack of attention to detail.

There are few definite contraindications to IPPB.[47] Relative contraindications to IPPB are focused on its lack of documented efficacy. Untreated pneumothorax is a definite contraindication to IPPB. Relative contraindications include elevated intracranial pressures (>15 mm Hg), hemodynamic instability, esophageal and gastric conditions such as recent surgery or fistulas, and recent intracranial surgery. Good clinical contraindications are lack of a definite indication for IPPB or an available, less expensive alternative therapy.

D. Noninvasive Ventilation

Administration of positive pressure by noninvasive means, such as a face mask, nasal mask, or helmet, avoids the adverse events associated with endotracheal intubation (e.g., pneumonia, airway trauma). Noninvasive ventilation (NIV) is a cornerstone of treatment for COPD exacerbations and cardiogenic pulmonary edema, but a full discussion of NIV is beyond the scope of this chapter. Its use in the perioperative period is gaining acceptance and warrants discussion.

CPAP is the application of the same level of positive airway pressure through the entire respiratory cycle. The subsequent increase in intrathoracic and alveolar pressure supports patency of the airway, prevents alveolar collapse and atelectasis, maintains functional residual capacity, and decreases the work of breathing. PPV also reduces afterload by decreasing left ventricular transmural pressure and supporting left ventricular output. BiPAP adds pressure support above the level of CPAP during the inspiratory phase. With the addition of pressure support, CPAP is the baseline pressure during exhalation and is defined as PEEP. Pressure support allows for larger V_T and VC values, recruitment of atelectatic alveoli, increased ventilation, and improved oxygenation.

1. Indications

Perioperative NIV use can be viewed as prophylactic or therapeutic.[48] Prophylactic use of NIV involves administration of NIV after extubation to patients at risk for respiratory distress (e.g., cardiac, thoracic, or abdominal surgery, obstructive sleep apnea, COPD, congestive heart failure). Data continue to emerge regarding the potential beneficial use of perioperative CPAP in reducing postoperative pulmonary complications in patients undergoing cardiothoracic and abdominal surgery.[49,50] The therapeutic use of NIV in the perioperative setting may aid in reducing symptoms of respiratory distress, hypoxemia, or

hypoventilation. Further studies need to validate NIV for prophylactic and therapeutic use in a broader patient population.

2. Limitations

NIV requires that patients are cooperative with therapy, spontaneously ventilating, and able to protect their airway. It is most effective when a proper seal is achieved around the airway to minimize air leak. The use of high levels of positive pressure above 25 cm H_2O increases the risk of gastric insufflation and therefore limits its use in this circumstance. Patients with copious secretions may not be ideal candidates for NIV due to a constant requirement for bronchial hygiene.

IV. INHALATION THERAPY

Inhalation therapy is often used synonymously with the term *respiratory care*. In a general context, inhalation therapy can be thought of as the delivery of gases for ventilation and oxygenation, as aerosol therapy, or as a means of delivering therapeutic medications.

Therapeutic aerosols have been employed in the treatment of pulmonary patients with bronchospastic airway disease, COPD, and pulmonary infection. The basic goals of aerosol therapy are to improve bronchial hygiene, humidify gases delivered through artificial airways, and deliver medications. The first two goals are discussed earlier in this chapter.

The advantages of delivering drugs by inhalation include the following: easier access, rapid onset of action, reduced extrapulmonary side effects, reduced dosage, coincidental application with aerosol therapy for humidification, and general psychological support with treatment.[5,7,9] In the nonintubated patient, aerosol therapy necessitates the patient's cooperation and skilled help. The equipment is a potential source of nosocomial infections.[19] Aerosol therapy has many of the same disadvantages as humidification. Although drug use is often reduced, precise titration and dosages are difficult to ascertain because of variable degrees of drug deposition in the airway.

The following sections provide an overview of inhalation pharmacology and discuss the basic principles, devices for medication delivery, and specific pharmacologic agents that are employed. A more comprehensive topic review and specific drug information are available in reference texts.[48-50]

A. Basic Pharmacologic Principles

The pharmacology of inhalation therapy necessitates a brief review. A *medication* is a drug that is given to elicit a physiologic response and is used for therapeutic purposes. Undesired responses (side effects) are also produced. The medication can interact with receptors by direct application (topical effect) or absorption into the bloodstream.

Various routes of pharmacologic administration are used for respiratory care. Subcutaneous, parenteral, gastrointestinal, and inhalation administrations are commonly employed in the management of pulmonary diseases. Inhalation therapy employs the increased surface area of the lung parenchyma as a route of medication administration. This necessitates the drug reaching the alveolar and tracheobronchial mucosal surfaces for systemic capillary absorption.

Although inhaled medications can have topical effects, the primary reasons for the inhalation of medications are convenience, a safe method for self-administration, and maximal pulmonary benefit with reduced side effects. If the drug depends on systemic absorption, the drug's distribution and blood concentration are important. Blood concentration is altered by several mechanisms, such as dosage, route of administration, absorption, metabolism, and excretion. Alteration in liver and kidney function can produce unexpected drug levels and side effects.

If multiple drugs are employed for respiratory care, drug interactions can occur. Potentiation is the result of one drug with limited activity changing the response of another drug; synergism results when two drugs with similar action produce a greater response than the sum of the individual responses. If the response to the two drugs is the sum of the responses to the individual medications, they are additive. Tolerance necessitates increasing drug levels to elicit a response, and tachyphylaxis results in the inability of larger doses to produce the expected response.

The nomenclature for drug dosages should be understood. Two common methods for expressing drug dosage are ratio strength (drug dilutions) and percentage strength (percentage solutions). A solution is a homogeneous mixture of two substances. A solute is the dissolved drug, and a solvent is the fluid in which the drug is dissolved. A gram of water equals 1 mL of water, and 1 g equals 1000 mg. Ratio strength is expressed in terms of parts of solute in relation to the total parts of solvent (or grams of solute per grams of solvent). A 1:1000 solution is 1 g of a drug in 1000 g of solvent (1000 mg/1000 mL [1 mg/mL]). Percentage strength is expressed as the number of parts of solute in 100 parts of solvent (or grams of solute per 100 g of solvent). A 1% solution is 1 g of drug in 100 g of solvent.

B. Aerosolized Drug Delivery Systems

Therapeutic aerosols are commonly employed in respiratory care. Inhalation delivery of drugs can often produce therapeutic drug effects with reduced toxicity. The effectiveness of aerosols is related to the amount of drug delivered to the lungs. The pulmonary deposition of aerosolized drugs is a result of drug sedimentation that is due to gravity, inertial impact that is due to airway size, and directional change of airflow and kinetic energy.[7] Aerosol delivery also depends on particle size, pattern of inhalation, and degree of airway obstruction. Particle size should be smaller than 5 μm; otherwise, the particles may become trapped in the upper airway rather than following airflow into the lungs. Aerosol particles that can traverse artificial airways (e.g., ETT) are usually less than 2 μm in diameter. Particles less than 2 μm are deposited in peripheral airways. Particles less than 0.6 μm in diameter are often exhaled before reaching their site of action.

The ideal pattern of inhalation should be large volume, slow inspiration (5 to 6 seconds), and accentuated by an inspiratory hold (10 seconds). This breath-holding enhances sedimentation and diffusion. Faster inspiratory inflows increase deposition of particles on oropharyngeal and upper airway surfaces. If airway obstruction is significant, adequate deposition of drugs may be compromised. If the obstruction is not relieved, larger dosages or increased frequency of administration may be necessary. Application of the aerosol early in inspiration allows deeper penetration into the lungs, whereas delivery of medications at the back end of the breath enhances application to slower filling lung units. Concerns are raised in areas of the lung with poor ventilation related to airflow obstruction or low compliance. There are several methods for delivering aerosolized medications to the patient: jet nebulizers, pressurized metered-dose inhalers (MDIs), dry-powder inhalers (DPIs), ultrasonic nebulizers, and IPPB.

DPIs and pressurized MDIs are the most common delivery systems because of their low cost and ease of use. The MDI is a convenient, self-contained, and commonly employed method of aerosolized drug delivery (Figs. 14-11 and 14-12).[5,9] These prefilled drug canisters are activated by manual compression and deliver a predetermined unit (metered) of medication. Appropriate instruction is necessary for optimal use.[51] With the canister in the upside-down position, the device should be compressed only once per inhalation. A slow maximal inspiration with a breath-hold is typically recommended. It is imperative that the tongue not obstruct flow, but it is controversial whether the device should be placed in the mouth or held several centimeters from the lips with the mouth wide open. Concerns about excessive oral deposition of large particles must be offset against consistency of administration when the device is held away from the mouth. Other issues regarding use of MDIs include ideal lung volume for actuation, time of inspiratory hold, and inspiratory flow rate. If multiple doses are prescribed, an interval of several minutes between puffs is advisable. Most pharmaceutical manufacturers recommend 1 to 2 minutes between doses. However, studies have not shown any consistent difference in pulmonary function in extending the time interval between doses.[52,53]

Figure 14-12 Metered-dose inhaler for handheld use.

MDI drug delivery is associated with several problems. Manual coordination is necessary to activate the canister. Arthritis can cause difficulty, as can misaiming the aerosol. Pharyngeal deposition can lead to local abnormalities (e.g., oral candidiasis from aerosolized corticosteroids). Systemic effects that are caused by swallowing the drug can be reduced if the pharynx is rinsed after inhalation to reduce pharyngeal deposition.[5] Newer MDI devices have been designed to reduce some of these problems. Several spacing devices are available as extensions to MDIs. Spacers are designed to eliminate the need for hand-breath coordination and reduction of large-particle deposition in the upper airway.

The gas-powered nebulizers can be handheld or placed in line with the ventilatory circuit (Fig. 14-13).[5,9] The handheld devices are typically employed for more acutely ill individuals and as an alternative to an MDI. The full handheld system uses a nebulizer, a pressurized gas

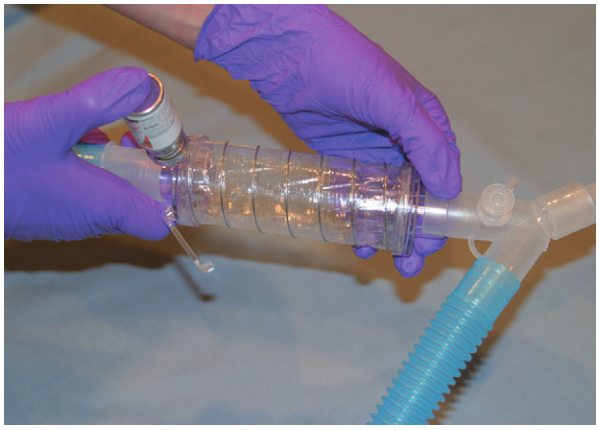

Figure 14-11 Metered-dose inhaler and circuit inspiratory limb spacer (Aero Vent). (Courtesy of Monaghan Medical, Plattsburgh, NY.)

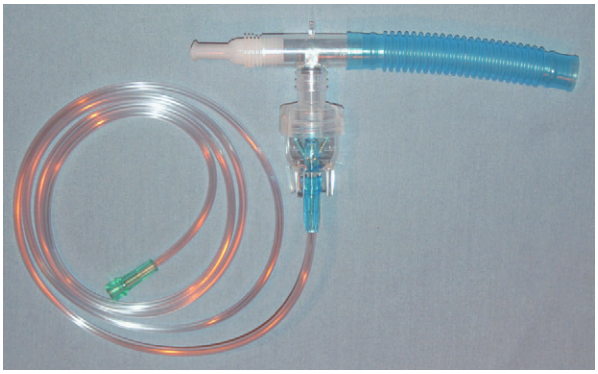

Figure 14-13 Gas-powered nebulization system.

source, and a mouthpiece or face mask. Patients' cooperation is not required, and high doses of drugs can be delivered. Disadvantages include expense and decreased portability.

These systems are more expensive, cumbersome, and often less efficient than MDIs. Supervision is usually necessary for appropriate drug preparation and administration. Typically, the drug is diluted in saline. The drug is usually more concentrated because most of the drug is never aerosolized or is lost during exhalation. Only the drug that is inspired can reach the lung.

The total volume to be nebulized is usually 3 mL (see "Pharmacologic Agents") at gas flows of 6 to 8 L/min (flow is device dependent). The treatment time is usually 5 to 10 minutes. During the course of treatment, the patient's vital signs and subjective tolerance must be monitored. Aerosolization of medication for drug delivery is different from aerosol therapy for humidification (see "Humidifiers").

The MDI and the gas-powered nebulizers can be used in line with an artificial airway or ventilator circuit, or both (see Figs. 14-11 and 14-13) The drug delivery system is positioned in the inspiratory limb and as proximal to the artificial airway as possible. With this configuration, drug delivery is equivalent between MDI and nebulizer.[54] In-line drug delivery is usually less efficient in ventilated patients than in spontaneously breathing, nonintubated patients because of the breathing pattern, drug deposition on the ETT, and airway disease.[55]

C. Pharmacologic Agents

Numerous drugs are used in the management of pulmonary diseases. Inhaled medications offer advantages over intravenous or oral administration. These include more specific targeting to the site of action and resulting lower doses limiting systemic side effects. Nebulized (aerosolized) drug delivery is commonly employed to improve mucociliary clearance (mucokinetics) and to relieve bronchospastic airway disease. The major drugs employed for inhalation therapy can be categorized by their ability to affect these two issues. Certain anti-inflammatory, antiasthmatic, antifungal, antiviral, and antibacterial drugs are given by aerosol. The following sections review some of the commonly employed aerosolized drugs but are not meant to be a comprehensive review of respiratory pharmacology. All listed dosages are meant to be representative for adult patients (if needed, specific product literature should be referred to before use).

1. Mucokinetic Drugs

Mucokinetic drugs are employed to enhance mucociliary clearance. These agents can be classified according to their mechanism of action. Hypoviscosity agents are the most commonly employed mucokinetic agents. Saline, sodium bicarbonate, and alcohol have been used to affect mucus viscosity by disrupting the mucopolysaccharide chains that are the primary components of mucus. The other category of mucokinetic aerosol agents is made up of the mucolytics. The following sections offer a synopsis of the various drugs in these two groups.[56]

a. HYPOVISCOSITY AGENTS

Saline is the most commonly employed mucokinetic agent. It can be used as a primary drug or a solvent. The mechanism of action is reduction of viscosity by dilution of the mucopolysaccharide strands. The indication for use is thick, tenacious mucous secretions. The typical concentration is 0.45% to 0.9% of sodium chloride (NaCl). The two major side effects associated with aerosolized saline are overhydration and the promotion of bronchospasm in patients with hyperactive airway disease (especially in newborns).

Hypertonic saline (HTS) is able to encourage osmosis of water from the interstitium and alveoli into mucus and act as a cough stimulant. HTS may induce bronchospasm, and inhaled bronchodilators are employed to mitigate the associated bronchospastic effects. Because the mechanism depends on migration of water from the alveolar tissue, HTS has an additional theoretical benefit of reducing adventitial edema. With repeated use, hypovolemia may follow repeated administration.

Alcohol (ethyl alcohol and ethanol) decreases the surface tension of pulmonary fluid. The typical concentration is 30%, and the dosage is 4 to 10 mL.[57] The primary indication is pulmonary edema. This agent should be administered by side-arm nebulization or IPPB but not as a heated aerosol. The contraindication is a hypersensitivity to alcohol or its derivative. Side effects include airway irritation, bronchospasm, and local dehydration.

b. MUCOLYTIC AGENTS

Thickened secretions are problematic for the intubated patient or patient with chronic pulmonary disease. Secretions can directly obstruct the airways, predispose the patient to obstructive pneumonia, and become a nidus for infection. Vigorous suctioning intended to clear the burden of secretions can cause direct injury to the airways. As a result, altering the rheologic properties of tenacious secretions encourages the return of normal pulmonary function.

Acetylcysteine 10% (Mucomyst) is an effective mucolytic. The mechanism of action is lysis of the disulfide bonds in mucopolysaccharide chains, reducing the viscosity of the mucus. The indication is for management of viscous, inspissated, mucopurulent secretions. The actual effectiveness in the treatment of mucostasis is inconclusive, and each individual must be monitored to determine the benefit of therapy. The usual dosage is 2 to 5 mL every 6 hours.[54] Hypersensitivity is a contraindication. In general, acetylcysteine is relatively nontoxic. Side effects include unpleasant taste and odor, local irritation, inhibition of ciliary activity, and bronchospasm. For these reasons, pretreatment with a bronchodilator is recommended. Other reported side effects include nausea and vomiting, stomatitis, rhinorrhea, and generalized urticaria. Acetylcysteine is incompatible with several antibodies. The drug should be avoided or used with extreme caution in patients with bronchospastic airway disease. Other special concerns are a need for refrigeration, reactivity with rubber, and its limited use after opening (96 hours).[58]

Mesna (mistabron) is a thiol-containing compound that can lyse the disulfide bonds on mucoproteins, and it has been shown to support thinning of secretions.[59] In addition to the direct mucolytic activity, Mesna is a hypertonic solution and may reduce viscosity of secretions by a second mechanism. As for acetylcysteine, studies of Mesna have been unable to demonstrate conclusive benefit of secretion clearance or improvement in lung compliance despite concomitant bronchodilator adminstration.[59] When given by nebulizer, 1 mL of Mesna is combined with a bronchodilator, such as albuterol or salbutamol. It can also be administered as a bolus of 600 mg (3 mL) through the ETT. It usually is well tolerated, with bronchospasm and hypersensitivity as possible side effects.

Recombinant human DNase (rhDNase) promotes lysis of DNA that is present in the secretions of patients with CF or infected secretions. The abundance of DNA increases the viscosity of these secretions. A few reports and retrospective analyses have shown rhDNase to improve secretion clearance and atelectasis.[60] The increased cost of rhDNAse limits its widespread use in clinical practice.

2. Bronchodilators and Antiasthmatic Drugs

Acute and chronic bronchospastic airway diseases afflict many individuals. Many drugs that vary primarily by their mechanism of action and route of delivery are available to manage this problem. The following sections deal only with aerosolized drugs that are commonly employed in the therapy of bronchospastic airway disease (Table 14-8).[16,61,62] The drugs are grouped by their mechanism of action: sympathomimetics, anticholinergics, corticosteroids, and cromolyn. A comprehensive review of these drugs, the various mechanisms for bronchodilation, and the management of specific pathophysiologic problems is beyond the scope of this chapter.

a. SYMPATHOMIMETICS

Sympathomimetics include the β-adrenergic agonists and methylxanthines (not available in aerosol). The rhDNase-adrenergic agents couple to the β_2-adrenoreceptor through the G protein α subunit to adenylate cyclase, which results in an increase in intracellular cyclic adenosine monophosphate (cAMP), which leads to activation of protein kinase A. Activated protein kinase A inhibits phosphorylation of certain muscle proteins that regulate smooth muscle tone and inhibits release of calcium ion from intracellular stores. Responses of sympathomimetic drugs usually are classified according to whether the effects are α, β_1, or β_2. The β_2 receptors are responsible for bronchial smooth muscle relaxation. The common side effects associated with β-adrenergic agonists result from their additional β_1 and α effects. The β_1 effects cause an increase in heart rate, dysrhythmias, and cardiac contractility; α effects increase vascular tone. Potent β_2 stimulants can produce unwanted symptoms: anxiety, headache, nausea, tremors, and sleeplessness. Prolonged use can lead to receptor downregulation and reduced drug response. Ideally, the more pure the β_2 response, the better the therapeutic benefit relative to side effects. The following sympathomimetics are commonly employed in clinical practice.[5,7,39,58]

Albuterol (Ventolin, Proventil) is a sympathomimetic agent available in an MDI. It has a strong β_2 effect with limited β_1 properties. Its β_2 duration of action is approximately 6 hours.

Racemic epinephrine 2.25% (Vaponephrine) is a mixture of levo and dextro isomers of epinephrine. It is a weak β and mild α drug. The α effects provide mucosal constriction. In the aerosol form, this drug acts as a good mucosal decongestant. The drug has minimal bronchodilator action. Cardiovascular side effects are limited. Typical dosage is 0.5 mL (2.25%) in 3.5 mL of saline, given as frequently as every hour in adult patients. Racemic epinephrine is commonly mixed with 0.25 mL (1 mg) of dexamethasone or budesonide for the management of post-extubation swelling and croup (see "Antiallergy and Asthmatic Agents").

Isoproterenol (Isuprel) is the prototype pure β-adrenergic bronchodilator. Bronchodilation depends on adequate blood levels. In addition, isoproterenol is a pulmonary and mucosal vascular dilator. This causes an increased rate of absorption, higher blood levels, and increased β_1 side effects. The side effects can be quite significant and often reduce the use of this agent in patients with cardiac disease; dysrhythmias, myocardial ischemia, palpitations, and paradoxical bronchospasm can occur. If the pulmonary vasculature vasodilates to areas of low ventilation, the potential to augment ventilation-perfusion mismatch and increase intrapulmonary shunt exists. Typical dosage is 0.25 to 0.5 mL (0.5%) in 2 to 2.5 mL of saline. The effect lasts 1 to 2 hours. Isoproterenol is also available as an MDI.

Newer inhaled β-adrenergic drugs include salmeterol, pirbuterol, and bitolterol (a catecholamine). Salmeterol can be administered as an oral inhalation powder twice a day 50 μg. Pirbuterol acetate is usually administered through a pressurized MDI (200 μg). Bitolterol can be provided as a pressurized MDI or a solution. Salmeterol was the first long-acting adrenergic bronchodilator approved for use in the United States. Its duration of action is about 12 hours, with an onset of about 20 minutes and a peak effect occurring in 3 to 5 hours. It is particularly useful in patients with nocturnal asthma because of its longer duration of action. The prolonged effect of some of the newer bronchodilators results from their increased lipophilicity (Table 14-9).

b. ANTICHOLINERGIC AGENTS AND ANTIBIOTICS

Anticholinergic drugs play an increasing role in the management of bronchospastic pulmonary disease but have been found more effective as maintenance treatment of bronchoconstriction in COPD. These drugs inhibit acetylcholine at the cholinergic receptor site, reducing vagal nerve activity. This produces bronchodilation (preferentially in large airways) and a reduction in mucus secretion. Major side effects include dry mouth, blurred vision, headache, tremor, nervousness, and palpitations.

Ipratropium bromide (Atrovent) is a commonly used anticholinergic. Its effects are primarily on the muscarinic receptors of bronchial smooth muscle. It is available as an MDI. The standard dosage is 34 μg taken four times

TABLE 14-8
Aerosolized Bronchodilators and Antiasthmatic Drugs

Type of Drug (Mechanism)	Method	Dose*
Sympathomimetics		
(β_2-Agonists; increase in cyclic AMP)		
Short-Acting Beta Agonists		
Albuterol (Ventolin, Proventil)	MDI/Neb	2 puffs (90 µg/puff) q4hr prn
Levalbuterol hydrochloride (Xopenex)	Neb	0.63–1.25 mg nebulized solution q6–8hr
Pirbuterol acetate (Maxair)	MDI	2 puffs (200 µg/puff) q4hr prn
Racemic epinephrine	Neb	0.25 mL in 3.5 mL
Long-Acting Beta Agonists		
Salmeterol xinafoate (Serevent)	DPI	1 puff (50 µg) bid
Formoterol fumarate (Foradil)	DPI	1 capsule (12 µg) by Aerolizer inhaler bid
Anticholinergics		
(Cholinergic blockers; increase β stimulation)		
Ipratropium bromide (Atrovent)	MDI/Neb	2 puffs (17 µg/puff) qid 17 µg (0.02%) qid
Tiotropium bromide (Spiriva)	DPI	1 capsule inhaled (18 µg) by HandiHaler qd
Anti-Inflammatories		
Inhaled Corticosteroids		
(Anti-inflammatory; inhibit leukocyte migration; potentiate β agonists)		
Beclomethasone acetate (Vanceril, Beclovent)	MDI	1–4 puffs (40 µg/puff) bid
Flunisolide (AeroBid)	MDI	2–4 puffs (250 µg/puff) bid
Triamcinolone acetonide (Azmacort)	MDI	2–8 puffs (100 µg/puff) bid
Budesonide (Pulmicort)	DPI/Neb	1–4 puffs (200 µg/puff) bid 0.25 mg/2 mL bid 0.5 mg/2 mL bid
Fluticasone propionate (Flovent)	MDI	44, 110, or 220 µg; up to a maximum of 880 µg/day
Mometasone furoate (Asmanex)	DPI	1–2 puffs (220 µg/puff) qd
Combination Products		
Albuterol sulfate/ipratropium bromide (Combivent)	MDI/Neb	2 puffs (0.09 mg/0.018 mg/puff) qid 1 vial (3 mg/0.5 mg) qid
Fluticasone propionate/salmeterol Xinafoate (Advair)	DPI	100, 250, or 500 µg/50 µg; 1 puff bid

AMP, Adenosine monophosphate; *bid,* twice per day; *DPI,* dry-powder inhaler; *MDI,* metered-dose inhaler; *Neb,* nebulizer; *qd,* once per day; *qid,* four times per day.
*Dosages may vary; references to specific drug inserts are recommended.

per day (17 µg/puff). Hypersensitivity to the drug is a contraindication. Caution should be exercised in patients with narrow-angle glaucoma. Tiotropium is a long-acting anticholinergic agent that has shown to improve lung function and reduce exacerbations of COPD with once-daily dosing.[63] The dosage is 2 puffs of an 18-µg capsule taken once daily using the supplied DPI. The side effects are similar to ipratropium bromide, with most common symptoms being dry mouth and upper respiratory tract infections. Rarely, inhaled anticholinergic drugs have been associated with paradoxical bronchospasm.

Antibiotics are also delivered by an inhalational route. Aerosolized tobramycin is used in patients with CF, and ribavirin is employed in children against respiratory syncytial virus. Pentamidine can be employed as prophylaxis against *Pneumocystis (carinii) jiroveci*. However, the support for the general use of nebulized antibiotics in ventilator-associated pneumonia (VAP) is inconclusive. As a result, the addition of nebulized antibiotics is reserved for multidrug-resistant organism pneumonia refractory to first-line therapy. The use of aerosolized gentamycin or vancomycin, in addition to systemic antibiotics, for treatment of tracheobronchitis led to quicker resolution of pneumonia, decreased bacterial resistance, and less recurrence of VAP.[64] Nebulized polymyxins (e.g., colistin) allow focused delivery of antibiotics that were historically underutilized because of significant nephrotoxicity with systemic administration. The evidence for the use of nebulized colistin is promising but remains

TABLE 14-9
Onset and Duration of Commonly Used Bronchodilators

Drug	Onset (min)	Peak (min)	Duration (hr)
Isoproterenol*	2–5	5–30	1–2
Isoetharine*	2–5	15–60	1–3
Bitolterol*	3–5	30–60	5–8
Albuterol	15	30–60	3–8
Pirbuterol	5	30	5
Salmeterol	20	180–300	12

*A catecholamine.

inconclusive. When added to a regimen of systemic antibiotics in patient with multidrug-resistant gram-negative bacteria, nebulized colistin has shown to be beneficial for treatment of pneumonia without systemic side effects.[65]

c. ANTIALLERGY AND ASTHMATIC AGENTS

The two main groups of aerosolized agents for treating allergies and asthma are cromolyn and corticosteroids. These drugs are often used concomitantly with other medications.

Newer mediator antagonists include zafirlukast, montelukast, and zileuton. Zafirlukast and montelukast work as leukotriene receptor antagonists and selectively inhibit leukotriene receptors LTD_4 and LTE_4. Leukotrienes are produced by 5-lipoxygenase from arachidonic acid and stimulate leukotriene receptors to cause bronchoconstriction and chemotaxis of inflammatory cells. As with cromolyn sodium, these agents should not be used for acute asthmatic attacks but rather for long-term prevention of bronchoconstriction.[62]

Corticosteroids are commonly used for maintenance therapy in patients with chronic asthma.[66,67] The mechanism of action is attributed to their anti-inflammatory properties, reducing leakage of fluids, inhibiting migration of macrophages and leukocytes, and possibly blocking the response to various mediators of inflammation. Corticosteroids have been reported to potentiate the effects of the sympathomimetic drugs.[9] Systemic and topical side effects can occur with inhaled corticosteroids. These effects include adrenal insufficiency, acute asthma episodes, possible growth retardation, and osteoporosis. Local effects include oropharyngeal fungal infections and dysphonia. Adrenal suppression is usually not a concern with doses below 800 μg/day.

Beclomethasone dipropionate (Vanceril, Beclovent) is an aerosolized corticosteroid that is highly active topically and that has limited systemic absorption or activity. The typical dosage is 1 to 4 puffs (40 μg/puff) taken two times per day. Hoarseness, sore throat, and oral candidiasis are reported side effects. The risk of candidiasis can be minimized with oral rinse after drug administration, and candidiasis can be managed with topical antifungal drugs. Mild adrenal suppression is reported with high doses, and caution is advised when switching from oral to inhaled corticosteroids.

The preceding pharmacologic agents are representative of those commonly employed by aerosol in respiratory care. Appropriate pharmacologic management necessitates assessing response to therapy. Objective and subjective relief of symptoms and improvement in pulmonary function while minimizing side effects of these drugs are the endpoints of good inhalation therapy. Effective inhalation therapy involves relief of symptoms, improvement in pulmonary function, and minimizing drug side effects.

V. CONCLUSIONS

Oxygen therapy, bronchial hygiene, and inhalation therapy are some of the interventions available to the physician in order to improve pulmonary function. Oxygen delivery systems attempt to prevent rebreathing of exhaled air and can be differentiated based on the ability to maintain near-consistent oxygen delivery. Low-flow oxygen systems entrain room air to meet the patient's ventilatory demands, but inspired oxygen concentration becomes unpredictable with changes in ventilatory patterns. High-flow systems have high flows rates and attempt to provide a reliable oxygen concentration despite variations in minute ventilation. Humidification is added to these oxygen delivery systems to prevent cooling and drying of the respiratory tract.

Other modalities may be required to correct specific or more significant derangements of pulmonary function. Airway suctioning is often employed to clear secretions and optimize tracheobronchial toilet. Chest physical therapy, including postural drainage and percussion therapy, can assist mucociliary action to mobilize secretions. Incentive spirometry attempts to optimize lung inflation and prevent atelectasis, although it requires patient teaching and cooperation. Noninvasive positive pressure ventilation increases intrathoracic and alveolar pressure to prevent atelectasis, maintain functional residual capacity, maintain airway patency, and decrease the work of breathing.

Inhalation therapy delivers therapeutic medications and aerosols to humidify the airway or elicit a physiologic response. The MDI, nebulizer, and DPI can be used to deliver medications to the airways. Mucokinetic agents can decrease the viscosity of secretions, and include hypertonic saline and mucolytics. The β-adrenergic agonists, methylxanthines, and anticholinergics produce bronchodilation, albeit by different mechanisms. Corticosteroids, leukotriene receptor antagonists, and mast cell stabilizers are often used in prevention or management of bronchospasm due to asthma or allergic stimuli.

Most patients with mild pulmonary dysfunction may require only increasing inspired oxygen concentration, whereas more significant dysfunction requires understanding pulmonary physiology and choosing appropriate therapy. In the perioperative setting, hypoxemia is most commonly caused by ventilation-perfusion mismatch, hypoventilation, and capillary shunt. If left untreated, hypoxemia can cause tachycardia, acidosis, increased myocardial oxygen demand, and an increased work of breathing.

VI. CLINICAL PEARLS

- Hypoxemia may be defined as a deficiency of O_2 tension in the arterial blood, typically defined as a PaO_2 less than 80 mm Hg. The most common perioperative cause of hypoxemia is capillary shunt (atelectasis).
- A low-flow, variable-performance system depends on room air entrainment to meet the patient's peak inspiratory and minute ventilatory demands that are not met by the inspiratory gas flow or O_2 reservoir alone.
- High-flow, fixed-performance systems are nonrebreathing systems that provide the entire inspiratory atmosphere needed to meet the peak inspiratory flow and minute ventilatory demands of the patient. To meet the patient's peak inspiratory flow, the flow rate and reservoir are very important. Flows of 30 to 40 L/min (or

four times the measured minute volume) are often necessary.

- O_2 therapy must be used appropriately in patients with severe chronic obstructive pulmonary disease (COPD) due to a risk of developing respiratory distress. Disturbances in ventilation and perfusion develop in patients with COPD, and through hypoxic pulmonary vasoconstriction, the perfusion is redistributed to areas of higher O_2 tension. Increasing mixed venous or alveolar O_2 tension can reverse this shunting and worsen $\dot{V}/\dot{Q}$ matching.
- O_2 toxicity becomes clinically important after 8 to 12 hours of exposure to a high F_{IO_2} level. O_2 toxicity may result from direct exposure of the alveoli to a high F_{IO_2} level. Healthy lungs appear to tolerate F_{IO_2} levels of less than 0.6. In damaged lungs, F_{IO_2} levels greater than 0.50 may result in a toxic alveolar O_2 concentration.
- Airway suctioning is commonly employed in respiratory care to promote optimal tracheobronchial toilet and airway patency in critically ill patients. Because of the perceived simplicity and limited complications, airway suctioning is frequently employed.
- Percussion and vibration therapy are used in conjunction with postural drainage to loosen and mobilize secretions that are adherent to the bronchial walls.[17,48] Percussion involves a manually produced, rhythmic vibration of varying intensity and frequency.
- Normal, spontaneous breathing patterns have periodic hyperinflations that prevent the alveolar collapse associated with shallow tidal ventilation breathing patterns. Narcotics, sedative drugs, general anesthesia, cerebral trauma, immobilization, and abdominal or thoracic surgery can promote shallow tidal ventilation breathing patterns. Incentive spirometry (IS) is commonly employed in the postoperative period to encourage patients to generate a maximal tidal volume breath. However, IS has yet to be proved to reduce postoperative pulmonary complications.
- Perioperative noninvasive ventilation (NIV) is both a prophylactic and therapeutic modality. Prophylactic use of NIV has emerged as a measure to reduce postoperative pulmonary complications in patients undergoing cardiothoracic and abdominal. Therapeutic use of NIV in the perioperative setting may aid in reducing symptoms of respiratory distress, hypoxemia, or hypoventilation.
- The metered-dose inhaler (MDI) and the gas-powered nebulizers may be used with an artificial airway or ventilator circuit, or both. The drug delivery system is positioned in the inspiratory limb as proximal to the artificial airway as possible. This position makes drug delivery equivalent between MDI and nebulizer.

V. **Choosing an Airway Technique**

VI. **Conclusions**

VII. **Clinical Pearls**

I. OVERVIEW

Maintaining a patent airway is the first principle of resuscitation and life support. It is an essential skill for those caring for anesthetized or critically ill patients. Clinicians working in a hospital setting should be competent in the essentials of airway management.

Too frequently, inexperienced personnel believe airway management necessitates intubation of the trachea. This chapter reviews the tools and skills for nonintubation airway management and discusses airway management techniques. Endotracheal intubation and pharyngeal intubation (e.g., laryngeal mask airways [LMAs]) are discussed elsewhere in this textbook. The topic of airway management can be divided into the establishment and maintenance of a patent airway and ventilatory support. Airway patency is achieved by manipulating the head and neck in ways that maximize the native airway or by using artificial airway devices. Ventilatory support techniques control the composition of gases that the patient breathes and allow manual respiratory assistance.

A. Upper Airway Anatomy and Physiology

Nonintubation airway management seeks to produce patency to gas flow through the oropharynx, nasopharynx, and larynx without the use of artificial airway devices that extend into the laryngopharynx or trachea. A thorough understanding of upper airway anatomy and physiology is necessary to appreciate the therapeutic maneuvers and devices employed in airway management (Fig. 15-1). More detailed reviews of airway anatomy are found elsewhere in this book and in various atlases and texts.[1-3]

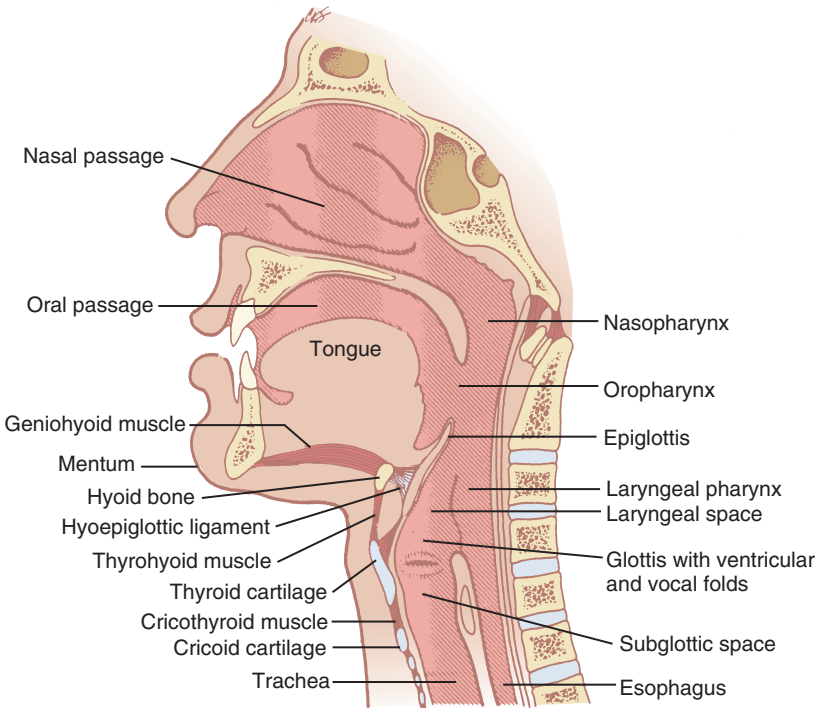

Figure 15-1 Normal anatomy of the airway and surrounding structures is demonstrated in a lateral view of the head and neck in the neutral position. Notice the right-angle geometry of the muscular connections from the mentum to the cricoid cartilage: mentum, geniohyoid muscle, hyoid bone, thyrohyoid muscle, thyroid cartilage, cricothyroid muscle, and cricoid cartilage. This line can be straightened by extending the head at the neck and anteriorly displacing the jaw, pulling the epiglottis and tongue away from the posterior wall of the airway.

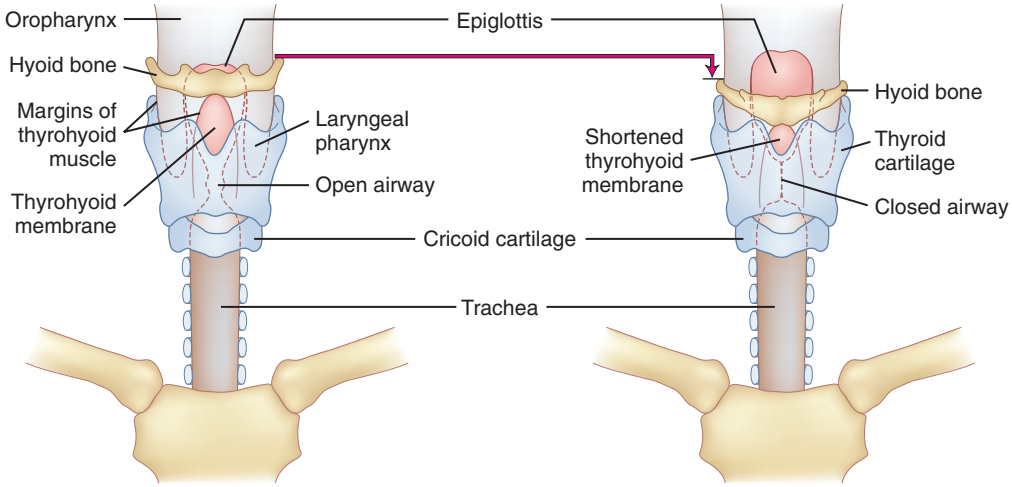
Gas passes from outside the body to the larynx through the nose or mouth. If through the nose, ambient gas passes through the nares, choanae, and nasopharynx (where it is warmed and humidified). The humidified gas then traverses the oropharynx and hypopharynx (also called laryngopharynx) on its way to the larynx. If through the mouth, the oropharynx and hypopharynx are traversed before entering the glottis. Nasal passages can be obstructed by choanal atresia, septal deviation, mucosal swelling, or foreign material (e.g., mucus, blood). Entry to the oropharynx can be blocked by the soft palate lying against the posterior pharyngeal wall. The pathway of gas by either route can be restricted by the tongue in the oropharynx or the epiglottis in the hypopharynx. These are sites of potential pharyngeal collapse.[4-7] Airway manipulation and devices can remedy these causes of obstruction. Laryngeal obstruction related to spasm, however, must be treated by positive airway pressure, deeper anesthesia, muscle relaxants, or endotracheal intubation.

Laryngeal closure is accomplished by the intrinsic or extrinsic muscles of the larynx. Tight closure, as seen in laryngospasm, results from contraction of the external laryngeal muscles, which force the mucosal folds of the quadrangular membrane into apposition (Fig. 15-2). Muscle groups also extend from the thyroid cartilage to the hyoid and cricoid cartilages. When they contract, the interior mucosa and soft tissue (ventricular and vocal folds) are forced into the center of the airway, and the thyroid shield is deformed (compressed inward), providing a spring to reopen the airway rapidly after these muscles relax.[8] The larynx closes at the level of the true cords by action of the intrinsic muscles of the larynx during phonation, but this closure is not as tight as the laryngospasm described earlier.

Opening of the pharynx and larynx is achieved by elongating and unfolding the airway from the hyoid to the cricoid cartilage.[8] Several muscle groups tether the various airway structures to one another to form a functional airway apparatus. When the head is tilted, the chin and mandible are displaced forward on the temporomandibular joint. This produces maximum stretch at the hyoid-thyroid-cricoid area. The hyoid bone is pulled in an anterior direction along with the epiglottis and base of the tongue, which opens the oropharynx. The ventricular and vocal folds flatten against the sides of the thyroid cartilage, opening the laryngeal airway.[8]



The inferior and middle constrictors close the superior part of the esophagus (cervical sphincter) to prevent regurgitation. Muscle relaxants open the airway by relaxing the intrinsic and extrinsic laryngeal muscles that close the airway, but they also relax the pharyngeal constrictors, potentially permitting regurgitation and aspiration of gastric contents. Balancing airway patency and airway protection represents the major dilemma of airway management without, and while placing, an endotracheal tube (ETT).

B. Upper Airway Obstruction

Upper airway obstruction is a common airway emergency necessitating nonintubation airway manipulation and airway devices. Soft tissue obstructions may occur at the level of the pharynx, hypopharynx, or larynx. Recognition of upper airway obstruction is an essential clinical skill that depends on observation, suspicion, and clinical data.

1. Pharyngeal Obstruction

The causes of soft tissue upper airway obstruction at the level of the pharynx include loss of pharyngeal muscle

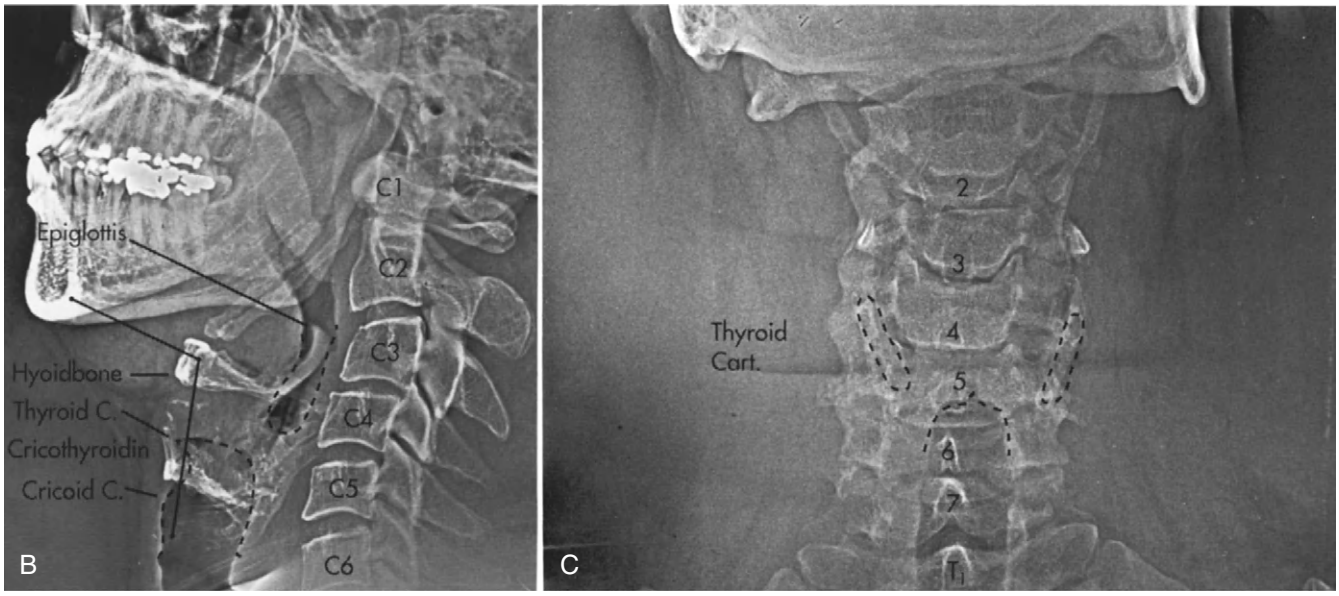


Figure 15-2 Laryngeal closure. Schematic frontal views **(A)** of the airway at the larynx show a patent airway *(left)* with a centrally located air column and the hyoid bone superior to the thyroid shield. Obliteration of the air column *(right)* is caused by apposition of the ventricular and vocal folds, and approximation of the hyoid bone to the thyroid cartilage is caused by contraction of the thyrohyoid muscle. Lateral **(B)** and frontal **(C)** xerograms were obtained during Valsalva-induced laryngeal closure. In the lateral view, notice the thyrohyoid approximation. An abrupt airway cutoff (with lack of an air column within the thyroid shield) can be seen at the C4-5 level in the frontal view.

tone resulting from central nervous system dysfunction (e.g., anesthesia, trauma, stroke, coma), anatomic and passive airway abnormalities as seen in obstructive sleep apnea, expanding space-occupying lesions (e.g., tumor, mucosal edema, abscess, hematoma), and foreign substances (e.g., teeth, vomitus, foreign body).

In patients susceptible to obstructive sleep apnea, the geometry of the pharynx can be altered during normal sleep.[9] Although it is usually oval with the long axis in the transverse plane, the pharynx in patients with obstructive sleep apnea is round or oval with the long axis in the anterior-posterior plane (the lateral walls are thickened).[10,11] This obstruction can often be treated effectively with nasal continuous positive airway pressure and with intraoral devices that advance the mandible as much as the jaw thrust maneuver.[12-14]

2. Hypopharyngeal Obstruction

Hypopharyngeal obstruction has been investigated by placing a nasal fiberscope at the level of the soft palate in anesthetized subjects.[15] The epiglottis and the glottic opening can be seen, recorded, and analyzed. The percentage of glottic opening (POGO) seen from this view can be determined. Typically, airflow increases and snoring decreases as POGO increases. However, a POGO of 100% has been documented with airway occlusion, and a POGO of 0% has been documented with no stridor and no obvious impairment to ventilation. Although less than perfect, these evaluations do support the potential for airflow restriction at the hypopharynx and are consistent with the cause being the epiglottis obstructing the airway.

3. Laryngeal Obstruction

Laryngeal obstruction is most often related to increased muscle activity from attempted vocalization or a reaction to foreign substances, such as secretions, vomitus, foreign bodies, and tumors. Obstruction of the laryngeal aperture by a foreign body can directly inhibit airflow. Alternatively, the presence of secretions or blood in the airway can cause laryngospasm. Treatment includes removal of foreign substances and, in the case of laryngospasm, positive-pressure ventilation (PPV) with or without muscle relaxation.

4. Clinical Recognition of Upper Airway Obstruction

Airway obstruction can be partial or complete. Partial upper airway obstruction is recognized by noisy inspiratory or expiratory sounds. The tone of the sounds depends on the magnitude, cause, and location of the obstruction. Snoring is the typical sound of partial airway obstruction in the oropharynx or hypopharynx, and it can be heard during inspiration and expiration. Stridor or crowing suggests glottic (laryngeal) obstruction or partial laryngospasm, and it is heard most often during inspiration. In addition to audible clues, signs and symptoms of hypoxemia or hypercarbia should alert the clinician to the possibility of an airway obstruction.

Complete airway obstruction is a medical emergency that requires immediate attention. Signs of complete obstruction in the spontaneously breathing individual are inaudible breath sounds or the inability to perceive air movement; use of accessory neck muscles; sternal, intercostal, and epigastric retraction with inspiratory effort; absence of chest expansion on inspiration; and agitation.

II. NONINTUBATION APPROACHES TO ESTABLISH AIRWAY PATENCY

Prevention and relief of airway obstruction are the focus of this chapter. The preceding information on airway anatomy and airway obstruction constitutes essential background for understanding airway maneuvers. When possible, rapid, simple maneuvers should take precedence in the management of this problem.

When the muscles of the floor of the mouth and tongue relax, the tongue may cause soft tissue obstruction by falling back onto the posterior wall of the oropharynx. It is also possible for the epiglottis to overlie and obstruct the glottic opening or to seal against the posterior laryngopharynx. This effect can be exaggerated by flexing the head and neck or opening the mouth, or both (Fig. 15-3), because the distance between the chin and the thyroid notch is relatively short in the flexed position. Any intervention that increases this distance straightens the mentum-geniohyoid-hyoid-thyroid line and therefore elevates the hyoid bone further from the pharynx. The elevated hyoid then secondarily elevates the epiglottis through the hyoepiglottic ligament, potentially alleviating the obstruction.

A. Simple Maneuvers for the Native Airway

Two well-described, simple maneuvers can lengthen the anterior neck distance from the chin to the thyroid notch: head tilt-chin lift and jaw thrust.

1. Head Tilt-Chin Lift

The head tilt-chin lift is accomplished by tilting the head back on the atlanto-occipital joint while keeping the mouth closed (teeth approximated) (Fig. 15-4). This technique may be augmented by elevating the occiput 1 to 4 inches above the level of the shoulders (sniffing position) as long as the larynx and posterior pharynx stay in their original position. The head tilt-chin lift is the simplest and first airway maneuver used in resuscitation, but it should be used with extreme caution in patients with suspected neck injuries.

In some patients, the cervical spine is stiff enough that elevating the head into the sniffing position also elevates the C4-5 laryngeal area, leaving the airway unimproved. In children younger than 5 years, the upper cervical spine is more flexible and can bow upward, forcing the posterior pharyngeal wall upward against the tongue and epiglottis and exacerbating an obstruction. A child's airway is usually best maintained by leaving the head in a more neutral position than that described for an adult.

2. Jaw Thrust

The jaw thrust maneuver more directly lifts the hyoid bone and tongue away from the posterior pharyngeal wall by subluxating the mandible forward onto the sliding part of the temporomandibular joint (mandibular advancement) (Fig. 15-5). The occluded teeth normally prevent forward movement of the mandible, and the thumbs must depress the mentum while the fingers grip the rami of the mandible and lift it upward. This results in the mandibular teeth protruding in front of the maxillary teeth (after the mouth opens slightly). In practice, the insertion of a small airway sometimes makes this procedure easier because it separates the teeth, allowing the mandible to more easily slide forward. In most people, the mandible is readily drawn back into the temporomandibular joint by the elasticity of the joint capsule and masseter muscles. Consequently, this position can be difficult to maintain with one hand.

In up to 20% of patients, the nasopharynx is occluded by the soft palate during exhalation when the airway muscles are relaxed. If the mouth and lips are also closed, exhalation is impeded. In these cases, the mouth must be opened slightly to ensure that the lips are parted. When the head tilt-chin lift, jaw thrust, and open mouth maneuvers are done together, it is known as the *triple airway maneuver* (see Fig. 15-5). The triple airway maneuver is the most reliable manual method to achieve patency of the native upper airway (Box 15-1).

3. Heimlich Maneuver

Airway maneuvers can aid in establishing and maintaining airway patency, but they do not relieve an obstruction due to foreign material lodged in the upper airway. Foreign body obstruction should be suspected after a witnessed aspiration when the patient cannot speak,

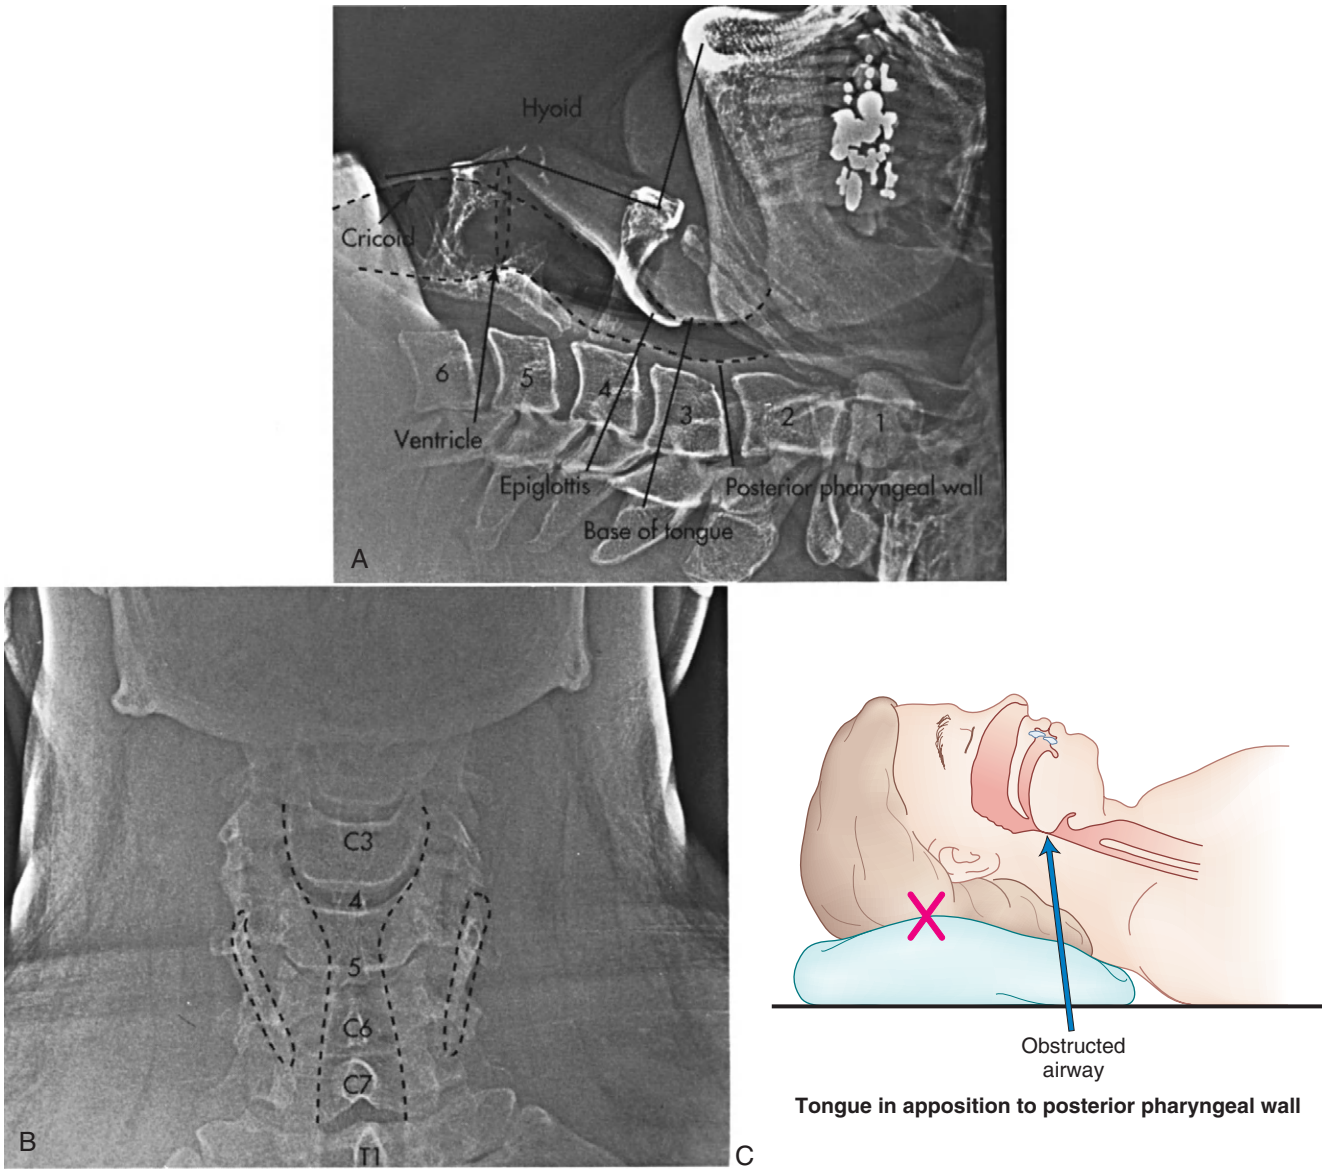

Figure 15-3 **A,** Lateral xerogram of the head and neck in the neutral position in an awake and supine patient shows the mentum is directly anterior to the hyoid bone, the base of the tongue and the epiglottis are close to the posterior pharyngeal wall, and the thyroid and cricoid cartilages are at the C5-6 level. Notice that an oropharyngeal airway could easily touch the tip of the epiglottis, pushing it downward. **B,** Frontal view of the same patient shows the air column within the thyroid shield with its narrowest site at the level of the vocal cords (C5-6). **C,** Diagram of a patient with a flexed neck shows the tongue in apposition to the posterior pharyngeal wall.

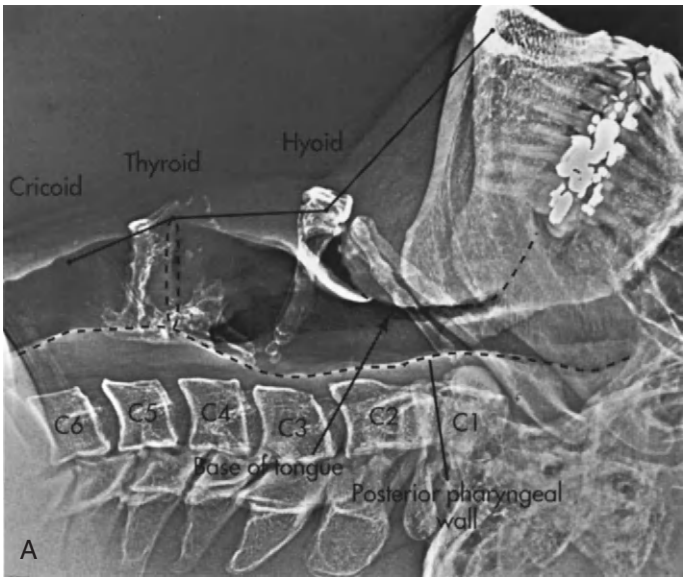

when spontaneous ventilation is absent, or when PPV remains difficult after routine airway maneuvers have been performed. A Heimlich maneuver (subdiaphragmatic abdominal thrusts) is recommended when coughing or traditional means, such as back blows, are unable to relieve complete airway obstruction due to foreign material (Fig. 15-6 and Box 15-2). The goal is to increase intrathoracic pressure sufficiently to simulate a cough. Alternatively, a forceful chest compression in the manner of a rapidly executed bear hug (for upright patients) or a sternal compression (for supine patients) can also be effective. In emergency situations, the failure of one technique to relieve an obstruction should not preclude additional attempts using the various alternatives.

B. Artificial Airway Devices

When simple airway maneuvers, such as those described previously, are inadequate to establish upper airway patency, it is often necessary to employ artificial airway devices. The next sections address some of the more commonly available devices and discuss techniques for insertion, indications, contraindications, and complications.

1. Oropharyngeal Airways

An oropharyngeal airway (OPA) is the most commonly used device to provide a patent upper airway. OPAs are manufactured in a wide variety of sizes from neonatal to large adult, and they are typically made of plastic or

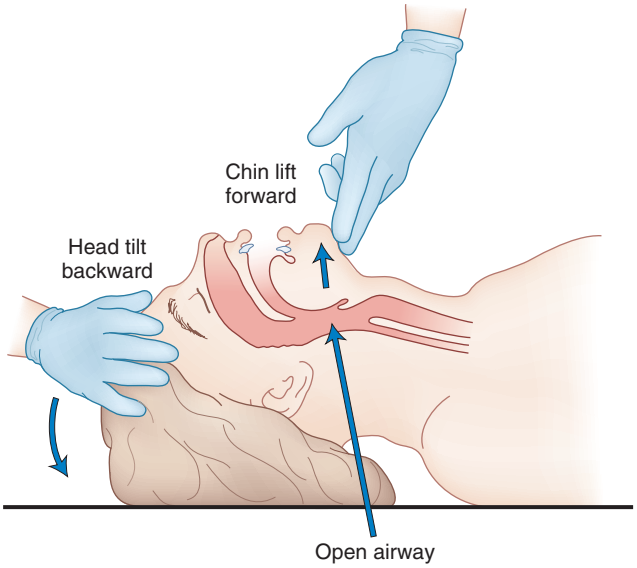

Figure 15-4 **A,** Lateral xerogram of the head and neck shows the extended position (head tilt) in an awake and supine patient (compare with Fig. 15-3A). The mentum is superior to the hyoid bone, the base of the tongue and the epiglottis are farther from the posterior pharyngeal wall, and the thyroid and cricoid cartilages are at the C4-5 level. The hyoid bone has been raised and elevated from C3-4 to C2-3. **B,** Diagram of the head tilt-chin lift maneuver.

rubber (Fig. 15-7). They should be wide enough to make contact with two or three teeth on each of the mandible and maxilla, and they should be slightly compressible so that the pressure exerted by a clenched jaw is distributed over all of the teeth while the lumen remains patent. OPAs are frequently designed with a flange at the buccal (proximal) end to prevent swallowing or over insertion. They also feature a distal semicircular section to follow the curvature of the mouth, tongue, and posterior pharynx so that the tongue is displaced anteriorly (concave side against the tongue). An air channel is often provided to facilitate oropharyngeal suctioning.

The most commonly used OPA in adults is the Guedel Airway (see Fig. 15-7). It has a plastic elliptical tube with a central lumen reinforced by a harder inner plastic tube at the level of the teeth and by plastic ridges along the pharyngeal section. Because the airway is completely enclosed (other than the proximal and distal ends), redundant oral and pharyngeal mucosae cannot occlude or narrow the lumen from the side. Its oval cross section allows the four central incisors to make contact with it during masseter spasm.

The Ovassapian Airway has a large anterior flange to control the tongue and a large opening at the level of the teeth (open posteriorly) to allow a flexible fiberoptic bronchoscope and ETT to be passed through it and later disengaged from the airway (see Fig. 15-7). Consequently, it is often employed during fiberoptic intubations to aid in maintaining upper airway patency.

BOX 15-1 Simple Maneuvers for the Native Airway

Head Tilt-Chin Lift

Procedure: With the patient supine, place one hand on the forehead and the first two fingers of the other hand on the underside of the chin. Simultaneously exert upward traction on the chin while tilting the forehead gently backward to extend the head on the atlanto-occipital joint.
Indications: Soft tissue upper airway obstruction
Contraindications: Cervical spine fracture, basilar artery syndrome, infants
Complications: Neck soreness, pinched cervical nerve roots

Jaw Thrust

Procedure: From above the patient's head, place the thumbs on the chin and the fingers behind the angle of the jaw bilaterally. Simultaneously open, lift, and displace the jaw forward, subluxating the mandible anteriorly on the temporomandibular joint.
Indications: Soft tissue airway obstruction when a head tilt-chin lift is contraindicated (e.g., fractured neck) or ineffective
Contraindications: Fractured or dislocated jaw, awake patient
Complications: Jaw dislocation, dental injury

Triple Airway Maneuver

Procedure: Perform the head tilt-chin lift followed by a jaw thrust maneuver. Maintain the mouth in an open position after subluxating the mandible during the jaw thrust.
Indications: Expiratory obstruction after a head tilt-chin lift and jaw thrust
Contraindications: Same as for a head tilt-chin lift and jaw thrust
Complications: Same as for a head tilt-chin lift and jaw thrust

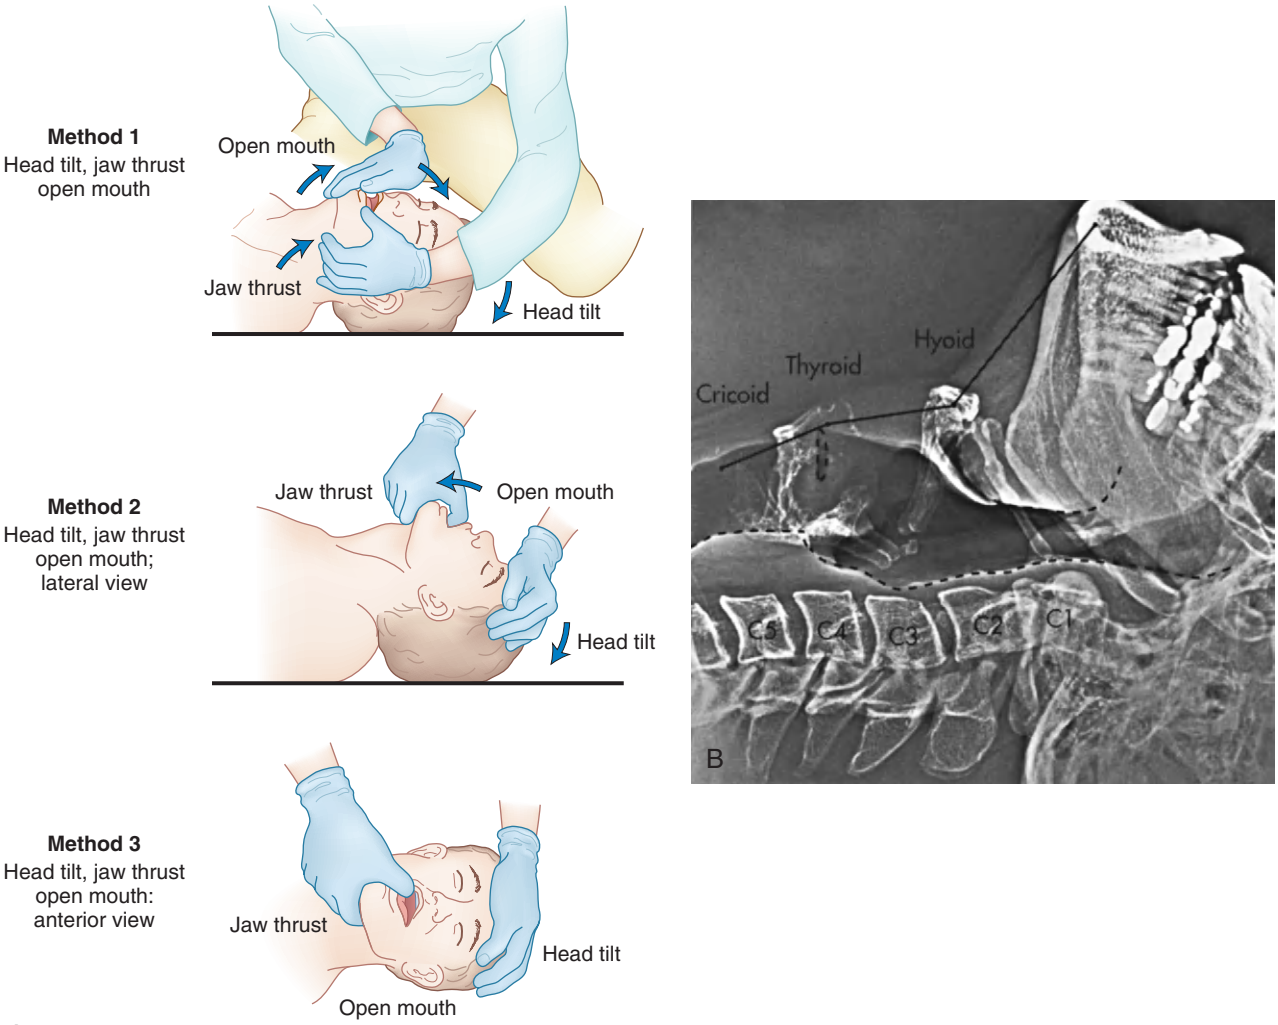

Figure 15-5 The triple airway maneuver includes the head tilt-chin lift, jaw thrust, and open mouth. **A,** Diagrams show three methods of performing the maneuver: (1) the head extended on the atlanto-occipital joint, (2) the mouth opened to take the teeth out of occlusion, and (3) the mandible lifted upward, forcing the mandibular condyles anteriorly at the temporomandibular joint. **B,** Lateral xerogram of the head and neck show the extended position with jaw protrusion (compare with Figs. 15-3A and 15-4A). Notice that the mandibular incisors protrude beyond the maxillary incisors and that the mandibular condyles are subluxated anteriorly from the temporomandibular joint.

BOX 15-2 The Heimlich Maneuver

Procedure: In the upright patient, wrap both arms around the chest with the right hand in a closed fist in the low sternal-xiphoid area and the left hand on top of the fist. With a rapid, forceful thrust, compress upward, increasing subdiaphragmatic pressure and creating an artificial cough.
Indication: Complete upper airway obstruction by a foreign body with impending asphyxia
Contraindications: Partial airway obstruction, fractured ribs (relative), cardiac contusion (relative)
Complications: Fractured ribs or sternum, trauma to liver, spleen, or pancreas

Use of an OPA seems deceptively simple, but the device must be used correctly. The patient's pharyngeal and laryngeal reflexes should be depressed before insertion to avoid worsening obstruction due to airway reactivity. The mouth is opened, and a tongue blade is placed at the base of the tongue and drawn upward, lifting the tongue off of the posterior pharyngeal wall (Fig. 15-8A). The airway is then placed so that the OPA is just off the posterior wall of the oropharynx, with 1 to 2 cm protruding above the incisors (see Fig. 15-8B). If the flange is at the teeth when the tip is just at the base of the tongue, the airway is too small, and a larger size should be inserted. A jaw thrust is then performed as described previously to lift the tongue off of the pharyngeal wall while the thumbs tap down the airway the last 1 to 2 cm so that the curve of the OPA lies behind the base of the tongue (see Fig. 15-8C). The mandible is then allowed to reduce back into the temporomandibular joint, and the mouth is inspected to ensure that neither the tongue nor the lips are caught between the teeth and the OPA.

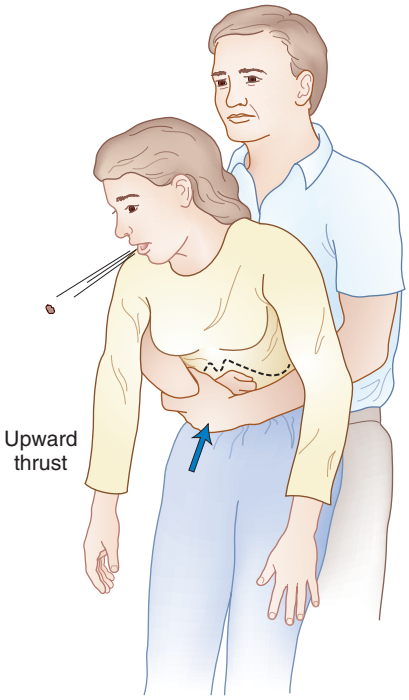

Figure 15-6 Heimlich maneuver. An airway obstructed by a laryngeal foreign body is opened by compressing the lungs through external pressure on the abdomen, forcing the diaphragm cephalad. An alternative method creates this "external cough" by compressing the thorax directly.

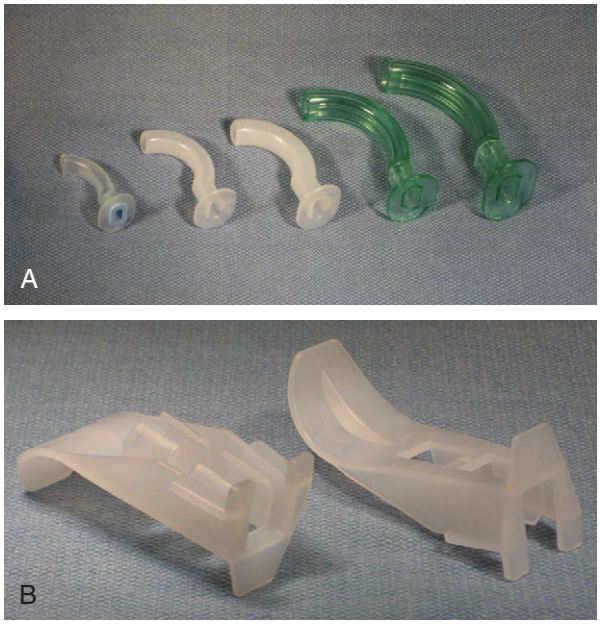

Figure 15-7 Oropharyngeal airways. **A,** Guedel Airways in sizes from neonatal to large adult. **B,** The Ovassapian Airway has a large anterior flange to control the tongue. The airway is open posteriorly (including no posterior flange) so that an endotracheal tube can be inserted with a flexible fiberoptic scope and the assembly later separated.

An alternative method of placement is to insert the airway backward (convex side toward the tongue) until the tip is close to the pharyngeal wall of the oropharynx. It is then rotated 180 degrees so that the tip rotates and sweeps under the tongue from the side (see Fig. 15-8D). This method is not as reliable as the tongue blade–assisted technique described earlier, and it has the added risk of causing dental trauma in patients with poor dentition.

If the upper airway is not patent after the placement of an OPA, the following situations must be considered. With an OPA that is too small, the pronounced curve may impinge on the base of the tongue, or the tongue may obstruct the native airway distal to the OPA. If a larger OPA still results in obstruction, the curve might have brought the distal end into the vallecula or the OPA might have pushed the epiglottis into the glottic opening or posterior wall of the laryngopharynx. In the lightly anesthetized or awake patient, this stimulation causes coughing or laryngospasm. The best treatment for this problem is to withdraw the OPA 1 to 2 cm. A topical anesthetic spray or a water-soluble local anesthetic lubricant reduces the chance of laryngeal activity, but it should be used judiciously or avoided in patients thought to be at increased risk for aspiration.

Two major complications can occur with the use of OPAs: iatrogenic trauma and airway hyperreactivity. Minor trauma, including pinching of the lips and tongue, is common. Ulceration and necrosis of oropharyngeal structures from pressure and long-term contact (days) have been reported.[16] These problems necessitate intermittent surveillance during extended use. Dental injury can result from twisting of the airway, involuntary clenching of the jaw, or direct axial pressure. Dental damage is most common in patients with periodontal disease, dental caries, pronounced degrees of dental proclination, and isolated teeth.

Airway hyperactivity is a potentially lethal complication of OPA use, because oropharyngeal and laryngeal reflexes can be stimulated by the placement of an artificial airway. Coughing, retching, emesis, laryngospasm, and bronchospasm are common reflex responses. Any OPA that touches the epiglottis or vocal cords can cause these responses, but the problem is more common with larger OPAs. Initial management is to partially withdraw the OPA. If an anesthetic is being administered, deepening the plane of anesthesia (most easily accomplished with an intravenous agent) is often effective in blunting airway hyperreactivity. In cases of laryngospasm, it may be necessary to apply mild positive airway pressure and, in trained hands, to cautiously administer small doses of succinylcholine to achieve resolution.

2. Nasopharyngeal Airways

The nasopharyngeal airway (NPA) is an alternative airway device for treating soft tissue upper airway obstruction. When in place, an NPA is less stimulating than an OPA and therefore better tolerated in the awake, semicomatose, or lightly anesthetized patient. In cases of oropharyngeal trauma, a nasal airway is often preferable to an oral airway. NPAs are pliable, bent cylinders made of soft plastic or rubber in variable lengths and widths (Fig. 15-9). A flange (or moveable disk) prevents the outside

Figure 15-8 Techniques for insertion of an oropharyngeal airway: standard technique **(A–C)** and alternative technique **(D)** without a tongue blade. **A,** The tongue blade is placed deep into the mouth and depresses the tongue at its posterior half. The tongue is then pulled forward in an attempt to pull it off the back wall of the pharynx. **B,** The airway is then inserted with the concave side toward the tongue until the tube is just off the posterior wall of the oropharynx with 1 to 2 cm protruding above the incisors. The tongue blade is then removed. **C,** A jaw thrust is performed while the thumb taps the airway into place. After the jaw is allowed to relax, the lips are inspected to ensure they are not caught between the teeth and airway. **D,** In an alternative technique, the airway is placed in a reverse manner (convex side toward tongue) and then spun 180 degrees into place so that the lower section of the airway rotates between the tongue and posterior pharyngeal wall.

end from passing beyond the nares, thereby controlling the depth of insertion. The concavity is meant to follow the superior side of the hard palate and posterior wall of the nasopharynx. The tip of the airway is beveled to aid in following the airway and minimizing mucosal trauma as it is advanced through the nasopharynx. A narrow NPA is often desirable to minimize nasal trauma but may be too short to reach behind the tongue. As an alternative, an ETT of the same diameter may be cut to the appropriate length to provide a longer airway. A 15-mm adapter should be inserted in the cut end of the ETT to prevent migration of the proximal end beyond the naris (see Fig. 15-9).

Before insertion of an NPA, the nares should be inspected to determine their size and patency and to evaluate for the presence of nasal polyps or marked septal deviation. Vasoconstriction of the mucous membranes can be accomplished with cocaine (which has the added benefit of providing topical anesthesia) or phenylephrine drops or spray. This can also be accomplished by soaking cotton swabs in either of these solutions and then

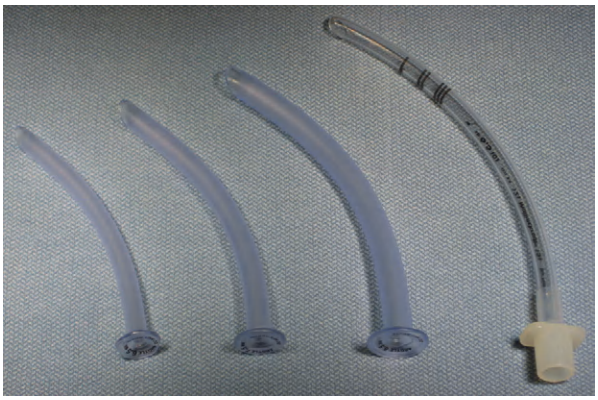

Figure 15-9 Nasopharyngeal airways. A flange prevents the outside end from passing beyond the nares, controlling the depth of insertion. Alternatively, an endotracheal tube may be cut down to provide a longer airway, with its 15-mm adapter reinserted in the cut end.

Figure 15-10 Insertion of a nasopharyngeal airway. The airway is oriented with its concave side toward the hard palate and inserted straight posteriorly. Gripping the airway near the top allows the tube to bend if there is resistance to passage. If it is gripped too close to the naris, the clinician can generate sufficient force to shear off a turbinate.

inserting them into the naris (with careful attention to removing the swabs before insertion of the NPA). The NPA is typically lubricated with a water-based lubricant (with or without a water-soluble local anesthetic) and then gently but firmly passed with the concave side parallel to the hard palate through the nasal passage until resistance is felt in the posterior nasopharynx (Fig. 15-10).

When there is resistance to passage, it is sometimes helpful to rotate the NPA 90 degrees counterclockwise, bringing the open part of the bevel against the posterior nasopharyngeal mucosa. As the tube makes the bend (indicated by a relative loss of resistance to advancement), it should be rotated back to its original orientation. If the NPA does not advance with moderate pressure, there are three management options: attempt placement of a narrower tube, redilate the naris, and attempt placement in the other naris. If the tube does not pass into the oropharynx, the clinician may withdraw the tube 2 cm and then pass a suction catheter through the nasal airway as a guide for advancement of the NPA. If the patient coughs or reacts as the NPA is inserted to its full extent, it should be withdrawn 1 to 2 cm to prevent the tip from touching the epiglottis or vocal cords. If the patient's upper airway is still obstructed after insertion, the NPA should be checked for obstruction or kinking by passing a small suction catheter. If patency of the NPA is confirmed, it is possible that the NPA is too short and the base of the tongue is occluding its tip. In this case, a 6.0 ETT can be cut at 18 cm to provide a longer airway.

Indications for an NPA include relief of upper airway obstruction in awake, semicomatose, or lightly anesthetized patients; in patients who are not adequately treated with OPAs; in patients undergoing dental procedures or with oropharyngeal trauma; and in patients requiring oropharyngeal or laryngopharyngeal suctioning. The contraindications (absolute or relative) include known nasal airway occlusion, nasal fractures, marked septal deviation, coagulopathy (risk of epistaxis), prior transsphenoidal hypophysectomy or Caldwell-Luc procedures, cerebrospinal fluid rhinorrhea, known or suspected basilar skull fractures, and adenoid hypertrophy.

The complications of NPAs consist of failure of successful placement, epistaxis due to mucosal tears or avulsion of the turbinates, submucosal tunneling, and pressure sores. Epistaxis often becomes evident when the NPA is removed, thereby removing the tamponade. It is usually self-limited. Bleeding from the nares usually is attributable to anterior plexus bleeding, and it is treated by applying pressure to the nares. If the posterior plexus is bleeding (with blood pooling into the pharynx), the physician should leave the NPA in place, suction the pharynx, and consider intubating the trachea if the bleeding does not stop promptly. The patient may be positioned on his or her side to minimize the aspiration of blood. An otolaryngology consultation may be necessary to further treat posterior plexus bleeding. The management of submucosal tunneling into the retropharyngeal space is to withdraw the airway and obtain otolaryngology consultation.

III. NONINTUBATION APPROACHES TO VENTILATION: MASK VENTILATION

In some cases, ventilation may still be inadequate despite a patent airway. Ventilatory assistance can be achieved through several alternatives other than intubation. Standard cardiopulmonary resuscitation courses have long taught the effectiveness of mouth-to-mouth and mouth-to-nose ventilation. Mouth-to-artificial-airway ventilation using a disposable face mask overcomes many of the sanitary objections to the previous techniques. More sophisticated approaches to ventilatory assistance (as in the course of anesthesia care) typically include the use of bag-mask-valve systems. Ventilation of a patient typically requires a sealed interface between the patient and a delivery system that supplies airway gases and can be pressurized. For nonintubation ventilation, this seal is on the skin of the face (face mask techniques) or in the hypopharynx (LMA). The most reliable seal, allowing high positive-pressures, is in the trachea through endotracheal intubation, but it is achieved at the expense of increased airway and hemodynamic reflex activity. The remainder of this chapter reviews nonintubation ventilation by face mask and discusses the factors that must be considered when choosing an airway technique.

A. Face Mask Design and Techniques for Use

The face mask is typically the starting point for linking a positive-pressure generating device to a patient's airway. Although face masks have different materials, shapes, types of seal, and degrees of transparency, all are composed of three main parts: a body, a seal (or cushion), and a connector (Fig. 15-11). The body is the main structure of the mask and the primary determinant of the mask's shape. Because the body rises above the face, all masks increase ventilatory dead space. However, this is rarely clinically significant for spontaneous or controlled ventilation. The seal is the rim of the mask that contacts the patient's face. The most common type of seal is an air-filled cushion rim. The connector is at the top of the body and provides a 22-mm female adapter for adult and large

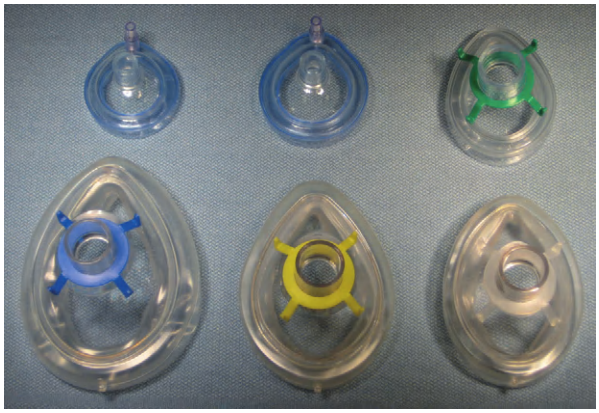

Figure 15-11 Assorted sizes of disposable, transparent face masks. The smallest masks have a 15-mm male adapter, and the larger sizes have a 22-mm female adapter to allow them to be connected to a standard breathing circuit or resuscitator bag.

pediatric masks or a 15-mm male adapter for small pediatric and neonatal masks to connect to a standard breathing circuit. A collar with hooks allows a retaining strap to be attached to hold the mask to the patient's face (Fig. 15-12). The precise application of the straps (crossed or uncrossed) is a matter of preference and is usually the result of a trial-and-error process to find the best seal for each individual patient.

Disposable, single-use, transparent plastic masks are the most common style. They are made with a high-volume, low-pressure cushion that seals easily to a variety of face shapes. The cushion may be factory sealed or have a valve that allows for the injection or withdrawal of air to alter the cushion's volume. They have little or no chin curve, however, which can sometimes make it difficult to maintain a patent airway.

The proper use of a face mask depends on establishing the best compromise between the adequacy of the seal to the patient's face and the patency of the upper airway. Successfully balancing these two factors is fundamental to providing adequate ventilation and inhalation anesthesia. The mask should comfortably fit the hand of the user and the face of the patient. If the mask is too long, the face can be elongated 1 to 2 cm by placing an OPA. If the mask is too short, it can be moved 1 to 2 cm cephalad along the bridge of the nose to make a good seal at the patient's chin. When this is done, careful attention is required to avoid ocular trauma.

Figure 15-12 Use of a retaining strap to help seal the face mask to the patient's face. The precise application of the straps (crossed or uncrossed) is a matter of preference.

Several methods are described for holding the mask, but regardless of the precise method chosen, close monitoring for leaks is necessary. Traditionally, the user's left hand grips the mask with the thumb and index finger around the collar (Fig. 15-13). The left side of the mask fits into the palm, with the hypothenar eminence extending below the left side of the mask. If it does not, the mask may be too large for the user's hand, and a smaller mask should be tried. The problem with a mask that is too large for the user is that the hypothenar eminence cannot pull the patient's cheek against the left side of the mask to maintain a seal if pronation is necessary to seal the right side. The patient may require a large mask in which case retaining straps are usually necessary to achieve a satisfactory seal throughout.

The user's middle finger can be placed on the mask or the patient's chin, depending on the span of the user's hand, the size of the mask and face, and the ease of the fit. The proximal interphalangeal joints of the fingers and the distal interphalangeal joint of the thumb should be at the midline of the mask. This allows the pads of the fingers to put pressure on the right side of the mask. The nasal portion of the mask is sealed by downward pressure of the user's thumb. To seal the chin section, the mandible is gripped with the user's fourth and fifth fingers, and the wrist is rotated so as to pull the mandible up into the mask with the fingers while pushing the bridge of the mask down with the thumb. This action of lifting the face up to the mask is critical to avoid obstructing the upper airway by simply applying downward pressure to seal the mask to the patient's face. To seal the left side, gather the patient's left cheek against the side of the mask with the hypothenar eminence. The right side is then sealed by pronating the user's forearm while pressing the ends of the thumb, index finger, and possibly middle finger onto the right side of the mask.

The sides of the mask are somewhat malleable to adjust to wide or narrow faces. In edentulous patients, the cheeks are often too hollow to allow for an adequate seal. Edentulous patients also lose vertical dimension to their faces that can be restored with an oral airway. In rare situations, dentures may be left in place to allow a better mask fit (though with the associated risk of dislodgement with consequent airway obstruction by this foreign body). Alternatively, a large mask can be used so that the chin fits entirely within the mask with the seal on the caudal surface of the chin. In this configuration, the cheeks fit within the sides of the mask, and the sides seal along the lateral maxilla and mandible. These maneuvers to make a difficult mask fit possible are often best sidestepped by endotracheal intubation or the use of an LMA, based on clinical judgment (see "Choosing an Airway Technique"). Mask retaining straps can be placed below the occiput and connected to the mask collar to assist the seal, but care should be taken to ensure that

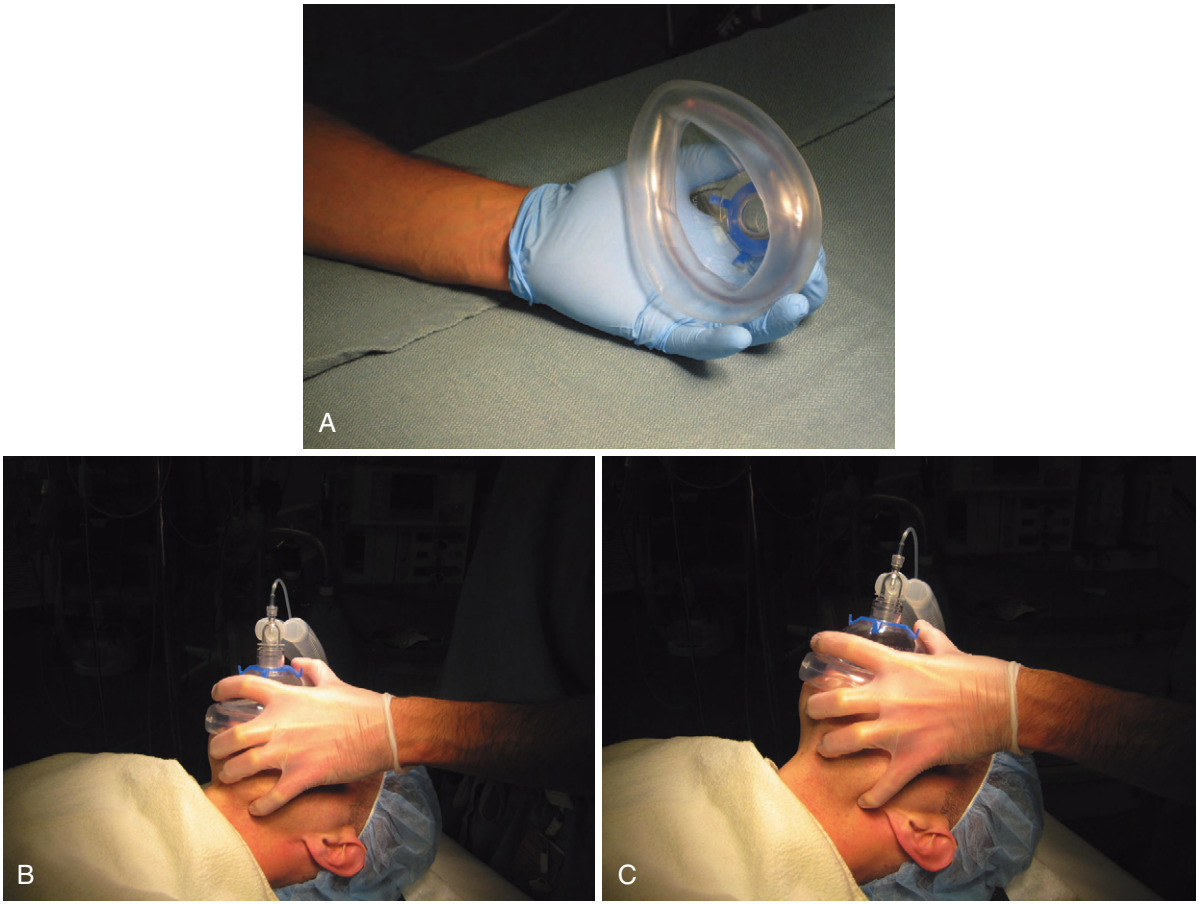

Figure 15-13 Suggested techniques for holding and supporting a face mask. **A,** In the proper hand grip of the face mask, the thumb and index finger encircle the collar while the hypothenar eminence extends below the left side of the mask. **B,** In the side view of the standard one-handed application of the face mask, the thumb and first finger (or first two) encircle the collar of the mask while the remaining fingers pull the mandible up into the mask while gently extending the head. **C,** During the one-handed mask grip with concurrent jaw thrust, notice how the little finger is located at the angle of the jaw, pulling backward and upward to maintain the jaw thrust (subluxation). Because of the increased span of the hand, only the first finger is on the mask while the middle and ring fingers pull the mandible up into the mask and extend the head.

the tension on the straps is no more than necessary to achieve a seal.

B. Controlled Ventilation by Face Mask

1. Anesthesia Circle System

Use of a face mask is a simple and reliable method of airway management for assisted spontaneous ventilation and controlled ventilation of patients during routine anesthesia care. When used as part of an anesthesia circle system, a face mask is used to seal a patient's airway to allow delivery of a precise composition of respiratory gases and inhaled anesthetics. This includes preoxygenation with spontaneous ventilation, controlled ventilation before endotracheal intubation, rescue ventilation when endotracheal intubation is unsuccessful or not feasible, and spontaneous or controlled ventilation during inhaled general anesthesia by mask alone.

Controlled ventilation by mask is relatively contraindicated in patients at increased risk for aspiration of gastric contents. Problems include the presence of a full stomach, hiatus hernia, esophageal motility disorders, and pharyngeal diverticula. When there is a likelihood of gas insufflating the stomach (e.g., mask ventilation requiring high airway pressures), an adverse patient position (usually any position other than supine), or inability to easily reach the head of the patient, use of a mask for PPV must be done cautiously. Mask ventilation is also relatively contraindicated when there is a need to avoid the head and neck manipulation that may be necessary to maintain the airway. The inability to sustain adequate assisted or spontaneous ventilation is a relative contraindication to further use of a face mask.

Use of a face mask is associated with several potential complications. A poor mask fit or seal can result in gas leaks that prevent the maintenance of positive airway pressure and contaminate the operating room environment with anesthetic gases. Pressure from a malpositioned mask, especially with the use of restraining straps, can potentially cause skin, nerve, and ocular injury. Gastric distention and aspiration constitute the most

Figure 15-14 Adult and pediatric sizes of air-mask-bag unit (AMBU). The AMBU is a portable, self-inflating, easy-to-use system for the delivery of positive-pressure ventilation. It can be used with a face mask, laryngeal mask airway, or endotracheal tube.

serious (and potentially lethal) complication of PPV by mask.

2. Resuscitator Bags

The air-mask-bag unit (AMBU) was described in 1955 by Henning Ruben (Fig. 15-14).[17] The AMBU provides an alternative means of controlled ventilation to the standard anesthesia circle system. The bag can be used with a face mask, LMA, or ETT. Its main advantages are that it is self-inflating and readily portable, but it lacks the "feel" (airway compliance and resistance) that the clinician has with a circle system, and it requires a compressed oxygen source to deliver oxygen concentrations above that of room air. Although there are various types of AMBU systems in use, all incorporate one-way valves to allow PPV and to prevent rebreathing. AMBUs are an excellent choice for portable, easy-to-use systems for the delivery of PPV and supplemental oxygen outside of the operating room environment.

C. Determining the Effectiveness of Mask Ventilation

The effectiveness of mask ventilation should be judged by careful attention to and frequent reassessment of exhaled tidal volume, chest excursion, presence and quality of breath sounds, pulse oximetry, and capnography (when available). Capnography is considered the best indicator of adequate ventilation, assuming the patient has adequate cardiac output. In the absence of cardiac output (i.e., cardiac arrest), no carbon dioxide (CO_2) is returned to the lungs, and minimal CO_2 is measured in the expired gases. In this case, the presence of breath sounds and chest excursion are the best indicators of adequate ventilation.

The mask seal should be sufficient to permit a positive pressure of 20 cm H_2O with minimal leak. Positive airway pressure should be limited to 25 cm H_2O to minimize insufflating the stomach, which increases the chance of regurgitation and aspiration. If the patient cannot be ventilated with 25 cm H_2O of positive pressure, the physician should evaluate for upper airway obstruction, decreased pulmonary compliance, and increased airway resistance.

Occasionally, it is sufficiently difficult to maintain an adequate mask seal and patent upper airway with one hand that the patient's safety is best served with the assistance of a second operator. In this case, the mask and airway are controlled with the first operator's two hands (one on each side of the face mask) while the second operator ventilates the patient by squeezing the bag (Fig. 15-15). This maneuver can be done from the side of the patient and from above the head. Because this usually is not a stable situation, an alternative airway technique (e.g., placement of an LMA or ETT) usually should be employed.

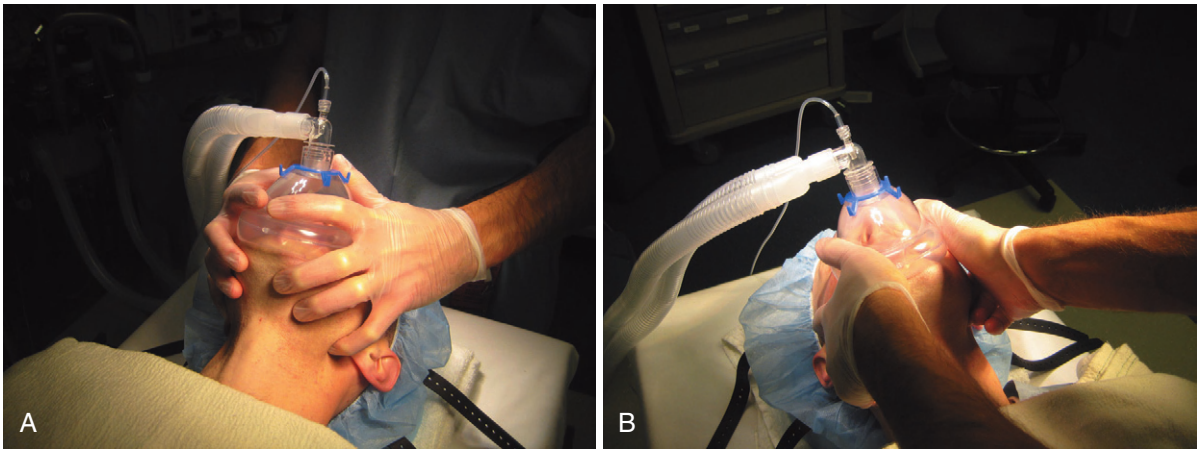

Figure 15-15 Two-hand control of a face mask. In both scenarios, a second provider must ventilate the patient. **A,** In the view of two-hand control of a face mask from above the patient, notice how the lower fingers on both hands apply a jaw thrust while the thumbs seal the mask to the face. **B,** In the view of two-hand control of a face mask from the side of the patient, the person ventilating the patient has improved access to the head as the airway is maintained from the patient's side. This arrangement is beneficial if the ventilating provider is preparing to perform laryngoscopy.

IV. NONINTUBATION AIRWAY MAINTENANCE IN SPECIFIC CLINICAL SCENARIOS

Airway maintenance without endotracheal intubation is a necessity of the practice of anesthesia, respiratory care, emergency medicine, and critical care. Occasionally, nonintubation techniques are preferable because they avoid the autonomic and airway reflexes (e.g., tachycardia, hypertension, coughing) that accompany endotracheal intubation. However, this approach is not well suited to prolonged periods of PPV. Three situations requiring airway maintenance without endotracheal intubation that deserve special mention are sedation anesthesia, transitional periods surrounding endotracheal intubation, and induction and maintenance of a general anesthetic by mask airway.

A. Sedation Anesthesia

When the painful stimuli of surgery have been largely ablated by regional, neuraxial, or local anesthetic infiltration, sedation anesthesia is used to allay anxiety or minimize discomfort related to patient positioning. Mild sedation during which the patient can converse typically does not require special airway management, although supplemental oxygen by nasal cannula is often used.

Moderate sedation to the point of somnolence or stertor generally requires intervention to ensure the adequacy of ventilation. A chin lift or jaw thrust maneuver can result in increased patient awareness and clearing of the stertor, reassuring the anesthetist that the patient is not overly sedated. If stertor returns, turning the head 45 degrees to one side or the other may help relieve the upper airway obstruction. A moderately sedated patient often allows a face mask (attached to a circle system) to lie over the nose and mouth, permitting monitoring of ventilation by capnography and providing a means to deliver supplemental oxygen. With moderate sedation, placement of an OPA is usually not advised because this level of stimulation may induce retching or other protective airway reflexes.

The use of deep sedation (often bordering on general anesthesia) has become an increasingly common part of modern anesthesia practice. This technique routinely requires airway support using a combination of nonintubation airway maneuvers and artificial airway devices to provide supplemental oxygen and to monitor ventilation. Given the ease with which this can transition into general anesthesia, deep sedation should be performed only by providers who are experienced in caring for patients under general anesthesia and who are facile in placing the advanced airway devices (e.g., LMAs and ETTs) that this often requires.

B. Transitional Airway Techniques for Endotracheal Intubation and Extubation

Before intubation of the trachea, the patient usually has received a neuromuscular blocker or, in the case of cardiopulmonary arrest, has no muscle tone. The larynx is open, and laryngospasm is not a consideration. The previously discussed techniques of airway maintenance are usually sufficient to permit controlled manual ventilation by face mask.

Airway maintenance from endotracheal extubation to smooth, spontaneous ventilation can be complicated by upper airway obstruction and by a reactive larynx capable of spasm. In these cases, the timing of extubation is an important consideration. Extubation can occur at a deep plane of anesthesia (with minimal airway reactivity) or during very light anesthesia (almost or fully awake) when there is full control of reflex activity. The patient extubated during the intermediate period may be at increased risk for laryngospasm.

Post-extubation upper airway obstruction is treated in the manner described earlier, with the following caveat. If an OPA is in place, it should not be removed with excessive force because lateral stresses may dislodge teeth. The anesthesiologist should wait for jaw relaxation or open the jaw with firm pressure on the mandibular ramus between the clenched teeth and the buccal mucosa. Post-extubation laryngospasm can be treated (as previously described) with PPV by mask, with reinduction of general anesthesia, or by the judicious administration of small doses of neuromuscular blockers. If spontaneous ventilation remains inadequate after extubation, the practitioner should consider performing laryngoscopy to investigate the cause and potentially reintubate the patient.

C. General Anesthesia by Mask Airway

Regardless of whether induction of general anesthesia is accomplished by intravenous or inhalational route, the most important feature of mask airway management during the maintenance of anesthesia is monitoring the progress of the operation and the status of the airway. Increasing levels of stimuli must be anticipated and the anesthetic deepened before their occurrence, usually by increasing the concentration of inhaled anesthetic. Failure to match the anesthetic depth to the intensity of the surgical stimuli can easily result in laryngospasm in patients who have not been administered neuromuscular blockers.

Fatigue of the anesthesiologist is a common problem in administering general anesthesia by mask if the operation is long and the airway is difficult to manage. There are many ways to minimize fatigue. Adjusting the height of the operating room table so that the patient's head is at a level between the anesthesiologist's waist and shoulders, while keeping the left arm and elbow tucked against the side helps to reduce shoulder and elbow strain. Use of a retaining strap can lessen reliance on the forearm muscles to maintain an adequate mask seal. The length of time for which general anesthesia by face mask can be safely administered depends in great part on the ease of maintaining the airway and mask seal.

1. Intravenous Induction

In the case of general anesthesia by mask airway after intravenous induction, the anesthesia workspace should be prearranged in the standard manner. Equipment for intubation should always be readily available, as should

various artificial airway devices, in case difficulty is encountered in mask ventilation of the native airway. All drugs expected to be used should be predrawn into labeled syringes. Premedication with a combination of an anxiolytic (e.g., midazolam), narcotic analgesic (e.g., fentanyl), and antisialogogue (e.g., glycopyrrolate) may be done at the discretion of the anesthesiologist.

Preoxygenation is then performed in the usual fashion, typically followed by an induction dose of intravenous anesthetic (most commonly propofol, but any potent, short-acting sedative or amnestic may be used successfully). This frequently results in apnea (particularly if the patient had been premedicated with a narcotic analgesic), which then mandates that the anesthesiologist manually ventilate the patient. During this period of controlled ventilation by mask, increasing concentrations of inhalation anesthetic are titrated to achieve the desired depth of anesthesia. Ventilation is best controlled until incision, when the increased stimulation is often sufficient to promote spontaneous ventilation. Attempts to achieve spontaneous ventilation before the onset of surgical stimulation usually require a decrease in the depth of anesthesia, and the patient often is too lightly anesthetized when the procedure begins. After the patient resumes spontaneous ventilation, the levels of inhalational anesthetic and narcotic analgesic can be titrated to achieve balanced anesthesia. If upper airway obstruction occurs at any time during this sequence, it should be managed as described in "Nonintubation Approaches to Establish Airway Patency."

2. Inhalation Induction

Inhalation induction of general anesthesia by mask is most commonly performed in children to avoid the discomfort and difficulty of placing an intravenous catheter in an awake patient. In an adult, inhalation induction is often considered when maintaining spontaneous ventilation is paramount (e.g., airway tumors, anterior mediastinal masses with airway compromise).

The first approach to inhalation induction is to preoxygenate the patient with 100% oxygen and then rapidly increase the inhaled concentration of volatile anesthetic to maximum levels. This is most commonly done with sevoflurane, because it is associated with a minimal degree of airway irritation (compared with desflurane), and its vaporizer can be set to deliver up to 8% inspired concentration (approximately 4 times the minimum alveolar concentration [4 MAC]). This approach frequently works well in young children who are unable to be coached through a slower induction, but it is associated with more bradycardia and coughing.

The second approach, which tends to be effective in older children and adults, involves preoxygenating the patient and then slowly introducing the inhalation agent in an incremental fashion while coaching the patient through the sensations experienced with increasing levels of anesthetic. As the patient nears the second stage of anesthesia (heralded by uneven respirations and agitation), it is common to rapidly increase the concentration of the volatile agent (and introduce up to 70% nitrous oxide) to more quickly achieve a deeper plane of anesthesia. After a sufficient depth of anesthesia is obtained, the concentration of inhalation anesthetic (and intravenous narcotic) can be titrated as described earlier.

V. CHOOSING AN AIRWAY TECHNIQUE

Choosing an airway technique for conducting general anesthesia is just as important a medical decision as choosing the drugs and doses to be used. It is based on a risk-benefit analysis of various factors related to the patient, the surgical procedure, the surgeon, and the anesthesiologist involved. The three commonly employed airway techniques that are compatible with a semiclosed or closed breathing system and allow for assisted or controlled ventilation are face mask, LMA, and endotracheal intubation. They vary in their ability to seal the airway, maintain airway patency, and free the hands of the anesthetist. They are associated with different degrees of patient stimulation and potential complications (Box 15-3).

VI. CONCLUSIONS

Nonintubation management of the airway by face mask continues to be a vital skill in the care of anesthetized and critically ill patients. Although its use as the primary airway management technique has largely been supplanted by the LMA, it remains an essential part of other approaches to airway management as a transitional technique during induction and emergence or as a back-up plan when other techniques fail. With the increasing use of moderate to deep procedural sedation in the operating room, the anesthesiologist is frequently required to employ nonintubation airway maneuvers and artificial airway devices to provide supplemental oxygen and to monitor and support ventilation. Understanding the advantages, disadvantages, and limitations of various airway management techniques continues to be a cornerstone of a safe and effective practice of anesthesia.

VII. CLINICAL PEARLS

- An understanding of nonintubation ventilation is critical for the safe management of the airway. It can be applied to many clinical scenarios as a primary management technique or a rescue technique.
- A thorough understanding of upper airway anatomy and physiology is necessary to appreciate the therapeutic maneuvers and devices employed in airway management.
- Airway obstruction can be partial or complete. Partial upper airway obstruction is recognized by noisy inspiratory or expiratory sounds (e.g., snoring). Complete airway obstruction is a medical emergency that requires immediate attention. Signs include inaudible breath sounds; use of accessory neck muscles; sternal, intercostal, and epigastric retraction with inspiratory effort; absence of chest expansion on inspiration; and agitation.

BOX 15-3 Airway Management Choices

Face Mask with Oropharyngeal Airway

Indications: Ventilation preceding endotracheal intubation, failed endotracheal intubation, awake or lightly sedated patient requiring a high inspired oxygen concentration

Advantages: Can be done on an awake patient, does not require neuromuscular blocking agents, minimally stimulating to the patient

Disadvantages: Requires constant attention (left hand of anesthesia provider is continuously on the patient's face or mask), gastric insufflation common if ventilatory pressures frequently exceed 20 cm H_2O, minimal protection from aspiration of regurgitated gastric contents

Contraindications: Known increased risk of vomiting or regurgitation, known significant airway obstruction, surgical duration to exceed 60 minutes, adverse patient position (any position other than supine)

Complications: Aspiration risk highest of the three techniques, lip or dental trauma, inadequate airway patency (laryngospasm, upper airway obstruction), facial pressure injury (nerve injury from fingers or retaining straps)

Laryngeal Mask Airway

Indications: Failed endotracheal intubation, difficult mask ventilation

Advantages: Does not require neuromuscular blocking drugs (return to spontaneous ventilation typically faster than with endotracheal intubation), generally smoother emergence than with endotracheal intubation, frees the hands of the anesthesia provider (after placement)

Disadvantages: Cannot reliably generate more than 30 cm H_2O of positive pressure, typically requires general anesthetic for placement, does not prevent laryngospasm, risk of atelectasis with extended duration (>2 hours), minimal protection from aspiration of regurgitated gastric contents

Contraindications: Known increased risk of vomiting or regurgitation, known significant airway obstruction, high positive ventilatory pressures required (e.g., laparoscopy)

Complications: Regurgitation and aspiration, laryngospasm, inadequate placement and inadequate ventilation, lingual nerve injury, pharyngeal trauma

Endotracheal Tube Airway

Indications: Increased risk of vomiting or regurgitation, high airway pressures anticipated, inaccessibility of airway during the procedure, need for prolonged controlled ventilation

Advantages: Most secure airway, seals the trachea from the upper airway (lowest risk of aspiration of gastric contents), can remain in place for extended duration (days), can generate the highest inspiratory pressures, laryngospasm not possible after placement

Disadvantages: Most difficult to place of the three techniques, most stimulating to the patient during placement (nociceptive response to tracheal foreign body), coughing during and after extubation and emergence, usually requires neuromuscular blocking drugs to place, can lead to death if esophageal misplacement unrecognized

Contraindications: Unavailability of capnography (relative), significant morbidity from possible minor voice changes (e.g., professional singer) (relative)

Complications: Coughing and straining at emergence and extubation, post-extubation laryngospasm, hypertension/tachycardia, bronchospasm, hoarseness, unrecognized esophageal intubation

- Two simple maneuvers can relieve upper airway obstruction by lengthening the anterior neck distance from the chin to the thyroid notch: head-tilt-chin lift and jaw thrust.
- When simple airway maneuvers fail to establish upper airway patency, it is often necessary to employ artificial airway devices, such as oropharyngeal airways and nasopharyngeal airways.
- Ventilatory assistance can be achieved through several alternatives other than intubation and typically include bag-mask-valve systems.
- To achieve adequate ventilation using a mask, the user's left hand grips the mask with the thumb and index finger around the collar. The left side of the mask fits into the palm, with the hypothenar eminence extending below the left side of the mask. To improve airway patency, a chin lift is performed using the middle or ring finger of the left hand. Proper sizing of the mask and continuous observation for leaks are crucial.
- The effectiveness of mask ventilation should be judged by careful attention to and frequent reassessment of many factors: exhaled tidal volume, chest excursion, presence and quality of breath sounds, pulse oximetry, and capnography (when available).

VI. Endotracheal Intubation for Anesthesia
VII. Conclusions
VIII. Clinical Pearls

I. INTRODUCTION

Endotracheal intubation is placement of an endotracheal tube (ETT) into the trachea as a conduit for ventilation or other lung therapy. The benefits of endotracheal intubation are shown in Box 16-1. Historically, endotracheal ventilation arose as a means of resuscitation by a tracheostomy and progressed with the development of the ETT, which provided protection of the lungs from aspiration. The eventual discovery of inhalation anesthesia facilitated surgical applications requiring a secure airway, controlled ventilation, and lung therapy. This chapter reviews these primary indications for endotracheal intubation in the context of resuscitation, prehospital airway management, emergency medicine, intensive care, and anesthesiology.

II. ENDOTRACHEAL INTUBATION FOR RESUSCITATION

In 1543, Andreas Vesalius, a Belgian anatomist, was probably the first to perform endotracheal intubation by inserting a cane tube through a tracheostomy into the trachea of a pig. This landmark development allowed controlled ventilation and laid the foundation for subsequent advances in resuscitation. Endotracheal intubation for human resuscitation was first performed in 1754 by an English surgeon, Benjamin Pugh, who orally intubated an asphyxiated neonate with his *air pipe*. This was followed in 1788 by Charles Kite, another English surgeon, who reported the use of his curved metal cannula, which he introduced blindly into the trachea of several drowning victims from the river Thames.[1]

Endotracheal intubation remains the gold standard for maintaining an airway and providing ventilation in patients requiring cardiopulmonary resuscitation (CPR).[2] Although alternative ventilation techniques have been successfully used, including bag-mask ventilation and supralaryngeal airway (SLA) devices, and there is no evidence to support any specific technique for airway maintenance and ventilation during CPR,[2] there are many advantages of endotracheal intubation during resuscitation. Endotracheal intubation provides ventilation during continuous chest compressions without interruption,[3] protection against aspiration, minimal gastric inflation, and a clear airway for effective ventilation (particularly in the presence of low lung compliance and high resistance). Disadvantages include unrecognized esophageal or endobronchial intubation,[4] prolonged intubation attempts, ETT dislodgement, and hyperventilation. These problems are particularly prevalent among inexperienced practitioners.

The best airway technique for resuscitation depends on the patient's needs and clinical circumstances, the availability of appropriate equipment, and the skill of the rescuer.[2,5] Solutions to these problems involve training in airway management, appropriate selection of airway devices, and patient monitoring.

Endotracheal intubation for resuscitation of the newborn is indicated if bag-mask ventilation has been prolonged or is ineffective or if chest compressions are indicated. Care and experience is required to avoid trauma and esophageal intubation. Endotracheal intubation may also be indicated for tracheal obstruction due to meconium or other causes in nonvigorous infants when suction is required; however, routine intubation and suctioning of vigorous infants born through meconium liquor are not recommended.[6,7]

Drowning victims who suffer cardiopulmonary arrest require early reversal of hypoxemia and airway protection, ideally with a cuffed ETT.[8] A range of ventilation techniques has been suggested for victims of drowning. Endotracheal intubation has the advantage of providing a clear secure airway with positive-pressure ventilation

BOX 16-1 Benefits of Endotracheal Intubation

1. A patent airway by oral, nasal or tracheal routes
2. Controlled ventilation with up to 100% oxygen
3. Ventilation with high airway pressure
4. Airway protection from aspiration
5. Removal of secretions
6. Lung isolation
7. Administration of medication including anesthetic gases

(PPV) in the presence of low lung compliance and high airway resistance.

Airway management for electrocution may require early endotracheal intubation if there are electric burns around the face and neck causing soft tissue edema and airway obstruction.[8] Chapter 44 provides further details.

III. ENDOTRACHEAL INTUBATION FOR PREHOSPITAL CARE

Emergency endotracheal intubation in the prehospital environment often occurs in unfavorable conditions on patients who can be critically ill with shock, cardiopulmonary arrest, traumatic brain injury (TBI), airway trauma, or uncorrected respiratory failure. There are no prospective, controlled trials comparing basic and advanced prehospital management of adult trauma patients, but the benefit of endotracheal intubation has been described in several studies.[9-11] Some evidence suggests that clinical outcomes of children who have had prehospital endotracheal intubation by paramedics are no better than outcomes of children who have only received bag-mask ventilation.[12] Another study of children, however, indicates that prehospital endotracheal intubation performed by a helicopter-transport medical team is safe and effective, but complications of this procedure performed by emergency medical service paramedics was unacceptably high.[13]

Prehospital endotracheal intubation is recommended by the international Brain Trauma Foundation guidelines for all patients with a Glasgow Coma Scale (GCS) score of 8 or less.[14] Early treatment of hypoxia, normoventilation, and prevention of aspiration are associated with improved outcomes in this group of patients.[10] Despite these recommendations, compliance is low, and some clinical data have shown an association between early intubation and increased mortality.[15-17]

The increased mortality associated with prehospital intubation may be caused by suboptimal intubation performance and hyperventilation.[18] Endotracheal intubation is significantly more difficult to manage in the prehospital setting. In a study of 1106 prehospital endotracheal intubations by anesthesia-trained emergency physicians, trauma patients were more often associated with difficult airway management and failed intubation than nontrauma patients.[19] In this study, the difficult airway occurred in 14.8% of prehospital intubations compared with an estimated incidence of 1% to 4% in the operating room.[20] This has prompted some to suggest techniques such as SLAs or alternatives to direct laryngoscopy should be used for prehospital airway management, particularly by less experienced personnel.[5,21]

Controlled ventilation improves the outcome of TBI, but prehospital control of P_{ACO_2} is inconsistent. In a randomized, controlled trial of prehospital ventilated TBI patients, normoventilation occurred in only 12.9% when capnography was not used, compared with 57.5% for the monitored group.[22] Although capnography is commonly used and recommended to confirm correct ETT placement and monitor mechanical ventilation, the P_{ETCO_2} is not a reliable indicator of P_{ACO_2}. Arterial blood gas monitoring may improve the quality of prehospital mechanical ventilation, particularly for patients who require tight control of P_{ACO_2} or patients needing lengthy transportation.[23]

IV. ENDOTRACHEAL INTUBATION FOR EMERGENCY MEDICINE

Management of the airway in the emergency department (ED) is often a fine balance between urgency and risk. The time to evaluate the patient, examine the airway, and prepare an airway plan can be limited because the patient is deteriorating or in extremis. The patient is often physiologically unstable, at risk for aspiration, uncooperative, or unconscious but in need of urgent attention. Managing the airway in the presence of a potentially unstable cervical spine is common. Medical history is often incomplete or unobtainable. Preoperative airway assessment may not be possible in the ED.[24] Such risks must be tempered by the urgency of the clinical situation.

In the ED, the urgency of many clinical situations means that the benefits of endotracheal intubation outweigh the risks. The benefits of endotracheal intubation for emergency medicine patients are the same as those for elective surgical patients: provision of a secure airway, controlled ventilation, airway protection, and removal of secretions. The risks of endotracheal intubation in critically ill patients include hemodynamic instability, esophageal intubation, pneumothorax, and pulmonary aspiration.[25] These risks make it essential that medical personnel, skilled in airway management and using suitable airway equipment, are available to attend the patient. Risks are heightened when airway management is required away from the operating room and when multiple endotracheal intubation attempts are made.[26,27] In a study observing more than 2500 endotracheal intubation attempts outside the operating room, Mort calculated the increased relative risk for more than two intubation attempts for hypoxemia, regurgitation of gastric contents, aspiration of gastric contents, bradycardia, and cardiac arrest and showed a significant increase in these complications with repeated laryngoscopic attempts.

The indications for endotracheal intubation often relate to clinical urgency. If the patient is in cardiorespiratory arrest, for example, or near arrest with absent muscle tone and loss of protective airway reflexes, endotracheal intubation in the ED becomes an emergency. In this situation, immediate direct laryngoscopy and oral intubation with a cuffed ETT, without adjunct drugs, is indicated.

Urgent endotracheal intubation is indicated for a range of situations involving the trauma patient, when the

airway may be at immediate or potential risk, or the patient's medical condition requires urgent airway management. These patients may be managed with a rapid sequence induction (RSI) and endotracheal intubation. RSI with preoxygenation followed by induction of anesthesia with a potent anesthetic agent (etomidate, propofol, ketamine, or thiopentone) and a rapid- and short-acting muscle relaxant (succinylcholine) is the gold standard technique for oral endotracheal intubation in the ER. RSI has a high success rate and is the main back-up procedure when other oral or nasal intubation techniques fail and require rescue, which occurs in up to 2.7% of emergency intubations.[28] The use of cricoid pressure for RSI is debatable and may compromise airway management.[29,30] Urgency may be assessed clinically from signs of respiratory distress and impending fatigue (Box 16-2).

Other medical conditions may justify a more conservative approach to airway management, depending on the progress of medical treatment, including anaphylaxis, burns, asthma, laryngotracheobronchitis, or acute epiglottis. These patients may require endotracheal intubation if the clinical situation deteriorates or if the progress of the condition is likely to deteriorate. Airway management for unconscious patients with drug overdose is often managed without endotracheal intubation.

RSI is contraindicated if the patient has a mouth opening that is impossible or severely limited and in patients with intrinsic pathology of the larynx, trachea, or distal airway. This includes patients presenting with stridor after a penetrating neck injury and patients in respiratory distress with a mediastinal mass. Restricted mouth opening can result from angioedema, Ludwig's angina, an immobile mandible, cervical spine pathology, a wired jaw, or airway distortion.[31] These patients may require alternative intubation techniques and may benefit from a collaborative multidisciplinary approach to airway management.[32]

Awake intubation with a flexible fiberoptic bronchoscope is promoted for cooperative, stable patients with a known or suspected difficult airway.[33] This technique is inappropriate in the ED for the rapidly deteriorating patient, especially when performed by inexperienced practitioners. Endotracheal intubation may also be warranted for the unstable emergency patient requiring a secure and safe airway during transfer for computed tomography or magnetic resonance imaging in the radiology department or to the intensive care unit (ICU).

V. ENDOTRACHEAL INTUBATION FOR INTENSIVE CARE

The most common indications for endotracheal intubation in the ICU are acute respiratory failure, shock, and neurologic disorders.[34] Endotracheal intubation is indicated for controlled ventilation of a patient with refractory hypoxemia, often in the presence of multiple organ failure. Predictors of hypoxemic respiratory failure appear in Box 16-3.

The decision to intubate is usually made on clinical grounds and based on the expected prognosis of the patient's condition. Clinical signs (see Box 16-2) or evolving deterioration in objective criteria (Table 16-1) may support this decision.

Urgent intubation in the ICU may be required immediately for apnea, airway obstruction, reintubation, or cardiopulmonary arrest. If the patient is unconscious, without airway reflexes, or paralyzed, endotracheal intubation can proceed without pharmacologic support.

RSI, commonly used in the ED, may not be as applicable for the unstable ICU patient. Preoxygenation of the patient with limited respiratory reserve is compromised by decreased functional residual capacity (FRC) and increased dead space.[35] Commonly used induction agents can adversely affect the unstable patient. In these situations, a non-RSI technique with sedation and local anesthetic may be used.

Noninvasive ventilation techniques have become increasingly popular over the past 20 years, with development of clear indications and a range of masks and interfaces. Indications include patients with cardiogenic pulmonary edema and exacerbations of chronic obstructive pulmonary disease (COPD). Noninvasive ventilation is contraindicated for respiratory arrest or patients who are unable to be mask ventilated.[36] Relative contraindications for noninvasive ventilation that favor endotracheal intubation are listed in Box 16-4.

The incidence of airway mishaps in the ICU involving endotracheal intubation is relatively low. In a study of 5046 intubated ICU patients, the airway accident rate was 0.7%. Accidents were less common with ETTs than with tracheostomies.[37] Self-extubation is the most common ETT accident, with rates of up to 16%. With strict clinical monitoring and in-service education, this rate can be reduced to 0.3%. After unplanned extubation, reintubation rates range from 14% to 65%.[38]

BOX 16-2 Signs of Respiratory Distress and Impending Fatigue

1. Look of anxiety (frowning)
2. Signs of sympathetic overactivity (dilated pupils, forehead sweat)
3. Dyspnea (decreased talking)
4. Use of accessory muscles (holds head off pillow)
5. Mouth opens during inspiration (licking of dry lips)
6. Self-PEEP (pursed lips, expiratory grunting, groaning)
7. Cyanosed lips
8. Restlessness and fidgeting (apathy and coma)

PEEP, Positive end-expiratory pressure.
Data from references 61 to 64.

BOX 16-3 Predictors of Hypoxemic Respiratory Failure

1. No or minimal rise in the ratio of PaO_2 to FIO_2 after 1 to 2 hours
2. Patients older than 40 years
3. High acuity illness at admission (simplified acute physiology score > 35)[65]
4. Presence of acute respiratory distress syndrome (ARDS)
5. Community acquired pneumonia with or without sepsis
6. Multiorgan failure

Adapted from Nava S, Hill N: Non-invasive ventilation in acute respiratory failure. *Lancet* 374:250–259, 2009.

TABLE 16-1
Objective Quantitative Criteria for Endotracheal Intubation

RESPIRATORY FUNCTION		Acceptable Range	Possible Intubation, Chest PT, Oxygen, Drugs, Close Monitoring	Possible Intubation, Probable Intubation, and Ventilation
Category	**Variable**			
Mechanics	Vital capacity (mL/kg)	67-75	65-15	<15
	Inspiratory force (cm H_2O)	75-100	50-25	<25
Oxygenation	$P_{AO_2} - P_{aO_2}$ (mm Hg) room air	<38	38-55	>55
	$F_{IO_2} = 1.0$	<100	100-450	>450
	P_{aO_2} (mm Hg) room air	<72	72-55	<55
	$F_{IO_2} = 1.0$	>400	400-200	<200
Ventilation	Respiratory rate (breaths/min)	10-25	25-40 or <8	>40 or <6
	P_{aCO_2} (mm Hg)	35-45	45-60	<60

$P_{AO_2} - P_{aO_2}$, Alveolar-arterial partial pressure of oxygen difference; P_{aCO_2}, arterial partial pressure of carbon dioxide; P_{aO_2}, arterial partial pressure of oxygen; F_{IO_2}, inspired concentration of oxygen; *PT*, physical therapy.
Adapted from Pontpoppidan H, Geffin B, Lowenstein E: Acute respiratory failure in the adult: 2. *N Engl J Med* 287:743–752, 1972.

In addition to mechanical ventilation, endotracheal intubation facilitates other types of respiratory therapy. Patients with moderate to severe carbon monoxide poisoning benefit from 100% oxygen. This concentration of oxygen in normobaric conditions is most reliably achieved through an ETT. Other therapy through an ETT includes synthetic surfactant for premature newborns with established respiratory distress syndrome (RDS). Nitric oxide is administered to adults, infants, and neonates receiving mechanical ventilation to treat acute lung injury, acute respiratory distress syndrome (ARDS), and RDS. Heliox is a blend of oxygen and helium gas used to improve gas flow to patients with airway narrowing such as in asthma. Use of the ETT as a route for emergency drug administration during CPR is no longer recommended due to unpredictable plasma concentrations and the reliability of the intraosseous route.[2]

Clearing secretions by suctioning through the ETT is important to maintain ventilation by avoiding atelectasis and consolidation. Suctioning is associated with a number of complications such as hypoxemia, cardiovascular instability, elevated intracranial pressure, atelectasis, infection, and trauma to the airway. Evidence-based recommendations for endotracheal suctioning of adult intubated intensive care patients are provided in Box 16-5.[39]

VI. ENDOTRACHEAL INTUBATION FOR ANESTHESIA

Significant improvements to the design of the ETT have been historically precipitated by evolving surgical techniques. Upper airway surgery performed in the early 19th century led to an increase in postoperative pneumonia cases caused by aspiration of surgical debris. In 1878, William Macewen first used an ETT in anesthesia for a patient with a tumor of the base of the tongue.[40] Macewen was also concerned with preventing aspiration, and in 1880, he developed a metal ETT with a sponge collar that he introduced blindly through the mouth for endotracheal intubation. In 1888, O'Dwyer designed a curved metal cannula with a conical end to provide a laryngeal seal. This device helped raise intratracheal pressure to avoid pulmonary collapse during thoracic surgery. In 1895, Alfred Kirstein performed awake direct laryngoscopy with the *autoscope*.[41] This primitive instrument was the precursor of other laryngoscopes developed by Jackson and others, aiding application of the ETT. World War I precipitated a demand for plastic surgery of the head and neck, which led to oral and nasal ETT designs with pharyngeal or tracheal cuffs by Rowbotham and Magill. Anesthetic management for thoracic surgery

BOX 16-4 Relative Contraindications to Noninvasive Ventilation and Indications for Endotracheal Intubation

1. Medically unstable
2. Agitated and uncooperative
3. Unable to protect the airway
4 Swallow is impaired
5. Excessive secretions that are not being adequately managed
6. Multiple organ failure (two or more organs)
7. Recent upper airway or upper gastrointestinal surgery
8. Failed noninvasive ventilation

Adapted from Nava S, Hill N: Non-invasive ventilation in acute respiratory failure. *Lancet* 374:250–259, 2009.

BOX 16-5 Recommendations for Endotracheal Suctioning of Intubated Adult Patients in Intensive Care

1. Suction no longer than 15 seconds.
2. Perform continuous rather than intermittent suctioning.
3. Avoid saline lavage.
4. Provide hyperoxygenation before and after suctioning.
5. Provide hyperinflation combined with hyperoxygenation routinely.
6. Always use an aseptic technique.
7. Use closed or open suction systems.

Adapted from Pedersen CM, Rosendahl-Nielsen M, Hjermind J, et al: Review. Endotracheal suctioning of the adult intubated patient—What is the evidence? *Intensive Crit Care Nurs* 25:21–30, 2009.

led to the next advance in ETT design with the introduction of the first endobronchial tubes in 1932 by Gale and Waters.[1] By this time, the technique of endotracheal intubation was established, prompting the statement by Macintosh that "the ability to pass an ETT under direct vision was the hallmark of a successful anesthesiology."[42]

Endotracheal intubation is used extensively in modern anesthesia for elective and emergency indications as a primary and a rescue airway. Patient characteristics and surgical indications often dictate the appropriateness of an ETT. Elective endotracheal intubation is indicated for patients requiring anesthesia for major surgery when controlled ventilation, resuscitation, airway access, patient positioning, and duration of surgery are factors in the overall airway plan. Specialized ventilation tubes are used for specific indications. Examples include thoracic surgery requiring lung isolation, laryngeal surgery requiring microlaryngoscopy or laser treatment, and nasal intubation for limited mouth opening, oral surgery, and maxillofacial surgery.

Endotracheal intubation may occur when the primary surgical plan changes. An example is conversion of a diagnostic procedure such as bronchoscopy to a lung resection. Occasionally, complications arise during simple anesthesia that necessitate endotracheal intubation during resuscitation, such as major hemorrhage, anaphylaxis, or malignant hyperthermia.

SLAs rival the oral ETT for routine airway management in the fasted elective patient. Limitations of the SLA include the inability to provide a nasal airway, the volume of the SLA in the oral cavity, and inadequate PPV due to a disrupted airway, low lung compliance, or high airway resistance. These are important considerations when choosing a suitable airway device. Second generation laryngeal masks with improved cuff seal and gastric drainage tubes have extended the application of the SLA.[43] Procedures that previously were only considered suitable for endotracheal intubation such as laparoscopic surgery,[44] prone position,[45,46] surgery in obese patients,[47,48] prolonged surgery,[49] tonsillectomy,[50] and craniotomy in sedated patients can now be managed with an SLA in experienced hands with close monitoring of airway quality.[51] Selection of an SLA as a ventilation device should be based on case selection with careful individual patient assessment.

Safe airway management should always include a plan B for failed mask or SLA ventilation. Conversion of the airway to endotracheal intubation may occur as plan B after inadequate mask or SLA ventilation. Impossible mask ventilation during anesthesia has an incidence of 0.15% and is associated with neck changes from irradiation, male gender, sleep apnea, a Mallampati III or IV score, and the presence of a beard.[52] In a study by Kheterpal of 53,041 operations that included an attempt at mask ventilation, 77 patients proved impossible to ventilate (0.15%). Of those 77 patients, 19 (25%) were also difficult to intubate, but 15 of the patients were intubated. Ultimately, 74 of the 77 impossible mask ventilation cases were intubated,[52] reinforcing the value of endotracheal intubation for failed ventilation.

The American Society of Anesthesiologists (ASA) *Practice Guidelines for Management of the Difficult Airway* recommend awake intubation for the patient with a known difficult airway.[33] This usually involves endotracheal intubation with a flexible fiberoptic bronchoscope, but other techniques have been described, including retrograde awake intubation,[53] submental awake intubation,[54] awake intubating LMA,[55] and awake lightwand intubation.[56] The outcome of each technique is a secure airway with an ETT.

Endotracheal intubation is regarded as the gold standard for protection against aspiration of gastric contents in anesthetized patients.[57] However, evaluation of the cuff seal is important because of the risk of fluid draining past the cuff. This particularly applies to high-pressure, low-volume cuffs.[58] Evidence evaluating the relative risk of an ETT or SLA for pulmonary aspiration is limited. An analysis of the relative risk in 65,712 procedures found that the use of an LMA was not associated with an increased risk of pulmonary aspiration compared with an ETT.[59]

VII. CONCLUSIONS

The benefits of endotracheal intubation apply to patients in many clinical situations. Although recent developments of SLAs have provided a useful alternative, particularly for day surgery procedures or for inexperienced practitioners in emergency situations, endotracheal intubation remains the first choice in many situations. The limiting factors for the safe application of this important technique are the skill of the practitioner, the use of patient monitoring, and an understanding of the indications for endotracheal intubation. The ability to safely perform endotracheal intubation remains one of the most important skills for airway specialists.

VIII. CLINICAL PEARLS

- The best airway technique for resuscitation depends on the patient's needs and clinical circumstances, the availability of appropriate equipment, and the skill of the rescuer.[2,5]
- Prehospital endotracheal intubation improves outcome for all patients with a GCS score of 8 or less, with early treatment of hypoxia, normoventilation, and prevention of aspiration, and it is recommended by the international Brain Trauma Foundation guidelines.[10]
- The increased mortality associated with prehospital intubation may be caused by suboptimal intubation performance and hyperventilation.[18]
- Elective endotracheal intubation is indicated for patients requiring anesthesia for major surgery when controlled ventilation, resuscitation, airway access, patient positioning, and duration of surgery are factors in the overall airway plan.
- SLAs rival the oral ETT for routine airway management in the fasted elective patient, but limitations of the SLA include inadequate PPV (particularly in the presence of a disrupted airway, low lung compliance,

or high airway resistance), the volume of the SLA in the oral cavity, and the inability to provide a nasal airway.

- Endotracheal intubation protects against aspiration of gastric contents in anesthetized patients[57]; however, the use of a LMA is not associated with an increased risk of pulmonary aspiration compared with an ETT.[59]
- Endotracheal intubation facilitates various types of respiratory therapy, including mechanical ventilation, 100% O_2 for carbon monoxide poisoning, nitric oxide, surfactant, Heliox, and suctioning.
- Risks of endotracheal intubation are heightened when airway management is required away from the operating room and when multiple endotracheal intubation attempts are made.[26,27,60]
- The limiting factors for the safe application of endotracheal intubation are the skill of the practitioner, the use of patient monitoring, and an understanding of the indications for endotracheal intubation. The ability to safely perform endotracheal intubation remains one of the most important skills for the airway specialist.

Creation
Our very breath, pre-language of the lingus,
Unspoken and unseen, lies all around us;
It tunnels through a darkened path to bring us
Before the guarded gates that would confound us:
Dentition, palate, epiglottic folds
Are navigated as the case is started
And followed through to cartilage that holds
The two true cords, those gleaming pillars, parted;
Here human hands, left trembling with creation,
Are re-creating life as it began,
Beginning with the step of intubation,
The God-breathed breath of life blown into man.
Stephen Harvey

I. A SHORT HISTORY OF ENDOTRACHEAL INTUBATION

As we participate in the 21st century practice of medicine, it is useful to recollect the origin and development of some of the techniques commonly used for airway management. It is remarkable that modern airway techniques are less than 50 years old but are derived from physiologic experiments done primarily in the 18th and 19th centuries. Skilled airway management is a central pillar of the practice of anesthesiology, resuscitation, and critical care, and an appreciation of the evolution and development of airway techniques can improve our understanding and application of these essential skills.

Cannulation of the trachea, or *aspera arteria*, as it was called by Robert Hooke,[1] was initially described as a technique for positive-pressure ventilation (PPV):

> *… the Dog being kept alive by the Reciprocal blowing up of his Lungs with Bellowes, and they suffered to subside, for the space of an hour or more, after his Thorax had been so display'd, and his Aspera Arteria cut off just below the Epigolotis, and bound on upon the nose of the Bellows*

The use of tracheal cannulation for the administration of anesthetics and provision of a patent airway was first reported in 1858 by John Snow in *On Chloroform and Other Anaesthetics*,[2] in which he described a tracheostomy and cannulation for the administration of chloroform in a spontaneously breathing rabbit. The first human use of tracheostomy for anesthesia and protection against aspiration was reported by Trendelenburg in 1869, and it also was accompanied by spontaneous ventilation.[3] In the next 10 years, numerous investigators developed nonsurgical techniques and apparatus for cannulation of the trachea for surgical (ear, nose, throat) or medical (diphtheria) indications. Matas was among the first to advocate the use of PPV through a tracheal cannula to avoid the catastrophic consequences of pneumothorax for a spontaneously ventilating patient during thoracotomy.[5]

Endotracheal anesthesia came into its own during and immediately after World War I because of the volume of facial and mandibular injuries treated in England, especially at the hospital in Sidcup. In 1936, I.W. Magill wrote one of many descriptive treatises on intubation in anesthesia[5]:

> *The maintenance of a free airway has long been recognized as a first principle in general anesthesia and the danger of complete laryngeal obstruction has always been obvious. On the other hand, the cumulative effects of partial respiratory obstruction have, in the past, been*

frequently overlooked and it is not improbable that many of the surgical difficulties, postoperative complications, and even fatalities attributed to the anesthetic agent have been primarily due to an imperfect airway. It may be said without exaggeration that in remedying this defect endotracheal anesthesia has proved as great a factor in the advances of anesthesia as the discovery of new drugs or the development of improved apparatus.

Immediately thereafter, Magill inserts a caveat:

… owing to the ease of control it affords, there is a tendency towards its employment in every operation, regardless of other considerations. This tendency is to be deprecated, especially in the teaching of students. The novice should learn airway control by simple methods in the first instance, for he may be called to administer an anesthetic in circumstances in which artificial devices are not available. Moreover, as the method involves instrumentation, which is not devoid of the risk of trauma, even though it may be slight, intubation should only be attempted when the necessity for it has been considered carefully.

The historical lesson here is that, no matter how routine endotracheal intubation becomes, it is still an invasive procedure with nontrivial risks and significant complications. It should be used for specific indications and only after careful consideration of the balance of risks to and benefits for the patient.

II. LARYNGOSCOPIC OROTRACHEAL INTUBATION

The conventional orotracheal route is the simplest and most direct approach to tracheal cannulation. Done under direct laryngoscopic vision, this technique is the easiest and most straightforward for the purposes of administering general anesthesia, ventilation of critically ill patients, and cardiopulmonary resuscitation. The vocal cords are visualized with the aid of a handheld laryngoscope, and the endotracheal tube (ETT) is introduced and positioned in the trachea under continuous direct observation. After confirmation of correct placement, the tube is secured in place and ventilation assisted or controlled as indicated.

A. Preparation and Positioning

Box 17-1 lists the basic materials required for conventional orotracheal intubation. The materials are grouped according to the temporal sequence of events. All items are required for routine intubation, dealing with common difficulties, or preventing complications. Redundancy is the key in preparing for a critical event, such as endotracheal intubation. All essential equipment (e.g., laryngoscope handles, ETTs) should have readily available back-up counterparts in case of unexpected failure. An assortment of laryngoscope blades, both straight (Miller) and curved (Macintosh), should be available.

BOX 17-1 Basic Equipment for Endotracheal Intubation

Preoxygenation and Ventilation

1. Oxygen (O_2) source
2. Ventilation bag or anesthesia circuit (for positive-pressure ventilation)
3. Appropriately sized face mask
4. Appropriately sized oropharyngeal and nasopharyngeal airways
5. Tongue blade

Endotracheal Tubes

6. Appropriately sized endotracheal tubes (at least twp)
7. Malleable stylet
8. Syringe for tube cuff, 10 mL
9. Jelly and/or ointment, 4% lidocaine (Xylocaine)

Drugs

10. Intravenous anesthetics and muscle relaxants (ready to administer)
11. Reliable, free-flowing intravenous infusion (some pediatric exceptions)
12. Topical anesthetics and vasoconstrictors (for nasotracheal intubation)

Laryngoscopy

13. Working suction apparatus with tonsil tip
14. Assortment of Miller blades with functioning battery handle
15. Assortment of Macintosh blades with functioning battery handle
16. Bolsters (folded sheets, towels) for positioning of head and shoulders

Fixation of the Endotracheal Tube

17. Tincture of benzoin
18. Appropriate tape or tie
19. Stethoscope
20. End-tidal carbon monoxide ($ETCO_2$) monitor
21. Pulse oximeter

The proper sequence of events before laryngoscopy should be followed:

1. Adequate access to the head of the bed or table is essential. Removal of side rails and headboard (if outside the operating room) ensures freedom of movement; confirming that the bed or table is locked in position prevents unnecessary and stress-inducing pursuit of the patient around the room. The height of the surface should be adjusted to the level of the laryngoscopist's chest. An experienced aide should be in constant attendance to provide items such as suction lines, airways, tubes, and drugs to the primary laryngoscopist, as well as to apply optimal external laryngeal manipulation (OELM), as needed.
2. The patient must be properly positioned before laryngoscopy. Patients who are uncooperative, agitated, or otherwise mobile may require rapid and efficient positioning after sedation. Pads or rolls should be prepared in advance and be readily at hand.

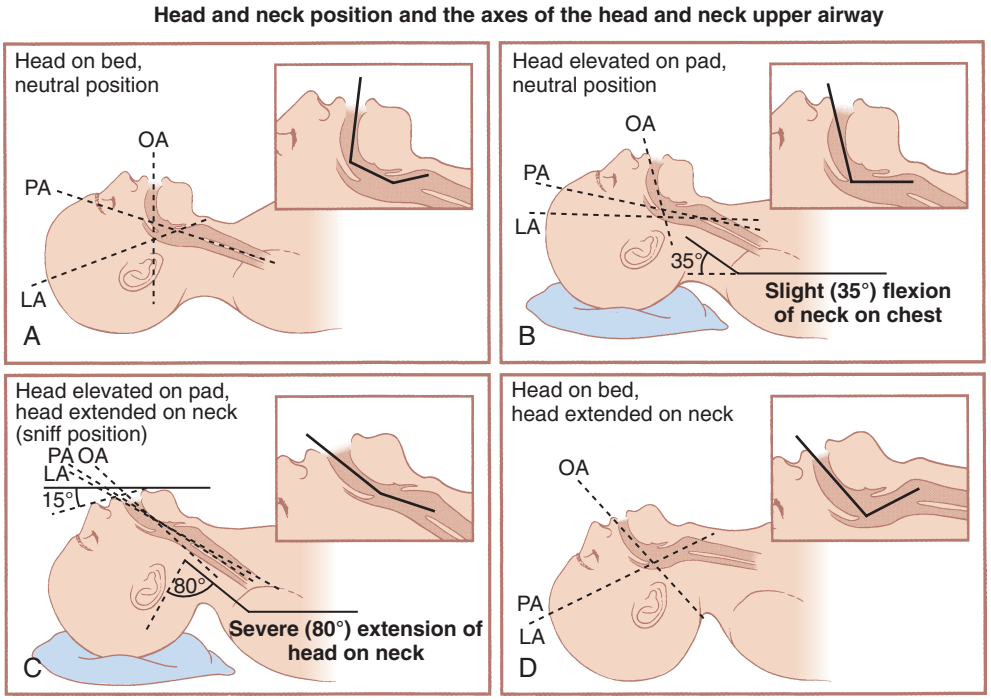

Figure 17-1 Schematic diagrams show the alignment of the oral axis *(OA),* pharyngeal axis *(PA),* and laryngeal axis *(LA)* in four different head positions. Each head position is accompanied by an *inset* that magnifies the upper airway (oral cavity, pharynx, and larynx) and superimposes *(bent bold line)* the continuity of these three axes within the upper airway. **A,** The head is in the neutral position with a marked degree of nonalignment of the LA, PA, and OA. **B,** The head is resting on a large pad that flexes the neck on the chest and aligns the LA with the PA. **C,** The head is resting on a pad (which flexes the neck on the chest). Concomitant extension of the head on the neck brings all three axes into alignment (sniffing position). **D,** Extension of the head on the neck without concomitant elevation of the head on a pad, which results in nonalignment of the PA and LA with the OA. (From Benumof JL, editor: *Airway management: principles and practice*, St. Louis, 1996, Mosby, p 263.)

The earliest attempts at laryngoscopy used the classic positioning of full extension. Described by Jackson in 1913, this position required full extension of the head and neck on a flat surface.[6] After 20 years, he amended his view to one that supported the contemporary *sniffing position* of flexion at the neck and extension at the head.[7] This was accomplished by supporting the head on a pillow that was at least 10 cm thick. Numerous investigators have examined radiographs of subjects to determine the optimal positioning for orotracheal access. Various theoretical models of positioning for intubation have been proposed. For the past 60 years, the three-axis theory has proposed that the oral, pharyngeal, and laryngeal axes should be brought into approximate alignment to best facilitate orotracheal visualization and intubation (Fig. 17-1). Proposed by Bannister and MacBeth in 1944, this model presumes that laryngoscopy is done in the midline (two-dimensional model) and that laryngeal axis alignment is necessary for proper intubation.[8] This idea has been challenged by the work of Adnet and colleagues in imaging studies and clinical comparisons.[9-11]

Adnet's conclusion, however, has been questioned at length.[12] Greenland and colleagues reexamined the issue, finding "the sniffing position the most favorable for direct laryngoscopy" as determined by magnetic resonance imaging (MRI).[13] This perspective has been corroborated by evidence indicating 9 cm as the optimal pillow height.[14] Others have advocated for an *extension-extension position*, in which the head and neck are extended by lowering the head of the table 30 degrees, proposing that direct laryngoscopy requires less axial force in this position than in the sniffing position.[15] Whether the lower cervical spine is flexed, extended, or neutral, the extension of the atlanto-occipital joint remains the critical factor for optimal positioning. The reasonable option in view of conflicting evidence (and patients' variability) is to position the patient with the occiput on a pad (traditional sniffing position) and be prepared to remove the pad (convert to simple extension) if the initial laryngoscopy becomes inadequate (Fig. 17-2).

Obese patients often require more extensive padding (planking) starting at the midpoint of the back to the head to assume an optimal position for laryngoscopy. Occasionally, it is necessary to place towels and blankets under the scapula, shoulders, nape of the neck, and head to flex the neck on the chest (see Figs. 17-1B and 17-2) and extend the head on the neck (see Figs. 17-1C and 17-2). In this instance, the purpose of the scapula, shoulder, and neck support is to give the head room so that it may be extended on the neck. When in doubt, the final assessment of the position should be from a lateral view of the patient, because only a lateral view enables precise assessment of the chest, neck, face, and head axes (see Figs. 17-1C and 17-2).

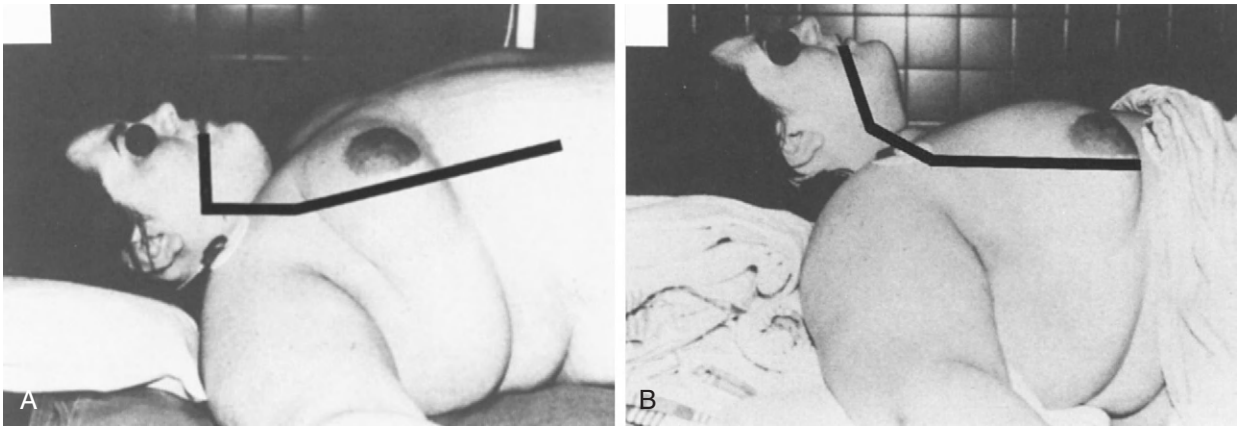

Figure 17-2 **A,** In some obese patients, placing the head on a pillow does not result in the sniffing position; in the obese patient shown and as illustrated by the overlying *bold black line,* the oral and laryngeal axes are perpendicular to one another, the neck is not flexed on the chest, and the head is not extended on the neck at the atlanto-occipital joint. **B,** In the same patient, placing support (e.g., blankets, towels) under the scapula, shoulders, nape of the neck, and head results in a much better sniffing position; the oral, pharyngeal, and laryngeal axes form only a slightly bent curve, the neck is flexed on the chest, and the head is extended on the neck at the atlanto-occipital joint. (From Benumof JL, editor: *Airway management: Principles and practice,* St. Louis, 1996, Mosby, p 264.)

B. Preoxygenation

Instrumentation of the airway may be done on an awake, spontaneously breathing patient. This sometimes is the safest and most prudent approach, but most commonly, laryngoscopy and intubation are performed on an anesthetized and (usually) apneic patient. Because this requires some finite period of time, the patient is at risk for arterial desaturation and hypoxic injury. Preoxygenation is done before laryngoscopy to minimize this risk.

Administration of 100% oxygen (O_2) through a tight-fitting face mask may occur by means of the patient's spontaneous respirations or by PPV by a bag-mask unit. In either case, adequate ventilation must occur to "wash out" alveolar nitrogen (N_2) and fill the lungs with O_2. The goal is to fill the alveoli used in normal tidal breathing and the remaining alveoli and airways constituting the functional residual capacity (FRC). This additional O_2 serves as a reservoir to delay the onset of arterial hypoxia for as long as 5 minutes. A number of guidelines have been proposed to accomplish this potentially lifesaving goal.

Depending on the minute ventilation of the patient (spontaneous or assisted), the time to complete effective preoxygenation varies from 1 to 5 minutes; although in an awake and cooperative patient, this may be mostly accomplished with three or four full, vital capacity (VC) breaths.[16,17] Work has documented the increased efficacy of eight full breaths in about 60 seconds, with times to desaturation approaching those of the more traditional 3- to 5-minute preoxygenation.[18] A higher minute ventilation level leads to more rapid and complete preoxygenation. Measures of the adequacy of preoxygenation include real-time gas analysis of expired O_2 concentration (goal = 95%) and analysis of expired N_2 (goal < 5%). Essential to either of these measurements is the presence of a capnograph waveform with a plateau reflecting the expected alveolar carbon dioxide (CO_2) concentration. This documents the presence of an effective seal of the circuit-bag system to the patient's airway and the effective delivery of 100% O_2. The use of an air-mask-bag unit (AMBU) without an expiratory valve may not provide optimal preoxygenation.[19]

The effectiveness of preoxygenation in preventing hypoxia during laryngoscopy is significantly reduced in the morbidly obese patient. Even with the most careful preoxygenation, the duration of apnea before the onset of hypoxia is one half of the duration seen in patients with normal body weight. This situation is attributed to the considerable reduction in FRC and VC in the obese patient and to the additional reduction attributable to the cephalad diaphragmatic shift related to supine positioning.[20] This places morbidly obese patients at significantly increased risk for injury if any difficulty with ventilation or intubation is encountered.

Pharyngeal insufflation of O_2 can significantly prolong the safe duration of apnea. In a typical adult, approximately 250 mL/min of O_2 is transferred from the lungs into the bloodstream, while only 200 mL/min of CO_2 enters the lungs from the bloodstream (respiratory quotient = 0.8). This alveolar gas deficit causes alveolar pressures to become slightly subatmospheric. If the airway is patent, there is a net flow of gas from the pharynx into the alveoli (apneic oxygenation). If, after adequate preoxygenation, the pharynx is filled with O_2, the onset of hypoxia is delayed because O_2, rather than air, is drawn into the lungs by this mechanism. Pharyngeal insufflation may be conveniently achieved by passing a catheter into the pharynx through a nasopharyngeal airway and attaching an O_2 source at 2 to 3 L/min. Alternatively, some laryngoscopes have a side port suitable for attachment of O_2 tubing. When preoxygenation is followed by pharyngeal insufflation as previously described, in normal but apneic patients, the O_2 saturation from pulse oximetry [Spo_2] remains equal to 98% for 10 or more minutes (although at the end of 10 minutes the arterial carbon dioxide tension [$Paco_2$] may be expected to be about 80 mm Hg).[21]

C. Laryngoscopy

The purpose of direct laryngoscopy is to provide adequate visualization of the glottis to allow correct placement of the ETT with the minimum effort, elapsed time, and potential for injury to the patient. Considerable effort has been expended to develop laryngoscopic techniques and equipment to facilitate this important procedure. Although this textbook outlines numerous techniques for tracheal cannulation, the facilitative use of direct laryngoscopy is by far the most common technique.

Two basic types of laryngoscope blades are the curved blade (Macintosh) and the straight blade with a curved tip (Miller).[22,23] They are designed for right hand–dominant use; the laryngoscope is held in the left hand while the right hand manipulates the ETT. Historically, either hand (or both) could be initially used, shifting the laryngoscope to the left hand while the right hand manipulated the tube. Both blade styles include a flange on the left side of the blade for lateral retraction of the tongue and contain a light-emitting area (bulb or fiberoptic tip). Each blade has a channel with an open right side for visualization of the larynx and for insertion of the ETT (Figs. 17-3 to 17-10). Despite numerous modifications and variations, they are all lighted, handheld retractors for oropharyngeal soft tissues.

Although contact with the upper incisors from the laryngoscope blade should be avoided, some patients with limited mouth opening, front caps, or obvious decay are at risk for damage by even the most innocuous, transient trauma. If the possibility of incisor trauma exists, it seems prudent to provide some protection for the upper teeth. Several materials have been used in the past to guard the upper teeth: a folded strip of lead (introduced by Magill and now obsolete), folded tape, cardboard or alcohol wipe, or a purpose-built mouth guard (as used in contact sports). The disadvantage of any of these is that they occupy a few millimeters of the available mouth opening, reducing the available aperture for laryngoscopy.

Two methods are used to open the mouth and facilitate the introduction of the blade. First, extension of the head on the neck (by pressure from the right hand at the vertex) causes the lips to part and the mouth to open (see Fig. 17-4). Alternatively, the thumb of the right hand can press down on the right lower molar teeth, and the index finger of the right hand can simultaneously press up on the right upper molar teeth (scissors maneuver) (see Fig. 17-5).

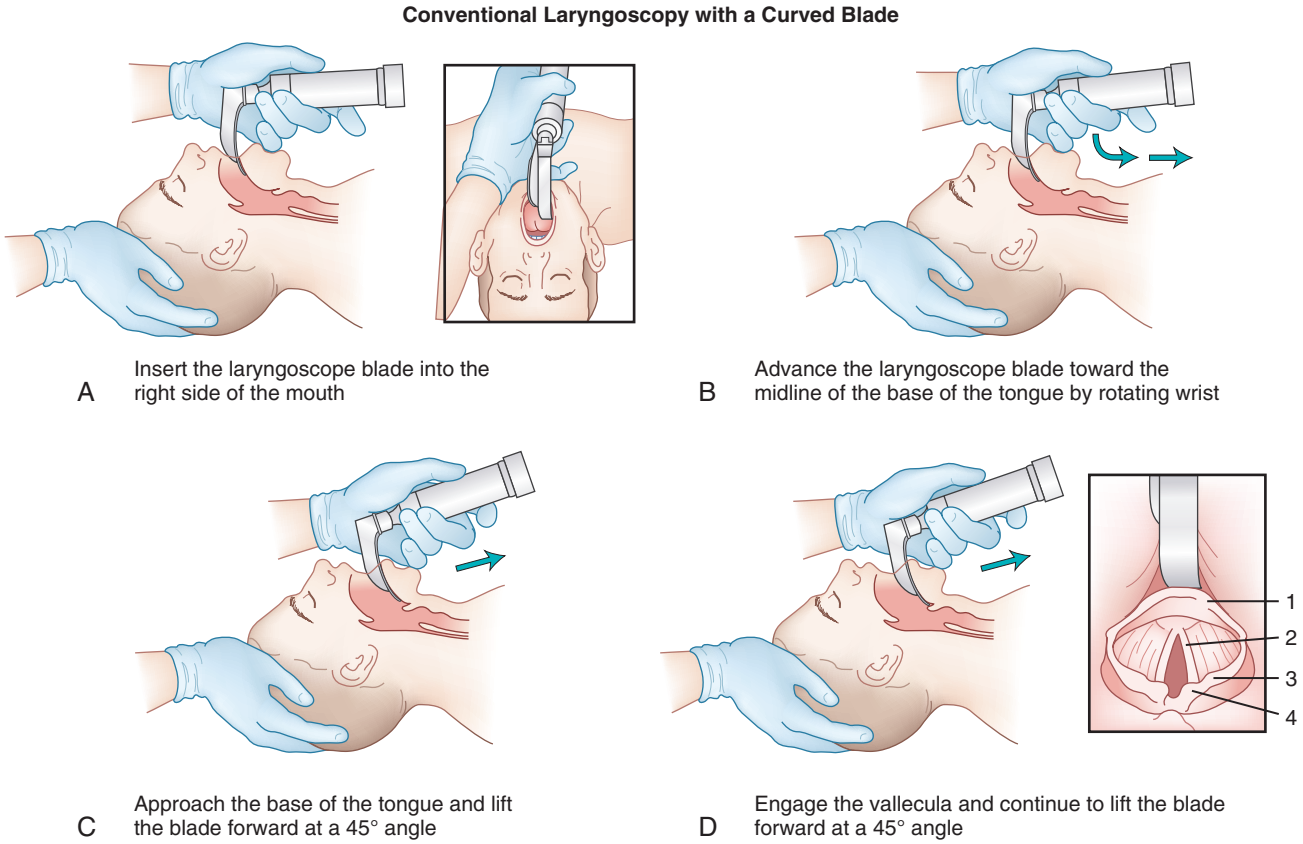

Figure 17-3 Schematic diagrams show how to perform laryngoscopy with a Macintosh blade (curved blade). **A,** As shown in lateral and frontal views, the laryngoscope blade is inserted into the right side of the mouth so that the tongue is to the left of the flange. **B,** In the lateral view, the blade is advanced around the base of the tongue, in part by rotating the wrist so that the handle of the blade becomes more vertical *(arrows)*. **C,** In the lateral view, the handle of the laryngoscope is lifted at a 45-degree angle *(arrow)* as the tip of the blade is placed in the vallecula. **D,** In the lateral view, continued lifting of the laryngoscope handle at a 45-degree angle results in exposure of the laryngeal aperture. The epiglottis *(1)*, vocal cords *(2)*, cuneiform part of arytenoid cartilage *(3)*, and corniculate part of arytenoid cartilage *(4)* are identified in the frontal view. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 267.)

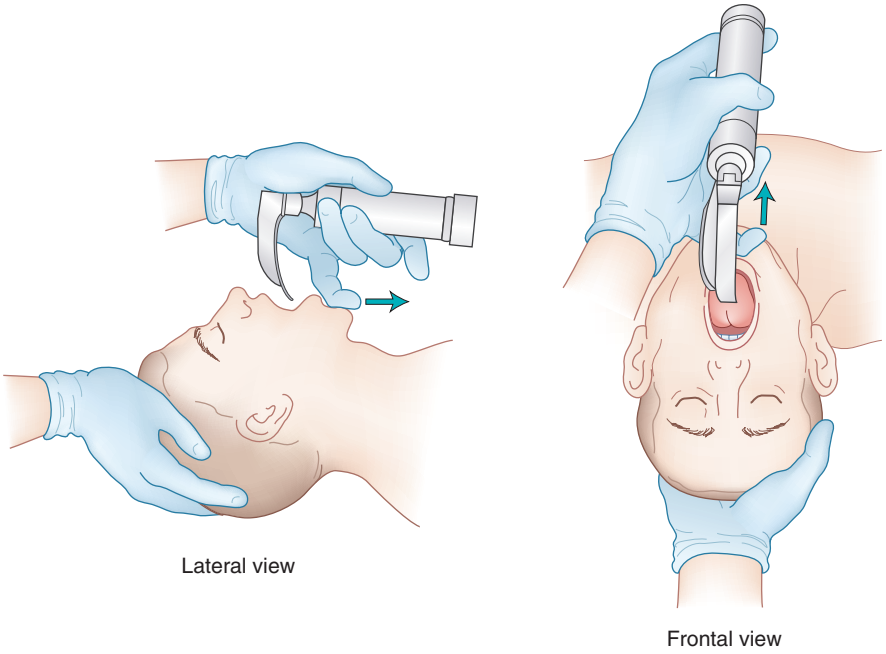

Figure 17-4 The mouth can be opened wide by extending the head on the neck with the right hand while the small finger and medial border of the left hand simultaneously push the anterior aspect of the mandible in a caudad direction (extraoral technique). As the blade approaches the mouth, it should be directed toward the right side of the mouth. Gloves should be worn during laryngoscopy because the hands may come in contact with patient's secretions. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 265.)

The laryngoscope blade is inserted into the right side of the mouth (see Fig. 17-3A). During the insertion of the laryngoscope, the patient's lower lip should be pulled away from the lower incisors (with the right hand or by an assistant) to prevent injury to the lower lip by entrapment of the lower lip between the laryngoscope blade and the lower incisor teeth. The blade is simultaneously advanced forward toward the base of the tongue and the tip directed centrally toward the midline so that the tongue is completely displaced to the left side of the mouth by the flange of the laryngoscope blade (see Fig. 17-3B). After the blade has been applied to the base of the tongue, the laryngoscope is lifted to expose the epiglottis (see Fig. 17-3C). During this process, the left wrist should remain straight, with all lifting done by the left shoulder and arm. If the laryngoscopist follows a natural inclination to radial-flex the wrist further, thereby using the laryngoscope like a lever whose fulcrum is the upper incisor or gum, injury is likely to result. With the patient properly positioned, the direction of force necessary to lift the mandible and tongue and expose the glottis is along an approximately 45-degree straight line above the long axis of the patient. The best aid for inexperienced laryngoscopists learning laryngoscopy may be a 10-pin bowler's wrist brace, which immobilizes the wrist.

After the epiglottis is visualized, the next step depends on the type of laryngoscope blade being used. If the blade is curved (Macintosh), the tip should be placed in the vallecula (space between the base of the tongue and the pharyngeal surface of the epiglottis) (see Fig. 17-3D). Subsequent forward and upward movement of the blade tenses the hyoepiglottic ligament, causing the epiglottis to move upward like a trapdoor, first exposing the arytenoid cartilages and then allowing more and more of the glottic opening and vocal cords to come into view (see Fig. 17-3D).

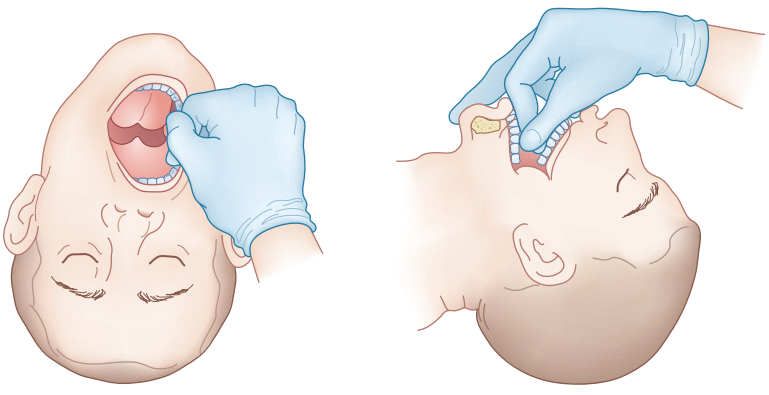

Figure 17-5 The mouth can be opened wide by pressing the thumb of the right hand on the right, lower, posterior molar teeth in a caudad direction while the index finger of the right hand simultaneously presses on the right, upper, posterior molar teeth in a cephalad direction (intraoral technique). Gloves should be worn during laryngoscopy because the hands may come into contact with patient's secretions. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 266.)

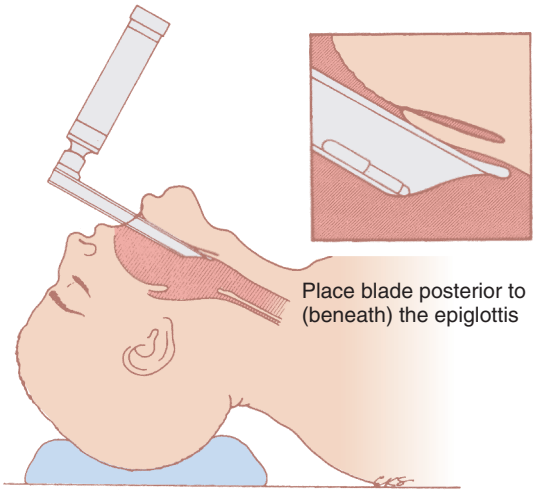

Figure 17-6 Conventional laryngoscopy with a straight blade. A straight laryngoscope blade (Miller blade) should be passed underneath the laryngeal surface of the epiglottis. The handle of the laryngoscope then should be elevated at a 45-degree angle, similar to the lifting that takes place with the use of a curved laryngoscope blade. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 268.)

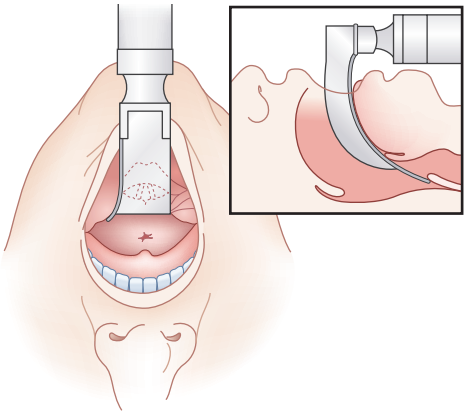

Figure 17-7 Insertion of the laryngoscope blade too deeply into the pharynx may result in elevation of the entire larynx so that the opening of the esophagus rather than the glottic aperture is visualized. The esophagus is located just to the right of the midline and posteriorly, and the esophageal opening is round and puckered with no structure around it. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 268.)

The ability to identify the epiglottis and then lift anteriorly to reveal progressively more of the glottic aperture has led to a convenient system for grading the laryngoscopic view of any patient.[24,25] A grade I laryngoscopic view consists of visualization of the vocal cords in their entirety. A grade II laryngoscopic view is visualization of the posterior portion of the laryngeal aperture (arytenoid cartilages) but not any portion of the vocal cords. A grade III laryngoscopic view is visualization of the epiglottis but not the posterior portion of the laryngeal aperture, and a grade IV laryngoscopic view is visualization of the soft palate but not the epiglottis. This grading system is necessarily subjective and skill dependent, but it does correlate somewhat with difficult intubation.

If the blade is straight (Jackson, Wisconsin, or Miller blades), the tip should extend just behind (posterior to) or beneath the laryngeal surface of the epiglottis (see Fig. 17-6). As with a curved laryngoscope blade, subsequent forward and upward movement of the straight blade (exerted along the axis of the handle, not by pulling back on the handle) exposes the glottic opening (see Fig. 17-6).

The use of a curved blade is thought to be less stimulating to the patient and possibly less traumatic to the epiglottis for two reasons. First, the tip of a curved blade does not normally touch the epiglottis. Second, the pharyngeal surface of the epiglottis is innervated by the glossopharyngeal nerve, whereas the superior laryngeal nerve supplies the laryngeal surface of the epiglottis. Stimulation of the laryngeal surface of the epiglottis is thought to predispose to laryngospasm and bronchospasm more than stimulation of the pharyngeal surface of the epiglottis. Curved blades are thought to be less traumatic to the teeth and to provide more room for passage of the ETT through the oropharynx. However, straight blades provide a better view of the glottis in a patient with a long, floppy epiglottis or an anterior larynx. Straight blades are preferred in infants, pediatric patients, and patients with an anterior larynx. Use of a longer blade (curved or straight) is more appropriate in very large patients and patients with a very long thyromental distance.

Four major common problems are encountered in performing laryngoscopy. First, with either laryngoscope blade, inserting the blade too deeply into the pharynx may elevate the entire larynx so that the opening of the esophagus is visualized rather than the glottic aperture (see Fig. 17-7). Insertion of a curved blade too far into the vallecula and continued rotation of the handle to the vertical may push the epiglottis down over the glottic opening, resulting in limited exposure of the larynx (see Fig. 17-8). The tracheal and esophageal openings are usually easily distinguished. The esophagus is located just to the right of the midline and more posteriorly, and the esophageal opening is round and puckered, with no

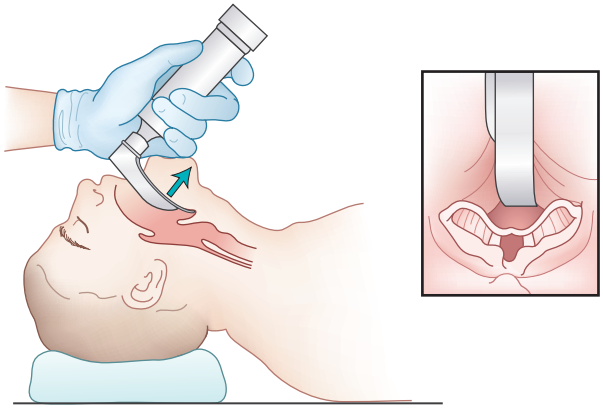

Figure 17-8 Insertion of the laryngoscope blade too deeply into the vallecula may push the epiglottis down over the laryngeal aperture, diminishing exposure of the vocal cords. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 267.)

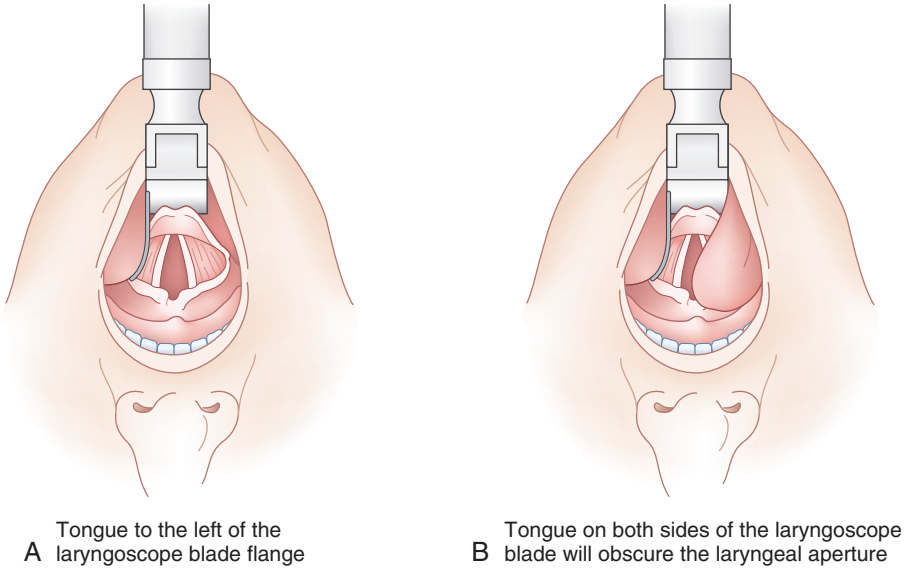

Figure 17-9 The tongue should be to the left of the laryngoscope blade. **A,** The flange on the laryngoscope blade should keep the tongue completely to the left side of the mouth. If this is accomplished, the tongue does not obstruct the view of the vocal cords. The tracheal rings on the anterior aspect of the trachea are evident. **B,** If the tongue slips over the laryngoscope blade and occupies part of the right side of the mouth, the view of the vocal cords is obscured by the part of the tongue that is on the right side of the mouth. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 269.)

structures around it. The glottis is located in the midline, has a triangular shape, and contains the prominent knobs of the arytenoids posteriorly and the pale white true vocal cords bilaterally.

Second, it is important to keep the tongue completely to the left side of the mouth with the flange of the laryngoscope blade. Many difficult or failed intubations result from the tongue protruding over the flange of the blade toward the right side of the mouth, obstructing a clear path through which the vocal cords must be visualized and the ETT passed (see Fig. 17-9B). Vision is obscured further when the ETT occupies part of the view. With a partially obstructed (tunnel) view the endoscopist can partially visualize but not instrument the larynx. All of the tongue must be to the left of the blade (Fig. 17-9A).

Third, in an effort to keep the tongue to the left, the blade tip may be displaced to the right of the midline. This position obscures the view of the epiglottis and may precipitate trauma and bleeding from friable tissue in the tonsillar bed. Especially with the use of the straight blade, the shaft of the blade can be to the right of midline (over the right molars), but the tip must reside exactly in the midline of the hypopharynx. An assistant may be useful in retracting the right cheek and enlarging the space to the right of the blade, facilitating visualization of the larynx, and introduction of the ETT.

Fourth, in barrel-chested, obese, or large-breasted patients, it may be difficult initially to insert the blade of a laryngoscope correctly into the mouth and avoid obstruction to movement of the handle of the laryngoscope by the chest wall. In these patients, further initial neck extension or a 45-degree rotation of the laryngoscope handle to the right permits easier introduction of the blade of the laryngoscope into the mouth. Alternatively, a short laryngoscope handle (designed for this situation) may be used instead of the full-length handle.

The use of OELM can significantly improve the laryngoscopic view. For example, routine use of OELM may reduce the incidence of a grade III view from 9% to between 1.3% and 5.4%.[26] Although backward, upward, and rightward pressure (BURP) placed on the thyroid cartilage is typically the most useful OELM, it is best for the laryngoscopist to determine what form of external manipulation is optimal. This can best be accomplished using his or her right hand when it becomes free after the patient's head is properly positioned (extended) and mouth fully opened (see Fig. 17-10).

D. Endotracheal Tube

Insertion of the ETT is frequently easy after the vocal cords are exposed and the tongue is out of the way (see Fig. 17-9A). However, endotracheal intubation is often problematic even if the vocal cords are visualized. Adult tracheas readily accept ETTs with 7- to 10-mm internal diameters (IDs) (see Chapter 36 for pediatric sizes). If it is thought that fiberoptic bronchoscopy (FOB) will be necessary subsequently for diagnosis or therapy, an 8-mm or larger ETT should be used. If it is thought that the space between the upper and lower teeth will be small, allowing the cuff of the tube to come in contact with the teeth, the distal part of the tube and cuff should be lubricated to facilitate orotracheal intubation and protect the cuff from tearing. In the case of limited mouth opening, air should be evacuated from the cuff to allow as low a profile as possible. The tip of the ETT should be introduced into the far right corner of the mouth and passed along an axis that intersects the line of the laryngoscope blade at the glottis. In this manner, the tube does not block the view of the vocal cords down the channel of the blade. The common error of trying to use the laryngoscope blade as a midline guide, through which the tube is passed, violates this principle, obscures vision, and is a significant source of difficulty for the inexperienced laryngoscopist. The tube tip is passed through the cords, stopping 2 cm after the tube cuff completely passes

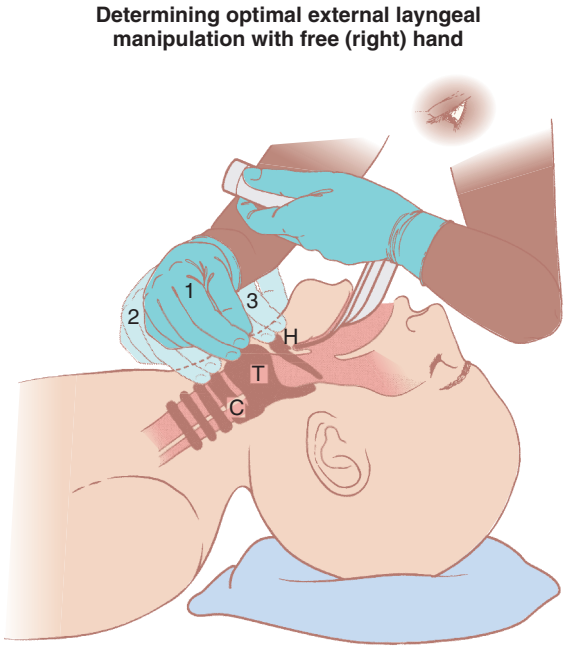

Figure 17-10 Optimal external laryngeal manipulation (OELM) to improve the laryngoscopic view is determined by the laryngoscopist by quickly pressing in the cephalad and posterior directions with the right hand over the thyroid *(T) (1),* which is most common. The cricoid *(C) (2),* and the hyoid cartilages *(H) (3).* If the laryngoscopic view is critically improved by this maneuver, the laryngoscopist can use an assistant's hands or fingers as an extension of his or her own right hand to reproduce the OELM. (From Benumof JL, editor: *Airway management: Principles and practice,* St. Louis, 1996, Mosby, p 268.)

through the vocal cords. Alternatively, when the external tube markings at the level of 22 to 24 cm reach the lower incisors, the tip of the tube is at the midtrachea.[7] The laryngoscopist must not take his or her eyes off the laryngeal aperture until the cuff disappears just beyond the vocal cords. The most common cause of inadvertent esophageal intubation is failure to clearly see the tube pass through the cords (and inspect it in situ after placement). The arytenoid cartilages frequently displace the tube tip posteriorly into the esophagus unless care is taken to pass the tip anteriorly and squarely into the tracheal lumen.

The use of a stylet may be valuable in controlling the direction of passage of an ETT. By providing increased rigidity and malleability, it allows more control of the tube. However, the ETT cannot be readily reshaped after it is introduced past the teeth. Insertion of an ETT through the mouth allows only two degrees of free movement: depth of insertion and rotation of the tip. The direction of the tube tip can be changed only by rotation. The ETT should be inserted as far to the right lateral aspect of the mouth as possible to facilitate the motion of the tip through torque applied to the connector end of the ETT. When speed of intubation is important (e.g., in a patient with a full stomach), an ETT should always be equipped with a stylet. A stylet should be easily malleable and well lubricated (although plastic-coated stylets may be adequately slippery) and not extend beyond the tip of the tube. Occasionally, a curved, styleted ETT impinges on the anterior tracheal wall as it is being inserted and after passage through the vocal cords. In these circumstances, after the ETT tip is through the vocal cords, the stylet should be withdrawn, which returns the tip of the ETT to its inherent flexibility and permits further passage distally.

After placement of the ETT, the laryngoscope is removed from the mouth, and the cuff of the tube is inflated to a cuff pressure of 22 to 32 cm H_2O. If a cuff pressure gauge is unavailable, the tube is inflated until moderate tension is felt in the pilot balloon to the cuff. The tube should then be connected to a source of PPV and held in place with one hand. The hand holding the ETT in place should be securely resting against the cheek (as a temporary fixation) until the ETT is secured to prevent any sudden movement from dislodging the ETT.

BOX 17-2 Signs of Endotracheal Intubation

Less Reliable Signs

1. Breath sounds in axillary chest wall
2. No breath sounds over stomach
3. No gastric distention
4. Chest rise and fall
5. Large, spontaneous exhaled tidal volume (V_T)
6. Hearing air exit from the endotracheal tube (ETT) when the chest is compressed
7. Reservoir bag having the appropriate compliance
8. Maintenance of arterial saturation by pulse oximetry

More Reliable Signs

1. Carbon dioxide (CO_2) excretion waveform
2. Rapid expansion of a tracheal indicator bulb

Most Reliable Signs

1. ETT visualized between vocal cords (laryngoscopy)
2. Fiberoptic visualization of cartilaginous rings of the trachea and tracheal carina

E. Verification of Correct Placement

The next, most important task is to determine definitively that the tube has been inserted into the trachea rather than the esophagus (Box 17-2). This issue is extensively discussed in Chapter 16, and only a brief summary of the signs of endotracheal intubation is given here. Helpful but not absolute signs of endotracheal intubation consist of breath sounds in the axillary chest wall, lack of breath sounds over the stomach, lack of gastric distention, chest rise with inspiration, large exhaled tidal volumes (V_T), the sound of air exiting from the ETT when the chest is compressed, and appropriate compliance of a reservoir bag during hand ventilation. A progressive decrease in Spo_2 may indicate failure to intubate the trachea, but it is a very late sign of esophageal intubation (especially on 100% O_2), and it may also indicate bronchospasm, endobronchial intubation, aspiration, kinking of the tube, machine or equipment malfunction, or merely the normal response delay inherent in pulse oximetry.

More reliable signs of endotracheal intubation are the presence of a normal CO_2 waveform (capnogram) and

rapid expansion of a large rubber tracheal indicator bulb (see Chapter 16). Cardiac arrest (when no CO_2 is excreted), severe bronchospasm, or kinking or plugging of the ET may prevent the appearance of CO_2 in the exhaled gas (false-negative finding), and CO_2 may appear if the tip of the tube is proximal to but near the larynx (false-positive finding). The self-inflating bulb has high sensitivity and specificity in normal patients, but it has a significant false-negative rate in obese patients.[27]

The only absolutely reliable methods of definitively determining endotracheal intubation are direct observation of the ETT going through the vocal cords and the use of FOB. Direct visualization of the tube lying in the glottic opening may be enhanced by displacing the tube posteriorly, which may pull the glottic opening posteriorly and into a better view. FOB allows visualization of the cartilaginous rings of the trachea and the tracheal carina but is not an accepted practice for routine determination of correct tube placement.

If a CO_2 waveform, breath sounds, and chest movement are lacking, the anesthesiologist should remove the ETT, ventilate the patient with a mask-bag system several times with 100% O_2, and attempt endotracheal intubation again after inspecting the used tube for defects or plugs in the lumen. Changes in the shape or curvature of the ETT and in the position of the head and neck, as well as the need for anterior tracheal pressure, should be considered and coordinated during the period of mask ventilation.

The next task is to ascertain that the tip of the ETT is above the carina. This is done by observing equal expansion of both hemithoraces and by stethoscopic examination for breath sounds throughout both peripheral lung fields. However, hearing uniform breath sounds throughout all lung fields does not guarantee correct tube position. If there is any question about a possible main stem bronchus intubation, the physician should retract the tube about 1 cm at a time and reexamine the breath sounds (stopping before complete withdrawal above the vocal cords). In one study, an insertion depth of 20 to 21 cm in adult women and 22 to 23 cm in adult men resulted in no incidence of main stem bronchial intubation.[28] Simultaneous palpation of pulsed pressures in the cuff in the suprasternal notch and the pilot balloon of the cuff is another simple way of determining the location of the tube in the trachea. FOB is another, but complex, way of determining the location of the tube in the trachea. Outside the operating room, it is always advisable to confirm ETT position by chest radiography. Ideally, the tip of the tube should be 2 to 4 cm above the carina at the clavicular (midtracheal) level.

When the ETT is placed and during taping of the tube, the marking of the ETT at the level of the teeth should be noted for reference should the tube become displaced.

F. Securing the Endotracheal Tube

After the depth of the ETT at the tooth level has been confirmed, the tube should be tightly secured in place. This is important to prevent accidental extubation and to minimize tube movement within the airway. Taping the tube to the facial skin with adhesive tape is the most common method of securing the ETT.

The skin of the maxilla should be considered the primary source of fixation for an orotracheal tube because it is less mobile and therefore less likely to allow excessive motion of the tube within the airway. The tube then lies along the palate and is less likely to be displaced by the tongue of a conscious patient. The fixation of the tube in place can be improved by having the lateral ends of the tape completely encircle the neck; however, the risk of restriction of venous return from the head (especially with intracranial pathology) requires careful consideration. Application of tincture of benzoin to the skin before the tape is applied helps provide a stronger bond between the tape and skin. In case of prolonged intubation, changing the tape and reapplying it to a new area on the face every 2 days helps prevent maceration of the skin.

In patients with beards or in whom the adhesive tape fails to stick to the skin, the tube can be tied into the place with a length of umbilical tape that is knotted around the tube and then encircles the neck. Adhesive tape may be used over the umbilical tape for added security. A surgical face mask, reversed so that the ties are in front and the mask at the occiput, can serve as a reasonable, temporary means of fixation. Another reliable method of securing an orotracheal tube is to wire the tube to a tooth. One or two layers of adhesive tape are wrapped around the tube at the level of the upper incisor teeth. Stainless steel wire (25 to 28 gauge) is passed around an upper incisor tooth and twisted around the tape on the ETT. In anesthetized patients, a suture may be passed through the gum and then around a ring of adhesive tape on the ETT (as with wire) or through the wall of the ETT and then tied to the tube. A bite block, rolled gauze, or an oropharyngeal airway (used in most endotracheal intubations for general anesthesia) should be placed between the teeth to prevent the patient from biting down and occluding the lumen of an oral tube. Numerous commercial products are available to attempt to improve the stability, patient's comfort, and convenience of stabilizing and immobilizing an orotracheal tube.

III. LARYNGOSCOPIC NASOTRACHEAL INTUBATION

Nasotracheal intubation usually is a more difficult procedure than orotracheal intubation. However, nasal tubes are thought to be better tolerated than oral tubes, and nasal tubes have been considered the tube of choice for medium-term mechanical ventilation. The issue of nasotracheal tubes contributing to the development of sinusitis and pneumonia has been investigated, and existing evidence has not demonstrated an association.[29] Nonetheless, the use of nasotracheal intubation for longer-term ventilation has been declining in favor of orotracheal intubation or early tracheostomy. The use of nasotracheal tubes is currently confined to surgical procedures requiring free access to the oropharynx (e.g., dental procedures, mandibular fixation) and to some pediatric procedures in which stability and security of the tube are of

overwhelming concern (usually because of proximity to the surgical field).

The ETT is inserted into a nostril (preferably the right) and then passed through the nasal cavity and nasopharynx to the oropharynx. After the tube has been passed into the oropharynx, it can be guided into the glottis under conventional direct laryngoscopic vision, or it can be grasped by a Magill forceps and directed into the glottis. Nasotracheal intubation is accompanied by a transient bacteremia, and endocarditis prophylaxis should be used in susceptible patients.

A. Preparation

Before insertion of the single-lumen nasotracheal tube, the nasal mucosa should be sprayed with a vasoconstrictor drug. Vasoconstriction of blood vessels in the nasal mucosa minimizes bleeding related to the unavoidable trauma, and it increases the diameter of the nasal passages by constricting (shrinking) the nasal mucosa. Softening the tip of the nasotracheal tube by soaking it in a warm saline solution may decrease the incidence of mucosal damage and bleeding. The naris selected should be the one that the patient thinks is the most patent (because of the significant incidence of septal deviation in patients). However, if both nares offer equal resistance, the right naris should be chosen because the bevel of the nasotracheal tube, when introduced through the right naris, more easily passes the vocal cords (Fig. 17-11).

The question of potential trauma to the turbinates by the open bevel of the tube and the best orientation of the bevel in passing the turbinates has not been resolved. There is a risk that the tube tip, in passing the inferior turbinate, may strike and damage or avulse the turbinate. In the worst case, the turbinate may be dislodged and occlude the lumen of the tube, causing epistaxis and complete tube obstruction. Care must be taken to pass the tube along the floor of the nose below the inferior turbinate and to avoid any excessive force in advancing the tube. Other measures may include preliminary vasoconstriction, lubrication of the tube, gentle rotation as the tube is advanced, and evacuation of all air from the cuff to minimize its effective diameter. Efforts to rationalize the direction of the bevel as it passes the turbinate have not been demonstrated to change the incidence of this complication.

In most adults, tubes with a 7.0 to 7.5 mm ID pass easily through the nares. Other prelaryngoscopic maneuvers described under direct-vision orotracheal intubation (positioning of the head, suctioning, and preoxygenation) should be performed for direct-vision nasotracheal intubation. The nasotracheal tube should be lubricated and passed through the nose in one smooth, posterior, caudad, medially directed movement until resistance to forward movement significantly decreases as the tube enters the oropharynx (usually at a distance of 15 to 16 cm). Significant resistance should be overcome not by force but by withdrawal, rotation, and reinsertion of the ETT. Difficult passage should prompt the selection of the opposite nostril or of a smaller tube.

The pathway that the nasotracheal tube takes should be visualized as lying on its side. The curve of the ETT should be aligned to facilitate passage along this curved course. As the tube passes through the nose into the nasopharynx, it must be directed inferiorly to pass through the pharynx. In making this turn, it may strike against the posterior nasopharyngeal wall and resist any attempt to push it further. The tube should be pulled back a short distance, and the patient's head should be extended further to facilitate attempts to pass this point smoothly and atraumatically. If this is not performed and the tube is forced, the mucosal covering of the posterior nasopharyngeal wall may be torn, and the tube may be passed into the submucous tissues. This false passage is accompanied by a boggy feeling and by complete obstruction of the tube lumen.

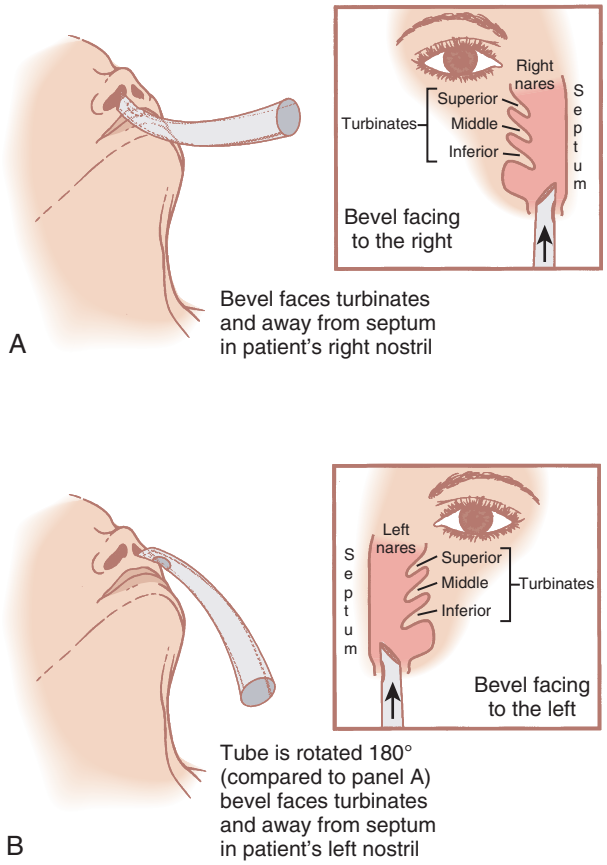

Figure 17-11 Insertion of a nasotracheal tube into the nares. **A,** When the nasotracheal tube is passed into the right naris, the bevel should be facing to the right toward the turbinates *(inset)*. In this way, the tip of the tube is against the septum, and the risks of catching the tip of the tube on a turbinate and tearing or dislocating it are minimized. In this orientation, the concavity of the tube is pointing anteriorly. **B,** When the nasotracheal tube is passed into the left naris, the bevel should be facing to the left toward the turbinates *(inset)*. In this way, the tip of the tube is against the septum, and the risks of catching the tip of the tube on a turbinate and tearing or dislocating it are minimized. In this orientation the concavity of the tube is pointing posteriorly. (From Benumof JL, editor: *Airway management: Principles and practice,* St. Louis, 1996, Mosby, p 273.)

B. Laryngoscopy

The laryngoscopy for nasotracheal intubation is identical to that described for orotracheal intubation.

C. Endotracheal Intubation

After the tube is in the oropharynx, the tip of the tube must be aligned with the glottic opening. This requires that the tip of the tube be visible in the hypopharynx. The tube should be advanced or withdrawn until this is the case. A combination of tube rotation and repositioning of the head may allow clear passage of the tube tip into the trachea, but it is likely that the tube will require guidance using Magill forceps held in the intubator's right hand.

The advantage of the design of these forceps is that when the grasping ends are parallel to the long axis of the ETT, the handle is outside the right side of the mouth and at a right angle to the long axis of the tube. Because the handle is outside the right side of the mouth, it is away from the line of sight. As the forceps are grasped parallel to the long axis of the tube, a backhand motion of the right hand passes the ETT toward the glottic opening (Fig. 17-12). The intubator can have the larynx exposed by the laryngoscope held in the left hand, the tube in full view, a means (using the forceps) of manipulating the alignment of the ETT, and a means of advancing the tube. However, it is often desirable to have an assistant advance the proximal end of the ETT so that the intubator is free to guide the tube into the larynx without having to pull it with the Magill forceps. The tip of the tube should be grasped to guide it into the trachea; grasping the cuff area is likely to lead to cuff trauma and possible damage. The addition of a small amount of air into the ETT cuff should center the tube within the glottis, and as the ETT is advanced, the cuff deflates.

In some patients, as the ETT enters the trachea, the tube's anterior curvature may direct it against the anterior tracheal wall and interfere with passage past this point. To resolve this difficulty, the head must be lifted (flexed) slowly as the ETT is advanced. A nasotracheal tube should be advanced until the cuff is 2 cm below the vocal cords or until the external markings are 24 to 25 cm for women and 26 to 27 cm for men (3 cm more than for oral ETTs) at the nares. The tube's correct placement must be verified as in any intubation (see "Verification of Correct Placement"), but this is particularly critical with nasotracheal intubations because the relation to external tube markings and the location of the tip are not as firmly established as for orotracheal intubations. If nasal bleeding occurs, it is probably wise to leave the ETT in place to provide tamponade. If the bleeding is severe, the ETT can be retracted and the cuff inflated to provide better tamponade.

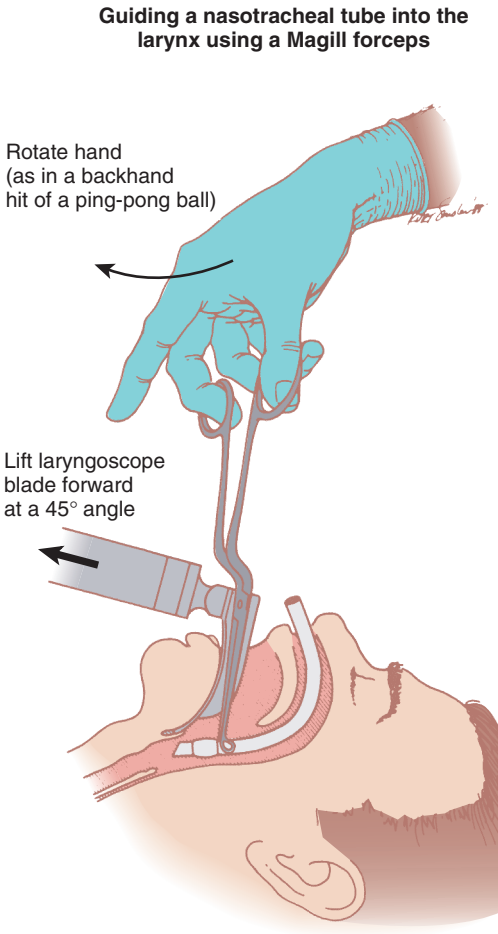

Figure 17-12 A nasotracheal tube can be guided under direct vision (laryngoscopic control) through the laryngeal aperture with a Magill forceps by rotating the hand as when using a backhand motion to hit a ping pong ball. The Magill forceps should grab the nasotracheal tube proximal to the cuff of the ETT. (From Benumof JL, editor: *Airway management: Principles and practice*, St. Louis, 1996, Mosby, p 275.)

D. Securing the Endotracheal Tube

The nasotracheal tube can be secured with adhesive tape as described for orotracheal intubation. A nasotracheal tube can be secured by a suture through the nasal septum and then tied, after being tightly wound around an adhesive band on the tube or passed through the wall of the tube by a needle and then tied.

IV. CONCLUSIONS

The art of laryngoscopic endotracheal intubation is one of infinite variety and unpredictability. We treat a diverse population of patients with many disease processes, and when their pathology includes airway abnormalities, gaining control of the airway can be a life-threatening or lifesaving process. Ongoing study and practice of airway techniques are the only protection we have in the intrinsically hazardous field of airway management. Mastery of the art begins with a mastery of the fundamentals. Although practiced by a wide variety of health professionals, laryngoscopic intubation is an extraordinarily complex and continually evolving branch of anesthesiology and critical care.

V. CLINICAL PEARLS

- Redundancy is the key to adequate preparation. All essential equipment (laryngoscopy handles and ETTs) should have back-up counterparts readily available in case of unexpected failure.

- Proper positioning is essential to successful intubation. Atlanto-occipital extension is the most critical component of positioning. The sniffing position (with the occiput elevated 9 cm) may provide a more favorable laryngoscopic view.
- Preoxygenation delays the onset of hypoxemia by denitrogenating the lungs and filling the functional residual capacity (FRC) with O_2. The benefit of preoxygenation is limited in morbidly obese patients due to a decrease in FRC and an exaggerated cephalad diaphragmatic shift related to supine positioning.
- Although numerous techniques for tracheal cannulation exist, direct laryngoscopy is by far the most common technique.
- The tip of the laryngoscopic blade is inserted into the right side of the mouth and advanced toward the midline base of the tongue, displacing the tongue to the left side of the mouth. Lifting of the laryngoscopist's arm at a 45-degree angle from the long axis of the patient without moving the wrist exposes the epiglottis while minimizing risk of injury to the airway. The tip of a curved blade is inserted into the vallecula, thereby tensing the hypoepiglottic ligament, lifting the epiglottis, and exposing the arytenoids and glottic opening. The tip of a straight blade is extended beneath the laryngeal surface of the epiglottis, and subsequent upward and forward movement of the blade exposes the glottic opening.
- The use of a curved blade is thought to be less stimulating and less traumatic to the teeth and epiglottis than a straight blade, and it may provide more room for passage of the ETT through the oropharynx. A straight blade may provide a better view in a patient with a long epiglottis or anterior larynx.
- The use of optimal external laryngeal manipulation (OELM) can significantly improve the laryngoscopic view.
- It is essential to confirm endotracheal intubation by auscultation of breath sounds, chest wall excursion, lack of gastric sounds or distention, large exhaled V_T value, and a normal capnogram finding.
- The most common cause of inadvertent esophageal intubation is failure to clearly visualize the ETT pass through the vocal cords.
- Depths of 20 to 21 cm for women and 22 to 23 cm for men can safeguard against endobronchial intubation during orotracheal intubation.
- The ETT must be tightly secured to prevent inadvertent extubation or tube movement within the airway.
- Because nasotracheal intubation is thought to be better tolerated and has not been shown to be associated with an increased incidence of sinusitis, it is preferred over orotracheal intubation for medium-term mechanical ventilation. The nasal mucosa should be pretreated with a vasoconstrictor drug to facilitate nasotracheal intubation and to minimize the risk of trauma. Gentle head flexion may assist in the passage of a nasotracheal tube as it contacts the anterior tracheal wall.

I. HISTORY

Although it was probably first described by Herholdt and Rafn in 1796 for the management of drowning victims,[1] blind digital orotracheal intubation did not receive much attention in the medical literature until its revival in emergency medicine and prehospital care by Stewart in the mid-1980s.[2,3] Notable publications over the years have portrayed the technique as an acceptable, if not preferable, alternative to standard laryngoscopic endotracheal intubation, particularly when the standard technique is contraindicated, has failed, or is not possible because of a lack of equipment.

In 1880, Macewen described the technique utilizing a curved metal tube in awake patients,[4] and Sykes[5] recommended routine use of the digital technique in anesthetic practice in the 1930s. Siddall and Lanham relegated the technique to last-ditch efforts following the failure of conventional intubation methods.[3,6,7] The technique has been described in neonatal resuscitation and as an adjunct in blind nasotracheal intubation.[8-10]

Currently, there is widespread variation in awareness, expertise, and application of the technique in anesthesia, emergency medicine,[11,12] and prehospital care. Although advances in airway management equipment and expertise have made obsolete the routine use of blind digital orotracheal intubation, it remains a valuable skill in some situations, especially in the emergency setting or under circumstances in which the anesthesiologist cannot be positioned at the head of the patient,[3] rendering laryngoscopic intubation impossible.

II. INDICATIONS

The use of the digital technique is neither aesthetically pleasing, easily accomplished, nor entirely safe. Placing the fingers far enough down a patient's throat to elevate the epiglottis and guide an endotracheal tube (ETT) into the trachea has implications related to selection of patients and the manual dexterity and anatomic features of the anesthesiologist.

The technique has received some popularity in the prehospital care environment, where difficult positioning of the patient, poor lighting conditions, disrupted anatomy, potential cervical spine instability, and unknown status regarding infectious disease are the norm. Digital intubation is ordinarily used when other maneuvers have failed or are likely to fail and when alternative equipment is unavailable or not functional.

Successful digital intubation demands that the patient be unconscious, both for the patient to tolerate the intense oropharyngeal stimulus and to prevent bite injuries to the anesthesiologist. Neuromuscular blockade facilitates the technique, although it is relatively contraindicated in patients with anatomically difficult or disrupted airways. Digital intubation may be indicated in the following scenarios:

1. When equipment required to undertake alternative techniques is unavailable or not functional.
2. When positioning of the patient or the anesthesiologist prevents conventional intubation.
3. When other methods have failed or are likely to fail and the skill and experience of the anesthesiologist make the digital technique a reasonable alternative.
4. In the presence of potential or actual cervical spine instability when the anesthesiologist selects the digital technique on the basis of the risk-benefit analysis. Although there is no evidence to suggest that the use of digital intubation alters the neurologic outcome of a patient, there may be less cervical spine motion during intubation with the digital technique compared with conventional laryngoscopic orotracheal intubation without in-line stabilization.

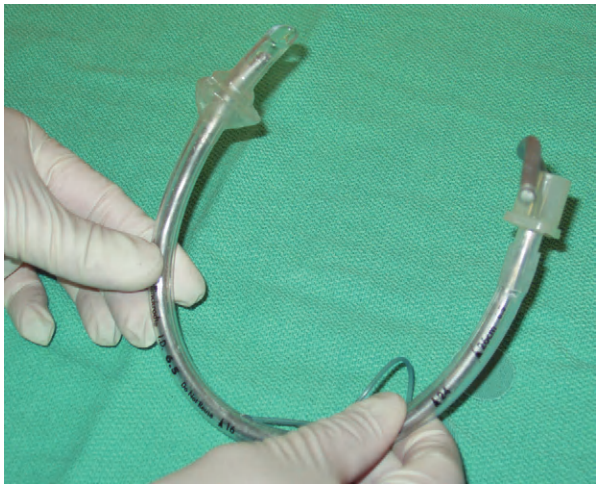

Figure 18-1 With the stylet in place, the distal half of the endotracheal tube is bent to a U shape.

5. When adequate visualization of the airway to allow conventional intubation is not possible because of the presence of copious secretions, blood, or vomitus in the oropharynx or traumatic disruption of the upper airway anatomy.

III. TECHNIQUE OF DIGITAL INTUBATION

A. Preparation

As with any intubation technique, preparation involves assembling the necessary equipment and personnel, including emergency drugs and adequate suction, to optimize success and preserve ventilation and oxygenation. An appropriately sized ETT is selected. The use of a stiff but malleable stylet improves maneuverability during the intubation. Lubrication of the stylet with a water-soluble lubricant ensures easy retraction after the tip of the ETT is placed in the glottic opening. The stylet is then inserted into the ETT so that the distal end of the stylet is at the level of the Murphy eye. With the stylet in place, the distal half of the styletted ETT unit (SETT) is bent into a "U" configuration (Fig. 18-1). The proximal half of the SETT is then bent approximately 90 degrees toward the dominant side of the ETT to allow manipulation of the SETT by the dominant hand during intubation (Figs. 18-2 and 18-3). The degree of bend should be individualized and is dependent on the anesthesiologist's experience.

Figure 18-2 The proximal half of the endotracheal tube is bent 90 degrees toward the dominant side of the anesthesiologist.

Figure 18-3 Final configuration of the styletted endotracheal tube (SETT) allows improved control of the ETT with both hands. During the intubation, the index finger of the dominant hand can help advance the ETT while the index and middle fingers of the nondominant hand guide the tip of the ETT into the glottis.

The tip of the ETT should be well lubricated with a water-soluble lubricant. In the uncommon event that the intubation is performed in an awake patient, especially an uncooperative patient, a bite block should be placed between the patient's molars on one side to minimize the risk of injury to the anesthesiologist's fingers.

B. Positioning

The patient should be supine with the head in a slight sniffing position, as for laryngoscopic intubation. The anesthesiologist stands (or kneels if the patient is on the ground) beside the patient so that his or her nondominant side is closest to the patient. An assistant can help to facilitate the intubating procedure.

C. Technique

Pulling the tongue forward by an assistant facilitates palpation of the epiglottis, thus improving the success rate for digital intubation. The patient's mouth is opened, and the tongue is grasped gently by the assistant with a piece of gauze (Fig. 18-4). Traction on the tongue moves the epiglottis slightly cephalad, enhancing its palpability and facilitating placement of the tip of the ETT into the glottic opening. The anesthesiologist then inserts the index and middle fingers of the nondominant hand into the oral cavity and slides the palm down along the surface of the tongue (Fig. 18-5). The tip of the middle finger touches the tip of the epiglottis, which is then directed anteriorly (Fig. 18-6). The ease of palpating and lifting the epiglottis depends on the length of the

Figure 18-4 The tongue is grasped gently by an assistant with a piece of gauze. Traction on the tongue moves the epiglottis slightly cephalad, enhancing its palpability and facilitating the placement of the tip of the endotracheal tube into the glottic opening. An upward (cephalad) and backward (posterior) pressure applied anteriorly to the larynx by the assistant may help the anesthesiologist to feel the epiglottis during digital intubation.

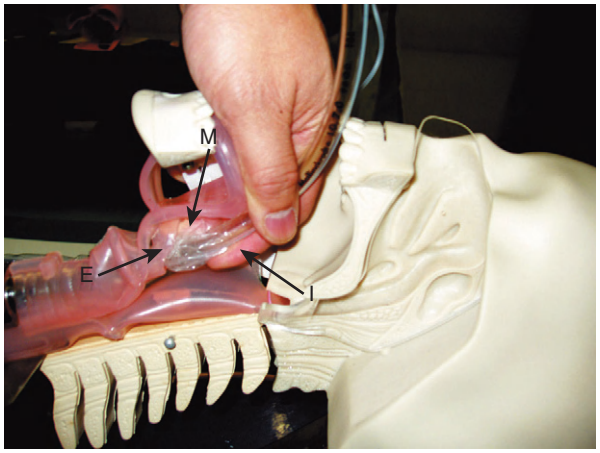

Figure 18-6 View of the larynx of a mannequin demonstrating the guidance of the endotracheal tube into the glottic opening by the tip of the index *(I)* and middle *(M)* fingers of the nondominant hand. The fingers are advanced to the point at which the middle finger is able to palpate the tip of the epiglottis *(E)* and push it anteriorly. Gloves should be worn at all times when performing the technique on patients.

anesthesiologist's fingers, the height of the patient, the anatomy of the oropharynx, and the presence or absence of teeth.

Once the epiglottis is identified and directed anteriorly, the SETT is inserted through the corner of the mouth. The SETT glides along the groove between the middle and index fingers on the palmar surface of the nondominant hand (see Fig. 18-3). While firm anterior pressure is maintained against the epiglottis with the middle finger, the SETT is advanced slowly into the glottic opening by the dominant hand. The index finger may be used to guide the tip of the SETT into the glottic opening (see Fig. 18-6).

The ETT should be stabilized while the stylet is withdrawn, and the ETT is then slowly advanced into the trachea. During the intubation, the SETT should never be advanced forcefully against resistance. Accurate placement is confirmed by conventional techniques, such as auscultation and carbon dioxide detection. Occasionally, the tip of the epiglottis cannot be palpated. An upward (cephalad) and backward (posterior) pressure applied anteriorly to the larynx by an assistant may be helpful (see Fig. 18-4). As an alternative, the index and middle fingers of the nondominant hand may be used to keep the SETT in the midline while tissue movement in the anterior neck is observed during gentle rocking of the SETT back and forth in an attempt to locate the glottic opening.

An alternative technique described by Cook begins with placement of the index and middle finger tips of the nondominant hand in the hypopharynx, posterior to the larynx.[13] The ETT held in the dominant hand is then passed into the pharynx. The volar surfaces of the fingers serve as a "basketball backstop" to guide the ETT held in the dominant hand through the glottic opening. If required, the index finger of the nondominant hand may be flexed to help guide the ETT through the glottis.

Figure 18-5 The index and middle fingers of the nondominant hand are inserted into the mouth with the palm facing down.

D. Tracheal Introducer–Assisted Digital Intubation

A recent case report highlighted the use of a tracheal introducer (commonly known as "bougie") in facilitating a digital intubation technique in a patient with an unanticipated difficult airway after direct laryngoscopy attempts were unsuccessful.[14] A SunMed ETT Introducer (SunMed, Largo, FL) was first guided into the trachea using the digital technique. Tracheal clicks were used to confirm successful placement of the introducer in the trachea. The ETT was then guided into the trachea using the introducer as conduit.

The advantage of this technique is that it is easier to advance a tracheal introducer through the glottic opening and then railroad the ETT into the trachea than it is to place a SETT in the trachea. The tracheal introducer has a small outer diameter and is easily manipulated with the fingers to enable passage through the vocal cords. In addition, the clicks that are felt as the tracheal introducer advances over the tracheal rings, combined with

"hold-up," will assist in confirmation of tracheal placement. ("Hold-up" is the inability to advance the tracheal introducer beyond the lower bronchial tree. Esophageal placement of the tracheal introducer typically meets with no resistance, particularly when no anatomical abnormality exists.) The SETT, which combines the ETT with the malleable stylet, is rigid and perhaps more likely to cause blunt trauma to the airway structures, especially if repeated manipulation is necessary for successful entry into the trachea.

E. Neonatal Digital Intubation

Blind digital intubation in neonates has not gained widespread acceptance as a primary technique of intubation. Moura and associates performed a randomized controlled trial comparing laryngoscopic intubation with the digital method in neonates.[15] They found that neonatal digital intubation had a higher success rate and a shorter intubation time. A single experienced anesthesiologist was responsible for performing all the procedures, and this was identified as a study limitation.

Neonatal digital intubation has been used in several third-world countries where experience with and access to standard laryngoscopes are limited.[8] Hancock and Peterson used the blind digital intubation technique in neonatal resuscitation and accidental extubation situations.[16] The anesthesiologist uses the gloved index finger of the nondominant hand to identify the epiglottis and glottic opening. The index finger is then used to guide the ETT through the glottic opening. The thumb of the nondominant hand can be used to apply external cricoid pressure. A SETT is recommended. The fifth finger of the nondominant hand can be used in very small neonates.

Advantages of the blind digital technique in neonates include reduced lip and gum trauma, controlled palpation of anatomic landmarks, and easy access to the airway in various transport scenarios without the need to adjust lines and monitoring equipment in unstable patients. The technique can also be used to confirm accidental extubation of the trachea. Caution should be exercised when airway pathology is suspected. Blind digital intubation of neonates and infants can be considered in situations in which other direct visualization techniques have failed.

F. Combined Techniques

The technique of blind digital intubation has been combined with the BAAM Whistle (Beck Airway Airflow Monitor, Great Plains Ballistics, Lubbock, TX) and the Endotrol tube (Mallinckrodt Medical, Argyle, NY) to facilitate endotracheal intubation in several situations after failure of direct laryngoscopy.[17,18] The BAAM device was initially developed to facilitate the teaching of blind nasotracheal intubation techniques under spontaneous ventilation. The BAAM produces a whistling sound of slightly different pitches during inspiration and expiration if the ETT is positioned within the air column leaving or entering the trachea. The device has also been shown to be effective in guiding nasotracheal tube placement in situations in which external cardiac massage is being applied.[18]

The Endotrol tube's unique design allows the anesthesiologist to bend the distal tip anteriorly by pulling on a plastic wire that runs along the concave curvature of the ETT. This motion allows better alignment of the distal tip of the tube with the glottic opening.

In fiberoptic intubation, it can be difficult to advance the ETT into the trachea. Asai and colleagues reported use of the digital technique to help guide a 39-F double-lumen tube off the flexible fiberoptic bronchoscope and into the trachea of a patient undergoing an anterior thoracic laminectomy procedure.[19] The anatomy of the patient's airway and that of the anesthesiologist's hand are key determinants in deciding which technique should be used in a given situation.

Light-guided endotracheal intubation using the Trachlight (Laerdal Medical, Wappingers Falls, NY) can be difficult in patients who have a long and floppy epiglottis.[20] This difficulty can be overcome by using the combined light-guided digital intubating technique. During the intubation, the middle finger of the nondominant hand can be used to lift the epiglottis off the posterior wall of the pharynx to allow the ETT with the Trachlight to go underneath the epiglottis into the glottic opening. The light glow at the anterior neck can be used to confirm the correct placement of the ETT tip into the glottis. During the past several years, we have performed more than 20 intubations using this combined light-guided digital intubating technique. The lightwand-guided intubation technique has also been described in newborns and infants with difficult airways.[21]

Digital assistance for nasotracheal intubation has been reported in the pediatric population to facilitate atraumatic passage of the tube behind the soft palate and entrance into the trachea.[22] However, this technique has not been systematically studied in a randomized controlled trial.

IV. CASE HISTORY

Blind digital intubation is a relatively simple technique that can be learned easily. The following case history serves to illustrate the role of digital intubation in the emergency airway management of a patient whose trachea could not be intubated by the conventional method.

A call was received by the 911 center of a large, urban Emergency Medical Services (EMS) system reporting a "man not breathing" at a downtown hotel. A mobile intensive care unit from the nearest ambulance station was dispatched immediately. When it arrived 3 minutes later, the EMS team was directed to the top floor of the hotel, where a wedding reception was in progress. On the floor of a small washroom, the 120-kg patient was found in cardiac arrest, pulseless, and not breathing. According to the history given by relatives, the patient had chest pain while dancing after a large meal. He went into the washroom and collapsed.

Cardiopulmonary resuscitation (CPR) with bag-mask ventilation was performed immediately. Vomiting ensued, obscuring the laryngoscopic view of the paramedic who was attempting orotracheal intubation using a Macintosh

laryngoscope. Suctioning was attempted with a portable suction unit, but so much vomitus was present that the collecting bottle of the suction unit filled rapidly and further suctioning was not possible in clearing the upper airway. "Quick-look" paddles revealed asystole.

While chest compressions and bag-mask ventilation continued, attempts at intravenous access were successful. Second and third attempts at direct laryngoscopic intubation resulted in esophageal placement, readily recognized by the paramedic team.

It became clear that further attempts at direct visualization of the airway would not be successful because of the large amount of vomitus in the oropharynx. A decision was made to place the ETT using the tactile (digital) method. An ETT with a 7.5-mm inner diameter was used. A physician carried out a digital intubation through the vomitus and secretions and was successful on the first attempt, as confirmed by colorimetric CO_2 detection. Ventilation and suctioning were performed through the ETT, and the patient's color improved. CPR continued during transport to a local hospital.

In another case, the editor of this book, who is director of advanced airway management at a Houston hospital, successfully performed blind digital intubation of a 51-year-old gentleman who had a history of insulin-dependent diabetes, hypertension, obesity, and peptic ulcer disease. An anesthesiologist was called emergently when this patient sustained a cardiac arrest in the intensive care unit after massive bleeding from a perforated gastric ulcer. When she arrived at the bedside, CPR was in progress. Although a Yankauer suction was immediately available and was being used, there was a continuous profuse stream of blood coming into the patient's oropharynx. While waiting for a cricothyrotomy kit to become available, she performed blind digital intubation and the airway was successfully secured with a size 8.0 ETT. The patient was resuscitated, and CPR was discontinued.

V. LIMITATIONS

Digital intubation in uncooperative patients is generally difficult. The more alert the patient is, the less likely it is that digital intubation will be tolerated or successful. Patients with limited mouth opening, carious or prominent dentition, a small mouth, or a large tongue, as well as very tall patients, can be predictably difficult to intubate regardless of the method employed, including the digital method. With practice, however, digital intubation has been shown to be an effective alternative method of intubation.[18]

The risk of injury to the anesthesiologist from the patient's teeth and body fluids can be minimized by selecting unconscious or paralyzed patients or by placing a bite block between the patient's molars. In our experience, double gloving provides a wider margin of safety in protection against barrier interruption, injury from teeth, and the potential for disease transmission.

As with other techniques of intubation, complications such as trauma to the upper airway can occur during digital intubation. However, trauma can be minimized by advancing the ETT gently during the intubation. Other potential complications of digital intubation, including esophageal intubation, can be minimized by a good technique, gentle manipulation, and use of tracheal placement confirmation techniques such as CO_2 detection.

Digital intubation is a "blind" technique and therefore is relatively contraindicated in patients with upper airway abnormalities resulting from infectious diseases, neoplasms, foreign bodies, caustic or thermal burns, or anaphylaxis.

VI. CONCLUSIONS

Digital intubation is seldom the method of first choice in securing a definitive airway. However, it offers an alternative that, in the event of failure of conventional techniques, may prove life-saving. Successful digital intubation depends largely on the anesthesiologist's preparation, experience, and skill.

VII. CLINICAL PEARLS

- Blind digital intubation should be considered as an airway management technique when alternative options are either unavailable or not functional.
- The technique may be considered in situations in which positioning for conventional intubation is not possible or soiling of the airway limits visualization of the larynx and glottis inlet.
- Universal infectious disease precautions must be taken at all times, and the patient's level of consciousness and state of paralysis must always be kept in mind.
- Pulling the tongue forward by an assistant during the technique facilitates traction on the epiglottis, thereby improving the overall chance of successful intubation.
- Blind digital intubation may be facilitated by the use of a tracheal introducer or bougie that produces confirmatory tracheal clicks before railroading of the ETT.
- Various intubation devices and techniques (e.g., BAAM whistle, Endotrol ETT, Trachlight, nasotracheal intubation, double-lumen ETT intubation) may be combined and facilitated by blind digital intubation.
- Successful ETT placement in the trachea after blind digital intubation should be confirmed with carbon dioxide detection devices.
- Experience with blind digital intubation in elective settings with patients who are anesthetized and paralyzed will enhance the clinician's skill acquisition and confidence in performance of the technique.

B. Assessing Planning and Technique

XV. Introducing Fiberoptic Intubation into One's Own Practice

XVI. Skill Retention

XVII. Conclusions

XVIII. Clinical Pearls

I. INTRODUCTION AND HISTORICAL BACKGROUND

In addition to covering fundamental and advanced aspects of flexible fiberoptic/endoscopic airway management, this chapter focuses on exciting current inventions in airway equipment, related devices, and techniques.

The purpose of this chapter is threefold:

1. Incorporate recent airway management developments for integration with flexible endoscopes.
2. Impart knowledge concerning flexible endoscopic techniques and tips for airway use.
3. Increase the likelihood that readers might achieve a level of expertise in flexible endoscopic intubation and airway management.

Historically, a wide variety of devices have been employed to visualize the airway in living human subjects. Manuel Garcia, a singing instructor, ingeniously used mirrors to reflect sunlight in 1854, allowing him to examine his own moving vocal cords. He was considered the "first laryngoscopist" after a presentation to the Royal Society of Medicine.[1] Using a blind digital technique, William Macewen completed the first endotracheal intubation under anesthesia as well as the first awake intubation for surgery and anesthesia in 1878.[2] On hearing of an accidental intratracheal insertion in 1895, Alfred Kirstein used an esophagoscope that incorporated a proximal light source and spatula-like area to perform the first "direct" laryngoscopy.[3]

Bronchoscopy history began to develop in 1887, when Gustav Killian extracted a foreign body from a farmer's respiratory tract with a rigid bronchoscope. Chevalier Jackson modified this rigid bronchoscope by inclusion of a distal tungsten light bulb and suction channel in 1904, resulting in the significantly greater likelihood of successful endotracheal intubation.[4]

Finally, a remarkable development took place in 1966. Shigeto Ikeda proposed his ideas for construction of a flexible fiberoptic bronchoscope (FOB) to two companies, Machida Endoscope and Olympus.[5] Meanwhile, in 1967, Peter Murphy ingeniously used a choledochoscope for endotracheal intubation.[6] In 1968, the Machida company at last produced an extremely "bendable," guided FOB, which featured an eyepiece for seeing images transmitted along 15,000 glass fibers that were 14 μm in diameter. Clinically, Ikeda's technique was to insert this very flexible instrument through a rigid bronchoscope. Later that year, Olympus produced a more maneuverable FOB with a working channel that allowed the application of cytology brushes. Ikeda's new FOB pictures of the distal airway, presented at the International Congress on Disease of the Chest in Copenhagen, were instantaneously news-making revelations. He was able to demonstrate a stand-alone FOB insertion method for endotracheal intubation in many countries, and he published his experiences in 1971.[7]

Initially many clinicians advanced FOB use for diagnostic purposes, for ordinary intubation procedures, and, eventually, for airway management in patients with very challenging airways.[8-12] The inherent characteristic of FOB superiority forged its involvement as an instrument of first choice in difficult intubation (DI) cases, cervical spine risk scenarios, and as a diagnostic and therapeutic tool for patients with hypoxemia, high airway pressure, pulmonary tumors, infection, foreign bodies, airway stenosis, obstructive sleep apnea, tracheomalacia, and many more wide-ranging abnormalities.

Raj advocated the role of FOB assistance in double-lumen tube (DLT) placement[11] while Ovassapian further delineated its advantages in one-lung isolation in 1987.[13] Through FOB use, Benumof compared bronchial insertions of right and left DLTs to explain why the relationship of bronchial anatomy to DLT construction inevitably resulted in less successful right-sided DLT positioning.[14]

In the 1980s, the Asahi Pentax Company's integration of the FOB with a preexisting invention, the charge-coupled device (CCD), permitted video monitor viewing of the airway and heightened its educational and clinical benefits.[15] FOB construction creativity has continued to evolve, with sizes available for all types of patients, many featuring full-color imaging and a working suction/injection channel. Light-emitting diodes (LED) and micro video complementary metal-oxide semiconductor chips (CMOS) for transmission capability have also been implemented.

Most recently, some flexible bronchoscopes have targeted the idea of being "single-use patient contact instruments," either as a reusable FOB with a disposable, sheath-like protective barrier or as an entirely disposable "non-fiberoptic" flexible bronchoscope.

Although universal acceptance of FOB use for intubation was somewhat slow for many years, Ovassapian and colleagues were leading and effective pioneers in the educational promotion of its use through workshop training and simulation, eventually popularizing this astonishingly effective technique.[16] Currently, the FOB resides worldwide within all algorithms for DI, and there is a clear, growing tendency to use this technique in combination with other recent advances as a multimodal approach to difficult airway (DA) management.

II. FLEXIBLE FIBEROPTIC AND NON-FIBEROPTIC BRONCHOSCOPE DESIGN AND CARE

FOBs and non-fiberoptic flexible bronchoscopes (non-FOBs) are available from a number of manufacturers, including Olympus, Pentax, Karl Storz, Ambu, and Vision Sciences. For simplicity, all "scopes" will be referred to as FOBs, unless indicated. Most FOBs are very expensive and quite delicate. Knowledge of their functionality and care is paramount to prevent damage and loss of clinical availability. Repair costs may reach more than $1000 per instrument per month in teaching hospitals in the United States but can drop to almost one-fiftieth of that with diligent care and training.

A. Fiberoptic Bronchoscope Design

Variations in design may seem endless, but all flexible endoscopes have certain commonalities. Differences are described later in this chapter. There are three main parts: handle, insertion tube, and flexible tip (Fig. 19-1).

At the end of the handle is either a battery-operated light source, which allows for more portability, or an optical cable connection to an external light source. The proximal "visual section" of the handle is the location of an eyepiece and lens, a video output adaptor, or an actual video screen with an integrated camera (depending on the model). FOBs with a CCD or CMOS camera chip at the tip have a wide-angle image and a higher resolution of the picture transmitted, compared with older models, which have a narrower field of view and less optical detail (Fig. 19-2). This makes video fiberscope deployment useful clinically, particularly in teaching.

Many FOBs have a visible black notch in the eyepiece at the 12-o'clock position to aid with orientation. Near the handle, an adjustable focusing ring or diopter can be

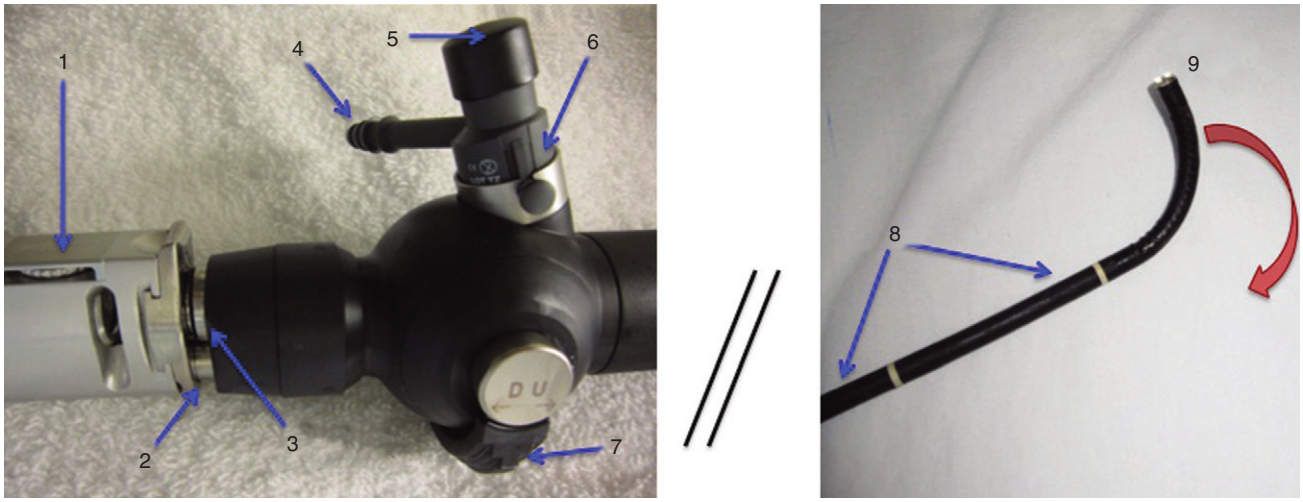

Figure 19-1 *Left,* Fiberoptic bronchoscope (FOB) handle (control section) design. *1,* Focus adjusting ring; *2,* light source connection; *3,* video output connection; *4,* suction port; *5,* valve; *6,* working channel; *7,* angulation control lever. *Right,* FOB insertion tube leading to flexible tip: *8,* Insertion tube; *9,* flexible tip.

fine-tuned to sharpen the image. Some models have a venting ethylene oxide sterilization cap nearby.

The handle is attached to the insertion tube (i.e., the section that goes into the patient). The tube's outer diameter (OD) determines the minimum internal diameter (ID) of the endotracheal tube (ETT) into which the FOB can easily pass. Insertion tubes average 50 to 65 cm in length and are surrounded by a flexible inner stainless steel mesh and a flexible outer, water-impermeable plastic wrap.

Four specific components travel inside the insertion tube along the FOB length (Fig. 19-3). The first allows the transmission of light going toward the tip by way of one or two light guide bundles constructed of noncoherent glass fibers. A high degree of light intensity is focused on the proximal light guide bundle, but heat filters or reflecting mirrors prevent injury to the insertion tube components.

The eyepiece lens in the handle and the objective lens of the FOB tip are perpendicular to the longitudinal axis of the insertion tube, enabling the second tube component to transmit identical patient images from the distal lens to the proximal one. This component involves 10,000 to 50,000 glass fibers, as low as 8 to 9 μm in diameter, which are arranged in coherent bundles to transmit the image to the visual section in a completely spatially oriented state. (By comparison, human hairs are 17 to 180 μm in diameter.) A secondary glass cladding layer surrounds each strand to reflect light internally and maintain intensity by preventing external absorption or reflection of light from the lateral surface of each fiber. The glass fibers are extremely sensitive to damage. Although many thousands of fibers might seem expendable, when one is broken, a black dot becomes visible within the transmitted image. Excessive FOB bending, dropping, or external pressure (e.g., by teeth) can quickly

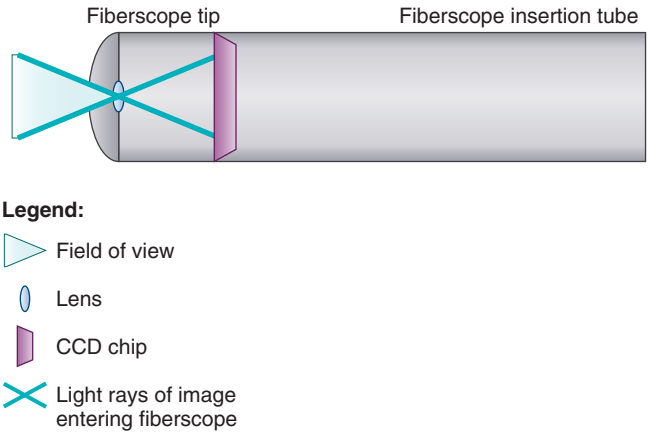

Figure 19-2 Fiberoptic tip mechanics: Field of view. Insertion tip transmission of light through a lens to the charge-coupled device *(CCD)* chip.

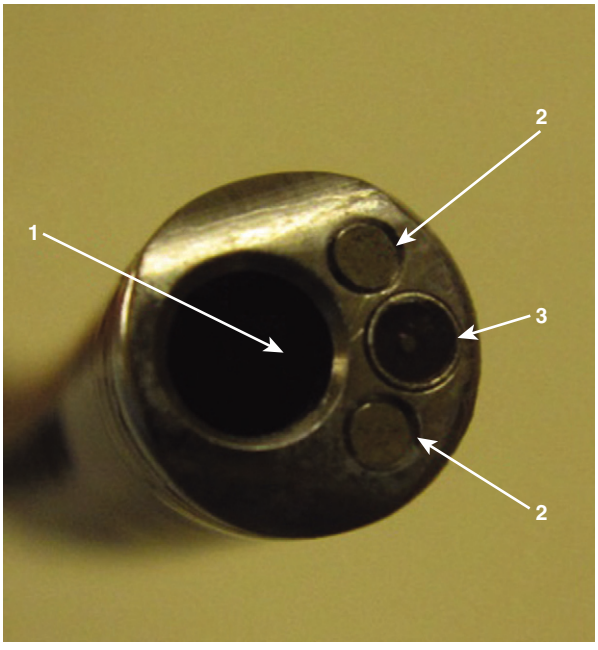

Figure 19-3 Fiberoptic tip components. *1,* Working channel; *2,* two angulation wires; *3,* cladded fiberoptic-lighted bundle.

add up to many dozens of black spots, rendering significant impairment of FOB visual acuity and necessitating costly repair.

On the back of the handle is a bending or angulation lever. Through an up or down movement of the thumb, it causes pulling on the third insertion tube component located along the sagittal plane, the two angulation wires. This initiates movement of the FOB tip in the opposite direction (i.e., down or up, respectively) by as much as 240 to 350 degrees (see Fig. 19-1). These delicate wires can also be broken with excessive pressure, including lever motion if the FOB tip is still within the ETT lumen.

The last component is termed the working channel; it is 1.2 to 2.8 mm in diameter and runs the length of the FOB from the suction or working port on the handle to the FOB tip. When the working port is attached to suction or oxygen tubing, the nearby spring valve can be opened by index finger pressure to allow suctioning or oxygen administration. Alternatively, a syringe with local anesthetic or other medication can be attached to the working port (also called the suction port) or to the biopsy/injection port below the handle (present in some models). When drugs are being given, the operator must make sure the suction is off so that the medication actually goes forward.

The FOB tip or bending section is hinged and has an objective lens (approximately 2 mm in diameter) with a fixed focal point and a short field of view (75 to 120 degrees) (see Figs. 19-1 to 19-3).

Many models are available in sizes from premature infant to large adult and with varying fields of view, video monitors, closed-valve systems, and other features (Table 19-1).

B. Fiberoptic Bronchoscope Cleaning

Almost half a million bronchoscopies are performed per year in the United States.[17] Whenever any equipment is

reused between patients, there is always a concern for avoiding the transmission of communicable diseases. Although there have not been any reports of infection or cross-contamination caused by fiberoptic intubation for elective or emergency purposes, sporadic references testify to instances of infection or contamination after flexible bronchoscopic procedures such as bronchial washings or bronchoscopic lavage. Between the years 2000 and 2007, the American Association for Respiratory Care (AARC), American College of Chest Physicians (AACP), American Association for Bronchology and Interventional Pulmonology (AABIP), and Association for Professionals in Infection Control (APIC) issued guidelines and consensus statements to assist in the prevention of FOB-associated infection or contamination.[18-20]

Since the 1970s, sources of contamination have included a number of factors: sentinel patients, contaminated water, inadequate sterilization technique (due to insufficient quality or quantity of sterilizing solution), repeated use of cleaning fluid or brushes, automated endoscope reprocessors, and FOB instruments with design errors or damage.[21-24] Valves and working channels are usually the most suspect areas for ineffective FOB sterilization. Multiple organisms have been found, including *Pseudomonas aeruginosa*, non-tuberculosis mycobacteria, *Serratia marcescens*, *Mycobacterium tuberculosis*, *Stenotrophomonas maltophilia*, *Legionella pneumophila*, *Rhodotorula rubra*, *Klebsiella* species, *Proteus* species, and fungi.[21,25-28]

When an FOB is being used for patient management, involved clinical sites automatically fall under the aegis of mandatory universal precautions. Constant vigilance in FOB care and high-level disinfection are imperative. Once used, an FOB should be directly handed off to trained assistants or placed in a vertical holding tube (e.g., ProShield, Seitz Technical Products, Avondale, PA) for rapid pickup. Holding tubes should be long enough to handle FOBs up to 65 cm in length; they prevent damage and contamination that might occur from contact with other equipment or people.

Disinfection may take up to 45 min (Fig. 19-4). The assistant should carefully insert a cleaning brush into portals entering the working channel. The brush must be advanced fully along the compete span of this conduit to effect early removal of secretions according to the instructions of the manufacturer and the health care organization.

Next, the FOB has to be diligently inspected for any damage, tears, indentations, or abnormalities along its entire length. A leak test to detect holes in the insertion tube sheath is essential at this point, and failures necessitate sending the FOB for repairs without any further sterilization.

The suction ports and biopsy ports (if present) need to be disassembled from the rest of the FOB. All nondisposable parts must be gently placed in glutaraldehyde, peracetic acid, orthophthaldehyde, hydrogen peroxide gas plasma, or other manufacturer-indicated sterilization solution, and the working channel must be syringe-flushed with this disinfectant conforming to manufacturer and health care organization instructions.[29-31]

After completion of the specified sterilization time, all parts must be removed to prevent caustic damage to the instrument. The FOB should be gently washed and thoroughly rinsed with sterile water, including flushing of the working channel to prevent toxicity from residual chemicals.[32] It is mandatory to dry the channel by suctioning or purging with 70% alcohol and compressed air for a time period in keeping with manufacturer and health care organization instructions.

Figure 19-4 Steris machine for sterilization of a fiberoptic bronchoscope. The working channel is flushed out before being carefully placed within the sterilizer.

Most bacteria, fungi, and viruses are susceptible to these sterilization processes, including human immunodeficiency virus (HIV) and hepatitis. FOBs that have been used in patients with contagious diseases (e.g., tuberculosis) may require a lengthy ethylene oxide sterilization and aeration procedure for up to 24 hours, with the venting cap secured to the venting connector. In the case of suspected prion infection (Creutzfeldt-Jakob or variants), it is best to avoid bronchoscopy if possible, because the sterilization process for most medical instruments would be damaging.[18-20,33]

Presently, routine surveillance cultures have not been recommended by the AARC, AACP, AABIP, or APIC because of lack of criteria to determine testing frequency, relevance when positive results occur, indeterminate courses of action, and costs of testing procedures.[18-20]

During all handling and sterilization techniques, keeping the FOB as straight as possible is extremely important to avoid damage. Once the device has been cleaned, it is preferable to store it suspended by its handle in a moderately lighted, climate- and humidity-controlled, safe location. Close proximity to radiation should be avoided because of deleterious effects on the FOB material.[34]

C. Disposable Flexible Bronchoscopes

Because efforts toward the production of a truly autoclavable FOB (e.g., Bronchosteril endoscope, Andromis, Geneva, Switzerland) did not lead to a widely accepted device, other solutions aimed at a simplified approach to the prevention of cross-contamination were developed.

1. Sheathed Fiberoptic Bronchoscope

Vision Sciences, Inc. (Orangeburg, NY) has produced two adult-sized, channel-less FOBs for use with a clear, durable, snugly fitting, presterilized flexible, thermoplastic, elastomer EndoSheath that incorporates its own 1.5- to 2.1-mm working channel. The disposable sheath potentially prevents transmission of organisms and may increase FOB availability by requiring no down-time for sterilization. It might also reduce costs in centers where economic factors limit the purchase of more than a minimum number of bronchoscopy systems or limit the availability of sterilization equipment or personnel.[35,36]

2. Non-fiberoptic Flexible Bronchoscope

The Ambu aScope (Ambu A/S, Ballerup, Denmark) is a fully disposable, sterile, battery-operated non-FOB with a small (0.8-mm) working channel capable of drug instillation but not suctioning. It has a CMOS chip, a steering button to flex the tip, and a distal LED (Fig. 19-5). Images are transmitted along a cable within the insertion tube and transferred to a small portable monitor by way of a video connection cable at the handle. In its early version, this non-FOB had a timing mechanism allowing it to function for a maximum of 30 minutes during an 8-hour period starting from the initial power startup. A more recent version of this device comes without these time limitations. The monitor can be used for 150 intubations and is connected to an external monitoring system. Apart from routine use of this instrument, a particular advantage may occur in patients with highly contagious disease (e.g., Creutzfeldt-Jakob), in immunosuppressed patients, or in situations in which cheaper devices may be beneficial (e.g., where economic factors limit purchases or where FOB is seldom used).[37,38]

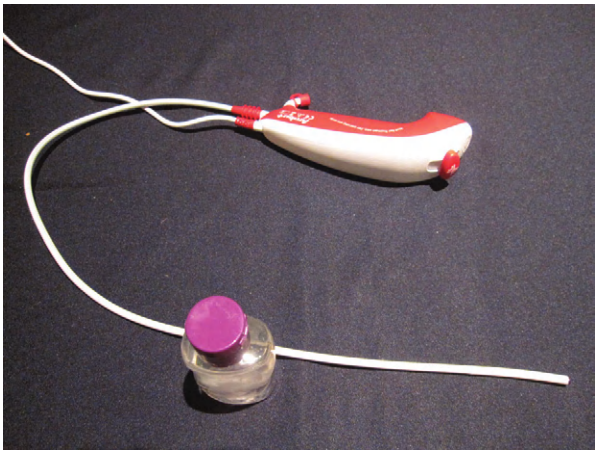

Figure 19-5 Disposable Ambu aScope with a button lever to angle the tip down or up.

III. RATIONALE FOR FIBEROPTIC INTUBATION

Airway management failure is a leading cause of patient morbidity and mortality in closed claims analyses.[39] During the period 1999 to 2005, failed intubation or DI was the cause of 2.3% of the 2211 anesthesia-related deaths in the United States.[40] With rigid laryngoscopes (RLs), DI was reported to have a frequency ranging from 1% to 13%.[41-45] Shiga and colleagues performed a meta-analysis of studies on 50,760 patients and estimated the average occurrence of difficult intubation to be 5.8%,[46] with a range of 4.5% to 7.5% overall[47,48] and an even greater incidence in obstetric or obese patients.[49-51] Anesthesia Associates, Inc. (AincA), San Marcos, CA Benumof's estimate of "cannot intubate, cannot mask-ventilate" scenario was verified by Heidegger and associates at 0.007%,[52,53] whereas Kheterpal and coworkers showed the incidence of impossible mask ventilation to be 0.15% in a prospective series of 53,041 patients.[54]

FOB intubation has always had a place in these scenarios, but this simple technique seems formidable to many. However, despite the increasing availability of less expensive intubating supraglottic airways (SGAs), lighted stylets, video laryngoscopes (VLs), and optical laryngoscopes (OLs), an explosion of improved laryngoscopic views, and greater intubating success rates, there is still a definite need for FOB intubation. A survey of American anesthesiologists by Rosenblatt and colleagues revealed a strong preference for FOB intubation for DA patients.[55] Avarguès and associates' survey of French anesthetists in 1999 revealed that 64% of responders expressed the need for more training in FOB intubation.[56] Furthermore, FOB use was mentioned twice in the revised 2003 DA algorithm by a panel of experts who formulated the American Society of Anesthesiologists (ASA) Practice Guidelines for Difficult Airway Management.[57] In a 2009 review of the existing algorithms for DA management, Frova and Sorbello affirmed that FOB is universally recognized as the gold standard in the awake, sedated, or anesthetized "difficult to intubate" patient.[58]

Finally and more practically, there have been numerous cases in which older devices and even the most recently developed airway management devices have proved to be inadequate. FOB employment and assistance steadfastly facilitates the execution of successful intubations, often rescuing these failures, either alone or as part of a multimodal approach to the DA.[59,60]

The FOB has a number of unique, wide-ranging characteristics:

- Its flexible, gliding attributes allow FOB skimming along the most twisted of DA obstacle courses while still posting the highest success rates for intubation.
- During intubation, the FOB is the device least likely to result in any cervical spine motion.[61]
- The FOB can be used for intubation in any body position, via oral or nasal routes, in all age groups.
- Under excellent local airway anesthesia, FOB intubation is associated with negligible hemodynamic changes.
- The FOB has multiple diagnostic capabilities for determining abnormal anatomy, assisting with

implementation of other airway devices, and trouble-shooting ventilatory problems.

A. Indications for Flexible Fiberoptic or Endoscopic Intubation

Although many anesthesiologists routinely carry out FOB intubation on all of their patients, most tend to adhere to specific indications. There is no hard or fast rule for "awake" versus "asleep" fiberoptic intubation. An awake approach is usually chosen to lessen significant patient risk in comparison to other methods, especially rigid laryngoscopy. The awake approach may be more advisable in cases of a very difficult airway or with a somewhat difficult airway in a patient with intolerant comorbidities endangered by the trauma or hypoxemia of non-FOB techniques (e.g., critical coronary artery disease). A list of indications for flexible airway endoscopy is presented in Box 19-1.

B. Contraindications: Absolute, Moderate, and Relative

The most important contraindication to FOB use may well be lack of skill of the endoscopist (i.e., FOB operator) due to inadequate training or inadequate maintenance of formerly acquired skills. Any lack of a trained assistant or of available, ready to use, proper equipment may also negate FOB plans. There are few other contraindications to FOB use. These may involve situations in which harm to the instrument may occur (e.g., uncooperative patients), cases in which FOB use is extremely likely to be unsuccessful (e.g., patients with known near-total upper airway obstruction [Fig. 19-6]), or rare instances in which another technique may pose less risk for airway management (e.g., patients who have massive facial trauma with excessive bleeding might do better with a tracheostomy). Contraindications for awake and asleep FOB intubation are listed in Boxes 19-2 and 19-3, respectively.

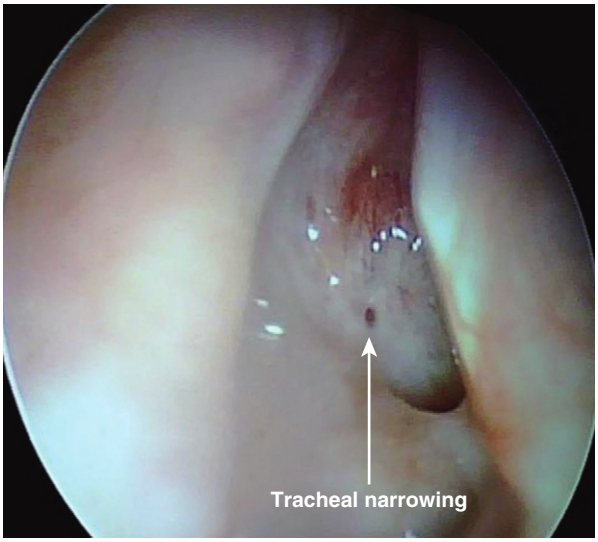

Figure 19-6 Severe subglottic stenosis appears as a pinpoint tracheal opening.

Box 19-1 Indications for Use of Flexible Fiberoptic or Endoscopic Intubation

1. Routine intubation
2. Difficult intubation (DI)
   a. History of prior DI
   b. Suspected DI from patient history or physical examination
   c. Rescue of failed intubation attempt
   d. Intubating patients with preexisting Combitube or Rüsch EasyTube
3. Prevention of cervical spine motion in at-risk patients
4. Avoidance of traumatic oral or nasal effects of intubation (e.g., loose teeth, nasal polyps)
5. Avoidance of aspiration in high-risk patients
6. Diagnostic purposes
   a. Trouble-shooting high airway pressures
   b. Trouble-shooting hypoxemia
   c. Observation for airway pathology (e.g., stenosis, tracheomalacia, vocal cord paralysis)
   d. Removal of airway pathology (e.g., secretions)
7. Therapeutic uses beyond planned FOB intubation
   a. Endotracheal tube exchange
   b. Assistance with airway placement (e.g., SGA, retrograde intubation, etc.)
   c. Positioning of double-lumen tubes or bronchial blockers
   d. Positioning of endotracheal tubes at specific depths
   e. Intratracheal observation of initial tracheostomy instrument entry

FOB, Fiberoptic bronchoscope; *SGA,* supraglottic airway device.

Box 19-2 Contraindications for Awake FOB Techniques

1. Absolute contraindications
   a. A completely wild, uncooperative patient
   b. Lack of endoscopist skill, assistance, or equipment
   c. Near-total upper airway obstruction unless for diagnostic purposes
   d. Massive trauma (but, if retrograde intubation is chosen, FOB may help; see text)
2. Moderate contraindications
   a. Relatively uncooperative patient
   b. Obstructing or obscuring blood, fluid, anatomy, or foreign body in the airway that might inhibit success
   c. Very small entry space
3. Relative contraindications
   a. Concern for vocal cord damage that might be caused by blind ETT passage over the FOB
   b. With some perilaryngeal masses, blindly advancing the ETT can "cork out" or seed the tumor (this situation should be discussed with the ENT specialist, if possible)
   c. Documented or suspected nonconventional infectious agents, agents resistant to multiple drugs, or infectious diseases in the absence of a single-use device

ENT, Ear, nose, and throat; *ETT,* endotracheal tube; *FOB,* fiberoptic bronchoscope.

Box 19-3 Contraindications for Asleep FOB Techniques

1. Absolute contraindications
   a. Lack of endoscopist skill, assistance, or equipment
   b. Near-total upper airway obstruction unless for diagnostic purposes
   c. Massive trauma (but, if retrograde intubation was chosen, FOB may help; see text)
2. Moderate contraindications
   a. Too high an aspiration risk or too difficult an airway
   b. Inability to tolerate even a short period of apnea
   c. Obstructing or obscuring blood, fluid, anatomy, or foreign body in the airway that might inhibit success
   d. Very small entry space
3. Relative contraindications
   a. Concern for vocal cord damage that might be caused by blind ETT passage over the FOB
   b. With some perilaryngeal masses, blindly advancing the ETT can "cork out" or seed the tumor (this situation should be discussed with the ENT specialist, if possible)
   c. Documented or suspected nonconventional infectious agents, agents resistant to multiple drugs, or infectious diseases in the absence of a single-use device

ENT, Ear, nose, and throat; *ETT,* endotracheal tube; *FOB,* fiberoptic bronchoscope.

IV. EQUIPMENT

A. Fiberoptic and Non-fiberoptic Bronchoscope Model Details

FOB specifications and characteristics have been presented in Table 19-1. Some models have eyepieces or video attachments. Others have varying degrees of portability. Sizes and ranges of view are also variable, from the smallest infant to the largest adult size. In 2010, Olympus developed a unique MAF-GM system; it features a lithium rechargeable battery-operated FOB with a fixed, rotatable video screen by the handle—all totally immersible for sterilization. Its CCD camera has a memory card and an xD chip for still photography and video recording.

B. Fiberoptic Bronchoscope Cart

Preparation for highly useful FOB techniques is important to increase the likelihood of success. The incorporation of an FOB cart as a movable asset capable of rapid transport to operating rooms, specialty units, or floors is ideal for routine or emergency use. Contents need to be arranged logically in a readily available design so that the composition and organization will be uniform across the facility in the event that more than one cart is needed for an institution. All airway specialists must be familiar with the contents of the FOB cart and know how to have it transported to required patient sites without delay. Preferably, the cart should have two widely separated tubular structures for hanging a clean FOB and, later, a used one (Fig. 19-7). Typically, the FOB cart will also have a light source, a video monitor (ideally), endoscopy masks, bronchoscopy swivel adapters, oral intubating airways, bite blocks, atomizers, tongue blades, cotton-tipped swabs, gauze, soft nasal airways, and local anesthetics (e.g., 2% and 4% lidocaine, 2% lidocaine gel or paste).

In addition to clinical use, FOB carts can be used for institutional continuous education programs and teaching workshops. All carts should be organized and upgraded by the anesthesiology team.

Optionally, an FOB cart setup could also be incorporated as part of a more complete DA cart that includes items needed to follow the DA algorithm. Among other items, a DA cart should contain a VL and screen, SGAs, intubating SGAs, ETT introducer/exchangers,[62,63] and percutaneous airway rescue sets.

C. Ancillary Equipment

1. Bronchoscopy Swivel Adapters and Endoscopy Masks

Bronchoscopy adapters and endoscopy masks are often used in asleep or awake patients for FOB examination, intubation, diagnosis, or therapy.

Bronchoscopy swivel adapters have the capacity to rotate when placed between the ventilating system and a mask, SGA, or ETT. They look like elbow adapters but are equipped with a "flip-cap port" covering a diaphragm with a central opening (Fig. 19-8). This permits passage

Figure 19-7 Mobile fiberoptic cart with a video screen and supplies underneath. The fiberoptic bronchoscope (FOB) is braced in the clean container on the left, and a holding tube for the used FOB is located on the right. The FOB insertion section lies within an endotracheal tube in a warm saline solution.

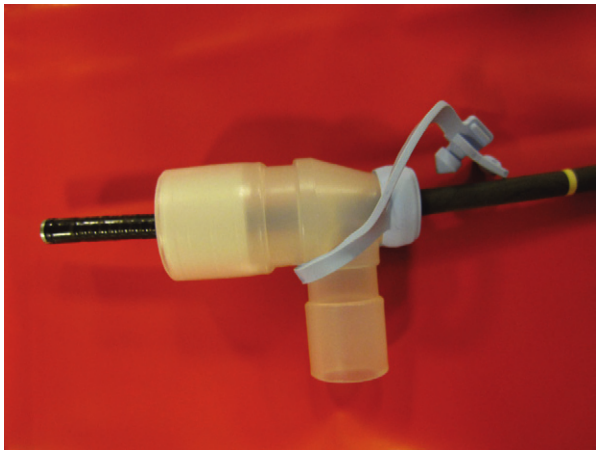

Figure 19-8 Bronchoscopy swivel adapter with a snug fiberoptic bronchoscope diaphragm opening that allows ventilation without leaking.

Figure 19-9 Endoscopy mask with connector tubing for ventilation (on the left) and a snug diaphragm (on top) for passage of a fiberoptic bronchoscope within an endotracheal tube.

of an FOB with virtually no leak during use of the continuous ventilation system on a patient.

Endoscopy masks differ from regular masks by having at least one larger additional opening whose function is similar to that of a bronchoscopy swivel adapter port (Fig. 19-9). The opening permits both FOB and ETT passage for intubation during continuous mask ventilation. Some masks have recessed one-way, valve-like openings for FOB and ETT entry.

2. Intubating Oral Airways

Intubating oral airways (IOAs) are often used in unconscious patients or in the topically anesthetized oropharynx of awake patients to act as a conduit through which an FOB is inserted for oral intubation (Fig. 19-10). It is extremely useful when an assistant holds the IOA midline throughout the intubation procedure. These airways should not be jammed fully into the patient if they seem too large for smaller mouth openings. If no IOA is used secondary to inadequate mouth opening or endoscopist preference, a bite block should be placed between the molars or incisors to prevent FOB injury.
