Acute pain management in opioid-dependent patients is a complex issue. There is a tendency among providers to use opioids sparingly, resulting in both poor pain management and withdrawal phenomena. As a result, patients may react with a degree of suspicion, mistrust, or even hostility. Patients need to be reassured that their drug history and dependence will not be an obstacle to the relief of pain. During assessment, care should be exercised to maintain privacy and confidentiality.

Despite the increasing prevalence of opioid dependency, there are few controlled studies available to guide the anesthesiologist in optimizing anesthetic and analgesic care. Because the minimum daily opioid dose that significantly increases postoperative opioid requirements and pain is not known, all patients on chronic opioids should be informed about the potential for difficult to control pain and increased opioid requirements during the postoperative period. Patients should be informed about alternative analgesic techniques that complement opioids.

The selection of anesthesia technique has to be done on an individual basis because there are no data favoring general, regional, or combined anesthesia for this specific patient

population. Although there is no evidence indicating superiority of regional anesthesia for chronic pain patients, individual consideration is likely to favor regional anesthesia. Expert opinion suggests that opioid-tolerant patients should be offered regional or neuraxial anesthesia or analgesia when possible.

B.6. What are the choices for perioperative pain management in opioid-tolerant patients?

Management of these patients should focus on two main goals: (1) effective analgesia and (2) prevention of withdrawal. Preexisting opioid medications must be continued throughout the perioperative period to provide baseline analgesia and to avoid withdrawal. This applies for general anesthesia as well as regional anesthesia. During surgery, the required opioid dose consists of the daily opioid dose taken before surgery and the opioid dose necessary for the surgical intervention. The use of a continuous infusion of opioid or long-acting intravenous opioid may be the best way to provide a steady serum concentration if the oral route is unavailable, as is the case intraoperatively.

Catching up on the opioid dose in the postoperative period can be difficult because of inevitable delays in obtaining and administering opioids at the bedside, the high levels of pain that patients may experience, and a possible reluctance of recovery room staff to administer a sufficiently large opioid dose. Requirements for individual patients are difficult to predict;

however, patients who use even modest opioid doses (<50 mg per day oral morphine equivalent) before surgery may require their baseline opioid dose plus two or more times the amount of opioids typically used for adequate pain control in opioid-naive patients.

Regional anesthesia techniques have many benefits and may be particularly useful in chronic opioid-consuming patients because they provide excellent analgesia, avoid the need for high-dose opioids, and may be extended in duration with use of catheter-based techniques. Neuraxial opioids have also been used effectively in opioid-tolerant patients, and although higher doses are often required, these generally do not result in an increase in adverse effects.

Nevertheless, chronic opioid-consuming patients treated with regional and neuraxial techniques for postoperative pain control should also have access to systemic opioids by the intravenous or oral route for prevention of opioid withdrawal. IV-PCA is a useful modality for pain relief in opioid-tolerant patients. Larger bolus doses will often be needed. Opioid rotation (i.e., using an opioid that is different from their preadmission opioid) may also be of use. If preoperative opioid use is substantial, a long-acting intravenous agent such as methadone or a basal rate PCA may be required, although in general the amount of opioid to avoid withdrawal is much lower than the patient's usual dose. Withdrawal from opioids should be prevented by maintenance of normal preadmission opioid regimens where possible, or appropriate substitutions with another opioid or the same opioid through another route.

Ketamine can reduce opioid requirements in opioid-tolerant patients, both intraoperatively and postoperatively. It is an *N*-methyl-D-aspartic acid receptor antagonist and results in analgesia by inhibiting the processing of nociceptive information. Evidence shows that the addition of *N*-methyl-D-

aspartic acid receptor antagonists with other analgesics or as a sole agent for chronic (e.g., complex regional pain syndrome), ischemic, or neuropathic pain states can reduce the requirement for other analgesic agents. When ketamine is used as a continuous infusion in the postoperative setting, it can have an opioid-sparing effect, although there is no reduction in opioid-related side effects. It can also serve as a bridge until the patient is able to tolerate their home oral regimen. Perioperatively, ketamine is best used as an adjunct to opioid medications.

Multimodal analgesic regimens including combinations of NSAIDs, APAP, gabapentinoids, and topical local anesthetics are likely to provide benefit as well. Opioid antagonists (naloxone, naltrexone) or mixed agonist–antagonists (e.g., buprenorphine, pentazocine) should be avoided because their use precipitates acute withdrawal reactions in the setting of high full-agonist opioids.

Subramaniam K, Subramaniam B, Steinbrook RA. Ketamine as adjuvant analgesic to opioids: a quantitative and qualitative systematic review. *Anesth Analg*. 2004;99:482–495.

B.7. What issues need to be considered before discharging an opioid-tolerant patient?

Discharge planning must take into account the potential for prescribed opioids to be abused or misused by the patient as well as the home situation and anyone at risk for harm from misuse (children). Appropriate use of nonopioid analgesics where possible, communication with the primary physician, and patient education and support must all be considered.

Chronic opioid-consuming patients typically require

significantly higher postoperative opioid doses for adequate pain control than they received before surgery for their chronic pain symptoms. Attempting to discharge chronic opioid-consuming patients on the same opioid regimen they adhered to before surgery often results in inadequate pain control. Whatever the final oral dose chronic opioid-consuming patients are stabilized on at discharge, a tapering from this dose toward the preoperative opioid dose over 2 to 4 weeks is often a reasonable goal. In the case under consideration, the transdermal fentanyl patch should be left in place to provide the patient's preexisting opioid requirement, and additional short-acting analgesics should be prescribed for postoperative pain. It is also advisable to counsel the patient to discuss opioid prescribing with the existing outpatient provider preoperatively because many physicians require an opioid contract with single-provider prescribing for controlled substances.

C. Perioperative Pain Management for Ambulatory Surgery

C.1. What would be your preoperative considerations and advice to the patient?

Adequate postoperative pain management is often the limiting factor when determining whether a patient can have surgery performed as an ambulatory surgical procedure. Ensuring that the patient has appropriate expectations of the outcome of laparoscopic cholecystectomy is critical for a successful

conclusion to the procedure, especially with regard to postoperative pain. Unrealistic expectations for no pain at all can be met with anger, disappointment, and the fear and anxiety that something has gone wrong.

Planning for postoperative pain management should begin in the preoperative period. Patient education regarding the degree of pain that might be expected and discussion of the pain assessment tools and modalities of pain treatment that might be utilized should reduce the patient's anxiety and the fear of unrelieved pain. Reduced patient anxiety has been shown to reduce the incidence and severity of postoperative pain. In addition, patients have to be made aware of the importance of communicating their analgesic needs. Patients should receive instruction on the importance of coughing, deep breathing, ambulation, and postoperative rehabilitation. Patient information on acute postoperative pain management is available from reliable public sources such as the American Society of Anesthesiologists website, and patients can be directed to these sources for self-study.

Details of the complications of laparoscopic cholecystectomy given to patients vary between countries and cultures. The most relevant for postoperative pain is to mention the risk of conversion to open laparotomy in a small percentage of cases, which will be associated with a significantly larger incision, more pain, and longer period of hospitalization. Patients need to be informed that there are three types of pain often associated with laparoscopic cholecystectomy: (1) incisional, (2) visceral, and (3) shoulder pain. It is helpful to describe, in particular, the high incidence of referred pain in the shoulder and to reassure the patient that this is related to the laparoscopy and not necessarily his or her heart or chest. The patient should be informed that there is a relatively high risk of postoperative nausea and vomiting after laparoscopic cholecystectomy

(approximately 30% to 50%) and that appropriate prophylaxis will be administered (antiemetic strategies can be tailored based on clinical risk assessments such as the Apfel risk score for nausea and vomiting).

Predischarge patient information should also include the following: (1) that patients will receive analgesic and/or antiemetic medications for management of pain and postoperative nausea and vomiting at home, (2) that the care team will make a follow-up call and schedule a follow-up appointment, and (3) that he or she will get contact numbers in case there are problems or questions.

Apfel CC, Heidrich FM, Jukar-Rao S, et al. Evidence-based analysis of risk factors for postoperative nausea and vomiting. *Br J Anaesth*. 2012;109(5):742–753.

Farrell C, McConaghy P. Perioperative management of patients taking treatment for chronic pain. *BMJ*. 2012;345:e4148.

C.2. What are the consequences of inadequate pain management after ambulatory surgery?

In the ambulatory setting, the type of surgery is a significant predictor of severity of postoperative pain. Even when postoperative pain is effectively treated in the postanesthesia care unit, it often recurs once the patient has returned home. A common example is a peripheral nerve block for orthopedic surgery, which provides excellent analgesia until the block has worn off several hours later.

Uncontrolled pain is associated with an increased incidence of postoperative nausea, agitation, prolonged postanesthesia care unit stay, delayed discharge from an ambulatory facility, and unanticipated hospital admission. Inadequate postoperative pain control is also the most frequent reason for patients to contact their provider after discharge from the hospital. More important,

the presence of postoperative symptoms including pain contributes to patient dissatisfaction with their surgical experience (**Table 51.1**).

TABLE 51.1 Consequences of Inadequate Pain Management after Ambulatory Surgery

Increased postanesthesia care unit stay
Increased phase II unit stay
Delayed discharge at home
Unanticipated hospital admission
Increased contact with family practitioner
Delayed return to daily living function
Decreased patient satisfaction

Dickerson DM. Acute pain management. *Anesthesiol Clin*. 2014;32(2):495–504.

C.3. What is the role of premedication or preoperative analgesic?

Preoperative administration of nonopioid analgesics reduces postoperative morphine requirements and pain scores. Commonly used agents include NSAIDs, acetaminophen, and gabapentinoids. These may be continued throughout the perioperative period or given as a one-time preoperative dose. Most commonly, these agents are given the morning of surgery with a small sip of water as part of a protocol for specific surgeries (orthopedic hip and knee arthroplasty having the most data).

Preemptive analgesia refers to the concept that an analgesic medication or intervention administered before surgical tissue injury may produce a greater effect than the same medication or intervention administered following surgical tissue injury. This preemptive analgesic effect has been demonstrated for several different medications in animal models, but clinical studies do not support a significant role for preemptive analgesia in human

patients. For multiple surgical procedures including thoracic and abdominal procedures, laparoscopic, and open, there is no strong evidence that preincisional timing of analgesic administration (preemptive analgesia) decreases the intensity or duration of postoperative pain, when compared with intraoperative or postoperative administration.

Møiniche S, Kehlet H, Dahl JB. A qualitative and quantitative systematic review of preemptive analgesia for postoperative pain relief: the role of timing of analgesia. *Anesthesiology*. 2002;96:725–741.

C.4. Does the choice of anesthetic technique influence postoperative pain?

The choice of anesthetic technique has been shown to have a significant influence on postoperative analgesia in patients undergoing ambulatory surgery. Regional or neuraxial anesthesia techniques offer a number of advantages in outpatient surgery, including prolonged postoperative analgesia and decreased opioid side effects, but at the expense of prolonged recovery and time to discharge. For the case in question, a neuraxial or regional technique is not recommended for routine anesthetic management as most patients undergoing laparoscopic cholecystectomy do not convert to open procedures, and thus, the incisions are small and minimally painful postoperatively.

Total intravenous anesthesia (TIVA) offers an alternative to inhalational anesthesia, and although rapid recovery from anesthesia and reduction in nausea and vomiting are recognized benefits, the analgesic components of commonly used agents in TIVA have either no analgesic effect (propofol) or a very short duration (remifentanil) and do not contribute significantly to postoperative analgesia.

Opioids remain the primary drugs used to provide intraoperative and postoperative analgesia in the United States. However, the role of opioids in ambulatory surgery remains controversial. The use of opioids may be associated with a dose-dependent increase in adverse effects, including nausea, vomiting, sedation, bladder dysfunction, and respiratory depression, all of which may contribute to a delayed recovery.

Consensus recommendations for anesthetic management of laparoscopic cholecystectomy include use of paracetamol or acetaminophen and NSAID preoperatively, dexamethasone intraoperatively, and opioids primarily for rescue analgesia. Gabapentinoids, intraperitoneal local anesthetic, neuraxial techniques, and transversus abdominis plane blocks are not usually indicated.

Barazanchi AWH, MacFater WS, Rahiri JL, et al. Evidence-based management of pain after laparoscopic cholecystectomy: a PROSPECT review update. *Br J Anaesth*. 2018;121(4):787–803.

Kehlet H, Gray AW, Bonnet F, et al. A procedure-specific systematic review and consensus recommendations for postoperative analgesia following laparoscopic cholecystectomy. *Surg Endosc*. 2005;19:1396–1415.

C.5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?

The opioid-sparing effects of NSAIDs lower the risk of postoperative nausea and vomiting, pruritus, constipation, and respiratory depression, thereby improving patient comfort and allowing for an earlier discharge.

The introduction of parenteral preparations of NSAIDs and the widespread acceptance of the concept of multimodal "balanced" analgesia has increased their use in the management of perioperative pain. NSAIDs commonly available for intravenous use include ketorolac, diclofenac, and ibuprofen. NSAIDs have weaker analgesic properties than opioids and also exhibit a "ceiling effect" but may be more effective to decrease

the risk of breakthrough pain because of their more prolonged duration of action and are valuable adjuvants when used in combination with other agents.

There is no documented evidence of superiority of any particular NSAID for perioperative use. Therefore, the choice of NSAID is dependent on the route of administration, the duration of analgesia, propensity for side effects, availability, and cost. The oral bioavailability of most NSAIDs is high, and this is the preferred route when tolerated.

COX-2 inhibitors have been demonstrated in multiple clinical trials to produce analgesic efficacy equal to that of the traditional nonselective NSAIDs with fewer cyclooxygenase-1 (COX-1)–mediated adverse effects (gastrointestinal discomfort, decreased renal blood flow, platelet inhibition). NSAIDs used over a short period for postoperative analgesia have not been demonstrated to cause any major adverse events in healthy patients, although use can precipitate congestive heart failure (CHF) exacerbation in at-risk patients and has been associated with anastomotic leak in colorectal surgery.

C.6. What is the role of surgical technique in influencing postoperative pain after a laparoscopic cholecystectomy?

There are three types of pain after laparoscopic cholecystectomy: incisional, subphrenic, and shoulder pain. Factors responsible for the pain may be related to surgical

incisions, carbon dioxide (CO_2) insufflation during surgery, and residual gas postprocedure. Higher insufflation pressures should be avoided because they can significantly increase the severity of postoperative pain. Subphrenic and shoulder pain after laparoscopic procedures can arise from diaphragmatic and phrenic nerve irritation due to insufflated CO_2. Residual insufflating gas can also increase the intensity of postlaparoscopic pain. This pain tends to be aggravated positionally and may persist for several days after surgery. Evidence from prospective studies to prevent postoperative pain after laparoscopy includes the following findings:

- Low-pressure CO_2 pneumoperitoneum is superior to conventional CO_2 pneumoperitoneum.
- Peritoneal saline lavage after CO_2 pneumoperitoneum is effective in reducing postoperative pain.
- Aspiration of residual pneumoperitoneum prior to closure is recommended.
- Single-port incision techniques have not been found to decrease postoperative pain.

Phelps P, Cakmakkaya OS, Apfel CC, et al. A simple clinical maneuver to reduce laparoscopy-induced shoulder pain: a randomized controlled trial. *Obstet Gynecol*. 2008;111(5):1155–1160.

C.7. What would be your strategy for pain control after discharge home?

After discharge, APAP, NSAIDs, or opioids, either alone or in combination, are frequently used to provide postoperative pain relief.

APAP and paracetamol are thought to work through central inhibition of prostaglandin synthesis, possibly through a

cyclooxygenase-3 (COX-3) inhibitory mechanism. They are commonly used due to easy tolerability and good safety profile. Care should be taken when using opioid/APAP combination products as the APAP component of the combination should be considered the limiting factor for use, generally no more than 3 to 4 g daily.

NSAIDs inhibit cyclooxygenase either nonspecifically or targeted to COX-2, thereby decreasing inflammation and pain related to local tissue injury. They inhibit platelet function to variable degrees and for this reason are sometimes contraindicated in the immediate postoperative period. Nonetheless, because the majority of postoperative pain is nociceptive and inflammatory, NSAIDs can often be of great benefit.

Opioids are indicated in the acute postoperative period, exerting their effects centrally in the spinal cord and brain. Generally, because postsurgical pain is acute rather than chronic in nature, short-acting opioids such as oxycodone, hydromorphone, or hydrocodone for breakthrough pain every 3 to 4 hours as needed are sufficient. If necessary, a dose range may be provided to cover mild, moderate, and severe pain. In patients with frequent need for breakthrough dosing and history of chronic opioid use and tolerance, however, a long-acting formulation (methadone, fentanyl patch, or extended-release formulation of a short-acting opioid) on a scheduled basis may also be required.

If pain does not improve or if escalating rather than tapering doses of opioids are observed, antineuropathic agents are often initiated. These include topical agents such as lidocaine 5% cream or patch, gabapentinoids, tricyclic antidepressants, and selective norepinephrine reuptake inhibitors. If a patient requires these additional interventions, they will often benefit from an APS consult and possible outpatient pain management follow-

up.

Jacob B, Chen D, Towfigh S, eds. *The SAGES Manual of Groin Pain*. Switzerland: Springer International; 2016: 267–276.

D. The Role of an Acute Pain Service (APS)

D.1. What is the extent of the problem, and which patients are at greatest risk of undertreatment?

Pain relief after surgery continues to be a major medical challenge. Despite a significant improvement over the last decade in our understanding of acute and chronic pain mechanisms and the establishment of APSs, recent studies continue to report that postoperative pain management is not satisfactory for many patients. In addition, publications of guidelines for acute pain management, the introduction of pain as "the fifth vital sign," and the incorporation of the standards advocated by The Joint Commission have not yet translated into improved postoperative analgesia.

More than 30% of patients report moderate-to-severe pain after surgery. More recent surveys of postdischarge pain put that number even higher. Clinical risk scores to identify patients most at risk for postoperative pain are scarce and not commonly used in practice. Certain patient subpopulations are at greater risk of undertreatment, including infants and children, the elderly, ethnic minorities, and patients with psychiatric illness or those unable to communicate.

Apfelbaum JL, Chen C, Mehta SS, et al. Postoperative pain experience: results from a national survey suggest postoperative pain continues to be undermanaged. *Anesth Analg*. 2003;97:534–540.

Ashburn MA, Caplan RA, Carr DB, et al. Practice guidelines for acute pain management in the perioperative setting. *Anesthesiology*. 2004;100:1573–1581.

D.2. What are the consequences of inadequate postoperative pain relief?

Evidence suggests that inadequate relief of postoperative pain results in harmful physiologic and psychological consequences that lead to significant morbidity, delaying recovery and the return to activities of daily living. Acutely, postoperative splinting can lead to atelectasis, whereas autonomic lability associated with pain can result in increased myocardial oxygen demand and increased incidence of perioperative myocardial infarction in at-risk adults. In children, postoperative pain has been found to be an important cause for long-lasting temper tantrums and behavioral changes. In addition, the presence of postoperative pain significantly contributes to patients' dissatisfaction with their anesthesia and surgical experience.

CPSP has long been recognized as a major factor in delaying recovery and return to normal daily living. Long-lasting pain is often reported after several common surgical procedures including thoracotomy, mastectomy, hernia repair, and limb amputation. Predisposing risk factors include the severity of preoperative and postoperative pain, intraoperative nerve injury, and psychological vulnerability. Specific early analgesic interventions may reduce the incidence.

Mittnacht A, Shariat A, Weiner M, et al. Regional techniques for cardiac and cardiac-related procedures. *J Cardiothorac Vasc Anesth*. 2019;33:532–546.

D.3. What is the role of an APS in improving postoperative pain management?

The immediate solution to the problem of inadequate pain relief

lies not so much in the development of new analgesic drugs or technologies but in the development of an appropriate organization to utilize existing expertise effectively.

Moreover, effective acute pain management results from education and organizational structure for the delivery of pain relief rather than the specific analgesic techniques themselves. Even simple methods of pain relief can be more effective if proper attention is given to their appropriate, evidence-based use. In many institutions, APSs assume responsibility for managing more advanced methods of pain relief such as patient-controlled analgesia, epidural analgesia, and peripheral nerve catheters to ensure patients receive optimum care from providers well-versed with these analgesic modalities. Additionally, APSs often follow chronic pain patients who are difficult for primary teams to manage and whose complex pain issues are best treated using a multimodal approach. With a growing focus on the perioperative surgical home and the anesthesiologist's place in providing continued care before and after surgery, the role of APSs is likely to expand even further.

American Society of Anesthesiologists. Practice guidelines for acute pain management in the perioperative setting: an updated report by American Society of Anesthesiologists, Task Force on Acute Pain Management. *Anesthesiology*. 2012;116:248–273.

Zaccagnino MP, Bader AM, Sang CN, et al. The perioperative surgical home: a new role for the acute pain service. *Anesth Analg*. 2017;125(4):1394–1402.

D.4. Does an APS improve postoperative outcome?

The introduction of APSs has led to an increase in the appropriate use of specialized analgesic techniques such as IV-PCA, neuraxial blockade, and peripheral nerve catheters. The implementation of these techniques is an advance in improving analgesia and patient well-being and in reducing postoperative morbidity. In addition, an APS may reduce "analgesic gaps" that can occur during the transition from IV-PCA or epidural

analgesia to oral analgesic therapy. Although evaluating the safety of analgesic techniques is an important objective of an APS, its role in preventing and reducing adverse events has not been well-documented; however, consolidation of decisions regarding pain regimens under one service is likely to have several benefits. First, standardization of protocols decreases prescription or drug administration error. Second, having one service responsible for pain orders decreases the incidence of redundancy and multiple opioid orders. Finally, the availability of a service primarily dedicated to pain is likely to increase the speed and efficacy of interventions and decrease patient pain scores.

In a literature review, evaluating the effects of an APS on postoperative outcome in 44 retrospective and 4 prospective clinical trials including 84,097 postoperative patients, the authors found that the implementation of an APS was associated with a significant decrease in pain scores. In addition, the introduction of an APS was associated with less postoperative nausea and vomiting and urinary retention. However, the authors could not draw clear conclusions about patient satisfaction or postoperative morbidity due to a large variability in the studies regarding composition of the APSs and services provided.

52 Acupuncture

Yuan-Chi Lin

A 58-year-old woman with a history of osteoarthritis was scheduled for arthroscopic surgery of her right knee. She experienced severe postoperative nausea and vomiting in the postanesthesia care unit. Despite the use of conventional therapies, her nausea and vomiting persisted. Her past medical history was significant with knee osteoarthritis for 10 years, a mastectomy 5 years ago related to breast cancer, an anxiety disorder, chronic headaches, chronic neck and back pain, peptic ulcer disease, and an allergy to Novocain. What role can acupuncture therapy play in her care?

5. Can acupuncture be used for the treatment of osteoarthritis?
6. What role can acupuncture play in the care of patients with cancer?
7. Can acupuncture/acupressure be used to decrease anxiety?
8. What is ear acupuncture/acupressure? Can it be useful for alleviating anxiety and pain? (**Video 52.2**)

C. Complications

1. What are the possible complications of acupuncture treatment?

A. Acupuncture as a Complementary Medical Therapy

A.1. What is acupuncture?

Acupuncture is one of the treatment modalities of comprehensive traditional Chinese medicine (TCM). The word *acupuncture* is derived from the Latin words *acus*, "needle," and *punctura*, "a pricking." The original Chinese term for acupuncture is *Jin Jiao*, which describes the practice of "acupuncture and moxibustion." Moxibustion is the burning of moxa (*Artemisia vulgaris*) over the acupuncture points.

The history of TCM can be traced back 3,000 years. *The Yellow Emperor's Classic of Internal Medicine* from the fourth century BC described the practice of puncturing the body for pain relief. TCM is a system of thoughts and practices that are based on the investigations of nature, causes, and effects. It takes the principles of realism and ethics and then employs them for the

prevention of diseases and healing of illnesses.

The concept *yin and yang* underlies the theoretical framework of acupuncture. Yin and yang are two opposite dynamics that cannot exist in isolation. Rather, they are in a constant state of dynamic balance. If yin and yang are not balanced, illnesses can occur.

The human body is controlled by a vital force called *Qi* (pronunciation "chee"). *Qi* circulates throughout the body and defends its various parts. There are 365 identified acupuncture points in the body, which fall along 12 principal and 8 extrameridian systems. *Qi* is postulated to flow through these meridians in the body.

A.2. How is acupuncture practiced? (Video 52.1)

Acupuncture utilizes a technique of inserting very fine thread-thin needles into strategic points in the body called *acupuncture points*. Acupuncture needles vary from 36 to 42 gauge and 0.5 to 5 inches in length. There are a wide variety of needles currently available. In *The Yellow Emperor's Internal Classic*, book of Ling Shu, it described nine shapes of acupuncture needles. Sterile, disposable stainless-steel acupuncture needles are the current standard for acupuncture treatment.

After cleaning the site of the needle entrance on the skin, the acupuncture needle is inserted a few millimeters into the epidermis. Following placement of the acupuncture needle, stimulation of the acupuncture point may be achieved manually or by the application of low-voltage electrodes onto the needle in a method called *electroacupuncture*.

Each acupuncture point has a prescribed depth of insertion. Manual techniques may involve the lifting and thrusting of the needle, or twisting and twirling. *De-Qi* is a typical sensation that is associated with proper acupuncture needle position. Patients describe the sensation as a feeling of soreness, numbness,

warmth, heaviness, or pressure around the area where the needle is inserted. Many practitioners consider this sensation to be crucial in achieving the effects of acupuncture. Electroacupuncture achieves a similar effect through the use of high- or low-frequency electricity.

Minimal pain is associated with acupuncture. For various conditions, multiple acupuncture treatment sessions over an extended period may be required to achieve its greatest effectiveness.

Auricular, hand, and scalp acupuncture can be used as microsystems of acupuncture. For example, auricular acupuncture (**Fig. 52.1**) manipulates the upper region of the external ear to alleviate conditions in the leg and feet. The middle region of the external ear corresponds to chest and back pain. The lower regions are used to relieve headache and neurologic conditions. Auricular acupuncture can also be used for preoperative anxiety control.

FIGURE 52.1. Auricular acupuncture. Δ, heart point; •, shen men; ♦, autonomic point. (*Reprinted from www.permacharts.com with permission.*)

The frequency, as well as the number of acupuncture treatments, varies among acupuncture providers. Most practitioners would agree that more than one treatment is necessary to experience the full effect of acupuncture.

Chernyak GV, Sessler DI. Perioperative acupuncture and related techniques. *Anesthesiology*. 2005;102:1031–1049.

A.3. What are the mechanisms of acupuncture analgesia?

Acupuncture inhibits the transmission of pain according to the gate control theory. It may act by stimulating sensory A-β fibers, thereby directly inhibiting the spinal transmission of pain by a smaller A-δ and C fibers.

Acupuncture stimulates the production of endogenous opioid peptides, such as endorphins and enkephalins, and stimulates the endogenous descending inhibitory pathways. In human studies, analysis of cerebrospinal fluid showed elevated levels of serotonin, endorphins, and enkephalins following acupuncture treatments. Acupuncture analgesia is mainly achieved by the activation of the endogenous antinociceptive system to modulate pain transmission and pain response. Low-frequency (2 Hz) and high-frequency (100 Hz) electrical acupuncture selectively induces the release of enkephalins and dynorphins in both experimental animals and humans. Acupuncture analgesia can be reversed by naloxone.

Functional magnetic resonance imaging has been used to investigate the effect of acupuncture in normal volunteers. With functional magnetic resonance imaging, acupuncture needle manipulation on the LI4 (He Gu, 合谷) point (**Fig. 52.2**) is seen to modulate the activity of the limbic system and subcortical structure. Individual variation occurs in the cortical activation patterns elicited by electrical acupuncture stimulation. Real

acupuncture elicited significantly higher activation than sham acupuncture over the hypothalamus and primary somatosensory and motor cortex and deactivation over the rostral segment of anterior cingulated cortex.

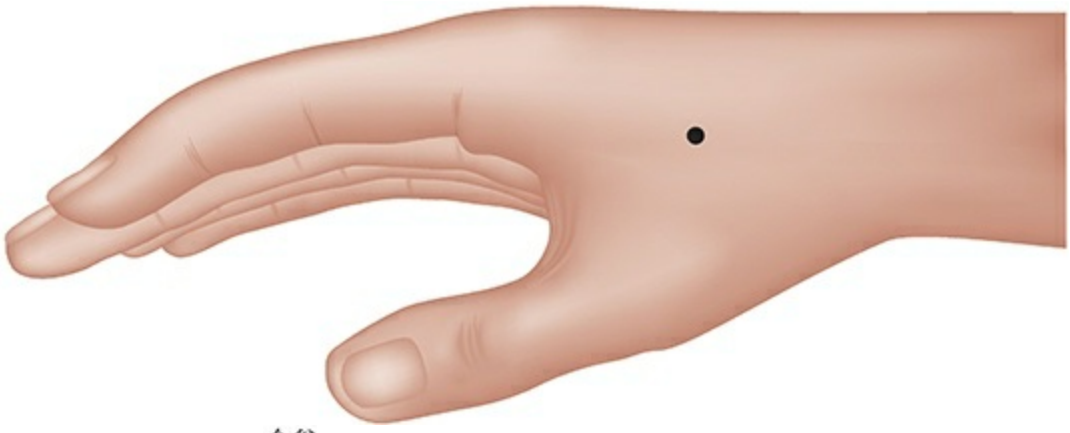

FIGURE 52.2. LI4 (He Gu, 合谷) acupuncture point is on the dorsum of the hand, between the first and second metacarpal bones, radial to the midpoint of the second metacarpal bone. (*Reprinted from www.permacharts.com with permission.*)

A.4. What were the conclusions of the National Institutes of Health Consensus Conference about acupuncture?

A National Institutes of Health Consensus Conference concluded that acupuncture is an effective therapeutic intervention that is widely practiced in the United States. Promising results have emerged supporting the efficacy of acupuncture in adult postoperative and chemotherapy-related nausea and vomiting and in postoperative dental pain. In other conditions, such as addiction, stroke rehabilitation, headache,

menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma, acupuncture may also be useful as an adjunct treatment or as an acceptable alternative when included in a comprehensive management program. Further research is expected to uncover additional areas in which acupuncture interventions are useful.

National Institutes of Health Consensus Conference. Acupuncture. *JAMA*. 1998;280:1518–1524.

A.5. Can acupuncture be a novel nonopioid alternative pain therapy?

Prescribing opioid analgesics has been used in the management of acute and chronic pain. However, there are adverse effects associated with opioid use and the potential for addiction with chronic usage. More concerned about whether the overprescribing of opioids for chronic pain is contributing to the current opioid crisis. Novel nonopioid alternative pain therapies are being investigated given the current opioid crisis; however, focus on exploration in complementary and alternative therapies is also of importance. Acupuncture as an integrative medicine for pain can play a major role in reducing the frequency and amount of opioid usage. Supported by evidence review, acupuncture is categorized as having strong positive evidence in pain management. It may be integrated more routinely into pain management.

B. Acupuncture for the Treatment of Chronic

Conditions

B.1. What are the rationales in integrating acupuncture for the treatment of postoperative nausea and vomiting?

Postoperative nausea and vomiting occur frequently following surgery and are best avoided whenever possible. Acupuncture is a commonly used therapy for the treatment of these symptoms. Stimulation of the acupuncture PC6 (*Nei Guan* 內關 *acupuncture point*; in Chinese, this means *gate of the internal organ*) points by acupuncture needles, electrical apparatus, pressure, or magnets is used to achieve relief of nausea and vomiting. The PC6 acupuncture point is located 2 cun (tsun), approximately 2.6 in., above the transverse crease of the wrist, and between the tendons of the muscle palmaris longus and muscle flexor carpi radialis (**Fig. 52.3**).

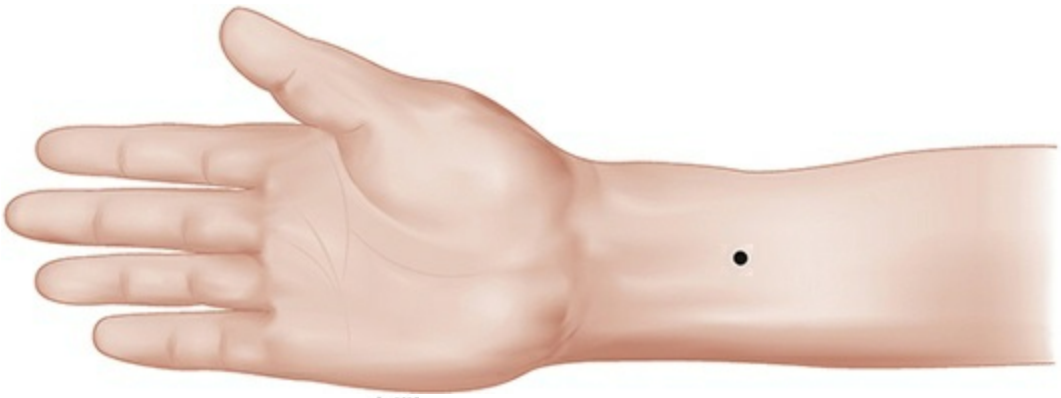

FIGURE 52.3. The PC6 (Nei Guan, 內關) acupuncture point is located 2 cun (tsun), approximately 2.6 in., above the transverse crease of the wrist, between the tendons of the muscle palmaris longus and muscle flexor capri radialis.

Studies support the use of acupuncture for the treatment of postoperative nausea and vomiting. A systemic review was conducted of 33 randomized controlled trials of acupuncture and acupressure. The results were positive in 27 of these trials. A randomized controlled trial of pediatric patients undergoing

tonsillectomy using electroacupuncture in conscious patients showed significant reduction in the occurrence of nausea compared with those in the sham and control groups. The efficacy of acupuncture for postoperative nausea and vomiting prevention is similar to that of commonly used pharmacotherapies. A double-blind, randomized, placebo-controlled study revealed that hand acupressure is an effective method for reducing postoperative vomiting in children after strabismus repair.

PC6 acupressure is a noninvasive method that may have a place as prophylactic antiemetic therapy during gynecologic surgery. Alkaissi et al. did a prospective randomized controlled trial of acupressure for the prevention of postoperative nausea and vomiting for women undergoing general anesthesia for elective gynecologic surgery with positive results.

Alkaissi A, Evertsson K, Johnsson VA, et al. P6 acupressure may relieve nausea and vomiting after gynecological surgery: an effectiveness study in 410 women. *Can J Anaesth*. 2002;49:1034–1039.

Gan TJ, Diemunsch P, Habib AS, et al. Consensus guideline for the management of postoperative nausea and vomiting. *Anesth Analg*. 2014;118:85–113.

B.2. Can acupuncture be used for the treatment of chemotherapy-induced nausea and vomiting?

Acupuncture/acupressure at the PC6 acupuncture point has been shown to have a protective effect on people experiencing chemotherapy-induced nausea and vomiting. A review of 11 randomized controlled trials studying the effectiveness of acupuncture point stimulation on chemotherapy-induced nausea and vomiting revealed that electroacupuncture reduced chemotherapy-induced acute vomiting.

Ezzo JM, Richardson MA, Vickers A, et al. Acupuncture-point stimulation for chemotherapy-induced nausea or vomiting. *Cochrane Database Syst Rev*. 2006;(2):CD002285.

B.3. How effective is acupuncture for the management of chronic headache?

Acupuncture therapy for migraine headaches has been reported to be effective in several adult studies. In a randomized controlled trial of 160 women with migraines, acupuncture was proven to be adequate for migraine prophylaxis. Relative to flunarizine, acupuncture treatment exhibited greater efficacy in the first months of therapy and better patient tolerance. A systemic review of 22 trials including a total of 1,042 patients suggests that acupuncture has a role in the treatment of recurrent headaches. In a randomized controlled trial of 401 patients with chronic migraine headaches, it was also shown that through 12 months of follow-up, acupuncture was relatively cost-effective. Compared with the patients in the control groups, patients receiving acupuncture used 15% less medication, made 25% fewer visits to general practitioners, and took 15% fewer sick days from work.

Cochrane database of systematic review of 11 trials with 2,317 patients with episodic or chronic tension-type headache revealed that acupuncture could be a valuable nonpharmacologic tool in patients with frequent episodic or chronic tension-type headaches. In regard to acupuncture for migraine prophylaxis, meta-analysis of 22 trials with 4,419 participants shows acupuncture to be at least as effective as, and possibly more effective than, prophylactic drug treatment with fewer adverse effects. Acupuncture should be considered a treatment option for patients willing to undergo this treatment.

B.4. Can acupuncture be used for the treatment of chronic neck and back pain?

In a randomized controlled trial of 177 patients with chronic neck pain, the effectiveness of acupuncture, massage, and "sham" laser acupuncture were compared. A study followed 14,161 patients with chronic neck pain for a period of more than 6 months. The patients in the acupuncture group received up to 15 acupuncture sessions over 3 months. The reported neck pain levels and disability scores of the members of the acupuncture group were improved over those of the control group. Treatment success was followed and maintained for 6 months.

A large German clinical study involved 1,162 patients with chronic low back pain indicated that both "real" and "sham" acupuncture treatment were significantly better than conventional therapy for at least 6 months. Another large German study of 1,549 patients with chronic low back pain showed acupuncture plus routine care was associated with marked clinical improvements in patients with chronic low back pain and was relatively cost-effective. A systemic review that involved 23 trials of 6,359 patients with low back pain revealed that acupuncture can be a useful supplement to other forms of conventional therapy for nonspecific low back pain.

Haake M, Müller HH, Schade-Brittinger C, et al. German Acupuncture Trials (GERAC) for chronic low back pain: randomized, multicenter, blinded, parallel-group trial with 3 groups. *Arch Intern Med*. 2007;167:1892–1898.

Yuan J, Purepong N, Kerr DP, et al. Effectiveness of acupuncture for low back pain: a systematic review. *Spine*. 2008;33:887–900.

B.5. Can acupuncture be used for the treatment of osteoarthritis?

Evidence exists for the efficacy of acupuncture for reducing the pain and dysfunction of osteoarthritis. In a study of 300 patients with chronic osteoarthritis of the knee, participants were randomly assigned to acupuncture, minimal acupuncture, or wait-list control group. After 8 weeks of treatment, pain and joint function were improved more with acupuncture than with minimal or no acupuncture.

In another randomized controlled trial of 570 patients with osteoarthritis of the knee, the acupuncture group received 23 true acupuncture sessions over 26 weeks. Acupuncture was shown to provide improvement in function and pain relief as an adjunctive therapy for osteoarthritis of the knee when compared with credible sham acupuncture and education control groups.

In a trial of 30 patients with symptomatic osteoarthritis of the knee, participants were randomized into one of three treatment groups. One group of patients received acupuncture alone, another group of patients received acupuncture but continued on their symptomatic medication, and the third group of patients used their symptomatic medication for the first 5 weeks and then had a course of acupuncture added. The patients receiving acupuncture were treated twice weekly over 5 weeks. The results of this study concluded that manual and electroacupuncture causes a significant improvement in the symptoms of osteoarthritis of the knee, either alone or as an adjunct therapy, with no loss of benefit after 1 month.

Current evidence supports the usage of acupuncture for osteoarthritis. A systemic review of acupuncture in osteoarthritis

pain management indicates reduction in pain intensity, improvement in functional mobility and quality of life.

B.6. What role can acupuncture play in the care of patients with cancer?

A report of a randomized controlled trial of 90 patients with cancer pain revealed clear benefit from auricular acupuncture for cancer patients experiencing pain, despite stable analgesic treatment. It is reasonable to use acupuncture for the management of chronic cancer-related pain management. Acupuncture can also be used to control chemotherapy-related nausea and vomiting.

Ezzo JM, Richardson MA, Vickers A, et al. Acupuncture-point stimulation for chemotherapy-induced nausea or vomiting. *Cochrane Database Syst Rev*. 2006;(2):CD002285.

B.7. Can acupuncture/acupressure be used to decrease anxiety?

Acupuncture or acupressure on Yin-Tang acupuncture point is effective in producing sedation. The Yin-Tang acupuncture point is on the forehead, at the midpoint between the two

eyebrows.

Acar et al. did a prospective, randomized, single-blind, controlled study of 52 patients receiving acupuncture on Yin-Tang or sham acupuncture. The bispectral index (BIS) values in the acupuncture group were significantly lower than in the sham group. Paraskeva et al. did a study of 50 patients randomly assigned to acupuncture of the Yin-Tang point or control point. Acupuncture application significantly decreased the BIS value compared to the control group.

Paraskeva A, Melemeni A, Petropoulos G, et al. Needling of the extra 1 point decreases BIS values and preoperative anxiety. *Am J Chin Med*. 2004;32(5):789–794.

B.8. What is ear acupuncture/acupressure? Can it be useful for alleviating anxiety and pain? (Video 52.2)

Auricular acupressure is an effective treatment for anxiety during ambulance transport. Kober et al. studied 36 patients who required ambulance transport to medical facilities; patients were randomized to receive auricular acupressure at the relaxation point or at a sham point. Patients in the auricular acupressure group reported significantly less anxiety than patients in the sham group on arrival to the hospital. Barker et al. reported a randomized controlled trial of 38 patients with acute hip fractures receiving either bilateral auricular acupressure or the sham control during ambulance transport; the patients in the acupressure group had less pain, less anxiety, and lower heart rates on arrival to the hospital.

Auricular acupuncture points may be stimulated for a longer period of time by using ear seeds or ear tacks. Ear seeds can be small seeds from the dry Vaccaria plant or can be made from stainless steel seed. These seeds are held in place on the ear with

a small piece of adhesive tape (**Video 52.3**).

C. Complications

C.1. What are the possible complications of acupuncture treatment?

Acupuncture is extremely safe. Rarely, a patient may have some bruising at an acupuncture site that is swiftly resolved. The major risk is infection from the use of improperly sterilized needles. This can be avoided by using disposable sterile acupuncture needles and the proper insertion of the needles. Vasovagal scope may occur in very rare incidents. Case reports have documented a pneumothorax caused by improperly inserted acupuncture needles.

A study of the adverse effects of 34,000 acupuncture consultations in the United Kingdom revealed that the most common adverse events were bleeding, needling pain, and aggravation of symptoms. None of these events were serious. Similarly, a review of nine surveys showed that the most common adverse events were needle pain, tiredness, and bleeding. Feelings of faintness and syncope were uncommon. Feelings of relaxation were reported by as many as 86% of patients. The report of pneumothorax was extremely rare, occurring only twice in nearly a quarter of a million treatments.

A study was conducted involving a prospective postal audit of treatments performed by 1,848 professional acupuncturists in the United Kingdom over a 4-week period. They reported 43 minor

adverse events, a rate of 1.3 per 1,000 treatments. The events report included severe nausea, fainting, prolonged aggravation of the symptoms, pain, and bruising. The overall frequency of acupuncture-related adverse events is exceptionally low, and prospective studies have indicated that even minor adverse events are uncommon.

Acupuncture is considered to be a very safe intervention when applied appropriately by a competent practitioner; adverse effects from acupuncture are particularly uncommon.

SECTION 12 Miscellaneous

53 Myasthenia Gravis

James B. Eisenkraft and
Bryan S. Carter

A 28-year-old woman with a history of myasthenia gravis (MG) presents for bilateral video-assisted thoracoscopic surgery (VATS) and complete thymectomy. She was diagnosed with MG 3 years ago after developing progressive bilateral ptosis, proximal limb weakness, dysphagia, and intermittent dyspnea (MG class IIIb). Her current medications are pyridostigmine (Mestinon) 60 mg TID and prednisone 10 mg QD. Vital signs are: pulse rate, 75 beats per minute; blood pressure, 120/74 mmHg; respiratory rate, 18 breaths per minute; and Spo_2, 100% breathing room air. She is 163 cm tall and weighs 56 kg, and her body mass index (BMI) is 21 kg per m^2.

A. Medical Disease and Differential Diagnosis

1. What is MG?
2. What is the etiology and pathophysiology of MG?
3. Describe the clinical classification of MG.
4. How is the diagnosis of MG made?

5. What should be considered in the differential diagnosis?
6. How does myasthenic syndrome (Lambert-Eaton syndrome) differ from MG?
7. What treatments are available for a patient with MG?

B. Preoperative Evaluation and Preparation

1. Describe the preoperative evaluation of this patient.
2. What preoperative laboratory data are required?
3. How should the patient's medications be managed preoperatively?

C. Intraoperative Management

1. What are your considerations in the choice of anesthetic technique?
2. How should this patient be monitored intraoperatively?
3. What anesthetic regimen would you choose for this patient?
4. Can neuromuscular blocking drugs be used safely in a patient with MG?
5. Should the MG patient who is in remission (i.e., symptom free without treatment) be managed differently?

D. Postoperative Management

1. What factors will help you predict this patient's need for continued intubation or other postoperative ventilatory support?
2. How will you determine if this patient's trachea can be safely extubated?
3. How will you manage postoperative analgesia?
4. How will you define and manage postextubation ventilatory failure in this patient?

A. Medical Disease and Differential Diagnosis

A.1. What is MG?

MG is an autoimmune disorder affecting the neuromuscular junction and therefore of great significance to the anesthesiologist. It is a chronic disorder characterized by fluctuating painless weakness and fatigability of voluntary muscles made worse on exertion with improvement following rest. The onset is usually slow and insidious; any skeletal muscle or muscle group may be affected. The most common onset is ocular, presenting with ptosis and diplopia. If the symptoms remain localized to the eyes for 2 years, the likelihood of progression to generalized disease is about 10%. In many cases, however, MG is generalized and may involve the bulbar musculature (muscles innervated by cranial nerves IX, X, XI, and XII), causing problems with breathing, speaking, mastication, and swallowing. Proximal muscles are more commonly involved than distal. Peripheral muscle weakness may manifest as clumsiness, difficulty holding up the head, or in ambulating. Respiratory muscle weakness may cause dyspnea as well as a decrease in the ability to cough and clear secretions.

The annual incidence of MG is estimated at 7 to 23 new cases per 1,000,000 people per year; the prevalence is approximately 70 to 320 per 100,000. It occurs more commonly in women than men. The disease affects all ages, but the age of onset has a bimodal distribution displaying an early peak in the second and third decades (female predominance) and a late peak in the sixth to eighth decades (male predominance).

McGrogan A, Sneddon S, de Vries CS. The incidence of myasthenia gravis: a systematic literature review. *Neuroepidemiology*. 2010;34(3):171–183.

A.2. What is the etiology and pathophysiology of MG?

In normal neuromuscular transmission, the acetylcholine released from the motor nerve terminal stimulates postsynaptic nicotinic receptors at the motor end plate to generate an action potential leading to depolarization of the membrane and contraction of the motor unit. The normal neuromuscular junction has a very large number of postsynaptic acetylcholine receptors (AChRs) such that muscle weakness only becomes apparent when 75% or more of the receptors have been blocked. This excess of receptors has been termed the "margin of safety of neuromuscular transmission." MG patients have a significant decrease in the number of postsynaptic AChRs at the end plates of affected muscles resulting in a decreased margin of safety of neuromuscular transmission.

MG is an autoimmune disorder, and about 80% of affected patients have detectable circulating antibodies to the nicotinic AChR. These anti-AChR antibodies may cause complement-mediated lysis of the postsynaptic membrane, directly block the receptors, or may modulate the receptor turnover such that the rate of degradation exceeds the rate of resynthesis. Studies of the motor end plate area show loss of synaptic folds and a widening of the synaptic cleft. Approximately 10% of MG patients who do not have anti-AChR antibodies have antibodies to muscle-specific tyrosine kinase (MuSK). The MuSK antibody–positive MG patients often develop prominent oculobulbar muscle weakness, but the MG is not limited to the eyes. In MuSK antibody–positive individuals, cholinesterase inhibitors have little or no effect and may even exacerbate symptoms.

The cause of MG is unknown but appears to be related in some way to the thymus gland. It has been suggested that thymic T cells are stimulated to produce antibodies following sensitization by a protein similar to the AChR. MG patients also have a higher incidence of other autoimmune diseases including autoimmune thyroid disease, rheumatoid arthritis, and systemic

lupus erythematosus.

A.3. Describe the clinical classification of MG.

Since the original clinical classification by Osserman and Genkins (1971), who described four classes and two subclasses, several other classifications have been published. The one now most commonly used is that of the Medical Scientific Advisory Board of the Myasthenia Gravis Foundation of America Clinical Classification, which describes five main classes and several subclasses as follows:

- Class I: any ocular muscle weakness; may have weakness of eye closure; all other muscle strength is normal.
- Class II: mild weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity
  - Class IIa: predominantly affecting limb, axial muscles, or both; may also have lesser involvement of oropharyngeal muscles
  - Class IIb: predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both
- Class III: moderate weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity
  - Class IIIa: predominantly affecting limb, axial muscles, or both; may also have lesser involvement of oropharyngeal muscles

  - Class IIIb: predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both
- Class IV: severe weakness affecting other than ocular muscles; may also have ocular muscle weakness of any severity
  - Class IVa: predominantly affecting limb, axial muscles, or both; may also have lesser involvement of oropharyngeal muscles
  - Class IVb: predominantly affecting oropharyngeal, respiratory muscles, or both; may also have lesser or equal involvement of limb, axial muscles, or both; use of a feeding tube without intubation
- Class V: defined by the need for intubation, with or without mechanical ventilation, except when used during routine postoperative management

A.4. How is the diagnosis of MG made?

The diagnosis of MG is suspected from the patient's history and confirmed by clinical, electrophysiologic, pharmacologic, or immunologic testing. Typically, the patient cannot sustain or repeat muscular contraction. Clinical tests of fatigability include maintaining an upward gaze, holding out an affected limb, and respiratory function testing (vital capacity, maximum breathing capacity).

The electrical counterpart of fatigability is demonstrated by the repetitive nerve stimulation (RNS) test. The RNS involves the application of supramaximal stimulation to a peripheral

nerve at 2 to 5 Hz. If a decrement of ≥10% is observed in the compound muscle action potential amplitude between the first and the fourth or fifth waveforms, this is considered diagnostic of MG. This is the most specific neurophysiologic test for MG, but it can be performed only on certain muscles, which may not be the ones affected in an individual patient. A more sensitive electrophysiologic test is single-fiber electromyography (EMG), which examines the variability in time interval or "jitter" between two single-muscle fibers from the same motor unit.

Historically, pharmacologic testing for MG was performed by administering the anticholinesterase edrophonium (Tensilon) and observing a rapid improvement in function; mechanical and electrical (e.g., EMG) decrements improve with 2 to 10 mg of intravenous edrophonium (Tensilon test). However, this medication is no longer available in the United States but an equivalent dose of neostigmine or pyridostigmine should produce a similar improvement.

Antibodies to the AChR are detectable in 80% of patients with MG. In equivocal cases, a positive result of a test for anti-AChR or MuSK antibodies is considered diagnostic.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

A.5. What should be considered in the differential diagnosis?

A number of disorders can mimic MG and should be included in the initial differential diagnosis.

Thyroiditis and resulting thyrotoxicosis can present with generalized weakness and abnormal thyroid function. Patients with neurasthenia characteristically have weakness, which

disappears when individual muscle groups are tested. Progressive external ophthalmoplegia; restrictive cardiomyopathies; muscular dystrophies; brain tumors; amyotrophic lateral sclerosis; myasthenic polymyopathy with hypersensitivity to neostigmine; and drugs such as D-penicillamine, aminoglycosides, quinine, procainamide, and calcium channel blockers can also cause myasthenia-like symptoms.

Gilhus NE, Nacu A, Andersen JB, et al. Myasthenia gravis and risks for comorbidity. *Eur J Neurol*. 2015;22(1):17–23.

A.6. How does myasthenic syndrome (Lambert-Eaton syndrome) differ from MG?

Myasthenic syndrome is a very rare immune-mediated disorder of neuromuscular transmission, associated with antibodies to the presynaptic voltage-gated calcium channel. The prevalence is estimated to be about 3 to 4 per million. It is associated with small cell carcinoma of the lung in 50% to 60% of cases. Complaints of weakness may be mistaken for MG, but in Lambert-Eaton syndrome, symptoms do not respond to administration of anticholinesterases or steroids and activity improves strength. The defect in this condition is prejunctional, is associated with diminished release of acetylcholine from motor nerve terminals, and is improved by “facilitating” agents such as 4-aminopyridine or 2,3-diaminopyridine that potentiate the release of acetylcholine. Affected patients are particularly sensitive to the effects of nondepolarizing muscle relaxants, which should be used with great caution or avoided entirely. The possibility of Lambert-Eaton syndrome should be considered in all patients with known malignant disease and those patients undergoing diagnostic procedures for suspected carcinoma of the lung. Anesthesia considerations in these patients are

essentially the same as in those with MG.

A.7. What treatments are available for a patient with MG?

Medical Therapy

Mary Walker was the first physician to report the similarity between the symptoms and signs of MG and curare poisoning and to use an anticholinesterase to treat MG. Anticholinesterases are used to prolong the action of acetylcholine at the postsynaptic membrane and may also exert their own agonist effect at the postsynaptic AChRs. They are the most commonly used therapy in MG. Interestingly, no randomized controlled trial has been conducted on the use of acetylcholinesterase inhibitors in patients with MG because the response in observational studies was such that a placebo group could not be justified. MG patients learn to regulate their anticholinesterase medication and titrate dose to optimum effect (**Table 53.1**). If several muscle groups/functions are affected, the patient titrates therapy according to the most important group. Anticholinesterase overdose results in the muscarinic effects of acetylcholine and may cause a cholinergic crisis. Excessive amounts of acetylcholine at the neuromuscular junction cause persistent depolarization of the muscle membrane. Insufficient dosing causes weakness or a myasthenic crisis. In a patient with weakness, distinction between the two types of crisis may be

made by titrating small doses of neostigmine, or by examining pupil size, which will be large (mydriatic) in a myasthenic crisis but small (miotic) in a cholinergic crisis. Muscarinic side effects (bradycardia, bronchospasm, oral and respiratory tract secretions, and gastrointestinal cramps) are treatable with atropine; however, many MG patients treated with anticholinesterases seem to develop a resistance to the muscarinic effects.

TABLE 53.1 Anticholinesterase Drugs Used to Treat Myasthenia Gravis (Dose in mg)

Drug	Oral	IV	IM	Efficacy
Pyridostigmine (Mestinon)	60	2	2–4	1
Neostigmine (Prostigmin)	1.5	0.5	0.7–1.0	1

IM, intramuscular; IV, intravenous.

Pyridostigmine (Mestinon) is the anticholinesterase drug most commonly used to treat MG and has fewer muscarinic side effects than neostigmine (Prostigmin). Its onset of action following oral administration is 15 to 30 minutes, effect peaks at 1 to 2 hours, and duration of action is 3 to 4 hours. Daily dosage is typically 30 to 120 mg orally given in divided doses. For patients who are weak on awakening in the morning, a long-acting formulation of 180 mg is available and can be taken at bedtime. MG patients who are MuSK antibody–positive generally have little or no response to anticholinesterase medications.

The immunologic basis of MG has led to the use of short- and long-term immunosuppressive drugs. Patients who do not meet treatment goals typically require immunosuppressive therapy. First-line therapy is generally a steroid combined with an immunomodulatory agent. Prolonged use of steroids may produce unwanted effects, such as peptic ulcer disease and osteoporosis. Alternate day dosing of either prednisone or

prednisolone is generally prescribed to reduce side effects. Steroids often produce initial deterioration before an improvement. For long-term effect, immunomodulatory agents such as azathioprine, cyclophosphamide, cyclosporine, methotrexate, mycophenolate mofetil, rituximab, and tacrolimus have been used. Rapid short-term immunomodulation has been achieved in acute exacerbations or to improve muscle strength prior to surgery. Plasmapheresis (PLEX) may produce dramatic but transient improvements in muscle strength with decreases in anti-AChR and anti-MuSK titers as well as other inflammatory mediators. Intravenous immunoglobulin (IVIG) and PLEX are usually reserved for severe MG—both have been found to be equally effective therapies. PLEX has been shown to improve respiratory function in both postoperative and nonoperated patients with MG. PLEX also causes a decrease in plasma cholinesterase levels, which may prolong the effect of drugs such as succinylcholine that are normally broken down by this enzyme system.

Surgical Therapy

Thymectomy is always indicated in those patients with thymoma and is now considered the treatment of choice in most patients with MG, excluding those with only ocular myasthenia. A recent randomized control trial has demonstrated a benefit of thymectomy in adults with AChR-antibody-positive, nonthymomatous MG with the addition of glucocorticoids versus glucocorticoid therapy alone. Overall, these patients required less glucocorticoid over the 3-year study period, had an improvement in symptoms, and had fewer hospitalizations for management of MG symptoms. Patients who have either MuSK-antibody-positive disease do not benefit from a thymectomy. Approximately 70% of MG patients demonstrate thymic hyperplasia; 10% have a thymoma.

B. Preoperative Evaluation and Preparation

B.1. Describe the preoperative evaluation of this patient.

Several problems must be considered: history of MG, VATS procedure with the patient in both left and right lateral decubitus positions, and anxiety state.

The preoperative interview should be used to identify factors that suggest the need for postoperative ventilation. This information can guide the anesthesiologist in formulating the anesthetic plan, selection of preoperative medications, and arranging for postoperative care. When possible, patients with MG should be scheduled for elective surgery while in remission, and the surgery should be scheduled for early in the day when the patient is at her or his strongest. The patient's physical and emotional states should be optimized. Current drug therapy should be reviewed and possible drug interactions considered. The patient should be informed of the possible need for postoperative intubation and ventilation.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

Gilhus NE. Myasthenia gravis. *N Engl J Med*. 2017;376(13):e25.

B.2. What preoperative laboratory data are required?

Laboratory studies should be individualized to the patient. In addition to routine preoperative laboratory data, electrolyte

abnormalities, particularly hypokalemia, which can exacerbate weakness, should be ruled out. If the patient is or has recently been receiving corticosteroids, blood glucose levels should be determined. Because this particular patient will require a general anesthetic for the planned procedure, a preoperative arterial blood gas analysis and pulmonary function tests would serve as the baseline for determining readiness for extubation. A respiratory therapist should educate the patient about breathing exercises and the use of an incentive spirometer.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

B.3. How should the patient's medications be managed preoperatively?

Ideally, patients with MG should be scheduled to be the first case of the day in the operating room.

The management of anticholinesterase medication preoperatively should be individualized to the patient. Anticholinesterase therapy should be continued if the patient would be physically weak or if he or she is psychologically dependent on it. Traditional practice is to withhold pyridostigmine therapy on the morning of surgery so that the patient is weak on arrival to the operating room. This avoids interactions with other drugs used in the operating room. For example, anticholinesterase inhibits both plasma cholinesterase and acetylcholinesterase; therefore, the metabolism of succinylcholine will be slowed. Others recommend continuing pyridostigmine, including an oral dose just before induction (**Table 53.1**). Preoperative PLEX has been discussed previously but should not be necessary for this patient. Anxiolysis is satisfactorily achieved with a benzodiazepine. Opioids are usually avoided because of the potential for causing respiratory depression.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

C. Intraoperative Management

C.1. What are your considerations in the choice of anesthetic technique?

The necessity of one-lung ventilation, ability to control ventilation, and positioning require general endotracheal anesthesia for this patient. Some other surgical procedures may be possible with purely regional or local anesthesia, and in those cases, utilization of those methods should be prioritized. Additionally, for cases involving general endotracheal anesthesia, short-acting, easily titratable medications are preferred, along with avoidance of neuromuscular blocking drugs whenever possible. In anticipation of providing opioid-sparing postoperative analgesia, preoperative placement of a thoracic epidural catheter should be considered and discussed with the patient.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

C.2. How should this patient be monitored intraoperatively?

Standard American Society of Anesthesiologists (ASA) monitors must be used. In addition, an arterial line is useful to draw arterial blood samples for gas analysis intra- and postoperatively. A peripheral nerve stimulator, and ideally a means to quantify responses to stimulation (e.g., EMG, accelerometer, kinemyography), should be used from the beginning even if neuromuscular blocking drugs will be avoided. This is because the potent inhaled anesthetics also depress neuromuscular transmission, and a monitor of recovery

from this effect is similarly needed. Once the patient is asleep, baseline recordings should be made before any potent inhaled or neuromuscular blocking drug is administered. Subsequent responses may then be quantitatively compared to baseline. In MG patients, fade in response to train-of-four and tetanic stimulation occurs in the affected muscles at baseline (see section A4). If a total intravenous anesthesia (TIVA)–based anesthetic is used, a bispectral index monitor is helpful to evaluate depth of anesthesia.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

C.3. What anesthetic regimen would you choose for this patient?

For this procedure, the safest approach is general endotracheal anesthesia. Maintenance of anesthesia in the intubated, ventilated MG patient can be achieved with an inhalational anesthetic, a balanced technique, or TIVA.

Prior to induction of anesthesia, the patient should be well oxygenated breathing 100% oxygen until the end-tidal oxygen concentration is greater than 90%. Ideally, it should be 95%, the other 5% of the exhaled gas mixture being carbon dioxide. Induction of anesthesia is readily achieved with propofol or etomidate. In most cases, intubation of the trachea, maintenance, and relaxation may be achieved using a potent inhaled anesthetic agent. Anesthetic depth is increased using the potent inhaled agent and the trachea intubated under its effect. MG patients are more sensitive than normal patients to the neuromuscular depressant effects of the potent inhaled agents. In patients with MG, isoflurane at 1.9 minimum alveolar concentration (MAC) end-tidal concentration decreased train-of-four ratio by 41%, whereas halothane at 1.8 MAC decreased train-of-four ratio by 28%. The less soluble inhaled agents, sevoflurane and

desflurane, are even more rapidly taken up and withdrawn; they are now the most commonly used anesthetic drugs for patients with MG. Whichever agent is used, at the end of the procedure, the inhaled agent is discontinued and recovery of neuromuscular function begins. Another strategy for induction of anesthesia to achieve adequate intubating conditions without the use of neuromuscular blockade includes the use of propofol (1 to 2 mg per kg) and remifentanil (5 μg per kg).

C.4. Can neuromuscular blocking drugs be used safely in a patient with MG?

If the patient cannot tolerate the depth of anesthesia needed to produce relaxation with the potent inhaled agent, or TIVA, neuromuscular blocking drugs may be used, titrating dose against monitored effect. Patients with MG are sensitive (i.e., show a decrease in ED_{50} and ED_{95} when compared with non-MG patients) to the nondepolarizing neuromuscular blocking drugs because of the decreased number of postsynaptic receptors at the motor end plate. All nondepolarizing relaxants have been successfully and uneventfully used with careful monitoring in patients with MG. Because the sensitivity of any individual MG patient is unknown, these drugs should be titrated in 1/10 of the usual dose. Sensitivity to nondepolarizing neuromuscular blocking drugs is increased during the coadministration of a potent inhaled anesthetic. Upon completion of the surgical

procedure, the residual relaxation may be reversed using incremental doses of an anticholinesterase drug while neuromuscular transmission is carefully monitored to obtain maximum antagonism yet avoid a cholinergic crisis.

Sugammadex is a novel γ-cyclodextrin drug that was designed to bind rocuronium with a great affinity; it also binds vecuronium. Before the introduction of sugammadex, anticholinesterase drugs were the only options for antagonism of residual nondepolarizing neuromuscular blockade, and in MG patients, anticholinesterases must be administered with caution so as to avoid myasthenic or cholinergic crises. Sugammadex has been reported to safely reverse rocuronium-induced neuromuscular blockade within 117 seconds in patients with MG at various levels of neuromuscular blockade. It offers significant advantages in the management of the MG patient because anticholinesterase drugs would not be required for reversal. For reversal of neuromuscular blockade, the recommended doses of sugammadex are 2 mg per kg in patients who have two twitches present on train-of-four stimulation, 4 mg per kg in patients who have 1 to 2 posttetanic twitches, and 16 mg per kg for immediate reversal in patients who have just received an intubating dose of 1.2 mg per kg of rocuronium. If sugammadex is not available, cisatracurium may be the preferred neuromuscular blocking drug because of its short elimination half-life, small volume of distribution, lack of cumulative effect, and high clearance.

MG patients are resistant to the neuromuscular blocking effects of succinylcholine due to the decrease in number of postsynaptic receptors at the motor end plate. The ED_{95} is 2.6 times normal (0.8 mg per kg vs. 0.3 mg per kg) in these patients. Clinically, however, the use of succinylcholine has been without incident, with the usual clinical doses producing adequate relaxation for endotracheal intubation and a normal recovery

time, despite the occasionally reported early onset of phase II block. Doses of 0.2 to 1.0 mg per kg have been used in a number of patients with MG, and most did not show fasciculation before becoming paralyzed. Fade in response to train-of-four stimulation was observed in some patients during recovery, but recovery was not delayed. Prior administration of an anticholinesterase may complicate the response to succinylcholine by delaying its metabolism.

C.5. Should the MG patient who is in remission (i.e., symptom free without treatment) be managed differently?

Although it is well established that MG patients are sensitive to nondepolarizing and resistant to depolarizing neuromuscular blocking drugs, there is no consensus on the response to these drugs during a remission. It is therefore prudent to manage the patient as if he or she had active disease and titrate neuromuscular blocking drugs to effect while monitoring the responses.

D. Postoperative Management

D.1. What factors will help you predict this patient's need for continued intubation or other postoperative ventilatory support?

MG places the patient at an increased risk for respiratory failure after general anesthesia. Several studies have attempted to identify specific characteristics of MG patients undergoing surgery that could help predict increased likelihood of postoperative respiratory failure relative to other MG patients. Predictors of continued postoperative ventilation have shown to be increasing Osserman grade of disease, presence of thymoma, preoperative vital capacity less than 2.9 L, and presence of anti-AChR antibodies. Duration of disease was demonstrated in earlier studies to be associated with the need for continued postoperative ventilation. Maximum static expiratory pressure has also been suggested as a marker because expiratory effort necessarily determines the ability to clear respiratory secretions. A more recent (2014) scoring system to predict postoperative myasthenic crisis and need for ventilatory support has been proposed, which cites as its chief risk factors advanced staging of the patient's MG (bulbar involvement and rapid progression conferring greater risk), BMI >28 kg per m^2, history of prior myasthenic crisis, duration of symptoms >2 years, and association with a pulmonary resection. More invasive surgery increases risk of respiratory failure (transsternal vs. transcervical

thymectomy; open abdominal procedure vs. peripheral surgery), as does evidence of recent MG exacerbation (e.g., patient is currently receiving steroid therapy). Although a definitive risk stratification system has not yet been validated, it is important to assess each patient on a case-by-case basis and engage in frank preoperative discussions regarding risk of postoperative myasthenic crisis and possible need for prolonged ventilatory support.

Mori T, Yoshioka M, Watanabe K, et al. Changes in respiratory condition after thymectomy for patients with myasthenia gravis. *Ann Thorac Cardiovasc Surg*. 2003;9(2):93–97.

D.2. How will you determine if this patient's trachea can be safely extubated?

Postoperative weakness is the greatest contributing factor to perioperative respiratory failure in MG patients. As such, it is important to establish that the patient is fully awake and alert prior to attempting extubation and that any residual neuromuscular blockade has been completely reversed. If a quantitative neuromuscular monitoring device is used, a train-of-four ratio greater than 0.9 should be achieved prior to extubation. Adequate respiratory effort should be confirmed by ability to generate a negative inspiratory pressure of at least −20 cm H_2O. Although MG patients often experience improvement in respiratory function and other MG symptoms after thymectomy, it is more difficult to predict response to surgeries

unrelated to MG. After extubation, it is essential to monitor the patient closely for signs of fatigue, weakness, or evidence of deteriorating respiratory status (hypercarbia, hypoxemia, tachypnea). If the patient was taking pyridostigmine preoperatively, oral dosing should be reestablished as soon as possible after extubation; if necessary, alternative anticholinesterase medications may be used as a bridging measure. The dosage equivalents are shown in **Table 53.1**.

Care should be taken to ensure that somnolence related to opioid administration does not place the patient at increased risk for hypoventilation. In addition, vigilance is required to ensure that impending myasthenic crisis is not masked by intraoperative reversal agents that may wear off in the postanesthesia care unit.

Blichfeldt-Lauridsen L, Hansen BD. Anesthesia and myasthenia gravis. *Acta Anaesthesiol Scand*. 2012;56(1):17–22.

D.3. How will you manage postoperative analgesia?

MG patients are especially sensitive to the central respiratory depressive effects of parenteral opioid administration. On the other hand, inadequately treated pain related to abdominal or thoracic surgery can inhibit ventilatory effort and thus can also worsen respiratory status. Nonopioid pain regimens should be used whenever possible. Following the VATS thymectomy, this patient would benefit from thoracic epidural analgesia via the catheter that was placed preoperatively. Neuraxial analgesia and regional anesthesia where appropriate greatly reduce the total dose of opioid required compared to parenteral administration to achieve an equivalent analgesic effect. Paravertebral blocks have been demonstrated to decrease pulmonary complications such as atelectasis and pneumonia following thoracotomy, whereas thoracic epidural analgesia has not. More recently, continuous erector spinae plane blocks have been used to effectively control postoperative pain after thoracotomy. Intravenous nonsteroidal

anti-inflammatory drug (NSAID) regimens have also been effective in controlling pain in MG patients without causing respiratory depression. If oral or parenteral opioids are used, the dose should be decreased for MG patients receiving anticholinesterase therapy because these medications have been reported to increase the efficacy of opioids.

D.4. How will you define and manage postextubation ventilatory failure in this patient?

The postsurgical state is uniquely perilous to the MG patient for respiratory decompensation after extubation; indeed, cases have been reported in which previously undetected MG was diagnosed as a result of unexpected respiratory failure in the postoperative period. Suggested criteria for reintubation have included tachypnea (respiratory rate greater than 40 breaths per minute), respiratory acidosis not due to narcotics, or vital capacity ≤8 mL per kg; however, for a patient in myasthenic crisis, inspiratory and expiratory forces are a better indicator of muscle strength, although the presence of a radiologic finding of atelectasis is the strongest predictor of extubation failure or need for reintubation.

Although a myasthenic crisis and a cholinergic crisis may both present with muscle weakness, salivation, and sweating, cholinergic crisis is a rare complication. If available, the preferred therapies for myasthenic crisis are IVIG and PLEX.

Anticholinesterase therapy can also be administered and titrated to effect; however, if IVIG or PLEX is available anticholinesterase medications should be decreased or discontinued to reduce pulmonary secretions. The treatment for cholinergic crisis may incorporate antimuscarinic drugs to treat salivation and sweating but is mostly supportive and may require mechanical ventilation until the crisis is resolved.

54 Malignant Hyperthermia

Henry Rosenberg, Harvey K. Rosenbaum, and Vinod Malhotra

A 7-year-old boy with kyphoscoliosis was scheduled for ambulatory surgery for repair of strabismus under general anesthesia. Previous anesthetic history included an uneventful sevoflurane and nitrous oxide anesthesia for bilateral myringotomy. However, the mother was very nervous because a first cousin of the boy had died under anesthesia in Wisconsin the previous year.

A. Medical Disease and Differential Diagnosis

1. What was the problem of concern in this case?
2. What is malignant hyperthermia (MH)?
3. What are the clinical features of a susceptible patient?
4. Does the history of previous uneventful sevoflurane anesthesia reasonably exclude the patient's susceptibility to MH?
5. What are the clinical features of the syndrome?
6. What are the laboratory findings during an acute crisis of MH?
7. What is the incidence of this syndrome?
8. What is the mode of inheritance of the disease? Does MH "skip" generations?

9. What genetic disorder results in MH susceptibility?
10. What is the pathophysiology of the syndrome?
11. What laboratory tests can further substantiate the susceptibility of the patient to MH?
12. What is neuroleptic malignant syndrome (NMS)?

B. Preoperative Evaluation and Preparation

1. How would you prepare this patient for anesthesia and surgery?
2. Is dantrolene prophylaxis indicated?
3. What laboratory tests would you obtain before surgery?
4. Is outpatient surgery appropriate for this patient?
5. In anticipation of general anesthesia, what preparations would you make?

C. Intraoperative Management

1. What anesthetic techniques and agents would you employ?
2. Should body (core) temperature be monitored during general anesthesia lasting more than a short time?
3. What anesthetic agents are contraindicated?
4. If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?
5. What is the significance of masseter muscle spasm occurring after succinylcholine administration?
6. Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?
7. What modalities would you monitor closely during management of the crisis?
8. What steps should be taken to avoid major morbidity from MH?
9. How does the new formulation of dantrolene (Ryanodex) compare with the existing formulation of dantrolene (Dantrium

or Revonto)?

D. Postoperative Management

1. What complications may follow this syndrome?
2. What would be your follow-up in this case?
3. What would you advise the patient and the family?
4. What precautions should an MH-susceptible patient take outside of the operating room (OR)?

A. Medical Disease and Differential Diagnosis

A.1. What was the problem of concern in this case?

The patient was a 7-year-old boy with kyphoscoliosis and strabismus and a history of an anesthetic-related death in the family in Wisconsin. Therefore, in addition to the respiratory problems associated with kyphoscoliosis, he presented a likelihood of susceptibility to MH syndrome. The supporting factors for strong suspicion were the family history, kyphoscoliosis, and the geographic location. There is a high density of MH-susceptible families in Wisconsin.

A.2. What is malignant hyperthermia (MH)?

MH, first described by Denborough and Lovell in 1960, is an inherited clinical syndrome characterized by elevated core temperature, tachycardia, tachypnea, hypercarbia, rigidity, acidosis, and hyperkalemia. The underlying abnormality relates

to an uncontrolled elevation of intracellular calcium in skeletal muscle cells leading to activation of muscle contractile elements and hypermetabolism. These changes are reversed with the administration of dantrolene, but in the absence of timely treatment, death is likely. In almost every instance, the clinical syndrome occurs in a susceptible patient when a "triggering" anesthetic agent is employed. However, not all signs appear in all cases. In rare situations, an MH crisis has appeared in humans in the absence of anesthetic drugs.

Zvaritch E, Gillies R, Kraeva N, et al. Fatal awake malignant hyperthermia episodes in a family with malignant hyperthermia susceptibility: a case series. *Can J Anaesth*. 2019;66(5):540–545.

A.3. What are the clinical features of a susceptible patient?

A family history, if present, particularly in a first-degree relative, is a strong indicator of MH susceptibility. Epidemiologic studies have demonstrated that certain comorbidities such a scoliosis and muscle disorders are more frequent in MH-susceptible patients. There are a few myopathic disorders that are known to be associated with MH susceptibility. They include central core disease, King-Denborough syndrome, multiminicore disease, congenital myopathy with cores and rods, nemaline rod myopathy, idiopathic hyperCKemia, and Native American myopathy; hypokalemic periodic paralysis has been rarely associated with MH susceptibility (**Table 54.1**). However, most patients susceptible to MH do not have obvious musculoskeletal disorders or a positive family history.

Patients who have Duchenne or Becker muscular dystrophy

should not be anesthetized with MH trigger agents because hyperkalemia and rhabdomyolysis may result.

TABLE 54.1	Associated Musculoskeletal Disorders/Signs in Patients Susceptible to Malignant Hyperthermia
Scoliosis	
Hypotonia	
Exercise-induced rhabdomyolysis	
Strabismus	
Central core disease	
Multiminicore disease	
King-Denborough syndrome	
Congenital myopathy with cores and rods	
Nemaline rod myopathy	
Idiopathic hyperCKemia	
Native American myopathy	
Hypokalemic periodic paralysis (rarely associated with malignant hyperthermia susceptibility)

A.5. What are the clinical features of the syndrome?

The clinical features of MH are the result of an uncontrolled, exaggerated, hypermetabolic state triggered by the use of potent inhalation anesthetic agents and/or succinylcholine. In humans, a few cases of MH have been thought to occur as a result of environmental factors other than anesthetic agents. Common manifestations include the following:

Specific for MH

- Increase in end-tidal carbon dioxide (CO_2) during constant ventilation (the most sensitive and specific sign)
- Generalized rigidity (extremely high specificity); when due to MH, it does NOT improve with administration of paralytics or increasing anesthetic depth
- Masseter muscle rigidity (MMR)

Nonspecific

- Tachycardia (the earliest and most consistent clinical sign, however; not specific)
- Tachypnea
- Increased temperature, which may exceed 40°C
- Arrhythmias
- Skin mottling
- Profuse sweating
- Altered blood pressure—may observe hypotension or hypertension

Increased temperature is unexpected during anesthesia for an elective procedure or during trauma surgery. Although an important sign of MH, it is nonspecific. Failure to measure

temperature or reliance on inaccurate temperature monitors is associated with increased mortality from an MH episode.

Hyperkalemic Cardiac Arrest

Sudden hyperkalemic cardiac arrest has been reported after the administration of MH trigger agents in children with undiagnosed myopathy, especially the dystrophinopathies, Duchenne or Becker muscular dystrophy. This response is due to acute muscle membrane destruction leading to hyperkalemia. The pathway leading to the abnormal response to potent inhalational anesthetics is not clear. Fulminant MH may also result in hyperkalemic cardiac arrest associated with severe acidosis, rhabdomyolysis, and hyperthermia.

The treatment for hyperkalemia includes glucose and insulin, calcium chloride or gluconate, and hyperventilation.

A.6. What are the laboratory findings during an acute crisis of MH?

The laboratory values reflect changes of a hypermetabolic state and muscle tissue damage (**Table 54.2**). Hence hypercarbia,

respiratory and metabolic acidosis, hyperkalemia, elevated creatine kinase (CK), and myoglobinemia are common findings. If the hyperthermia is extreme, coagulopathy is common. In the early stage of an MH episode, metabolic acidosis, hyperkalemia, and CK elevation may be absent.

TABLE 54.2 The Laboratory Findings of Acute Malignant Hyperthermia

Metabolic and Respiratory Acidosis
Arterial blood gases
↓↓ pH
↑↑ PCO_2
Mild decreases in PO_2
Electrolytes
↑ K
Later decreased serum calcium
↑ Mg
Serum
↑ Lactate
↑ Pyruvate
↑ Creatine kinase
↑ Lactate dehydrogenase
↑ Aldolase
↑ Myoglobin
Increased INR, increased FSP, increased PT/PTT
Thrombocytopenia if DIC develops

DIC, disseminated intravascular coagulation; FSP, fibrin split product; INR, international normalized ratio; K, potassium; Mg, magnesium; P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen; PT/PTT, prothrombin time/partial thromboplastin time.

A.7. What is the incidence of this syndrome?

The incidence of clinical MH is difficult to measure because many clinical syndromes resemble MH and often the anesthetic management is altered when initial signs suggesting MH are

detected. The incidence also depends on the prevalence in a population of genetic mutations causal for MH as well as the prevalence of use of MH trigger agents. For most conditions, the incidence is determined by coded diagnoses in the medical record. However, in the case of MH because many clinicians are not familiar with the disorder, some cases of high fever with bad patient outcome are labeled generically as "malignant hyperthermia." In one small study based on such coded diagnoses, only 25% of cases coded as MH were determined to actually represent clinical episodes of MH by an expert panel.

One of the earliest epidemiologic studies of MH was conducted in Denmark where an estimate of the incidence of fulminant MH was noted to be 1 in 260,000 general anesthetics and 1 in 60,000 anesthetics where succinylcholine was used. The incidence was even higher, that is, 1 in 5,000 anesthetics, when such signs as MMR, unexplained tachycardia, and unexplained fever were included. Two recent studies of coded hospital discharge data showed that the prevalence of MH is 1 in 100,000 hospital discharges for adults and 4 per 100,000 discharges for children.

In a particular province of Quebec, Canada, the prevalence of MH was calculated as 0.2% of the population based on a detailed genealogic study of families with MH susceptibility. Genetic studies have suggested that the prevalence of MH causative mutations is 1 in 2,000 people in France and in Japan. Incomplete penetrance results in an incidence of MH episodes far lower than anticipated by mutation prevalence. However, mortality from acute MH ranges from 6% to 10%.

A.8. What is the mode of inheritance of the disease? Does MH "skip" generations?

MH is inherited in humans in an autosomal dominant fashion with reduced penetrance and variable expressivity. MH is heterogeneic with up to seven gene loci implicated but only three are confirmed—*RYR1*, *CACNA1S*, and *STAC3*. A missense mutation in *STAC3* is associated with Native American myopathy and MH susceptibility; the disorder displays autosomal recessive transmission. *STAC3*-related myopathy has been described in other ethnic groups and has not been described in heterozygous family members.

Over 70% of MH cases are linked to the skeletal muscle ryanodine receptor gene *RYR1* located on chromosome 19. Less than 2% are associated with mutations in the *CACNA1S* (α1 subunit of the dihydropyridine receptor) gene. Over 400 variants have been found in *RYR1* with 48 documented as causal mutations for the syndrome.

Because MH is usually inherited in an autosomal dominant manner, the susceptibility to MH does not "skip" generations. However, because of the low penetrance, not all those with MH

mutations display the syndrome on exposure to trigger agents. *De novo* mutations have also been described.

Some MH-susceptible patients with overt myopathy are homozygous or compound heterozygous for *RYR1* mutations that are causal or potentially causal for MH. Nonmyopathic family members may also be MH susceptible.

A.9. What genetic disorder results in MH susceptibility?

In most cases, the MH-susceptible patient has a defective calcium channel located in the membrane of the sarcoplasmic reticulum (SR) of skeletal muscle. This channel is termed the ryanodine receptor because it binds the plant alkaloid ryanodine.

The channel is closely associated with other proteins and structures, such as the dihydropyridine calcium channel that mediates transfer of voltage change to the RYR1 receptor. Other proteins associated with the ryanodine receptor include triadin, *STAC3*, DHPR subunit $\beta 1\alpha$, and FKB-12 binding protein. Mutations or potentially pathogenic variants in the *RYR1* gene are found in approximately 70% of MH-susceptible patients and their families. Hundreds of additional *RYR1* variants have yet to be characterized as to effects on calcium movements. One

reason for the slow progress in deciphering the significance of these many mutations is that, unlike many other conditions, there are many private mutations that predispose to MH. No single mutation accounts for more than about 10% of MH cases. The dihydropyridine receptor gene, also involved in intracellular calcium control, has been associated with MH susceptibility in a 1% to 2% of MH-susceptible families.

The *STAC3* gene encodes a T tubule protein that is essential for excitation-contraction coupling. Native American myopathy is an autosomal recessive disorder caused by a specific *STAC3* mutation and is associated with MH susceptibility.

There are probably mutations in other genes that may contribute to MH susceptibility. A recent estimate suggests that up to 23% of MH-susceptible families do not have mutations in *RYR1*, *CACNA1S*, or *STAC3*.

Of interest is the observation that mutations associated with central core disease and multiminicore disease, two myopathies that also predisposes to MH, are located on the *RYR1* gene as well. In central core disease, the SR is depleted of calcium to a significant extent due to the increased permeability of the ryanodine receptor. With a depletion of calcium, muscle contraction is weakened when the muscle is activated.

Genetically engineered mice have been developed that include one or more of the mutations causal for MH in the mouse genome. The mouse displays signs typical of MH during exposure to MH trigger agents and also on exposure to raised environmental temperature.

A.10. What is the pathophysiology of the syndrome?

The MH syndrome results from an abnormal and uncontrolled elevation of intracellular calcium levels in skeletal muscle. The pathophysiology is as follows: The process of calcium release from the SR normally begins with depolarization of the sarcolemma, which is transmitted via the T tubules to the dihydropyridine receptor that in turn activates the calcium channel termed the ryanodine receptor to release calcium.

The elevated calcium removes the inhibition of actin and myosin interaction that leads to mechanical force generation. Calcium release occurs via a channel within the SR called the ryanodine receptor. Reuptake of calcium returns the intracellular cytoplasmic concentration of calcium to normal and muscle relaxation takes place. Reuptake is mediated via sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA) pumps.

There are a variety of intermediate proteins that also regulate the intra-SR concentration of calcium such as calsequestrin, a calcium-binding protein. Genetically engineered mice that do no express calsequestrin have been shown to develop clinical signs of MH on exposure to trigger anesthetics. It is believed that in the absence of the calcium buffer, intracellular calcium levels increase significantly but only on exposure to MH triggers. Association of variants in the calsequestrin gene with human MH has not been confirmed.

The control of calcium release is highly regulated because when muscle contraction takes place, a variety of energy-consuming steps are required resulting in adenosine triphosphate (ATP) breakdown and heat production.

During an MH episode, the ryanodine receptor calcium channel is locked in an open position leading to an uncontrolled leak or release of calcium as well as increased extracellular calcium entry with elevation of intracytoplasmic calcium levels and continuous muscle activation as well as ATP breakdown. The SR calcium pump is unable to sufficiently resequester the calcium. ATP breakdown during this process aggravates heat production further.

Energy-consuming processes take place through glycolysis as well as oxidative phosphorylation. Eventually, ATP levels are insufficient to maintain sarcolemmal integrity and potassium leaks from the cell resulting in hyperkalemia. Myoglobinemia occurs for the same reason, as does an increase of a number of enzymes, including CK.

A.11. What laboratory tests can further substantiate the susceptibility of the patient to MH?

The most accurate diagnostic test for MH is the exposure of biopsied skeletal muscle to halothane, caffeine, and, more

recently, ryanodine or chlorocresol. In this test, about 2 g of muscle is harvested from the thigh under regional, or in the case of a child at least 8 years old, nontriggering general anesthesia. Strips or fascicles of muscle weighing 100 to 200 mg are suspended in a water bath at 37°C, and exposure is made to either halothane, caffeine, ryanodine, or chlorocresol in specific graded concentrations. The isometric contracture, not contraction, response to muscle is measured via strain gauge following specific guidelines. The threshold and height of the contracture is measured and a diagnosis of MH is made based on the contracture threshold and strength exceeding specific values.

The test is highly sensitive, close to 100%, but as many as 20% of positives are false positives. Nevertheless, the value of the test resides in ruling out MH susceptibility. Patients with MH-causal mutations and negative, that is, malignant hyperthermia non-susceptible (MHN) contracture tests have been described. Although these may be false-negative contracture tests, it may be possible that the patient is MHN phenotype due to unknown genetic or epigenetic factors that counteract the causal mutation. Caution dictates that such patients would nonetheless be treated as MH susceptible.

Because the test is invasive and costly and requires strict adherence to specific requirements, there are only five testing centers in North America. There are over 20 in Europe. Two slightly different versions of the test exist, the North American and the European versions. The main difference is in the concentration of drugs used during exposure of the muscle and the threshold for determining a positive response.

The patient and his or her history must be carefully evaluated by the biopsy center director prior to recommending the test in order to enhance its positive predictive value.

Molecular Genetic Testing for MH Susceptibility

The era of DNA testing for MH susceptibility began in 1990 when a single missense mutation in the *RYR1* gene was shown to be causal for MH in pigs. In humans, several genes have been associated with MH; however, the *RYR1* gene is probably responsible for most cases of MH. At present, 48 mutations in the *RYR1* gene have been found in humans that are causal for MH based on strict criteria related to in vitro calcium release or clinical MH in several generations and families. Unfortunately, no mutation accounts for more than a small percentage of all patients with MH susceptibility. The chief advantage of genetic testing is all that is required is a blood sample and the specimen may be shipped to the laboratory. The main limitation of genetic testing is the sensitivity of <75% as well as the frequent finding of variants of unknown significance in both *RYR1* and *CACNA1S*.

Undoubtedly, the sensitivity will improve as more mutations are identified and tested for their ability to alter the structure and function of the ryanodine receptor.

Patients should consider genetic testing if

1. They have had a positive contracture test.
2. A family member has had a positive contracture test.
3. They have suffered a very likely MH episode but have not had a contracture test.
4. A family member has been found to have a causal mutation.

In those patients who are tested and a causal mutation identified, those with the mutation are MH susceptible (high specificity). The absence of a confirmed or probable pathogenic variant does *not* rule out MH susceptibility as they may harbor another as yet undescribed mutation.

At present, there are five clinical testing laboratories in the United States that perform molecular genetic testing for patients suspected to be MH susceptible (https://www.mhaus.org/testing/genetic-testing/genetic-testing-

centers/). The decision to undergo genetic testing is complex because the test, although requiring only a blood sample, costs approximately $2,000 for examining *RYR1* and *CACNA1S*. However, once a mutation is found, the cost for screening family members is approximately $200 each. This compares to an approximate cost of $6,000 for the caffeine halothane contracture test.

The pros and cons of testing should be discussed with either an MH expert or a genetic counselor.

A.12. What is neuroleptic malignant syndrome (NMS)?

The NMS is characterized by altered mental status, hyperthermia, rigidity, rhabdomyolysis, acidosis, and tachycardia, features that mimic MH. However, NMS is

precipitated by a variety of neuroleptic drugs including haloperidol, the atypical antipsychotics, phenothiazines, and other centrally acting drugs.

This syndrome differs from MH in that central dopamine antagonism or depletion is thought responsible for the clinical picture, although NMS is an idiosyncratic reaction. Other factors such as antimuscarinic effect, acute inflammation, and hypovolemia are often associated with NMS. If a patient with NMS requires intubation and mechanical ventilation, nondepolarizing muscle relaxants usually result in partial or complete resolution of rigidity unlike MH. The mainstay of treatment are supportive care, benzodiazepines, and, if necessary, a dopamine agonist such as bromocriptine. Patients also respond symptomatically to dantrolene therapy. A recent report identified *RYR1* mutations in a small percentage of patients manifesting NMS.

A variety of drug-induced hyperthermic syndromes resemble MH such as the serotonin syndrome. The drug interaction resulting in potentially lethal serotonin toxicity is the administration of a monoamine oxidase (MAO)-A inhibitor, such as intravenous methylene blue, to a patient chronically taking a selective serotonin reuptake inhibitor (SSRI) antidepressant, or administration of a medication with SSRI activity, such as meperidine, to a patient taking an MAO-A or nonspecific MAO inhibitor. Ecstasy and other methylenedioxymethamphetamine (MDMA) agonists also produce hyperthermia. Again, the signs may resemble MH, but the pathophysiology is very different; unlike MH, severe serotonin toxicity consistently presents *after* discontinuation of general anesthesia.

Anesthesiologists may encounter NMS in patients who are sedated with haloperidol in the intensive care unit (ICU) and on infrequent occasions when patients are given dopamine agonist

agents such as metoclopramide and promethazine.

B. Preoperative Evaluation and Preparation

B.1. How would you prepare this patient for anesthesia and surgery?

Preoperative preparation should include a detailed medical history, assessment of the patient's physical status, evaluation of laboratory findings including CK, and specific investigations to determine the susceptibility of the patient to MH. Three possible scenarios are as follows:

- The caffeine halothane contracture test result is normal. The patient should be considered not susceptible to MH and the anesthetic should be nonrestrictive.
- The caffeine halothane contracture test is abnormal, implying MH susceptibility. Or, a mutation associated with MH or a probable pathogenic *RYR1* variant is identified. In this case, trigger-free anesthetic agents should be employed and all preparations should be made to quickly treat the syndrome if it develops.
- The caffeine halothane contracture test is not available. This is very frequently the case because this test is done in only a few centers in the United States. In such situations, the patient should be treated as MH susceptible, and all

appropriate steps should be followed.

Frei D, Stowell KM, Langton EE, et al. Administration of anaesthetic triggering agents to patients tested malignant hyperthermia normal and their relatives in New Zealand: an update. *Anaesth Intensive Care*. 2017;45(5):611–618.

Rosenberg H, Pollock N, Schiemann A, et al. Malignant hyperthermia: a review. *Orphanet J Rare Dis*. 2015;10:93.

B.2. Is dantrolene prophylaxis indicated?

If a nontriggering anesthetic is administered with appropriate monitoring to an MH-susceptible patient, dantrolene prophylaxis is not necessary.

With the judicious use of trigger-free anesthetics, MH is extremely unlikely. MH cases without trigger agents have been reported; however, because many syndromes may mimic MH, it is uncertain if each of the cases was really MH.

Dantrolene can cause side effects, such as nausea, vomiting, pain at the injection site, thrombophlebitis, and depression of the twitch response. In patients with preexisting muscle weakness, dantrolene may cause respiratory insufficiency in the postoperative period.

Carr AS, Lehman J, Cunliffe M, et al. Incidence of malignant hyperthermia reactions in 2,214 patients undergoing muscle biopsy. *Can J Anaesth*. 1995;42(4):281–286.

B.3. What laboratory tests would you obtain before surgery?

Chest radiograph and electrocardiogram (ECG) should be ordered if dictated by his scoliosis or other associated medical illness. Otherwise, there is no routine laboratory testing indicated for strabismus surgery in this child. Serum CK is of value as a baseline test and should be obtained.

B.4. Is outpatient surgery appropriate for this patient?

With the use of trigger-free anesthetics and appropriate monitoring, surgery normally performed in an outpatient setting is acceptable. The anesthesia provider and nursing team should be informed well in advance of the day of surgery to confirm preparedness to care for an MH-susceptible patient. Even when planning a trigger-free anesthetic, dantrolene for treatment of an acute MH episode should be available. Postoperative admission to the hospital solely on the basis of MH susceptibility is not warranted. When MH occurs, it is usually in the immediate postoperative period and usually not beyond 2 hours postoperatively. Therefore, it is prudent to keep the patient longer than usual in the postanesthesia care unit (PACU) in monitored setting and a little longer in the ambulatory discharge area.

All ambulatory surgery and office-based surgery settings should have a plan for managing an MH episode and transferring the patient to a hospital while continuing to assess and treat the episode and communicating key items to the receiving emergency department (ED) or ICU team.

Larach MG. A primer for diagnosing and managing malignant hyperthermia susceptibility. *Anesthesiology*. 2018;128(1):8–10.

Larach MG, Dirksen SJ, Belani KG, et al. Special article: creation of a guide for the transfer of care of the malignant hyperthermia patient from ambulatory surgery centers to receiving hospital facilities. *Anesth Analg*. 2012;114(1):94–100.

Pollock N, Langton E, McDonnell N, et al. Malignant hyperthermia and day stay surgery. *Anaesth Intensive Care*. 2006;34(1):40–45.

B.5. In anticipation of general anesthesia, what preparations would you make?

A satisfactory preparation for administering anesthesia to this patient should include measures to prevent and treat an acute crisis of MH. The following should be available:

Equipment

- Remove or disable vaporizers. Place a conspicuous warning on the anesthesia workstation that the patient is MH susceptible.
- Fresh circuit, reservoir bag, and soda lime
  - Flush machine and ventilator by flowing 10 L oxygen per minute for at least 10 minutes
  - For newer anesthesia work stations, the washout period may be prolonged up to 60 minutes. The manufacturers' guidelines for machine preparation should be followed. The use of activated charcoal filters greatly reduces the length of time required to prepare an anesthetic workstation for an MH-susceptible patient. After a 90-second flush with high flow oxygen, placement of activated charcoal filters on the inspiratory port immediately reduces residual breathing circuit vapor concentration to <5 ppm.
- Routine American Society of Anesthesiologists (ASA) monitors including
  - Pulse oximeter
  - Capnometer
  - Core temperature monitor using one of the following sites: distal esophagus or nasopharynx. For procedures where the patient will have a bladder catheter, bladder temperature may be monitored.
  - ECG and blood pressure monitors

Items to have available

Cooling aids

- Hypothermia blanket
- Crushed ice
- Cold 0.9% saline for intravenous infusion (e.g., 30 mL per kg): This is the most rapid, reliable technique of lowering

body temperature if the temperature is greater than 39°C or rapidly increasing.

Drugs

- Sodium bicarbonate, mannitol, furosemide, dantrolene (intravenous), sterile water, antiarrhythmics, insulin, 50% dextrose, and calcium chloride
- ***Avoid intravenous verapamil or diltiazem for treatment of arrhythmia during an MH episode*** because of interaction with dantrolene possibly resulting in cardiac arrest. On the other hand, in a patient taking oral verapamil or diltiazem who is suspected of having an acute MH episode, do ***NOT*** withhold dantrolene treatment.

C. Intraoperative Management

C.1. What anesthetic techniques and agents would you employ?

Potent inhalation agents and succinylcholine (excluding nitrous oxide) are to be avoided. Local or regional anesthesia with intravenous sedation as needed may be preferable if the surgeon and anesthesia provider are confident with these techniques. General anesthesia may be induced with propofol, benzodiazepine, or other intravenous hypnotic, and the patient be ventilated with 100% oxygen. Fentanyl or other opioid may be added to ensure adequate depth of anesthesia. Topical

anesthesia of the larynx and vocal cords is optional. The trachea is intubated with or without the use of an intermediate-acting nondepolarizing muscle relaxant. Anesthetic maintenance is achieved using oxygen with or without nitrous oxide, a narcotic, and a nondepolarizing relaxant as required. Total intravenous anesthesia (TIVA), with a continuous infusion of propofol and injections of analgesics as indicated, is most often employed for nontriggering general anesthetics expected to last more than 30 minutes.

Vital signs are monitored with very close attention to capnography.

C.2. Should body (core) temperature be monitored during general anesthesia lasting more than a short time?

Definitely. Although temperature elevation is often not the first sign of MH, it is one of the common early signs of the syndrome. Therefore, core temperature, esophageal, rectal, urinary bladder, or nasopharyngeal temperature should be monitored for all procedures lasting more than about 30 minutes. Temperature monitoring is also important in detecting hypothermia.

Sessler DI. Temperature monitoring and perioperative thermoregulation. *Anesthesiology*. 2008;109(2):318–338.

C.3. What anesthetic agents are contraindicated?

In general, the anesthetic agents to be avoided include potent inhalation agents and the depolarizing muscle relaxant succinylcholine. Of the agents commonly employed today, the following have been implicated in triggering MH:

- Inhalation agents—halothane enflurane, isoflurane, desflurane, and sevoflurane
- Muscle relaxants—succinylcholine

Larach MG. A primer for diagnosing and managing malignant hyperthermia

susceptibility. *Anesthesiology*. 2018;128(1):8–10.

Litman RS. Susceptibility to malignant hyperthermia: evaluation and management. https://www.uptodate.com/contents/malignant-hyperthermia-diagnosis-and-management-of-acute-crisis?search=malignant%20hyperthermia%20treatment&source=search_result&sele Accessed May 31, 2019.

C.4. If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?

Both ester and amide local anesthetics are considered safe for use in MH-susceptible patients.

D'Ambrosio J, Adragna MG. Guidelines for the use of local anesthetics in the dental treatment of patients who are susceptible to malignant hyperthermia. *Spec Care Dentist*. 1988;8(2):61–63.

Maccani RM, Wedel DJ, Melton A, et al. Femoral and lateral femoral cutaneous nerve block for muscle biopsies in children. *Paediatr Anaesth*. 1995;5(4):223–227.

C.5. What is the significance of masseter muscle spasm occurring after succinylcholine administration?

Rigidity of the jaw muscles after administration of succinylcholine is referred to as MMR or trismus. MMR presages clinical MH in up to 30% of cases. Even in the absence of clinical MH, myoglobinuria following succinylcholine-induced MMR is common postoperatively. MMR probably occurs in individuals of all ages; however, MMR is more common in children, particularly following gas anesthesia induction

MMR has been reported in 1% of children after halothane/succinylcholine induction and in adults after succinylcholine administration. Should MMR occur, elective surgery should be postponed, the patient observed in an ICU setting for 24 hours seeking myoglobinuria specifically as well as observing for early signs of MH. The patient should be followed until CK levels normalize.

In the case of emergency surgery, the anesthetic should be converted to a "nontriggering" technique and the patient observed for early signs of MH. Dantrolene and other MH treatment procedures should be made ready.

The patient and/or family should be advised to be evaluated for MH susceptibility.

The incidence of MMR in children has decreased as a result of recommendations that the use of succinylcholine in children be reserved for emergency situations.

Other causes of succinylcholine-induced MMR include any form of myotonia or periodic paralysis.

Hudig K, Pollock N, Bulger T, et al. Masseter muscle rigidity and the role of DNA analysis to confirm malignant hyperthermia susceptibility. *Anaesth Intensive Care*. 2019;47(1):60–68.

Parness J, Bandschapp O, Girard T. The myotonias and susceptibility to malignant hyperthermia. *Anesth Analg*. 2009;109(4):1054–1064.

C.6. Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?

Although tachycardia may arise from other more common causes, such as a light plane of anesthesia and/or hypovolemia, its association with dysrhythmia in this patient—who is MH susceptible—raises the suspicion that an MH crisis may be starting. End-expiratory CO_2 should be monitored, and if rising despite increasing minute ventilation, the diagnosis of MH should be strongly considered. Because time is of the essence, the following steps should be taken; this constitutes a critical

emergency. Use of a cognitive aid such as a checklist or poster is highly recommended.

- Stop all potent inhalational anesthetics and surgery (if possible).
- Hyperventilate the patient with a high fresh gas flow of 100% oxygen. It is recommended that one increase ventilation using mechanical ventilation, particular in settings of limited manpower.
- Obtain help and assistance through the MH hotline of the Malignant Hyperthermia Association of the United States (MHAUS): 1-800-MH-HYPER.
- Administer specific drug therapy—start dantrolene sodium (DS) early while muscle perfusion is still present. An initial intravenous dose of 2.5 mg per kg should be followed by repeated doses of 1 to 2 mg per kg to a total of 10 mg per kg depending on the patient's response. More dantrolene may be administered if clinically indicated.
- If available, place activated charcoal filters on the inspiratory and expiratory ports of the breathing circuit.
- Initiate aggressive cooling immediately for rapidly increasing temperatures and for those higher than 39°C. Methods for cooling include the following: surface cooling with the patient on a cooling blanket and packed in ice and cold intravenous 0.9% saline or Plasmalyte A. Cooling should be stopped when the patient's temperature falls to lower than 38°C, to prevent inadvertent hypothermia.
- Treat acidosis with sodium bicarbonate (2 mEq per kg initial dose and titrate as necessary).
- Treat hyperkalemia with intravenous calcium chloride or calcium gluconate, hyperventilation, sodium bicarbonate, insulin, and 50% dextrose.
- Treat arrhythmias with standard antiarrhythmics and avoid verapamil or diltiazem if dantrolene has been given. If

hyperkalemia is suspected, do not give lidocaine or procainamide.

- Arterial line and a Foley catheter should be inserted in all cases of fulminant MH. Central venous catheterization should be considered for unstable patients.
- Maintain urine output with mannitol or furosemide. Each 20 mg bottle of Dantrium or Revonto contains 3 g mannitol. In comparison, each 250 mg bottle of Ryanodex contains only 125 mg mannitol.
- Follow CK levels every 12 hours.
- Check electrolytes, hemoglobin/hematocrit, platelet count, and coagulation parameters.
- After the MH episode, register the patient and the event with the North American MH Registry (https://anest.ufl.edu/namhr/).

Hardy JB, Gouin A, Damm C, et al. The use of a checklist improves anaesthesiologists' technical and non-technical performance for simulated malignant hyperthermia management. *Anaesth Crit Care Pain Med*. 2018;37(1):17–23.

C.7. What modalities would you monitor closely during management of the crisis?

The modalities that should be monitored closely include the following:

- End-tidal CO_2 and minute ventilation
- Arterial blood gases/electrolytes/coagulation
- Core temperature

The following should be monitored for ongoing evaluation and management:

- CK levels
- Myoglobin levels—urine and serum
- Urine output

C.8. What steps should be taken to avoid major morbidity

from MH?

All sites where general anesthesia is administered should have 36 vials of dantrolene or 3 bottles of Ryanodex available within about 10 minutes.

All patients undergoing general anesthesia for more than 30 minutes should have core temperature monitored

It is highly recommended that ORs and procedure areas where general anesthesia is employed conduct an MH drill each year. This drill should involve all OR and procedure area personnel going through the steps of alerting the team, obtaining dantrolene, mixing dantrolene, simulating blood draw, cooling the patient, and discussing the episode with family members.

In addition, nonhospital sites should ensure that a hospital is designated to receive a patient who is experiencing an MH episode. The facility should have a plan as to who will accompany the patient, what drugs and monitors will accompany the transport personnel, and the local hospital has dantrolene as well as familiarity with treating the syndrome.

C.9. How does the new formulation of dantrolene (Ryanodex) compare with the existing formulation of dantrolene (Dantrium or Revonto)?

Present formulations of dantrolene (Dantrium and Revonto) are lyophilized, freeze dried, and dispensed as DS 20 mg in a 70-mL vial and contain 3,000 mg of mannitol. It should be reconstituted by adding 60 mL of sterile water without a bacteriostatic agent, and the vial needs to be shaken until clear. Warming the sterile water to 40°C immediately prior to mixing can speed up the process and also help drawing the drug in a syringe because the solution is fairly viscous. One may require 4 to 7 vials to start the treatment and may go up to 36 vials in an adult achieving maximum dosage. This can be a tedious and time-consuming process.

Recent formulation of dantrolene (Ryanodex) is a nanocrystalline dantrolene sodium suspension (DSS) that allows for a much larger dose of 250 mg to be dispensed in a vial that requires only 5 mL of sterile water to dissolve it in solution. It offers the advantage of rapid reconstitution and administration. In one animal study, the time for preparation for DSS (less than 60 seconds) was 10- to 15-fold shorter compared with DS (658 to 1,062 seconds), and the time taken to inject was a 100-fold faster. It contains only 125 mg of mannitol; hence, mannitol needs to be given separately. Because the diluent is in small amounts of water, fluid load is not as significant as in case of existing formulations. This becomes especially significant in pediatric patients.

The cost of DSS (required supply of 3 vials) is close to $7,000 in United States. It has a shelf life of 24 months. DS has a shelf life of 36 months and costs less than half as much (required supply of 36 vials). The cost of DSS may be substantially reduced when DSS is purchased for several locations within the same organization.

D. Postoperative Management

D.1. What complications may follow this syndrome?

Disseminated intravascular coagulation syndrome is a major complication of MH especially when the patient's temperature exceeds 41°C. Other complications include renal failure, hyperkalemia, compartment syndrome, and neurologic injury.

As a result of massive muscle breakdown, the patient may be weak for days and also complain of muscle cramps and pain.

Brandom BW, Larach MG, Chen MS, et al. Complications associated with the administration of dantrolene 1987 to 2006: a report from the North American Malignant Hyperthermia Registry of the Malignant Hyperthermia Association of the United States. *Anesth Analg*. 2011;112(5):1115–1123.

Rosenberg H, Pollock N, Schiemann A, et al. Malignant hyperthermia: a review. *Orphanet J Rare Dis*. 2015;10:93.

D.2. What would be your follow-up in this case?

The vigorous therapy started in the OR should be continued in the immediate postoperative period into the PACU or the ICU. Dantrolene administration should be continued for at least 24 hours after an episode is controlled at a dose of 1 mg per kg every 4 to 6 hours titrated to signs of MH. Serum CK should be followed until consistently trending downward.

Other laboratory values that should be followed until normalized include

- Arterial blood gases
- Electrolytes
- Coagulation profile

Body temperature should be monitored along with other vital signs. Recrudescence of MH occurs in about 20% of treated cases and therefore the patient should be watched in an ICU setting for at least 36 hours following an episode.

Burkman JM, Posner KL, Domino KB. Analysis of the clinical variables associated with recrudescence after malignant hyperthermia reactions. *Anesthesiology*. 2007;106:901–906.

D.3. What would you advise the patient and the family?

The patient and his family should be warned of the dangerous nature of this syndrome and should be advised to carry an identification band at all times. The pedigree of the family should be prepared, and the members should be investigated for

susceptibility to this syndrome and issued medical identification bracelets or pendants accordingly. While not changing his future anesthetic management, molecular genetic testing would be recommended for the patient; if an MH causal mutation is discovered, this will facilitate noninvasive confirmation of MH susceptibility in other family members.

The MHAUS has been active since 1981 and offers current information and advice on patient management as well as identification bracelets and a variety of material for health care professionals. The following are some useful contact information:
Emergency hotline: 1-800-MH-HYPER
Address: MHAUS, 39 East State Street, P.O. Box 1609, Sherburne, NY 13815
Phone: 1-800-98-MHAUS
Internet: www.mhaus.org

In addition, the patient and his family should consult with one of the MH diagnostic centers or with an MHAUS hotline consultant to discuss further evaluation. A complete listing is available through MHAUS.

The patient should be registered with the North American MH Registry.

Forms may be obtained through MHAUS.

The website for the North American MH Registry is https://anest.ufl.edu/namhr/; the phone number is 888-274-7899. The Registry is located at the University of Florida.

D.4. What precautions should an MH-susceptible patient take outside of the operating room (OR)?

In general, MH-susceptible patients should be cognizant of their response to heat and exercise. As for any patient, excess exposure to heat and humidity, especially with exercise should be limited or avoided. Although it is true that cases of what

appears to be “awake” MH have been reported without trigger anesthetics, these are rare. At present, there is no way to predict which previously asymptomatic patients may have an adverse response to environmental conditions. Even family members with the same MH-causal mutation may respond differently to vigorous exercise, heat, or infection.

55 Postoperative Residual Neuromuscular Weakness and Prolonged Apnea

Mary So, Danielle McCullough, and David J. Kopman

A healthy 35-year-old, 65-kg female was scheduled for an elective abdominal hysterectomy. Anesthesia was induced with propofol (2.0 mg per kg) and rocuronium (1.2 mg per kg). Anesthesia, which lasted 90 minutes, was maintained with desflurane 6.0% end-tidal and was supplemented with fentanyl as needed. No reversal was given at the end of surgery because tidal volumes were deemed to be adequate. The train-of-four count (TOFC) using facial nerve stimulation was four with no detectable fade. Upon arrival in the postanesthesia care unit (PACU), the patient was tachypneic, had uncoordinated, floppy arm movements, and appeared to be agitated and in distress. Arterial oxygen saturation on room air was 89%.

A. Medical Diseases and Differential Diagnosis

1. What is the differential diagnosis for postoperative hypoventilation?

2. How is residual neuromuscular blockade (NMB) diagnosed?
3. What is the order of recovery of voluntary muscle groups from nondepolarizing muscle relaxants?
4. What is the mechanism of action of succinylcholine, and how is it metabolized? What are the side effects of succinylcholine?
5. If succinylcholine were the only muscle relaxant used during the case and the patient did not exhibit a response to train-of-four (TOF) stimulation, what is the likely diagnosis? How would you confirm it?
6. What are acetylcholinesterase and serum cholinesterase? What is the clinical significance of heterozygosity for atypical pseudocholinesterase (PChE)?
7. What is the incidence of atypical cholinesterase activity?
8. What are some factors that can lower PChE levels?

B. Intraoperative Management

1. How is the choice among muscle relaxants made?
2. What factors can alter sensitivity to nondepolarizing neuromuscular blockers?
3. What are the characteristics of nondepolarizing block?
4. What is a TOF stimulus?
5. Why is the TOF ratio of clinical importance?
6. How do we define adequate recovery of neuromuscular function?
7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?
8. How accurate are subjective estimates of the TOF ratio, and what purpose do peripheral nerve stimulator (PNS) monitors serve?
9. What is double burst stimulation (DBS)?
10. What is the posttetanic count (PTC)?
11. How can the TOF ratio be measured quantitatively?
12. What are the limitations of acetylcholinesterase antagonists?

13. Is there anything wrong with administering neostigmine when the TOFC is less than 3?
14. Is reversal of blockade always necessary?
15. Is there any way to rapidly antagonize a profound nondepolarizing block?

C. Postoperative Management

1. What is the incidence of residual NMB in the PACU?
2. Does undetected postoperative residual neuromuscular block (PORB) have clinical consequences?

A. Medical Diseases and Differential Diagnosis

A.1. What is the differential diagnosis for postoperative hypoventilation?

The differential diagnosis for postoperative hypoventilation includes the following:

- Residual anesthetic agent
- Residual narcotic
- Residual muscle relaxant
- Hypercarbia
- Occurrence of some medical complication during anesthesia, such as stroke or embolism

---

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2592–2593.

A.2. How is residual neuromuscular blockade (NMB) diagnosed?

When residual NMB is clinically suspected, it is diagnosed by testing the TOFC using a PNS. This patient showed clear signs of residual neuromuscular weakness upon arrival in the PACU. TOF stimulation at the ulnar nerve showed a TOFC of only 2 at the adductor pollicis (thumb). A diagnosis of residual blockade

was made and the patient received neostigmine 0.05 mg per kg plus an appropriate dose of glycopyrrolate (0.01 mg per kg). Seven minutes later, the TOFC was 4 with no evidence of fade on palpation of the thumb, and all signs of residual block had abated.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1354–1372.

A.3. What is the order of recovery of voluntary muscle groups from nondepolarizing muscle relaxants?

Onset and recovery of muscular blockade depend on blood supply to the muscle group in question. Peripheral muscles (e.g., adductor pollicis) tend to have poor blood supply compared to central muscles (e.g., diaphragm) leading to a slower onset and offset of nondepolarizing muscle relaxants. Muscles of the upper airway/pharynx are an exception to this "rule", however, because they exhibit a fast onset of blockade but are slower to recover than peripheral muscles. When the TOFC at the orbicularis oculi or corrugator supercilii muscles shows recovery from nondepolarizing block, the response at the adductor pollicis may be almost nonexistent. Thus, facial nerve stimulation may give the clinician a false sense of security about the adequacy of neuromuscular recovery at the end of a case.

Similarly, in the intubated patient breathing spontaneously, a normal tidal volume and maintenance of an acceptable P_{CO_2} do not necessarily indicate adequate neuromuscular recovery. The diaphragm is the first muscle to recover from nondepolarizing block and requires significantly higher plasma levels of relaxants to maintain paralysis. The muscles that protect the upper airway are far more sensitive to nondepolarizing relaxants and cannot be clinically tested in the intubated patient. Thus, a patient who is able to maintain adequate respiratory exchange while intubated may experience airway obstruction due to

inadequate pharyngeal muscle recovery when extubated.

A.4. What is the mechanism of action of succinylcholine, and how is it metabolized? What are the side effects of succinylcholine?

Succinylcholine is a depolarizing neuromuscular blocker. It is composed of two linked acetylcholine (ACh) molecules, which are capable of binding to the ACh receptor at the neuromuscular junction. This activates the receptor, depolarizing the membrane and causing the characteristic fasciculations (i.e., muscle contractions) seen when using this drug. Succinylcholine is metabolized by butyrylcholinesterase (BChE), also known as PChE.

The most common untoward side effect seen after succinylcholine administration is muscle pain occurring in the first 24 to 48 hours postoperatively. Women and patients undergoing ambulatory surgery appear most susceptible to this phenomenon. The reported incidence of succinylcholine-induced myalgia is variable but probably occurs in 25% to 50% of patients. Discomfort is typically characterized as being similar to the muscle soreness that occurs after heavy or unusual exercise. It has been postulated that the etiology of the phenomenon is related to muscle damage caused by asynchronous contractions during the initial muscle depolarization that precedes paralysis. Defasciculating doses of

nondepolarizing relaxants (10% of the ED95) given 2 to 5 minutes prior to succinylcholine have been shown to reduce the incidence of myalgia by as much as 50%. Pretreatment with nonsteroidal anti-inflammatory drugs has also been shown to reduce the incidence of muscle pain following succinylcholine administration.

Succinylcholine may also be associated with various cardiac dysrhythmias including bradycardia, tachycardia, and junctional and ventricular dysrhythmias. Stimulation of nicotinic receptors at sympathetic and parasympathetic ganglion and muscarinic receptors at the sinus node are believed to be involved in this phenomenon. Infants and children may be more likely to manifest clinically significant bradycardia following succinylcholine administration secondary to their relatively high degree of resting vagal tone as compared to adults; however, pretreatment with atropine is no longer recommended in this patient population. Junctional rhythms following succinylcholine administration are also relatively common. The postulated mechanism of action is muscarinic stimulation of the sinus node that results in diminished sinus activity and the subsequent emergence of the atrioventricular node as the dominant pacemaker. Various mechanisms have been postulated to explain ventricular dysrhythmias that sometimes occur after succinylcholine administration including potassium release from skeletal muscle, succinylcholine mediated sensitivity to catecholamines, and profound sinus and atrioventricular node slowing.

The most serious complication associated with succinylcholine administration is severe and potentially lethal levels of hyperkalemia in at-risk individuals. When succinylcholine is administered to an otherwise healthy patient during the induction of anesthesia, plasma potassium levels typically increase by 0.5 mEq per L as potassium ions move

from the intracellular to extracellular space. The increase is transient and is typically tolerated well by most patients. In at-risk patients, however, the efflux of potassium from the intracellular space can be in excess of 3.5 mEq per L, enough to induce malignant dysrhythmias and cardiac arrest. The list of susceptible patients includes those with congenital muscular dystrophies, upper or lower motor neuron defects, prolonged chemical denervation (e.g., muscle relaxants, magnesium, clostridial toxins), direct muscle trauma or inflammation, extensive burns, and disuse atrophy. In the event that succinylcholine is inadvertently given to an at-risk patient and an exaggerated hyperkalemic response is suspected, prompt treatment with calcium chloride (1 to 2 g), hyperventilation, sodium bicarbonate (1 mEq per kg), regular insulin, and dextrose should be initiated to prevent severe dysrhythmias and cardiac arrest.

Succinylcholine also causes increases in intraocular, intragastric, and intracranial pressures (ICP). The increase in intraocular pressure (IOP) caused by succinylcholine begins rapidly after drug administration. Peak pressures may rise as much as 5 to 15 mmHg before returning to baseline levels about 6 minutes after drug dosing. The etiology of this phenomenon is unclear, but detachment of the intraocular muscles from the globe fails to prevent the pressure rise, which is suggestive of an intraocular mechanism. It has been suggested that succinylcholine use should be avoided in the setting of open-eye injuries, although there is scant evidence that its administration has led to extrusion of intraocular contents or blindness. The increase in intragastric pressure (IGP) caused by succinylcholine is likely related to fasciculations of the abdominal skeletal musculature. A defasciculating dose of a nondepolarizing muscle relaxant given prior to succinylcholine administration can prevent any increase in IGP.

Succinylcholine can also cause a transient increase in ICP. The increase in ICP after succinylcholine administration correlates with muscle fasciculations, increased electroencephalogram (EEG) activity, and elevated cerebral blood flow. Prior administration of a nondepolarizing muscle relaxant can attenuate or even prevent this pressure increase. The use of succinylcholine in the setting of intracranial hypertension is probably best limited to emergency situations where the benefits of rapid airway control outweigh the risks of a transient increase in ICP.

Lastly, it should be remembered that succinylcholine is a potent trigger of malignant hyperthermia (MH). Its use should be restricted to settings where prompt recognition and treatment of MH are possible.

A.5. If succinylcholine were the only muscle relaxant used during the case and the patient did not exhibit a response to train-of-four (TOF) stimulation, what is the likely diagnosis? How would you confirm it?

The most likely diagnosis is atypical BChE. In the given patient, stimulation of the ulnar nerve with a PNS resulted in no response of the muscles of the hand, confirming the diagnosis of prolonged response to succinylcholine. Extreme prolongation in the duration of effect is usually a manifestation of an atypical BChE genotype. Following a 1.0 mg per kg dose of succinylcholine, patients homozygous for the most common

atypical genotypes will exhibit apnea for an hour or more; it may take as much as 3 hours for adequate respiratory efforts to return. However, the duration of apnea is highly dependent on the BChE variant in question and may be shorter or longer than the aforementioned figures.

Traditionally, identification of the human BChE variant has been performed by biochemical analysis. These tests, which have been used for decades, consist of the measurement of plasma cholinesterase activity with different substrates and of testing the degree of inhibition of this activity with a well-known inhibitor, such as dibucaine, fluoride, or R02-0683. These tests have identified multiple genes that can reside at the same allelic site, such as the atypical, silent, fluoride-resistant, J, K, H, and Newfoundland variants. However, biochemical testing often leads to equivocal results. More recently, molecular biologic techniques have been applied to identifying a patient's exact genotype.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:792–831.

A.6. What are acetylcholinesterase and serum cholinesterase? What is the clinical significance of heterozygosity for atypical pseudocholinesterase (PChE)?

Acetylcholinesterase is a relatively specific enzyme that hydrolyzes ACh faster than it does other choline esters. It is found in red blood cells, the central nervous system, and at the neuromuscular junction. It is responsible for hydrolyzing and inactivating the ACh produced during normal neuromuscular transmission. It does not hydrolyze succinylcholine.

Serum cholinesterase, also called *cholinesterase*, *PChE*, *BChE*, and *nonspecific cholinesterase*, hydrolyzes many choline esters, including succinylcholine. It is found in many human

tissues but not in the red blood cell. It is synthesized in the liver. Its physiologic function is unknown, but it may hydrolyze choline esters, such as propionylcholine and butyrylcholine, which may be formed by bacterial action in the gut and by the enzyme systems responsible for the formation of ACh.

A patient who is heterozygous for atypical PChE will exhibit a prolonged response to depolarizing NMB. Only after a strong, sustained response to indirect tetanic stimulation at the wrist can be demonstrated should sedation be terminated and an attempt made to wean the patient off controlled ventilation. Once the diagnosis of an atypical response to succinylcholine is ascertained, treatment is entirely supportive and symptomatic. Because the duration of residual block is hard to predict, the patient should remain intubated, artificially ventilated, and sedated.

Patients recovering from prolonged succinylcholine-induced block usually exhibit a “dual” or “phase II” block during recovery (fade on repetitive stimulation). Although neostigmine or edrophonium can under certain circumstances antagonize this block, this approach is risky when dealing with prolonged succinylcholine apnea. If significant plasma levels of succinylcholine are still present, the administration of an acetylcholinesterase inhibitor may be counterproductive.

The patient should be informed that she had a prolonged episode of muscular weakness and that the presumptive cause was an atypical reaction to succinylcholine. She should also be encouraged to have this diagnosis confirmed through laboratory testing. If an atypical genotype is confirmed, she should encourage her family members to be tested as well. Finally, the patient should be assured that this diagnosis has no adverse health consequences but that in the future when surgery is planned, her anesthesiologist needs to be informed of this diagnosis.

The dibucaine number (DN) is the percentage of BChE enzyme activity that is inhibited by dibucaine. The "normal" variant of BChE is 80% inhibited by dibucaine; therefore, a "normal" DN is 80. Together, the DN and the BChE enzyme activity results can help identify individuals at risk for prolonged paralysis following the administration of succinylcholine. Decreased BChE enzyme activity in conjunction with a DN less than 30 suggests high risk for prolonged paralysis. Normal to decreased BChE enzyme activity in conjunction with a DN 30 to 79 suggests variable risk. The relation between the DN and the duration of succinylcholine NMB is shown in **Table 55.1**.

TABLE 55.1 Relation between Dibucaine Number and Duration of Succinylcholine Neuromuscular Blockade

Type of Pseudocholinesterase	Genotype	Frequency	Dibucaine Number[a]	Response to Succinylcholine or Mivacurium
Homozygous typical	EuEu	Normal	70–80	Normal
Heterozygous	EuEa	1/480	50–60	Slightly prolonged
Homozygous atypical	EaEa	1/3,200	20–30	Markedly prolonged

[a]The dibucaine number indicates the percentage of enzyme inhibited.

A.7. What is the incidence of atypical cholinesterase activity?

The incidence of atypical cholinesterase activity varies with the population studied, but it is approximately 1 of 2,800 in the general population of the United States with a 1:1 male/female ratio.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:792–831.

A.8. What are some factors that can lower PChE levels?

Reduced PChE activity may be associated with the following:

- Abnormal genotype
- Normal physiologic variation (e.g., pregnancy). However, until BChE activity is reduced to <30% of normal, only modest increases in the duration of succinylcholine are to be expected.
- Liver disease
- Malnutrition
- End-stage renal disease
- Burns
- Plasmapheresis
- Noncompetitive cholinesterase inhibitors (e.g., pesticides, certain nerve gases)
- Other drugs including: neostigmine, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, tetrahydroaminacrine, metoclopramide, and hexafluorenium

B. Intraoperative Management

B.1. How is the choice among muscle relaxants made?

A muscle relaxant can be chosen based on onset characteristics, duration of action, and method of metabolism (**Table 55.2**). Muscle relaxants can be characterized as short, intermediate, and long duration. Metabolism may or may not be dependent on liver and kidney function (e.g., patients with hepatic dysfunction may have PChE deficiency). When surgical relaxation is not necessary, then NMB may be given solely to provide optimal intubating conditions by paralyzing the larynx, pharynx, and muscles of the jaw. Succinylcholine is useful for its rapid onset and recovery times, especially when performing a rapid sequence induction or facilitating motor nerve monitoring during the procedure.

If a rapid sequence induction is indicated, either succinylcholine or rocuronium may be used for NMB. Succinylcholine has a more rapid onset and is usually the preferred agent if there are no contraindications to its use (e.g., immobility, history of MH, hyperkalemia). In patients with hepatic or renal dysfunction, one can consider using cisatracurium. This nondepolarizing NMB agent undergoes Hofmann elimination and therefore is not affected by renal or hepatic dysfunction.

TABLE 55.2 Characteristics of Commonly Used Muscle Relaxants

					Elimi
ED95 under N_2O/O_2	Dose for Intubation	Clinical Duration	Metabolism	Kidne	

Drug	(mg/kg)	(mg/kg)	Time (sec)	(min)	(%)	(%)
Ultrashort acting						
Succinylcholine	0.5	1.0	60	5–10	Plasma cholinesterase (98–99)	<2
Short acting						
Mivacurium	0.08	0.2–0.25	120	12–15	Plasma cholinesterase (95–99)	<5
Intermediate acting						
Vecuronium	0.05	0.1–0.2	120	45–60	Liver (30–40)	40–50
Rocuronium	0.3	0.6–1.0	90	45–55	None	<10
Cisatracurium	0.05	0.15–0.2	120	45–60	Hofmann elimination (77)	16
Long acting						
α-Tubocurarine	0.5	0.5–0.6	150	100–120	None	80
Pancuronium	0.07	0.08–0.12	150	100–120	Liver (10–20)	85
Pipecuronium	0.05	0.08–0.10	180	100–120	10	>90
Doxacurium	0.025	0.05–0.08	240	120–150	None	>90

B.2. What factors can alter sensitivity to nondepolarizing neuromuscular blockers?

In any group of healthy patients, there exists a wide variability in the sensitivity to the effects of neuromuscular blocking agents (NMBAs). The potency of these drugs is expressed as the agent's ED50 or ED95 (i.e., the dose that will produce 50% or 95% depression of a single twitch [T1] in an average individual). The coefficient of variation (the standard deviation as a percentage of the mean value) for the ED95 of most agents approximates 20% to 25%. Thus, if the ED95 for drug X is 1.0 mg per kg, in 5% of normal individuals, the ED95 may be <0.60 mg per kg. Because of the shape of the dose-response curve of nondepolarizing relaxants, this modest difference in drug

requirement may have large consequences as to the depth of block. In these individuals, a plasma level that produces only 50% block of T1 in the average subject may produce >90% instead.

Similarly, the duration of effect of administered relaxants is quite variable. For example: Following a 1.2 mg per kg dose, the clinical duration of rocuronium (time to 25% T1 recovery) in a sample size of only 12 averaged 67 minutes; however, the range in responses went from 39 to 118 minutes. Following a dose two times the ED95 of a blocker of intermediate duration (e.g., vecuronium), 30% of individuals will still need pharmacologic antagonism 2 hours later.

In the aged or in patients with renal or hepatic disease, this variability is even more pronounced. This is especially true of aminosteroid blockers, such as vecuronium or rocuronium, when compared to atracurium or cisatracurium.

Arain SR, Kern S, Ficke DJ, et al. Variability of duration of action of neuromuscular-blocking drugs in elderly patients. *Acta Anaesthesiol Scand*. 2005;49:312–315.

Kopman AF, Kahn NA, Neuman GG. Precurarization and priming: a theoretical analysis of safety and timing. *Anesth Analg*. 2001:93:1253–1256.

B.3. What are the characteristics of nondepolarizing block?

The distinguishing feature of nondepolarizing block is fade on repetitive stimulation. For example, consider a situation in which the amplitude of twitch height (T1) is reduced by 50% with a nondepolarizing blocker when stimuli are delivered at 0.10 Hz (1 every 10 seconds). If the rate of stimulation is

increased to 1 Hz, the height of T1 may fall to <20% of control, and at 2 Hz to about 10% of control. This fade is most easily appreciated subjectively when tetanic stimuli (rates ≥30 Hz) are delivered.

Lee C, Katz RL. Fade of neurally evoked compound electromyogram during neuromuscular block by d-tubocurarine. *Anesth Analg*. 1977;56:271–275.

B.4. What is a TOF stimulus?

A "train-of-four" consists of four stimuli delivered at half-second intervals (2 Hz). The TOF ratio is the height of the fourth indirectly elicited response divided by the amplitude of the first response. This ratio in unparalyzed individuals normally approximates a value of 1.0 when measured by mechanomyography (MMG), electromyography (EMG), or kinemyography but may exceed a value of 1.10 when measured by acceleromyography (AMG) (see section B.11). As the depth of block increases, this ratio becomes smaller and eventually the fourth, then the third, and so on responses "drop out." If only two responses to a TOF stimulus are present, we speak of a TOF count of 2.

Ali HH, Utting JE, Gray C. Stimulus frequency in the detection of neuromuscular block in humans. *Br J Anaesth*. 1970;42:967–978.

B.5. Why is the TOF ratio of clinical importance?

The TOF fade is a far more sensitive index of residual block than single twitch depression. In addition, the TOF ratio is useful because each TOF sequence serves as its own control. It is not necessary to know the amplitude of the evoked response prior to administration of NMB or to worry about baseline drift over time. Traditionally, the TOF ratio is measured at the hand by noting the response of thumb adduction to stimulation of the ulnar nerve. While clinicians are much more interested in the neuromuscular function of the diaphragm, masseter, and

laryngeal adductors, correlation with adductor pollicis muscle function has served as a useful clinical surrogate.

Ali HH, Utting JE, Gray TC. Quantitative assessment of residual antidepolarizing block. I. *Br J Anaesth*. 1971;43:473–477.

Kopman AF. Surrogate endpoints and neuromuscular recovery. *Anesthesiology*. 1997;87:1029–1031.

B.6. How do we define adequate recovery of neuromuscular function?

Once the TOF ratio at the adductor pollicis has recovered to a value of 0.70, tests of mechanical respiratory reserve, such as vital capacity and peak expiratory flow rate, have usually recovered to within 90% of control. Clinically, this means that a patient may exhibit spontaneous respiration but may require pressure support or have upper airway obstruction when extubated.

Studies done in the 1970s suggested that a TOF ratio of 0.70 was synonymous with adequate neuromuscular recovery, and this was the accepted standard for the next two decades. However, by the late 1990s, this assumption was questioned. Work in awake volunteers demonstrated that at a TOF ratio of 0.70, grip strength was decreased by more than 40%. At a TOF ratio of 0.70, the vast majority of subjects had difficulty apposing their incisor teeth and could not sip water from a straw because they could not make a tight seal around the straw with their lips. All individuals had double vision at TOF ratio <0.90. It was clear that these health volunteers were not “street ready” until their TOF ratios reached or exceeded a value of 0.90. In addition, other volunteer studies revealed even more alarming data. At a TOF ratio of 0.70, there is a decreased ventilatory response to hypoxia (via a mechanism at the carotid body), and the swallowing mechanism is disorganized. Partial paralysis (a TOF of 0.70) causes pharyngeal dysfunction, and there is an

increased risk for aspiration with mechanical adductor pollicis TOF ratios <0.90. Pharyngeal function is not normalized until an adductor pollicis TOF ratio of >0.90 is reached. Thus, the current standard for adequate neuromuscular recovery is a TOF of 0.90 or better.

Heier T, Caldwell JE, Feiner JR, et al. Relationship between normalized adductor pollicis train-of-four ratio and manifestations of residual neuromuscular block: a study using acceleromyography during near steady-state concentrations of mivacurium. *Anesthesiology*. 2010;113:825–832.

Kopman AF, Yee PS, Neuman GG. Relationship of the train-of-four fade ratio to clinical signs and symptoms of residual paralysis in awake volunteers. *Anesthesiology*. 1997;86:765–771.

B.7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?

The first commercially available PNS did not appear until the mid-1960s, and units capable of delivering TOF stimuli did not arrive for another decade. Even today, devices that can quantify or measure the TOF ratio in real time are not widely distributed. Thus, clinicians have been reluctant to abandon clinical tests of neuromuscular recovery first suggested half a century ago, including tidal volume, negative inspiratory force, grip strength, the 5-second head lift, the ability to protrude the tongue, and so on. Unfortunately, most of these tests share one fundamental weakness. They require an awake and cooperative patient. Ideally, we would like to know the state of neuromuscular recovery prior to awakening the patient and certainly prior to tracheal extubation.

The most widely cited test, the 5-second head lift, is clearly not a sensitive test of residual block. At a TOF ratio of 0.50, the majority of patients may still pass this test. Other widely mentioned tests are no better and may actually be very

misleading. Traditional "bedside" tests of residual muscle weakness lack sensitivity and must be considered unreliable.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1354–1372.

Heier T, Caldwell JE, Feiner JR, et al. Relationship between normalized adductor pollicis train-of-four ratio and manifestations of residual neuromuscular block: a study using acceleromyography during near steady-state concentrations of mivacurium. *Anesthesiology*. 2010;113:825–832.

B.8. How accurate are subjective estimates of the TOF ratio, and what purpose do peripheral nerve stimulator (PNS) monitors serve?

Visual or tactile estimations of the TOF ratio are notoriously inaccurate. Once the TOF ratio exceeds a value of 0.40 to 0.50, a majority of experienced anesthesiologists are unable to detect the presence of any fade at all. Thus, failure to detect fade may indicate a true value anywhere from 0.50 to 1.0. Accurate assessment of the TOF ratio requires an objective or quantitative monitor.

Because subjective estimates of the TOF ratio are so unreliable, one may ask does intraoperative TOF stimulation serve any purpose. The answer is a resounding yes. The only satisfactory method of determining the degree of neuromuscular block is to stimulate a motor nerve with an electric current and observe the contraction of the muscles innervated by that nerve. The TOFC (e.g., the number of evoked responses at the thumb that can be detected) gives a useful estimate of the depth of neuromuscular block. A rough rule of thumb follows: A TOFC of 1 = 5% recovery, TOFC of 2 = 15% recovery, TOFC of 3 = 25% recovery, and TOFC of 4 (with fade) = ≥35% recovery. This information allows the clinician to determine whether the patient can be given reversal and the appropriate dose.

Kopman AF. Tactile evaluation of train-of-four count as an indicator of

reliability of antagonism from vecuronium- or atracurium-induced neuromuscular blockade. *Anesthesiology*. 1991;75:588–593.

Viby-Mogensen J, Jensen NH, Engbaek J, et al. Tactile and visual evaluation of the response to train-of-four nerve stimulation. *Anesthesiology*. 1985;63:440–443.

B.9. What is double burst stimulation (DBS)?

Because of the limitations in subjective interpretation of TOF fade, other patterns of stimulation have been investigated. A somewhat more sensitive test is the response to DBS; however, this test should not replace more quantitative measures of NMB recovery. This sequence consists of a very brief tetanic pulse (3 stimuli at 50 Hz), a 0.75-second pause, and another brief tetanic pulse. The observer feels two strong twitches. Most observers lose the ability to detect DBS fade at a TOF ratio of about 0.60.

Engbaek J, Ostergaard D, Viby-Mogensen J. Double burst stimulation (DBS): a new pattern of nerve stimulation to identify residual neuromuscular block. *Br J Anaesth*. 1989;62:274–278.

B.10. What is the posttetanic count (PTC)?

As the level of NMB is progressively increased, the TOFC eventually falls to zero. Because posttetanic potentiation is a prominent feature of nondepolarizing block, it is still possible to get additional information about the depth of block once the TOF response disappears. The following sequence is employed: a 5-second 50-Hz tetanus, a 3-second pause, and then 20 single-twitch stimuli at 1 Hz. The number of responses elicited is referred to as the PTC. Generally, when the count approximates a value of 10, the first response to TOF stimulation appears.

Viby-Mogensen J, Howardy-Hansen P, Chraemmer-Jørgensen B, et al. Posttetanic count (PTC): a new method of evaluating an intense nondepolarizing block. *Anesthesiology*. 1981;55:458–461.

B.11. How can the TOF ratio be measured quantitatively?

Prior to the current decade, the vast bulk of clinical research on

neuromuscular function was done by measuring either evoked mechanical force (MMG) or summated electrical action potentials (EMG) at the adductor pollicis. Although these techniques represent gold standards for reliability, they are unfortunately cumbersome to use in daily practice. In addition, at present, there are no commercially available free-standing MMG or EMG monitors designed for use in the operating room. However, using a different method of measurement, AMG, it is now possible to obtain a real-time display of the TOF ratio using a small handheld device, which is relatively easy to set up and has a user-friendly interface. The rationale for AMG is based on Newton's second law of motion, which states that force is equal to mass times acceleration. Presumably, the mass of the thumb remains constant so that acceleration is directly proportional to force. For measurement of acceleration, a piezoelectric ceramic wafer is fixed to the thumb. When an evoked mechanical response of the thumb is elicited, an electrical signal proportional to the acceleration is generated in the ceramic transducer. This signal can then be digitized, processed, and electronically displayed in real time. Thus, it is now finally possible for the clinician to accurately and easily determine the extent of neuromuscular block (the TOF ratio) in real time. An excellent review of the pros, cons, and limitations of AMG may be found in the following references.

B.12. What are the limitations of acetylcholinesterase antagonists?

Nondepolarizing NMBAs are competitive in nature. Molecules of an NMBA compete with molecules of Ach for access to nicotinic binding sites or receptors at the myoneural junction. The NMBA-receptor or Ach-receptor binding is evanescent in duration (millisecond). Thus, the relative concentration of NMBA versus Ach determines which molecule is most likely to succeed in the contest for receptor access. Anticholinesterases such as neostigmine affect antagonism by preventing Ach degradation and thus increasing the concentration of Ach in the synaptic cleft. However, there is a ceiling to this effect. Once the cholinesterase enzyme is completely inhibited, the addition of additional neostigmine or edrophonium will have no further effect. In contrast, there is no limit to the concentration of NMBA that may exist at the receptor if excessive doses of relaxant are administered. In practical terms, the maximum depth of block that can be rapidly antagonized by anticholinesterases approximately corresponds to the reappearance of the fourth response to TOF stimulation. To achieve rapid (within 10 minutes) reversal to a TOF ratio of 0.7 in more than 87% of patients, three or four tactile responses should be present at the time of neostigmine administration. It is not possible within 30 minutes to achieve a TOF ratio of 0.9 in all patients, regardless of the number of tactile responses present at neostigmine administration.

Beemer GH, Goonetilleke PH, Bjorksten AR. The maximum depth of an atracurium neuromuscular block antagonized by edrophonium to effect adequate recovery. *Anesthesiology*. 1995;82:852–858.

Kirkegaard H, Heier T, Caldwell JE. Efficacy of tactile-guided reversal from

cisatracurium-induced neuromuscular block. *Anesthesiology*. 2002;96:45–50.

B.13. Is there anything wrong with administering neostigmine when the TOFC is less than 3?

As noted earlier, when the TOFC is only 1 or 2, anticholinesterases cannot be counted on to achieve satisfactory reversal in a timely manner. The peak effect of the antagonist is followed by a plateau phase that represents the balance between diminishing anticholinesterase activity and spontaneous recovery. The latter becomes the major determinant at profound levels of NMB. However, even at a TOFC of 1 to 2, it may be possible to achieve a TOF ratio >0.40 within 10 minutes. The problem for the clinician is that further recovery may be quite slow, and unless an objective monitor of neuromuscular function is being used, the clinician is likely to have the false impression that adequate recovery has been achieved as subjective detection of fade at TOF ratios >0.40 is highly unreliable.

Kopman AF, Kopman DJ, Ng J, et al. Antagonism of profound cisatracurium and rocuronium block: the role of objective assessment of neuromuscular function. *J Clin Anesth*. 2005;17:30–35.

B.14. Is reversal of blockade always necessary?

If a quantitative monitor of neuromuscular function is used, the answer to this question is simple. If the TOF ratio approximates a value of 0.90 or better, anticholinesterase administration is pointless and is best avoided. Neostigmine, edrophonium, atropine, etc., all have their own side effects and should not be administered unnecessarily. Similarly, if the TOFC is less than 4 or 4 with obvious fade, then anticholinesterase administration is indicated. However, objective monitors are still not widely available. What should be done when the TOFC is 4 with no detectable fade?

Many clinicians base the decision of whether to reverse or not on the time interval since the last dose of relaxant.

Unfortunately, this is often an unreliable way to proceed. Two hours after a single dose of an intermediate-duration blocker, 30% of individuals may have TOF ratios <0.90, and 10% will still not have returned to a value of 0.70. Therefore, in the absence of objective evidence that the TOF ratio is >0.85 to 0.90, an antagonist should be administered. However, when no fade to TOF stimulation can be subjectively detected, the dose of neostigmine can be safely reduced to only 0.02 mg per kg.

Caldwell JE. Reversal of residual neuromuscular block with neostigmine at one to four hours after a single intubating dose of vecuronium. *Anesth Analg*. 1995;80:1168–1174.

Fuchs-Buder T, Meistelman C, Alla F, et al. Antagonism of low degrees of atracurium-induced neuromuscular blockade: dose-effect relationships for neostigmine. *Anesthesiology*. 2010;112:34–40.

B.15. Is there any way to rapidly antagonize a profound nondepolarizing block?

A radically new approach to reversal presented itself with the introduction of sugammadex. This drug was recently approved by the U.S. Food and Drug Administration for use to reverse the effects of NMB induced by rocuronium bromide and vecuronium bromide. Sugammadex is a γ-cyclodextrin (**Fig. 55.1**).

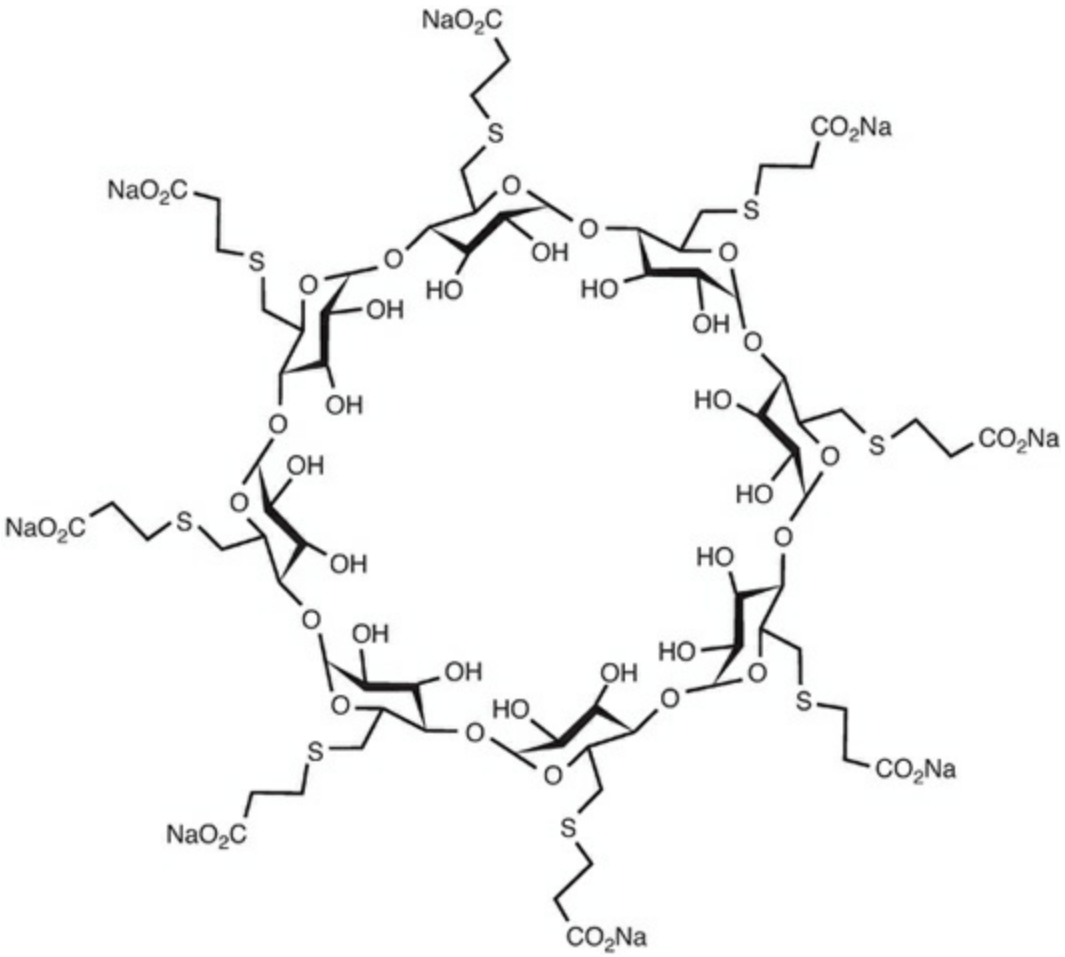

FIGURE 55.1. Structure of sugammadex, a synthetic γ-cyclodextrin. (*Reprinted with permission from Naguib MMB. Sugammadex: another milestone in clinical neuromuscular pharmacology*. Anesth Analg. *2007;104[3]:575–581*.)

It has a three-dimensional (3D) appearance similar to a doughnut with a hydrophobic interior and hydrophilic exterior. The hydrophobic core acts by strongly binding with monoquaternary aminosteroid blocking agents (e.g., rocuronium and vecuronium) thus "trapping" the drug (**Fig. 55.2**). The resulting sugammadex–rocuronium complex is water soluble and excreted renally. The complex formed creates a concentration gradient for molecules in the neuromuscular junction to move out and be further excreted. It forms a very "tight" bond utilizing hydrogen bonds, van der Waals forces, and hydrophobic interactions so molecule dissociation from the "trap" is not a concern. (Note: Sugammadex is not an effective

antagonist of benzylisoquinolinium-based relaxants such as cisatracurium.)

FIGURE 55.2. X-ray crystal structure of sugammadex (green) and rocuronium (blue) with encapsulation of a rocuronium molecule by a sugammadex molecule at 1:1 ratio. (*Reprinted with permission from Gijsenbergh F, Ramael S, Houwing N, et al. First human exposure of Org 25969, a novel agent to reverse the action of rocuronium bromide*. Anesthesiology. *2005;103:695–703*.)

Sugammadex can be used to rapidly reverse intubating doses of steroidal NMB in "cannot intubate" or "cannot ventilate" situations or when surgery concludes more quickly than anticipated. Sixteen milligrams per kilogram is given for rapid reversal of steroidal NMB when there are no posttetanic twitches. After sugammadex is given, it takes approximately 4 minutes to fully recover from a 1.2 mg per kg dose of rocuronium. This is faster than spontaneous succinylcholine recovery, which takes approximately 7 minutes. Four milligram per kilogram of sugammadex is given when there are 1 to 2 posttetanic twitches, and 2 mg per kg is given when there are 2+ twitches (i.e., the TOFC is 2 or more). Randomized controlled trials have demonstrated that TOFC recovery with similar density of blockade is faster with sugammadex than with both neostigmine–glycopyrrolate and edrophonium–atropine. Sugammadex dose is determined by actual body weight, even in the morbidly obese patient. Hepatic dysfunction does not alter drug kinetics as the molecular complex is cleared by the kidneys.

There is no need for anticholinergic drugs because sugammadex does not affect acetylcholinesterase. Because most

of the common side effects (e.g., tachycardia) when giving reversal come from anticholinergic effects, patients treated with sugammadex exhibit none of these undesirable signs and symptoms. Instead, most common side effects include postoperative nausea and vomiting (PONV), dry mouth, headache, hypotension and parosmia (abnormal smell). Rare but significant side effects of sugammadex include anaphylaxis and bradycardia. Sugammadex also sequesters (oral) hormonal contraceptives, and patients need to be advised to use alternative forms of contraception for 7 days after sugammadex administration.

C. Postoperative Management

C.1. What is the incidence of residual NMB in the PACU?

Numerous reports since 2000 make clear that even with agents of intermediate duration, undetected residual weakness in the

postoperative period is not a rare event. Large studies from Europe, where routine reversal with cholinesterase inhibitors were not administered, report that 20% to 40% of patients arrived in their PACU with TOF values <0.70.

As might be expected when a TOF ratio of 0.90 is set as the standard of adequate antagonism, the incidence of PORB approaches 40%. The incidence of PORB is highly variable from institution to institution and very dependent on individual practice patterns. Diligent intraoperative monitoring and routine antagonism of residual block can result in dramatic reductions in the incidence of PORB. In a study from France between 1995 and 2004, quantitative measurement and reversal of neuromuscular block in the operating room of one institution increased from 2% to 60% and from 6% to 42%, respectively. During the same time, the incidence of residual neuromuscular block, defined as a TOF ratio less than 0.9, decreased from 62% to 3%. Unfortunately, the lessons vividly demonstrated by these authors are far from universally understood or applied. A recent survey of North American and European clinical practices indicates that even in the year 2009, 10% of clinicians rarely or never monitor neuromuscular function with even the simplest of PNS, and the routine administration of antagonists is even less common.

C.2. Does undetected postoperative residual

neuromuscular block (PORB) have clinical consequences?

In North America, an excess of 20 million patients each year receive an anesthetic. The size of the subgroup that receives a nondepolarizing blocking agent is unknown but obviously still numbers in the millions. As indicated previously, the exact incidence of PORB probably varies greatly from institution to institution. Nonetheless, even if it is as low as 5% overall (highly optimistic), the number of individuals who arrive in the PACU with suboptimal neuromuscular recovery is substantial. In truth, the majority of patients who arrive in the PACU with TOF ratios <0.90 do not experience complications. However, not all individuals are so fortunate. Undetected PORB is clearly associated with potentially adverse respiratory events and increased morbidity. A recent prospective case-controlled study of critical respiratory events (CREs) (e.g., episodes of hypoxia, signs of airway obstruction, need for reintubation) in a university hospital's PACU is instructive. Sixty-one patients with CREs were identified. Their mean TOF ratio as measured by AMG was 0.62. The TOF value in 42 matched controls was 0.98. The same authors in a separate study were also able to demonstrate a lower frequency of residual NMB in the PACU (4.5%) (TOF ratio ≤0.9) in cases where intraoperative AMG was employed compared with the cases where conventional PNS were used (30%). During transport to the PACU, fewer AMG patients developed arterial oxygen saturation values, measured by pulse oximetry, of less than 90% (0%) or airway obstruction (0%) compared with (subjective monitoring) control patients (21.1% and 11.1%, respectively). The incidence, severity, and duration of hypoxemic events during the first 30 minutes of PACU admission were less in the AMG group (all $P < .0001$). These findings add credence to the hypothesis that incomplete neuromuscular recovery is an important contributing factor in

the development of adverse respiratory events in the PACU.

56 Burns

Shreyajit R. Kumar, Anup Pamnani

A 45-year-old man, who was smoking in bed, sustained 40% second- and third-degree burns over his face, neck, chest, and upper extremities. He had a history of hypertension, angina, and angioplasty of the right coronary artery 1 year ago. He has smoked 3 packs of cigarettes per day for 20 years, and he drinks alcohol daily. He is scheduled for tangential excision of eschar on the third postburn day. His blood pressure is 190/100 mmHg with a heart rate of 120 beats per minute, and he weighs 110 kg.

A. Medical Disease and Differential Diagnosis

1. How do you classify the burn injury?
2. How do you express the extent of the burn injury?
3. Should the "rule of nines" be used in children?
4. What functions does the skin perform?
5. What pathophysiologic changes accompany major thermal injury?
6. What is the prognosis for this patient? What major factors affect his prognosis?
7. What are the common causes of death in burn patients?
8. Does this patient have a smoke inhalation burn? How do you make the diagnosis?

9. What is carbon monoxide poisoning? How do you diagnose and treat carbon monoxide poisoning?
10. What resuscitative measure would you institute immediately in this patient with 40% burns?
11. What fluid formula would you use?
12. What cardiovascular changes typify the burn injury?
13. What changes occur in hepatic function? What are the anesthetic implications of such changes?
14. What are Curling ulcers? How can they be prevented?
15. What complications are associated with electrical burns?

B. Preoperative Evaluation and Preparation

1. What preoperative preparations would you order? What are particular concerns in this patient?
2. What are the various operative and management options available for severely burned patients?
3. What are the advantages and disadvantages of early tangential excision split-thickness skin grafting (TE/STSG)?
4. What is this patient's mean arterial blood pressure? How do you calculate it?
5. Are you concerned about this patient's blood pressure? What treatment would you institute?
6. This patient was ventilated with respirator settings of tidal volume, 800 mL; respiratory rate, 20 breaths per minute; fraction of inspired oxygen (F_{IO_2}), 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.24; P_{O_2}, 56 mmHg; P_{CO_2}, 60 mmHg; and oxygen saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high P_{CO_2} and low P_{O_2}?
7. How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues?

C. Intraoperative Management

1. What monitors would you use in the operating room?
2. What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations performed?
3. If the patient had not been intubated, how would you proceed with the anesthetic induction?
4. Why is awake intubation considered the safest?
5. What anesthetic agents would you use? Discuss inhalation versus intravenous agents.
6. Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?
7. How is temperature best maintained?
8. What derangements occur with hypothermia?
9. What muscle relaxant would you use?
10. Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?
11. What other adverse effects are associated with succinylcholine?
12. How are the doses of nondepolarizing muscle relaxants affected by burn injury?
13. How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?

D. Postoperative Management

1. How would you monitor this patient during transport?
2. What is meant by diffusion hypoxia? How do you prevent it?
3. Why do patients often shiver in the recovery room on emergence from anesthesia?
4. Discuss the causes of oliguria in the recovery room.

A. Medical Disease and Differential Diagnosis

A.1. How do you classify the burn injury?

Burns classification is based on both depth and degree of tissue injury. First-degree burns are superficial and confined to epidermal injury. Second-degree burns are partial thickness, involving the epidermis and dermis. Third-degree burns are full thickness and characterized by irreversible destruction of all dermal and epidermal elements. Fourth-degree burns involve injury to underlying tissue structures—muscle, fascia, tendon, and bone (**Table 56.1**).

TABLE 56.1 Classification of Burn Depth

Classification	Burn Depth	Outcome
Superficial		
First degree	Confined to epidermis	Heals spontaneously
Partial thickness		
Second degree		
Superficial dermal burn	Epidermis and upper dermis	Heals spontaneously
Deep dermal burn	Epidermis and deep dermis	Requires excision and grafting for rapid return of function
Full thickness		
Third degree	Destruction of epidermis and dermis	Wound excision and grafting required
		Some limitation of function and scar formation
Fourth degree	Muscle, fascia, bone	Complete excision required, limited function

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

A.2. How do you express the extent of the burn injury?

Extent of burn injury is expressed as a total body surface area (TBSA) percentage. Burn size is estimated by the "rule of nines" (**Fig. 56.1**). In adults, each upper extremity and the head and neck are 9% of TBSA. The lower extremities and anterior and posterior trunk are 18% each, and the perineum is approximately 1% of the TBSA. The burn proportions are additive, yielding a TBSA burn.

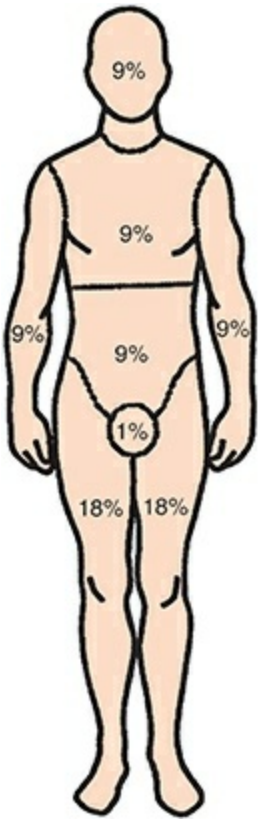

FIGURE 56.1. The rule of nines for determining the percentage of body surface area burned in adults. (*Adapted with permission from MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury*. Anesthesiology. *1998;89:749–770*.)

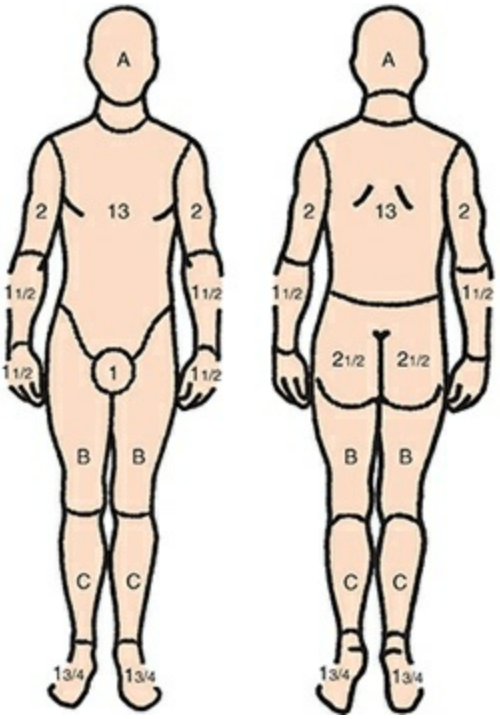
Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

A.3. Should the "rule of nines" be used in children?

The "rule of nines" will not estimate TBSA burns in children

because the head and neck comprise a relatively larger portion of the body surface area and a smaller surface area in the lower extremities. The Lund and Browder chart represents a precise method, accounting for the changing proportions of the TBSA from infancy to adulthood (**Fig. 56.2**).



Relative percentages of areas affected by growth

	AGE IN YEARS					
AREA	0	1	5	10	15	Adult
A: half of head	9½	8½	6½	5½	4½	3½
B: half of thigh	2¾	3¼	4	4¼	4½	4¾
C: half of leg	2½	2½	2¾	3	3¼	3½

FIGURE 56.2. Diagram and table for determining the percentage of body surface area burned in children. (*Adapted with permission from MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury.* Anesthesiology. *1998;89:749–770.*)

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

A.4. What functions does the skin perform?

The skin is the largest organ of the body with a surface area and is the primary immune barrier, protecting against microorganism invasion. The skin provides thermal regulation, fluid and electrolytes homeostasis, vitamin D metabolism, and sensation (touch, temperature, pain).

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:93–114.

A.5. What pathophysiologic changes accompany major thermal injury?

The pathophysiologic alterations that accompany major thermal injury are complex. Destruction of the skin—the largest organ of the body—has a profound systemic impact. Thermal regulation, fluid and electrolyte homeostasis, and protection against bacterial infection are all lost. Inflammatory mediators released from burn injury result in a leaky capillary syndrome; fluid and albumin are sequestered from the intravascular compartment into the burn wound, causing hemoconcentration and hypoalbuminemia. Increased secretion of antidiuretic hormone may cause oliguria or anuria.

The metabolic rate is markedly increased after the burn injury. Depending on the size of the burn, the increase in metabolic rate can be doubled or tripled with a proportionate increase in oxygen consumption and carbon dioxide (CO_2) production. This hypermetabolic state will continue for weeks or months until full tissue repair is complete.

Cardiac output (CO) is often decreased in patients with major burns. This decrease is partially due to a rapid reduction in circulating blood volume as well as an upregulation of circulating myocardial-depressant factor.

Changes in vascular integrity occur in other areas remote from the injury site. The entire vascular compartment becomes permeable to circulating macromolecules, manifesting as edema. Severe pulmonary edema can be life-threatening. Airway edema is the impetus for early intubation.

Pulmonary function is significantly altered. A reduction occurs in functional residual capacity, lung capacity, and chest wall compliance. Increases occur of the alveolar–arterial oxygen

gradient (P_{AO_2}–Pa_{O_2}) and minute ventilation (as high as 40 L per minute; normal, 6 L per minute).

Brunicardi FC, Andersen DK, Billiar TR, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:251–271.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders-Elsevier; 2018:103–115.

MacLennan N, Heimbach DM, Cullen BF. Anesthesia for major thermal injury. *Anesthesiology*. 1998;89:749–770.

A.6. What is the prognosis for this patient? What major factors affect his prognosis?

The prognosis for this patient is very poor. Statistical survival based on TBSA alone predicts a less than 50% chance of survival. Other factors that affect his prognosis are age, size and depth of burn, associated pulmonary injury, and preexisting medical disease. In this patient with a history of angioplasty for coronary artery disease, hypertension, heavy smoking, and obesity, the risk of myocardial infarction is greatly increased.

A.7. What are the common causes of death in burn patients?

The major early cause of death is asphyxia. The most common cause of long-term mortality is septic complications. Hypovolemic shock is no longer common in the United States due to enhanced early goal-directed resuscitation.

A.8. Does this patient have a smoke inhalation burn? How do you make the diagnosis?

This patient probably sustained a smoke inhalation burn. Smoke inhalation should be highly suspected in patients who were burned in an enclosed space, received burns of the face, were burned while under the influence of alcohol or drugs, or lost consciousness at the time of the accident.

A patient with smoke inhalation often exhibits no physical

signs or symptoms during the first 24 hours after the burn—the "lucid period." The early symptoms and signs of respiratory tract injury include burned nasal mucosa/lips/mouth, singed nasal hair, and/or soot in the sputum. The posterior pharynx may appear red and edematous. Radiographic findings are usually negative immediately after injury. Laboratory tests include blood gas analysis, carboxyhemoglobin concentration, xenon scans, and fiberoptic bronchoscopy.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:251–271.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:184–195.

A.9. What is carbon monoxide poisoning? How do you diagnose and treat carbon monoxide poisoning?

Carbon monoxide is the leading cause of hypoxia in survivors of burn injuries; it is liberated from the incomplete combustion of carbon-containing substrates (wood, coal, and gasoline). Carbon monoxide has a 250 times greater affinity for hemoglobin than oxygen, displacing oxygen from its hemoglobin-binding sites. CO-oximetry is necessary for diagnosis of carbon monoxide poisoning because the arterial blood gas Pa_{O_2} will be falsely normal.

Expeditious oxygen therapy will displace carbon monoxide from hemoglobin moieties. The standard half-life of carbon monoxide elimination is 4 to 6 hours at room air. This is reduced to 40 to 80 minutes with 100% oxygen and 15 to 30 minutes with hyperbaric oxygen therapy.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:251–271.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:174–184.

A.10. What resuscitative measure would you institute immediately in this patient with 40% burns?

Early and aggressive fluid resuscitation will combat the distributive, third-spacing hypovolemia. Liberal fluid administration will ensure end-organ perfusion and adequate urine output. If an upper airway burn is involved, endotracheal intubation is indicated to prevent edematous airway compromise.

A.11. What fluid formula would you use?

The Parkland formula will guide the initial resuscitation in hypovolemic shock after burn injury. It has been adopted as the standard of practice at most burn centers due to its simplicity, reduced cost, and equivalent outcome when compared to other calculations for fluid administration.

Other formulas differ widely in the colloid/crystalloid ratio and in the rate of fluid administration. Although much controversy still surrounds the use of "the solution" for resuscitation in burn shock, scientific investigation supports the need for both crystalloid and colloid solutions (**Table 56.2**). Current sentiment supports the Parkland calculation as a resuscitation "starting point." Emphasis should then be placed on factors used to guide resuscitation; urine output of 0.5 to 1.0 mL/kg/hr is the important parameter.

TABLE 56.2 Fluid Resuscitation for Adults with Major Burns

Crystalloid Regimens		
Parkland	Lactated Ringer's	4 mL/kg/% burn
Modified Brooke	Lactated Ringer's	2 mL/kg/% burn
Colloid Regimens		
Evans	Normal saline	1 mL/kg/% burn
	Colloid	1 mL/kg/% burn
	5% Dextrose	2,000 mL/24 hr

Brooke	Lactated Ringer's	1.5 mL/kg/% burn
	Colloid	0.5 mL/kg/% burn
	5% Dextrose	2,000 mL/24 hr

Parkland Formula

First 24 hours

- *Electrolyte solution (lactated Ringer's)*—4 mL/kg/percentage of body area with second- and third-degree burn
- *Administration rate*—half the solution given in the first 8 hours, one-quarter in the second 8 hours, and one-quarter in the third 8 hours
- *Urine output*—maintain at 0.5 to 1.0 mL/kg/hr

Second 24 hours

- *Glucose in water*—to replace evaporated water loss and maintain serum sodium concentration of 140 mEq per L
- *Colloid solutions (e.g., albumin)*—amount proportional to burn
  - *30% to 50% burn*: 0.3 mL/kg/percentage of burn
  - *50% to 70% burn*: 0.4 mL/kg/percentage of burn
  - *Larger than 70% burn*: 0.5 mL/kg/percentage of burn
- *Urine output*—maintain at 0.5 to 1.0 mL/kg/hr

Blumetti J, Hunt JL, Arnoldo BD, et al. The Parkland formula under fire: is the criticism justified? *J Burn Care Res*. 2008;29(1):180–186.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:227–326.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:77–87.

A.12. What cardiovascular changes typify the burn injury?

Microvascular destruction of capillary membranes results in acute fluid sequestration from intravascular compartment to interstitial spaces. Decreased plasma volume leads to depressed CO and hypotension. Catecholamine release triggers vasoconstriction, which may further compromise tissue

perfusion. Ventricular dysfunction is attributed to myocardial-depressant factor present in lymphatic fluid.

Herndon DN, ed. *Total Burn Care*. 4th ed. Philadelphia, PA: Saunders Elsevier; 2012:361–369.

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

A.13. What changes occur in hepatic function? What are the anesthetic implications of such changes?

Decreased circulating volume during the initial burn phase may result in shock liver and restrict hepatic detoxification capacity. Albumin levels will decrease, which may increase the free fraction levels of benzodiazepines and phenytoin. In contrast, a rise in the acute-phase reactant α_1-acid-glycoprotein, increases the binding of pH basic drugs, such as lidocaine, propranolol, and muscle relaxants.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:259–268.

Jeevendra Martin JA, Fukushima Y, Chon JY, et al. Muscle relaxants in burns, trauma, and critical illness. *Int Anesthesiol Clin*. 2006;44:123–143.

A.14. What are Curling ulcers? How can they be prevented?

A Curling ulcer is a gastric or duodenal stress ulcer resulting from a systemic thermal injury. Without treatment, the incidence is as high as 80%. Atrophy of the small bowel mucosa occurs within 12 hours of injury and is proportional to burn extent. Additional decreases in intestinal blood flow exacerbate the gastric injury. Curling ulcers can be prevented prophylactically with antacids, H_2-antagonists, and early enteral feeding.

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed.

Philadelphia, PA: Elsevier Saunders; 2017:505–532.

A.15. What complications are associated with electrical burns?

Electrical burns result in small skin area necrosis, with large amounts of damage to deep tissue structures—muscles, tendons, blood vessels, and nerves. Thus, the fluid losses are greater than predicted from Parkland calculation. The total injury is determined by the duration of current flow, the resistance of the tissue, and the area of contact. Muscle necrosis may cause myoglobinuria and acute tubular necrosis. Thrombotic phenomena may manifest late. Cardiac conduction abnormalities, ectopy, and congestive heart failure may all be secondary to electrical injury.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:396–403.

B. Preoperative Evaluation and Preparation

B.1. What preoperative preparations would you order? What are particular concerns in this patient?

A thorough medical history and physical examination should be conducted, with a focus on this patient's salient risk factors. In this patient, hypertension, ischemic heart disease, angioplasty of left main coronary artery, and the history of heavy smoking and heavy alcohol consumption are of particular concern. The following laboratory tests should be ordered—complete blood count, basic metabolic profile, venous lactate, coagulation profile, liver function tests, electrocardiogram (ECG), urinalysis, chest radiograph, and arterial blood gas. With respect to this patient's left main coronary artery disease, cardiac enzymes would be beneficial. Any concern about a tenuous cardiac status should prompt involvement by a cardiologist.

Urine output, central venous pressure (CVP), pulmonary artery occlusion pressure (PAOP), CO, and cardiac index will all be beneficial in guiding fluid resuscitation.

B.2. What are the various operative and management options available for severely burned patients?

Early tangential excision of burn tissue and early wound closure, primarily by skin grafting, has significantly improved mortality among the severely burned population. Eschar, or burned skin, is an active medium for bacterial propagation, and topical antibiotic creams—silver sulfadiazine—should be applied for infection control.

Early removal of injured tissue prevents wound infection and decreases systemic inflammatory response. A widely adopted strategy involves a 48-hour period of initial resuscitation to achieve hemodynamic stability, followed by TE/STSG. The extent of escharotomy is limited to 20% of TBSA and repeated every 2 days until excision is complete.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:251–271.

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

B.3. What are the advantages and disadvantages of early tangential excision split-thickness skin grafting (TE/STSG)?

The expeditious escharotomy—within 2 days—will remove the bacterial load, reduce the risk of bacteremia and sepsis, and shorten the recovery phase and overall hospital length of stay. Very early excision—within 24 hours—has the disadvantage of a major operative stress during the resuscitative phase of the injury. The patient is not optimized, and there is an increase in anesthetic risk.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:386–396.

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

B.4. What is this patient's mean arterial blood pressure? How do you calculate it?

This patient's mean arterial pressure (MAP) can be calculated from his blood pressure of 190/100 mmHg; his MAP is 130 mmHg. The equation is MAP = two-thirds of diastolic pressure + one-third of the systolic pressure. An equivalent calculation is MAP = diastolic pressure + one-third of the pulse pressure; the pulse pressure is the difference between systolic and diastolic pressure.

B.5. Are you concerned about this patient's blood pressure? What treatment would you institute?

We are concerned with this patient's extreme blood pressure, given his history of angina and coronary disease requiring left main coronary angioplasty. We would like to maintain his blood pressure in the normal range.

β-Blockers (labetalol, metoprolol), calcium channel blockers (nicardipine), angiotensin-converting enzyme inhibitors (enalapril), and hydralazine are all intravenous vasodilators that may be used.

This tachycardic patient—heart rate 120 beats per minute—would benefit from β-blockade with labetalol or Lopressor. Reduction of afterload and tachycardia will decrease overall myocardial oxygen demand and reduce his risk of infarction.

Adequacy of volume resuscitation should be assessed. Measuring CVP, PAOP, CO, cardiac index, and systemic vascular resistance will aide in treatment initiation.

B.6. This patient was ventilated with respirator settings of

tidal volume, 800 mL; respiratory rate, 20 breaths per minute; fraction of inspired oxygen (FIO_2), 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.24; PO_2, 56 mmHg; PCO_2, 60 mmHg; and oxygen saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high PCO_2 and low PO_2?

Arterial blood gas analysis demonstrates an uncompensated respiratory acidosis with a substantial hypoxic Alveolar–arterial (A–a) gradient. This patient was hypoventilated given the high PCO_2 of 60 mmHg (normal PCO_2 is 35 to 45 mmHg).

The etiology of this patient's hypercapnia may be a hypermetabolic state with marked increase in CO_2 production.

The most common cause of hypoxemia with an increased A–a gradient is a ventilation/perfusion mismatch. Atelectasis, pneumonia, pulmonary edema, or malposition of endotracheal tube with single-lung ventilation will increase dead space or shunt fractionation, resulting in ventilation/perfusion mismatch.

B.7. How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues?

The oxygen content of arterial blood (CaO_2) is the sum of two components, the oxygen dissolved in plasma and the oxygen bound to hemoglobin (Hgb). It is expressed as:

$$CaO_2 \text{ (mL per dL)} = 1.31 \times \text{Hgb (g per dL)} \times SaO_2 (\%) + 0.003 \times PaO_2$$

Normal arterial oxygen content: CaO_2 = 20.73 mL per 100 mL

Oxygen delivery (DO_2) is directly proportional to the CO and

arterial oxygen content:

$$DO_2 = CO \times CaO_2 = CO \times ([1.31 \times Hgb\ (g\ per\ dL) \times SaO_2\ (\%)] + 0.003 \times PaO_2)$$

Thus, the three main factors that govern the oxygen delivery to tissues are CO, hemoglobin, and arterial oxygen saturation.

Criner GJ, Barnette RE, D'Alonzo GE, eds. *Critical Care Study Guide: Text and Review*. 2nd ed. New York: Springer; 2010:493–494.

C. Intraoperative Management

C.1. What monitors would you use in the operating room?

All standard monitors, noninvasive blood pressure, ECG (leads II and V_5), pulse oximetry, capnography, and temperature, should be used in this patient. A Foley catheter is essential for assessing urine output and volume status. An indwelling arterial line may be helpful if the standard blood pressure cuff interferes with the surgical field. A pulmonary artery catheter with CVP monitoring will be beneficial in this severely burned patient with ischemic heart disease.

C.2. What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations performed?

The arterial line displays beat-to-beat continuous blood pressure measurements. This is most useful in fluctuating hypotensive or hypertensive situations. During dysrhythmias such as atrial fibrillation or ventricular tachycardia, variations in ventricular response or blood pressure will be recognized instantly. The morphology of the waveform can also provide information about arterial resistance (i.e., a narrow waveform is suggestive of both a reduced stroke volume and an increased systemic vascular resistance), stroke volume (area under the curve), and preload

(pulse pressure variation, particularly in response to mechanical positive pressure ventilation). In addition, it serves as ready vascular access for blood sampling (e.g., arterial blood gas analyses, electrolytes, hematocrit, and blood sugar levels).

A pulmonary artery catheter allows the measurement of PAOP, a surrogate of left atrial pressures. Left atrial pressure reflects left ventricular end-diastolic pressure, which is helpful in assessing the preload status of the left ventricle. CVP, although useful as a rough estimate of preload, does not correlate with left ventricular end-diastolic pressure when either isolated right-sided or left-sided cardiac dysfunction occurs. The multilumen pulmonary artery catheters are capable of measuring CVP and CO through the thermodilution method. It also permits sampling of mixed venous blood. These measurements permit calculation of many hemodynamic variables.

$$\text{Cardiac index (CI)} = \frac{\text{CO}}{\text{Body surface area}} \quad \text{(normal 2.8 to 4.2 L/min/m}^2\text{)}$$

$$\text{Stroke volume (SV)} = \frac{\text{CO}}{\text{Heart rate}} \quad \text{(normal 60 to 80 mL per beat)}$$

$$\text{Stroke index (SI)} = \frac{\text{CI}}{\text{Heart rate}} \quad \text{(normal 40 to 65 mL/beat/m}^2\text{)}$$

$$\text{Systematic vascular resistance (SVR)} = \frac{\text{Mean BP} - \text{CVP}}{\text{CO}} \times 80 \quad \text{(normal 900 to 1,400 dynes/sec/cm}^5\text{)}$$

$$\text{Pulmonary vascular resistance (PVR)} = \frac{\text{Mean PAP} - \text{PCWP}}{\text{CO}} \times 80 \quad \text{(normal 150 to 250 dynes/sec/cm}^5\text{)}$$

Mixed venous blood samples are needed for shunt calculations:

$$\frac{Q_s}{Q_t} = \frac{(Cc\text{O}_2 - Ca\text{O}_2)}{(Cc\text{O}_2 - C\bar{v}\text{O}_2)}$$

$Cc\text{O}_2$ = pulmonary capillary oxygen content
$Ca\text{O}_2$ = artery oxygen content
$C\bar{v}\text{O}_2$ = mixed venous oxygen content

A low mixed venous oxygen level (<30 mmHg) is suggestive

of inadequate tissue perfusion.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

C.3. If the patient had not been intubated, how would you proceed with the anesthetic induction?

This patient has a facial burn, which portends a difficult intubation. Burns on the face may cause severe airway and facial edema; careful assessment of the mouth opening, pharynx, and larynx is warranted. The safest way to secure the airway is to perform an awake intubation with topical anesthesia and mild sedation; it can be achieved by either direct or fiberoptic-guided intubation. If prolonged postoperative intubation is anticipated, the nasotracheal route is more easily secured, provides optimal patient comfort, and permits better oral hygienic care. Phenylephrine drops will achieve nasal mucosa vasoconstriction. Alternatively, a tracheostomy should be considered early in those patients with acute lung injury who will require prolonged mechanical ventilation.

C.4. Why is awake intubation considered the safest?

Awake intubation is the safest modality to secure an airway because when the patient is breathing spontaneously, the patient retains airway protective reflexes, is at lower risk for upper airway obstruction, and is less likely to have oxygen desaturation. This precludes the need for mask ventilation and avoids the risk of stomach distention.

When the patient is breathing spontaneously and maintains adequate oxygenation, the anesthesiologist has more time to do laryngoscopy. Identifying the passage of air from the glottis may be helpful in blind intubation.

C.5. What anesthetic agents would you use? Discuss inhalation versus intravenous agents.

For the severely burned patient, once the airway is secured, a high-dose narcotic muscle relaxant technique would be preferred because this technique confers intraoperative hemodynamic stability and optimal postoperative analgesia.

The narcotics, such as morphine, meperidine (Demerol), fentanyl, or sufentanil, do not interfere with myocardial contractility, whereas potent inhalation agents will depress the myocardium. If inhalation agents are chosen, the concentration should be carefully titrated to prevent hemodynamic embarrassment.

C.6. Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?

Massive burn injury with loss of skin integrity will lead to considerable evaporative fluid losses and the risk of profound intraoperative hypothermia. This tendency is exacerbated by the vasodilatory effects of general anesthesia on central thermoregulatory centers and by the cool, arid operating room milieu. The infusion of large volume intravenous fluids at room temperature also contributes to the development of hypothermia.

Normothermia for a burned patient is approximately 38.5°C. The stress of thermal injury results in a resetting of the hypothalamic thermostat.

Brunicardi FC, Anderson DK, eds. *Schwartz's Principles of Surgery*. 11th ed. New York: McGraw-Hill; 2019:251–271.

Herndon DN, ed. *Total Burn Care*. 5th ed. Philadelphia, PA: Saunders Elsevier; 2018:131–157.

Townsend CM Jr, Beauchamp D, Evers MB, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:505–532.

C.7. How is temperature best maintained?

Hypothermia is a chief concern from loss of the insulator effect

of the skin organ. Heat losses occur through convection, conduction, evaporation, and radiation. Methods to maintain normothermia should involve active warming and prevention of heat loss. Crystalloid and blood transfusions must be administered through the blood- and/or fluid-warming device. A prewarmed forced air mattress, such as a Bair Hugger, is placed under a single-layer sterile sheet on the operating table. Warming the operating room to temperatures between 24°C (75.2°F) and 27°C (80.6°F) with a relative humidity higher than 50% is particularly effective. The nonsurgical areas of the patient's body must be covered. Heated, humidified airway circuits are most effective in minimizing the heat loss from ventilation with cold anesthetic gases.

C.8. What derangements occur with hypothermia?

Hypothermia causes many physiologic changes. Hypothermia decreases metabolism, heart rate, CO, and blood pressure. At temperatures less than 28°C (82.4°F), atrial pacing becomes irregular and ventricular ectopy increases. Ventricular fibrillation occurs between 25°C (77°F) and 30°C (86°F) in the human adult.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

C.9. What muscle relaxant would you use?

A nondepolarizing muscle relaxant should be used. Depolarizing relaxants, that is, succinylcholine, should be avoided. In general, the choice of muscle relaxant should be based on the duration of the operation and the presence of any coexisting diseases affecting drug elimination. Muscle relaxants without histamine release would be preferred, such as vecuronium and rocuronium.

C.10. Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?

Succinylcholine is contraindicated in burned patients because it may cause a significant transient increase in serum potassium levels as high as 13 mEq per L, resulting in ventricular fibrillation and cardiac arrest. This hyperkalemic response begins approximately 5 to 15 days after the burn and persists for 2 to 3 months or longer, irrespective of degree and size of burn injury.

The exact mechanism responsible for this response is not known. It is hypothesized that the abrupt release of potassium is from the hypersensitive muscle membranes. Extrajunctional acetylcholine receptors are located on the muscle membranes of burned patients. Stimulation of these receptors may mediate a potentially lethal efflux of potassium.

The exact time for this hypersensitivity is unclear. Most authors advocate against succinylcholine use from 24 to 48 hours after the burn injury until complete healing has occurred. A hyperkalemic response has been reported in a patient after 480 days. The recommended limit now is extended to approximately 2 years after the burned skin has healed.

Gronert GA. Succinylcholine hyperkalemia after burns. *Anesthesiology*. 1999;91(1):320–322.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

Schaner PJ, Brown RL, Kirksey TD, et al. Succinylcholine-induced hyperkalemia in burned patients. 1. *Anesth Analg*. 1969;48:764–770.

C.11. What other adverse effects are associated with succinylcholine?

The adverse effects of succinylcholine are many. Its side effects are as follows:

- Hyperkalemia, particularly following burns, spinal cord injuries, and generalized major trauma: a single case report of

a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis

- Increased intracranial and intraocular pressures: the practical importance of which is controversial
- Increased intragastric pressure: counterbalanced by the increase in lower esophageal pressure, which reduces or eliminates the increased risk of regurgitation
- Muscle pains: more likely to concern the patient with minor injuries who ambulates soon after surgery
- Prolonged paralysis in patients with atypical pseudocholinesterase
- Cardiac arrhythmias, particularly bradycardia after repeated doses
- Trigger for malignant hyperthermia

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

C.12. How are the doses of nondepolarizing muscle relaxants affected by burn injury?

In general, burn patients show great resistance to the nondepolarizing relaxants. Martyn et al. first reported that burn patients required a five times higher plasma concentration of D-tubocurarine to attain a given percentage of twitch depression compared with healthy subjects. The dose of pancuronium is increased by 2.5 times.

This increased requirement appears secondary to an upregulation of and altered affinity for junctional receptors. The burn patient also has increased plasma protein binding of nondepolarizing relaxants.

Jeevendra Martin JA, Fukushima Y, Chon JY, et al. Muscle relaxants in burns, trauma, and critical illness. *Int Anesthesiol Clin*. 2006;44:123–143.

C.13. How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?

See **Table 56.3**.

TABLE 56.3 The Metabolism, Elimination, and Histamine Release of Muscle Relaxants

	Elimination			
Relaxant	Kidney (%)	Liver (%)	Plasma Metabolism (%)	Histamine Release
Succinylcholine	<2	0	98	Slight
Atracurium	10–40	0	60–90	Slight
Cisatracurium	16	7	77	None
Vecuronium	40	60	0	None
Pancuronium	85	15	0	None
Rocuronium	25	70	0	None
D-Tubocurarine	80	20	0	Moderate

D. Postoperative Management

D.1. How would you monitor this patient during transport?

This patient was most likely intubated, paralyzed, apneic, and still under the influence of general anesthetic. Monitoring should be directed toward respiration, oxygenation, and hemodynamics. These can be achieved by utilizing a transport monitor capable of monitoring ECG, blood pressure, CVP, and pulse oximeter.

During transport, ventilation should be controlled with positive pressure ventilation via an Ambu bag with supplemental oxygen.

D.2. What is meant by diffusion hypoxia? How do you prevent it?

In 1954, Fink et al. first reported diffusion hypoxia during recovery from nitrous oxide–oxygen anesthesia. A mild degree of hypoxia may develop for more than 10 minutes after cessation of a nitrous oxide–oxygen anesthetic if the patient is breathing room air. The arterial oxygen saturation may fall 5% to 10% and often reaches values less than 90% (Pa_{O_2} <60 mmHg). This desaturation occurs upon rapid nitrous oxide elimination. Nitrous oxide is 35 times more soluble in blood than nitrogen. Alveolar oxygen is diluted by the high nitrous oxide concentration diffusing from blood. Diffusion hypoxia can be prevented by the administration of a high fractional inspired oxygen for several minutes before allowing the patient to breathe room air.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

D.3. Why do patients often shiver in the recovery room on emergence from anesthesia?

Postanesthetic shivering is commonly observed in the recovery room after emergence from inhalational general anesthetics. It is postulated that inhalation agents inhibit central hypothalamic thermoreceptors and that shivering is a thermoregulatory response to intraoperative heat loss. Shivering will produce energy to maintain normothermia. Secondarily, tremors may be

the result of anesthetic-induced disinhibition of descending spinal reflexes. Similar nonthermoregulatory tremors have been seen in women during labor after neuroaxial anesthesia.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2746–2773.

D.4. Discuss the causes of oliguria in the recovery room.

Oliguria is arbitrarily defined as the production of less than 400 mL of urine in 24 hours. It is the functional manifestation of *acute renal failure* (ARF). The syndrome of ARF may be classified into the following three groups:

- *Prerenal ARF (hypovolemic)*. A reduction of renal blood flow decreases both the filtration rate and the overall urinary flow. There is no structural damage to the kidney. Prerenal azotemia is reversible with volume expansion. However, if untreated, it can progress to the ischemic form of acute tubular necrosis.
- *Renal ARF (acute tubular necrosis)*. Ischemia or nephrotoxic substances result in structural damage to the renal tubules.
- *Postrenal ARF (obstruction of urinary outflow)*. Obstruction occurs distal to the kidney, at the level of the ureter, bladder, or urethra. Pus, tubular debris, blood clots, nephrolithiasis, tumor burden, prostatic hypertrophy, or a nonfunctioning Foley catheter can cause mechanical cessation of urinary flow.

Determining the underlying etiology of oliguria is essential because management strategies vary greatly. To identify the cause of oliguria, one must make a careful assessment of the urinary sediment. Presence of renal tubular cells, renal tubular cell casts, and pigmented granular casts is strong evidence supporting acute tubular necrosis. Normal urinary sediment is consistent with prerenal azotemia. Other data, such as CVP and PAOP, provide valuable information about the state of

hydration. Postrenal etiologies of ARF are supported by bladder ultrasonography (demonstrating an enlarged, distended bladder) or an elevated pressure on bladder manometry (supporting intraabdominal hypertension).

57 Trauma

Rohan K. Panchamia, Jaideep K. Malhotra, Ralph L. Slepian

A 31-year-old man sustained multiple stab wounds to the left upper quadrant of his abdomen and to his left hemithorax. Vital signs were as follows: blood pressure, 85/60 mmHg; heart rate, 130 beats per minute; respiratory rate, 32 breaths per minute; and temperature, 34.5°C (94.1°F). His hematocrit was 27%. He was emergently brought to the operating room for an exploratory laparotomy and possible thoracotomy.

A. Medical Disease and Differential Diagnosis

1. How is trauma classified?
2. What are the injuries associated with thoracic trauma?
3. What are the injuries associated with cardiac trauma?
4. What is the pathophysiology of acute pericardial tamponade?
5. What are the anesthetic implications for treating cardiac tamponade?
6. How is the initial assessment and management of the trauma patient performed?
7. What constitutes a primary survey, and what is its objective?
8. What constitutes a secondary survey, and what is its objective?
9. What is the definition of massive hemothorax? What are the signs and symptoms of a hemothorax?

10. What are the indications for a thoracotomy to treat a hemothorax?
11. How are pneumothoraces categorized?
12. What is an occult pneumothorax?
13. If the patient has a widened mediastinum on chest radiograph, what are your concerns?
14. What are the most commonly injured organs in blunt abdominal trauma?
15. What is a focused abdominal sonography for trauma (FAST) examination?
16. What is diagnostic peritoneal lavage (DPL)?
17. Why was DPL not performed for this patient?
18. Define shock.
19. What are the four types of shock?
20. List the signs and symptoms of shock.
21. What is the pathophysiology of hypovolemic shock?
22. How would you classify hemorrhage?
23. What is the initial treatment of hemorrhagic shock?
24. Would you choose crystalloid, colloid, or blood products to treat hemorrhagic shock?
25. Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?

B. Preoperative Evaluation and Preparation

1. What premedication would you order?
2. What preoperative testing would you order?

C. Intraoperative Management

1. How would you monitor this patient?
2. How would you induce anesthesia?
3. What technique could you use if single-lung ventilation was indicated?
4. What agents would you choose to maintain anesthesia?
5. What muscle relaxant would you choose?

6. What can be done to decrease the incidence of intraoperative awareness?
7. Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?
8. How would you make a diagnosis of tension pneumothorax?
9. What is the treatment of tension pneumothorax?
10. The patient's blood loss was continuing, and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?
11. What precautions should be taken if more than 2 units of low titer type O uncrossmatched whole blood are given?
12. What are the complications associated with any blood transfusion?
13. What is considered a massive transfusion (MT)? What is the Assessment of Blood Consumption (ABC) score?
14. What are the complications associated with an MT?
15. Can the shift of the oxygen–hemoglobin dissociation curve be quantified?
16. How is hypothermia defined?
17. What are the adverse effects of hypothermia?
18. What is the treatment of hypothermia?
19. What are the effects of blood transfusion on the immune system?
20. What are the guidelines for transfusion of blood products?
21. What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in an MT?
22. If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?
23. If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?
24. What are the concentrated factors and hemostatic agents available for bleeding patients?

25. What is thromboelastography (TEG) and thromboelastometry? How can they guide transfusion?

D. Postoperative Management

1. What is acute respiratory distress syndrome (ARDS)? What is acute lung injury?
2. How is ARDS treated?
3. In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this patient?
4. If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?

A. Medical Disease and Differential Diagnosis

A.1. How is trauma classified?

Trauma is usually separated into two distinct categories: penetrating and blunt trauma. Both can cause havoc on the body's vascular, visceral, musculoskeletal, and nervous systems.

A.2. What are the injuries associated with thoracic trauma?

Penetrating injuries associated with thoracic trauma are typically associated with stabbings and gunshot wounds. The latter causes far more destruction because of the large amount of kinetic energy transferred to the thoracic cavity from the impact of the bullet. As a result, gunshot wounds to the thorax are diffuse and much more likely to be fatal when compared to stabbings.

Blunt injuries to the chest are far more common than penetrating injuries. The most common causes of blunt injuries are deceleration injuries (as a result of motor vehicle accidents) and crush injuries. These can range from relatively minor injuries such as rib fractures to more severe ones such as lung

contusion, tracheobronchial tears, flail chest, pneumothorax, hemothorax, injuries to the great vessels, and traumatic ruptures of the esophagus or diaphragm.

Barbeito A, Shaw AD, Grichnik K, eds. *Thoracic Anesthesia*. New York: McGraw-Hill; 2012:379–402.

A.3. What are the injuries associated with cardiac trauma?

Penetrating cardiac injuries often lead to immediate cardiovascular collapse, and patients rarely survive to reach the operating room. Injuries associated with penetrating cardiac trauma include pericardial tamponade, cardiac perforation, rupture of a chamber, and fistula formation.

Blunt cardiac injuries (BCI) include cardiac contusion (most common), pericardial ruptures, rupture of a chamber, valvular tears, coronary artery injuries, and ventricular aneurysms. Screening for BCI includes electrocardiogram (ECG) and troponin I level; an echocardiogram is reserved for those with new ECG changes, elevated troponin I levels, hypotension, and/or arrhythmias. At the very least, patients with abnormal cardiac studies should be admitted for monitoring.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017:1506–1510.

Barbeito A, Shaw AD, Grichnik K, eds. *Thoracic Anesthesia*. New York: McGraw-Hill; 2012:379–402.

Clancy K, Velopulos C, Bilaniuk J, et al. Screening for blunt cardiac injury: an Eastern Association for the Surgery of Trauma practice management guideline. *J Trauma*. 2012;73(5, suppl 4):S301–S306.

A.4. What is the pathophysiology of acute pericardial tamponade?

Acute pericardial tamponade represents a rapid increase in intrapericardial pressure exceeding intracardiac pressures. This process results in cardiac chamber compression and diminished

diastolic filling, leading to reduced cardiac output and systemic hypoperfusion, and may be followed by bradycardic arrest. Clinically unstable patients present with Beck triad (hypotension, distended neck veins, and muffled heart sounds), tachycardia, and pulsus paradoxus (>10 mmHg); some of these signs can be easily missed on a hypovolemic trauma patient. The diagnosis of cardiac tamponade can be aided with transthoracic echocardiography, demonstrating key echo findings: pericardial effusion, dilated inferior vena cava (IVC), chamber collapse during diastole, exaggerated respirophasic transvalvular flow velocities, respirophasic septal shift, and a swinging heart. It is important to understand that the hemodynamic effect of the pericardial effusion depends on the change in ventricular diastolic function in response to increased intracardial pressure and not size of the effusion per se. If the diagnosis of acute pericardial tamponade is made and the patient is unstable, immediate evacuation of the pericardium via a pericardiocentesis or a pericardial window is required (also see Chapter 12).

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017:1506–1510.

Klein AL, Abbara S, Agler DA, et al. American Society of Echocardiography clinical recommendations for multimodality cardiovascular imaging of patients with pericardial disease: endorsed by the Society for Cardiovascular Magnetic Resonance and Society of Cardiovascular Computed Tomography. *J Am Soc Echocardiogr*. 2013;26:965–1012.

A.5. What are the anesthetic implications for treating cardiac tamponade?

The anesthetic goal for treating acute cardiac tamponade is to maintain intrinsic sympathetic tone. These patients are extremely dependent on intrinsic sympathetic tone, and therefore, maintenance of heart rate and preload are of utmost importance. A preinduction intra-arterial catheter and large-bore

intravenous access are essential. Ketamine and etomidate are considered appropriate agents for induction. A rapid sequence induction with succinylcholine or an awake intubation can be performed. If possible, preinduction sedation should be avoided. Inotropes such as epinephrine should be readily available and can be given in small doses to avoid bradycardia and hypotension. Induction should be delayed until after patient preparation and draping is completed. In the event the patient becomes hemodynamically unstable, the effusion can then be drained as quickly as possible (also see Chapter 12).

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017:1506–1510.

Barbeito A, Shaw AD, Grichnik K, eds. *Thoracic Anesthesia*. New York: McGraw-Hill; 2012:310–312, 379–402.

A.6. How is the initial assessment and management of the trauma patient performed?

A systematic and organized approach to the assessment and management of the trauma patient has been developed by the American College of Surgeons and is taught as Advanced Trauma Life Support. Initial evaluation and management as stated by Advanced Trauma Life Support consists of five components:

- The primary survey
- Resuscitation
- The secondary survey
- Continued monitoring and reevaluation
- Definitive care

Barbeito A, Shaw AD, Grichnik K, eds. *Thoracic Anesthesia*. New York: McGraw-Hill; 2012:379–402.

A.7. What constitutes a primary survey, and what is its objective?

The assessment of the trauma patient consists of the primary and secondary survey. The function of the primary survey is to identify and treat immediately life-threatening injuries. The life-threatening injuries associated with chest trauma are the following:

- Lost airway/airway obstruction
- Tension pneumothorax
- Massive hemothorax
- Open pneumothorax
- Cardiac tamponade
- Flail chest

ATLS Subcommittee, American College of Surgeons' Committee on Trauma, International ATLS Working Group. Advanced trauma life support (ATLS®): the ninth edition. *J Trauma Acute Care Surg*. 2013;74(5):1363–1366.

Barbeito A, Shaw AD, Grichnik K, eds. *Thoracic Anesthesia*. New York: McGraw-Hill; 2012:379–402.

Chest trauma: initial evaluation. http://www.trauma.org/archive/thoracic/CHESTintro.html. Published February 2004. Accessed October 20, 2015.

A.8. What constitutes a secondary survey, and what is its objective?

The secondary survey is a more detailed examination aimed at identifying other non–life-threatening injuries, planning further laboratory and radiographic studies, and forming a workable differential diagnosis. It begins only after abnormalities identified during the primary surgery have been appropriately addressed and treated. Examples of chest injuries identified on secondary survey are the following:

- Simple pneumothorax
- Hemothorax
- Rib fractures
- Pulmonary contusion
- Tracheobronchial tree injury

- Non–life-threatening blunt myocardial injury

ATLS Subcommittee, American College of Surgeons' Committee on Trauma, International ATLS Working Group. Advanced trauma life support (ATLS®): the ninth edition. *J Trauma Acute Care Surg*. 2013;74(5):1363–1366.

Chest trauma: initial evaluation. http://www.trauma.org/archive/thoracic/CHESTintro.html. Published February 2004. Accessed October 20, 2015.

A.9. What is the definition of massive hemothorax? What are the signs and symptoms of a hemothorax?

A massive hemothorax is defined as a rapid accumulation of greater than 1,500 mL of blood in the thoracic cavity. It is usually caused by rib fractures (intercostal or internal mammary vessel bleeding), lung injury, great vessel injury, cardiac injury, or diaphragmatic injury. The signs and symptoms of a hemothorax include diminished breath sounds on the affected side, hemorrhagic shock, and mediastinal shift.

Reed AP, Yudkowitz FS. *Clinical Cases in Anesthesia*. 4th ed. London: Elsevier Saunders; 2014:395–410.

A.10. What are the indications for a thoracotomy to treat a hemothorax?

Hemothorax, if severe enough, can lead to hemorrhagic shock. Therefore, timely diagnosis and treatment are of utmost importance. After a chest tube is placed, if drainage of blood is greater than 1,500 mL or one-third of blood volume, or if drainage is greater than 200 mL per hour for over 2 to 4 hours, a thoracotomy is indicated. Alternatively, if the patient is older than 60 years, then if drainage is greater than 100 mL per hour for over 4 hours, a thoracotomy is also indicated. If the patient does not meet these criteria but is still hemodynamically unstable or if ventilation is difficult, emergent surgery should be

performed.

ATLS Subcommittee, American College of Surgeons' Committee on Trauma, International ATLS Working Group. Advanced trauma life support (ATLS®): the ninth edition. *J Trauma Acute Care Surg*. 2013;74(5):1363–1366.

Reed AP, Yudkowitz FS. *Clinical Cases in Anesthesia*. 4th ed. London: Elsevier Saunders; 2014:395–410.

A.11. How are pneumothoraces categorized?

Pneumothoraces are categorized into three broad categories: simple, open, and tension pneumothorax. The principal physiologic changes are hypoxemia due to reduced vital capacity and alveolar hypoventilation and impaired venous return secondary to increased intrathoracic pressure.

Simple pneumothorax can result from both blunt and penetrating trauma to the chest. It is defined as the presence of air in the pleural space without an open chest wound and evidence of tension pneumothorax. Diagnosis can be made radiographically, via a chest radiograph or computed tomography (CT), although in many trauma situations, the patients' condition precludes obtaining conventional imaging. In such cases, diagnosis can be made by lung ultrasound. The lack of pleural sliding, lung pulse, and vertical artifacts over the anterior chest wall, coupled with the presence of a lung point, are highly sensitive and specific findings for pneumothorax. Recent studies have demonstrated that using lung ultrasound can be a faster and more sensitive test than a supine anterior-posterior chest radiograph. Definitive treatment is the placement of a chest tube or pleural pigtail if the patient is experiencing cardiopulmonary instability, and/or if the pneumothorax is sizeable, that is, greater than 10% of the pleural cavity. Of note, pigtail catheters have been shown to be equally as effective as chest tubes with decreased rate of complications.

Open pneumothorax is the result of an open wound in the

thoracic cavity that favors constant entrainment of air through the wound. Treatment entails placing an occlusive dressing on three sides over the wound, to create a "flutter valve" and allow egress of air but not entrainment of air, followed by chest tube placement.

Tension pneumothorax is the rapid buildup of air within the pleural space that cannot escape, causing an acute rise in airway pressures with resulting mediastinal shift and obstructive shock. Management is the immediate decompression of the thoracic cavity via needle thoracentesis or finger thoracostomy and then proceeding to chest tube insertion.

A.12. What is an occult pneumothorax?

An occult pneumothorax is a pneumothorax that is seen on CT but was not identified previously on the chest radiograph, comprising as many as 50% of all pneumothoraces, with an overall incidence of 5% in all trauma patients.

In many cases, this type of pneumothorax is managed conservatively with serial imaging and resolves over time, without requiring placement of a chest tube. However, decompression should be considered if the patient is

symptomatic, hemodynamically unstable, or has a pneumothorax greater than 10% in size. Another indication for decompression, although controversial, is the delivery of positive pressure ventilation. Whether these patients should have a chest tube or pigtail placed preemptively is up for debate; for now, the decision should be made on a case-by-case basis.

A.13. If the patient has a widened mediastinum on chest radiograph, what are your concerns?

A chest radiograph revealing a widened mediastinum may indicate the presence of a thoracic aortic injury; other radiographic features suggestive of aortic injury include abnormal mediastinal contour, hemothorax, pleural cap, and tracheal deviation. However, the best screening tool is contrast-enhanced CT of the chest.

These types of injuries are often life-threatening, necessitating immediate identification and intervention. Blunt aortic injury is associated with high-speed deceleration and is the second leading cause of death in trauma patients, accounting for 16% of all trauma-related deaths. Open surgical repair requires a double-lumen tube, single-lung ventilation, and clamping of the proximal aorta while taking measures to protect the spinal cord. In patients with coexisting conditions, such as increased intracranial pressure, profound bleeding, or hypoxemia, this procedure is extremely high risk and may be contraindicated. Mainstay of treatment of an aortic transection includes control of blood pressure and ventricular ejection force (dP/dt) with β-blocker infusions and/or mixed β-blocker/α-antagonist

medications, followed by endovascular repair. At high-volume centers, endovascular repair is associated with a higher survival benefit and decreased incidence of complications, especially paraplegia, compared to open surgical repair.

A.14. What are the most commonly injured organs in blunt abdominal trauma?

In blunt abdominal trauma, the most commonly injured organs are the spleen, liver, kidneys, and bowel. Generally, blunt abdominal trauma leads to higher mortality rates than penetrating trauma. The reason is multifactorial and includes greater difficulty in diagnosis and frequent association with other injuries, such as head injury, chest trauma, and fractures.

A.15. What is a focused abdominal sonography for trauma (FAST) examination?

FAST is a rapid ultrasonography examination that is routinely performed in the setting of blunt or penetrating torso trauma. It is designed to evaluate for free fluid (blood until proven otherwise) in the peritoneum, pleural space, and around the heart; four areas are interrogated with ultrasound: the subxiphoid, right upper quadrant, left upper quadrant, and suprapubic areas. The most dependent space in supine adult patients is the hepatorenal space (Morrison pouch) and therefore is the most likely to collect fluid. One downside to the FAST

exam is the fact that usually 200 to 250 mL of fluid needs to accumulate before it can be visualized sonographically. Furthermore, it cannot evaluate the retroperitoneum and misses solid organ injuries. The utility of FAST resides in the bedside examination of the hemodynamically unstable trauma patient, determining operative management versus considering other potential sources of shock. It has largely replaced DPL as the initial screening tool for intra-abdominal injury.

Rozycki GS, Root HD. The diagnosis of intraabdominal visceral injury. *J Trauma*. 2010;68(5):1019–1023.

A.16. What is diagnostic peritoneal lavage (DPL)?

In abdominal trauma, DPL allows for rapid identification of a hemoperitoneum and, therefore, the discovery of an intraperitoneal injury. A minilaparotomy is performed, then a catheter is placed into the abdomen and aspirated looking for gross blood. Aspiration of 10 mL of blood is considered a positive finding, suggesting visceral or vascular injury. As previously mentioned, the FAST exam is preferred over DPL because of its noninvasive nature and less false-positives, in comparison to DPL; however; DPL may have utility in detecting hemoperitoneum in the patient who is hemodynamically unstable and either has a negative or equivocal FAST.

If less than 10 mL of blood is aspirated, then 1 L of lactated Ringer's solution or normal saline is allowed to drain into the abdomen. The lavage fluid is then allowed to return by gravity and is sent to the laboratory for analysis. Criteria for a positive peritoneal lavage are an erythrocyte count of 100,000 per μL, a

white blood cell count of 500 per μL, the presence of bile or food particles, and a fluid amylase concentration of 175 units per dL. The white blood cell level itself should not determine the need for laparotomy. The level of white blood cells also does not rise initially but requires several hours to rise. Alkaline phosphatase and amylase are contained in the small bowel and spill into the abdominal cavity after injury. These levels tend to rise early in injury. Amylase in lavage fluid has been seen as a more accurate marker than alkaline phosphatase. If the peritoneal lavage meets one or more of these criteria, the patient goes to the operating room for an exploratory laparotomy.

Roberts JR, Hedges JR, Custalow CB, et al, eds. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*. Philadelphia, PA: Elsevier Saunders; 2014:852–872.

A.17. Why was DPL not performed for this patient?

DPL was not done for two reasons. First, it is felt that all penetrating wounds to the abdomen need to be surgically explored. Second, this patient was exhibiting signs of shock and obviously needed to be sent to the operating room without delay.

Before CT and ultrasonography technologies, DPL was the only diagnostic test available to rapidly evaluate the abdomen for injury. Although DPL is highly sensitive, it can also result in false-positive results, leading to unnecessary exploratory laparotomies. CT now allows for evaluation of all intraperitoneal organs, the diaphragm, and the retroperitoneum (an area inaccessible to DPL) while also allowing for identification of the specific organ injured. CT should be used in the evaluation of hemodynamically stable trauma patients.

Rozycki GS, Root HD. The diagnosis of intraabdominal visceral injury. *J Trauma*. 2010;68(5):1019–1023.

A.18. Define shock.

Shock is defined as inadequate oxygen delivery and/or tissue oxygenation to maintain normal cellular processes, for example, aerobic metabolism. End-organ hypoperfusion seems to be the final common denominator in all forms of shock.

Townsend CM Jr, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:44–97.

A.19. What are the four types of shock?

Shock is classified according to its cause:

- *Hypovolemic (hemorrhagic) shock*: characterized by a loss of circulatory blood and plasma volumes
- *Cardiogenic shock*: characterized by an inability of the myocardium to pump blood
- *Distributive (neurogenic, septic) shock*: leads to reduced systemic vascular resistance
- *Obstructive*: characterized by an impairment in cardiac function due to direct cardiac compression or decreased venous return.

Tisherman SA, Forsythe RM, eds. *Trauma Intensive Care*. New York: Oxford University Press; 2013:63–72.

Townsend CM Jr, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2017:44–97.

A.20. List the signs and symptoms of shock.

Tachycardia, decreased capillary refill, reduced pulse pressure, tachypnea, pallor, cool extremities, oliguria, anxiety, restlessness, and loss of consciousness may present as manifestations of shock. Hypotension tends to be a late finding; however, its absence does not rule out shock.

Tisherman SA, Forsythe RM, eds. *Trauma Intensive Care*. New York: Oxford University Press; 2013:63–72.

A.21. What is the pathophysiology of hypovolemic shock?

Cardiovascular Derangement

A number of neurohormonal responses occur in the setting of hypovolemic shock. An acute decrease in circulating blood volume activates aortic and carotid baroreceptors, leading to an outpouring of catecholamines from the sympathetic nervous system and adrenal gland, with an increase in heart rate, blood pressure, contractility, and minute ventilation. The α-adrenergic agonist is responsible for vasoconstriction, shunting blood from the skin, viscera, and muscle, thereby preserving flow to the coronary and cerebral circulations. Vasopressin and the renin–angiotensin–aldosterone system contribute to renal water retention, sodium and chloride resorption, and peripheral vasoconstriction.

Various immunologic and inflammatory mediators, such as tissue necrosis factor and nitric oxide, are released in response to tissue injury. These substances can cause myocardial depression, inappropriate vasodilatation, and end-organ dysfunction.

Acid–Base Disturbance

Metabolic acidosis is almost always seen in association with a shock state. As a result of tissue hypoperfusion, oxygen delivery to vital organs is reduced resulting in tissue hypoxia and oxygen debt. At the cellular level, there is a change from aerobic to anaerobic metabolism. This switch leads to the production of anaerobic metabolites, such as lactic acid. Sequelae include hypotension, decreased myocardial contractility, arrhythmias, encephalopathy, and worsening end-organ function.

A.22. How would you classify hemorrhage?

Classification of hemorrhage based on blood loss is as follows:
Class I: blood loss of up to 15% of the blood volume: normal pulse and blood pressure
Class II: blood loss of up to 30% of the blood volume: tachycardia, decreased urine output, and anxiety
Class III: blood loss of up to 40% of the blood volume: marked tachycardia, hypotension, tachypnea, oliguria, and anxiety
Class IV: blood loss of more than 40% of the blood volume: tachycardia and hypotension, tachypnea, anuria, confusion, and lethargy

Dutton RP. Shock and trauma anesthesia. *Anest Clin North Am*. 1999;17:83–95.

A.23. What is the initial treatment of hemorrhagic shock?

From a resuscitation standpoint, the initial approach to traumatic hemorrhagic shock entails (1) restoring intravascular volume with a high ratio of blood products to maintain oxygen delivery and tissue perfusion, (2) treating the coagulopathy, and (3) managing complications related to shock and MT, that is metabolic acidosis and hypothermia. For more than a decade, trauma centers have adapted the practice of initial resuscitation with hemostatic components, such as plasma and platelets. This strategy for treating massive hemorrhage was pioneered from experience and knowledge gained during combat in Afghanistan and Iraq; it involves limiting the total volume of crystalloid administered and replacing intravascular volume with packed red blood cells and fresh frozen plasma (FFP) in a ratio approaching 1:1. The overall goal is to provide fluids with oxygen-carrying capacity and hemostatic capabilities while avoiding the acute coagulopathy associated with major trauma and blood loss, which has been shown to increase mortality rates.

A.24. Would you choose crystalloid, colloid, or blood products to treat hemorrhagic shock?

Crystalloid solutions can sustain hemodynamics and deliver adequate oxygenation in healthy patients who have lost as much as 30% of their total blood volume. Still, controversy remains over the use of crystalloid versus colloid therapy for the initial therapy of hypovolemic shock.

Proponents of crystalloid therapy believe that both intravascular and interstitial fluid losses occur in hypovolemic shock and that these can be readily replaced with crystalloids. Another benefit of crystalloids is the decrease in blood viscosity, which may enhance perfusion. A particular advantage to lactated Ringer's solution is that lactate is metabolized to bicarbonate, which may help to buffer the patient's acidosis. Finally, in this age of medical economics, the cost of crystalloid is much less than that of colloid. Because crystalloid leaves the intravascular space and enters the interstitial space, large quantities are needed, and some fear that these quantities may lead to both pulmonary and peripheral edema, although studies have not confirmed this fear.

Proponents of colloid therapy, on the other hand, argue that much less volume of fluid is needed to counteract hypovolemic shock and that early colloid therapy can prevent the complications associated with large-volume crystalloid resuscitation such as dilutional coagulopathy, hyperchloremic acidosis, and edema. Colloids maintain the oncotic pressure and

hold the interstitial fluids in the intravascular space, which is felt to possibly prevent pulmonary edema. If leaky alveolar capillary membranes are seen within the lung, colloids may worsen pulmonary edema.

The best resuscitative fluid to treat hemorrhagic shock is whole blood. It provides a balanced resuscitation, reversing shock and coagulopathy, by containing all components of blood, including 100% clotting activity. A major advantage whole blood possesses over crystalloid and colloid is that it does not promote dilutional coagulopathy. From a logistical standpoint, it requires a limited amount of processing and is feasible to use. In terms of its safety profile, the administration of uncrossmatched, cold-stored, low-titer, group O+ whole blood was shown too well tolerated, not causing any episodes of hemolysis or suspected transfusion reactions.

A.25. Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?

Dextran and hetastarch are synthetic polysaccharide solutions with varying mean molecular weights. Dextran 40, dextran 70, and hetastarch have all been used as volume expanders. Dextrans are relatively inexpensive, increase effective blood volume, and decrease blood viscosity. Nevertheless, their negative aspects are considerable. They impair coagulation by coating platelets as well as impair typing and crossmatching by

coating red blood cells. Furthermore, anaphylactic reactions have been reported.

Kozek-Langenecker SA. Effects of hydroxyethyl starch solutions on hemostasis. *Anesthesiology*. 2005;103:654–660.

B. Preoperative Evaluation and Preparation

B.1. What premedication would you order?

None. This is a critically ill patient who is coming to the operating room for emergency surgery. Narcotics and sedatives are contraindicated because they could worsen his already tenuous hemodynamic state.

B.2. What preoperative testing would you order?

Because of the emergent nature of the trauma setting, preoperative tests and imaging studies are frequently limited. If the patient is hemodynamically unstable, any preoperative evaluation is aborted and the patient is taken directly to the operating room.

If the patient is stable, a portable chest radiograph, arterial blood gas, complete blood count, and FAST can be done in a relatively short period in the resuscitation bay before surgery. Often, these tests are obtained while the patient is being prepared for emergency surgery. This information is then combined with other primary survey adjuncts, such as oxygen saturation and ECG, to evaluate the patient and formulate an appropriate management strategy. Although it is usually not possible to clinically clear the cervical spine before surgery, it is important to know the results of any radiologic studies that have been done (e.g., in order to rule out an unstable cervical spine fracture) and to adjust the anesthetic plan accordingly.

C. Intraoperative Management

C.1. How would you monitor this patient?

Routine noninvasive monitor would include ECG, blood pressure cuff, pulse oximeter, end-tidal carbon dioxide, esophageal stethoscope, temperature probe, and Foley catheter.

Invasive monitors for this patient include an arterial line and a central venous catheter. An arterial line is useful for serial blood sampling and continuous arterial blood pressure monitoring. There is a low threshold to place a central venous line, for example, an introducer, to assist with resuscitation efforts. A pulmonary artery catheter may be indicated if the patient has a history of heart failure, myocardial dysfunction, mixed shock picture, and/or poor response to resuscitation.

C.2. How would you induce anesthesia?

Because all trauma patients are considered to have a full stomach, the best way to protect the patient's airway is to perform a rapid sequence induction with cricoid pressure, while maintaining in-line cervical spine immobilization for any patient in a cervical collar. For the patient with a suspected difficult airway, one could do an awake fiberoptic intubation. An awake fiberoptic intubation in this population can be difficult because they may be confused, uncooperative, and sometimes even combative. First, if tolerated, the patient should be preoxygenated for 3 to 5 minutes. Next, ketamine 1 to 2.5 mg per kg might be given followed by succinylcholine 1.5 mg per kg while maintaining cricoid pressure. Ketamine was chosen in this case because of its cardiovascular-stimulating effects and the patient's unstable hemodynamics. Etomidate (0.2 mg per kg) would be another appropriate choice for an induction agent.

If the patient is comatose, in severe shock, or in full arrest on admission to the resuscitation room, no drug other than oxygen

and possibly a neuromuscular blocking drug is required until the patient's blood pressure and heart rate sufficiently rebound so that anesthetics can be titrated. In awake traumatized patients who are thought to be hypovolemic, etomidate is best tolerated.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2115–2152.

C.3. What technique could you use if single-lung ventilation was indicated?

If the patient does not already have a secure airway, the airway should be secured in the manner described in the previous question. Single-lung ventilation is indicated in this situation if the patient is bleeding from one lung and protection of the other lung is required or to improve the surgical field (lower priority). Once the airway is secured, there are several ways to obtain single-lung ventilation. The easiest and safest technique would be to use an Arndt or Cohen bronchial blocker through the endotracheal tube. If those blockers are not available, one could pass an embolectomy catheter (bronchial blocker) into the trachea and then the endotracheal tube. The bronchial blocker could then be positioned under direct vision using fiberoptic bronchoscopy. Alternatively, the bronchial blocker could be placed through a bronchoscopy adapter and endotracheal tube, and its position can be confirmed by fiberoptic bronchoscopy. The point at which the bronchial blocker enters the bronchoscopy adapter can then be sealed with pliable "bone wax" (a form of sterile bees wax that is soft and kneadable).

Another method of obtaining single-lung ventilation would be to change the endotracheal tube to a double-lumen tube using a Cook exchange catheter. The major risks of this option are losing a previously secured airway and aspiration while attempting to change the tube.

C.4. What agents would you choose to maintain anesthesia?

As the patient stabilizes and the hemodynamics improve, other anesthetic agents can be carefully titrated to prevent hypotension, as follows:

- Sedatives or amnestics should be added to the anesthetic as soon as tolerated. Remember to start with small doses and check the patient's reaction to the drugs between doses.
- Opioids should be titrated to control the hemodynamic response to surgery.
- Nitrous oxide must be carefully considered because it has the capacity to accumulate in closed airspaces or because of the high possibility that this patient has an occult pneumothorax.
- Inhalational anesthetics may be used in low concentrations, so the patient's hemodynamics are not compromised.

C.5. What muscle relaxant would you choose?

Vecuronium, rocuronium, and cisatracurium are free of cardiovascular side effects and have an intermediate duration of action. They are acceptable choices. Pancuronium is a long-acting muscle relaxant with vagolytic properties that may be deleterious to the patient.

D-Tubocurarine, metocurine, atracurium, and mivacurium all have the potential to cause hypotension and therefore would not be chosen for this patient.

C.6. What can be done to decrease the incidence of intraoperative awareness?

The incidence of intraoperative awareness is commonly cited as approximately 0.2%. This is probably an overestimation. In other sources, the incidence of traumatic intraoperative recall associated with pain is less that 0.03%. The American Society of Anesthesiologists Closed Claims database states that claims

associated to recall during anesthesia constitute 1.5% of claims. An increased relative risk for recall is seen in certain types of surgery, including cardiac surgery, cesarean sections, and trauma surgery. This most likely represents intentional light anesthesia associated with higher levels of stimulation. Bispectral index monitoring may be potentially useful; the application of these monitors during a trauma resuscitation may not be easily accomplished. It has been shown that patients with a bispectral index value of 50 were able to respond to verbal commands less than 10% of the time.

Johansen JW. Update on bispectral index monitoring. *Best Pract Res Clin Anaesthesiol*. 2006;20(1):81–99.

O'Connor MF, Daves SM, Tung A, et al. BIS monitoring to prevent awareness during general anesthesia. *Anesthesiology*. 2001;94:520–522.

Rampil IJ. Monitoring depth of anesthesia. *Curr Opin Anaesthesiol*. 2001;14:649–653.

C.7. Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?

The possible causes of peak airway pressure increase are as follows:

- Tension pneumothorax
- Bronchospasm
- Endobronchial intubation
- Pulmonary edema
- Secretions
- Kink in the anesthesia circuit or endotracheal tube

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:22.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

C.8. How would you make a diagnosis of tension

pneumothorax?

A tension pneumothorax can be diagnosed by the absence of breath sounds on the affected side. The chest movement may be asymmetric. Neck veins will be full, and systemic hypotension can occur if the tension pneumothorax is severe. Any patient who deteriorates under anesthesia and has wounds to the upper abdomen, lower neck, or ribs should be assumed to have a tension pneumothorax until proven otherwise.

Marx JA, Hockberger RS, Walls RM, et al, eds. *Rosen's Emergency Medicine-Concepts and Clinical Practice*. 8th ed. Philadelphia, PA: Elsevier Saunders; 2014:431–458.

C.9. What is the treatment of tension pneumothorax?

Immediate decompression of the chest is mandatory for tension pneumothorax because otherwise the patient's hemodynamics will deteriorate. The diagnosis is made clinically and not by a chest radiograph. A 16- or 18-gauge Angiocath is placed into the second intercostal space at the midclavicular plane. After the air escapes confirming your diagnosis and the lung is decompressed, a chest tube should be placed.

Marx JA, Hockberger RS, Walls RM, et al, eds. *Rosen's Emergency Medicine-Concepts and Clinical Practice*. 8th ed. Philadelphia, PA: Elsevier Saunders; 2014:431–458.

C.10. The patient's blood loss was continuing, and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?

This patient should have blood transfused as soon as possible. Type O Rh-negative packed red blood cells are the universal donor. This should be started while type-specific blood is being made available. Whenever the type-specific blood is ready, one can switch to it. Usually, by the time a patient reaches the operating room from the emergency room, a partial crossmatch

can be done. This usually takes 5 to 10 minutes, after which time type-specific blood can be transfused. If, however, the transfusion begins with low titer group O *whole blood* because the patient's ABO type was unknown and is found later not to be type O, follow your blood bank's criteria for switching to type-specific blood.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1546–1576.

Roberts JR, Hedges JR, Custalow CB, et al, eds. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*. Philadelphia, PA: Elsevier Saunders; 2014:496–517.

C.11. What precautions should be taken if more than 2 units of low titer type O uncrossmatched whole blood are given?

The plasma from type O *whole blood* contains anti-A and anti-B antibodies, which can cause hemolytic reactions with type A and B red blood cells if given in significant quantities. Therefore, low titer type O uncrossmatched *whole blood* (i.e. It has low titers of anti-A and anti-B antibodies.) should be given and should continue to be transfused, although this will lead to minor hemolysis of the patient's own red blood cells if they are not type O. The patient should not receive his type-specific blood until the blood bank determines that the transfused anti-A and anti-B antibody levels are sufficiently low to permit safe transfusion of type-specific blood.

Packed red blood cells have smaller volumes of plasma and are virtually free of anti-A and anti-B antibodies. Therefore, whenever type-specific blood is not yet available, type O Rh-negative uncrossmatched packed red blood cells should be given in preference to low titer O *whole blood*. Once type-specific blood is available, it can be used safely.

C.12. What are the complications associated with any blood transfusion?

Complications associated with blood transfusion are as follows:

Transfusion Reactions

- Transfusion-related acute lung injury (TRALI) is characterized by the onset of hypoxemia and bilateral pulmonary edema within 6 hours of a transfusion, in the absence of other causes such as heart failure. It is attributed to donor plasma human leukocyte antigen class I and II antibodies activating recipient neutrophils, leading to a lung immune response. In 2006, U.S. blood collection agencies instituted a male-only plasma donor policy because multiparous females are more likely to carry the offending antibodies. The TRALI rate decreased to about one-third of its previous level. TRALI is now the leading cause of transfusion-related mortality. The treatment of this noncardiogenic pulmonary edema is aggressive supportive care.
- Transfusion-associated circulatory overload (TACO) occurs in 1% to 6% of transfused patients and can cause pulmonary edema secondary to fluid overload. Large amounts of plasma that may be transfused during MT or coagulopathy correction increase the likelihood of TACO.
- Transfusion-related immunomodulation (TRIM) is a risk with allogenic red blood cell transfusion. Although incompletely understood, there is a decrease in immunity with an increased incidence of nosocomial infection, postoperative infection,

and cancer recurrence.

- Febrile reactions occur in approximately 1% of all transfusions. In an awake patient, this is usually no more than an annoyance that requires antipyretics and decreasing the infusion rate. Leukoreduction decreases the likelihood of a febrile reaction occurring.
- Allergic (nonanaphylactic/nonanaphylactoid) nonhemolytic reactions to properly crossmatched blood will manifest as an increase in temperature, pruritus, and urticaria. This may be difficult to diagnose in the anesthetized patient. Treatment consists of the administration of antihistamines and discontinuation of the transfusion.
- Hemolytic reactions occur when incompatible blood is administered. The risk of an ABO-incompatible transfusion is 1:33,500 for red blood cell transfusions. Mortality associated with this remains high at approximately 40%. Caused by activation of the complement system, hemolytic reactions can be life-threatening. In the awake patient, fever, chills, dyspnea, substernal, and lumbar pain are seen in addition to hypotension. Under general anesthesia, the only sign that is not masked is hypotension. Free hemoglobin can be detected in the plasma or urine is indicative of a transfusion reaction. Substances released by the hemolyzed cells can lead to disseminated intravascular coagulation (DIC) and acute renal failure (ARF). Treatment consists of immediate discontinuation of the transfusion. Hypotension should be treated with hydration, vasopressors, and inotropic agents if needed. Urinary output must be maintained by adequate hydration. Although its value is uncertain, sodium bicarbonate has been used to alkalinize the urine to improve the solubility of the hemoglobin-degradation products.
- Other reactions include posttransfusion purpura, microchimerism, and graft-versus-host disease.

Transmission of Disease

- Human immunodeficiency virus (HIV), hepatitis B virus, hepatitis C virus, and cytomegalovirus can all be transmitted by transfusion of blood products. Because the risk of disease transmission increases with each unit of blood or its components given, they must be carefully scrutinized before being administered. Currently, the incidence of posttransfusion HIV 1 and 2 infection is 1:1,476,000 per transfused unit of blood, almost similar to the risk of hepatitis C transmission, which is 1:1,149,000 per unit transfused. In comparison, the risk of hepatitis B transmission is higher, approximately 1 per 350,000 units. Nevertheless, cytomegalovirus remains the most common viral agent transmitted by transfusion; it produces clinically important infections only in immunosuppressed patients. Laboratory testing done to detect these viruses includes enzyme immunoassays and nucleic acid testing.
- Malaria, syphilis, Lyme disease, Chagas disease, West Nile virus, Creutzfeldt-Jakob disease, and other diseases may also be transmitted through transfusion of blood.
- Bacterial infection occurs in 1:75,000 transfusions. As new nonhemoglobin solutions appear on the market, less blood will be transfused and disease transmission will diminish.

Microembolization

Microembolization can occur from the transfusion of blood or its components. Stored blood forms microaggregates that are too small to be removed by the standard 170-μm blood filters. Smaller filters have been developed to remove these particles. When using blood filters of the 20- to 40-μm range, the rate of transfusion is dramatically decreased because of the increased resistance of the filters. Some early reports suggested that these microaggregates may lead to pulmonary dysfunction, but this

has never been proven.

What is considered a massive transfusion (MT)? What is the Assessment of Blood Consumption (ABC) score?

The conventional definition of MT is the replacement of the patient's total blood volume (≥10 units of packed red blood cells) in 24 hours. However, this definition is considered arbitrary and retrospective; it fails to identify those at an increased risk for hemorrhagic death. In contrast, the critical administration threshold (CAT) definition of ≥3 units in 1 hour has a stronger association with mortality compared to MT; it may serve as an activation trigger for initiating an MT protocol.

The ABC score is a validated, nonlaboratory scoring system, designed to identify patients who will require MT. It looks at four parameters: (1) penetrating mechanism, (2) positive FAST, (3) arrival systolic blood pressure ≤90 mmHg, and (4) arrival heart rate ≥120. A score of 2 (positive cutoff) or greater was 75% sensitive and 86% specific for predicting MT.

C.14. What are the complications associated with an MT?

Complications of an MT include hypothermia, acidosis, coagulopathy, DIC, fibrinolysis, citrate toxicity, hyperkalemia, hypokalemia, acid–base imbalance, and impaired hemoglobin function.

- Hypothermia is a consequence of exposure, impaired thermoregulation, and the transfusion of cold, banked blood. Therefore, it is recommended that the room temperature be increased, and all fluids and blood pass, in order to help prevent hypothermia.
- Acute coagulopathy of trauma is a combination of dilutional coagulopathy and thrombocytopenia. The coagulopathy is preexisting and/or due to the acute production of endogenous substances, for example, activated protein C. It is often exacerbated by acidosis, hypothermia, and dilution of procoagulants with aggressive crystalloid/colloid resuscitation. The optimal ratio of blood components is unknown. In cases requiring MT when there is insufficient time to obtain conventional labs or point-of-care testing to guide transfusion, it may be necessary to take the "damage control" approach of transfusing a set ratio of pRBC:FFP:platelets, such as a 1:1:1 ratio. DIC and fibrinolysis may occur in the setting of trauma. An important triggering event of DIC and fibrinolysis is shock, with its accompanying tissue ischemia, acidosis, and waste product accumulation. Therefore, early and prompt treatment of hypoperfusion is mandatory.
- Hypocalcemia may result from inadequate citrate metabolism. Citrate is present in stored blood to bind calcium and prevent clotting. Consequences of hypocalcemia include prolongation of the QT interval, decreased myocardial contractility, and

depressed procoagulant activity—calcium is clotting factor IV.

- Hyperkalemia can occur in the massively transfused patient. Plasma potassium levels of stored whole blood range between 12 and 32 mEq per L. The potassium level increases approximately 1 mEq/L/day in stored blood. A unit of whole blood would contain between 4 and 8 mEq of potassium, which is hardly enough to cause hyperkalemia. A unit of packed red blood cells contains insignificant amounts of potassium because most of the plasma is removed. However, in the shock state with hypoperfusion and acidemia, hyperkalemia may become evident.
- Hypokalemia is also a possibility after an MT. Citrate is metabolized to bicarbonate, resulting in a metabolic alkalosis that can cause hypokalemia. Furthermore, transfused red blood cells take up potassium, potentially potentiating hypokalemia.
- Acid–base imbalance is a problem after MT. Banked blood with a pH level of 6.8 is acidotic and may worsen the acidosis that accompanies shock. This acidosis is reversible with the restoration of normal perfusion. Supplemental bicarbonate should not be given based on an arbitrary number of units transfused. Nevertheless, if metabolic acidosis persists, sodium bicarbonate may be warranted, especially in the setting of renal failure and severe muscle damage. As previously stated, citrate from stored blood and lactate from Ringer's lactate solution are metabolized to bicarbonate, resulting in a metabolic alkalosis.
- Impaired hemoglobin function is a theoretic possibility after MT. The 2,3-diphosphoglycerate levels are decreased in banked blood, shifting the oxygen–hemoglobin dissociation curve to the left. A leftward shift causes oxygen to be held more tightly by the hemoglobin molecule. No studies have

documented any clinical adverse effects from this.

Shaz BH, Dente CJ, Nicholas J, et al. Increased number of coagulation products in relationship to red blood cell products transfused improves mortality in trauma patients. *Transfusion*. 2010;50(2):493–500.

C.15. Can the shift of the oxygen–hemoglobin dissociation curve be quantified?

Yes, the shift of the oxygen–hemoglobin dissociation curve is quantified by means of the P_{50} value (i.e., oxygen tension at which hemoglobin is 50% saturated). The normal P_{50} value of blood is 27 mmHg. Decreased levels of 2,3-diphosphoglycerate (normal level is 4.8 mmol per mL of erythrocytes) would cause a leftward shift of the curve, lowering the P_{50} value and reducing oxygen unloading at the tissues.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2017:169–202.

C.16. How is hypothermia defined?

Hypothermia is defined as a core body temperature of less than 35°C (95°F). Prolonged exposure to a cold operating room, evaporative heat loss from the respiratory tract, infusions of cold fluids, and loss of heat production secondary to shock, cause decreased core temperatures in trauma most patients.

Hypothermia can be avoided by covering skin surfaces not in the surgical field with warm blankets (reduce convective and radiant heat losses), humidifying inspired gases (reduce evaporative heat loss from the lung), using a warming device for fluids and blood, and increasing the room temperature.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed.

Philadelphia, PA: Elsevier; 2020:2341–2344.

Roberts JR, Hedges JR, Custalow CB, et al, eds. *Roberts and Hedges' Clinical Procedures in Emergency Medicine*. Philadelphia, PA: Elsevier Saunders; 2014:496–517.

C.17. What are the adverse effects of hypothermia?

- Shivering-induced increase in oxygen consumption by as much as 400%
- A leftward shift in the oxygen–hemoglobin dissociation curve
- Decreased blood clotting ability (10% reduction in coagulation factor activity for every 1°C drop in body temperature)
- Increased epinephrine and norepinephrine levels causing vasoconstriction
- As hypothermia becomes severe, possible decreases in both heart rate and blood pressure
- Cardiac arrhythmias that can progress to ventricular fibrillation

Tanaka M, Nagasaki G, Nishikawa T. Moderate hypothermia depresses arterial baroreflex control of heart rate during, and delays its recovery after general anesthesia in humans. *Anesthesiology*. 2001;95:51–55.

C.18. What is the treatment of hypothermia?

The normal response to hypothermia is shivering, which is blocked by general anesthesia. Therefore, it is of utmost importance to prevent and treat hypothermia. Recommendations include the following:

- Increase the temperature of the operating room.
- Use a warming blanket.
- Preheat intravenous fluids.
- Pass all fluids through a warming device.

- Use low-flow anesthesia.
- Use a heat moisture exchanger in the anesthesia circuit.

C.19. What are the effects of blood transfusion on the immune system?

Blood transfusion will result in immunologic changes that can be harmful in some patients. This immunomodulation occurs from immunosuppression or the production of alloantibodies. The blood components crucial to these changes are thought to be leukocytes and plasma. In patients who have cancer, a possible harmful effect of immunosuppression is the increased cancer recurrence rate seen in patients who have had prior transfusions. Finally, clinical studies have demonstrated that perioperative transfusions are associated with an increased incidence of infection and sepsis.

C.20. What are the guidelines for transfusion of blood products?

The NewYork-Presbyterian Hospital Guidelines for blood product usage are as follows:

Red Blood Cell Transfusion Criteria

- Hgb <7 g/dL
- Hgb <8 g/dL (with history or risk factors for cardiovascular disease)
- Neonates requiring:
  - Mechanical ventilation with Hgb <11.5 g/dL
  - CPAP or O_2 with Hgb <9.5 g/dL

- Exchange transfusion
- Symptomatic anemia
- Greater than 15% blood volume loss

Platelet Transfusion Criteria

- Platelet count <10,000/μL
- Platelet count <50,000/μL with minor bleeding/procedure
- Platelet count <100,000/μL with ECMO/imminent procedure (<4 hours)/neurosurgery intracranial hemorrhage/pulmonary hemorrhage
- Platelet count <25,000/μL in neonates (0–28 days)
- Neonates with plt count <50,000/μL with minor bleeding, ventilatory support, risk of intracranial hemorrhage or minor surgery
- Neonates with plt count <100,000 with major bleeding or major surgery
- Bleeding with loss of one blood volume and no labs available
- Bleeding with qualitative platelet defect

Fresh Frozen Plasma Transfusion Criteria

- INR >1.6 for patients with bleeding and/or surgery
- PTT >55 with factor deficiency and bleeding and/or surgery
- Infants with active bleeding, undergoing surgery and PT or PTT >1.5 × the upper limit of reference range for age
- Bleeding with loss of one blood volume and no labs available
- TTP, HUS
- Patients receiving plasma exchange with coagulopathy or imminent procedure
- Patients treated with L-asparaginase

Cryoprecipitate Transfusion Criteria

- Acquired hypofibrinogenemia <60 mg/dL
- Fibrinogen <150 mg/dL with bleeding/procedure
- DIC

- Abnormal fibrinogen (dysfibrinogenemia)
- Uremic bleeding refractory to DDAVP and dialysis

NewYork-Presbyterian Hospital. *NYP Transfusion Guidelines*. New York: Weill Cornell Medical Center; 2016.

What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in an MT?

Most trauma centers have implemented MT protocols that use the strategy of "hemostatic resuscitation." These protocols are highly variable but largely involve minimizing aggressive crystalloid use, delivering early resuscitation with blood products, and providing early administration of FFP and platelets.

At present, the optimal ratio of blood product transfusion is not known. Although more studies are required, current literature shows an association toward increased survival when a ratio of FFP to packed red blood cells is 1:2 or higher during MT. In 2015, the "Pragmatic, Randomized Optimal Platelets and Plasma Ratios" study was published, which randomized 680 severely injured trauma patients to receive FFP:platelets:RBCs in a 1:1:1 or 1:1:2 fashion. The 1:1:1 cohort was found to be noninferior to 1:1:2, as there was no significant difference in mortality or adverse events between the groups.

C.22. If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?

Jehovah's Witnesses are best known for refusing the transfusion of blood and blood products. This belief is based on the Bible (Acts 15:28–29). In the awake and otherwise competent adult, courts have ruled that physicians cannot be held liable if they comply with a patient's directive and withhold life-saving blood administration after specific and detailed informed consent of the consequences of such an omission of treatment. The issue becomes clouded when patients are incompetent, unconscious (most Jehovah's Witnesses carry cards informing medical personnel of their religious beliefs), or minors. They believe all hope of eternal life is forfeited if they accept a transfusion. Therefore, a blood transfusion is considered a physical violation. The right of a Jehovah's Witness to refuse a blood transfusion is absolute; the courts have upheld their rights to refuse a blood transfusion. Most Jehova's Witnesses take legal steps to relieve the liability of the medical personnel. Moreover, the vast majority will carry a medical alert card that states their wishes, and they usually have made arrangements for proxy or surrogate decision makers. It is crucial an open and honest avenue of communication exist between the patient, surgeon, and anesthesiologist.

Witnesses will refuse transfusion of whole blood, packed red blood cells, white blood cells, plasma, and platelets; however, they will allow the use of cardiopulmonary bypass, dialysis, or similar equipment, as well as intraoperative blood salvage, in which the extracorporeal circulation is uninterrupted. Their religious understanding does not absolutely prohibit albumin, immune globulins, or hemophiliac preparations; those products must be decided on an individual basis. They accept all

nonblood replacements, including nonblood colloids, crystalloids, dextrans, and oxygen-carrying blood substitutes.

An anesthesiologist may refuse to care for any patient when a procedure is elective. In an emergency situation, legal and ethical requirements apply. Conversely, any competent adult also has the right to refuse any therapy, and to treat such a patient against that person's will is to commit battery.

Waters JH, Potter PS. Cell salvage in the Jehovah's Witness patient. *Anesth Analg*. 2000;90:229–230.

C.23. If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?

Care of minors presents the greatest concern and often leads to legal action against the parents under child-neglect status. Such actions are questioned by Jehovah's Witnesses who do seek good medical care for their children while claiming that consideration be given to their families' religious beliefs. Doctors can appeal to the court for permission to transfuse blood to children of this sect who are underage. In an unforeseeable emergency, blood may be given without consulting a court.

C.24. What are the concentrated factors and hemostatic agents available for bleeding patients?

Recombinant Activated Factor VII (rFVIIa, NovoSeven)

NovoSeven is approved in the United States for prophylaxis and treatment of hemorrhage in hemophiliacs with inhibitors to factor VIII or IX or congenital factor VII deficiency. Despite its

limited approval, it has been used off-label in patients with refractory traumatic hemorrhage. Although NovoSeven is extremely effective at stopping uncontrolled bleeding, it may not provide a survival benefit versus placebo, as suggested by the CONTROL study. Moreover, there have reports linking it to thromboembolic adverse events, such as an increased risk of stroke. A meta-analysis by Zangrillo et al. showed that recombinant NovoSeven was associated with a decreased need for surgical revision after cardiac surgery; however, it was also associated with an increase in perioperative stroke.

Four-Factor Prothrombin Complex Concentrate

Four-factor prothrombin complex concentrate (PCC) contains II, VII, IX, and X as well as low doses of anticoagulants protein C, protein S, and heparin. It has the advantages of requiring significantly less volume for infusion versus plasma, achieving a more rapid reversal of international normalized ratio (INR), and almost eliminating the risk of TRALI. PCC has U.S. Food and Drug Administration (FDA) approval for the reversal of vitamin K antagonists (VKA), for example, warfarin, in patients with acute major bleeding but has shown promise in treating acute coagulopathy in trauma. In fact, its administration is recommended by the European trauma guidelines in managing patients with evidence of delayed thrombin generation.

Fibrinogen Concentrates

Fibrinogen concentrate is a pasteurized collection from human plasma that is approved for the use in patients with congenital fibrinogen deficiency to treat acute bleeding episodes. It acts to replenish fibrinogen levels in the blood in place of FFP or cryoprecipitate. A Cochrane Review by Wikkelsø et al. showed no difference between fibrinogen concentrate versus blood products in regard to adverse events, bleeding, or recovery.

Tranexamic Acid

Tranexamic acid (TXA) is an antifibrinolytic that blocks the interaction of plasminogen with fibrin, effectively preventing clot breakdown and lysis. It may be used to treat hyperfibrinolysis in trauma, which in an independent predictor of mortality in trauma patients. The CRASH-2 trial, an international clinically randomized study of over 20,000 trauma patients, found TXA was associated with a significant reduction in all-cause mortality versus placebo (14.5% vs. 16%, p = 0.035). Subsequent analyses revealed the greatest benefit of TXA was only seen when given <3 hours from injury, supporting its early administration in trauma.

What is thromboelastography (TEG) and thromboelastometry? How can they guide transfusion?

Rotation thromboelastometry (ROTEM®) and TEG are two different viscoelastic hemostatic assays used to assess clot

kinetics. Both assays employ a suspended pin that sits in a metal cup containing whole blood. As the blood clots, they detect the change in tensile force and use this change to assess the strength of the clot formed.

Rotation Thromboelastometry

The ROTEM® uses a rotating pin in a stationary cup to detect increases in tensile force as a clot forms or decreases as a clot lysis. It is a point-of-care test, which looks at several different parts of the coagulation cascade:

- INTEM—intrinsic pathway of the coagulation cascade
- HEPTEM—intrinsic pathway of the coagulation cascade with the addition of heparinase, which removes the effects of heparin from the results
- EXTEM—extrinsic pathway of coagulation cascade
- FIBTEM—extrinsic pathway of the coagulation cascade after the addition of cytochalasin D, which inhibits the effects of platelets on the formation of the clot
- APTEM—extrinsic pathway with the addition of aprotinin to block fibrinolysis

These tests will generate images based on a patient's coagulation status, which can be used to guide transfusion therapy (**Figs. 57.1** to **57.6**). Bolliger et al. developed a chart to guide therapy based on ROTEM® results (**Fig. 57.7**).

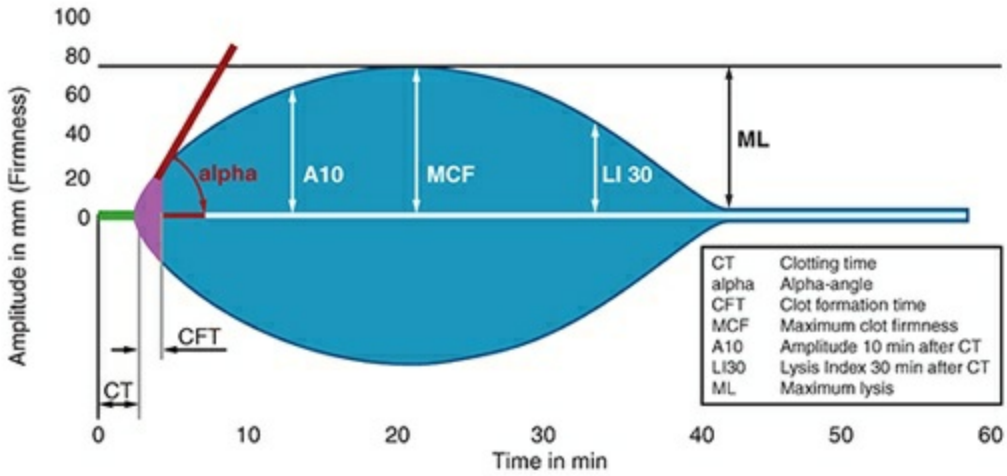

FIGURE 57.1. Basic ROTEM® image. Clot time: the measured time until clot formation starts; affected by clotting factors and anticoagulants. Clot formation time: a measure of initial rate of clot formation, the time from clot formation until the clot forms to an amplitude of 20 mm; depends on platelets and fibrinogen. *α* Angle: a measure of the initial rate of clot formation. Maximum clot firmness: the maximum tensile strength of the clot; describes quality of clot and is dependent on platelets, fibrinogen, factor XIII, and fibrinolysis. Maximum lysis: reduction of clot firmness during measurement; abnormality in the ML at 30 minutes indicated fibrinolysis. Amplitude: A5/10/15 is the amplitude of the clot at 5, 10, and 15 minutes.

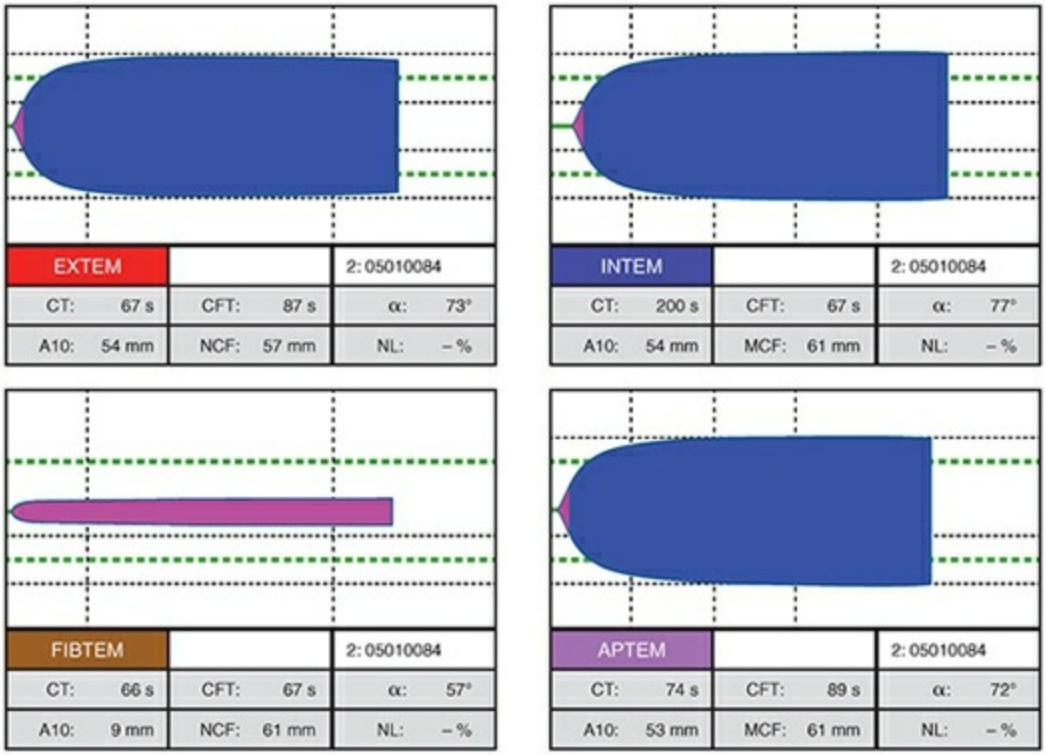

FIGURE 57.2. ROTEM® in a patient with normal coagulation parameters.

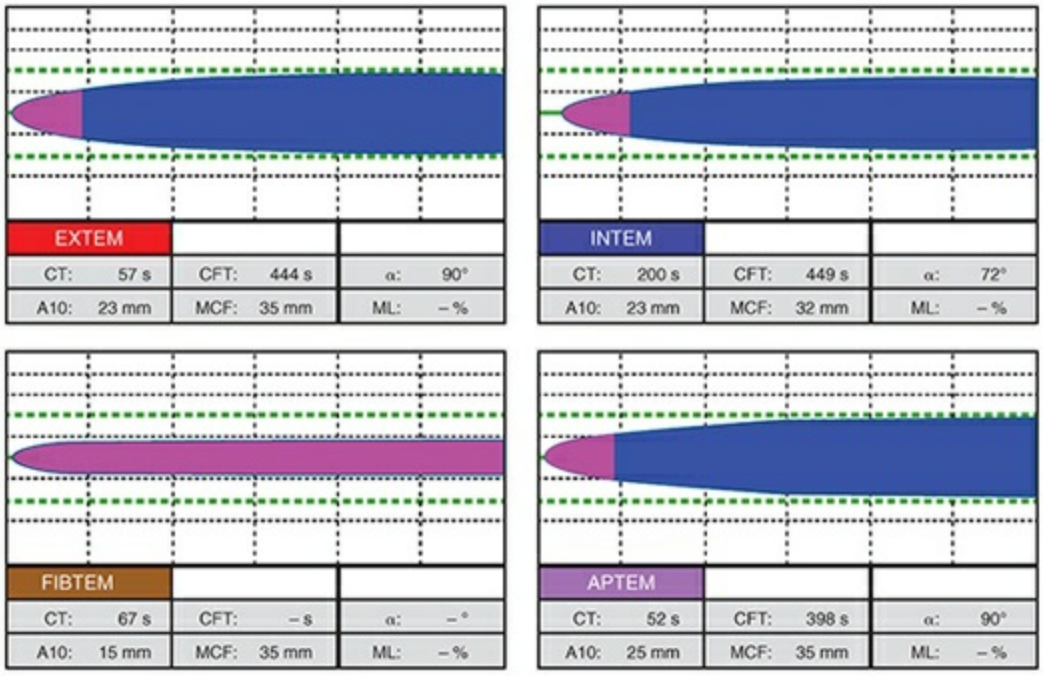

FIGURE 57.3. ROTEM® in a patient with a platelet deficiency.

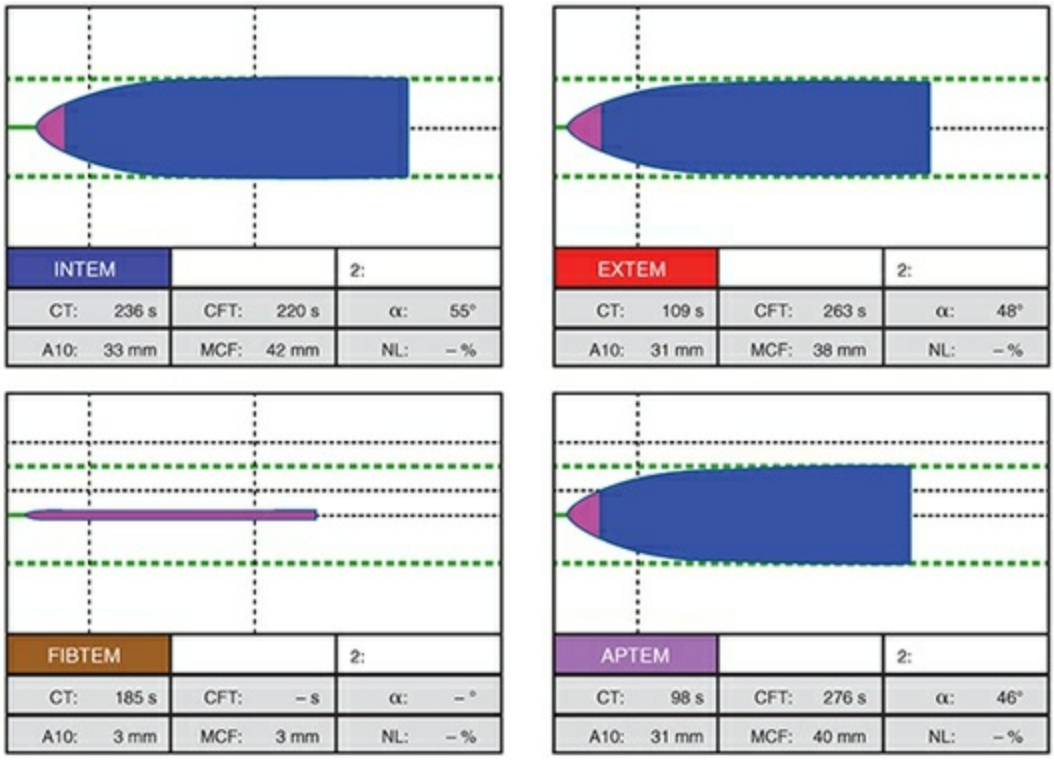

FIGURE 57.4. ROTEM® in a patient with a fibrinogen deficiency.

Thromboelastography

The TEG is based on the same principles as the ROTEM®. The difference is that instead of having a mobile pin in a stationary cup, TEG has a stationary pin in a mobile cup. A sample will generate an image (**Fig. 57.8**). The TEG values can be compared to ROTEM® values (**Table 57.1**). Some examples of the effect of different coagulation states on TEG (**Fig. 57.9**) and a guideline for transfusion therapy (**Fig. 57.10**) are shown.

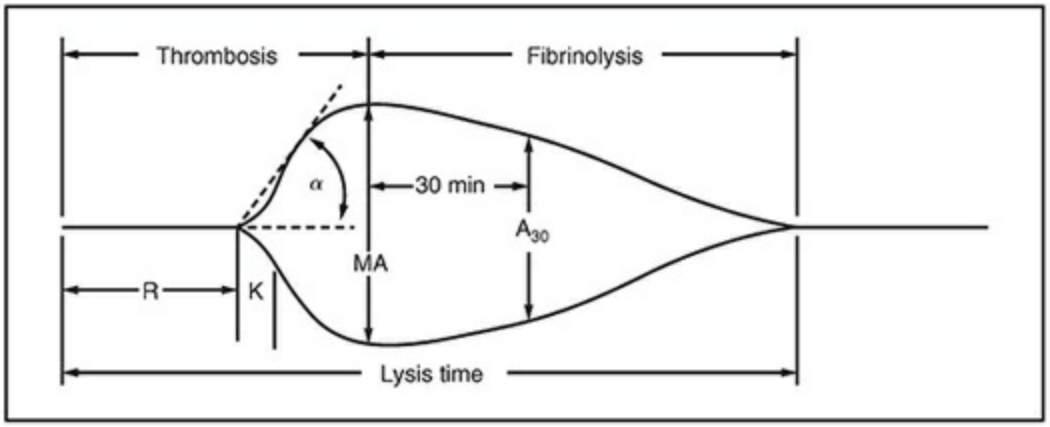

FIGURE 57.8. **Basic TEG image.**

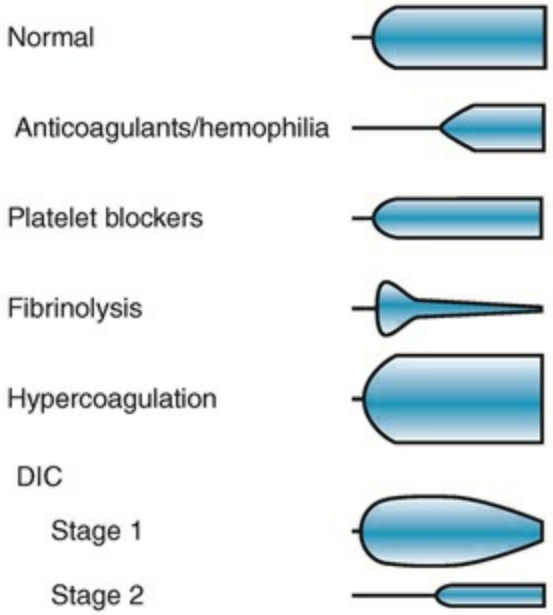

FIGURE 57.9. **Effects of different coagulation states on TEG results.**

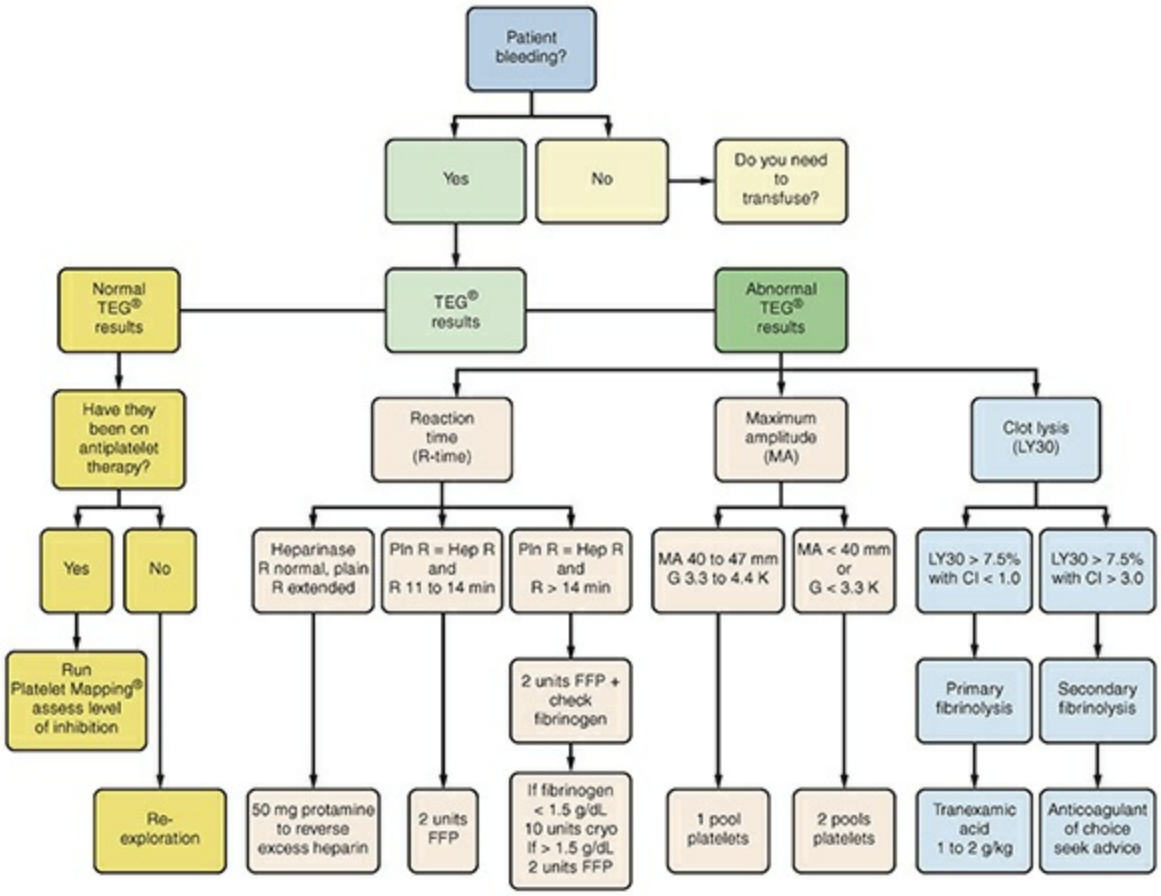

FIGURE 57.10. A guideline for transfusion based on TEG results. CI, coagulation index; FFP, fresh frozen plasma; G, clot elasticity; K, kinetics; Pln, plain.

TABLE 57.1 Thromboelastography (TEG) Values Compared to Their Rotation Thromboelastometry (ROTEM®) Equivalents

TEG	Measures	ROTEM® Equivalent
R time	Time to 2 mm amplitude	CT
K time	Time from 2 to 20 mm	CFT
α Angle	Slope between R and K	α Angle
MA	Maximum amplitude of clot	MCF
LY30	Percentage of clot lysis at 30 min after MA	ML
A30	Size of clot at 30 min after MA	A10
G	Clot elasticity	MCE
CI	Coagulation index is value determined by a manufacturer created mathematical formula which takes into account R, K, α angle, and MA to give an overall assessment of the state of coagulation.	

CFT, clot formation time; CI, coagulation index; CT, clotting time; K, kinetics; MA, maximum

amplitude; MCE, maximum clot elasticity; MCF, maximum clot firmness; ML, maximum lysis.

D. Postoperative Management

D.1. What is acute respiratory distress syndrome (ARDS)? What is acute lung injury?

ARDS is a type of acute respiratory failure seen in patient after being exposed to direct (e.g., aspiration) or indirect (e.g., severe trauma) lung injury. Initially, when this clinical syndrome was thought to be related to the underlying shock state and its resuscitation, names such as “shock lung” and “traumatic wet lung” were applied to the subsequent acute respiratory insufficiency. It is now recognized that many types of insults will result in damage to the alveolar capillary membrane, resulting in leakage of proteinaceous fluid into the alveolar space. This injury with its resulting interstitial and alveolar edema, produces a clinical picture ranging from mild to severe pulmonary dysfunction that can be fatal.

ARDS was formerly defined as:

- The acute onset of respiratory failure
- Bilateral infiltrates on chest x-ray

- Pa_{O_2}/fraction of inspired oxygen (F_{IO_2}) ratio of 200 or less
- A pulmonary capillary wedge pressure <18 mmHg

However, this definition was reevaluated in 2012 secondary to concerns regarding its accuracy. First, the diagnosis of bilateral infiltrates on chest x-ray was found to have wide interobserver variability and thus was inconsistent. Next, the Pa_{O_2}/F_{IO_2} ratio varied greatly based on the patient's ventilator status and needed to be refined. Third, heart failure patients with elevated left atrial pressures can have ARDS, so high pulmonary capillary wedge pressures are not enough to rule out the diagnosis of ARDS. Finally, the definition was found to have low specificity when compared to autopsy results of patients with diffuse alveolar damage.

For these reasons, the Berlin definition was established, which characterizes ARDS by the following:

Oxygenation

- Mild—Pa_{O_2}/F_{IO_2} <200 mmHg or ≤300 mmHg with positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) ≥5 cm H_2O
- Moderate—Pa_{O_2}/F_{IO_2} ≤100 mmHg or ≤200 mmHg with PEEP ≥5 cm H_2O
- Severe—Pa_{O_2}/F_{IO_2} ≤100 mmHg with PEEP ≥5 cm H2O

Timing—onset within 1 week of a known clinical insult, or the patient has worsening respiratory symptoms

Chest radiograph—demonstrates opacities bilaterally that are not due to pleural effusions, atelectasis, or nodules

Origin of edema—respiratory insufficiency that is not solely caused by cardiogenic causes, that is, left heart failure or volume overload

Acute lung injury—a term for a less severe form of ARDS was removed from the definition and is no longer used

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2017:1644–1645.

D.2. How is ARDS treated?

The treatment of ARDS is primarily supportive. Currently, mechanical ventilation is the mainstay of supportive therapy for ARDS. The principal goal of mechanical ventilation is to allow times for the lungs to heal. Unfortunately, mechanical ventilation can cause further lung injury, known as ventilator-induced lung injury (VILI). Excessive alveolar volumes (volutrauma), high mean and peak airway pressures (barotrauma), and shearing forces caused by frequent collapse and opening of alveolar units, contribute to VILI.

Investigators have looked at protective ventilator strategies in patients with ARDS. Amato et al. used a strategy to limit peak inspiratory pressures by using low tidal volumes (<6 mL per kg) and the institution of PEEP. Their approach was associated with a lower 28-day mortality (38% vs. 71%), higher weaning rate (66% vs. 29%), and lower barotrauma rate (7% vs. 42%).

The National Heart, Lung, and Blood Institute ARDS Network reported improved survival with a low tidal volume strategy (6 mL per kg vs. 12 mL per kg). Moreover, there was a decrease in mortality of approximately 25% in the intervention group compared with the control group.

D.3. In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this patient?

Oliguria is a decrease in urinary output to less than 0.3 to 0.5 mL/kg/hr.

ARF is a syndrome characterized by a rapid (hours to weeks) decline in glomerular filtration rate (GFR) and retention of waste products such as urea. Most cases of ARF are reversible, as the kidney is remarkable in its ability to recover from almost complete loss of function. ARF is associated with major in-hospital morbidity and mortality. The diagnosis of ARF usually hinges on changes in serum creatinine, GFR, and urine output.

Causes of renal failure can be grouped into one of three categories:

Prerenal

Prerenal failure is the most common cause of ARF. It is usually caused by a low flow state, such as hypovolemia or cardiac failure. Evaluation begins with reviewing hemodynamic trends, fluid balance, and relevant studies (e.g., echocardiogram). If hypovolemia is suspected, then treatment would consist of a fluid bolus. If the patient's cardiac output is inadequate, then inotropic support and/or diuretics could be administered. Severe renal hypoperfusion may cause ischemic acute tubular necrosis (ATN); therefore, prerenal azotemia and ischemic ATN are part of a spectrum of manifestations of renal hypoperfusion.

Renal

Intrinsic renal failure is generally due to toxic injury or ischemia resulting in glomerular and tubular damage. Ischemic ATN,

unlike prerenal azotemia, is associated with injury to renal parenchyma and does not typically resolve immediately on restoration of renal perfusion. In its more extreme form, renal hypoperfusion may result in bilateral renal cortical necrosis and irreversible renal failure. Urinalysis may show cells or casts that are indicative of ARF. Intrinsic renal failure can be minor and short-lived, or it can progress to chronic renal failure, depending on the severity of the insult.

Postrenal

Urinary tract obstruction accounts for less than 5% of cases of ARF. Urinary tract obstruction must be sought and corrected to treat possible causes of postrenal oliguria. This usually requires irrigation or changing of the Foley catheter. Consider the possibility of an intraoperative mishap causing postrenal obstruction.

Taal MW, Chertow GM, Marsden PA, et al, eds. *Brenner and Rector's The Kidney*. 9th ed. Philadelphia, PA: Saunders Elsevier; 2012:844–867.

D.4. If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?

Leakage of myoglobin from muscles and damaged tissue secondary to a crush injury can result in rhabdomyolysis. Myoglobin at high concentrations precipitates in the nephron, appearing pigmented and causing acute renal injury. The urine may look suspicious for hematuria or have a "tea-colored" appearance. Rhabdomyolysis can be diagnosed by the presence of myoglobinuria or elevated serum creatine kinase levels. Preventing ARF in these patients is essential because the development of ARF is associated with increased mortality. The treatment is hydration with large volumes of crystalloid, resulting in goal urine outputs as high as 100 to 300 mL per

hour. In addition, alkalization of the urine, with agents such as bicarbonate, may help by decreasing the rate of precipitation. Mannitol has also been used to induce an osmotic diuresis and flush the myoglobin through the kidney. Other electrolyte abnormalities, including hyperkalemia, hyperphosphatemia, hypocalcemia, and metabolic acidosis, can develop with crush injury and the patient should be monitored.

58 Scoliosis

Jordan M. Ruby, Victor M. Zayas

A 14-year-old girl with scoliosis is scheduled for posterior spine fusion with segmental instrumentation. She has been told that her scoliosis is idiopathic. Her past medical history is unremarkable, but her mother states that she appears to get short of breath more easily than her friends when she plays basketball.

A. Medical Disease and Differential Diagnosis

1. What is scoliosis?
2. What is the most common type of scoliosis?
3. What are the other types of scoliosis?
4. How is the severity of scoliosis assessed, and why is the severity important?
5. What are the nonoperative treatment options of scoliosis?
6. What abnormalities in pulmonary function tests (PFTs) are most commonly seen in scoliosis? What is the cause of these abnormalities?
7. What is the most common arterial blood gas abnormality seen in scoliosis? What are possible causes for this abnormality?
8. What abnormalities of ventilatory drive may be associated with scoliosis?
9. How may the cardiovascular system be affected in patients

with scoliosis?

10. What is the relationship between scoliosis and malignant hyperthermia?

B. Preoperative Evaluation and Preparation

1. What should the anesthesiologist know about the nature of the spinal curve?
2. What aspects of the history are most important?
3. What aspects of the physical examination are most important?
4. Why is a preoperative neurologic assessment important?
5. What tests would you order preoperatively?
6. What is an enhanced recovery after surgery (ERAS) pathway? How has it been applied to the recovery for pediatric patients undergoing posterior spinal instrumentation and fusion?
7. How will the surgical procedure influence the anesthetic management?

C. Intraoperative Management

1. What monitoring would you use?
2. What is the incidence of neurologic complications in scoliosis surgery, and which patients are at highest risk?
3. What monitoring techniques are used to minimize neurologic complication?
4. What are somatosensory evoked potentials (SSEPs), and how are they used?
5. How reliable are SSEPs for predicting spinal injury?
6. What are motor evoked potentials (MEPs), and how are they used?
7. How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?
8. What is the optimal anesthetic technique for scoliosis surgery?
9. What should be done if the SSEPs or MEPs become abnormal during surgery?
10. How is the “wake-up” test performed? What complications can

occur during this test?

11. Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mmHg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?
12. How common is significant air embolism during scoliosis surgery?
13. What should be done if an air embolus is suspected?
14. What complications occur related to positioning the patient?
15. What is transfusion-related acute lung injury (TRALI)? How do you distinguish it from transfusion-associated circulatory overload (TACO)?
16. What techniques can be used to minimize transfusion requirements?

D. Postoperative Management

1. When would you extubate the patient?
2. What should be done to optimize pulmonary status?
3. What laboratory tests should be ordered postoperatively?
4. What fluid therapy would you use postoperatively?
5. What complications may occur following scoliosis surgery?
6. Upon arrival to the recovery room, you notice that the urine appears to be tea colored. What is your diagnosis, and how should this be managed?
7. How would you manage this patient's pain, nausea, and vomiting postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is scoliosis?

The spine normally curves posteriorly in the thoracic region and anteriorly in the lumbar region. These physiologic curves are the thoracic kyphosis and the lumbar lordosis, respectively. The spine is not normally curved when viewed from the front or back. Scoliosis refers to a lateral curvature of the spine. Curves are classified as structural or nonstructural. A nonstructural curve, such as lumbar scoliosis from a leg length discrepancy, will resolve when the patient is supine or uses a shoe lift and does not require surgical correction. In contrast, structural scoliosis lacks normal flexibility and does not correct with bending or lying supine. In addition to the lateral curvature of the spine, the vertebrae are rotated and the rib cage may be markedly deformed (**Fig. 58.1**). As demonstrated in the computed tomography scan image in **Figure 58.2**, this thoracic deformity may lead to a significant decrease in total lung volume. Particularly, note the decrease in left lung volume relative to the right.

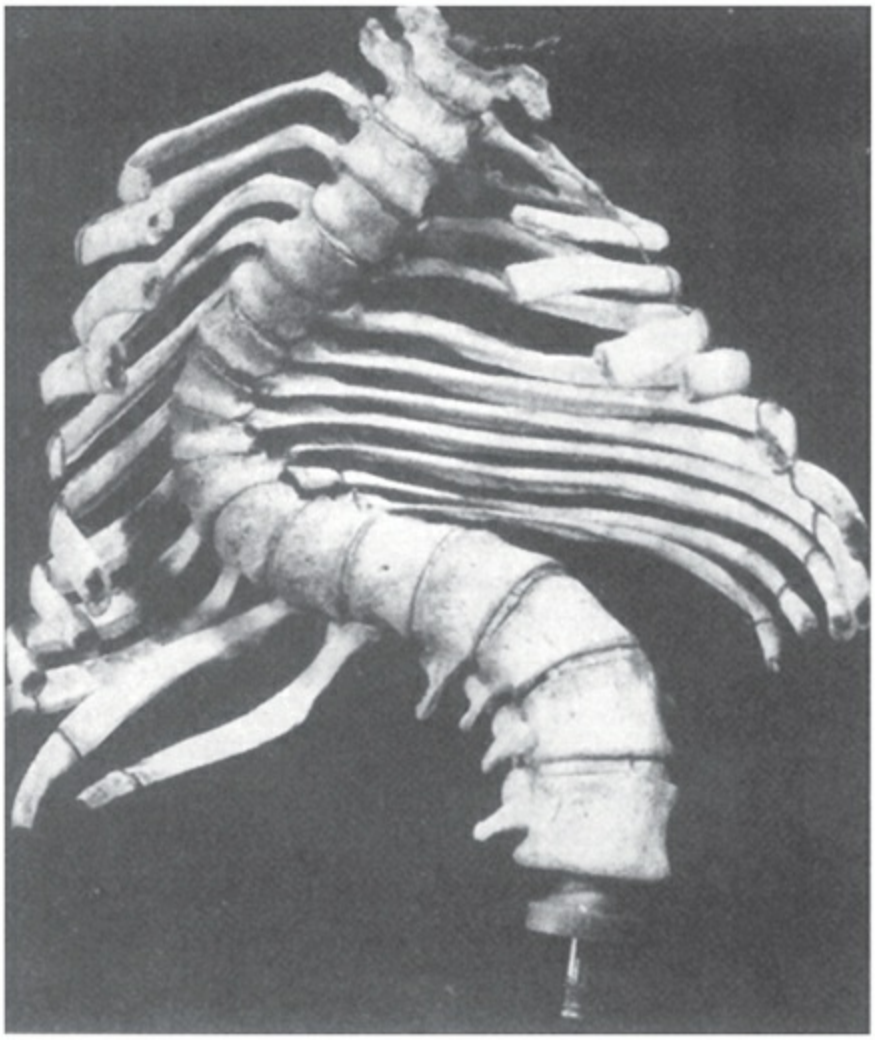

FIGURE 58.1. In addition to producing a lateral deformity of the spine, scoliosis also results in rotation of the vertebral bodies and significant rib cage deformity.

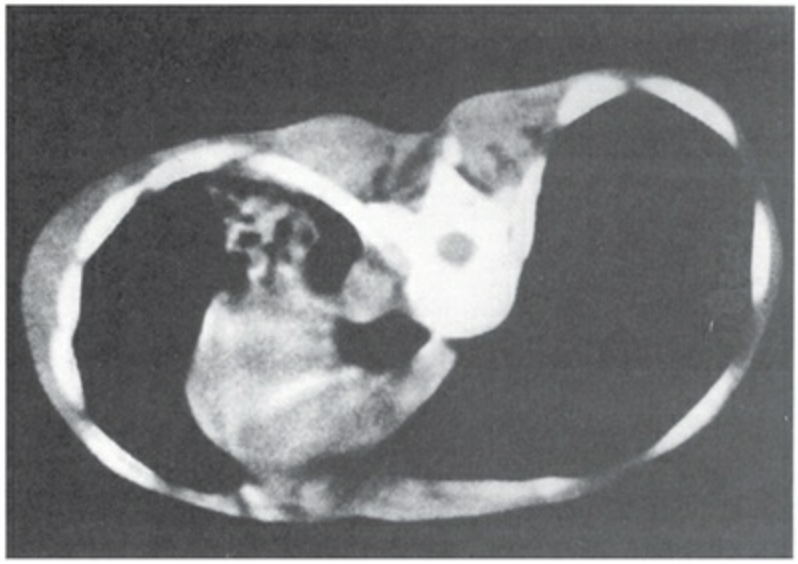

FIGURE 58.2. A computed tomography scan of the thorax demonstrating significant loss of lung volume resulting from the rib cage deformity.

A.2. What is the most common type of scoliosis?

Idiopathic scoliosis is the most common type of scoliosis (70% of all cases) and occurs in infantile, juvenile, and adolescent forms. As the name implies, the cause is unknown but appears to be multifactorial, including abnormalities of collagen, brainstem function, equilibrium, hormones, and growth. Genetic factors are important in its development as evidenced by an 11% incidence of idiopathic scoliosis in first-degree relatives of affected patients. Furthermore, there is a 73% concordance of idiopathic scoliosis among monozygotic twins. Understanding the genetic basis of idiopathic scoliosis is becoming increasingly complex based on the number of associated genes identified by genome-wide association studies. However, the significance of many other genes remains indeterminate. Research is ongoing to further understand the genetic basis of idiopathic scoliosis.

The prevalence of idiopathic scoliosis in large screening

studies depends on the definition of scoliosis and the population screened. The prevalence of spinal curves greater than 10 degrees is 1.5% to 3%; greater than 20 degrees, it is 0.3% to 0.5%; and greater than 30 degrees, it is 0.2% to 0.3%. The adolescent form of idiopathic scoliosis is by far the most common in the United States. The male-to-female prevalence ratio depends in part on the age of the patient, but scoliosis requiring surgical correction is more common in women. The ratio increases with the severity of the curve, with a ratio of girls to boys at 2:1 for curves of 10 degrees, and increasing to 10:1 for curves over 30 degrees.

A.3. What are the other types of scoliosis?

Many etiologic classifications exist for structural scoliosis. Neuromuscular scoliosis may occur as a result of diseases such as cerebral palsy, muscular dystrophy, poliomyelitis, and familial dysautonomia. This type of scoliosis is associated with significantly increased intraoperative blood loss compared with idiopathic scoliosis. Congenital scoliosis is the result of congenital anomalies such as hemivertebrae and fused vertebrae or ribs. Neurofibromatosis and Marfan syndrome are also associated with scoliosis. These underlying conditions may have

a major impact on the anesthetic plan. The classification of scoliosis is as follows:

Idiopathic

- Infantile (birth to 3 years of age)
- Juvenile (4 years of age to 10 years of age)
- Adolescent (10 years of age to skeletal maturity)

Neuromuscular

- Neuropathic
  - Upper motor neuron (e.g., cerebral palsy, spinal cord injury)
  - Lower motor neuron (e.g., poliomyelitis, myelomeningocele, spinal muscular atrophy)
  - Familial dysautonomia

Myopathic

- Muscular dystrophy
- Myotonic dystrophy

Congenital

- Hemivertebrae
- Congenitally fused ribs

Neurofibromatosis

Mesenchymal Disorders

- Marfan syndrome
- Osteogenesis imperfecta
- Arthrogryposis

Trauma

- Vertebral fracture or surgery
- Postthoracoplasty
- Postradiation

A.4. How is the severity of scoliosis assessed, and why is the severity important?

In 1966, the Scoliosis Research Society standardized the method for assessing the severity of scoliosis. The most common measure of severity is Cobb angle. **Figure 58.3** illustrates how Cobb angle is measured on a spine radiograph. A perpendicular (*2*) is constructed from the bottom of the lowest vertebrae (*1*) whose bottom tilts toward the concavity of the curve, and another perpendicular (*4*) from the top of the highest vertebrae (*3*) whose top tilts toward the concavity. The angle (*5*) at which these perpendiculars intersect is Cobb angle. Numerous studies have documented that the more severe the thoracic curve (greater Cobb angle), the more profound the disturbance in pulmonary function. Surgical treatment is usually recommended for curves greater than 45 to 50 degrees. Curves greater than 60 degrees are usually associated with decreases in pulmonary function.

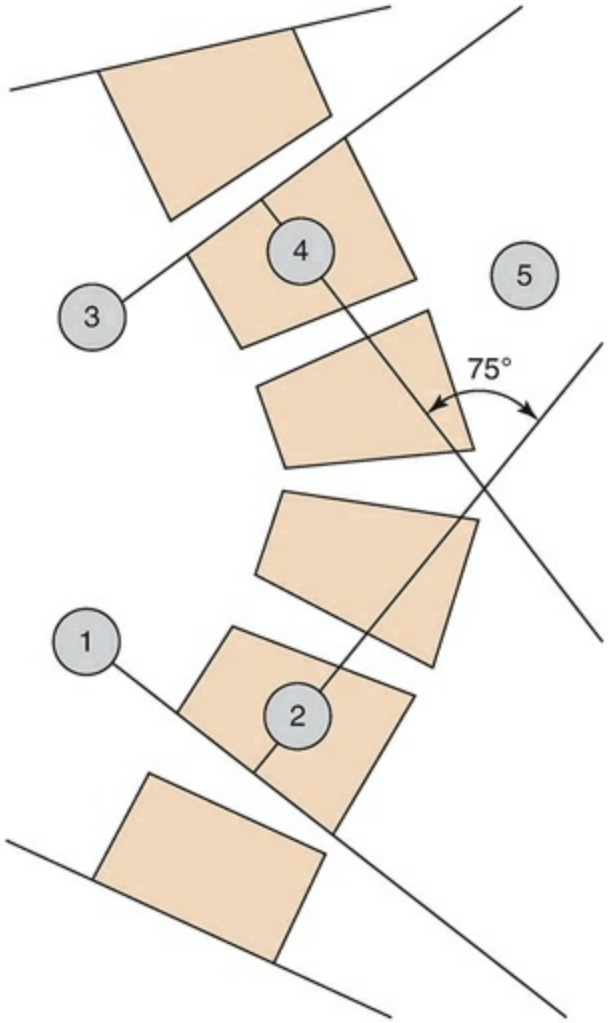

FIGURE 58.3. Measurement of the curve in scoliosis using Cobb angle. (*Reprinted with permission from Levine DB. Scoliosis*. Curr Opin Rheumatol. *1990;2[1]:190-196*.)

In a series of 79 patients with thoracic scoliosis, the mean Cobb angle was 45 degrees and vital capacity was decreased by an average of 22%. **Figure 58.4** demonstrates that forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1) decrease with increasing thoracic curve severity.

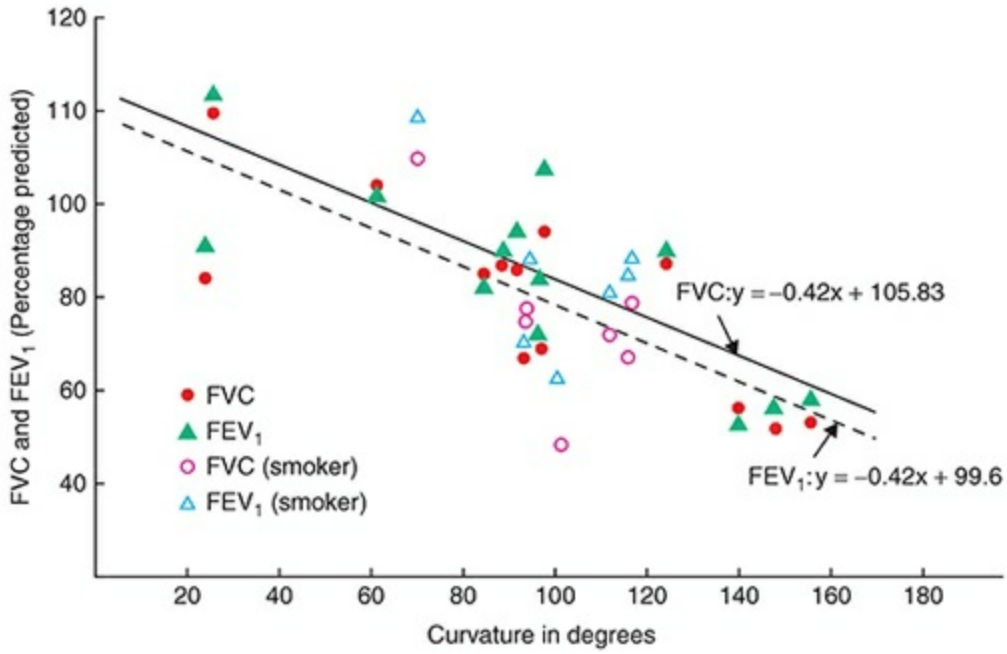

FIGURE 58.4. Relation between forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and size of the curve in 20 patients with thoracic scoliosis. (*Reprinted with permission from Weinstein SL, Zaval DC, Ponseti IV, et al. Idiopathic scoliosis: long-term follow-up and prognosis in untreated patients*. J Bone Joint Surg Am. *1981;63:702–712*.)

Scoliosis severity and impairment of pulmonary function also increase with greater number of vertebrae involved, more cephalad location of the curve, and loss of the normal thoracic kyphosis. Severe curves have a worse prognosis because they tend to progress and, if long-standing, can cause permanent damage of the lung parenchyma, respiratory failure, cor pulmonale, and death. It is important to note that patients with neuromuscular types of scoliosis may have a much more profound decrease in pulmonary function for any given curve severity.

Azar FM, Canale ST, Beaty JH, eds. *Campbell's Operative Orthopaedics*. 13th ed. Philadelphia, PA: Elsevier Mosby; 2017:1897–2120.

Nnadi C, ed. *Early Onset Scoliosis: A Comprehensive Guide from the Oxford Meetings*. Stuttgart, Germany: Thieme; 2015:23–25.

A.5. What are the nonoperative treatment options of

scoliosis?

Those with progressive curves of greater than 25 degrees may be treated initially with rigid bracing (thoracolumbosacral orthosis [TLSO]). Compliance can be problematic due to patient comfort and social stigma. However, the importance of compliance was demonstrated in the Bracing in Adolescent Idiopathic Scoliosis Trial (BrAIST), which showed that bracing significantly decreased the progression to need surgical intervention, with the benefit increasing with more hours of brace compliance.

Similarly, infantile scoliotic curves are sometimes treated with noninvasive measures prior to proceeding with surgical correction. These noninvasive measures are noted to be most successful to halt curve progression when used prior to the development of a 60-degree curve and before 20 months of age. Serial full-body casting is used for infantile scoliosis in lieu of orthotics given the patient's rapid skeletal growth. In order to appropriately place the cast, these patients need to have general endotracheal anesthesia and be placed in a suspension table (**Fig. 58.5**). As these patients grow, they require frequent cast changes, and thus general anesthesia, every 2 to 3 months. The extent to which various anesthetic drugs affect the developing human brain has yet to be fully elucidated thereby warranting a preoperative discussion with the parents, particularly with repeated anesthetics. Care must be taken during the molding of the cast because considerable pressure can be applied to the chest and abdomen. This may result in a significant increase in peak airway pressures and arterial desaturation.

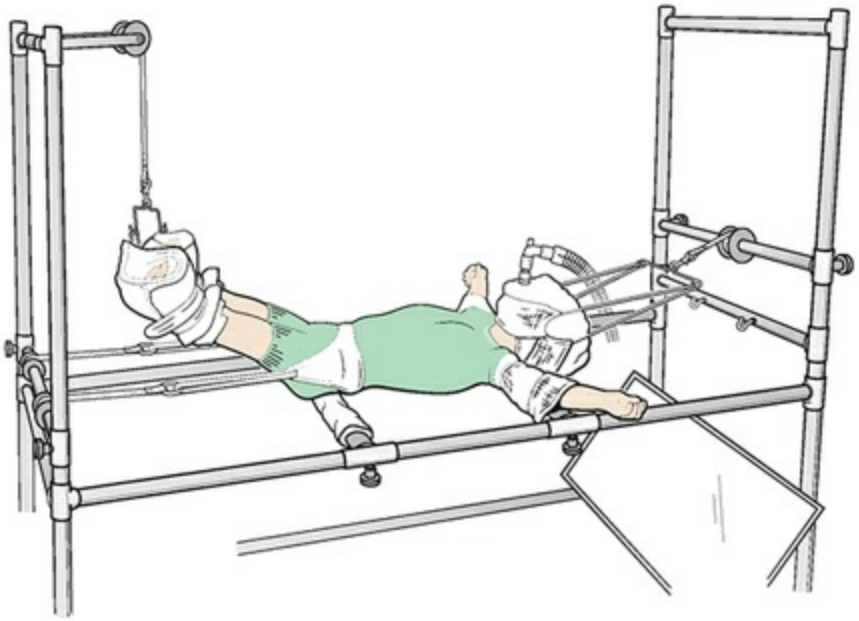

FIGURE 58.5. Example of a positioning used on a traction table for full body casting of infantile scoliosis. (*Reprinted with permission from Sanders JO, D'Astous J, Fitzgerald M, et al. Derotational casting for progressive infantile scoliosis*. J Pediatr Orthop. *2009;29:581*.)

A.6. What abnormalities in pulmonary function tests (PFTs) are most commonly seen in scoliosis? What is the cause of these abnormalities?

A restrictive pattern with decrease in lung volumes is the most common PFT abnormality in thoracic scoliosis. The greatest reduction occurs in vital capacity, which is typically reduced to 60% to 80% of predicted. Total lung capacity, functional residual capacity, inspiratory capacity, and expiratory reserve volume are also decreased. An increase in residual volume has been reported in patients with congenital scoliosis and in patients with idiopathic scoliosis 3 years following corrective

spine fusion.

During exercise, ventilation is adequate, but tidal volume is reduced and respiratory rate is increased. Maximal work capacity may also be decreased. Unless there is coexisting obstructive airway disease, the ratio of FEV_1/FVC is normal. Impaired respiratory muscle function also occurs in scoliosis, as evidenced by a decrease in inspiratory force to 70% of normal values. The decrease in inspiratory force is probably due to the inspiratory muscles working at a mechanical disadvantage because of the chest wall deformity.

These abnormalities in pulmonary function are usually the result of abnormal thoracic cage geometry producing a marked decrease in chest wall compliance rather than any abnormality in the lungs or respiratory muscles themselves. In dynamic magnetic resonance imaging, adolescent girls with idiopathic scoliosis and healthy controls showed no difference in diaphragmatic motion. The changes in chest wall compliance can be mimicked in normal volunteers by chest strapping. Exceptions include congenital and infantile scoliosis in which growth of the lungs may be impaired early in development by the thoracic deformity.

A.7. What is the most common arterial blood gas abnormality seen in scoliosis? What are possible causes for this abnormality?

It has been documented that patients with thoracic scoliosis have arterial oxygen desaturation compared to normal controls. Both arterial P_{CO_2} and pH are usually normal. Several studies have failed to show a correlation between the severity of the spinal curve and the degree of arterial oxygen desaturation.

Arterial hypoxemia is probably caused by ventilation/perfusion ($\dot{V}/\dot{Q}$) inequalities. Decreased diffusing capacity and alveolar hypoventilation may also play a role. Nevertheless, the diffusing capacity is not decreased sufficiently to be the sole cause of the hypoxemia. Similarly, alveolar ventilation at rest and during exercise is usually normal; therefore, arterial P_{CO_2} is usually normal. It has been reported that some patients have a closing capacity higher than functional residual capacity, resulting in premature airway closure during normal tidal breathing. Other studies have failed to demonstrate this finding. Some authors have reported an increase in the ratio of dead space to tidal volume (V_D/V_T), whereas other recent series have found V_D/V_T to be normal. This discrepancy may be related to the patient population studied, the severity of the scoliosis, or both. Severe and long-standing scoliosis can produce severe abnormalities, alveolar hypoventilation, carbon dioxide retention, and more severe hypoxemia. If not surgically treated, severe scoliosis increases the risk of premature death from respiratory failure after 40 years of age. A survey of

patients with respiratory failure in Sweden found that a vital capacity less than 50% of predicted and a Cobb angle greater than 100 degrees indicated an increased risk of respiratory failure.

A.8. What abnormalities of ventilatory drive may be associated with scoliosis?

The slope of the ventilatory response to carbon dioxide may be decreased in patients with scoliosis. This is probably not specific to scoliosis because this response is known to be reduced in situations in which the work of breathing is increased even in the absence of a chest wall deformity. Patients with mild scoliosis have been reported to exhibit abnormal ventilatory patterns in response to hypoxemia and hypercarbia. This pattern tends to minimize the work of breathing, a higher respiratory rate, and lower tidal volume.

It has also been demonstrated that during maximal exercise, patients with mild-to-moderate scoliosis exhibit a significantly decreased ventilatory capacity, reduced exercise tolerance, and oxygen consumption despite normal pulmonary function testing at rest.

Barrios C, Pérez-Encinas C, Maruenda JI, et al. Significant ventilatory functional restriction in adolescents with mild or moderate scoliosis during maximal exercise tolerance test. *Spine (Phila Pa 1976)*. 2005;30:1610–1615.

A.9. How may the cardiovascular system be affected in patients with scoliosis?

Patients with scoliosis may develop elevated pulmonary vascular resistance and pulmonary hypertension. This may result in right ventricular hypertrophy and eventually right ventricular failure. A 50-year study of untreated scoliosis demonstrated that the mortality rate of these patients was twice that of the general population and respiratory failure or right-sided heart failure accounted for 60% of the deaths.

The increase in pulmonary vascular resistance is probably due to several factors. Hypoxemia produces pulmonary vasoconstriction, an increase in pulmonary vascular resistance, and hence an increase in pulmonary arterial pressure. Chronic hypoxemia will produce hypertensive vascular changes, and pulmonary hypertension may become irreversible. It has also been proposed that the chest wall deformity compresses some lung regions, increasing vascular resistance in those regions. Finally, if scoliosis develops in the first 6 years of life, the growth of the pulmonary vascular bed may be impaired by the chest wall deformity. Supporting this concept are reports of a decrease in the number of vascular units per lung volume in patients with scoliosis.

The most common cardiovascular abnormality in patients with scoliosis is mitral valve prolapse. Some conditions that are associated with scoliosis also affect the cardiovascular system. Patients with Duchenne muscular dystrophy develop a cardiomyopathy in the second decade of life that may not be appreciated on the basis of clinical symptoms because these patients are unable to exercise. The electrocardiogram (ECG)

may reveal tachycardia, prolonged PR and QRS intervals, ST abnormalities, bundle branch block, Q waves in the left precordial leads, and tall R waves in the right precordial leads. The ejection fraction may be decreased on echocardiogram.

Patients with Marfan syndrome may have mitral and aortic insufficiency, aneurysm of the proximal ascending aorta, and abnormalities of the conduction system.

The association of scoliosis and congenital heart disease has been well established. Although no specific cardiac lesion has been identified, some series have suggested that scoliosis is more common in patients with cyanotic heart disease.

A.10. What is the relationship between scoliosis and malignant hyperthermia?

In the past 40 years, there has been no supportive evidence of a direct relationship. However, some scoliosis patients may have associated or underlying muscle disorders such as central core disease or multiminicore disease (also see Chapter 54, section A.3). These muscular dystrophies are associated with an increased risk of malignant hyperthermia.

B. Preoperative Evaluation and Preparation

B.1. What should the anesthesiologist know about the nature of the spinal curve?

It is important to identify the location of the curve, the age of onset, its severity, the direction of the curve, and the etiology of the scoliosis. The location of the curve is important because thoracic scoliosis is associated with pulmonary function abnormalities. Cervical scoliosis may cause difficulties in airway management and may be associated with other congenital anomalies.

The age of onset of scoliosis is of critical importance because the lung continues to grow and develop from birth until 8 years of age. The number of alveoli increases from approximately 20 million at birth to 250 million at 4 years of age. The development of significant thoracic scoliosis during this phase of rapid growth impairs lung development. A significant reduction in alveolar number has been demonstrated in patients with early-onset thoracic scoliosis, predisposing these patients to impaired gas exchange and pulmonary hypertension.

The severity of the curve is important because thoracic curves greater than 60 degrees generally produce significant decreases in pulmonary function. Curves greater than 100 degrees may be associated with significant impairment in gas exchange. Most curves in adolescent idiopathic scoliosis are convex to the right, just as most people are right-handed. A left thoracic convexity should raise the index of suspicion to look for other underlying conditions and congenital anomalies. Finally, an understanding of the etiology of the scoliosis is important because underlying conditions such as muscular dystrophy or cerebral palsy will influence anesthetic management.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of*

Anesthesia for Infants and Children. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

B.2. What aspects of the history are most important?

Initially, cardiopulmonary function should be assessed by inquiring about the patient's exercise tolerance. As a general rule, patients who can exercise normally and "keep up with friends" in vigorous activities will have good cardiopulmonary function. Pulmonary symptoms such as episodes of wheezing or cough may indicate parenchymal or reactive lung disease and alter perioperative management. Patients with muscular dystrophy, Marfan syndrome, and neurofibromatosis should be questioned about symptoms suggestive of cardiac conduction abnormalities such as palpitations or syncope.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

B.3. What aspects of the physical examination are most important?

Particular emphasis in the physical examination should be directed toward the heart and lungs. Auscultation of the lungs may reveal wheezing or rales suggesting obstructive airway disease or parenchymal lung disease. On examination of the heart, in addition to auscultating for murmurs and gallops, signs of pulmonary hypertension and right ventricular hypertrophy should be sought. Pulmonary hypertension causes accentuation of the pulmonic component of the second heart sound, and a right ventricular lift indicates right ventricular enlargement. Signs of right ventricular failure include engorged neck veins, an enlarged liver resulting from passive liver congestion, and lower extremity edema. If neurofibromatosis is suspected, the skin should be examined for the presence of *café au lait spots* or cutaneous neurofibroma. The airway should be evaluated closely

for abnormalities such as cervical scoliosis, neurofibroma, or high-arched palate associated with Marfan syndrome that may make endotracheal intubation difficult.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

B.4. Why is a preoperative neurologic assessment important?

A preoperative neurologic assessment is important because patients who have preexisting neurologic deficits are at increased risk for developing spinal cord injury during scoliosis surgery. Furthermore, it is important to document preoperative neurologic function in order to avoid confusion about postoperative neurologic complications.

If a patient has a ventriculoperitoneal shunt for hydrocephalus, it should be evaluated preoperatively by the patient's neurosurgeon. The shunt can malfunction during correction of the spinal deformity via disconnection, fracture, kinking, or inadequate length.

Abu-Sneineh K, Lipton GE, Gabos PG, et al. Dysfunction of a ventriculoperitoneal shunt after posterior spinal fusion in children with cerebral palsy: a report of two cases. *J Bone Joint Surg Am*. 2003;85:1119–1124.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

B.5. What tests would you order preoperatively?

It is best to tailor diagnostic testing based on the severity of the scoliosis and underlying conditions. In the current climate emphasizing medical cost containment, each institution needs to critically reassess preoperative testing. Preoperatively, this healthy 14-year-old may only need a complete blood count and a

type and screen. If the history or physical examination suggests that pulmonary reserve is decreased, then standard pulmonary function testing should be considered. If vital capacity is significantly diminished, an arterial blood gas measurement is indicated. If routine pulmonary function testing reveals evidence of obstructive airway disease (a decrease in the ratio of FEV_1/FVC or a decrease in forced expiratory flow [25% to 75%]), a bronchodilator should be administered to determine if the airway obstruction is reversible.

Patients with onset of scoliosis in the first 8 years of life should have pulmonary function testing, arterial blood gas analysis, and an ECG. If the ECG reveals abnormalities such as right ventricular hypertrophy (large R wave in V_1 and V_2), right atrial enlargement (P_{wave} greater than 2.5 mm), or evidence of a cardiomyopathy, an echocardiogram or even cardiac catheterization may be indicated, particularly if pulmonary hypertension is suspected.

B.6. What is an enhanced recovery after surgery (ERAS) pathway? How has it been applied to the recovery for pediatric patients undergoing posterior spinal instrumentation and fusion?

The concept of ERAS was initially developed to examine and address the variability of surgical practices in concordance with evidence-based best practices. The first evidence-based consensus ERAS protocol was described in 2005 in adult

patients undergoing colorectal surgery. In 2010, the ERAS Society was founded with a mission to improve recovery through research, education, and implementation of evidence-based best practices. Recently, many centers have developed pathways for pediatric patients undergoing posterior spinal instrumentation and fusion. These protocols adapt components of ERAS with a standardized multidisciplinary perioperative approach for each patient during the preadmission, preoperative, intraoperative, and postoperative periods with an overarching goal of creating a best practice for these patients. However, a consensus best practice ERAS protocol encompassing the entire scope of perioperative care for pediatric patients undergoing spinal instrumentation and fusion has not been formulated.

Nevertheless, many centers have adapted components of ERAS protocols to their pathways while managing the perioperative care of patients with adolescent scoliosis. Prior to surgery, these patients will have the appropriate labs drawn and will be instructed to scrub with chlorhexidine the evening prior to surgery to reduce the incidence of infection. Patients may also be advised to drink a carbohydrate-rich beverage the morning of surgery, which has been shown to significantly reduce postoperative insulin resistance. Some will consider donating autologous blood in the weeks leading up to surgery to avoid an allogeneic transfusion. Patients will be educated how to use an incentive spirometer and how to potentially undergo a wake up test (see subsequent text). Intraoperatively, posterior spinal fusion pathways will focus on initiating multimodal analgesic therapies, preventing neurologic complications associated with the operation and positioning, and decreasing perioperative blood loss and the need for an allogeneic blood transfusion with antifibrinolytic therapy and the use of cell salvage. The postoperative course is structured to facilitate early recovery, rehabilitation, and the return to normal function. Several

multidisciplinary professionals, including orthopedic surgery, pain management, physical therapy, and nursing will work collectively to facilitate these goals. Implementation of posterior spinal fusion recovery pathways has demonstrated a decrease in length of hospital stay and a decrease in health care costs.

B.7. How will the surgical procedure influence the anesthetic management?

A variety of surgical procedures are commonly performed for posterior spine fusion. The blood lost during these procedures may be considerable and varies according to the procedure, the operative time, the number of segments fused (>6), the degree of Cobb angle (>50 degrees), the need for osteotomies, whether deliberate hypotension is used, and other factors. Even when deliberate hypotension is employed, blood loss in the range of 15 to 25 mL per kg is not uncommon during uncomplicated spine fusion with segmental instrumentation. This represents a

blood loss of 1 to 2 L for a 70-kg patient.

Postoperative bleeding may equal or exceed this, emphasizing the need for continued monitoring of these patients in the postoperative period. More extensive procedures such as combined anteroposterior spine fusion, instrumentation into the pelvis, or especially osteotomy of the spine to correct rigid deformities may be associated with blood loss exceeding the patient's own blood volume (75 mL per kg). Patients who require these more extensive procedures are frequently those with neuromuscular scoliosis (Duchenne muscular dystrophy, cerebral palsy) who may already have diminished reserves. Before the patient is taken to the operating room, the anesthesiologist should confirm that the blood bank has the anticipated blood products readily available.

Moderate third-space losses of intravascular fluid occur during scoliosis surgery. These should be replaced with balanced salt solution at a rate of 5 to 7 mL/kg/hr. This is in addition to any deficit or maintenance requirements. Procedures that are more extensive may require higher infusion rates.

The anesthesiologist should speak with the surgeon about the surgical approach and technique. The surgical plan could affect the patient's position during the case. For example, patients undergoing an anterior approach or thoracotomy may need to be positioned laterally. Another consideration is whether the surgeon requires single-lung ventilation in which case the patient may need a double-lumen endotracheal tube.

C. Intraoperative Management

C.1. What monitoring would you use?

Basic monitoring for posterior spine fusion should include blood pressure, ECG, pulse oximetry, end-tidal carbon dioxide, esophageal stethoscope, core temperature, and spinal cord monitoring. A radial artery catheter is used for continuous monitoring of blood pressure, particularly if deliberate hypotension is planned to reduce blood loss. This will also facilitate obtaining blood samples for blood gas and hematocrit determination. All patients should have a urinary catheter placed to document urine output during and particularly after the surgical procedure. Monitoring of central filling pressures may be indicated if the expected blood loss is large, or cardiovascular disease is present or suspected. Although rarely placed in routine idiopathic scoliosis surgery, a pulmonary artery catheter may be useful in patients with cardiomyopathy from Duchenne muscular dystrophy, and patients with pulmonary hypertension or right ventricular failure, in order to optimize volume replacement therapy. When placing pulmonary artery catheters in patients with pulmonary hypertension, it must be considered that the risk of pulmonary artery rupture, a complication with a mortality rate of 50%, is increased in patients with pulmonary hypertension. An alternative technique is the transesophageal echocardiography (TEE), but this requires special expertise, and vigilance must be used when using the TEE probe for a lengthy operation in the prone position.

If neuromuscular block is used throughout the case, be certain to monitor continuously and discuss this with the neuromonitoring team in case there is any confusion interpreting the MEPs.

Anesthesia for Infants and Children. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

C.2. What is the incidence of neurologic complications in scoliosis surgery, and which patients are at highest risk?

In a morbidity report of the Scoliosis Research Society (2006), the rate of complete or partial paraplegia was 0.26%. A study of 6,334 patients undergoing anterior, posterior, or combined anteroposterior spinal fusion reported an overall rate of spinal injury of 0.28%. Of note, combined anteroposterior procedures had a significantly higher rate of spinal cord injuries (1.12%) compared to anterior (0.0%) and posterior (0.21%) procedures.

It has been proposed that distraction of the cord and straightening of the deformity compresses the spinal cord and disrupts the arterial blood supply of the cord. The spinal cord and nerve roots may also be injured directly by hooks or instrumentation.

Prevention of neurologic complications begins with identification of the high-risk group. Patients are at increased risk for developing paraplegia if they have a severe rigid deformity (greater than 120 degrees), kyphosis, neurofibromatosis, congenital or postinfectious scoliosis, a preexisting neurologic deficit, or more invasive instrumentation. Congenital scoliosis is associated with intraspinal anomalies including lipomas, tethered cord, cysts, and teratomas that also increase the risk of postoperative neurologic complications. A preoperative myelogram or magnetic resonance imaging is indicated in these patients. Preoperative prophylaxis with high-dose corticosteroids should be considered for patients with a preexisting neurologic deficit.

Kocher MS, Millis MB, eds. *Operative Techniques: Pediatric Orthopaedic Surgery*. Philadelphia, PA: Elsevier Saunders; 2011:719–730.

C.3. What monitoring techniques are used to minimize neurologic complication?

The two monitoring techniques most commonly used in the United States to monitor spinal cord function during scoliosis surgery are SSEPs and MEPs. Some centers continue to use the intraoperative wake-up test, although MEP monitoring has replaced the routine use of the wake-up test in many centers. The intraoperative wake-up test may still be required if SSEPs or MEPs become abnormal during the surgical procedure.

Schwartz D, Auerbach J, Dormans JP, et al. Neurophysiological detection of impending spinal cord injury during scoliosis surgery. *J Bone Joint Surg Am*. 2007;89(11):2440–2449.

C.4. What are somatosensory evoked potentials (SSEPs), and how are they used?

Sensory information from the periphery passes through the posterior columns of the spinal cord on its way to the cerebral cortex. The functional integrity of this pathway can be continually assessed by monitoring SSEPs. This technique involves applying repeated electrical stimuli to a peripheral nerve (e.g., posterior tibial nerve) and measuring the evoked response over the cerebral cortex and subcortical regions using standard electroencephalogram scalp electrodes (**Fig. 58.6**). These evoked potentials are of very low amplitude, so computer averaging or summation must be used to distinguish these potentials from background noise and the patient's electroencephalogram. A typical evoked potential waveform is

shown in **Figure 58.7**. The time interval between electrical stimulation of peripheral nerve to recording the evoked response over the cortex is defined as the latency. An increase in the latency (slower conduction), a decrease in the amplitude, or a complete loss of the evoked potential should be considered indicative of surgical injury or ischemia until proved otherwise. It is difficult to define standard values for latency and amplitude because of the differences in recording technique among laboratories, and therefore, it is important to be familiar with the normal limits for the system that is in use. In general, an increase in latency of 10% to 15% or more and a decrease in amplitude of greater than 50% should be cause for concern.

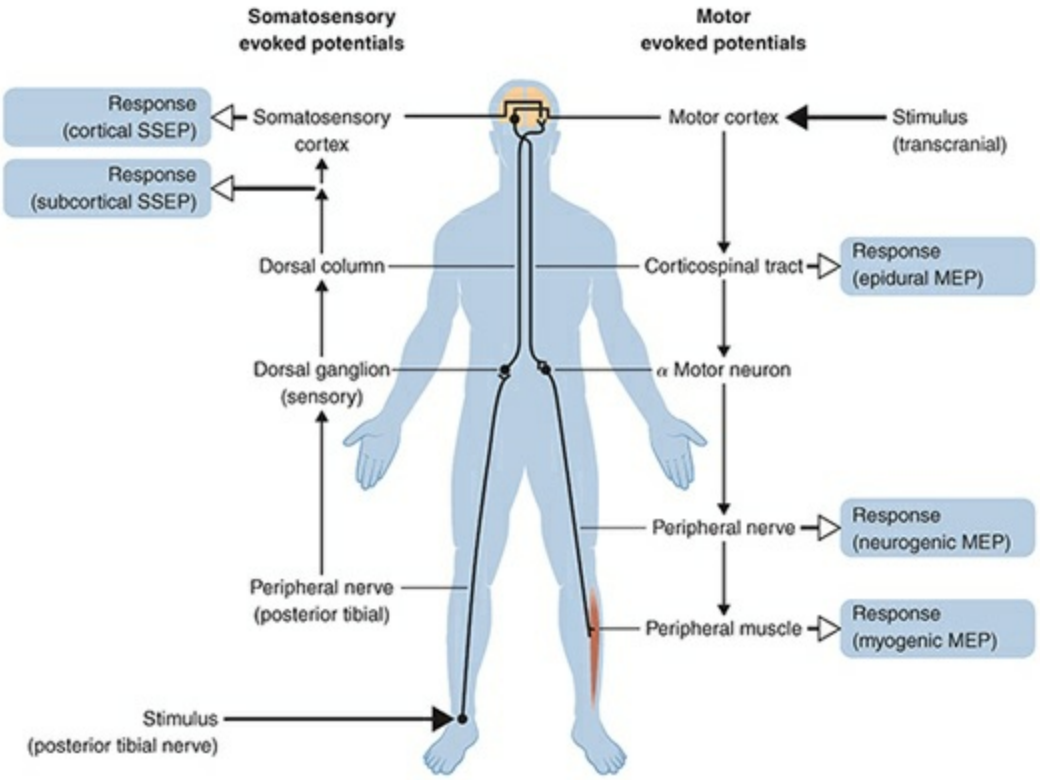

FIGURE 58.6. Outline of pathways involved in somatosensory evoked potential (SSEP) and motor evoked potential (MEP) monitoring. (*Modified from de Haan P, Kalkman CJ. C.5. How reliable are SSEPs for predicting spinal injury?

Normal intraoperative SSEPs are good predictors of normal postoperative sensory function. Although posterior (sensory) and anterior (motor) spinal injuries tend to occur together during spine surgery or spinal trauma, there have been reports of postoperative paraplegia with normal intraoperative SSEPs. This probably represents selective ischemia in the distribution of the anterior spinal artery. Sensory function and SSEPs are preserved because the posterior columns receive their blood supply from the posterior spinal arteries. For this reason, it is probably best not to rely exclusively on SSEPs to monitor spinal cord function during scoliosis surgery.

In a survey of 173 orthopedic spinal surgeons, it was found that experienced SSEP monitoring teams had fewer neurologic complications per 100 cases than teams with less experience.

Neurologic defects with normal SSEPs (false negative) occurred in only 0.063% of cases.

C.6. What are motor evoked potentials (MEPs), and how are they used?

MEPs assess the integrity of the spinal motor pathways (anterior columns). MEPs are elicited by transosseous electrical stimulation of the motor cortex using scalp electrodes or by stimulation of the anterior columns using epidural electrodes. Conduction of these stimuli through the motor pathways is monitored as peripheral nerve impulses, electromyographic signals, or actual limb movements (**Fig. 58.6**).

In a study of 144 patients undergoing spinal deformity correction surgery, the authors report a sensitivity of 1 and a specificity of 0.97 using transcranial MEPs as the sole modality. No patient had any new neurologic deficits.

Koht A, Sloan TB, Toleikis JR, eds. *Monitoring the Nervous System for*

Anesthesiologists and Other Health Care Professionals. New York: Springer; 2017:19–34.

C.7. How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?

All anesthetic agents may affect spinal monitoring to a varying degree. This has been documented for potent inhalation agents, propofol, nitrous oxide, benzodiazepines, droperidol, etomidate, ketamine, barbiturates, and even opioids. Opioids probably have the least effect on SSEPs of all of these agents. Cortical SSEPs and MEPs are very sensitive to nitrous oxide and potent inhalational agents, whereas subcortical SSEPs are more resistant. The addition of nitrous oxide to isoflurane has been shown to have a profound effect on MEPs. MEPs are also profoundly affected by benzodiazepines and thiopental, whereas ketamine may enhance MEPs.

Nitrous oxide produces a decrease in amplitude in SSEPs without an increase in latency. Isoflurane, sevoflurane, halothane, and so on have similar effects on SSEPs; a dose-dependent increase in latency and decrease in amplitude. The addition of nitrous oxide appears to produce a larger decrease in amplitude than addition of 1% isoflurane or enflurane to a fentanyl-based anesthetic.

Muscle relaxants have no effect on SSEPs or MEP impulses monitored from peripheral nerves. They will affect the intensity of the motor response, which may lead to confusion in interpreting MEPs.

Although it is important to realize that anesthetic agents can affect spinal cord monitoring, excellent results can be obtained if anesthetic depth is stable. For example, it is preferable to administer opioids by continuous infusion rather than by intermittent doses. It is most important to maintain a stable

anesthetic before and during periods when monitoring is critical, that is, during spine distraction or instrumentation.

A decrease in arterial pressure below levels of cerebral autoregulation, hypothermia, hematocrits below 15%, and hypoxia will affect both SSEPs and MEPs.

Bernard JM, Péréon Y, Fayet G, et al. Effects of isoflurane and desflurane on neurogenic motor- and somatosensory-evoked potential monitoring for scoliosis surgery. *Anesthesiology*. 1996;85:1013–1019.

C.8. What is the optimal anesthetic technique for scoliosis surgery?

There is no simple answer for the optimal anesthetic technique. Most patients with idiopathic scoliosis are healthy adolescents who tolerate anesthesia and surgery well, and a wide variety of techniques have been used successfully. Many healthy teenagers have a much higher tolerance for opioids and benzodiazepines and will have higher requirements for these agents intraoperatively, compared to adults. The primary concern is the ability to provide an anesthetic that is suitable for spinal cord monitoring while providing analgesia and amnesia. Prior to the use of MEP monitoring, anesthetic techniques were tailored to facilitate the wake-up test. Monitoring of MEPs has now replaced routine use of the wake-up test in many centers. Although cortical SSEPs and MEPs may be measurable in most healthy adults receiving 50% to 70% nitrous oxide and 0.5 minimal alveolar concentration isoflurane, this combination is not suitable in small children with immature corticospinal tracts or those with preexisting neurologic deficits. Furthermore, MEPs may be more sensitive to the combination of nitrous oxide

and potent inhalational agents than cortical SSEPs.

Therefore, a typical anesthetic is a combination of a low-dose potent agent (e.g., isoflurane 0.4%) in 50% oxygen per air mixture, with a low-dose propofol infusion and primarily opioid-based intravenous anesthetic. Intravenous midazolam should be given before induction for anxiolysis and amnesia. Small doses may be repeated later if necessary. An infusion of ketamine at a low dose (0.1 to 0.2 mg/kg/hr) may improve MEP monitoring. Many centers use total intravenous anesthesia. Dexmedetomidine has been used as an adjunct in total intravenous anesthesia with minimal effect on MEPs and SSEPs. Muscle relaxants, if used, should be administered by continuous infusion and titrated to a constant train-of-four because the neuromuscular blockade will affect the intensity of the motor response. A baseline set of SSEPs and MEPs should be performed by the neuromonitoring technician as early as possible, ideally before incision, so that changes to the anesthetic or monitoring technique can be made before the most critical part of the operation (i.e., spine distraction and instrumentation).

Succinylcholine should be avoided in patients with muscle disorders. Its administration in patients with Duchenne muscular dystrophy may produce hyperkalemia, cardiac arrhythmias, myoglobinuria, or precipitate malignant hyperthermia. Patients with myotonic muscular dystrophy may exhibit sustained skeletal muscle contractions in response to succinylcholine. This may produce difficulty in ventilation and intubation.

C.9. What should be done if the SSEPs or MEPs become abnormal during surgery?

If spinal cord monitoring becomes abnormal, the anesthesiologist should ensure that oxygen delivery and spinal cord perfusion are adequate. Hypovolemia and anemia should be corrected. Arterial oxygen tension should be optimized, and arterial P_{CO_2} should be normalized if the patient is being hyperventilated. It has been reported that normalizing arterial pressure if deliberate hypotension is being used or raising arterial pressure above normal may improve spinal cord perfusion and restore SSEPs to normal. The surgeon should seek a surgical cause such as too much distraction or surgical trespass with instrumentation and correct the problem as quickly as possible. If the abnormality persists despite corrective action, a wake-up test should be considered to determine if the instrumentation should be adjusted or removed. Some surgeons may elect to abort the procedure if there is no improvement of neurophysiologic signals. Additionally, some centers advocate to administer high-dose steroids when evoked potential signals do not recover. There is evidence that the shorter the interval between detection of injury and removal of instrumentation, the better is the neurologic outcome.

correction of scoliosis. *J Neurosurg Anesthesiol*. 2004;16(2):167–170.

C.10. How is the "wake-up" test performed? What complications can occur during this test?

The wake-up test is used to assess the integrity of the spinal motor pathways and is performed by "lightening" the depth of anesthesia sufficiently to allow the patient to follow commands. This is usually done as soon as all instrumentation is in place or if an abnormality has been detected with spinal cord monitoring. The patient is first instructed to squeeze the anesthesiologist's hand, confirming that he or she is responsive, and then asked to move his or her feet and toes. Often, the patient wake-up is not a calm event, and the patient wakes up suddenly and moves his or her head and limbs simultaneously. If the patient is able to squeeze his or her hands but unable to move his or her feet, the amount of spine distraction must be reduced until a safe degree of correction is achieved, and in some cases, the hardware is removed. When the patient moves his or her feet, anesthesia is quickly deepened with small doses of propofol (0.5 mg per kg). Additional short-acting benzodiazepines may be given. Recall of intraoperative events is very unusual with this technique.

The anesthesiologist should have one or two assistants available in the event the patient moves excessively during the wake-up test. Although this occurs rarely when an adequate amount of opioid has been administered, it is best to be prepared. The authors do not recommend use of opioid antagonists because of the potential for the patient to experience pain and become agitated in the prone position. If naloxone is deemed necessary to arouse the patient, a small dose (0.3 to 0.5 μg per kg) should be administered and repeated every 2 to 3 minutes until the respiratory depression of the opioid is reversed. It is not typically necessary to reverse neuromuscular blockade if at least three twitches are present on train-of-four stimulation.

Complications of this technique include extubation in the prone position, recall of intraoperative events, myocardial ischemia, self-injury, and dislodgment of instrumentation or intravenous access. Air embolus from open venous sinuses may occur if the patient is breathing spontaneously and inhales vigorously.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

Kocher MS, Millis MB, eds. *Operative Techniques: Pediatric Orthopaedic Surgery*. Philadelphia, PA: Elsevier Saunders; 2011:719–730.

C.11. Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mmHg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?

This constellation of symptoms strongly suggests venous air embolism. There are at least two reports indicating that air bubbling in the wound may be the first clinical sign of an air embolus before cardiovascular collapse. This is thought to occur as a result of retrograde flow of blood containing entrained air through the valveless venous system as a result of an increase in central venous pressure. Central venous pressure rises as a result of an air lock in the right heart. Positive pressure ventilation and pressure on the spine during placement of hardware may also produce bubbling of entrained air.

Spinal Disord. 1990;3:1–5.

Wills J, Schwend RM, Paterson A, et al. Intraoperative visible bubbling of air may be the first sign of venous air embolism during posterior surgery for scoliosis. *Spine (Phila Pa 1976)*. 2005;30:E629–E635.

C.12. How common is significant air embolism during scoliosis surgery?

Fortunately, clinically significant air embolism is uncommon. Nevertheless, cases of fatal air embolism have been reported during scoliosis surgery in children. Most, but not all, cases involve extensive surgical dissection with excessive bleeding. The mortality rate in the reported cases may be 50%.

Wills J, Schwend RM, Paterson A, et al. Intraoperative visible bubbling of air may be the first sign of venous air embolism during posterior surgery for scoliosis. *Spine (Phila Pa 1976)*. 2005;30:E629–E635.

C.13. What should be done if an air embolus is suspected?

If an air embolus is suspected, the surgical field should be immediately flooded with saline, ventilation begun with 100% oxygen, and intravascular fluid administered to increase central venous pressure. Air is most likely entrained from open epidural and paravertebral veins and venous sinuses in decorticated bone. Flooding the field with saline prevents air entrainment. Ventilation with 100% oxygen reduces the volume of the air embolus, particularly if nitrous oxide was administered. Hypovolemia and low central venous pressure favor air entrainment by increasing the pressure gradient between open veins and the right atrium.

If the patient requires cardiopulmonary resuscitation, placing the patient in the left lateral decubitus position during external cardiac massage may improve blood flow by breaking the air lock of the pulmonary outflow tract. Removing air through either a central catheter or by direct intracardiac aspiration has also been advocated.

Sutherland RW, Winter RJ. Two cases of fatal air embolism in children undergoing scoliosis surgery. *Acta Anaesthesiol Scand*. 1997;41:1073–1076.

C.14. What complications occur related to positioning the patient?

If the head is not positioned carefully, pressure on the eyes may cause thrombosis of the central retinal artery producing loss of vision or blindness. The horseshoe-type headrest (**Fig. 58.8**) has been implicated in a number of reports of unilateral eye blindness and should not be used for long procedures. The head should be positioned without excessive flexion or extension and in such a way that the face and eyes can be inspected easily. The position of the head and neck will move during surgical manipulation of the spine and should be inspected frequently during the procedure. It is extremely helpful to have a mirror under the patient's face that can be viewed throughout the case (**Fig. 58.9**). Patients with Marfan syndrome and neurofibromatosis may have abnormalities of the cervical spine and must be turned and positioned with great caution.

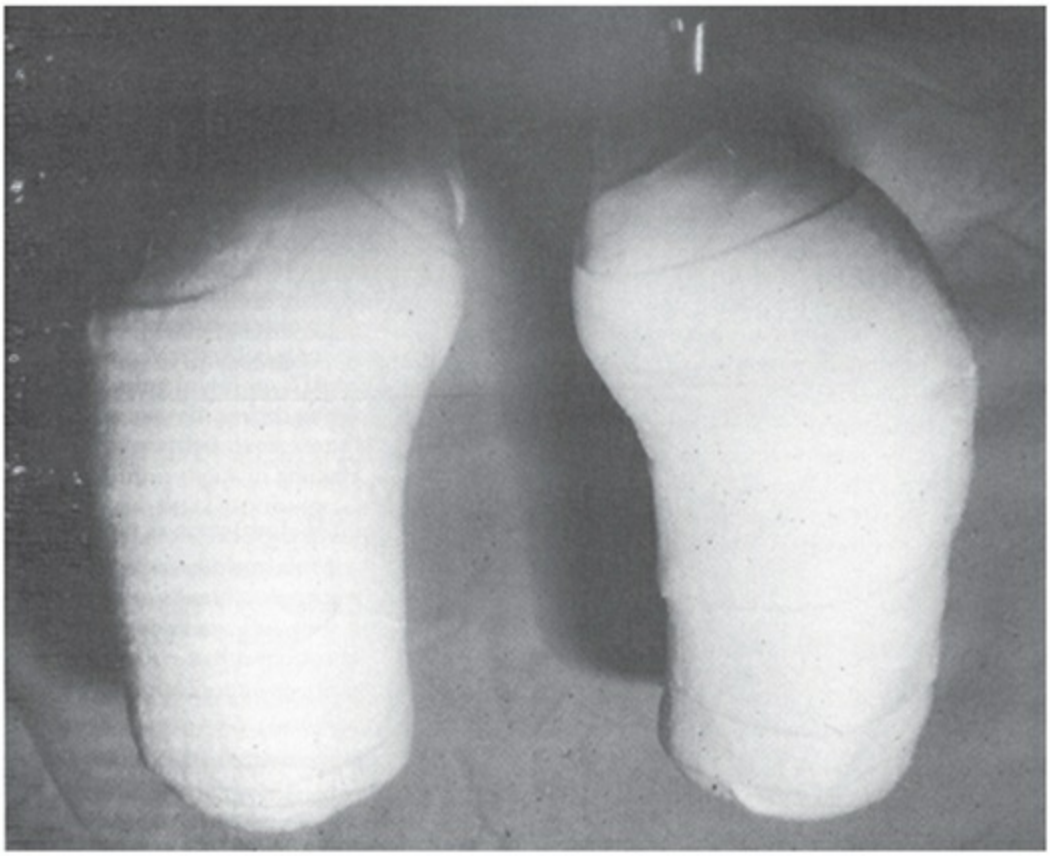

FIGURE 58.8. This horseshoe-type headrest has been associated with unilateral eye blindness resulting from pressure on the eye during surgery. The forehead rests on the upper portion, with the chin free in the wider, open portion.

FIGURE 58.9. Foam face rest with mirror.

The upper extremities should be positioned at no more than 90 degrees of abduction to the trunk, as illustrated in **Figure 58.10A**. **Figure 58.10B** demonstrates improper arm positioning because the arms are abducted above the head. This stretches the brachial plexus and may result in a brachial plexus palsy. Both axillae should be inspected to ensure that the frame does not compress the axillary sheath. Proper positioning is shown in **Figure 58.11A**. Note that there is ample space between the thoracic bolster of the frame and the axilla. **Figure 58.11B** demonstrates improper positioning on the frame resulting in pressure on the axilla. Care should be taken to pad the ulnar nerves at the elbow. Often, the surgeons will compress or unintentionally move the upper extremities, so the arms and shoulders must be continuously monitored. Impairment of ventilation and increased bleeding from increased venous

pressure may occur if the abdomen is compressed by the operating frame.

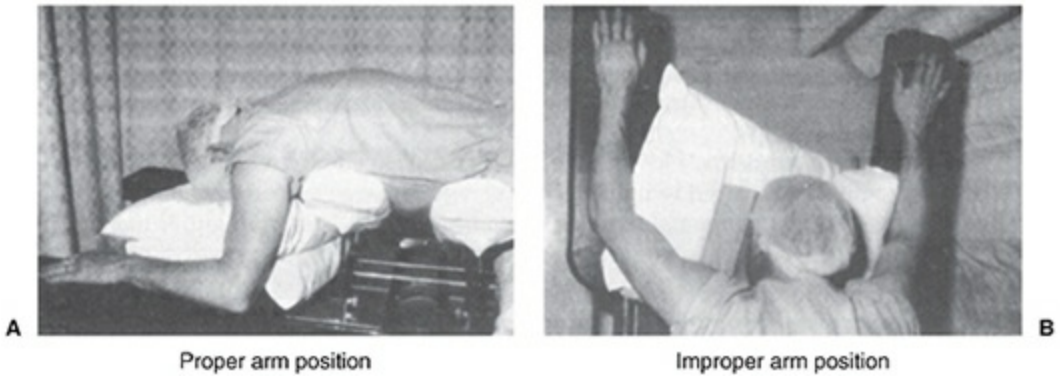

FIGURE 58.10. Proper arm position and improper arm position during scoliosis surgery. A. Degrees of abduction (relative to the trunk). **B.** Improper arm positioning with the arms abducted above the head. This results in stretching of the brachial plexus.

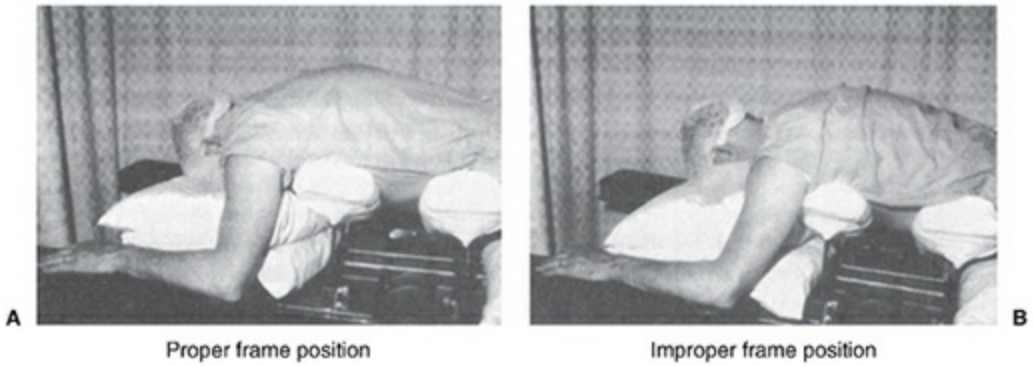

FIGURE 58.11. Proper and improper positioning on the four-poster frame during spine surgery. A. Proper positioning on the frame with ample space between the axilla and the thoracic bolster of the frame. **B.** Improper positioning on the frame resulting in compression of the axillary sheath by the thoracic bolster of the frame.

Life-threatening cardiovascular events have occurred due to right ventricular outflow tract obstruction and resultant decreased venous return due to positioning of bolsters.

Neira VM, Gardin L, Ryan G, et al. A transesophageal echocardiography examination clarifies the cause of cardiovascular collapse during scoliosis surgery in a child. *Can J Anaesth*. 2011;58:451–455.

C.15. What is transfusion-related acute lung injury (TRALI)? How do you distinguish it from

transfusion-associated circulatory overload (TACO)?

TRALI is noncardiogenic pulmonary edema occurring within 1 to 6 hours of transfusion of a plasma-containing blood product. In intubated patients, it presents as copious, pink, and frothy pulmonary edema fluid in the endotracheal tube. Although clinically indistinguishable from adult acute respiratory distress syndrome, TRALI is associated with a much lower mortality rate (5% to 10%). Typically, the chest radiograph and arterial oxygen saturation return to baseline within 72 hours. The exact mechanism of TRALI is unknown, but evidence points to pathologic leukocyte antibodies in donor plasma causing agglutination of white blood cells on pulmonary endothelial cells, resulting in increased permeability. Platelet transfusions have been most commonly implicated. Therapy is supportive, similar to that for acute respiratory distress syndrome.

TACO, on the other hand, is a result of increased hydrostatic pressure in the capillaries causing pulmonary edema. The clinical features and radiologic findings are similar, and the two are difficult to differentiate from each other. A thorough understanding of patient's fluid status, cardiovascular function, and amount and type of blood products transfused is helpful in identifying the cause.

C.16. What techniques can be used to minimize transfusion requirements?

Several techniques can be used to minimize homologous blood

transfusion requirements and subsequent risks, such as alloimmunization, infections, immunosuppression, and graft-versus-host disease in addition to TRALI and TACO. A simple and important way to minimize bleeding is to minimize intra-abdominal pressure because any increase in abdominal pressure is transmitted to the vertebral venous plexus, increasing venous bleeding. Careful positioning will avoid external pressure on the abdomen, and muscle relaxants or deeper levels of anesthesia have been used to prevent a rise in abdominal wall tension.

Isovolemic hemodilution may also be used to minimize red blood cell loss during surgery. Before incision, the hematocrit is lowered 20% to 25% by removing blood aseptically and storing it in anticoagulated bags. Intravascular volume is maintained by replacing the blood with 3 times the volume of a balanced saline solution or an equal volume of colloid. Intraoperatively, the previously collected blood is replaced as needed. Obviously, this technique requires careful monitoring of intravascular volume status and hemoglobin level. Most patients will require a central venous catheter to perform this technique. Some patients who are Jehovah's Witnesses and will not accept blood transfusions may accept this type of blood conservation method if the tubing is kept connected because the blood in the bag and the tubing is in continuity with the circulation.

Salvaging of blood during the surgical procedure can play an important role as an adjunct to an autologous blood program. Using standard salvaging techniques, 50% to 60% of the red blood cells lost can be recovered, concentrated, washed, and returned to the patient using commercially available autotransfusion devices. These red blood cells are obviously lacking in platelets and plasma. Some Jehovah's Witness patients may also accept this technique if the autotransfusion device is kept in continuity with the circulation.

The use of an antifibrinolytic drug such as aminocaproic acid

or tranexamic acid has been shown to decrease blood loss in pediatric patients undergoing scoliosis surgery. These drugs may be of particular benefit in patients with neuromuscular scoliosis. These patients have significantly greater intraoperative blood loss compared to patients with idiopathic scoliosis, as much as a twofold to eightfold increased risk. The antifibrinolytic agent is administered as a loading dose followed by a continuous infusion before the activation of the fibrinolytic system, which occurs with surgical incision. It is important to administer the full loading dose before surgical incision for maximum benefit. Some centers choose to use aminocaproic acid as their antifibrinolytic of choice because tranexamic acid has been associated with postoperative seizures, especially at elevated doses. This is of particular importance in patients with neuromuscular scoliosis who often have an underlying seizure disorder.

Deliberate (controlled) hypotension has been frequently used until recently to decrease blood loss and improve operating conditions during spine fusion surgery. Decrease in blood loss and transfusion requirement has been less significant in spine surgery when compared with oral-maxillofacial surgery employing controlled hypotension techniques. Safety of moderate controlled hypotension (mean arterial pressure [MAP] 50 to 65 mmHg) with close monitoring of invasive arterial and central venous pressures in conjunction with SSEPs and MEPs has been documented.

However, the major concern of using deliberate hypotension during scoliosis surgery is the potential for spinal cord blood flow to be compromised with resultant spinal cord injury. This is of particular concern when the spine is distracted because levels of hypotension that are considered safe under normal conditions may compromise spinal cord blood flow after spine distraction. In addition, the use of deliberate hypotension can interfere with

neuromonitoring signals, particularly the MEPs. For these reasons, the potential benefits of controlled hypotension should be carefully considered and discussed with the surgeon.

D. Postoperative Management

D.1. When would you extubate the patient?

The decision to continue mechanical ventilation in the postoperative period is often made preoperatively. Most patients with adolescent idiopathic scoliosis have mild-to-moderate pulmonary function abnormalities and may be extubated in the operating room after they have moved all extremities to the surgeon's satisfaction. Mechanical ventilation should be

continued in patients with severe restrictive lung defects (vital capacity less than 30% of predicted) or severe gas exchange abnormalities such as carbon dioxide retention. Postoperative mechanical ventilation should be considered for patients with Duchenne muscular dystrophy, familial dysautonomia, or severe cerebral palsy. Patients who are mechanically ventilated postoperatively should be managed by nurses and physicians in an intensive care setting. Patients should be sedated to tolerate the endotracheal tube, yet arousable enough to be examined every hour for potential neurologic complications. Dexmedetomidine is a good choice for short-term sedation in this population. It offers potent synergy with opioids for analgesia, and it is titrated easily for frequent wake-ups.

The parameters for extubation given below are the same as for other respiratory disorders:

- Vital capacity greater than 10 mL per kg
- Tidal volume greater than 3 to 6 mL per kg
- Spontaneous respiratory rate less than 30 per minute
- Negative inspiratory force greater than 30 cm H_2O

Yuen VM. Dexmedetomidine: perioperative applications in children. *Paediatr Anaesth*. 2010;20:256–264.

D.2. What should be done to optimize pulmonary status?

Incentive spirometry should be taught preoperatively and should be used aggressively in the postoperative period. Coughing and deep breathing should be encouraged. Patients with obstructive or reactive airway disease will benefit from bronchodilators. Opioids should be used on a patient-controlled basis with the goal of providing adequate analgesia to allow coughing and incentive spirometry without excessive respiratory depression.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:727–753.

D.3. What laboratory tests should be ordered postoperatively?

Upon the patient's arrival in the postanesthesia care unit, blood should be sent for analysis of arterial blood gases, hematocrit, serum electrolytes, blood urea nitrogen, serum creatinine, and, if blood loss has been significant, platelet count, prothrombin, and partial thromboplastin time. Determination of arterial blood gases should be repeated if clinically indicated. Hyponatremia with high urinary sodium excretion has been reported following scoliosis surgery and has been attributed to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). These patients produce small amounts of concentrated urine and excrete large amounts of urinary sodium. Efforts to increase urine output by administration of fluid are unsuccessful and worsen the hyponatremia. Therefore, serum electrolyte concentrations should be measured at least every 12 hours for the first 24 hours and then daily for the first 2 days. Rapid decreases in serum sodium concentration or sodium concentrations less than 125 mEq per L may produce cerebral edema and seizures.

Taal MW, Chertow GM, Marsden PA, et al, eds. *Brenner & Rector's the Kidney*. 10th ed. Philadelphia, PA: Elsevier Saunders; 2016:460–510.

D.4. What fluid therapy would you use postoperatively?

Significant losses of intravascular fluid continue to occur in the postoperative period. These should be replaced with balanced salt solution such as lactated Ringer's solution to maintain urine output at a minimum of 0.5 to 1 mL/kg/hr. Hypotonic fluids

should be avoided in the first 24 to 36 hours postoperatively. The risk for postoperative hyponatremia is increased if fluid replacement is excessive or if hypotonic fluid is administered. Some authors recommend the use of colloid replacement solutions because serum albumin is often decreased following scoliosis surgery.

Taal MW, Chertow GM, Marsden PA, et al, eds. *Brenner & Rector's the Kidney*. 10th ed. Philadelphia, PA: Elsevier Saunders; 2016:460–510.

D.5. What complications may occur following scoliosis surgery?

The most common postoperative complications in patients undergoing posterior spinal fusion for idiopathic scoliosis include wound infection (1.35%), pulmonary complications excluding pulmonary embolism (0.95%), and neurologic injury (0.32%). The pulmonary complications that have been reported in the postoperative period include pneumothorax, atelectasis, pleural effusion, hemothorax, and thoracic duct injury. Pneumothorax may occur as a result of anterior and posterior surgical dissections as well as secondary to central venous line placement. A chest radiograph should be obtained upon arrival in the postanesthesia care unit. Atelectasis may occur because of prolonged supine positioning and the use of opioids. Anterior spine fusion by thoracotomy poses the greatest risk of pulmonary complications. Almost 100% of patients undergoing these procedures will develop some degree of atelectasis. Incentive spirometry and deep breathing should be emphasized and may require specialized nursing care.

In addition to intraoperative neurologic complications during instrumentation or distraction of the spine, delayed paraplegia

has been also been reported shortly after arrival in the recovery room and during the initial postoperative days. This emphasizes the need for continued monitoring of neurologic status postoperatively.

In the first few postoperative days, an ileus can occur, particularly in conjunction with opioid use. Less commonly, superior mesenteric artery syndrome has been reported to occur in 0.5% of patients. This presents with nausea, vomiting, and abdominal pain after a mean time of 7.2 days. This is probably due to compression of the distal third of the duodenum by the superior mesenteric artery as a result of anatomic changes related to straightening of the spine.

D.6. Upon arrival to the recovery room, you notice that the urine appears to be tea colored. What is your diagnosis, and how should this be managed?

Tea-colored urine (**Fig. 58.12**) in the setting of a prolonged surgical procedure suggests rhabdomyolysis. Other possible diagnoses include a hemolytic transfusion reaction or a drug reaction. The pathogenic process of rhabdomyolysis results from an increase of intracellular calcium causing a complex series of intracellular processes ultimately leading to prolonged muscle cell contraction, mitochondrial damage, and the production of

reactive oxygen species. Skeletal tissue necrosis ensues with the subsequent release of toxic muscle cell contents, notably myoglobin, into the systemic circulation.

FIGURE 58.12. Example of tea-colored urine secondary to rhabdomyolysis.

Initial diagnostic workup should include serum creatine kinase (CK), a full electrolyte panel, and serum creatinine. The presence of blood in the urine on dipstick testing without red blood cells on urinalysis suggests rhabdomyolysis. Patients can have a CK value 5 times normal. The major concern of rhabdomyolysis is acute kidney injury (AKI). The pathophysiology of rhabdomyolysis of induced AKI is multifactorial and includes myoglobin cast formation in the distal convoluted tubules and the direct cytotoxic action of myoglobin on renal tubular cells. Acidity of the urine predisposes to deposition of myoglobin in the tubules; thus, the urine should be alkalinized by infusion of sodium bicarbonate in

the intravenous fluids. In order to prevent precipitation of myoglobin, urine output should be maintained above normal during the initial resuscitation period (>1 mL/kg/hr). Management should also include correction of electrolyte abnormalities. Hyperkalemic cardiac arrest is a perilous complication that can occur in cases of severe rhabdomyolysis.

D.7. How would you manage this patient's pain, nausea, and vomiting postoperatively?

Most centers advocate for the use of multimodal analgesia to optimize postoperative pain control in pediatric patients undergoing posterior spinal fusion. Patients with idiopathic scoliosis are typically developmentally mature enough to use intravenous patient-controlled analgesia (PCA). The two commonly employed opioids for PCA are hydromorphone and morphine. Many practitioners will initiate oral opioid therapy (e.g., oxycodone) once the patient is tolerating a diet with a goal to wean the PCA by the end of the first postoperative day or the beginning of the second. Perioperative gabapentin has been shown to decrease the amount of morphine needed postoperatively in patients with idiopathic scoliosis undergoing spinal fusion. Acetaminophen is an effective analgesic that can be given intravenously intraoperatively and continued orally postoperatively. Intravenous acetaminophen has been shown in

this patient population to improve analgesia but not decrease opioid needs. Diazepam is typically administered on an as needed basis for muscle spasms.

Recently, ketorolac has become more accepted as a postoperative pain adjunct, even for spine surgery. A meta-analysis in 2011 showed no increased risk of nonunion in spine patients receiving nonsteroidal anti-inflammatory drugs (NSAIDs) postoperatively. Patients at several children's centers receive it for 48 to 72 hours after spine surgery.

Antiemetics should be given prophylactically, starting in the operating room. Serotonin receptor antagonists are the first-line treatment, but dexamethasone may also be used. Histamine-2 receptor blockers can also be helpful the first few days. A transdermal scopolamine patch may be placed preoperatively for patients with risk factors (female of childbearing age, history of motion sickness or postoperative nausea, nonsmokers). More children's centers are also encouraging chewing gum postoperatively to speed the return of normal bowel function after spine surgery.

59 Hypoxia and Equipment Failure

James B. Eisenkraft and
Garrett W. Burnett

A 60-year-old woman with a past medical history of type II diabetes mellitus is to undergo robotic-assisted laparoscopic hysterectomy, bilateral salpingo-oophorectomy, and node dissection under general anesthesia and in steep Trendelenburg position. Breathing room air (fraction of inspired oxygen [F_{IO_2}] = 0.21), her pulse oximeter saturation reading (Spo_2) is 94%.

A. Medical Disease and Differential Diagnosis

1. What is hypoxia, and what is hypoxemia?
2. Is the partial pressure of oxygen in arterial blood (Pao_2) related to age?
3. Was this patient hypoxemic?
4. What is a pulse oximeter, and what is a hemoximeter?
5. How does a pulse oximeter work?
6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?
7. What may affect the accuracy of a two-wavelength pulse oximeter?
8. How do the dyshemoglobins, methemoglobin (metHb), and

carboxyhemoglobin (HbCO) affect Spo_2 readings?

9. What is a capnometer, and what is capnography? Of what value are they in patient monitoring?
10. What is meant by the term *end-tidal carbon dioxide* ($EtCO_2$)?
11. What is the appearance of a normal capnogram, and what is its significance?
12. What are mainstream and sidestream capnometers?
13. Show some common capnograms and provide a differential diagnosis of each event.
14. What is the arterial–alveolar difference in carbon dioxide (CO_2)?
15. What are some of the important safety features of the contemporary anesthesia workstation?
16. What are the common sites for gas leakage?
17. How is the anesthesia machine checked for leaks?

B. Preoperative Evaluation and Preparation

1. What should be included in the equipment checkout in preparation for anesthesia?
2. What emergency equipment should be easily available to the anesthesiologist?
3. How should this patient be premedicated?

C. Intraoperative Management

1. How should this patient be monitored?
2. Following uncomplicated induction of anesthesia and endotracheal intubation, the procedure begins. Upon insufflation of the abdomen with CO_2, the Spo_2 decreases to 78%. What acute diagnostic and therapeutic interventions would you perform?
3. The endotracheal tube was withdrawn 2 cm. Squeezing the reservoir bag in the circle breathing system failed to generate positive pressure in the circuit. What are the common sites for

gas leaks in the circle breathing system?

4. The patient was taken out of Trendelenburg position. Direct laryngoscopy revealed the endotracheal tube to be supraglottic. Additionally, green secretions were noted to be pooled in the posterior pharynx. What should be done next?

D. Postoperative Management

1. What criteria would you use for tracheal extubation?
2. What are the causes of postoperative hypoxemia?
3. What is the difference between shunt, ventilation/perfusion mismatch, and dead space?
4. Postoperatively, the patient developed hypoxia and pulmonary edema. What is the differential diagnosis of pulmonary edema? What is the most likely cause of pulmonary edema in this patient?
5. How should the ventilator be set if mechanical ventilation is required postoperatively?
6. If this patient had acute respiratory distress syndrome (ARDS) secondary to aspiration, besides low-tidal volume ventilation, what other changes in routine therapy should be considered?
7. What therapies routinely administered by the anesthesiologist may cause acute lung injury?
8. What methods of oxygen administration may be used postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is hypoxia, and what is hypoxemia?

Hypoxia is defined as reduction of oxygen supply to tissue below physiologic levels. Hypoxemia is defined as deficient oxygenation of the blood. From the anesthesiologist's perspective, hypoxia is usually considered to be decreased oxygen tension (Po_2) inside the body at the tissue level or

outside the body (e.g., hypoxic gas mixture), and hypoxemia is decreased oxygen tension in the arterial blood (PaO_2).

Dorland WAN. *Dorland's Illustrated Medical Dictionary*. 32nd ed. Philadelphia, PA: Saunders; 2012.

Longnecker DE, Newman MF, Zapol WM, et al, eds. *Anesthesiology*. 3rd ed. New York: McGraw-Hill; 2018:411–424.

A.2. Is the partial pressure of oxygen in arterial blood (PaO_2) related to age?

Yes. There is an age-dependent decrease in the PaO_2. Sorbini et al. suggested the following relationship in subjects breathing room air:

$$\text{Mean } PaO_2 \text{ in mmHg} = 109 - 0.43 \text{ (age in years) mmHg}$$

About this regression line, there are 95% confidence limits (2 standard deviations [SDs]) of 10 mmHg.

Cerveri et al. studied PaO_2 in normal nonsmoking subjects aged 40 to 90 years. They found that PaO_2 was related to age in subjects between 40 and 74 years and constructed the following reference equation:

$$PaO_2(\text{mmHg}) = 143.6 - (0.39 \times \text{age}) - (0.56 \times \text{body mass index [BMI]}) - (0.57 \times PaCO_2)$$

For subjects ≥75 years old, there was no correlation with age.

Cerveri I, Zoia MC, Fanfulla F, et al. Reference values of arterial oxygen tension in the middle-aged and elderly. *Am J Respir Crit Care Med*. 1995;152:934–941.

Sorbini CA, Grassi V, Solinas E, et al. Arterial oxygen tension in relation to age in healthy subjects. *Respiration*. 1968;25:3–13.

A.3. Was this patient hypoxemic?

No. An SpO_2 reading of 94% does not signify hypoxemia when the age of the patient is taken into consideration. Using Sorbini

et al.'s equation for expected Pa_{O_2}:

$$PaO_2 = 109 - (0.43 \times 60) = 83 \text{ mmHg}$$

Assuming normal adult hemoglobin, temperature, and pH, this Pa_{O_2} corresponds to a hemoglobin oxygen saturation of approximately 94% on the normal hemoglobin oxygen saturation versus P_{O_2} curve.

Although the definitions of hypoxemia given in sections A.1 and A.2 must take age into consideration, from a practical point of view, hypoxemia (in the absence of anemia) is generally considered to exist when the Pa_{O_2} is less than 60 mmHg, which is equivalent to a hemoglobin oxygen saturation of 90%.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:169–202.

A.4. What is a pulse oximeter, and what is a hemoximeter?

The pulse oximeter is a noninvasive device that provides a real-time estimate (designated the Spo_2%) of the arterial hemoglobin saturation with oxygen. It is a transmissive oximeter in which the patient's fingertip (or other probe site; e.g., earlobe) serves as an in vivo cuvette through which light at two different wavelengths is transmitted.

If one requires an accurate determination of the arterial hemoglobin saturation with oxygen, an arterial blood sample must be drawn and analyzed in a laboratory co-oximeter, sometimes called a *hemoximeter*. The laboratory co-oximeter is a transmissive oximeter that uses numerous wavelengths of light (e.g., radiometer's co-oximeter uses 128 wavelengths of light) to measure total hemoglobin (Hb_{TOT}), oxygenated hemoglobin (Hbo_2), deoxygenated ("reduced") hemoglobin (RHb), metHb, Hb_{CO}, and other dyshemoglobins, such as sulfhemoglobin.

Because each species of hemoglobin has a characteristic absorbance spectrum (i.e., absorbance vs. wavelength), examination of a sample of blood using these six or eight wavelengths permits identification and quantification of each hemoglobin species. Conventional pulse oximeters use only two wavelengths of light; therefore, they are unable to determine all of the different hemoglobin species and assume that only HbO_2 and RHb are present. *Fractional saturation* (*HbO_2%*) is defined as HbO_2 / (HbO_2 + RHb + HbCO + metHb)—that is, HbO_2 per total Hb. *Functional saturation (SaO_2)* is defined as HbO_2 / (HbO_2 + RHb). Note that dyshemoglobins are absent from the denominator in the definition of SaO_2.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:256–270.

A.5. How does a pulse oximeter work?

The pulse oximeter combines the technologies of spectrophotometry and optical plethysmography. In the pulse oximeter probe, light-emitting diodes transmit red light at wavelength 660 nm and infrared light at wavelength 940 nm through the fingertip or other probe site. Light that passes through the probe site is sensed by a single photodetector and expressed as absorbance at each wavelength. It can be shown that the ratio of absorbances, 660/940 nm, is related to the hemoglobin saturation with oxygen. This is spectrophotometry. Detection of pulsatile flow is by optical plethysmography. With each pulse of arterial blood, the probe site (e.g., fingertip) increases in volume, the path length of the transmitted light increases, and the absorbance of light at 660 nm and 940 nm increases. This *pulse-added* absorbance is considered to be due to the pulsatile flow of arterial blood at the probe site, so that the ratio of pulse-added absorbances, 660/940 nm, can be used to

provide an estimate of hemoglobin oxygen saturation in arterial blood.

A.6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?

Each pulse oximeter manufacturer creates an empiric calibration algorithm, that is, one based on observations in human volunteers. The algorithm relates the average ratio of pulse-added absorbances, 660/990 nm, to the actual hemoglobin oxygen saturation in arterial blood samples drawn simultaneously and analyzed in a laboratory hemoximeter. Observations are made with the volunteers breathing varying F_{IO_2} values so that data for saturations as low as 70% are obtained. The calibration algorithm that is created relates the ratio (R) of pulse-added absorbances, 660/940 nm, to the laboratory hemoximeter readings of Hb_{O_2} or Sa_{O_2}% (depending on the pulse oximeter manufacturer). The calibration algorithm is then stored in the software of the pulse oximeter as a "lookup" table. Therefore, the pulse oximeter merely measures R, consults its lookup table, and displays the corresponding saturation reading as Sp_{O_2}. The pulse oximeter does not actually measure saturation; it infers it from R, and therefore, it predicts what the laboratory hemoximeter would read if an arterial sample drawn at that moment were analyzed.

A high value for R corresponds to a low Sp_{O_2} reading; R = 1 corresponds to an Sp_{O_2} reading of 85%, and a low value for R corresponds to a high Sp_{O_2} reading. Whenever the Sp_{O_2} reading is approximately 85%, one should consider the possibility of a

spurious reading as a result of the "R = 1" phenomenon. This is commonly due to malpositioning of the probe on the fingertip.

The pulse oximeter (Spo_2) reading is usually specified by the manufacturer to have an SD of ±2%. Therefore, assuming a normal distribution, if the Spo_2 reading is 96%, there is a 68% likelihood that the true saturation (as measured by a hemoximeter) is 96% ± 2% (i.e., ±1 SD) and a 95% likelihood that the true saturation is 96% ± 4% (i.e., ±2 SD).

A.7. What may affect the accuracy of a two-wavelength pulse oximeter?

The two-wavelength pulse oximeter is most accurate when the conditions of its clinical use most closely resemble those of its calibration. Spurious readings or failure may occur during patient movement (e.g., shivering, peripheral nerve stimulation, "twitching"), presence of intense ambient light (low signal/noise ratio), electrocautery use, administration of intravenous dyes with absorbance peaks at 660 nm (e.g., methylene blue), presence of dyshemoglobins (e.g., metHb, HbCO, and sulfhemoglobin), certain colors of nail polish, poor pulsatile flow at the probe site (e.g., hypotension, vasoconstriction, Raynaud disease), and venous pulsations (e.g., tricuspid regurgitation or earlobe placement of the probe in a patient who is in a head-down position).

Recent improvements in pulse oximetry technology include paradigms to increase the signal/noise ratio, thereby permitting motion artifact reduction and increased sensitivity to pulsatile flow. Such pulse oximeters have significantly lower failure rates

during patient movement (such as in the postanesthesia care unit) and during conditions of low flow (e.g., hypothermia).

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:256–270.

A.8. How do the dyshemoglobins, methemoglobin (metHb), and carboxyhemoglobin (HbCO) affect Spo_2 readings?

In metHb, iron in the heme moiety is oxidized (such as by dapsone, benzocaine, nitric oxide, prilocaine) to the Fe^{3+} state rather than being in the normal Fe^{2+} state. metHb cannot carry oxygen and creates a physiologic anemia. The absorbance spectrum for metHb shows it to have similar absorbances to light at 660 nm and 940 nm. Therefore, the more metHb that is present, the more R tends toward 1 and the Spo_2 reading toward 85%. In the presence of metHb, the Spo_2 reading overestimates the Hbo_2% and underestimates the Sao_2.

In carbon monoxide (CO) poisoning, CO combines with hemoglobin to create a physiologic hypoxemia. HbCO has a similar absorbance to Hbo_2 at 660 nm but a very low absorbance at 940 nm. In the presence of HbCO, the Spo_2 overestimates Hbo_2% and underestimates functional saturation. Although blood that is poisoned with CO appears "cherry red" to the naked eye, and therefore may look like it is fully saturated with oxygen, it is important to recognize that the ratio of absorbances 660/940 nm will suggest that the blood hemoglobin oxygen saturation is in the 90s. In a subject breathing an Fio_2 of 1 (when functional saturation is 100%), as the level of HbCO increases, Spo_2 decreases from close to 100% to approximately 91%.

If the presence of dyshemoglobins is suspected, arterial blood

must be drawn and analyzed in a laboratory hemoximeter to obtain accurate readings of saturation.

Pulse oximetry technology has evolved rapidly, and multiwavelength pulse oximeters, called pulse co-oximeters, are clinically available. They use more than seven wavelengths of light (Masimo Rainbow SET Pulse CO-Oximetry, Masimo Company, Irvine, CA), similar to a laboratory hemoximeter. This technology makes it possible to estimate carboxyhemoglobin (SpCO), methemoglobin (SpMet), and total hemoglobin (SpHbt), all noninvasively and in real time.

It should be noted that while continuous noninvasive total hemoglobin measurement provides information in real time, it may have a wide limits of agreement when compared to a traditional invasive laboratory value. Due to this, patients who have low SpHbTOT on a noninvasive monitor should have confirmation by sending a blood sample to the laboratory for analysis.

A.9. What is a capnometer, and what is capnography? Of what value are they in patient monitoring?

A capnometer is a device that measures the tension (in units of millimeters of mercury [mmHg] or kilopascals [kPa]) or

concentration (volumes %) of CO_2 in the gas near the patient's airway throughout the respiratory cycle. Capnography is the graphic display of the CO_2 concentration on the y-axis against time on the x-axis.

Capnometry may be achieved using different technologies that can monitor CO_2. Most capnometers now use infrared spectroscopy to measure the P_{CO_2} (i.e., CO_2 partial pressure in millimeters of mercury). A built-in barometer measures barometric pressure (P_B) so that CO_2 can also be displayed as a percentage ($P_{CO_2} \times 100/P_B = \%CO_2$).

Capnography is one of the American Society of Anesthesiologists' standards for basic anesthetic monitoring (i.e., "Continual monitoring for the presence of expired CO_2 shall be performed unless invalidated by the nature of the patient, procedure or equipment."). It is the "gold standard" for establishing the presence of ventilation.

American Society of Anesthesiologists. *Standards for Basic Anesthetic Monitoring*. Schaumburg, IL: American Society of Anesthesiologists; 2010. Last affirmed on October 28, 2015.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:245–254.

A.10. What is meant by the term *end-tidal carbon dioxide ($EtCO_2$)*?

Et_{CO_2} is the tension of CO_2 in the exhaled gas at the end of an exhalation. Because this gas originates from the alveoli, it is considered to represent the CO_2 tension in the alveolar gas (P_{ACO_2}). The P_{ACO_2} results from the combination of gases coming from ideal alveoli, where ventilation and perfusion are perfectly matched and the CO_2 concentration is the same as arterial (Pa_{CO_2}), and alveolar dead space (alveoli that are ventilated but not perfused) where CO_2 concentration is the

same as inspired (P_{ICO_2}) and is normally zero.

The presence of a normal capnogram and Et_{CO_2} depends on (1) production of CO_2 by the tissues, (2) cardiac output and pulmonary blood flow to carry CO_2 to the lungs, and (3) ventilation. Monitoring of Et_{CO_2} can be used to adjust the setting of a mechanical ventilator and monitor ventilation as well as to detect ventilator malfunctions and breathing system problems, such as leaks, incompetent unidirectional valves, exhausted CO_2 absorbent, metabolic problems (e.g., malignant hyperthermia), and gas embolism.

Lumb AB. Carbon dioxide. In: *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–167.

A.11. What is the appearance of a normal capnogram, and what is its significance?

A typical normal capnogram (P_{CO_2} vs. time) is shown in **Figure 59.1**. Four phases have been described.

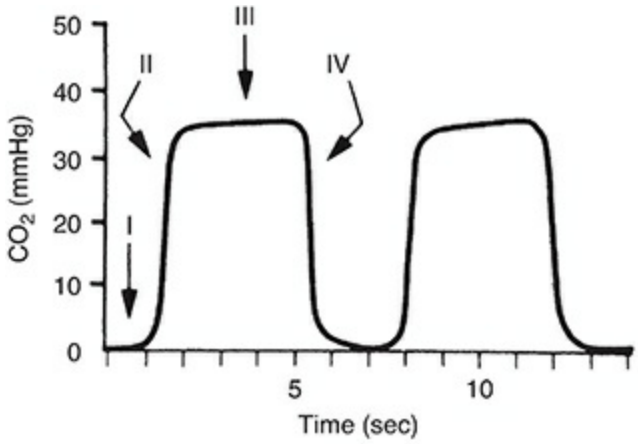

FIGURE 59.1. Phases of the normal capnogram. (*Phase I*) Inspiratory baseline. (*Phase II*) Expiratory upstroke. (*Phase III*) Expiratory plateau. (*Phase IV*) Inspiratory downstroke. (*Reprinted with permission from Good ML. Capnography. Uses, interpretation, and pitfalls. In*: ASA Refresher Courses in Anesthesiology. *1990;18:179.*)

Phase I. This is the expiratory baseline. During exhalation, CO_2-free gas from the mechanical (apparatus) dead space (e.g., flexible or "goose-neck" connector) and anatomic dead space (large conducting airways) flows past the CO_2 sampling port.

Phase II. This is the expiratory upstroke. It is due to CO_2 from alveoli mixed with anatomic dead space gas passing the gas sampling port and is usually a steep upslope.

Phase III. This is the expiratory or alveolar plateau and is due to alveolar CO_2.

In patients with healthy lungs, it is nearly horizontal, but in patients with obstructive airway disease, there is a more pronounced upward slope. The maximum expired CO_2 is usually considered as the Et_{CO_2}.

Phase IV. This is the inspiratory downstroke. During the commencement of inspiration, fresh (i.e., CO_2-free) gas is inhaled past the sensor, and the capnogram falls sharply to baseline.

The angle between the upstroke of phase II and the plateau of phase III is referred to as the *α angle*. The angle between phase III and IV is the *β angle*. An increase in the *α* angle and slope of phase III is seen commonly in acute bronchospasm. The angle usually decreases with treatment of the bronchospasm.

A.12. What are mainstream and sidestream capnometers?

In a mainstream or nondiverting type of analyzer, the gas analyzer sensor is brought to the airway itself, and no gas is removed from the breathing system. A cuvette with a quartz

window is placed between the breathing system Y-piece and the tracheal tube connector. As respired gases flow past the window in the cuvette, a beam of infrared radiation (wavelength 4.3 μm) is directed through the window. Absorbance of infrared radiation at 4.3 μm is used to measure P_{CO_2}. Advantages of the nondiverting analyzer are rapid response time, accurate waveform, and no need to scavenge gases. Disadvantages are that this additional device in the airway can be a site for a disconnect and needs sterilization (or replacement of a disposable single-use cuvette) between cases, needs to be heated because water vapor condensing on the window causes error, and can be blocked by secretions or blood on its window.

A sidestream or diverting gas analyzer aspirates gas from the breathing circuit through a sampling adapter placed by the airway. The sampled gas passes through a sampling catheter (usually 6 to 10 ft in length) to reach the gas analyzer. Advantages of diverting analyzers are that the breathing circuit adapter is disposable. The analyzer, being remote from the airway, can be more versatile and incorporate several technologies in one "box" to analyze multiple gases (e.g., infrared analysis for CO_2, nitrous oxide, anesthetic agents; paramagnetic sensor or fuel cell for oxygen). Disadvantages of sidestream sampling analysis are slower response times, the possibility of sampling leaks, errors resulting from the length of the gas sampling tube, the need to scavenge gases from the analyzer after analysis, and susceptibility of the sampling tube to becoming clogged by water or secretions. Because of their versatility in regard to gas monitoring, most anesthetizing locations now use sidestream sampling analyzers.

A.13. Show some common capnograms and provide a

differential diagnosis of each event.

Elevated baseline equals the amount of CO_2 present in inspired gas (**Fig. 59.2A**).

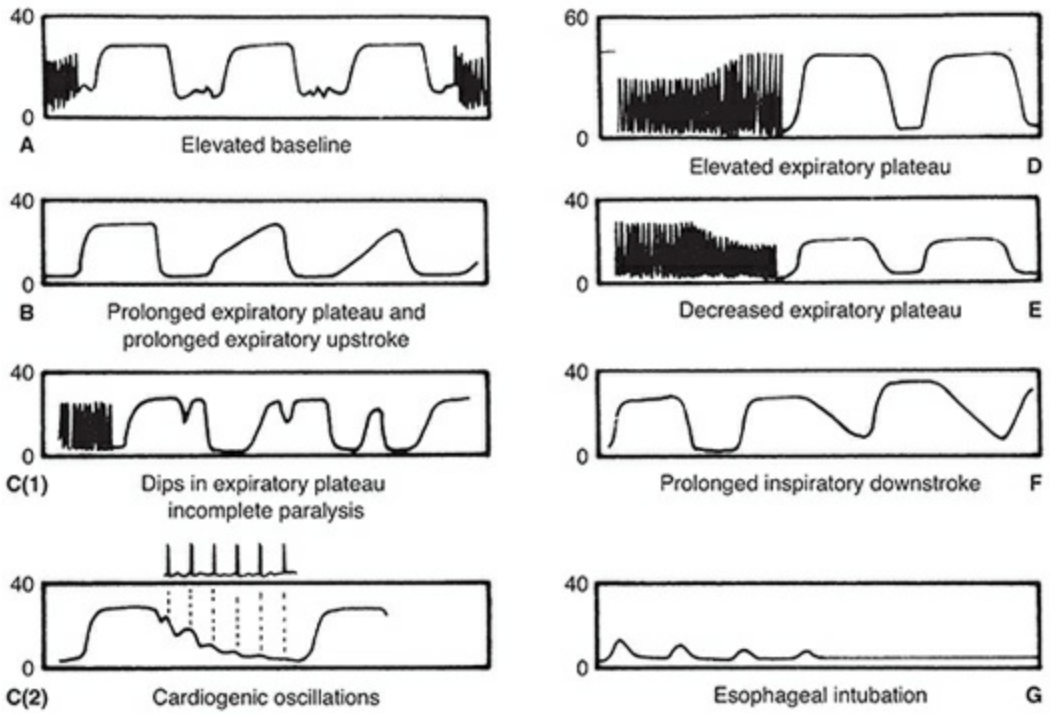

FIGURE 59.2. Abnormal capnograms.

- Capnometer not properly calibrated to zero
- Delivery of CO_2 to breathing system through fresh gas inflow
- Incompetent unidirectional valves
- Failure of CO_2 absorber (channeling, exhaustion, bypass)

Prolonged expiratory plateau and expiratory upstroke (**Fig. 59.2B**)

- Mechanical obstruction to exhalation
- Chronic obstructive pulmonary disease
- Bronchospasm

Dips in expiratory plateau (**Fig. 59.2C[1]**)

- Patient making spontaneous inspiratory effort
- "Curare cleft"

Cardiogenic oscillations if synchronized with

electrocardiogram (**Fig. 59.2C[2]**)

- Ventilator pressure relief valve perturbations

Elevated expiratory plateau (**Fig. 59.2D**)

- Incorrect calibration
- Increased CO_2 production/delivery versus laparoscopic CO_2 gas insufflation
- Decreased CO_2 removal
- Hypoventilation
- Leak

Decreased expiratory plateau (**Fig. 59.2E**)

- Incorrect calibration
- Air leak into gas sampling system
- Hyperventilation
- Decreased CO_2 production (hypothermia)
- Increased arterial–alveolar CO_2 gradient (ventilation/perfusion mismatch pulmonary embolus)

Prolonged inspiratory downstroke and raised baseline (**Fig. 59.2F**)

- Incompetent or missing inspiratory unidirectional valve
- Inspiratory obstruction to gas flow (e.g., kinked tracheal tube)

Esophageal intubation (**Fig. 59.2G**)

- As CO_2 that has been insufflated into the stomach during bag-mask ventilation or produced as a result of ingestion of a carbonated beverage is washed out during esophageal ventilation, the CO_2 waveform disappears within a few breaths.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:245–254.

A.14. What is the arterial–alveolar difference in carbon dioxide (CO_2)?

The arterial–alveolar difference in CO_2 is usually expressed as

the difference between the arterial and Et_{CO_2} tensions. In an ideal alveolus, the Pa_{CO_2} equals P_{ACO_2} and the "Pa_{CO_2}–P_{ACO_2}" difference is zero. Ventilation of unperfused alveoli leads to alveolar dead space or wasted alveolar ventilation. Because the Et_{CO_2} comprises gas from both ideal and dead space alveoli, the Pa_{CO_2}–P_{ACO_2} difference is a measure of alveolar dead space ventilation. For example,

$$\begin{aligned}
&\text{Tidal volume} = 500\ \text{mL, anatomic dead space} = 150\ \text{mL}\\
&\text{PaCO}_2 = 40\ \text{mmHg; EtCO}_2 = 36\ \text{mmHg}\\
&\text{Alveolar tidal volume} = (500 - 150) = 350\ \text{mL}\\
&\text{Ratio of}\ \frac{\text{Alveolar dead space}}{\text{Alveolar tidal volume}} = \frac{(\text{PaCO}_2 - \text{EtCO}_2)}{\text{PaCO}_2} = \frac{(40 - 36)}{40} = 10\%
\end{aligned}$$

Therefore, 350 mL × 10% = 35 mL of wasted ventilation from each alveolar tidal volume.

$$\begin{aligned}
&\text{Ideal alveolar ventilation} = (350 - 35) = 315\ \text{mL per breath}\\
&\text{In this example, physiologic dead space} = \text{anatomic} + \text{alveolar}\\
&\qquad = 150 + 35 = 180\ \text{mL per breath}\\
&\frac{\text{Physiologic dead space}}{\text{Tidal volume}} = \frac{185}{500} = 37\%
\end{aligned}$$

Therefore, Pa_{CO_2}–Et_{CO_2} measures alveolar dead space ventilation as a percentage of total *alveolar* ventilation. The alveolar dead space is increased by ventilation in excess of perfusion or a decrease in perfusion, such as occurs with pulmonary embolism. Shunt has minimal effect on the Pa_{CO_2}–Et_{CO_2} difference.

The Pa_{CO_2}–Et_{CO_2} difference is normally 3 to 5 mmHg in the patient under general anesthesia, but it is not constant. Therefore, although one commonly uses Et_{CO_2} to noninvasively estimate Pa_{CO_2}, only analysis of an arterial blood sample in a blood gas analyzer can provide an accurate measure of Pa_{CO_2}, and this should be measured when critical, such as during

neurosurgical anesthesia.

Lumb AB. Carbon dioxide. In: *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–167.

A.15. What are some of the important safety features of the contemporary anesthesia workstation?

Because most problems with anesthesia machines are due to use error, safety design of the contemporary workstation is at four levels.

Features Intended to Prevent Human Error

The medical gas pin index and diameter index safety systems ensure that medical gas connections are made correctly. Therefore, one cannot hang a nitrous oxide cylinder in an oxygen hanger yoke or connect a nitrous oxide hose to the oxygen pipeline inlet of the machine.

The "fail-safe" valve is a pressure-sensitive device that interrupts flow of all hypoxic gases on the machine to their flow control valves if the supply pressure of oxygen in the intermediate-pressure system (i.e., components downstream of the first stage oxygen regulator that reduces the high pressure in the tank to 45 lb psi, and upstream of the oxygen flow control needle valve) falls below a threshold (approximately 20 psi in GE machines; 12 psig in Dräger machines).

When the pressure of oxygen in the intermediate-pressure system falls below 30 psig, an oxygen supply pressure failure alarm is annunciated. The oxygen flow control knob is "touch coded"; that is, it is fluted and larger in diameter than the other gas flow control knobs and is normally located on the right of all other gas flow control valves. In the Dräger Fabius GS workstation, the gas flow controls are arranged vertically, with the oxygen flow control knob as the lowest.

Key-fill systems for anesthesia vaporizers are safety features

that also decrease the likelihood of atmospheric contamination during vaporizer filling. The most important of such systems is the Safe-T-Fill system used on desflurane bottles and desflurane vaporizers because filling a vaporizer specific for another agent with desflurane could result in a lethal overdose of desflurane.

A pressure relief valve built into the machine common gas outlet, breathing system, or ventilator provides some protection against positive pressure barotrauma.

Features to Correct for Use Error

Gas flow proportioning systems ensure a minimum oxygen concentration of 25% when nitrous oxide and oxygen are being used. Therefore, if the anesthesiologist were to accidentally attempt to increase the flow of nitrous oxide, either the oxygen flow would be increased automatically or the flow of nitrous oxide would be limited according to the flow of oxygen that was set.

On older machines, during use of the anesthesia ventilator, changes in fresh gas flow, inspiratory–expiratory (I:E) ratio, or respiratory rate cause changes in delivered tidal volume that might result in over-ventilation, under-ventilation, or even barotrauma. On modern systems (e.g., GE workstations that incorporate a ventilator with the Smart Vent feature; Dräger Fabius GS, and Dräger Apollo workstations), once the ventilation parameters have been set; they are maintained because the ventilator or circuit automatically compensates for changes in fresh gas flow settings. In the GE workstations with Smart Vent, tidal volume is monitored continually by a computer. If measured tidal volume changes from that set to be delivered, the computer adjusts the volume delivered by the ventilator bellows. Dräger workstations use fresh gas decoupling to maintain a constant tidal volume. In this system, during the inspiratory phase, a decoupling valve closes so that fresh gas

entering the breathing system is directed into the reservoir bag and only gas from the ventilator is delivered to the patient. During exhalation, the ventilator chamber refills from the fresh gas flow and the fresh gas that was collected in the reservoir bag during the previous inspiration.

A vaporizer interlock system prevents the unintentional simultaneous use of more than one vaporizer.

Monitoring Systems

A monitor of oxygen in the gas delivered to the patient is mandatorily enabled, and the low oxygen concentration alarm is activated whenever the anesthesia workstation is capable of delivering an anesthetic gas mixture into the breathing system.

Other monitors in the anesthesia workstation include pressure, volume, flow, and gas composition. Some also incorporate airway gas flow monitoring. The breathing system low-pressure monitor alarm is automatically enabled when the ventilator is turned on.

Alarm Systems

Contemporary workstations incorporate an integrated prioritized alarm system with visible and audible alerts when set parameter limits are exceeded.

An important safety feature of all modern machines/workstations is the preuse checkout. In 1993, the U.S. Food and Drug Administration (FDA) published anesthesia apparatus checkout recommendations. The machine should be checked by an educated user. Item 1 on the FDA checklist is that an alternative means to ventilate the patient's lungs should be present and functioning. Therefore, if a problem arises with the machine, the patient's lungs can be ventilated using a self-inflating resuscitation bag (e.g., Ambu bag). If a machine problem arises and the cause/remedy is not immediately obvious, one should instinctively reach for the self-inflating

resuscitation bag and call for help. A recent analysis of the American Society of Anesthesiologists Closed Claims Project data found that 35% of adverse outcomes were likely preventable if a proper preuse checkout had been performed.

In 2008, recognizing that not all of the FDA 1993 checkout recommendations can be applied to many of the contemporary anesthesia workstations, the American Society of Anesthesiologists published guidelines applicable to all anesthesia delivery systems so that individual departments can develop their own workstation-specific preuse checkout that can be performed consistently and expeditiously. The 2008 guidelines are intended to provide a template for developing checkout procedures that are appropriate for each individual anesthesia machine design and practice setting. They discuss which systems and components should be checked, the checkout interval (e.g., before first case vs. before every case), and who may be responsible for performing each checkout procedure—the anesthesiologist or technician (**Table 59.1**). Examples of user-developed workstation-specific checkouts are available on the American Society of Anesthesiologists' website (http://www.asahq.org).

TABLE 59.1 Preanesthesia Equipment Checkout Procedures

To Be Completed Daily		Responsible Party
Item to Be Completed		
Item 1:	Verify auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.	Provider and Tech
Item 2:	Verify patient suction is adequate to clear the airway.	Provider and Tech
Item 3:	Turn on anesthesia delivery system and confirm that AC power is available.	Provider and Tech
Item 4:	Verify availability of required monitors, including alarms.	Provider and Tech
Item 5:	Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.	Provider and Tech
Item 6:	Verify that the piped gas pressures are ≥50 psig.	Provider and Tech

Item 7:	Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed.	Provider and Tech
Item 8:	Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.	Provider and Tech
Item 9:	Test scavenging system function.	Provider and Tech
Item 10:	Calibrate, or verify calibration of, the oxygen. Monitor and check the low oxygen alarm.	Provider and Tech
Item 11:	Verify carbon dioxide absorbent is not exhausted.	Provider and Tech
Item 12:	Breathing system pressure and leak testing	Provider and Tech
Item 13:	Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.	Provider and Tech
Item 14:	Document completion of checkout procedures.	Provider and Tech
Item 15:	Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)	Provider

A.16. What are the common sites for gas leakage?

Because gas can leak from numerous points in the anesthesia workstation and breathing system, the anesthesiologist must be educated and able to trace the flow of gases from the supply and storage sources through the system components. Most commonly, leaks occur in the breathing system and low-pressure parts of the machine (i.e., components downstream of the gas flow control valves). For the breathing system, trace the flow of gas from the common gas outlet (if accessible), through the anti-disconnect fitting and hose, to the breathing circuit fresh gas inlet. Trace the flow of gas past the inspiratory valve, inspiratory limb, gas sampling connector, elbow adaptor, to the tracheal tube or airway device. Common sites for leaks include a partially deflated tracheal tube cuff or a disconnection of the sidestream sampling gas analyzer sampling line. Check flow back down the expiratory limb, spirometer, expiratory valve, absorber, pressure gauge, pressure sampling lines, and any user-added components such as filters, humidifiers, condensers, and positive end-expiratory pressure (PEEP) valves. Check both the bag and the ventilator circuits for leaks.

Leaks in the machine low-pressure system can occur as a result of cracked rotameter flow tubes, incorrectly mounted vaporizers, vaporizer leak around agent filling device, or fracture in the gas piping. Leaks in the high-pressure and intermediate-pressure systems usually result from defective valves, connectors, and hanger yokes.

Raphael DT, Weller RS, Doran DJ. A response algorithm for the low-pressure alarm condition. *Anesth Analg*. 1988;67:876–883.

A.17. How is the anesthesia machine checked for leaks?

Leaks in the machine low-pressure system should be tested for according to the manufacturer's specific recommendations for that particular brand and model.

In general, older model Dräger machines (Narkomed 2, 3, 4) are tested using a positive pressure leak check. In principle, the inspiratory and expiratory connections on the absorber are connected by a short length of 22-mm diameter tubing (i.e., the circle breathing system tubing is removed). The reservoir bag (usually 3 L size) is removed, and a test terminal is connected to the bag mount. A short piece of plastic tubing and a sphygmomanometer bulb are connected to the test terminal. With no gases flowing and with the pop-off valve closed, the system is pressurized to 50 cm H_2O by squeezing the sphygmomanometer bulb. Pressure should not decrease by more than 20 cm H_2O in 30 seconds. In this test, the pressure is applied to all of the rigid components of the breathing system and through the fresh gas hose into the machine low-pressure system all the way back to the flow control valves. This test is then repeated with each vaporizer turned on in turn to test for leaks in each vaporizer.

Some anesthesia machines (e.g., GE Excel) have a one-way outlet check valve just upstream of the common gas outlet. Other models have no outlet check valve. The presence of an outlet check valve precludes the application of a positive pressure leak check. If such a valve is present, a negative pressure leak test can be used to check the low-pressure system. In this test, a suction bulb (negative pressure leak-check device) is connected to the common gas outlet. With all gas flows turned off and vaporizers off, the bulb is squeezed empty (to create a negative pressure of −65 mmHg) and then connected to the common gas outlet of the workstation. Reexpansion of the bulb should not occur in less than 30 seconds. The test is repeated with each vaporizer turned on in turn to check for leaks in the

vaporizers.

The FDA 1993 preuse checkout recommendations describe the use of the negative pressure (bulb) leak-check device and state that the bulb should not refill within 10 seconds. The anesthesiologist must understand how to perform a low-pressure system leak check and must have the means (i.e., appropriate leak-check device) to check his or her own particular machine.

The newer electronic anesthesia workstations incorporate a partially automated checkout to test for leaks. The user of the workstation must understand what the automated checkout is designed to check and, more importantly, what it does not check. Even with an automated preuse checkout, some steps must be performed manually as prompted and directed by the checkout screen.

U.S. Food and Drug Administration. Anesthesia apparatus checkout recommendations, 1993. http://vam.anest.ufl.edu/FDApreusecheck.pdf. Updated April 20, 2006. Accessed October 29, 2018.

B. Preoperative Evaluation and Preparation

B.1. What should be included in the equipment checkout in preparation for anesthesia?

In 1993, the FDA published its *14-Step Anesthesia Apparatus Checkout Recommendations* (accessible at http://vam.anest.ufl.edu/fdacheckout.html). It is worthwhile to review in principle the steps in this checkout, recognizing that in contemporary computerized workstations many of the steps have been automated.

The preamble to the FDA 1993 recommendations states that:

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are valid only for an anesthesia system that conforms to the then current (1993) and relevant standards and includes an ascending bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step 5).

Emergency ventilation equipment

Step 1. Verify backup ventilation equipment is available and functioning.

High-pressure system

Step 2. Check oxygen cylinder supply.

- Open oxygen cylinder and verify at least half full (approximately 1,000 psi).
- Close cylinder.

Step 3. Check central pipeline supplies.

- Check that hoses are connected and pipeline gauges read approximately 50 psi.

Low-pressure systems

Step 4. Check initial status of low-pressure system.

- Close flow control valves and turn vaporizers off.
- Check fill level and tighten vaporizer filler caps.

Step 5. Perform leak check of machine low-pressure system.

- Verify that the machine master switch and flow control valves are off.
- Attach "suction bulb" to common fresh gas outlet.
- Squeeze the bulb repeatedly until it is fully collapsed.
- Verify that the bulb stays fully collapsed for at least 10 seconds.
- Open one vaporizer at a time and repeat the tests as discussed earlier.
- Remove suction bulb, and reconnect fresh gas hose.

Step 6. Turn on machine master switch and all other necessary electrical equipment.

Step 7. Test flowmeters.

- Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes.
- Attempt to create a hypoxic oxygen/nitrous oxide mixture and verify correct changes in flow and/or alarm.

Scavenging system

Step 8. Adjust and check scavenging system.

- Ensure proper connections between the scavenging system and both the adjustable-pressure limit (APL, or "pop-off") valve and ventilator relief valve.
- Adjust waste gas vacuum (if possible).
- Fully open APL valve and occlude Y-piece.
- With minimum oxygen flush activated, allow the scavenger reservoir bag to distend fully and then verify that the absorber pressure gauge reads less than 10 cm H_2O.

Breathing system

Step 9. Calibrate oxygen monitor.

- Ensure monitor reads 21% in room air.
- Verify low oxygen alarm is enabled and functioning.
- Reinstall sensor in circuit and flush breathing system with

oxygen.
- Verify that monitor now reads more than 90%.

Step 10. Check initial status of breathing system.
- Set selector switch to "bag" mode.
- Check that breathing circuit is complete, undamaged, and unobstructed.
- Verify that CO_2 absorbent is adequate.[1]
- Install breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.

Step 11. Perform leak check of the breathing system.
- Set all gas flows to zero (or minimum).
- Close APL (pop-off) valve and occlude Y-piece.

[1] Note that in step 10, checking adequacy of the CO_2 absorbent should include changing or hydrating it if there is any possibility that it may have become desiccated. This is because desiccated soda lime can react with desflurane, enflurane, and isoflurane, and sevoflurane to produce high levels of CO in the breathing system. Also be aware that the color of the new absorbent, Amsorb, changes to violet when it is desiccated and when it is exhausted.

- Pressurize breathing system to approximately 30 cm H_2O with oxygen flush.
- Ensure that pressure remains fixed for at least 10 seconds.
- Open APL (pop-off) valve and ensure that pressure decreases to zero.

Manual and automatic ventilation systems

Step 12. Test ventilation systems and unidirectional valves.
- Place a second breathing bag on the Y-piece.
- Set appropriate ventilator parameters for the next patient.
- Switch to automatic ventilation ("ventilator") mode.
- Fill bellows and breathing bag with oxygen flush and then turn the ventilator on.
- Set oxygen flow to minimum, and other gas flows to zero.
- Verify that during inspiration, bellows deliver appropriate

tidal volume, and that during expiration, bellows fill completely.

- Set fresh gas flow to approximately 5 L per minute.
- Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end expiration.
- Check for proper action of unidirectional valves.
- Exercise breathing circuit accessories to ensure proper function.
- Turn ventilator off and switch to manual ventilation ("bag/APL") mode.
- Ventilate manually and ensure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
- Remove second breathing bag from the Y-piece.

Monitors

Step 13. Check, calibrate, and/or set alarm limits of all monitors.

- Capnometer
- Pulse oximeter
- Oxygen analyzer
- Respiratory volume monitor (spirometer)
- Pressure monitor
- High- and low-airway alarms

Final position

Step 14. Check final status of machine.

- Vaporizers off
- APL valve open
- Selector switch to "bag"
- All flowmeters to zero
- Patient suction level adequate
- Breathing system ready to use

The preanesthesia equipment checkout procedures are shown

in **Table 59.1**.

Although many modern anesthesia machines have automated many of the steps described earlier, it is important to understand the principles of each step of a pre-anesthesia checkout procedure.

American Society of Anesthesiologists. *Summary of American Society of Anesthesiologists 2008 Checkout Recommendations by Frequency and Responsible Party. Recommendations for Pre-Anesthesia Checkout Procedures*. Schaumburg, IL: American Society of Anesthesiologists; 2008.

Loeb RG, Gravenstein N. Simultaneous color change at opposite ends of carbon dioxide absorbent canisters. *Anesthesiology*. 2018;129:1170.

B.2. What emergency equipment should be easily available to the anesthesiologist?

In checking the anesthesia machine, step 1 on the FDA 1993 checklist and the 2008 American Society of Anesthesiologists' guidelines is to verify that backup ventilation equipment is available and functioning. This means a self-inflating resuscitation bag appropriate for patient size (adult vs. pediatric) is present and tested. Emergency airway management equipment must be available.

One method for having emergency airway management equipment available and accessible is to have a "difficult airway cart" for the "cannot intubate, cannot ventilate" scenario. This cart should include supraglottic airways such as a laryngeal mask airway, nasal trumpets, or oral airways as well as supplies for a needle cricothyrotomy and jet ventilation.

Other emergency equipment includes a working flashlight, a backup battery for any electricity-dependent workstation, an oxygen tank and regulator, a malignant hyperthermia cart, a "code" cart and defibrillator, a difficult airway cart, a fire extinguisher, knowledge of appropriate response to a fire, and an evacuation plan.

ECRI Institute. New clinical guide to surgical fire prevention. Patients can catch fire—here's how to keep them safer. *Health Devices*. 2009;38:314–330.

B.3. How should this patient be premedicated?

The goal of premedication must be established preoperatively. Commonly considered objectives listed in order of most to least common are as follows:

- Anxiolysis
- Minimization of gastric volume and acidity when "full stomach" is of concern
- Antibiotic prophylaxis administered within 1 hour of incision per Surgical Care Improvement Project (SCIP) guideline
- Antisialagogue effect

This patient may require anxiolysis. Premedication for anxiolysis in an ambulatory patient must consider the patient's need to arrive from home and ambulate as well as the desire for rapid return of clear mental status postoperatively. Most commonly, therefore, no agent is administered preoperatively. Alternatively, for the highly anxious patient, a small dose of a short-acting agent (e.g., midazolam 1 to 2 mg intravenously) may be administered.

C. Intraoperative Management

C.1. How should this patient be monitored?

The "Standards for Basic Anesthetic Monitoring" are

established by the American Society of Anesthesiologists and were last amended in October 2010 and affirmed in October 2015. In summary, they are as follows:

- *Standard I*: Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.
- *Standard II*: During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

Oxygenation

- *Inspired gas*: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*
- *Blood oxygenation*: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.* When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.* Adequate illumination and exposure of the patient are necessary to assess color.*

Ventilation

- Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful. Continual monitoring for the presence of expired CO_2 shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.*
- When an endotracheal tube or laryngeal mask is inserted, its

correct positioning must be verified by clinical assessment and by identification of CO_2 in the expired gas. Continual $Etco_2$ analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.* When capnography or capnometry is utilized, the $Etco_2$ alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.*

- When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
- During regional anesthesia and monitored anesthesia care, the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and/or monitoring for the presence of exhaled CO_2.

Circulation

- Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
- Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every 5 minutes.*
- Every patient receiving general anesthesia shall have, in addition to earlier, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

Body temperature

- Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

The reader should visit the American Society of Anesthesiologists' website for the most recent version of the standards: https://www.asahq.org/standards-and-guidelines/standards-for-basic-anesthetic-monitoring.

C.2. Following uncomplicated induction of anesthesia and endotracheal intubation, the procedure begins. Upon insufflation of the abdomen with CO_2, the SpO_2 decreases to 78%. What acute diagnostic and therapeutic interventions would you perform?

Immediately, it should be determined if the tracheal tube is in the trachea. Visualization of the tube passing between the vocal cords, visualization of bilateral chest rise, equal breath sounds bilaterally with auscultation, and sustained end-tidal CO_2 are rapid methods for confirming endotracheal placement of the tube.

The differential diagnosis for a desaturation is shown in **Table 59.2**.

TABLE 59.2 Differential Diagnosis of Low SpO_2 Reading

Cause	Examples
Hypoxic gas mixture	Low FIO_2, altitude
Hypoventilation	Airway obstruction, splinting associated with chest or abdominal surgery, bronchospasm

Right-to-left shunt	Atelectasis, main-stem intubation, mucus plug, intracardiac shunt, pulmonary edema
$\dot{V}/\dot{Q}$ mismatch	Chronic obstructive pulmonary disease, pulmonary embolism, pneumonia, pulmonary edema
Diffusion impairment	Interstitial lung disease
Spurious reading	Sensor not properly applied to extremity causing penumbra effect; methemoglobinemia

FIO_2, fraction of inspired oxygen; $\dot{V}/\dot{Q}$, ventilation/perfusion.

In this patient, the presence of bilateral breath sounds and the quality of those breath sounds must be ascertained. The FIO_2, $EtCO_2$, heart rate, and blood pressure also need to be checked.

Therapeutically, the FIO_2 should be increased immediately to 1 (i.e., 100%) and a change to manual ventilation should be initiated. The surgeon should desufflate the abdomen until the patient has stabilized. If unilateral breath sounds are heard, potential sources include endobronchial intubation, mucus plug, bronchospasm, or pneumothorax.

Given the steep Trendelenburg positioning and insufflation of the abdomen required for this procedure, main-stem intubation is most likely, in which case the endotracheal tube should be gradually withdrawn until breath sounds become bilateral; the tube should then secured.

Maerz DA, Beck LN, Sim AJ, et al. Complications of robotic-assisted laparoscopic surgery distant from the surgical site. *Br J Anaesth*. 2017;118:492–503.

C.3. The endotracheal tube was withdrawn 2 cm. Squeezing the reservoir bag in the circle breathing system failed to generate positive pressure in the circuit. What are the common sites for gas leaks in the circle breathing system?

A leak can occur anywhere in the breathing circuit. One might logically check for a leak in the circuit starting from the tip of

the tracheal tube and working backward toward the anesthesia workstation, checking the following common potential leak sites:

- Incomplete seal between the endotracheal tube cuff and the trachea (e.g., deflated cuff, supraglottic position, incompetent valve on pilot balloon)
- Connection between the endotracheal tube and the breathing circuit (e.g., disconnected elbow adapter)
- Spirometric and end-tidal monitoring connections at both the patient end (near the connection between the breathing circuit and endotracheal tube) and the monitor end
- Connection between inspiratory and expiratory gas hoses and the anesthesia machine
- Within the low-pressure system, including the unidirectional valves, APL valve, reservoir bag or bellows housing, absorber, vaporizers, flowmeters, and scavenging system

One method for rapidly determining if a leak is proximal or distal to the connection of the circuit to the endotracheal tube involves disconnecting the endotracheal tube from the circuit and attaching a manual self-inflating resuscitator bag. If positive pressure ventilation is possible without a leak using the manual self-inflating resuscitator bag, the leak is within the circuit or anesthesia machine. If positive pressure ventilation is not possible, the leak is within the endotracheal tube or patient.

In the case of a leak following withdrawal of the tube from an endobronchial position, two likely sources of the leak can be identified. Withdrawal of a tube requires deflation of the cuff and reinflation after repositioning to seal the system; the cuff pilot balloon should be palpated to confirm inflation of the cuff and air should be added if necessary. Secondly, the tube may have been withdrawn too far and the tip may have become supraglottic. Correct endotracheal placement must be confirmed. Fiberoptic bronchoscopy may be utilized to visualize the

endotracheal tube in position proximal to the carina.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:591–620.

C.4. The patient was taken out of Trendelenburg position. Direct laryngoscopy revealed the endotracheal tube to be supraglottic. Additionally, green secretions were noted to be pooled in the posterior pharynx. What should be done next?

The endotracheal tube should be replaced in order to protect the airway from possible aspiration. The posterior oropharynx should be suctioned thoroughly. Once the endotracheal tube is secured, the trachea should be suctioned to determine if gastric contents were aspirated. If aspiration is confirmed, the trachea should be suctioned prior to initiation of positive pressure ventilation to prevent distal spread of the aspirate. If the airway cannot be secured, the patient should be placed in the lateral and head down position to prevent further aspiration.

Bronchoscopy and pulmonary lavage are only necessary if particulate aspiration has occurred. Antibiotics are warranted postoperatively only if aspiration pneumonitis develops. There is currently no evidence that administration of steroids reduces mortality or improves outcomes.

In a patient with a history of poorly controlled diabetes, delayed gastric emptying may result in retained gastric contents despite appropriate fasting times. Rapid sequence intubation followed by orogastric tube placement to empty any remaining contents should take place in such patients as this.

Robinson M, Davidson A. Aspiration under anaesthesia: risk assessment and decision-making. *Contin Educ Anaesth Crit Care Pain*. 2014;14:171–175.

D. Postoperative Management

D.1. What criteria would you use for tracheal extubation?

In the operating room, traditional extubation criteria fall into two categories: global and respiratory. Global criteria include return of consciousness, demonstration of ability to protect the airway, adequate reversal of residual neuromuscular blockade, absence of hypothermia, and presence of a normal metabolic milieu (e.g., no significant anemia, acidosis, and electrolyte abnormality). Commonly applied respiratory criteria are a vital capacity greater than 15 mL per kg, a tidal volume of ≥6 mL per kg, and a predicted Spo_2 >90% while breathing an Fio_2 <0.40.

Patients with a respiratory insult and the need for postoperative mechanical ventilation in the postanesthesia care unit or intensive care unit will be assessed using additional and more stringent criteria. The ratio of respiratory rate to tidal volume is widely used and commonly referred to as the *rapid shallow breathing index* (RSBI). Slow, deep breathing during minimal respiratory support predicts successful extubation and rapid, shallow breathing predicts probable failure. To determine this ratio, the patient is observed breathing from a T-bar, or a low level of pressure support (PS) (e.g., usually approximately 5 cm H_2O); this is referred to as a spontaneous breathing trial (SBT). The following is then calculated:

RSBI = respiratory rate (breaths per minute) / tidal volume (liters)

An RSBI greater than 100 is rapid, shallow breathing, and predictably the patient will fail an extubation attempt. When the RSBI is less than 100, it is predicted that the patient will breathe at a rate and tidal volume that can be easily maintained after extubation and will be able to adequately maintain a normal Pao_2 and $Paco_2$. It does not, however, rule out the possibility of an upper airway obstruction complicating that effort. If during the period of observation while breathing from a T-bar or on PS,

the patient develops signs of distress such as diaphoresis, agitation, tachycardia, bradycardia, hypertension, hypotension, hypoxemia, or hypercarbia, the trial is abandoned and the patient is said to have had a "weaning" or "SBT" failure.

Although more sophisticated measurements might be helpful, including measurement of the maximum negative inspiratory force, vital capacity, elastance index, etc., the routine application of this basic and easy-to-reproduce measurement has stood the test of time and certainly for most patients who are intubated and mechanically ventilated for less than 7 to 10 days should be a daily routine.

Frutos-Vivar F, Ferguson ND, Esteban A, et al. Risk factors for extubation failure in patients following a successful spontaneous breathing trial. *Chest*. 2006;130:1664–1671.

Yang KL, Tobin MJ. A prospective study of indexes predicting the outcome of trials of weaning from mechanical ventilation. *N Engl J Med*. 1991;324:1445–1450.

D.2. What are the causes of postoperative hypoxemia?

The etiology of hypoxemia can be classified physiologically or pathologically.

Physiologically, all instances of hypoxemia have only four basic potential causes:

- Low F_{IO_2}
- Hypoventilation (which will also be associated with an increased P_{aCO_2})
- Ventilation/perfusion mismatch
- Shunt

Pathologically, common etiologies likely to present postoperatively include airway obstruction, atelectasis (especially with upper abdominal retraction and Trendelenburg positioning), right main-stem intubation, aspiration, pulmonary edema, and pulmonary embolus.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2592–2593.

D.3. What is the difference between shunt, ventilation/perfusion mismatch, and dead space?

The relative quantity of perfusion and ventilation defines these terms. A normal lung has a small portion in which perfusion and ventilation are perfectly matched. Two extreme conditions may exist at either end of the spectrum of perfectly matched perfusion and ventilation; those extremes are shunt and dead space ventilation.

In a shunt, the alveolus is perfused, but it is not ventilated. The physiologic result is hypoxemia. This is characterized by a failure of the Pa_{O_2} to rise despite an increase in the F_{IO_2}. Hypoxemia caused by small amounts of shunted blood (i.e., less than 20% of cardiac output) is easily overcome by increasing the F_{IO_2}. This is because the blood that is not shunted will contain enough "extra" dissolved oxygen to make up for the deficit that the shunted blood contributes to the combined total blood oxygen content. Once the shunt fraction approaches 0.3 (30%), increasing the F_{IO_2} even to 1 will not be effective in preventing hypoxemia. The term *venous admixture* is often used synonymously for shunt.

In dead space, the alveolus is ventilated, but it is not perfused; hence, the alveolar space is essentially "dead." The physiologic result is hypercarbia. This is characterized by a failure to maintain a normal Pa_{CO_2} despite an increase in minute ventilation (i.e., tidal volume × respiratory rate).

Ventilation/perfusion mismatch is the term applied to any condition that is not a perfect match, completely shunt, or completely dead space. The physiologic result is a variable combination of hypoxemia and hypercarbia. The resultant degree of hypoxemia and hypercarbia depends on the relative

contribution of partial shunt and dead space.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:109–135.

D.4. Postoperatively, the patient developed hypoxia and pulmonary edema. What is the differential diagnosis of pulmonary edema? What is the most likely cause of pulmonary edema in this patient?

Pulmonary edema is categorized into cardiac or noncardiac in etiology. The differential diagnosis of pulmonary edema is shown in **Table 59.3**.

TABLE 59.3 Differential Diagnosis of Pulmonary Edema

Condition	Pathophysiology	Sample Cause
Congestive heart failure	↑ Filling pressure, ↓ cardiac output	Myocardial infarction
Negative pressure pulmonary edema	↑ Outside–inside pressure gradient	Laryngospasm
Acute respiratory distress syndrome	↑ Permeability	Sepsis, aspiration, fat embolus, TRALI

↓, decrease; ↑, increase; TRALI, transfusion-related acute lung injury.

Conditions that physiologically result from an increase in the pressure within the vessel that cause transudation of fluid from inside the vessel to outside the vessel are traditionally termed congestive heart failure (CHF). CHF will be associated with a diminution of cardiac function (e.g., ejection fraction) and an increase in the left ventricular end-diastolic pressure.

A decrease in the pressure outside of the vessel may also result in the net movement of fluid from inside to outside. A classic example is negative pressure pulmonary edema—a condition seen in patients who inspire against a closed glottis and generate a large net negative force, which acutely draws fluid into the alveolus, leading to pink frothy sputum and

hypoxemia almost instantaneously.

A change in the permeability of the vessel wall is the major cause of pulmonary edema seen in ARDS. These conditions require a history of exposure to a risk factor within 1 week, the development of bilateral infiltrates on chest radiography, decreased oxygenation, and respiratory failure not explained by cardiac failure or volume overload. Previously, a pulmonary artery catheter was required for diagnosis of ARDS, but this was removed in 2012 when the Berlin definition for ARDS was determined. The requirement for pulmonary artery catheter was removed due to declining use of pulmonary artery catheters and because hydrostatic edema may coexist with ARDS. The diagnostic criteria for ARDS are listed in **Table 59.4**.

TABLE 59.4 Diagnostic Criteria for Acute Respiratory Distress Syndrome

Timing	Within 1 week of clinical insult or new or worsening respiratory symptoms
Imaging	Bilateral infiltrates on chest radiography
Origin of edema	Respiratory failure not explained by cardiac failure or volume overload
Decreased oxygenation	*Mild:* PaO_2/FIO_2 ≤300 mmHg with PEEP or CPAP ≥5 cm H_2O
	Moderate: PaO_2/FIO_2 ≤200 mmHg with PEEP ≥5 cm H_2O
	Severe: PaO_2/FIO_2 ≤100 mmHg with PEEP ≥5 cm H_2O

CPAP, continuous positive airway pressure; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen in arterial blood; PEEP, positive end-expiratory pressure.

Risk factors for ARDS include aspiration, long bone fracture, transfusion-related acute lung injury (TRALI), pancreatitis, inhalational injury, and sepsis.

Aspiration pneumonitis leading to ARDS is most likely to develop in this patient who had gastric secretions in the posterior pharynx and an unprotected airway.

ARDS Definition Task Force. Acute respiratory distress syndrome: the Berlin definition. *JAMA*. 2012;307: 2526–2533.

Longnecker DE, Newman MF, Zapol WM, et al, eds. *Anesthesiology*. 3rd ed.

New York: McGraw-Hill; 2018: 1251–1268.

D.5. How should the ventilator be set if mechanical ventilation is required postoperatively?

Parameters that must be set include the mode, respiratory rate, tidal volume, PEEP, and F_{IO_2}.

Patients with an acute need for mechanical ventilation should be given full support with the mode set as volume control (sometimes also known as *assist control*) or pressure control, so that all the breaths are delivered by the ventilator, even those initiated by the patient. Other modes to be considered as the patient improves include synchronized intermittent mandatory ventilation (SIMV), PS, and combinations of SIMV and PS.

Tidal volume was traditionally set at 10 mL per kg. Normally, during spontaneous ventilation, the respiratory rate is 12 to 16 breaths per minute, and the tidal volume is 6 mL per kg. However, during spontaneous ventilation, there are yawns and sighs that prevent atelectasis. Yawns and sighs are not administered during routine mechanical ventilation. Therefore, standard mechanical ventilation settings developed more than 50 years ago use a lower respiratory rate and higher tidal volume than spontaneous values, resulting in the same minute ventilation and no need for sigh (150% of tidal volume) breaths.

More recently, traditional mechanical ventilation utilizing a tidal volume of 10 mL per kg has been recognized as a potential cause of morbidity and mortality when applied to injured lungs and may even have adverse consequences when applied routinely in the operating room. The excessive tidal volume is associated with alveolar injury and worsened pulmonary function (i.e., volutrauma). This should be distinguished from the more easily recognized concern of pneumothorax, resulting from ventilation of stiff lungs with high inflation pressures, commonly referred to as barotrauma. Hence, the current

recommendation in ARDS is that the tidal volume be set at 6 mL per kg of premorbid weight. Additionally, the peak inspiratory pressure should ideally be less than 35 cm H_2O. This may result in CO_2 retention, but if the pH is more than 7.25, no intervention is necessary. If CO_2 retention is severe and the pH is less than 7.25 after increasing the respiratory rate to as high as 20 breaths per minute, administration of sodium bicarbonate should be considered. To maximize oxygenation and limit exposure to potentially toxic concentrations of oxygen (i.e., $FIO_2 = 1$), usually an end-expiratory pressure of 10 cm H_2O is set.

In addition to standard monitoring, prolonged mechanical ventilation in ARDS will require arterial line placement to facilitate frequent arterial blood gas determinations. Further, a daily chest radiograph will be required.

The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med*. 2000;342: 1301–1308.

D.6. If this patient had acute respiratory distress syndrome (ARDS) secondary to aspiration, besides low-tidal volume ventilation, what other changes in routine therapy should be considered?

Other management strategies include efforts at minimizing lung water and usual standard intensive care unit measures aimed at deep venous thrombosis (DVT) prophylaxis, gastrointestinal (GI) aspiration prophylaxis, daily sedations breaks, and early mobility. Conservative administration of intravenous fluids originated in a National Institutes of Health-sponsored study; the excessive administration of fluid is harmful, whereas minimizing intravenous fluids appears to be safe and not associated with other organ insufficiency or failure.

Wiedemann HP, Wheeler AP, Bernard GR, et al. National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Comparison of two fluid-management strategies in acute lung injury. *N Engl J Med*. 2006;354:2564–2575.

D.7. What therapies routinely administered by the anesthesiologist may cause acute lung injury?

TRALI has become the leading cause of transfusion-related morbidity and mortality in the United States. This injury is almost always recognized during or shortly after transfusion and is diagnosed by the absence of cardiac failure and fluid overload. Although any blood product can cause this injury, the transfusion of fresh frozen plasma and platelets, especially those donated by women who were previously pregnant, is most often responsible. This injury can be seen even after the transfusion of a single blood product unit and "massive" transfusion is not, as previously thought, a prerequisite.

Alam A, Huang M, Yi QL, et al. Perioperative transfusion-associated lung injury: the Canadian Blood Service experience. *Transfus Apher Sci*. 2014;50:392–398.

D.8. What methods of oxygen administration may be used postoperatively?

Most postoperative patients who are prone to develop hypoxemia may be managed with a nasal cannula or face mask. Nasal cannulas are inexpensive and comfortable, but regardless of flow rates, they cannot achieve an F_{IO_2} of more than 0.30 unless special high-flow devices are used. Face masks have the capability of delivering a wide range of precise F_{IO_2} levels of up to 1.

Occasionally, a patient may require more aggressive oxygen therapy than can be provided by nasal cannula or face mask but less invasive than tracheal intubation and mechanical ventilation. Noninvasive positive pressure ventilation should be

considered. Continuous positive airway pressure, bilevel positive airway pressure, or high-flow nasal cannula may be applied. Additionally, a single-use nasal positive airway pressure device called SuperNO_2VA can be used intraoperatively or postoperatively. These modes may be used in patients who either have previously used these devices at home or who are on the verge of requiring tracheal intubation and mechanical ventilation but have conditions thought to be rapidly resolving (e.g., CHF and chronic obstructive pulmonary disease exacerbation). These patients usually do not require an arterial catheter for blood sampling but do need frequent assessment of their respiratory effort, particularly their respiratory rate and use of accessory muscles, as well as continuous Spo_2 monitoring. A respiratory therapist should be involved to individually achieve the best mask fit and patient comfort possible. In case noninvasive ventilation fails, preparation to emergently tracheally intubate must always be maintained.

Jaber S, Chanques JS, Jung B. Postoperative noninvasive ventilation. *Anesthesiology*. 2010;112:453–461.

60 Electroconvulsive Therapy

Patricia Fogarty Mack

A 72-year-old man with major depressive disorder who has failed medication therapy and psychotherapy is scheduled for electroconvulsive therapy (ECT). His past medical history reveals significant coronary artery disease status after three-vessel coronary bypass surgery 5 years ago. He also has chronic atrial fibrillation. He had a transient ischemic attack (TIA) 2 years previously after which he underwent left carotid endarterectomy. In addition, he has sleep apnea and gastroesophageal reflux disease (GERD). The patient weighs 115 kg and is 5 ft 3 in. tall and had a Mallampati class 2 airway. Medications include venlafaxine, rivaroxaban, atenolol, and esomeprazole.

A. Medical Disease and Differential Diagnosis

1. What are the indications for ECT?
2. Are there any contraindications to ECT?
3. What is the mechanism of action of ECT?

B. Preoperative Evaluation and Preparation

1. How would you assess the cardiac status of this patient?
2. How should his anticoagulation be managed during ECT?
3. What implications do his history of sleep apnea have on

management of ECT?
4. How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?
5. Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardioverter-defibrillator?
6. Are there any psychiatric medications he is taking that would impact your anesthetic care?

C. Intraoperative Management

1. Describe the hemodynamic and cardiac response to ECT in a typical patient.
2. Is an arterial line warranted in this patient?
3. By what means would you attempt to maximize hemodynamic stability?
4. Describe the cerebral hemodynamic effects of ECT.
5. How would you proceed with an anesthetic induction for this procedure?
6. How do you intend to manage his airway during each treatment?

D. Postoperative Management

1. The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options.
2. After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?

A. Medical Disease and Differential Diagnosis

A.1. What are the indications for ECT?

For centuries, it had been noted that psychosis did not tend to occur in those people with epilepsy. Since the 16th century, patients with severe mental illness were treated with various

agents, such as camphor, to induce seizures (pharmacoconvulsive therapy). ECT was first instituted in the late 1930s and gained acceptance in providing a better controlled seizure. The addition of curare followed in 1951 by succinylcholine greatly diminished incidence of fracture due to the convulsions. Finally, the advent of methohexital, which ensured unconsciousness without significantly diminishing the seizure, led to the acceptance of ECT as an efficacious and safe treatment.

From the mid-1970s to the 1980s, many new drug treatments for psychiatric illness were developed and found to be efficacious. ECT fell into disfavor as a barbaric treatment when compared to pharmacotherapy.

In the past three decades, the pendulum has again swung back in favor of ECT as a safe and effective treatment for drug-resistant major depressive disorder and bipolar disorder.

Specific indications for ECT include, but are not limited to, major depressive disorder and bipolar disorder, acute schizophrenia (especially with affective or catatonic symptoms), and schizoaffective disorder. Although usually reserved as a second-line therapy for those who are resistant to pharmacologic treatment, ECT has, in some circumstances, been recommended as a first-line therapy, especially if a rapid response is urgently required as in patients with severe suicidal potential, malnutrition/dehydration, and catatonia. Finally, ECT has been recommended in patients who are unable to tolerate pharmacotherapeutic agents for any reason, including during pregnancy.

Kellner CH. *Handbook of ECT: A Guide to Electroconvulsive Therapy for Practitioners*. Cambridge, United Kingdom: Cambridge University Press;

2019:19–20.

A.2. Are there any contraindications to ECT?

There is no absolute contraindication to ECT. There is considered to be significantly increased risk in patients with intracranial space occupying lesions, any condition associated with intracranial hypertension, recent myocardial infarction with diminished ventricular function, severe hypertension especially associated with pheochromocytoma, evolving stroke, retinal detachment, and any American Society of Anesthesiologists physical status 4 or 5 patient.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:27–30.

Kellner CH. *Handbook of ECT: A Guide to Electroconvulsive Therapy for Practitioners*. Cambridge, United Kingdom: Cambridge University Press; 2019: 19–20.

A.3. What is the mechanism of action of ECT?

The mechanism of ECT is unknown. There are many neurochemical, neuroendocrine, electrophysiologic, and neuropsychological theories regarding the mechanism of ECT (**Table 60.1**).

TABLE 60.1 Mechanism of Action of Electroconvulsive Therapy—Physiologic Theories

Neurophysiologic
Anticonvulsant (changes in seizure threshold)
Cerebral blood flow and metabolic rate change
Increased slow-wave EEG activity
Antidelirium/sleep theories
Neuroendocrinologic
Prolactin release
Neuropeptide release
Melatonin
Neurochemical

Stimulation of β-receptors
Monoamine release
Modulation of serotonin
Neuropeptide/Neurotrophic
Brain-derived neurotrophic factor
Increased endorphins
Increased gray matter volume and cortical thickness amygdala, hippocampus, and other brain areas

EEG, electroencephalography.

In addition, although it was long assumed that a generalized seizure of adequate duration is sufficient for effective treatment, research has shown that barely suprathreshold stimulation, especially with unilateral ECT, is also efficacious. The cognitive impairment associated with ECT may be reduced by utilizing "ultrabrief" stimulus, marked by a shorter pulse width of electrical stimulation, apparently without sacrificing efficacy.

Cognitive impairment after ECT has been extensively investigated. In addition, the major depressive state is associated with a decline in cognition. Although acute confusion and amnesia, both anterograde and retrograde, may occur as a result of ECT, studies have shown that verbal memory showed greater improvement in depressed patients treated with ECT as compared to controls.

In addition, there is no increased risk of dementia for patients with major depression who are treated with ECT versus patients who did not receive ECT.

B. Preoperative Evaluation and Preparation

B.1. How would you assess the cardiac status of this patient?

The cardiac status of the patient needs to be assessed as it would for any other general anesthetic. Because there can be periods of significant tachycardia and hypertension following seizure induction, it would be useful to ensure that there is no longer significant myocardium at risk for ischemia and that systolic function is not compromised. If this information cannot be obtained from patient history and assessment of his functional status, it may be useful to obtain a stress test and echocardiogram. Bear in mind that it may be difficult to get an accurate history of functional status from patients who are psychotic or severely depressed.

B.2. How should his anticoagulation be managed during ECT?

The anticoagulation for his atrial fibrillation should be continued throughout his course of therapy, maintaining an international

normalized ratio (INR) between 2.0 and 3.0. Although intracerebral hemorrhage is a theoretic concern, a retrospective study from the Mayo Clinic suggests that ECT can be safely performed in patients on warfarin therapy. Although the safety of newer anticoagulants has not been formally investigated in ECT, case series do not report any hemorrhagic complication in patients receiving either dabigatran or rivaroxaban. Finally, if a patient has drug-eluting arterial stents, aspirin and clopidogrel or any alternative antiplatelet maintenance medication should be continued.

B.3. What implications do his history of sleep apnea have on management of ECT?

His history of sleep apnea is important because suboptimal management of respiratory function may reduce efficacy of treatment and increase complications. Hypocarbia is sometimes required to ensure adequate seizure duration. Additionally, after onset of seizure activity, oxygen consumption is increased dramatically as is carbon dioxide (CO_2) production. Hypercarbia

can exacerbate the tachycardia and hypertensive responses to seizure. Therefore, adequate mask ventilation is required to ensure optimal respiratory status. The use of a supraglottic airway device may be required to ensure adequate ventilation in this patient.

Finally, if the patient uses continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BIPAP) at home, it may be useful to have that machine available to the patient in the postprocedure period when postanesthetic and postictal somnolence may compromise his ability to maintain a patent airway.

Trakada G, Velentza L, Konsta A, et al. Complications of anesthesia during electroconvulsive therapy due to undiagnosed obstructive sleep apnea: a case study. *Respir Med Case Rep*. 2017;20:145–149.

B.4. How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?

A history of TIA or stroke is an indication for magnetic resonance imaging (MRI) of the head before their first course of ECT. Additionally, this study may be utilized to rule out an organic cause for depression. Although a comprehensive neurologic examination before ECT is routinely recommended by the American Psychiatric Association, it may be that in this patient, more sophisticated neuropsychological testing would be useful in documenting subtle deficits and establishing a true baseline. Finally, if the patient has not had follow-up carotid Doppler examination, it may be useful to ensure that there has not been restenosis or that no new plaques have formed. This is particularly important in view of the fact that the rate pressure product may be increased by as much as 400% in the

sympathetic phase of the cardiac response.

American Psychiatric Association. *The Practice of Electroconvulsive Therapy: A Task Force Report of American Psychiatric Association*. 2nd ed. Washington, DC: American Psychiatric Association; 2001:77–80.

B.5. Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardioverter-defibrillator?

See Chapter 8, section C.11.

B.6. Are there any psychiatric medications he is taking that would impact your anesthetic care?

Medications for depression can have many serious side effects. In fact, one of the indications for ECT is that the patient cannot tolerate pharmacologic therapy. Furthermore, there are many possible drug interactions between antidepressant medications and anesthetic agents as well as other medications that might be administered in the course of an anesthetic. The most common of these side effects and interactions are shown in **Table 60.2**.

TABLE 60.2 The Most Common Side Effects and Anesthetic Interactions of Psychiatric Medications

Drug Group	Examples of Drug	Mechanism	Side Effects/Toxicities	Perioperative Concerns
SSRI/SNRI	Venlafaxine, fluoxetine	Presynaptic inhibition of SER/NE	Nausea, vomiting Sexual dysfunction Headache Agitation SIADH (rare) Cytochrome P450 inhibition	Prolonged/increased action of β-blockers, benzodiazepines, barbiturates, anticholinergics
Bupropion		SNRI/dopamine reuptake antagonist	Dry mouth, nausea, tremor	Theoretically reduced seizure threshold, prolonged seizure
Lithium	Lithium	Unclear	Sinus node dysfunction	Prolongation of

			AV block Bradycardia Nephrogenic diabetes insipidus	nondepolarizing muscle relaxants Reducing MAC
TCAs	Amitriptyline, imipramine	Presynaptic inhibition of SER uptake	Conduction deficits (wide QRS, prolonged QT Postural hypotension Anticholinergic symptoms Sedation	Muscarinic, histaminergic, and α_1-adrenergic blocking effects
MAOIs	Phenelzine, tranylcypromine	Inhibit breakdown of NE and SER by MAO enzyme	Hypertension Nausea Dizziness Headache Sleep disturbance Severe hypertension with tyramine-containing foods Thrombocytopenia and anemia	Avoid indirect acting sympathomimetics. Avoid serotonin crisis precipitants.
Antipsychotics	Prochlorperazine, chlorpromazine	Block D2 dopamine receptors Atypical antipsychotics also block some serotonin receptors. Also block histamine and α_1-adrenergic receptors	Hypotension Tachycardia, prolonged QT interval Extrapyramidal symptoms Tremor Tardive dyskinesia Neuroleptic malignant syndrome Muscle rigidity, hyperthermia, autonomic dysfunction	

Serotonin syndrome: hyperreflexia, agitation, hyperthermia. AV, atrioventricular; ECT, electroconvulsive therapy; MAC, minimal alveolar concentration; MAO, monoamine oxidase; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; NSAIDs, nonsteroidal anti-inflammatory drugs;

SER, serotonin; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCAs, tricyclic antidepressants; TIVA, total intravenous anesthesia.

C. Intraoperative Management

C.1. Describe the hemodynamic and cardiac response to ECT in a typical patient.

First, a parasympathetic discharge occurs within a few seconds of application of the electrical stimulus. This may result in bradycardia, which may be profound and even progress to asystole. Because many patients are volume-depleted due to poor oral intake or mildly hypotensive secondary to their psychotropic medications, they can be susceptible to further hypotension due to anesthetic induction. Within 1 minute, sympathetic activation due to the seizure results in a tachycardia and at times dysrhythmias as well as hypertension to up to 150% of baseline values. This hypertension usually lasts for between 2 and 5 minutes. If the patient is not adequately ventilated, hypercarbia may add to the hypertension. During the first ECT treatment, the electrical stimulus may often be titrated upward in succession until a generalized seizure occurs. When a generalized seizure does not follow the electrical stimulation, the parasympathetic response predominates and the patient may experience a sustained bradycardia.

With such a dramatic increase in heart rate and blood pressure, the rate pressure product, an indicator of myocardial oxygen demand, is significantly elevated. This can lead to electrocardiographic ischemia as well as regional wall motion abnormalities on echocardiography.

Messina AG, Paranicas M, Katz B, et al. Effect of electroconvulsive therapy on the electrocardiogram and echocardiogram. *Anesth Analg*. 1992;75:511–514.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

C.2. Is an arterial line warranted in this patient?

No, in spite of the potential dramatic perturbations in heart rate and blood pressure, these responses are fairly predictable and can be attenuated by judicious use of anticholinergics and antihypertensives. Atropine (0.4 mg) or glycopyrrolate (0.2 mg) are used to prevent the bradycardia associated with the parasympathetic discharge. The tachycardia and hypertension seen as part of the sympathetic response may be prevented with short-acting β-blockade, nitroglycerin, or even remifentanil, administered just at the beginning of the sympathetic stimulation. Pretreatment with dexmedetomidine may also ameliorate the tachycardia and hypertension that occurs immediately post seizure.

Patients may have transient ECG changes around the time of the procedure. There is also evidence that patients may experience a transient decrease in left ventricular function. Rarely, Takotsubo cardiomyopathy occurs. Although severe cardiac complications during ECT have been thought to be very rare, even in patients with underlying coronary disease, a recent meta-analysis identified indicates a rate of cardiac event as frequent as 1 out of 50 patients or 1 in 200 ECT treatments. Another meta-analysis indicated a mortality of 1 in 200,000 treatments.

C.3. By what means would you attempt to maximize hemodynamic stability?

First, one should continue antihypertensive medication on the evening before and the morning of the procedure. Second, a small dose of atropine (0.4 mg) or glycopyrrolate (0.2 mg) may be given several minutes before the electrical stimulation in order to prevent the subsequent bradycardia. At Weill Cornell Medical Center, we are more likely to use glycopyrrolate as it is a quaternary compound, which will not cross an intact blood–brain barrier. In addition, the tachycardic response from the seizure is not as pronounced when glycopyrrolate is used as compared with atropine. Anticholinergic pretreatment is most important during the first treatment when the electrical stimulation is being titrated, and it is likely not to progress into a generalized seizure on the first or second stimulus. If the pretreatment with an anticholinergic leaves a fragile patient with an undesirable tachycardia, we may omit it during subsequent treatments as long as the bradycardia is not too severe or prolonged.

Similarly, medications to attenuate the sympathetic response are typically not administered until it is certain that the seizure will generalize. This results in a requirement for very fast-acting drugs to control heart rate and blood pressure. The drug of

choice at Weill Cornell Medicine is esmolol (0.5 to 1.0 mg per kg) or labetalol (5 to 20 mg). If there is a contraindication to β-blockers, diltiazem, or nicardipine may be substituted. Nitroglycerin may be particularly useful in patients with ischemic cardiac disease. Remifentanil has also been found to be effective in attenuating the sympathetic response.

A study of American Society of Anesthesiologists Physical Status I and II patients assessed echocardiographic and hemodynamic parameters when the sympathetic response was pretreated with intravenous β-blocker, calcium channel blocker, or nitroglycerin prior to the electrical stimulus. No new regional wall motion abnormalities were found, but β-blocker seemed to be the most effective medication at attenuating fractional shortening and the entire sympathetic response.

C.4. Describe the cerebral hemodynamic effects of ECT.

Electrically induced seizures lead to cerebral hyperemia (increase in cerebral blood flow) as documented by transcranial Doppler and near-infrared spectroscopy. This response occurs even if the seizure does not generalize, suggesting that they are a result of the electric stimulation itself. The increase in cerebral blood flow has been shown to be related to the degree of systemic hypertension and occurs whether bilateral or unilateral stimulus is applied. Although there is a correlation with systemic hypertension, the systemic antihypertensives do not fully

ameliorate the increase in cerebral blood flow. This is due to the fact that these drugs have differing effects on the cerebral and systemic circulations.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

C.5. How would you proceed with an anesthetic induction for this procedure?

Anesthetic induction may be accomplished with any one of a number of medications. Traditionally, methohexital (0.5 to 1.0 mg per kg) has been the induction agent of choice because it has very little effect on seizure duration and has a rapid onset and recovery profile. Other medication includes etomidate (0.2 to 0.3 mg per kg) or propofol (0.5 to 1.0 mg per kg). In research studies, etomidate provides for longer seizure duration when compared to methohexital and propofol; however, postictal hypertension is more severe and myoclonic contractions may be undesirable. In addition, there is a greater incidence of nausea, increased confusion, and prolonged recovery time. Although adrenal suppression has been reported in patients on continuous infusions of etomidate, there are no reports of adrenal suppression in patients receiving multiple bolus doses of etomidate as part of a course of ECT. In patients in whom etomidate is not well tolerated, propofol or thiopental may be used. Studies concur that propofol and thiopental reduce seizure duration; however, there is controversy as to how this reduction in seizure duration impacts the efficacy of therapy.

Ketamine has been noted to have antidepressant effects and potentiate the early reduction of depressive symptoms when given in conjunction with ECT. It appears that ketamine may be useful in some patients in whom a rapid decrease in depressive symptoms is essential, such as those with extreme suicidal ideation or catatonia. A randomized controlled trial of “ketofol,”

a combination of ketamine and propofol, determines that ketofol was associated with a longer seizure time than propofol, faster recovery than ketamine, with good hemodynamic stability. Current investigations are focused on the optimal dosing of the optimal anesthetic agent to improve ECT efficacy.

Muscle relaxation is usually achieved with succinylcholine (0.5 to 1.0 mg per kg) unless there is a contraindication. In that case, a short-acting nondepolarizing muscle relaxant may be substituted.

Okamoto N, Nakai T, Sakamoto K, et al. Rapid antidepressant effect of ketamine anesthesia during electroconvulsive therapy of treatment-resistant depression: comparing ketamine and propofol anesthesia. *J ECT*. 2010;26:223–227.

C.6. How do you intend to manage his airway during each treatment?

The diagnosis of sleep apnea and the patient's body habitus raise concerns regarding the ease and effectiveness of mask ventilation. In spite of these concerns, a plan to proceed with mask ventilation as well as a backup plan of supraglottic airway or intubation is reasonable. As ECT is usually administered three times a week, repeated intubations may lead to airway trauma and edema. GERD may also be of concern; however, patients for ECT are not intubated solely because of GERD. Continuation of medication to reduce stomach acid and promote gastric emptying as well as a dose of preinduction sodium bicitrate may be used to reduce gastric acidity.

Effective mask ventilation is important for several reasons. First, hypocapnia may lower seizure threshold and promote more effective therapy. Second, avoidance of postseizure hypercapnia is necessary as hypercapnia will exacerbate hypertension and tachycardia.

In anticipation of potential difficult ventilation during ECT,

the patient is preoxygenated for 3 to 5 minutes prior to induction. As soon as induction is accomplished, both an oral and a well-lubricated nasal airway may be placed. A second person ideally is available in case two-person ventilation is required. Jackson-Rees circuits are advantageous for ventilation during ECT. First, it allows adjustment of the amount of positive pressure administered; second, the weight of a tradition bag-valve–mask ventilator may make maintenance of ideal mask placement difficult; finally, as the patient regains spontaneous ventilation, he or she may breathe comfortably and effectively through the Jackson-Rees circuit. If mask ventilation were not effective, an appropriately sized supraglottic airway may be placed.

If necessary for adequate ventilation, intubation may be considered. Unfortunately, repeated intubations over several days and weeks may lead to glottic edema and trauma.

Saito S. Anesthesia management for electroconvulsive therapy: hemodynamic and respiratory management. *J Anesth*. 2005;19:142–149.

D. Postoperative Management

D.1. The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options.

PIA manifests as disorientation, inability to consistently follow commands, and motor agitation. Risk factors for PIA include prolonged seizure duration, bilateral versus unilateral ECT, and concomitant lithium therapy. In addition, low doses of induction agent as well as very low doses of succinylcholine are considered risk factors. The use of low-dose succinylcholine may be related to excess lactate production in those patients who have greater manifestation of clinical seizure activity. Increased

lactate levels were noted in patients who experienced PIA versus those who did not.

It is of critical importance to rule out nonconvulsive status epilepticus as an etiology for the PIA. Nonconvulsive status may present as agitation or conversely as mutism.

Treatment of PIA usually consists of benzodiazepine, such as midazolam 1 to 2 mg. If this is not effective, haloperidol may be added. In some circumstances, propofol as a bolus or an infusion have been effective. Current management of PIA may include the use of dexmedetomidine, either as a pretreatment or postseizure therapy.

Other potential adverse effects of ECT include aspiration, headache, nausea, and dental or tongue injuries.

Aksay SS, Bumb JM, Remennick D, et al. Dexmedetomidine for the management of postictal agitation after electroconvulsive therapy after S-ketamine anesthesia. *Neuropsychiatr Dis Treat*. 2017;13:1389–1394.

Tzabazis A, Schmitt HJ, Ihmsen H, et al. Postictal agitation after electroconvulsive therapy: incidence, severity, and propofol as a treatment option. *J ECT*. 2013;29:189–195.

D.2. After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?

Outpatient ECT has become an acceptable therapeutic option for many patients. Primarily, it is used for maintenance therapy. It may also be used to complete an initial course of ECT provided that the first several treatments are uneventful medically (i.e., no respiratory or cardiovascular problems) and that the patient is demonstrating improvement in psychiatric status. In addition, because psychiatric patients may be unreliable in following preoperative instructions, such as nothing by mouth status, they

must have another adult who assumes responsibility for ensuring that those instructions are followed. Of course, they must also have an escort to bring them home.

Finally, there needs to be close communication between the treating psychiatrist and the ECT psychiatrist to keep abreast of any change in psychiatric status or in any medical condition.

Ambulatory Surgery

Melinda Randall, Hugh C. Hemmings Jr.

61

A 71-year-old female with mild discomfort and an outward bulge in the abdominal area is scheduled for open ventral hernia repair in the ambulatory surgery center. The surgeon's history and physical indicate that it is a small hernia. The patient has a significant family history of hernias. Her preoperative outpatient questionnaire indicates that she has hypertension that is well controlled by medication. She walks and exercises >4 metabolic equivalent of task (METS) physical activity four to five times per week without symptoms of chest pain or shortness of breath. She is 165 cm in height with a weight of 82 kg. The only medication she takes is lisinopril for hypertension. There is a history of postoperative nausea and vomiting (PONV) with prior anesthetics, even with monitored anesthesia care (MAC) for a bunionectomy. This patient is concerned about memory loss after anesthesia; she had some issues after colonoscopy with midazolam, fentanyl, and propofol.

A. Medical Disease and Differential Diagnosis

1. Is this patient morbidly obese?
2. What medical conditions may be associated with obesity and morbid obesity?
3. Is there a link to a decline in memory and thinking with

anesthesia and surgery?

B. Preoperative Evaluation and Preparation

1. What advantages does outpatient surgery offer?
2. What are the goals of the preoperative evaluation of the surgical outpatient?
3. In order to thoroughly screen for disease, should one put all outpatients through a full battery of laboratory testing?
4. What preoperative laboratory testing is necessary for surgical outpatients?
5. Which outpatients should receive a preoperative chest roentgenogram?
6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?
7. Would age or physical status influence the decision to perform outpatient surgery?
8. What patients are considered inappropriate for ambulatory surgery?
9. What questions are critically important to ask this patient when obtaining her history?
10. What instructions should the patient be given with regard to continuing or discontinuing lisinopril in the perioperative period?
11. What is an enhanced recovery after surgery (ERAS) protocol, and how would you apply it in the outpatient setting?
12. How would you premedicate this patient?
13. Should every outpatient receive prophylaxis against aspiration pneumonitis?
14. Is an overnight fast justified for all outpatients?

C. Intraoperative Management

1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?
2. How would you monitor this patient?

3. What is the bispectral index (BIS) monitor, and what information does it convey?
4. What benefits might be derived from using a BIS monitor?
5. Is BIS monitoring applicable to children?
6. What are the major limitations of BIS monitoring?
7. What does a BIS reading of 56 mean?
8. What anesthetic agents would you use to induce and maintain general anesthesia in this patient?
9. Under what circumstances might spinal anesthesia be appropriate for outpatient surgery?

D. Postoperative Management

1. What are the common causes of nausea and vomiting in outpatients?
2. How would you pharmacologically prevent PONV in the susceptible ambulatory patient?
3. How is postoperative pain treated?
4. What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?
5. How would you decide when to discharge a patient after regional anesthesia?
6. What instructions should be given to an ambulatory surgical patients upon discharge?

A. Medical Disease and Differential Diagnosis

A.1. Is this patient morbidly obese?

Morbid obesity is defined by a body mass index greater than 40 kg per m^2. This patient has a body mass index of 30.2 and would, therefore, be considered obese (>30 kg per m^2) but not morbidly obese.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1278–1297.

A.2. What medical conditions may be associated with obesity and morbid obesity?

An abundance of medical conditions may be associated with obesity and morbid obesity. Obstructive sleep apnea (OSA) is the most prevalent sleep-related breathing disorder in *severely obese patients*. Screening tools such as the *STOP-BANG questionnaire* (also see Chapter 63, section B.1) help to identify patients at high risk for OSA, and it is prudent to observe these patients for a minimum of 3 hours postoperatively in an ambulatory setting.

Obesity hypoventilation syndrome is defined as hypoventilation in an obese individual that cannot be attributed to other conditions associated with alveolar hypoventilation. These patients may exhibit hypoxemia and serum electrolyte abnormalities. Transesophageal echocardiography to assess global cardiac function, pulmonary hypertension, and specifically right heart function is recommended in these patients.

Other conditions associate with obesity include the following:

- Hypertension
- Cardiovascular disease
- Diabetes mellitus, type 2 is strongly associated with obesity
- Metabolic syndrome, or the co-occurrence of metabolic risk factors in both type 2 diabetes mellitus and cardiovascular disease (abdominal obesity, insulin resistance, dyslipidemia, and hypertension).
- Kidney disease

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1278–1297.

A.3. Is there a link to a decline in memory and thinking with anesthesia and surgery?

Postoperative cognitive dysfunction (POCD) or neurocognitive

decline is an objectively measured decline in cognition postoperatively compared with preoperative function. Cognitive change after anesthesia was described over 100 years ago, initially as delirium and dementia. The term POCD was applied in the 1980s to refer to cognitive decline assessed purely on the basis of a change in neuropsychological test results. Increasing age, baseline cognitive impairment, and fewer years of education are consistently associated with POCD. According to the Mayo Clinic Study of Aging, 2,000 participants showed that anesthetic exposure after the age of 70 years was positively associated with long-term changes in brain physiology. The decline in cognitive function was small but significant for those who were already suffering from low cognitive function or preexisting mild impairment when exposed to general anesthesia for surgery. Elderly people whose clinical symptoms of cognitive dysfunction are not yet clinically symptomatic can manifest if exposed to anesthesia. It is not possible to determine whether anesthesia, surgery, or the underlying conditions necessitating surgery cause the decline.

There are two anesthesia-related risks that are more common in older people: **Postoperative delirium** is a temporary condition that causes the patient to be confused, disoriented, unaware of her surroundings and to have problems with memory and attention. It may not start until a few days after surgery, may come and go, and usually disappears after about a week. Both hyperactive and hypoactive forms exist, the latter being particularly difficult to diagnose. Many older elective orthopedic surgical patients have probable cognitive impairment preoperatively. Such impairment is associated with development of delirium postoperatively, a longer hospital stay, and lower likelihood of going home upon hospital discharge. *POCD* is a more serious condition that can lead to long-term memory loss with difficulties in learning, concentration, and thinking.

Because some of these problems are already common in elderly people, the only way to determine if a patient actually has POCD (more recently termed postoperative neurocognitive dysfunction [NCD]) is to conduct cognitive testing before and after surgery/anesthesia. Certain conditions including heart disease (especially congestive heart failure), lung disease, Alzheimer disease, Parkinson disease, and previous stroke increase the risk for POCD. Also see Chapter 24, sections D.4 and D.5.

The American College of Surgeons and the American Geriatric Society have suggested that preoperative cognitive screening should be performed in older surgical patients. Recently, the clock drawing task has been promoted as a cognitive screening tool—either by asking a patient to draw a clock free hand with a specific time or handing a patient a piece of paper with a circle on it and asking them to fill it in with the numbers and time on a clock.

B. Preoperative Evaluation and Preparation

B.1. What advantages does outpatient surgery offer?

Outpatient surgery typically offers greater convenience to the patient (less time away from home, family, and work), a more pleasant environment with less stress and emotional disturbance, and a reduced risk of infection, particularly for immunocompromised or pediatric patients. Outpatient surgery is

more economical and enables more efficient use of operating rooms with greater flexibility in scheduling surgery, and does not depend on hospital bed availability.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:847–861.

B.2. What are the goals of the preoperative evaluation of the surgical outpatient?

The objectives of the preoperative evaluation are:

- To perform necessary medical assessments, obtain data, arrange for laboratory tests and consultations as indicated, and prescreen for relevant conditions in order to optimize perioperative outcome
- To obtain informed consent
- To provide information and instructions to reduce patient anxiety and improve perioperative management

Organization of preoperative screening varies among ambulatory surgical facilities. The screening process may be organized with an office or facility visit before the day of surgery, by a telephone interview or review of health questionnaire without a visit, or by preoperative screening and visit on the morning of surgery. Each of these systems has its advantages and disadvantages. Nevertheless, the system for preoperative evaluation of ambulatory surgical patients should ensure that screening is performed far enough in advance so that preexisting diseases can be evaluated, treatment optimized, and laboratory data recorded before the patient presents for anesthesia. Written instructions should be supplied to the patient in advance describing the preoperative workup, medications to be taken or held preoperatively, admission, and recovery periods.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:586–611, 847–861.

B.3. In order to thoroughly screen for disease, should one put all outpatients through a full battery of laboratory testing?

Extensive preoperative laboratory testing is rarely required for ambulatory surgery. The practice of preoperative "shotgun" laboratory screening for outpatient surgery has received much criticism. In addition to unnecessarily adding billions of dollars annually to the cost of health care, laboratory screening tests in asymptomatic patients have are of dubious value and can actually increase complications from unnecessary follow-up procedures. History and physical examination are a better means of screening for disease and bleeding risks and should serve to reduce expensive, potentially harmful, and inappropriate tests.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:586–611.

Chung F, Yuan H, Yin L, et al. Elimination of preoperative testing in ambulatory surgery. *Anesth Analg*. 2009;108:467–475.

Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2013:8–13.

B.4. What preoperative laboratory testing is necessary for surgical outpatients?

Most outpatient surgical facilities consider the operative procedure and patient's age, medical condition, medication history, and state and local regulations in determining which preoperative tests are "required." For the healthy ambulatory patient between the ages of 1 and 40 years having a minor surgical procedure, no laboratory testing may be required. Pregnancy testing is a controversial issue. Many believe that pregnancy testing should be offered to all consenting females of childbearing potential. This approach, however, does not substitute for an appropriate pregnancy history and physical examination. Hemoglobin or hematocrit determination is

appropriate for surgical procedures associated with potential blood loss (unlikely in the ambulatory venue) and for patients at risk for anemia or polycythemia, such as children younger than 1 year or with suspected sickle cell disease, patients with a history of anemia, blood dyscrasia or malignancy, congenital heart disease or chronic disease, or women with heavy menstrual flow, or patients older than 60 years old. Additional testing depends on preexisting conditions. For example, serum electrolyte testing is indicated for a patient with a history of hypertension, diabetes mellitus, renal disease, or taking diuretics, digoxin, steroids, or angiotensin-converting enzyme inhibitors (ACEIs). Likewise, measurement of the partial thromboplastin time (PTT) and the prothrombin time (PT) would be indicated in the presence of a bleeding disorder, anticoagulant use, liver disease, or poor nutritional status. Preoperative urinalysis has been shown to be not useful as a screening test and is no longer required in a routine anesthetic evaluation.

Finegan BA, Rashiq S, McAlister FA, et al. Selective ordering of preoperative investigations by anesthesiologists reduces the number and cost of tests. *Can J Anaesth*. 2005;52:575–580.

Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2013:8–13, 26–30.

B.5. Which outpatients should receive a preoperative chest roentgenogram?

Abnormalities in the chest radiograph in asymptomatic patients are rare, and the risks to the patient probably exceed the benefits. A preoperative chest radiograph is indicated only for patients with a history or clinical findings of active pulmonary disease. Extremes of age, smoking, stable chronic obstructive pulmonary disease, stable cardiac disease, or resolved recent upper respiratory infection should not be considered absolute

indications.

American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. Practice advisory for preanesthesia evaluation: a report by the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. *Anesthesiology*. 2002;96:485–496.

Joo HS, Wong J, Naik VN, et al. The value of screening preoperative chest x-rays: a systematic review. *Can J Anaesth*. 2005;52:568–574.

B.6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?

It has not been established that information obtained from the preoperative ECG affects clinical care. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines published in 2007 were silent on the need for a preoperative ECG based on age alone. According to the updated 2014 ACC/AHA guideline, a preoperative ECG is "reasonable for patients with known coronary artery disease, significant arrhythmia, peripheral arterial disease, cerebrovascular disease, or other significant structural heart disease, except for those undergoing low-risk surgery." The 2014 guideline specifically states that a preoperative ECG is "not useful for asymptomatic patients undergoing low-risk surgical procedures." The 2007 ACC/AHA guidelines considered ambulatory surgery as one entity, classifying *all* ambulatory procedures as low-risk, with reported cardiac mortality <1%. The 2014 version, however, defines a *low-risk* procedure as one in which the combined surgical and patient characteristics predict a risk of a major adverse cardiac event (MACE) of death or myocardial infarction to be <1%, such as cataract or plastic surgery. A further refinement in the 2014 guideline was to eliminate the separate categories of *intermediate risk* and *high risk*, substituting the category of *elevated risk*, reflecting procedures with a risk of

MACE of ≥1%. These guidelines reflect the belief that in the absence of active cardiac conditions (defined as unstable coronary syndromes, decompensated heart failure, and significant arrhythmias [e.g., high-degree atrioventricular block, symptomatic ventricular arrhythmias, and supraventricular tachycardia with uncontrolled ventricular rate]), cardiovascular testing in stable patients would rarely result in a change in management and it would be appropriate to proceed with surgery without further testing.

Nonetheless, Correll and colleagues found that age older than 65 years is an independent predictor of preoperative ECG abnormalities. In general, a preoperative ECG should be considered in ambulatory patients in whom there is a reasonably high likelihood of cardiac dysfunction and the results of the ECG would have the potential to influence perioperative management. The patient's history, including a thorough exploration of activity level and exercise tolerance, the physical examination, and the proposed surgical procedure are vital elements in the assessment of whether an ECG is indicated.

on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary. *J Am Coll Cardiol*. 2014;64:2373–3405.

B.7. Would age or physical status influence the decision to perform outpatient surgery?

Patients at the extremes of age (e.g., younger than 6 months and older than 80 years) can be managed successfully at ambulatory centers. With the exception of the former preterm infant and newborns in the first few weeks of life, age alone should not be considered a deterrent in the selection of patients for outpatient surgery. Premature infants (gestational age at birth <37 weeks) who undergo general anesthesia during the first months of life are at increased risk for postoperative apnea for up to 12 hours. This risk is greatest for infants younger than 46 weeks postconceptional age, but some investigators have reported apnea in infants as old as 60 weeks postconceptional age. Unfortunately, the postconceptional age at which the former premature infant no longer has an increased risk for postoperative apnea, and therefore would be considered an acceptable candidate for an ambulatory surgical procedure, is not known. It is safest to admit to a hospital or to a 24-hour recovery unit all former premature infants less than 46 weeks postconceptional age so that they can be monitored for apnea. Many anesthesiologists are more conservative and adhere to cut-offs ranging from 52 to 60 weeks postconceptional age. If anemia, bronchopulmonary dysplasia, or other neonatal problems are present, this period may need to be extended. Postoperative apneic episodes have been described in otherwise healthy full-term infants who are anesthetized in the first few weeks of life. For this reason, many anesthesiologists are reluctant to proceed with outpatient anesthesia and surgery on a healthy full-term infant of younger than 2 to 4 weeks of age.

For geriatric patients, recent clinical experience has not

shown an age-related effect on the duration of recovery or the incidence of postoperative complications after outpatient surgery. However, in determining the acceptability of a geriatric patient for an ambulatory surgical procedure, one must consider physiologic age and physical status, the surgical procedure, the anesthetic technique, and the quality of care that will be provided at home. Chronologic age is not a determinant of suitability for ambulatory surgery.

No longer is outpatient surgery restricted to patients of American Society of Anesthesiologists (ASA) physical status I and II. ASA physical status III and IV patients whose diseases are well controlled preoperatively may be considered acceptable candidates for outpatient surgery.

B.8. What patients are considered inappropriate for ambulatory surgery?

An individual may be considered inappropriate for ambulatory surgery for the following reasons:

- Existence of a condition that places an infant at risk
- History of prematurity in an infant less than 46 to 60 weeks postconceptional age
- Apneic episodes, feeding difficulty, or failure to thrive
- Respiratory distress syndrome that has required intubation and ventilatory support (may take up to a year for symptoms to resolve)
- Bronchopulmonary dysplasia with any significant decrease in pulmonary function or requirement for supplemental oxygen

- Acute concurrent illness
- ASA physical status III or IV with poorly controlled disease
- Active cardiac conditions, as defined by ACC/AHA guidelines
- Acute substance abuse
- Morbid obesity with other serious systemic diseases, such as severe OSA and ventricular dysfunction
- Placement of a bare metal stent within 4 to 6 weeks of the proposed surgery
- Placement of a drug-eluting stent less than at least 1 year before the date of proposed surgery
- No available adult at home
- Refusal to have surgical procedure done as an outpatient
- Unwilling to follow instructions

The appropriateness of each patient must be evaluated on an individual basis, taking into account a combination of several factors, such as the patient's circumstances, the nature of the surgical procedure, anesthetic technique, anticipated severity of postoperative pain, and comfort level of the anesthesiologist.

B.9. What questions are critically important to ask this patient when obtaining her history?

It is important to rule out OSA in view of the patient's obesity, hypertension, and complaints of fatigue. Does she snore, have frequent awakenings during the night, and daytime somnolence? Not all patients with OSA are appropriate candidates for ambulatory surgery. It is, therefore, important to probe this possibility further with an assessment instrument such as the STOP-BANG questionnaire. A high STOP-BANG score indicates a high probability of OSA. Moreover, obese patients with severe sleep apnea and certain associated conditions (pulmonary hypertension, ventricular dysfunction, etc.) having painful surgery under general anesthesia that may require significant amounts of opioids postoperatively for pain control are typically considered poor candidates for planned outpatient surgery.

American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: an updated report by the American Society of Anesthesiologists Task Force on the Management of Patients with Obstructive Sleep Apnea. *Anesthesiology*. 2014;120:268–286.

B.10. What instructions should the patient be given with

regard to continuing or discontinuing lisinopril in the perioperative period?

This is a controversial issue, perhaps especially for ambulatory surgery patients. Notable hypotension has been reported after induction of general anesthesia in patients continuing to take ACEIs and angiotensin II subtype 1 receptor antagonists (angiotensin II receptor blockers [ARBs]) on the morning of surgery. A recent study, however, compared two groups of ambulatory and same-day admission patients who were taking either ACEIs or ARBs; one group took the ACEI or ARB on the day before surgery but not on the day of surgery, whereas the other group took the drug on the day of surgery at least 2 hours preoperatively along with other prescribed medications. Discontinuing ACEIs and ARBs on the morning of surgery did not place patients at risk for preoperative hypertension, increased cancellations, unplanned admissions, or notable hypertension in the postoperative care unit. Moreover, patients who continued treatment on the day of surgery did not have more stable hemodynamics perioperatively than did those who discontinued these drugs. Although current opinion generally favors continuation of antihypertensive medications, especially *β*-blockers, up to the time of surgery, it would appear that discontinuing ACEIs and ARBs on the day of surgery is safe and does not increase the incidence of adverse hemodynamic outcomes. Specifically, the 2014 ACC/AHA guidelines state that continuation of ACEIs or ARBs perioperatively is "reasonable" and that if these drugs are held before surgery, it is "reasonable to restart as soon as clinically feasible postoperatively."

B.11. What is an enhanced recovery after surgery (ERAS) protocol, and how would you apply it in the outpatient setting?

ERAS programs are perioperative protocols of evidence-based interventions that have been grouped together with the goals of speeding functional recovery and improving postoperative outcomes. Also known as "enhanced recovery protocols" (ERPs) or "fast-track surgery," ERAS programs typically include multidisciplinary and multimodal interventions aimed at minimizing the physiologic changes associated with surgery. Patient benefits associated with ERAS include reduction in postoperative opioid use and length of stay. An enhanced recovery program includes education and engagement through the preoperative, intraoperative, and postoperative period.

Preoperative:

- Preoperative medical optimization, preoperative nutrition, avoidance of prolonged fasting including a carbohydrate drink and clear liquids up to 2 hours prior to surgery. Multimodal anesthesia given preoperative, which can be divided into pharmacologic and nonpharmacologic techniques. Systemic pharmacologic modalities involve opioids and nonopioids, such as acetaminophen, nonsteroidal anti-inflammatory drugs, *N*-methyl-D-aspartate receptor antagonist, anticonvulsants (e.g., γ-aminobutyric acid analogues), β-blockers, α_2-agonists, transient receptor

potential vanilloid receptor agonists (capsaicin), and glucocorticoids.

Intraoperative:

- Central neuraxial techniques, surgical site infiltration with local anesthetics and regional anesthesia.
- Adjunctive techniques include acupuncture, music therapy, transcutaneous electrical nerve stimulation, and hypnosis.

Tan M, Law LS, Gan TJ. Optimizing pain management to facilitate enhanced recovery after surgery pathways. *Can J Anaesth*. 2015;62:203–218.

B.12. How would you premedicate this patient?

Whether the ambulatory surgical patient should receive premedication has been the subject of much interest and debate. Keeping in mind that a prompt recovery is an important consideration in outpatient anesthesia, many authors recommend that little or no premedication (especially centrally active depressant premedicants) be given to surgical outpatients so that recovery is not prolonged. Interestingly, most prospective clinical studies have failed to demonstrate a prolonged recovery following premedication with sedative-anxiolytic and analgesic drugs. However, opioid premedicants have been shown to increase the incidence of postoperative nausea, which could prolong recovery time, and are not recommended unless the patient is in pain preoperatively.

In view of the goals one might want to achieve with outpatient preoperative medication, including anxiety relief, sedation, amnesia, analgesia, vagolysis, prophylaxis against aspiration pneumonia, and prevention of PONV, premedicant drugs may be safely used if needed, provided the drug and dosage are carefully chosen. Drugs commonly used as premedicants for outpatients include sedative-hypnotics, opioids, anticholinergics, antacids, gastro-prokinetics, H_2-receptor antagonists, and antiemetics. Most prospective studies

have not found recovery to be prolonged after the use of appropriate doses of sedative premedication (e.g., midazolam 1 to 2 mg intravenous [IV]). Appropriate use of premedication may actually expedite discharge by reducing postoperative side effects. Grant et al. found that administration of preoperative or intraoperative midazolam is associated with a significant decrease in overall PONV, nausea, vomiting, and rescue antiemetic use. Providers may consider administration of IV midazolam as part of a multimodal approach in preventing PONV. Lorazepam very long duration of action makes it unsuitable for use in the ambulatory surgical patient.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:586–611.

Grant MC, Kim J, Page AJ, et al. The effect of intravenous midazolam on postoperative nausea and vomiting: a meta-analysis. *Anesth Analg*. 2016; 122(3):656–663.

B.13. Should every outpatient receive prophylaxis against aspiration pneumonitis?

Despite early studies demonstrating that a large percentage of outpatients are potentially at risk for gastric aspiration, the actual incidence of pulmonary aspiration is very low (<1 per 35,000) in surgical patients with no specific risk factors. The possibility that outpatients have a greater potential for acid aspiration than inpatients prompted several authors to recommend some form of aspiration prophylaxis for all patients scheduled for outpatient surgery. This is costly and may result in undesired side effects. Although individual ambulatory surgery centers must determine their own policies, pharmacologic prevention of acid aspiration should not be routine but rather reserved for outpatients with predisposing factors (e.g., pregnancy, symptomatic hiatal hernia, diabetes mellitus with autonomic neuropathy). When antacids are used, they should be restricted to nonparticulate antacids.

American Society of Anesthesiologists Committee. Practice guidelines for perioperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114:495–511.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:586–611.

B.14. Is an overnight fast justified for all outpatients?

Several investigators have questioned the value of the traditional overnight fast for surgical outpatients, particularly pediatric outpatients. Prolonged fasting does not guarantee an empty stomach at the time of induction. It does, however, cause patient discomfort and may produce significant physiologic disturbances in infants and young children. Studies in children and adults found no increase in volume or decrease in pH of gastric fluid when clear liquids were administered as late as 2 hours before induction of anesthesia. Therefore, arbitrary restrictions on the preoperative fast for surgical outpatients without risk factors for pulmonary aspiration, such as “nothing by mouth (NPO) after midnight,” appear unwarranted. Clear fluids in reasonable amounts (3 mL per kg) may be safely ingested until 2 hours before surgery. Although coffee is not transparent, it is devoid of particulate matter and is accepted as a clear liquid. There is some evidence that briefer periods of preoperative fasting (2 hours) are accompanied by less PONV as well as a reduced incidence of dizziness, drowsiness, and thirst. Breast milk should be withheld for at least 4 hours in neonates and infants who are being breastfed. Intake of nonclear liquids, nonhuman milk, and solid food should be discontinued at least 6 hours before induction of anesthesia.

American Society of Anesthesiologists Committee. Practice guidelines for perioperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective

procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114:495–511.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:847–861.

C. Intraoperative Management

C.1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?

Important goals in ambulatory anesthesia include the following:

- Smooth and rapid onset of action
- Intraoperative amnesia and analgesia
- Hemodynamic stability
- Good operating conditions
- Rapid recovery period without side effects
- Cost-effectiveness

No ideal anesthetic drug or technique has been identified for outpatient anesthesia. No single agent or combination of agents, either inhaled or IV, has been clearly shown to reduce recovery time and allow faster discharge of the ambulatory surgical patient. However, with its smooth induction profile and short elimination half-life, propofol may prove to be the induction, if not the maintenance, agent of choice for most outpatient anesthesia. The newer halogenated ether compounds, sevoflurane and desflurane, have become increasingly popular in ambulatory anesthesia owing to their rapid onset and quick termination of clinical effects. Currently, desirable anesthetic conditions with an acceptable recovery profile may be produced by a large array of pharmacologically active drugs administered in conjunction with either general, regional, or local anesthesia techniques. It is essential, however, to combine these agents in a rational manner with carefully titration to optimal effect.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:847–861.

C.2. How would you monitor this patient?

The effects of anesthesia during ambulatory procedures should be monitored using the same standards applicable to inpatient procedures. Standard monitoring in this patient would include a blood pressure cuff, ECG, pulse oximeter, precordial or esophageal stethoscope, temperature probe, and measurement of inspired oxygen and end-tidal carbon dioxide.

Standards for Basic Anesthetic Monitoring. Committee of Origin: standards and practice parameters (approved by the ASA House of Delegates on October 21, 1986, last amended on October 20, 2010, and last affirmed on October 28, 2015.

C.3. What is the bispectral index (BIS) monitor, and what information does it convey?

The BIS monitor is a noninvasive monitoring system that is derived from a two-electrode electroencephalogram (EEG). Using a proprietary bispectral analysis of the EEG waveform and other features within the EEG, the BIS monitor is used to detect changes in purported depth of anesthesia or hypnosis. The proprietary algorithm translates complex data generated from the analysis of the EEG over a 30-second period into a single dimensionless number between 0 (i.e., no brain activity) and 100 (i.e., the patient is fully awake) that is displayed on the BIS monitor. The BIS is one of many brain function monitors that record or process brain electrical activity and convert these signals mathematically into a continuous measure, typically scaled from 0 to 100. It is important to appreciate that intraoperative awareness cannot be measured during the intraoperative phase of general anesthesia because the recall component of awareness can only be determined postoperatively by obtaining information directly from the patient. Although

clinically important, intraoperative awareness under general anesthesia is a rare occurrence, with a reported incidence of 0.1% to 0.2% in adults.

C.4. What benefits might be derived from using a BIS monitor?

Information about the patient's hypnotic state obtained from the BIS, in combination with other monitored parameters and clinical signs, may allow better balancing of hypnotic and analgesic administration. Titration of hypnotic agents based on individual requirements arguably is improved, potentially reducing the incidence of relative under- and overdosing. Furthermore, selection of anesthetic interventions (e.g., administration of hypnotics, analgesics, and vasoactive drugs) may be more rational. Reduced drug usage, earlier awakening, and faster recovery have all been associated with using the BIS monitor to help guide anesthesia maintenance. This translates into a higher potential for bypassing the stage 1 postanesthesia care unit (PACU) and earlier discharge eligibility from the PACU. It is not known whether these benefits ultimately reduce medical costs significantly. A recent meta-analysis based on 1,380 subjects from 11 trials found that BIS monitoring reduced anesthetic consumption by 19%, reduced the incidence of

nausea/vomiting, and reduced time in the PACU by 4 minutes. However, these benefits did not lead to a significant reduction in time until patient discharge from the ambulatory surgery unit. Additionally, BIS monitoring actually increased the cost per patient by $5.55 owing to the cost of the BIS electrodes.

There has been considerable recent interest in depth of anesthesia and 1-year mortality. The investigators in the B-Aware trial reported a secondary analysis of long-term mortality and found that the absence of low BIS values (BIS <40 for >5 minutes) was associated with improved long-term survival and reduced morbidity (myocardial infarction, stroke). However, this association does not imply causation. Preoperative comorbidity is an important independent risk factor for postoperative mortality.

Not surprisingly, that patients with a history of intraoperative awareness are at increased risk to develop the complication again. These patients, and others at high risk of intraoperative awareness (e.g., use of total intravenous anesthesia [TIVA], patients having trauma surgery or cesarean delivery, patients with refractory hypotension), may well benefit from BIS monitoring. Other modalities can also be used to monitor purported anesthetic depth. These include, but are not limited to, end-tidal anesthetic concentration monitoring, auditory evoked potentials, and EEG entropy.

C.5. Is BIS monitoring applicable to children?

The BIS was developed and tested on adults. Because the EEG in infants and young children is different from that of an adult and changes as the brain matures, the BIS value may not necessarily apply directly to children. Validating the BIS monitor in infants and young children poses significant problems. End points used to confirm BIS in adults, such as assessment of sedation, sleep, or purposeful movement in response to voice commands, cannot be reliably obtained in young children. Furthermore, there are serious ethical problems in recruiting healthy children as volunteers in studies of general anesthesia. Nevertheless, recent data comparing BIS values between adults and children at various clinical end points during general anesthesia, such as before anesthesia, during maintenance, at emergence, and with increasing concentrations of volatile anesthetic, suggest that BIS generally performs similarly in adults and children with respect to dose response to anesthetic agents. However, in children aged 6 months to 12 years, the BIS increased paradoxically as end-tidal sevoflurane concentration increased from 3% to 4%. BIS values showed a wide variation at the same end-tidal sevoflurane concentration, and the age was considered to be a factor affecting BIS values. A consensus seems to be forming that BIS monitoring should be used with caution in infants younger than 1 year of age, and further work in this area is needed. Definitive studies correlating level of sedation, awareness, and anesthetic outcome with BIS in children have not been published. Nonetheless, consensus is emerging that the incidence of intraoperative awareness is greater in children than adults. Children, however, seem to be

less disturbed by the experience than adults who appear to be more vulnerable to the development of posttraumatic stress.

C.6. What are the major limitations of BIS monitoring?

The BIS monitor is not a measure of global anesthetic depth but a measure of level of sedation and hypnotic state. As such, it helps the anesthesiologist assess the potential for patient awareness, but it cannot prevent it. In fact, use of the BIS has not been proven to reduce or eliminate the risk of intraoperative awareness. The BIS will not predict patient movement or hemodynamic response to noxious stimulation nor will it predict the exact moment when consciousness will return. Sedation produced by ketamine or nitrous oxide does not produce the expected decrease in BIS. The utility of BIS in patients with neurologic disease has not been adequately studied to validate its use in these patients. Finally, more work is necessary to establish whether BIS is an accurate measure of hypnosis in pediatric patients.

It is important to appreciate that a specific numerical value

may not correlate with a specific depth of anesthesia. Moreover, the measured values do not have uniform sensitivity across different anesthetic drugs or types of patients. Artifacts can be introduced by electrocautery, lasers, warming devices, and other devices and circumstances. The BIS cannot be relied on in all situations, including hypothermia, circulatory arrest, and brain death. Moreover, a small study recently reported that patient position may affect BIS readings, with the head-down position producing an increase in BIS value, and the head-up position being associated with a reduction in BIS value. Intraoperative monitoring of depth of anesthesia to minimize the risk of awareness should rely on multiple modalities, including clinical observations of purposeful or reflex movement, blood pressure, heart rate, end-tidal anesthetic analyzer, and capnography.

The consensus of the ASA Task Force on Intraoperative Awareness is that brain function monitoring is not routinely indicated for patients undergoing general anesthesia and that the decision to use a brain function monitor should be made on a case-by-case basis by the individual practitioner for selected patients at increased risk.

C.7. What does a BIS reading of 56 mean?

The BIS scale is a dimensionless scale from 0 to 100. Typically, BIS values between 40 and 60 correspond with a moderate hypnotic state of general anesthesia and are associated with a low probability of patient consciousness. Deep sedation with a low probability of explicit recall occurs in the 60 to 70 BIS range, with higher values up to 85 associated with light to moderate sedation. A BIS number below 40 indicates a deep hypnotic state, with probability of EEG isoelectricity increasing as BIS approaches 0. However, there are multiple exceptions to these generalities, and the BIS is perhaps best thought of as a trend monitor rather than an "absolute" monitor of hypnotic depth.

C.8. What anesthetic agents would you use to induce and maintain general anesthesia in this patient?

A number of anesthetic agents in a variety of combinations can be used successfully to provide general anesthesia in this patient. A reasonable approach would be to induce anesthesia with propofol after a preinduction dose of a short-acting benzodiazepine. After intubation, anesthesia is maintained with a volatile anesthetic, such as sevoflurane or desflurane in an air–oxygen mixture, supplemented with a short-acting opioid as needed and a muscle relaxant. Alternatively, a total IV technique with propofol as the primary agent could be used.

Although nitrous oxide has been thought to contribute to PONV, conclusive evidence is lacking to demonstrate an important effect of nitrous oxide on the incidence of postoperative emesis after laparoscopic cholecystectomy or pelvic laparoscopy. A recent review and meta-regression analysis reported that the increase in PONV sometimes seen with administration of nitrous oxide depends on the duration of exposure and is clinically unimportant up to at least 1 hour of exposure. Therefore, any potential benefit from its elimination for surgical cases of limited duration must be balanced against the potential increased risk of intraoperative awareness.

The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults, commonly called the Beers List, are guidelines for health care professionals to help improve the safety of prescribing medications for older adults.

- *Dementia or cognitive drugs impairment in the geriatric population: drugs to avoid*
  - Anticholinergics, benzodiazepines, H_2-receptor antagonists, nonbenzodiazepine benzodiazepine receptor agonist hypnotics (eszopiclone, zolpidem, zaleplon), antipsychotics
- *Delirium: drugs to avoid*
  - Anticholinergics, antipsychotics, benzodiazepines, chlorpromazine, corticosteroids, H_2-receptor antagonists (cimetidine, famotidine, nizatidine, ranitidine), meperidine, sedative-hypnotics

C.9. Under what circumstances might spinal anesthesia be appropriate for outpatient surgery?

Spinal anesthesia is a quick and reliable technique. The limitations of using spinal anesthesia in the ambulatory setting include delayed ambulation, risk of urinary retention, and pain after block regression. In contrast, general anesthesia with fast-acting drugs provides a fast recovery that facilitates an early discharge. Reducing the dose of the commonly used long-acting local anesthetics can reduce recovery time, but discharge times are still prolonged compared with general anesthesia. 2-Chloroprocaine is an amino-ester local anesthetic with a very short half-life that can be used as a local anesthetic for ultra-short outpatient procedures; it has also shown to have a very low risk of urinary retention and transient neurologic symptoms when compared with bupivacaine or lidocaine.

D. Postoperative Management

D.1. What are the common causes of nausea and vomiting in outpatients?

Nausea and vomiting are significant problems after ambulatory

surgery, causing patient discomfort and delayed recovery and discharge from the ambulatory center. Prolonged vomiting is one of the most frequent causes of unexpected hospital admission from the ambulatory surgical facility and is a major cause of patient dissatisfaction with their anesthesia care. Patients who have a history of motion sickness or PONV are more likely to develop postoperative symptoms of emesis, as are patients who are obese, pregnant, or have diabetes mellitus. PONV are common in children; the incidence decreases with age. Men and women are equally affected until puberty, when the incidence becomes considerably higher in women. Excessive anxiety and noncompliance with fasting can increase gastric volume and predispose patients to PONV. Interestingly, smoking has been shown to decrease the incidence of PONV.

The use of opioid analgesics, particularly morphine and meperidine, as premedication, as part of the anesthetic technique, or postoperatively to control pain, increases the incidence of PONV after outpatient anesthesia. Methohexital is less likely than either thiopental or etomidate to cause postoperative nausea. Propofol has a low incidence of emetic symptoms postoperatively and can be antiemetic, a desirable property in this setting.

Although the Apfel scoring system to predict the likelihood of PONV emphasizes female gender, nonsmoking status, history of PONV or motion sickness, and opioid administration as the major risk factors, there is no or insufficient evidence for a number of commonly held factors, such as preoperative fasting, menstrual cycle, and surgery type; using these factors may be counterproductive in assessing risk for PONV. In addition, pain, hypotension, and early ambulation are postoperative factors shown to increase nausea and vomiting.

Apfel CC, Heidrich FM, Jukar-Rao S, et al. Evidence-based analysis of risk

factors for postoperative nausea and vomiting. *Br J Anaesth*. 2012;109:742–753.

Apfel C, Kranke P, Eberhart LH, et al. Comparison of predictive models for postoperative nausea and vomiting. *Br J Anaesth*. 2002;88:234–240.

D.2. How would you pharmacologically prevent PONV in the susceptible ambulatory patient?

Because of concerns about medication cost and potential side effects, routine prophylactic administration of an antiemetic is not considered appropriate for all ambulatory surgical patients. Instead, antiemetic prophylaxis should be reserved for patients who are considered to be susceptible to developing PONV. Many medications have been used as prophylaxis for PONV in the outpatient, some with only limited success. Unfortunately, the ideal medication for each patient is not known. Serotonin antagonists, such as ondansetron 4 to 8 mg IV in adults and 0.1 mg per kg IV in children, are highly effective, but their use as single agents in high-risk patients may not suffice. Droperidol is effective, inexpensive, and without an increase in postoperative sedation when used in low doses, such as 0.625 to 1.25 mg in adults (or as low as 10 to 20 μg per kg). However, the U.S. Food and Drug Administration (FDA) issued a black box warning on the use of droperidol for antiemetic prophylaxis based on concerns about prolongation of the QTc interval and subsequent potentially dangerous ventricular arrhythmias. Charbit et al. reported that droperidol and ondansetron induce similar clinically relevant QTc prolongation and concluded that the safety of 5-hydroxytryptamine type 3 (5-HT_3) antagonists may not be superior to that of low-dose droperidol. Although the serotonin antagonists are classically believed to lack efficacy with regard to preventing or treating nausea, the newest 5-HT_3 blocker, palonosetron, appears to reduce its severity, and the extended benefits of palonosetron may last up to 3 days, given its long half-life. In addition, palonosetron purportedly has no

QT-interval issues.

Prophylactic administration of dexamethasone, 1 to 10 mg IV in adults and 0.5 to 1 mg per kg IV in children, is effective in the prevention of PONV and appears to offer no evidence of any clinically relevant toxicity. Combining dexamethasone with a serotonin antagonist further decreases the incidence of nausea and vomiting and may prove to be the best prophylactic regimen, although optimal doses of this combination are not currently known. Transdermal scopolamine effectively reduces PONV if given as a premedicant well in advance of the surgery, but the high incidence of anticholinergic side effects and prolonged residual effects on cognitive performance, especially in the elderly, detract from its usefulness in the ambulatory patient.

Aprepitant is a highly selective, brain-penetrating neurokinin-1 receptor antagonist that is effective against centrally induced emesis. A recent study showed that aprepitant was superior to ondansetron for prevention of vomiting in the first 24 to 48 hours, but no notable differences were detected between aprepitant and ondansetron for nausea control, use of rescue drugs, or complete response.

Because the etiology of PONV is multifactorial, there is increasing evidence that a multimodal approach may lead to improved outcomes. Double and triple antiemetic combinations, using drugs with different mechanisms of action, are recommended for patients at high risk of PONV. Moreover, liberal hydration and effective analgesia play an important role in reducing the incidence of PONV. General anesthesia with volatile agents should be avoided, if possible, in high-risk patients. If general anesthesia is necessary, a total IV approach with propofol may be advantageous. Moreover, if rescue therapy for PONV is needed within 6 hours of surgery, patients should not receive a repeat dose of the drug that was administered

prophylactically. Rather, a rescue drug with a different mechanism of action should be selected.

D.3. How is postoperative pain treated?

Pain control is one of the most important factors in determining when a surgical outpatient can be discharged. Pain should be treated rapidly and effectively to minimize postoperative symptoms so that ambulation and discharge are not delayed. The

optimal strategy is to use a preemptive, multimodal approach. Begin controlling postoperative pain intraoperatively by supplementing the anesthetic technique with a short-acting opioid analgesic or a regional block. IV fentanyl is usually the opioid of choice for postoperative pain relief. It may be given in small doses of 25 μg at 5-minute intervals and titrated to relief of pain. Ketorolac, a nonsteroidal anti-inflammatory drug, has become increasingly popular in the management of postoperative pain in the ambulatory patient because of its lack of opioid-related side effects (e.g., sedation, nausea, vomiting, respiratory depression). It is available for oral and parental administration, and its use may decrease a patient's requirement for opioid analgesics. Controversy still surrounds the perioperative use of ketorolac because of the potential for bleeding complications and renal dysfunction. Local and regional anesthetic techniques can be used to provide effective postoperative analgesia and, when used to supplement general anesthesia, facilitate a pleasant emergence and minimize the need for opioids. Commonly used techniques include local infiltration of the incision site, intra-articular injection, nerve blockade (e.g., dorsal nerve penile block for circumcision or ilioinguinal and iliohypogastric nerve blocks for inguinal hernia repair), and caudal blocks. Bupivacaine liposomal injectable suspension (Exparel®; Pacira Pharmaceuticals, Inc, Parsippany, NJ), formulated using the DepoFoam® (Pacira Pharmaceuticals, Inc, Parsippany, NJ) lipid-based delivery system, was approved for administration into the surgical site after bunionectomy and hemorrhoidectomy, offering long-acting analgesia without opioid-associated side effects. In February of 2018, the FDA approved a new indication for use in interscalene brachial plexus nerve block for postsurgical analgesia for shoulder surgery. One randomized study in 200 patients compared efficacy and safety of transversus abdominis plane (TAP) blocks with Exparel

versus epidural anesthesia using a continuous infusion of local anesthetic plus fentanyl. Systemic opioid use was less in patients with a TAP block, and there were no differences in postoperative complications or length of hospital stay.

When the patient has resumed intake of oral fluids, oral analgesics (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs, oxycodone, hydrocodone, and other opioid analgesics) may be administered for control of pain after discharge.

D.4. What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?

For patients to be discharged from an ambulatory facility, they must satisfy specific criteria that are usually summarized on simplified checklists. Although each ambulatory surgical facility must determine its own set of criteria, generally accepted guidelines for safe discharge home after ambulatory surgery include the following:

- Stable vital signs
- No evidence of respiratory depression
- Oriented to person, place, and time
- Able to walk unassisted
- Able to dress unassisted
- Minimal nausea or vomiting
- No active bleeding or oozing

- Pain controllable with oral analgesics
- Responsible adult to escort patient home and to remain with the patient overnight
- Discharge by both the person who administered anesthesia and the person who performed surgery, or their designees
- Written instructions for the postoperative period at home must be supplied to the patient before discharge as well as a phone number to call in the case of emergency.

The requirement for patients to drink and void before discharge is no longer considered mandatory, except in the case of certain patients who had central neuraxial blockade.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:847–861.

Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2013:343–351.

D.5. How would you decide when to discharge a patient after regional anesthesia?

Patients recovering from regional anesthesia must satisfy the discharge criteria listed earlier. In addition, if spinal or epidural anesthesia is used for outpatients, it is important to ensure recovery from the sympathetic and the motor blocks. Hypotension and syncope on standing may be signs that the sympathetic nervous system is still blocked. An indication that the motor block is no longer functioning is the ability to move the legs and feet freely. A simple test is to have the patient run each heel up and down the opposite leg from the big toe to the knee. Ability to walk to the bathroom and void are excellent recovery tests after epidural or spinal anesthesia because these abilities reflect recovery of both the motor and the sympathetic functions.

Mulroy et al. have suggested that delaying discharge for voiding after spinal or epidural anesthesia with *short-acting*

local anesthetics is unnecessary in *low-risk* patients (e.g., age younger than 70 years; no hernia, rectal, or urologic surgery; no history of voiding problems). Nonetheless, appropriate measures must be in place for bladder catheterization if the inability to void persists after discharge home. The use of ultrasonographic monitoring of bladder volume before discharge may reduce the incidence of urinary retention after discharge.

Darrah DM, Griebling TL, Silverstein JH. Postoperative urinary retention. *Anesthesiol Clin*. 2009;27:465–484.

Fleisher LA, ed. *Evidence-Based Practice of Anesthesiology*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2013:343–352.

Pavlin DJ, Pavlin EG, Gunn HC, et al. Voiding in patients managed with or without ultrasound monitoring of bladder volume after outpatient surgery. *Anesth Analg*. 1999;89:90–97.

D.6. What instructions should be given to an ambulatory surgical patients upon discharge?

Patients should be discharged to the care of a responsible adult. Additionally, they should be instructed that after surgery, they should not ingest an alcoholic beverage or depressant medication unknown to their surgeon or anesthesiologist, drive a car, or operate complex machinery for at least 24 hours. In addition, the discharge instructions should provide a list of problems that require immediate notification of the surgeon (e.g., bleeding that does not stop, inability to void, and persistent PONV).

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:847–861.

62 Magnetic Resonance Imaging

Jayanth Swathirajan, Dana L. Gurvitch, and Hugh C. Hemmings Jr.

You are consulted by the pediatric intensive care unit (PICU) team on an 11-year-old, 35-kg boy for urgent magnetic resonance imaging (MRI). He is 2 days removed from a partial temporal lobectomy for seizure management and now has altered mental status and is thrashing in the PICU. The child has intractable seizures but no other medical history. He was able to cooperate enough to perform a computed tomography (CT) scan that showed no acute bleeding, but the team wants an MRI and does not believe he will stay still for the 1.5-hour scan. He is currently extubated, but on your review of his previous anesthetic record, you see that he required an oral airway to achieve adequate mask ventilation. On conventional direct laryngoscopy only the epiglottis was visualized (Cormack-Lehane grade III view), but when a video laryngoscope was used the epiglottis, arytenoid cartilages and posterior vocal cords were visualized (Cormack-Lehane grade IIa view) and an endotracheal tube was passed atraumatically. Your patient has a left hand 20 gauge peripheral intravenous catheter and a right radial arterial catheter for close blood pressure monitoring. He is current with all his antiepileptic medications and is otherwise appropriately nothing

orally (NPO).

A. Medical Disease and Differential Diagnosis

1. What is MRI, and how does it work?
2. What are some advantages of MRI?
3. What are some disadvantages associated with MRI? What are some safety concerns?
4. How do you manage patients with implanted devices?
5. What are the biologic effects of clinical MRI?
6. What are the anesthetic considerations for this procedure?
7. What is intraoperative MRI (iMRI)? What is real-time MRI, and in what setting can this be used?

B. Preoperative Evaluation and Preparation

1. What type of patients may require sedation or general anesthesia for MRI?
2. Do all children require sedation for MRI?
3. What preoperative laboratory testing would you require for this patient?
4. How would you premedicate this patient? What are some options that can be used to premedicate other patients for MRI?

C. Intraoperative Management

1. What are some of the anesthetic options for this patient?
2. How is an MRI conducted?
3. How would you monitor this patient?
4. What special considerations apply to monitoring equipment used during MRI?
5. How would you induce and maintain general anesthesia in this patient?
6. What are ways to maintain the airway during an MRI scan?
7. During the scan, you notice loss of end-tidal carbon dioxide.

You immediately go into the scanner, remove the patient from the MRI scanner and initiate bag ventilation. However, you are still unable to ventilate the patient, and asystole follows. What do you do next?

8. What is the risk to the patient of gadolinium administration in the presence of acute renal insufficiency?

D. Postoperative Management

1. How will you recover the patient from anesthesia?

A. Medical Disease and Differential Diagnosis

A.1. What is MRI, and how does it work?

MRI is a noninvasive diagnostic technique that uses the magnetic properties of atomic nuclei to produce high-resolution, multiplanar cross-sectional images of the body. MRI is utilized both as an interventional aid in diagnosis and in disease therapy in lieu of conventional approaches. Atoms having an odd number of protons and/or neutrons in their nuclei, most notably hydrogen, have an associated magnetic dipole. The net rotation of protons or neutrons produces a local magnetic field similar to the electromagnetic field produced by the flow of electrons in a wire loop. Biologic tissues have high water content and therefore have abundant hydrogen. The detection of hydrogen's single proton serves as the basis for MRI. Normally, the magnetic fields surrounding these nuclei are randomly oriented. When placed in the setting of a powerful static magnetic field of the MRI scanner, the nuclei align themselves longitudinally so they lie parallel or antiparallel (in line but moving in an opposite direction) to the magnetic field. The hydrogens aligned antiparallel have a slightly higher energy than those aligned parallel, thereby causing the tissue to have a slight net magnetic field that can be detected by the MRI scanner. The higher the

strength of the magnet used, the stronger the tissue magnetic field.

Within the MRI, a quick specific radiofrequency (RF) pulse of energy (a second magnetic field) is directed toward the patient at right angles to the tissue's generated static magnetic field, displacing the aligned nuclei from the longitudinal magnetic field. As the RF pulse is removed, the nuclei return to their original magnetic alignment positions. This is termed *relaxation*. The energy released from the tissue as the nuclei relax is termed an RF signal. It can be detected by the receiver coil of the scanner placed close to the patient and is used to produce the magnetic resonance (MR) image. There are two ways to measure relaxation time, T1 and T2; certain tissues and/or pathologies are best viewed either with T1 or T2 weighted imaging. This allows for differentiation of body structures as well as between normal and pathologic tissue.

Resolution of the image requires a strong magnetic field. The magnetic field strength used to quantify the scanners is in Tesla (T) units. One tesla is equivalent to 10,000 gauss. Most MRI scanners used now have a magnetic field of 0.5 to 3.0 T (the magnetic field of the earth is 5×10^{-5} T). Also, the smaller the opening to the scanner, the stronger the possible magnet. Therefore, although patients may prefer an "open" magnet, which induces less claustrophobia, this generates a weaker image.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

A.2. What are some advantages of MRI?

The advantages of MRI include the lack of ionizing radiation; the capability of using noniodinated intravenous contrast agent, thereby reducing the risk of an anaphylactic or nephrotoxic reactions; and the production of multiplanar, temperature

sensitive, contrast amplified images. MRI also provides excellent resolution of normal tissues (e.g., gray and white matter and soft tissues) without image artifact from bone, and it can differentiate between normal and pathologic tissue. MRI may be used to evaluate blood and cerebrospinal fluid flow, to assess contraction and relaxation of organs such as the heart, and to provide images of tissues in proximity to bone. Specifically, brain MRI is indicated to evaluate for indicating developmental delay, cause of seizures, failure to thrive, apnea, cyanosis, and vascular lesions.

MRI-guided intervention is another major potential advantage in cases where conventional CT imaging is lacking. These images of the soft tissues and tumors are exceptionally delineated, thus facilitating interventions for biopsies of these areas. MRI offers better capture of the temperature-related changes that occur during cryoablation and has been effectively used in safely treating liver, kidney, breast, and prostate tumors as well as in uterine fibroids. MRI has also proven advantageous during interventional electrophysiology studies and catheter ablation procedures. MRI offers structural real-time three-dimensional (3D) images of the anatomy and presence of scar tissue in the heart and nearby structures, and exact localization of the ablation catheter. It can also delineate potential gaps in ablation. Delayed enhancement (DE) MRI is currently the gold standard for outlining scar/fibrosis in the heart that may serve as an arrhythmogenic source for patients with ventricular tachycardia (VT). Based on the staging of atrial fibrosis, DE MRI can also provide vital preprocedural information in identifying those patients who might be at risk for relapse of atrial fibrillation. In experienced hands and centers, real-time MRI provides vital information while eliminating the radiation required by conventional fluoroscopy.

A.3. What are some disadvantages associated with MRI? What are some safety concerns?

There are many hazards associated with an MRI suite. The constant static magnetic field, the pulsed (time-varied) gradient magnetic fields, and the high-frequency RF waves all interact; when combined with a ferromagnetic object, this can pose significant risk to the patient or operator. Not only can attraction of external objects be fatal but also implantable objects can dislodge and malfunction or burn the patient. Depending on the distance from the core of the magnet, the magnetic field strength diminishes. Distances less than the 5-gauss line can make pacemakers malfunction, and less than 50-gauss line can make ferromagnetic gas cylinders lethal projectile missiles.

Owing to the potential for catastrophic events, recommendations for MRI safety have been proposed by the American College of Radiology. Briefly, the MRI suite should be separated into four zones: zone I is the public zone immediately outside the MRI suite, zone II is the reception area monitored by MRI personnel, zone III encompasses the control room with access restricted from the public, and zone IV is the physical MRI scanner room. To ensure safety, entry into zones III and IV must be screened by MRI personnel (**Fig. 62.1**). Ferromagnetic objects should not be brought into zone III, but if necessary, they should be brought in with extreme caution. Items such as credit cards, pens, keys, laryngoscopes, scissors, stethoscopes, paper clips, and ferromagnetic gas cylinders are

excluded from zone IV. One important way to ensure safety is to use aluminum oxygen E-gas cylinders instead of magnetic ones. Adherence to these zones must be maintained especially during emergent situations.

FIGURE 62.1. The MRI suite should be separated into four zones.

Safety terminology for devices and implants was developed by the ASTM International. *MR safe* refers to items with no known hazards in any MR environment. *MR conditional* refers

to items that pose no known hazards in a specified MR environment (i.e., the conditions present at your scanner). *MR unsafe* refers to items that pose definite hazards in all MR environments (i.e., ferromagnetic scissors). Concerns about a specific device and its potential hazards should be addressed by staff members, on-site radiologists, and/or manufacturer to determine whether the exam can be conducted in a safe manner.

Additional patient-related risks include (1) need for intensive or critical care (vasoactive infusion requirement), (2) comorbidities that may contribute to adverse MRI effects (burns, obesity-related temperature increases), and (3) impaired respiratory function (obstructive sleep apnea, tonsillar hypertrophy).

Other major disadvantages of MRI include the potential for malfunction of electronic equipment (e.g., monitors and infusion pumps) and the limited access to the patient. MR safe/conditional monitors and machines should be used in the scanner. Thermal injuries have been reported from electrocardiogram (ECG) electrodes and pulse oximeter probes. All cables and monitoring equipment should be placed in a straight manner without coiling to ensure no such injuries. MR safe/conditional infusion pumps can be used in zone IV, but otherwise, pumps can be left in zone III and the tubing passed through a wave guide. The relatively long scan time necessary to obtain images (as much as 15 minutes per image, with a total scanning period of 1 to 3 hours) and image degradation from any motion including cardiac contractions, respirations, cerebrospinal fluid flow, and bowel peristalsis are additional disadvantages. MRI safe anesthesia machines and monitoring equipment are available; however, cost may prove prohibitive for institutions that do not regularly do MRI under anesthesia. MR conditional anesthesia machines can cost $60,000, monitors $120,000 to $140,000, and infusion pumps $12,000 to $18,000.

Another potential hazard to both patients and operators is the high decibel level of sound emanating from the scanner due to RF pulses (>90 dB). Hearing protection for both is mandatory even if the patient is under anesthesia.

Quenching of the MRI machine is a rare hazard that refers to a sudden loss of superconductivity of the magnet, which can occur either spontaneously or be triggered by a significant safety event. During a quench, the temperature of the magnet coil suddenly rises, resulting in an explosive boil-off of surrounding liquid helium and deactivation of the magnet. In the event of a quench, the patient should be quickly removed from the now hypoxic room. The magnet should almost never be quenched on purpose because it creates a dangerous room for the patient as well as other providers. In the case of a medical emergency for a patient, the best practice would be to remove the patient to zone II or zone III and initiate resuscitation. Once the magnet is quenched, it cannot be reactivated for days.

A.4. How do you manage patients with implanted

devices?

Patients with certain implanted biologic devices, such as pacemakers, implantable cardioverter-defibrillators (ICDs), and certain pumps, should be excluded from MRI studies because of the possibility of device malfunction, inactivation, or damage in the magnetic field. The safety of various cardiovascular devices for MR examination was reviewed based on ex vivo, animal, and in vivo studies and reported by the American Heart Association (AHA). Although many coronary stents, peripheral stents, sternal wires, inferior vena cava filters, prosthetic heart valves, and annuloplasty rings have been deemed MR safe or conditional, it is important to review each type carefully and decide whether the proposed MRI exam is in line with the specified safety of the particular device. Currently, the AHA and the American Society of Anesthesiologists (ASA) Practice Advisory Task Force on Anesthetic Care for Magnetic Resonance Imaging regard the presence of a pacemaker or an ICD as a strong relative contraindication to routine MRI examination. In 2011, MR conditional ICDs, pacemakers, and leads became available and are available in the United States; they are approved in certain settings and up to 1.5 T MRI examinations. Intact pacemaker leads are unlikely to move; however, an electrical current could be generated if fractured leads are exposed to the magnet, causing a lethal arrhythmia. MRI is currently contraindicated in patients with an artificial heart or ventricular assist device. Also see Chapter 8, section B.8.

If the benefits far outweigh the risks of the exam, MRI should be performed in an experienced center with collaboration between the cardiologist, radiologist, device manufacturer, and MRI technician. Written consent must detail all risks to the patient including death. Full resuscitation equipment must be readily accessible in the MRI suite in case of an arrhythmia or

equipment malfunction.

According to the Heart Rhythm Society (HRS), for MR conditional devices it is reasonable to proceed with standard monitoring but have external defibrillators and personnel capable to reprogram the cardiovascular implantable electronic device (CIED) available. If the device is not MR conditional and the patient is pacemaker dependent, then the device should be programed to asynchronous pacing and ICD features deactivated. The device should be interrogated before and after the scan.

Clips used in vascular surgery and neurosurgery must be verified and the model and type of clip documented. All intracranial aneurysm clips manufactured after 1995 that the company identifies it as MR conditional need no further testing. Clips manufactured before 1995 require some pretesting and may need approval of an MRI attending radiologist. Despite a prior history of MRI, variations can occur in different magnetic fields under the influence of different pulsed frequencies, so verification may still be needed.

Coronary artery stents, especially after 2007, are proven safe for patients having an MRI procedure at ≤3 T. Most aortic stent grafts are MR safe, but the Zenith AAA and TAA endovascular graft (Cook Medical, Bloomington, IN) are MR conditional, and their timing for scanning needs to be individualized. Coil embolization materials, such as platinum, iridium, and nitinol, are safe for MRI examinations. Most heart valves and annuloplasty rings can be safe under certain conditions, that is, ≤3 T, but if possible, delay the scan for up to 6 weeks after implantation.

Certain cochlear implants are MR conditional and may be safe if the patient is over 8 years of age and ≤1.5 T is used. Care must be taken for patients with retained shrapnel and bullets; there may be potential risks if it is ferromagnetic due to

movement and heating near vital organs. Patients with implanted stimulators need to be investigated, and some may be MR unsafe or conditional. MRI may be performed on a limited basis for patients with certain deep brain stimulators and vagal nerve stimulators. In each case, care must be individualized and decisions made with the on-site level 2 MRI attending radiologist.

For a more thorough evaluation of these devices, please refer to the website http://www.mrisafety.com, which has a thorough list of MR safe, conditional, and unsafe devices. Orthodontic braces and dentures and tattoos or cosmetics that contain metallic dyes, although safe, can degrade the image quality significantly.

A.5. What are the biologic effects of clinical MRI?

Although an area of controversy and ongoing investigation, most human data to date suggest that there are no significant deleterious effects to patients or health care professionals from exposure to the static magnetic field of an MRI machine. However, MRI capabilities were developed relatively recently

(the 1960s), and epidemiologic evidence of harmful exposure may not yet be apparent. It seems prudent, therefore, to limit repetitive and readily avoidable exposure to the magnetic field.

Also controversial is the use of MRI during pregnancy because the effects of magnetic fields on the human fetus cannot be easily determined. Current evidence does not support the suggestion that routine clinical exposure of the pregnant patient to MRI causes developmental abnormalities in the fetus. Pregnant patients have undergone MRI safely during all stages of pregnancy. Nevertheless, caution is advised. Studies have shown that gadolinium-based contrast agents enter the fetal circulation and are filtered in the fetal kidneys into the amniotic fluid, which can potentially form free gadolinium ions that can theoretically pose risks to the developing fetus. The appropriateness of MRI examination and the acuteness of the diagnostic need must be considered. Ultrasonography is preferred if it can provide equivalent diagnostic information, and consideration should be given to postponing the MRI until late in the pregnancy or until after delivery.

MRI contrast agents have fewer side effects compared to iodinated contrast agents. However, there are some potential reactions with gadolinium-based contrast agents in patients with moderate to severe chronic renal disease. Patients with severe chronic renal disease, hepatorenal syndrome, and/or perioperative liver transplant have developed “nephrogenic systemic fibrosis,” which can be fatal. Nephrogenic systemic fibrosis primarily involves the skin, but other organs such as the liver, heart, lungs, diaphragm, and skeletal muscle can be affected. Care must be taken when considering the use of MRI contrast agents in these patients. If a pediatric patient with advanced renal disease requires gadolinium, the US Food and Drug Administration (FDA) suggests prompt hemodialysis be considered.

Kanal E, Barkovich AJ, Bell C, et al. ACR guidance document on MR safe practices: 2013. *J Magn Reson Imaging*. 2013;37:501–530.

A.6. What are the anesthetic considerations for this procedure?

The problems that complicate anesthetic management of any patient outside the operating room environment exist for patients requiring sedation or general anesthesia for MRI. The MRI suite is often located some distance from the operating room and the anesthesia department, thus limiting the availability of backup assistance and supplies. As with any remote anesthetizing location, the personnel may not be familiar with the requirements of anesthetized patients, thereby decreasing their ability to provide assistance. Frequently, MRI suites have been designed without consideration for anesthetic needs, such as pipeline gases, suction, or an anesthetic exhaust system. Access to a recovery suite for postanesthesia care may not be readily available, thereby necessitating a trip to the main recovery room.

In addition, there are anesthetic challenges unique to the MRI suite. Because of the bulkiness of the unit, the patient is often far removed from the anesthesiologist, and access to the airway is limited. Intravenous lines, anesthesia circuits, oxygen tubing, and monitoring cables must be of sufficient length to reach the patient deep within the scanner. The strong magnetic field necessitates the exclusion of all ferromagnetic objects and equipment. The displays of standard monitoring devices can be distorted or displaced by the magnetic field and the monitors themselves can degrade the MR image by disturbing the signal/noise ratio. The ASA task force understands that the

interpretation of the ECG may be limited due to the superimposed voltages from blood flow in a high magnetic field (i.e., ST-segment interpretation unreliable even with filters). Safe monitoring conditions must be maintained with MR safe/conditional monitors and remote monitoring and must be in compliance with ASA standards. **Figure 62.2** shows that the anesthesiologist is watching the patient (in zone IV) and anesthesia monitors in zone III control room during MRI scan.

Finally, for a machine to be MR conditional, its components must be less than 2% ferromagnetic. Vaporizers themselves are not ferromagnetic so conventional ones can be used.

A.7. What is intraoperative MRI (iMRI)? What is real-time MRI, and in what setting can this be used?

Since 1993, image-guided surgery systems have been introduced that combine the resources of an operating room with MRI technology and high-performance computing. Several low-, mid-, and high-field strength interventional MRI systems have been developed that permit access to the patient by surgeons and provide near real-time imaging during surgical procedures. Intraoperative MRI furnishes the surgeon with simultaneous combination of direct vision and beyond-the-surface MRI, allowing for more accurate localization and targeting during surgery. In addition, iMRI allows the surgeon to detect the full extent of lesions, to devise a surgical approach that is safe with less potential operative morbidity, and to monitor for unseen hemorrhage. In some cases, iMRI may obviate the need for postoperative imaging that may necessitate additional sedation for pediatric patients. In addition to tumor resections, iMRI can be utilized in the surgical revascularization of moyamoya arteriopathy and during the management of arteriovenous malformations (AVMs), placement of deep brain stimulator for Parkinson disease and other movement disorders, evaluation of hematoma, and resection of epileptogenic foci. Other fields of medicine that incorporate iMRI include surgeries of the liver,

pancreas, and kidney as well as radiation therapy guidance when tumors shift. Not surprisingly, iMRI systems are expensive and require MRI-compatible surgical instruments and monitoring equipment. One of the largest challenges anesthesiologists face in this setting is dealing with the high-energy iMRI-generated electrical noise that can interfere with the ECG. Unlike in an MRI suite, there are multiple people and objects to account for when the iMRI unit is brought out and engaged around the patient. All personnel working in an iMRI environment must take MRI safety courses to ensure patient safety as well as personal safety. For the duration of the scan, the anesthesiologist has limited or no access to the patient, and visualization of the patient may be limited when enclosed in an electrical noise shield. All ferromagnetic objects, such as laryngoscopes, stylets, and beepers, must be left outside the operating room or placed in a secure area. Lastly, as opposed to MRI in a dedicated suite, anesthetic considerations for iMRI must also include the needs of the ongoing complex surgical procedure.

As opposed to iMRI, real-time MRI integrates exceptional soft tissue visualization in a 3D anatomic and functional manner with delineation of suspected lesions without exposure to radiation. In the electrophysiology suite, use of real-time MRI allows a number of catheter ablation procedures for the treatment of and risk stratification of various arrhythmias, with reduction in fluoroscopy usage. In addition, DE MRI is the gold standard for scar and fibrosis mapping, which serves as an arrhythmogenic source for VT. This preprocedural MRI may be difficult to obtain because these patients often have ICDs that are contraindicated for MRI. DE MRI can also be used to predict potential atrial fibrillation ablation failure based on the amount of left atrial fibrosis that is present. After an intervention, MRI can help identify complications, such as pulmonary vein stenosis and esophageal injury. MRI thermography is another useful tool

used to show tissue heating during RF ablation.

There are many hazards associated with real-time MRI and iMRI. Special MRI conditional and safe monitors, devices, and catheters need to be utilized to avoid catastrophic complications.

B. Preoperative Evaluation and Preparation

B.1. What type of patients may require sedation or general anesthesia for MRI?

Although MRI is painless, patients must remain still throughout the time required to make each scan (as much as 15 minutes) in order to obtain images free of movement artifacts. Patients who are unable to cooperate adequately (e.g., infants, young children, and adults who are confused, mentally ill, or intellectually compromised) usually require an anesthesiologist to assist with the examination. Most children younger than 5 years of age and as old as 11 years of age require some form of sedation or general anesthesia. Not only children need anesthesia; 30% of adult patients experience some form of anxiety during MR scanning. Anesthesiologists are frequently managing claustrophobic or anxious adults as well as those requiring either airway protection (unconscious or critically ill patients) or mechanical ventilation (patients with head injuries or elevated intracranial pressure) to ensure that an adequate examination is

obtained safely and efficiently.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

Wu J, Mahmoud M, Schmitt M, et al. Comparison of propofol and dexmedetomedine techniques in children undergoing magnetic resonance imaging. *Paediatr Anaesth*. 2014;24:813–818.

B.2. Do all children require sedation for MRI?

Performing general anesthetics in neonates and children with a potentially challenging airway in a remote location can be dangerous. In addition, due to the risks associated with potential neurotoxicity in the developing brain, there are many looking for methods to perform MRI scans without sedation. For instance, in small infants and neonates the "feed and swaddle" method can be used. Although this strategy is associated with an increased likelihood of obtaining inadequate images, it can be used as a first-line method with general anesthesia reserved as a backup. In older children, one can use multimedia, trained child life experts, and handheld device application-based technologies to calm children and help them stay still. This method can be sufficient in developmentally appropriate and cooperative children. It is important to discuss cases with the attending radiologist to determine whether MRI is appropriate for the clinical question. The harms from ionizing radiation on the developing child are well known; however, the amount of radiation required to obtain quality CT images has decreased with modern CT scanners. Because CT exams are far shorter (minutes instead of 1 hour for MRI), children likely do not need general anesthesia or sedation.

B.3. What preoperative laboratory testing would you require for this patient?

For this patient, it would be prudent to obtain a complete blood count (CBC) and a basic metabolic panel (BMP), the CBC to evaluate for postoperative bleeding and the BMP to evaluate electrolyte derangements (particularly sodium) as contributing to the patient's altered mental status. However, if the patient were otherwise healthy, no further laboratory studies would be warranted.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

B.4. How would you premedicate this patient? What are some options that can be used to premedicate other patients for MRI?

The goal of premedication is to provide anxiolysis yet not precipitate hypoxemia or hypercarbia. In this patient who already has altered mental status, long-acting sedatives should be avoided. However, other children may be good candidates for premedication for anxiolysis.

At some centers, ambulatory pediatric patients are not routinely given pharmacologic premedication; rather, parents are allowed to be present at the time of induction in order to help

allay anxiety and ease the induction. The most commonly used premedication in pediatrics is oral midazolam. Although the standard dose is 0.5 mg per kg, some advocate for an increased dose in younger children, up to 1 mg per kg in children 1 to 3 years old. A relatively high dose is likely needed due to the poor bioavailability of the drug orally (15%). Midazolam should be administered at least 20 to 25 minutes prior to intended onset for maximal effect. The side effects include respiratory depression, bad taste, and in some patients paradoxical agitation.

There are other medications that can be used for anxiolysis in children, including dexmedetomidine and ketamine. Dexmedetomidine can be given either intranasally (2.5 to 3 μg per kg) or orally (4 μg per kg). Dexmedetomidine is a centrally acting α_2-agonist that is a sedative without respiratory depression. It is odorless and tasteless so can be much more palatable for children. Dexmedetomidine can also reduce the incidence of postoperative emergence delirium, an added benefit.

Ketamine can be given orally (6 mg per kg) or intramuscularly (1 to 2 mg per kg). The oral route is preferred because many children have a needle phobia. The side effects of ketamine include an increase in oral secretions. This can cause upper airway obstruction, bronchospasm, laryngospasm, and microaspiration, even in the presence of intact upper airway reflexes. Ketamine can also cause significant postsedation delirium, especially if the child is not pretreated with a benzodiazepine.

A novel premedication is melatonin (0.5 mg per kg), which can provide comparable anxiolysis as oral midazolam. Melatonin is an endogenous indolamine produced and secreted by the pineal gland that normally regulates circadian rhythm and promotes sleep. However, it can have sedative effects that have been well studied in adults. Melatonin can reduce the amount of

propofol needed for induction of anesthesia in pediatric patients.

C. Intraoperative Management

C.1. What are some of the anesthetic options for this patient?

There are many techniques used to anesthetize children undergoing MRI or other painless radiologic procedures. This can range from moderate sedation with intravenous boluses of midazolam or fentanyl to deep sedation, with various combinations of intravenous ketamine/propofol/dexmedetomidine, or general anesthesia with inhaled anesthetics or total intravenous anesthesia (TIVA). Because conscious sedation of children is frequently insufficient to prevent patient movement, deeper levels of sedation or general anesthesia are often required to successfully anesthetize the pediatric patient for MRI. The ideal anesthetic should allow the anesthesiologist the ability to titrate and maintain stable drug concentrations in order to prevent undesired patient movement

during the scan and to provide rapid rates of induction and recovery with a minimal requirement for special MRI-compatible equipment.

Intravenous anesthesia with propofol meets several of the aforementioned criteria, and it can be an excellent technique for MRI. Continuous intravenous infusion of propofol allows for a precise, rapid titration to the desired effect and has for a rapid recovery. Propofol use eliminates the need for a nonferromagnetic, MRI-compatible anesthesia machine and for scavenging of waste anesthetic gases, both of which are major drawbacks of an inhalational technique. Ketamine is another useful drug for deep sedation while maintaining airway reflexes. However, in addition to the issue with increased secretions mentioned earlier, ketamine may elicit undesirable myoclonic movements, increased intracranial pressure, and emergence delirium, especially at higher dosages and in ages younger than 2 and older than 13 years.

Dexmedetomidine can be used as a maintenance agent as well as a premedication. No major respiratory effects are known with this agent, although hemodynamic side effects can occur, especially at higher doses. Wu et al. compared propofol and dexmedetomidine infusions for sedation in MRI and concluded that for longer scans, the dexmedetomidine group had longer induction times and overall hospital times than the propofol group. Due to potential hemodynamic side effects, such as hypotension and bradycardia, and life-threatening complications when used with digoxin, dexmedetomidine should be used cautiously in patients with cardiac compromise. MRI scans performed under propofol sedation have been shown to have better image quality than those performed with dexmedetomidine alone. Dexmedetomidine is a good adjunct agent, especially in a patient where spontaneous ventilation is paramount, however may not be a suitable agent by itself.

Another viable alternative to deep sedation with intravenous agents would be general anesthesia with inhalational anesthetics. In children younger than 3 years of age or in patients with comorbidities requiring or necessitating airway management, general anesthesia may be the preferred choice.

C.2. How is an MRI conducted?

The patient is placed on a long, thin table outside the scanner. After obtaining an adequate level of anesthesia, the patient is positioned. If the head is to be examined, it is often enclosed within a small coil or tube. Next, the table with the patient is moved into the long tube of the MRI magnet. The portion of the body to be examined is usually centered in the magnet approximately 1 m from the end of the tube. During the examination, delivery of the RF pulses produces a loud thumping noise, which can average 95 dB in a 1.5 T scanner. To obtain a high-quality scan, the patient must refrain from moving during the acquisition of an individual cut or from changing position at any time during the entire examination. An individual scan can take several minutes, and the total scanning time may range from 1 to 3 hours. Body surfaces can absorb some of the

RF energy during the sequence, although this is unlikely to increase core temperature by more than 1°C. Nevertheless, the specific absorption rate (SAR) of energy by the body as measured in watts per kilogram is monitored. Depending on the patient, if the SAR is too high the sequence may need to be aborted and adjusted.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

C.3. How would you monitor this patient?

Reliable and accurate monitoring of an unconscious individual during an MRI is essential because the patient cannot be seen adequately or accessed easily by the anesthesiologist. During sedation, the ASA standard monitors including blood pressure, pulse oximetry, and ECG must be used. ECG electrodes should be placed together and toward the middle of the magnetic field, and the leads should be insulated from the patient's skin to avoid any potential thermal injuries. During general anesthesia, capnography and temperature should also be monitored. The assessment of ventilation in a spontaneously breathing patient may be difficult especially when the patient is within the magnet and far from view. Monitoring end-tidal carbon dioxide from one limb of the nasal oxygen prongs or through a nasal catheter is frequently successful. Pulse oximetry is a marker for oxygenation and should not be used as a marker for ventilation. Hypothermia can be problematic, especially in pediatric patients. Because of the high airflow through the scanner cavity, the patient should be covered in blankets. Hyperthermia can also occur, and if suspected based on SAR, the sequence may need to be temporarily stopped. Temperature monitoring can be

accomplished by using nonferromagnetic temperature strips or probes with RF filters when feasible. It is currently not mandatory for the anesthesiologist to remain in the scanner room during the examination as long as remote monitoring with direct vision of the patient is possible.

The patient outlined in this case requires invasive blood pressure monitoring. However, one may need to place extension tubing as the transducer should be placed at least 50 gauss away from the scanner, potentially leading to a dampened signal.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

Practice advisory on anesthetic care for magnetic resonance imaging: a report by the Society of Anesthesiologists Task Force on Anesthetic Care for Magnetic Resonance Imaging. *Anesthesiology*. 2009;110:459–479.

C.4. What special considerations apply to monitoring equipment used during MRI?

Unshielded ferromagnetic materials, such as those within monitors and cables, or metallic pieces on patient clothing can interfere with imaging signals causing distortion of MRI results and burns. Similarly, the RF signals can induce currents in ferromagnetic elements of monitors, causing a distortion of the monitoring signal and making the monitor unusable. Use of MR safe/conditional monitors and equipment (e.g., ECG electrodes) are preferable because they contain shielding nonferromagnetic components and filters to produce satisfactory results without major distortion of signal. To avoid magnetic pull, monitors should be placed at least 5 to 8 ft from the magnet bore or be permanently mounted.

The ECG may show significant changes within a static magnetic field. In particular, T waves and late ST segments can

mimic ECG changes associated with conditions such as hyperkalemia and pericarditis. This is due to an induced voltage in blood (a conducting fluid) flowing through the magnetic field. These changes are directly related to field strength, but they do not appear to represent any significant physiologic alteration.

Pulse oximeter cables must be nonconducting, fiberoptic, and MRI compatible. Traditional pulse oximeter probes may contain metal and when adjacent to the patient can cause burns.

The high RF power used in MRI poses the risk of excessive heat at monitoring sites. This can lead to thermal injury. To minimize the risk of burns, one should

- Inspect the insulation on all monitoring wires to ensure that it is intact.
- Place cables and lead wires in straight alignment. Do not allow monitoring wires to form loops.
- Remove all leads or wires not in use.
- Separate cables from patient's skin.
- Keep the cable and sensor out of the scanning area (e.g., place a pulse oximeter probe on the toe of a patient whose chest is being examined).
- Avoid excessive power.
- Remove patient gown or any clothing that may have metal.

It is the role of the anesthesiologist to confirm all monitors used in zone IV are MR compatible. In addition, a monitor should be available to view vital signs from zone III when the anesthesia provider is not in zone IV.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:880–896.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

C.5. How would you induce and maintain general

anesthesia in this patient?

This patient will likely require general anesthesia to complete the MRI scan due to his altered mental status and the necessity to avoid hypoxia/hypercarbia in this postneurosurgical patient. General endotracheal anesthesia is the best option. However, the child was clearly difficult to intubate in the operating room and required use of a videolaryngoscope. Therefore, it would be prudent to ensure that help from experienced and trained anesthesiologists is available and to induce general anesthesia away from the scanner such that difficult airway equipment would be readily available. An intravenous induction should be performed to control oxygenation and carbon dioxide as quickly as possible. MRI-compatible monitors should be placed prior to induction to allow a smooth transition to the scanner. The pilot balloon on the cuff of the endotracheal tube (or supraglottic device, if used) must be taped away from the patient to minimize artifact from the cuff's spring. Once under general anesthesia, the child is moved into the scanner room and placed on the MRI table. The patient and monitors are carefully positioned before attempting to advance the table into the magnet bore. Anesthesia can be maintained with either a continuous intravenous infusion of propofol or an inhalational agent combined with oxygen.

Wu J, Mahmoud M, Schmitt M, et al. Comparison of propofol and dexmedetomedine techniques in children undergoing magnetic resonance imaging. *Paediatr Anaesth*. 2014;24:813–818.

C.6. What are ways to maintain the airway during an

MRI scan?

Securing the airway with an endotracheal tube is not required to successfully sedate a patient during an MRI scan, which can be performed with patients breathing spontaneously with a native airway. This should be considered in patients with a good natural airway whose ventilation is being monitored adequately. Infusions of propofol or dexmedetomidine can be considered in this situation. Placing a shoulder roll under the patient with the chin taped up may help prevent airway obstruction during the MRI scan. This should only be performed when there are no contraindications, such as potential spinal injuries with head and neck manipulations.

However, limited access to the patient's airway is one of the greatest challenges for the anesthesiologist during MRI. In patients whose airway may be problematic, it may be prudent to place either an endotracheal tube or supraglottic airway device. Respiration can be spontaneous or controlled depending on personal preference and the needs of the patient. However, supraglottic airway devices can alter the appearance of cervical soft tissue masses causing problems in diagnosis and should be used only after consulting with a radiologist if the neck is being imaged. The literature is not conclusive as to whether the use of a tracheal tube decreases the incidence of airway complications during MRI scans. As long as a plan is in place should emergencies occur, any type of anesthetic can be used to accomplish the scan.

C.7. During the scan, you notice loss of end-tidal carbon dioxide. You immediately go into the scanner, remove the patient from the MRI scanner and initiate bag ventilation. However, you are still unable to ventilate the patient, and asystole follows. What do you do next?

The initial picture represents severe bronchospasm. The management of bronchospasm includes increasing fraction of inspired oxygen (FIO_2) to 100%, checking the tracheal tube for kinking, secretions or obstruction, and deepening the anesthetic if the blood pressure allows. If this is unsuccessful, boluses of low-dose epinephrine should be used. However, as this patient has progressed to cardiopulmonary arrest, the patient should be removed from zone IV, if not done so already, as you initiate advanced cardiac life support (ACLS) and cardiopulmonary resuscitation (CPR). You should request additional assistance from other providers. It is important to remove the patient from the MRI scanner to have complete access as well as reduce the risk of bringing in magnetic devices such as oxygen tanks and defibrillator into zone IV.

Practice advisory on anesthetic care for magnetic resonance imaging: an updated report by the American Society of Anesthesiologists Task Force on Anesthetic Care for Magnetic Resonance Imaging. *Anesthesiology*. 2015;122(3):495–520.

C.8. What is the risk to the patient of gadolinium administration in the presence of acute renal

insufficiency?

For patients with acute renal insufficiency (serum creatinine >1.5 mg per dL), gadolinium should not be administered due to the increased risk of nephrogenic systemic fibrosis. Gadolinium based contrast should also be avoided in patients with previous allergic/anaphylactoid reaction and in patients who are or might be pregnant.

Ergün I, Keven K, Uruç I, et al. The safety of gadolinium in patients with stage 3 and 4 renal failure. *Nephrol Dial Transplant*. 2006;21(3):697–700.

Practice advisory on anesthetic care for magnetic resonance imaging: an updated report by the American Society of Anesthesiologists Task Force on Anesthetic Care for Magnetic Resonance Imaging. *Anesthesiology*. 2015;122(3):495–520.

D. Postoperative Management

D.1. How will you recover the patient from anesthesia?

Postanesthesia recovery care after MRI is the same as that required after any anesthetic. This can be accomplished in a designated area of the MRI suite provided that adequate facilities and trained personnel are available. For most, such a facility may not be available, and the patient will require transport to the main recovery room. To transport the patient quickly and safely, one must ensure that adequate personnel and the proper equipment are organized in advance. It is useful to have the location of recovery and logistics of transport (if necessary) planned before the procedure begins.

Coté CJ, Lerman J, Anderson BJ, et al, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier/Saunders; 2019:1077–1094.

63 Morbid Obesity, Obstructive Sleep Apnea, and Bariatric Anesthesia

Jon D. Samuels and Fun-Sun F. Yao

A 27-year-old man was scheduled for elective robotic sleeve gastrectomy. He had a past medical history significant for morbid obesity (MO) (height, 182.9 cm; weight, 272.16 kg; body mass index [BMI], 81.4 kg per m^2), Pickwickian habitus, osteoarthritis, mild asthma, hypertension, adult-onset diabetes mellitus, peptic ulcer disease with symptomatic gastroesophageal reflux, and obstructive sleep apnea (OSA). He experienced daytime somnolence, heavy nighttime snoring, and had slept in a seated position for the previous 2 years. He was able to walk around the house with a cane but was unable to climb any stairs. A preoperative diagnostic polysomnography (PSG) was performed, and an apnea–hypopnea index (AHI) of 64 was calculated. Home oxygen therapy with bilevel positive airway pressure (BIPAP) settings had been started at the following settings, with symptomatic improvement: fraction of inspired oxygen (F_{IO_2}) of 0.40, respiratory rate 10 breaths per minute, inspired positive airway pressure (IPAP) of +12 cm H_2O, and expired positive airway pressure (EPAP) of +5 cm H_2O, spontaneous mode.

Cardiology clearance was obtained as a high-risk candidate, after an echocardiogram revealed mild right-sided cardiomegaly and mild pulmonary hypertension. The patient's blood pressure was 155/82 mmHg, pulse 60 beats per minute, and respirations 20 breaths per minute. The patient was determined to have a difficult airway. Prior to scheduling surgery, the patient was scheduled for an upper endoscopy and a Bravo procedure.

A. Medical Disease and Differential Diagnosis

1. What problems exist with this patient? The patient asks you if he is high risk. What is the evidence? Is surgical therapy a safe and viable alternative for this patient?
2. Define the terms overweight, obesity, MO, super obesity (SO), super-SO (SSO), normal weight, ideal body weight (IBW), and lean body weight (LBW). What is the impact of obesity on society?
3. What is OSA? What are the risk factors for OSA?
4. How is OSA diagnosed? What is a sleep study, or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the subtypes of OSA? Are there genetic disorders with a predisposition to OSA? What is the role of OSA screening tests in the preoperative setting?
5. How does OSA differ in the pediatric population in clinical presentation and pathogenesis?
6. What is the Pickwickian syndrome (PS)? What is obesity hypoventilation syndrome (OHS)? Describe the pathogenesis of severe OSA.
7. What is the association between obesity and OSA? What is the etiology of OSA in severe obesity?
8. What are the anesthetic implications of OSA?
9. What type of metabolic problems would you expect to find in morbidly obese patients? What are the roles of leptin and

ghrelin in obesity?

10. Describe the changes that occur in the following respiratory parameters in morbidly obese patients:
    - Pulmonary mechanics: tidal volume (V_T), functional residual capacity (FRC), residual volume (RV), vital capacity (VC), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and total lung capacity (TLC)
    - Flow–volume loops
    - Pressure–volume loops
    - Diffusing capacity for carbon monoxide (DLCO)
    - Compliances: lung (C_L), chest wall (C_{CW}), and total (C_{RS})
    - Resistance: airway and total respiratory system
    - Closing capacity (CC)
    - Work of breathing (WOB)
11. What changes occur in Pa_{O_2} and Pa_{CO_2} in morbidly obese patients?
12. What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in MO? Describe the Shunt equation and the physiologic dead space, or Bohr equation.
13. What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output, blood volume, blood pressure, and pulmonary arterial pressure.
14. Are there any other disease entities commonly associated with obesity? What is their relationship?
15. What anatomic changes that affect the airway are associated with MO and OSA?
16. What derangements of the gastrointestinal system are associated with MO?

B. Preoperative Evaluation and Preparation

1. How would this patient be optimized for surgery preoperatively? Would you use preoperative screening questionnaires to diagnose OSA? Summarize the workup for

this patient.

2. One of the recent developments in bariatric surgery is that many patients are receiving prebariatric screening procedures performed in the endoscopy suite. Describe the anesthetic considerations.
3. Summarize the evidence-based workup, risk, chance of various adverse outcome, and expected length of stay for this patient.
4. What is the role of enhanced recovery after surgery (ERAS) in bariatric surgery? How does the public find a quality bariatric surgery team and surgical facility? What is the role of robotics in bariatric surgery?
5. Would you premedicate the patient?
6. Describe the mechanism of action of each premedication in the ENERGY protocol.
7. How would you adjust doses of anesthetics in the morbidly obese?

C. Intraoperative Management

1. How would you monitor this patient?
2. The American Society of Anesthesiologists' (ASA) Difficult Airway Algorithm (DAA) provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?
3. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques. What is the importance of continuous positive airway pressure (CPAP) during the induction of general anesthesia? Describe use of the nasal CPAP mask in the induction of general anesthesia.
4. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?
5. How would you induce anesthesia? Describe the intubation

technique.

6. How would you maintain general anesthesia? What agents would you choose? How would you prepare for emergence?
7. Which muscle relaxants would you use?
8. Is postoperative pain severe after bariatric surgery? What are the pain generators? What is the role of regional anesthesia to decrease opioid requirements for bariatric surgery? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?
9. What is the pathophysiology of pneumoperitoneum (PNP)? What is the effect on the cardiopulmonary system? How does it change perioperative care? What are the optimal ventilator strategies for morbidly obese patients undergoing bariatric surgery?
10. What are the devices that anesthesiologists place in the upper gastrointestinal canal during laparoscopic bariatric surgery? Are there risks associated with placement and management of these devices?
11. When will you extubate this patient? Describe weight-based extubation criteria.
12. What is apneic oxygenation?
13. What is diffusion hypoxia (DH)? How do you prevent it?

D. Postoperative Management

1. What are the early postoperative complications of bariatric surgical procedures?
2. What are the late complications of bariatric surgical procedures?
3. What is the effect of position on respiratory function in the obese patient?
4. How would you prevent postoperative atelectasis?
5. How long would you prescribe supplementary oxygen postoperatively?

6. How would you control postoperative pain?

A. Medical Disease and Differential Diagnosis

A.1. What problems exist with this patient? The patient asks you if he is high risk. What is the evidence? Is surgical therapy a safe and viable alternative for this patient?

Preoperative significant past medical history in this patient consists of MO, OSA, possible PS, right ventricular hypertrophy, early-onset coronary artery disease, mild pulmonary hypertension, systemic hypertension, adult-onset diabetes mellitus, osteoarthritis, and severe gastroesophageal reflux disease (GERD). Epidemiologically, this patient is at increased risk of coronary artery disease, cardiac arrhythmias, left- and right-sided congestive heart failure, peripheral vascular disease, venous thrombosis and pulmonary emboli, cerebrovascular disease, biliohepatic disease, hepatic steatosis, hepatic cirrhosis, degenerative joint disease, metabolic syndrome, and socioeconomic and psychosocial impairment.

This is a high-risk patient, with increased risk of both perioperative morbidity and mortality. Major anesthetic concerns include risk of difficult airway, difficult mask ventilation, decreased apneic threshold to anesthetics, sedatives and narcotics, prolonged anesthesia emergence, postemergence resedation, positional ventilatory collapse, restrictive and obstructive lung disease, ventilation/perfusion mismatch, worsening of reactive pulmonary hypertension, and cor pulmonale. This patient must receive continuation of his preoperative oxygen therapy with CPAP in the immediate recovery period, at the values determined by his sleep study (PSG), or greater. Additional anesthetic concerns include

difficult monitoring, difficult vascular access, and positioning issues. Additionally, there is a risk of postoperative massive pharyngeal collapse, rhabdomyolysis with renal failure, increased risk of infection including pneumonia, and positional injuries. Meticulous attention to acute pain management is essential.

Safe perioperative care for this patient requires triage to a specialized facility with additional personnel, surgeons with advanced laparoscopic training, and anesthesiologists with advanced airway skills and optimal equipment. Overall, the evidence for the long-term effectiveness of bariatric surgical therapy is quite compelling. The most widely quoted studies are on the gastric bypass, which has the longest track record; the Swedish Obese Subjects (SOS) study, and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK)-National Institute of Health Longitudinal Assessment of Bariatric Surgery (LABS). Both of these seminal studies showed that compared with conventional treatment, the surgery group was associated with favorable short-term (low 30-day mortality of 0.3%, low rates of adverse outcomes comparable to a laparoscopic cholecystectomy) and long-term (reduction in overall mortality, decreased incidence of diabetes, myocardial infarction, stroke, cancer) outcomes. Bariatric surgery is the most effective long-term therapy for patients with severe obesity and has been recommended in all current guidelines.

A.2. Define the terms overweight, obesity, MO, super obesity (SO), super-SO (SSO), normal weight, ideal body weight (IBW), and lean body weight (LBW). What is the impact of obesity on society?

Obesity is a multifactorial chronic disease involving social, cultural, physiologic, psychological, metabolic, endocrine, genetic, and behavioral components, resulting in excess adipose and tissue mass. The modern basis for the determination of demographics is the BMI, or Quetelet Index, after the Belgian statistician, Adolphe Quetelet, published in 1842, and is measured in body weight in kilograms divided by the height in meters squared (kg per m^2). The standard for *IBW*, the sex-specific desirable weight for persons with small, middle, and large frames, is published in the Metropolitan Life Insurance Tables. *LBW* accounts for the added muscle mass supporting the added weight, and corresponds to the well-perfused portion, of 120% to 140% of the IBW, or 1.3 times the IBW.

- *Anorexia* is defined as a BMI of less than 17.5 in males or females.
- *Underweight* is defined as a BMI of 17.6 to 19.0 in females or 17.6 to 20.6 in males.
- *Ideal (normal) weight* is defined as a BMI of 19.1 to 25.8 in females and 20.7 to 26.4 in males.
- *Marginally overweight* is defined as a BMI of 25.9 to 27.2 in females and 26.5 to 27.8 in males.
- *Overweight* is defined as a BMI of 27.3 to 32.3 in females

and 27.9 to 31.1 in males.

- *Obesity* is defined as a BMI of greater than 20% of IBW, 32.4 to 34.9 in females and 31.2 to 34.9 in males.
- *Severe obesity* is defined as a BMI of 35.0 to 39.9 in both sexes.
- *MO* is defined as a BMI of greater than 40 or greater than 35 with associated comorbidities such as hypertension and diabetes mellitus. MO is the accepted medical term for all cases of severe obesity.
- *SO*, a relatively new term, is defined as a BMI of 50 to 59.9. *SSO* is defined as a BMI of greater than 60.

There exist imperial and metric system BMI tables and web-based calculators.

Occasionally, an approximate, non–sex-specific system is used. In this system, a *healthy (normal) weight* is a BMI of 18.6 to 24.9, *overweight* is a BMI of 25 to 29.9, *obesity* is a BMI of 30 to 34.9, *severe obesity* is a BMI of 35 to 39.9, and MO is a BMI of more than 40.0.

The older definitions of obesity may occasionally suffice. Overweight was formerly defined as a body weight of up to 20% greater than the predicted ideal weight and obesity of more than 20%. MO was formerly defined as a body weight of 100 lb above the IBW, or alternatively, of twice the IBW. These definitions involved value judgments and inaccuracies and were later abandoned in favor of more objective terminology.

Alternative systems for the determination of obesity exist. In the triceps skinfold thickness test, for example, obesity is defined as a value of greater than 23 mm in males or greater than 30 mm in females. In the Broca Index (height in centimeters minus 100 for males and minus 105 for females), the IBW is calculated in kilograms.

- Males: IBW (kg) = height (cm) − 100
- Females: IBW (kg) = height (cm) − 105

There are different patterns of distribution of obesity. In *peripheral obesity* (e.g., gynoid or gluteal pattern), the individual has a pear shape, and adipose tissue deposition is predominantly in the lower body. In *central obesity* (e.g., android, or cushingoid), and especially upper body obesity, the individual has an apple shape, and adipose tissue deposition occurs predominantly in the upper body. Central obesity has greater associations with perioperative risk and OSA.

Much has been written on the obesity epidemic; according to the World Health Organization (WHO), obesity remains one of the most critical health challenges of the modern era. Obesity has reached epidemic proportions in the industrialized world and currently poses a greater worldwide health risk than malnourishment. In the United States alone, 65% of the U.S. population, or 127 million adults, are obese and is annually responsible for 300,000 premature deaths.

The financial impact on society of obesity is rue to *direct medical costs*, *increased incidence disease associated with* obesity, *associated medical costs*, *cost associated with lost* productivity, *absenteeism*, *presenteeism*, disability, increased health insurance issues, and increased indirect costs and have been discussed elsewhere. Together, the total cost of obesity has been estimated in 2010 at annual costs of $215 billion for the United States economy and $2 trillion a year for the world economy.

A.3. What is OSA? What are the risk factors for OSA?

OSA is a sleep disorder. Sleep disorders may be grouped into the following types: conditions with excessive daytime somnolence (e.g., OSA), conditions with disorders initiating and maintaining sleep (e.g., insomnia), and circadian rhythm disorders (e.g., jet lag). In the older terminology, OSA referred to both OSA proper and to obstructive sleep hypopnea (OSH) syndrome, a milder variant. Today, it is more precise to refer to OSA and hypopnea syndrome (OSAHS) when naming the general condition.

OSA is defined as cessation of airflow for more than 10 seconds despite continuing ventilatory effort, five or more times per hour of sleep, associated with a decrease in arterial oxygen saturation (Spo_2) of greater than 4%. OSH is defined as a decrease in airflow of more than 50% for more than 10 seconds, 15 or more times per hour of sleep, associated with a decrease in Spo_2 of greater than 4%. Both forms of OSAHS are usually associated with snoring, sleep disruption from increased ventilatory effort–induced arousal, hypersomnolence (daytime sleepiness), altered cardiovascular function, and pathophysiologic alterations, of which hypoxemia and hypercarbia are primary events, and polycythemia, systemic and pulmonary hypertension, various cardiac arrhythmias, myocardial ischemia, right and left ventricular (LV) hypertrophy, and eventually failure are secondary events.

Severe obesity is a strong independent risk factor for OSAHS. Other risk factors include male gender, middle age, evening ingestion of alcohol, and drug-induced sleep. In nonobese individuals, risk factors are craniofacial dysostoses, particularly micrognathia (absolute or relative), cartilaginous abnormalities

(e.g., lingual tonsillar hyperplasia), chronic nasal obstruction, and tonsillar hypertrophy.

A.4. How is OSA diagnosed? What is a sleep study, or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the subtypes of OSA? Are there genetic disorders with a predisposition to OSA? What is the role of OSA screening tests in the preoperative setting?

OSA may be suspected by history, physical examination, or comorbidities, but definitive diagnosis requires a sleep study. The hallmark of OSA is a history of heavy snoring. Nocturnal apnea, arousal during sleep, and daytime somnolence are commonly reported. Most adults with OSA have upper body obesity, increased neck circumference, micrognathia, and poor Mallampati scores on physical examination. Patient characteristics typically associated with OSA are a higher BMI, hypertension, and certain cephalometric measurements. In 90% of cases, the patient has a BMI in excess of 28 kg per m^2. OSA, however, may result from any condition that predisposes to upper airway obstruction. Some examples are pregnancy, upper airway abnormalities (e.g., deviated nasal septum, hypertrophic tonsils, and adenoids), cartilaginous abnormalities (e.g., lingual tonsillar hyperplasia), craniofacial dysostoses, certain congenital and genetic conditions (e.g., Prader-Willi syndrome, Down syndrome, Marfan syndrome, Pierre Robin sequence,

acromegaly, muscular dystrophy, cerebral palsy), as well as certain medical conditions (hypothyroidism). The absence of a typical or compelling presentation, however, does not rule out the possibility of OSAHS.

Adult OSA consists of a continuum from asymptomatic, to paroxysmal snoring, to severe nocturnal airway closure, requiring the patient to sleep in a sitting position, and daytime somnolence. The pathophysiology of OSAHS is central, peripheral, or mixed. Peripheral disease is caused by redundant adipose tissue in the upper airway, in the setting of severe obesity, sometimes with a superimposed craniofacial dysostosis. The symptomatology of OSAHS consists of intermittent snoring, apneic episodes, with daytime somnolence. *OSH*, a milder form of OSA, may be clinically indistinguishable. *OHS* is severe OSA with chronic daytime hypoventilation, SO, and hypercapnia not related to pulmonary disease. *PS* is OHS with cor pulmonale.

Definitive diagnosis of OSA is made by sleep specialists with a formal sleep study or a PSG. A PSG is an involved study, performed at sleep study centers, that examines nocturnal sleeping patterns by monitoring physiologic parameters. In its most comprehensive form, the following parameters are studied: two to six electroencephalographic (EEG) channels to measure electrical activity of the brain and to document sleep cycles, two electrooculogram (EOG) channels to distinguish rapid eye movement (REM) from non-REM sleep, chin electromyogram (EMG) to monitor arousal and activity of the upper airway (genioglossus and digastric muscles), an airway microphone to monitor airflow from the nose and mouth, elastic belts placed on the chest and abdomen to monitor respiratory effort, an infrared video camera to monitor body position, one channel of electrocardiogram (ECG) to monitor cardiac activity, a pulse oximeter to monitor oxygen saturation, and two-leg EMG

channels to monitor leg movements. A PSG may be ordered to definitively diagnose a sleep disorder, as part of medical management, or in the surgical workup of a high-risk population (e.g., preoperative screening of bariatric surgical candidates).

A PSG will diagnose the presence of OSAHS, type (central, peripheral, or mixed), and grade severity. Results are reported in as the total number of apneas and hypopneas per hour of sleep or the AHI. AHI values correspond to OSA severity as follows: 6 to 20 (mild), 21 to 40 (moderate), and greater than 40 (severe). The total number of arousals hourly is the arousal index (AI), which is the number of hourly arousals. The sum of the AHI and the AI is the respiratory disturbance index (RDI). Because the PSG is an expensive and time-consuming study that not covered by all insurance plans, simpler tests have been proposed, such as a partial (level 2) portable polysomnography and nocturnal oximetry. OSA is primarily a clinical diagnosis. Because only a very small percentage of patients presenting for surgery have been tested, have available results, and are compliant with recommendations, great importance is placed on preoperative sleep apnea screening tools and questionnaires. Of these, the STOP-BANG questionnaire is the most widely used and has been recently ratified in a meta-analysis across different populations.

The ASA has developed official policy for the perioperative management of OSA patients. In its most recent iteration of the practice guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea, all aspects of anesthetic care are described, including a scoring system for perioperative risk for OSA patients, based on OSA severity, invasiveness of surgery and anesthesia, and requirement for postoperative opioids.

A.5. How does OSA differ in the pediatric population in clinical presentation and pathogenesis?

Childhood OSA (COSA) consists of a continuum from snoring, to upper airway resistance syndrome, to the fully expressed syndrome. The pathophysiology of COSA is most commonly peripheral in origin due to nocturnal airway blockage from nasal pathophysiology, hypertrophic tonsils and adenoids, or craniofacial dysostoses. The symptomatology in COSA consists of snoring (usually continuous), rare daytime sleepiness, and frequent behavioral disturbances (e.g., attention deficit hyperactivity disorder [ADHD]). It is distinguished from adult OSA by the following: Snoring is more continuous, there is no sex predilection, and surgery (commonly adenotonsillectomy, rarely uvulopalatopharyngoplasty [UPPP]) is curative.

COSA occurs in 2% of young children and is frequently underdiagnosed. Most cases are idiopathic. COSA may be also related to severe chronic disease, such as chronic asthma, cystic fibrosis, pulmonary fibrosis, bronchopulmonary dysplasia, or chest wall abnormality. Rarely there is a genetic basis (see section A.4); and in these cases, apnea may be of central, or mixed, origin. The American Academy of Pediatrics (AAP) recommends that all children be screened for snoring. Polysomnography has been recommended as the most reliable diagnostic test and has been described elsewhere in detail. The American Academy of Otolaryngology—Head and Neck

Surgery has published guidelines clinical practice guidelines for polysomnography to screen children with sleep-disordered breathing prior to tonsillectomy.

A.6. What is the Pickwickian syndrome (PS)? What is obesity hypoventilation syndrome (OHS)? Describe the pathogenesis of severe OSA.

PS was so named by Burwell in 1956, as a reference to Joe, an obese, somnolent boy in *The Posthumous Papers of the Pickwick Club*, written in 1837 by Charles Dickens. In Joe, Dickens provided the first accurate description of the most severe type of OSA, consisting of a BMI over 50 kg per m^2 or SO, alveolar hypoventilation (hypoxemia and hypercarbia), heavy nighttime snoring with periodic respiration, hypersomnolence (daytime somnolence), secondary polycythemia, right and LV hypertrophy, and right-sided heart failure.

In these individuals with PS, there are repeated cycles of sleep, arousal, and sleep, accompanied by obstructed breathing, with snoring and restlessness. Hypoxemia and hypercarbia result from disruption of a normal sleep pattern, with loss of REM sleep and cardiovascular changes. Loss of REM sleep induces hypersomnolence, personality, behavior, and cognitive changes and predisposes these individuals to be accident-prone.

Eventually, severe OSA leads to OHS, with nocturnal, and later diurnal alterations in the control of breathing, manifested as central apneic events, or apnea without ventilatory efforts. They also develop an alveolar–arterial oxygen gradient by ventilation/perfusion mismatch and may develop pulmonary hypertension. The major factor in the pathogenesis of this syndrome is unknown but may be due to decreased hypoxic and hypercarbic ventilatory drive. Late in the disease process, there is progressive daytime hypoxia and hypercarbia. When cor pulmonale supervenes, PS is complete. Recently, the term *PS* has been abandoned in favor of OHS.

There are several cardiovascular changes in severe OSA, all related to the episodic airway closure, with hypoxemia and hypercarbia. Hypoxemia and alterations in autonomic tone may induce bradycardia during apneic episodes; in half of these patients, long sinus pauses, second-degree heart block, and ventricular ectopy may result. These arrhythmias may lead to nocturnal angina and myocardial infarction in susceptible individuals. Pulmonary hypertension may be caused directly by hypoxic pulmonary vasoconstriction, or indirectly by either increased transmural pulmonary artery pressures from negative thoracic pressure created by a sustained ventilatory effort against the upper airway obstruction, or by increases in pulmonary artery tone from increased sympathetic tone created by episodic hypoxemia. Pulmonary hypertension initially causes right ventricular hypertrophy, resulting in a higher right ventricular end-diastolic pressure (RVEDP), and later culminates in right ventricular failure, or cor pulmonale. The systemic circulation is also affected by episodic increases in sympathetic tone, with systemic hypertension presenting early, and LV hypertrophy, followed by LV failure, presenting much later. Systemic hypertension may also lead to increased stroke volume.

A.7. What is the association between obesity and OSA? What is the etiology of OSA in severe obesity?

Obesity and OSAHS are both common, coexisting diseases. The prevalence of severe obesity, a strong risk factor for OSAHS, is 3.15% in males and 6.70% in females, according to U.S. population data. Incidence and severity of OSAHS correlates loosely with BMI, better with neck circumference, and most closely with waist circumference. OSAHS is 2.6 times more likely when the waist-to-hip ratio exceeds 1.0 in obese males and 0.85 in obese females.

Sixty percent to 90% of OSA patients are obese, and it has been estimated that 9% of women and 24% of men in the United States suffer from the syndrome, a total of 18 million individuals, of which 2% of women and 4% of men, are symptomatic. These figures will almost certainly increase, as the demographics shift toward an older and more obese population. Many of these patients do not have diagnosis of OSA on their medical record at the time of surgery, representing potential perioperative complications. The prevalence of OSA in morbidly obese patients presenting for weight loss surgery is 78%.

There are three reasons why severe obesity per se may cause or exacerbate OSAHS. First, there is an inverse relationship

between obesity and pharyngeal volume. The pharyngeal area decreases in obesity from deposition of adipose tissue into pharyngeal structures, in particular, the uvula, the tonsils, the tonsillar pillars, the tongue, the aryepiglottic folds, and, most importantly, the lateral pharyngeal walls. The volume of adipose in the lateral pharyngeal walls correlates with the clinical severity of airway obstruction. Increased deposition of pharyngeal adipose increases the likelihood that relaxation of the upper airway muscles will result in collapse of the soft-walled retroglossal space, between the uvula and the epiglottis. The shape of the pharynx remodels from an ellipse with the long axis transverse to an ellipse with the long axis anterior-posterior. The muscles that open the collapsible pharynx on expiration during sleep (e.g., tensor palatini, genioglossus, hyoid muscles) in response to stretch receptors in the pharynx are located in the anterior pharynx and do not function well with a remodeled pharynx.

Second, patency of the collapsible pharynx is determined by the transmural pressure (the difference between the extraluminal and intraluminal pressure) and compliance of its wall. If the compliance of the pharyngeal wall and intraluminal pressure (inspiratory pressure) is constant, then the remaining important determinant of upper airway patency is extraluminal pressure. In obese patients, extraluminal pressure is increased by superficially located fat masses; that is, the upper airway is compressed externally. Therefore, neck circumference is greater in obese patients with OSAHS compared with obese non-OSAHS patients.

Third, pharyngeal patency is partially determined by lung volume. The collapsible (particularly in a supine position), soft-walled pharynx is kept patent during sleep by lung volumes above the FRC, which pulls on the carina, tenting open the pharynx. This is known as *the lung volume hypothesis*. Smaller

lung volumes allow a cephalad displacement of the carina, approximately 0.5 to 1.5 cm, resulting in collapse or even telescoping of the pharynx, with a smaller circumferential area.

A.8. What are the anesthetic implications of OSA?

Management of anesthesia in patients with severe OSAHS poses significant risks. These patients are extremely sensitive to minimal doses of central nervous system–depressant drugs, such as anesthetics, sedatives, and analgesics, and may exhibit prolonged sedation, resedation, or apnea as well as upper airway obstruction or, rarely, massive pharyngeal collapse. For these reasons, premedication with benzodiazepines or narcotics is used sparingly if at all, and sedation is generally reserved for painful or unpleasant situations (e.g., placement of invasive lines) where the patient is under the direct observation of a trained clinician.

Difficult tracheal intubation is expected in 13% to 24% of obese patients with OSAHS. In this particular case, the patient presents for laparoscopic bariatric surgery. Although the “ideal

general anesthetic" regimen for these patients is a matter of some discussion, the literature does support the following: a safe induction, a deep maintenance anesthetic with muscle relaxants, and a smooth emergence with rapid offset devoid of active metabolites or trace anesthetic. Anesthetic gases should be insoluble, resistant to metabolic degradation, and without lipid depot compartmentalization, combined with rapid return of airway reflexes. The only weak inhalation anesthetic, nitrous oxide (N_2O), has the advantage of being relatively insoluble, as measured by blood–gas solubility coefficient (0.46), but it causes intestinal inflation, may be emetic, and is not recommended in the presence of pulmonary hypertension, a condition that is more common in MO. Of the available potent inhalation anesthetics (desflurane, sevoflurane, and isoflurane), desflurane combines the quickest wake-up; fastest return of airway reflexes; lowest solubility, as measured by the blood–gas solubility coefficient (desflurane, 0.45; sevoflurane, 0.65; isoflurane, 1.4); and lowest percentage of hepatometabolization (desflurane, 0.02%; isoflurane, 0.2%; sevoflurane, 2% to 3%). Intravenous agents should be either lipophobic (hydrophilic), spontaneously degrade in vivo, or be ultrashort-acting.

Sedation or awake fiberoptic intubation: Ketamine and dexmedetomidine are optimal agents. *Induction of general anesthesia*: All agents have been utilized. *Maintenance agents*: air/oxygen mixtures, desflurane, cisatracurium, and remifentanil. *Last hour of general anesthesia and emergence*: N_2O (except in the presence of pulmonary hypertension), remifentanil, and hydromorphone. Use of regional anesthesia decreases opioid requirements and facilitates extubation.

Tracheal extubation is considered only when patients are fully awake with intact upper airway reflexes. Episodic arterial hypoxemia may occur early, in the first 24 hours, or late, from the second to the fifth day, postoperatively. Postoperative pain

management must take into account the exquisite sensitivity of these patients to the ventilatory-depressant effects of opioids.

Discharge from the postanesthesia care unit (PACU) may be made in the morbidly obese OSA, per protocol, after they have been started on CPAP or BIPAP and have been observed for at least 30 minutes, without stimulation, and found to be free of respiratory arrests. If respiratory arrests occur, PACU stay is extended for an additional 3 hours, and consideration is made to transfer the patient to a monitored bed.

Intravenous patient-controlled analgesia (IV-PCA) appears to be well tolerated in the morbidly obese, without deleterious effects on oxygen saturation, respiratory function, blood pressure, or heart rate. Hydromorphone is the most commonly used opioid for IV-PCA, morphine and fentanyl are second-line agents. It is important to individualize therapy. Use of multimodal analgesia, combined with the transversus abdominis plane (TAP) block after surgery, decreases opioid requirements. Recently, eliminating IV-PCA has been shown to accelerate hospital discharge after bariatric surgery.

A.9. What type of metabolic problems would you expect to find in morbidly obese patients? What are the roles of leptin and ghrelin in obesity?

In MO, there is an increase in both low metabolically active tissue (e.g., adipose) and normally active tissue (e.g., muscle). In general, LBW is equal to IBW plus 20% to 40% IBW. IBW is a value, based on population demographics, which could never be realized through weight reduction, in a severely obese individual.

Morbidly obese individuals have an increase in total oxygen consumption and carbon dioxide (CO_2) production due to an increased tissue mass. Increased metabolism demonstrates a linear relation with body weight and body surface area. Basal metabolic rate, however, remains normal in obese individuals.

Severely obese patients often have nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) increasing long-term risk of hepatic cirrhosis, dyslipidemia, inflammation, insulin resistance, and atherosclerosis. Metabolic syndrome, defined as a collection of central obesity, hypertension, dyslipidemia, and impaired glucose tolerance, is present in severe cases and increases perioperative risk of morbidity and death. Metabolic syndrome is mediated through adipocytokines, such as acute phase reactants (increases in C-reactive protein and serum amyloid A [SAA]), adipokines (decreased adiponectin, or increases in leptin or resistin), macrophage-derived factors (increased resistin or interleukin-1 beta [IL-1β]), proinflammatory cytokines and chemokines (increases in tissue necrosis factor-alpha [TNF-α], several

interleukins [IL-1, IL-6, IL-8, IL-10, IL-18]), chemokine (C-C motif), and prothrombotic factors (increases in plasminogen activator inhibitor-1 [PAI-1], fibrinogen, and factor VII).

Leptin is a satiety hormone secreted by adipocytes. Most obese adults have high inappropriate leptin levels or hyperleptinemia. Leptin levels are increased by overfeeding, insulin, glucocorticoids, endotoxin, and cytokines and are decreased by fasting, testosterone, thyroid hormone, and exposure to cold temperature. In the heart, increased leptin expression is seen following reperfusion after ischemia, and leptin concentration in cardiomyocyte culture serum is increased with endothelin (ET)-1 and angiotensin II treatment. Congenital leptin deficiency is a rare cause of obesity, caused by mutations in the LEP gene in an autosomal recessive pattern. Although polymorphism in leptin receptor gene expression has been identified in many diseases, such as diabetes, coronary artery disease, metabolic syndrome, and cancer, it also exists in healthy populations. Ghrelin is the hormonal stimulant of short-term hunger. In MO, there is a resistance to both leptin and ghrelin. The cellular and molecular basis for the interplay between leptin and ghrelin has been discussed in detail and is an area of intense research.

A.10. Describe the changes that occur in the following respiratory parameters in morbidly obese patients:

- **Pulmonary mechanics: tidal volume (V_T), functional residual capacity (FRC), residual volume (RV), vital capacity (VC), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), and total lung capacity (TLC)**
- **Flow–volume loops**
- **Pressure–volume loops**
- **Diffusing capacity for carbon monoxide (DLCO)**
- **Compliances: lung (C_L), chest wall (C_{CW}), and total (C_{RS})**
- **Resistance: airway and total respiratory system**
- **Closing capacity (CC)**
- **Work of breathing (WOB)**

Morbidly obese patients have reduced lung volumes, increased WOB, and alterations in control of breathing and gas exchange. Body fat distribution, as well as BMI, determines the effect of obesity on pulmonary function.

Pulmonary mechanics. Pulmonary function tests (PFTs), or lung volumes, are uniformly altered in obesity. V_T is normal or increased in the obese and is decreased in Pickwickian obesity. IRV is decreased. ERV is markedly decreased because the increased weight of the torso decreases the normal expansive tendency of the rib cage and pulmonary parenchyma. RV is normal. FRC or ERV plus RV is markedly decreased because of the decrease in ERV. VC or ERV + V_T + IRV is decreased because of decreased ERV. TLC or RV + ERV + V_T + IRV is decreased for the same reason as VC. Individuals with central, as opposed to peripheral, fat distribution have greater decreases

in the forced vital capacity (FVC), forced expiratory volume (FEV), and TLC. The maximum voluntary ventilation (MVV) may also be reduced.

Diffusing capacity for carbon monoxide. The DLCO is usually normal in individuals with obesity and mildly reduced in those with OHS because the lung parenchyma is normal, and changes in PFTs are due to abnormal chest wall mechanics and lower lung volumes. DLCO is a useful test to separate intrinsic lung pathology from obesity.

Compliance. There is a decrease in the total respiratory system compliance ($1 / C_{RS} = 1 / C_L + 1 / C_{CW}$), where C_{RS} is the total compliance, C_L is the compliance of the lung, and C_{CW} is the compliance of the chest wall. Total compliance is always decreased because of the weight of the torso and abdominal contents pressing against the diaphragm creating a restrictive component, markedly decreasing the C_{CW}. Lung compliance is often normal but is decreased when pulmonary and circulatory comorbidities are present (e.g., pulmonary hypertension).

Resistance. There are increases both in the airway resistance (reduced elastic tension of the lung) and in the total respiratory system resistance (increased elastic tension of chest wall) at lower lung volumes, which leads to reduction in the caliber of the smaller airways. The increase in total resistance is approximately 30% in simple obesity and 100% in OHS. Resistance increases further in the supine position, possibly due to extrinsic adipose pressure of the supralaryngeal airway and a decreased FRC.

Closing capacity. FRC is reduced in the morbidly obese patient and may be below the CC; resulting in small airway closure; ventilation/perfusion mismatch; right-to-left shunting; and possibly hypoxemia, the so-called positional ventilatory collapse. This may be worsened in the supine position,

Trendelenburg position, by general anesthesia and muscle relaxants, and improved by the use of lung recruitment strategies (e.g., positive end-expiratory pressure [PEEP]), and reverse Trendelenburg position.

Increased work of breathing. MO is associated with a 70% increase in the WOB and a fourfold increase in the oxygen cost of breathing (oxygen consumed by the respiratory muscles per liter of ventilation, used as a surrogate for the energy cost of breathing). This is due to decreased lung compliance, increased respiratory resistance, and threshold inspiratory load from adipose tissue mass. Obese individuals with obstructive sleep apnea syndrome (MO-OSAHS) have elevated pharyngeal and nasopharyngeal resistance, raising the WOB 60% above the obese and 250% above the nonobese.

A.11. What changes occur in PaO_2 and $PaCO_2$ in morbidly obese patients?

In the awake patient, positional reduction in lung volume and respiratory system compliance occur when moving from an upright position to a supine position. These changes are exaggerated in the severely obese patient, particularly ERV and FRC. FRC declines both with obesity and with induction of general anesthesia.

Hypoxemia is the most common blood gas abnormality in the

severely obese patient. The etiology is most commonly due to a low ventilation:perfusion ($\dot{V}/\dot{Q}$) ratio and less commonly as a result of hypoventilation. Pulmonary perfusion is increased in the obese as a result of increased cardiac output, increased circulating blood volume, and, occasionally, pulmonary hypertension. Alveolar ventilation is decreased in the obese as a result of upper airway closure and spirometric changes (decreased ERV and FRC). In addition, the closing volume is often greater than the ERV, particularly in the supine position, causing airway closure, resulting in right-to-left shunt and hypoxemia. These patients frequently develop atelectasis, both from cephalad position of the diaphragm and increased weight of thoracic adipose tissue. Many obese patients develop a restrictive respiratory pattern, with mild small-volume tachypnea, and increased use of accessory muscles of respiration.

The second most common blood gas abnormality in the severely obese is a variable change in the CO_2 tension ($PaCO_2$), not related to lung disease, and dependent on the alveolar ventilation. There are three patterns of ventilatory derangement described:

- *Alveolar hyperventilation* in response to a hypoxic drive. This occurs in young, active subjects. $PaCO_2$ is approximately 35 mmHg.
- *Periodic*, *nocturnal*, *alveolar hypoventilation* with normal daytime values. This is the hallmark of OSAHS.
- *Daytime, or constant, alveolar hypoventilation*. This occurs in OHS and PS.

In addition, lung disease, such as asthma and chronic obstructive pulmonary disease (COPD), is more common in the obese patient population, when compared with age- and sex-matched controls. Preexisting lung disease may become exacerbated perioperatively.

A.12. What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in MO? Describe the Shunt equation and the physiologic dead space, or Bohr equation.

Q_S/Q_T is normally less than 5%. In the MO, this is increased, because of the following:

- Lower $\dot{V}/\dot{Q}$ ratio
- Upper airway closure (e.g., OSAHS)
- Decreased FRC from abdominal compression
- Hypoventilation (e.g., OSAHS)
- Increased pulmonary circulation, from increased cardiac output, increased blood volume, and occasionally pulmonary hypertension

Shunt equation: $Q_S / Q_T = (CcO_2 - CaO_2) / (CcO_2 - CvO_2)$

where Q_S is pulmonary physiology shunt (milliliter per minute), Q_T is cardiac output (milliliter per minute), CcO_2 is end pulmonary capillary oxygen content, CaO_2 is arterial oxygen content, and C_VO_2 is mixed venous oxygen content.

Dead space is anatomic, alveolar, or physiologic. *Anatomic dead space* is the volume of the lung and upper airway that is not involved in gas exchange. Ventilation of this area does not result in gas exchange. The volume of the anatomic dead space in milliliters is approximately equal to the IBW in pounds.

Fowler's method of measuring anatomic dead space is by analyzing nitrogen concentration after single breath 100% oxygen. *Alveolar dead space* is the area of alveoli with ventilation and no perfusion, which has a $\dot{V}/\dot{Q}$ equal to infinity, or West Zone 1. *Physiologic dead space*, the sum of anatomic and alveolar dead space, is the total area of lung plus airways not involved in gas exchange. Physiologic dead space is approximately 30% of the V_T. It is decreased in the supine position, and increased with disease states that alter, and in OHS, because the latter individuals adopt a shallow ventilatory pattern. Physiologic dead space is decreased in SO due to increased V_T ventilation and unchanged anatomic dead space. Physiologic dead space, or V_D/V_T, is measured by the Bohr equation, with Enghoff modification.

$$\text{Bohr equation: } V_D/V_T = (Pa\text{CO}_2 - P\text{ECO}_2) / P\text{ECO}_2$$

where V_D is the physiologic dead space volume (mL), V_T is the tidal volume (mL), $Pa\text{CO}_2$ is the partial pressure of carbon dioxide in arterial blood, and $P\text{ECO}_2$ is the partial pressure of carbon dioxide in the average mixed expired air.

There are no changes in the physiologic dead space-to-V_T ratio or the alveolar–arterial oxygen gradient in obese patients undergoing laparoscopic gastric bypass surgery during general anesthesia compared with baseline.

Lumb AB, ed. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:119–123, 133–134, 135.e2, 306–307, 318.e1.

A.13. What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output, blood volume, blood pressure, and pulmonary arterial pressure.

MO produces changes in cardiac morphology and ventricular

function.

As BMI increases, both total and circulating blood volume increase. Although absolute blood volume is expanded, relative blood volume is decreased. Increase in circulating blood volume and decrease in systemic vascular resistance results in augmentation in cardiac output. Cardiac output increases by increased stroke volume, and heart rate remains unchanged. Cardiac output and stroke volume increase in proportion to oxygen consumption and the degree of obesity but more closely to the LBW. LV wall stress increases according to the law of Laplace ($P_2 - P_1 = 2T / R$), where P is the change in pressure produced by the increased volume, T is the LV wall stress, and R is the radius. Increase in afterload from hypertension produces eccentric LV hypertrophy and eventually LV dysfunction. They are thus sensitive to acute changes in preload and afterload. Morbidly obese patients presenting to the operating room (OR) require an ECG, chest x-rays, and an echocardiogram. Seventy percent of the echocardiograms in morbidly obese patients contain abnormalities.

Hypertension is more prevalent because of increased cardiac output and increased blood volume. Hypertension is more commonly systolic than diastolic in the obese. Obese patients without comorbidity have normal pulmonary artery filling pressures. Those individuals with OHS and PS, however, commonly have pulmonary hypertension, as a result of hypoxic pulmonary vasoconstriction and increased cardiac output. Hypertension and increased cardiac output lead to congestive heart failure in approximately 10% of obese individuals. There are two mechanisms in the pathogenesis of heart failure. In the first, pulmonary and systemic vascular congestion develops as a consequence of chronic volume overload superimposed on diminished diastolic compliance, caused by long-standing ventricular hypertrophy. In the second, chronic volume overload

and high cardiac output results in LV hypertrophy. The ventricular wall/cavity ratio decreases, and LV systolic dysfunction results. Echocardiography demonstrates LV hypertrophy in these patients, often in the absence of electrocardiographic evidence. Obesity leads to fatty infiltration of the cardiac conduction system, predisposing to sudden death, with a peak incidence occurring at 2:00 AM. Obesity is not a direct predictor of coronary artery disease. As an indirect predictor, obesity is linked to coronary artery disease via hyperlipidemia and systolic hypertension. Incidence of congestive heart failure and stroke are elevated.

Obese patients develop a particular pattern of ventricular remodeling. Centrally obese normotensives develop eccentric ventricular remodeling from chronic volume overload, increased diastolic pressure, increased diastolic wall stress, and chamber enlargement. This is in contrast to lean hypertensives, with concentric hypertrophy. The hypertensive obese may have both systolic and diastolic pressure overload and potentially earlier heart failure.

The term "syndrome Z" has been used to describe the association of components of the metabolic syndrome, including central obesity, type 2 diabetes with insulin resistance, hypertension, atherogenic dyslipidemia, increased sympathetic nerve activity, and OSA.

based cohort study of more than one million Swedish men. *Circulation*. 2008;118:1637–1642.

A.14. Are there any other disease entities commonly associated with obesity? What is their relationship?

Secondary obesity may be associated with hypothyroidism, Cushing disease, insulinoma, hypogonadism, and hypothalamic disorders. Although most obese patients are not diabetic, 80% to 90% of nonketotic diabetics are obese. Increased insulin secretion and insulin resistance resulting from peripheral tissue insensitivity are well-characterized features of obesity. Obesity exacerbates the diabetic state. Furthermore, malignancies of breast, prostate, cervix, uterus, colon, and rectum are more common in the obese.

In addition, there is a disproportionate increase in health-related risks from obesity. Above a BMI of 25, the risk of coronary artery disease more than doubles. Above a BMI of 29, there is an increased perioperative risk of pulmonary embolus. Above a BMI of 35, there is more than a 40-fold increase in adult-onset diabetes mellitus, respiratory disease, osteoarthritis, and OSAHS. Perioperative mortality during weight reduction surgery is statistically correlated with BMI, preoperative hypertension, anastomotic leak, and pulmonary embolus.

A.15. What anatomic changes that affect the airway are associated with MO and OSA?

Patient-specific anatomic changes in the MO are related to the

BMI, type of obesity (peripheral vs. central), and presence or absence of OSAHS. Not all MO patients have airway involvement. The anatomic changes affecting the airway are not always easily diagnosed on routine physical examination. At a given BMI, there is more airway involvement in central obesity compared with peripheral obesity, and the most severe airway involvement occurs in patients with OSAHS.

Anatomic alterations in the MO and OSA include the following:

- Deposit of adipose tissue in the lateral pharyngeal walls, and to a lesser extent in the uvula, the tonsillar pillars, the tongue, and the aryepiglottic folds, causing a decreased in the pharyngeal area
- Deposit of adipose tissue external to the upper airway (lateral parapharyngeal fat pads or jowls), extrinsically compressing the airway
- Presence of hypopharyngeal adipose tissue not evident on external examination that acts as a ball valve, obstructing the upper airway and interfering with the line-of-sight (LOS) at direct laryngoscopy (DL)
- Presence of pretracheal adipose tissue, which pushes the hyoid bone posteriorly into a less favorable position, causing the epiglottis to partially override the glottic entrance, worsening the laryngoscopic view
- Alteration in shape of the pharynx from an ellipse with the long axis lateral transverse to an ellipse with the long axis anterior-posterior
- Decreased efficiency of the anterior pharyngeal dilator muscles (tensor palatini [nasopharynx], genioglossus [oropharynx], hyoid muscles [laryngopharynx]), which promotes snoring
- The “lung volume hypothesis.” Decreased FRC in the asleep or anesthetized patient translates the tracheal carina cephalad

0.5 to 2 cm, relaxing the soft-walled hypopharynx and decreasing the internal volume. In severe cases, it may passively seal or telescope. Noninvasive positive pressure ventilation (NIPPV) tents open the hypopharynx, promoting gas exchange.

The anatomic changes that occur with MO are important for three reasons. First, these patients may obstruct their airway with light-to-moderate sedation (peripheral OSAHS). Various surgical procedures have been developed to improve this problem, such as the UPPP. Second, these patients may be difficult to mask ventilate, both because of external adipose tissue and internal collapse of redundant upper airway adipose. Third, there is a higher incidence of difficult intubation (DI) and failed intubation in the MO. When coupled with the precipitous desaturation, there is a need to revise the ASA DAA.

The literature is inconclusive on the relationship between obesity and difficult airways. According to some authorities, obesity is an independent risk factor for DI due to a disproportionately large tongue base or a short, thick neck. Other authors found that a higher BMI is not an indicator of DI but that increased neck circumference and poor Mallampati scores (classes 3 and 4) are. MO-OSAHS patients with other risk factors for DI (e.g., micrognathia) develop worsening of airway closure to an even greater degree than their counterparts.

A.16. What derangements of the gastrointestinal system are associated with MO?

There are several changes in the upper gastrointestinal tract that place severely obese individuals at risk of acid aspiration pneumonitis upon induction and emergence of general anesthesia: linear increase in intra-abdominal pressure with increasing body weight, increased incidence of GERD, decreased gastric pH, increased incidence of hiatal hernia, and impaired gastroesophageal antireflux mechanism, especially with foregut surgery. Ninety percent of fasting morbidly obese patients exceed Mendelson criteria, a gastric volume of greater than 0.35 mL per kg total body weight (TBW), with a pH less than 2.5. Severely obese patients have a normal gastric emptying rate with a larger pouch, so that after a controlled fasting (e.g., 2-day liquid diet for bariatric surgery), patients should have an empty stomach.

There is a substantially higher incidence of hepatobiliary disease in the morbidly obese, such as cholelithiasis, hepatitis, intra- and extrahepatic cholestasis, hepatic steatosis, and cirrhosis. Seventy-five percent of the morbidly obese have hepatic steatosis. Although there is a 25% incidence of severe hepatic dysfunction in the morbidly obese, there is no clear correlation between liver function tests (LFTs) and hepatic dysfunction, complicating medical and anesthetic management. There is a natural, step-wise progression from NAFLD, to NASH, to fibrosis and hepatocellular carcinoma. Typically,

NAFLD is stable and benign, with 1% to 2% risk of developing cirrhosis over 15 to 20 years. NASH is more progressive, with 3% to 15% progressing to cirrhosis over 10 to 20 years. Pancreatic disease is also more common in this population, specifically gallstone pancreatitis, adult-onset diabetes mellitus, and insulinoma. There is a higher incidence of colorectal malignancies in the morbidly obese. Long-standing central obesity in the presence of metabolic syndrome is associated with erosive esophagitis, Barrett esophagus, and esophageal adenocarcinoma. This is probably related to (1) dysfunctional gastroesophageal junction; (2) altered metabolism from visceral fat, with resulting lower levels of adiponectin and higher levels of IL-1β and TNF-α; and (3) the insulin-like growth factor (IGF) axis, particularly IGF-1 receptor (IGF-1R) gene polymorphism at G1013A.

B. Preoperative Evaluation and Preparation

B.1. How would this patient be optimized for surgery preoperatively? Would you use preoperative

screening questionnaires to diagnose OSA? Summarize the workup for this patient.

Key to a successful outcome in any high-risk surgery is a multidisciplinary approach, and bariatrics is no exception. After the initial visit, the patient was assigned an internal medicine physician, specializing in obesity medicine, with a plan to defer surgical intervention until medical optimization. Complete, comprehensive care, consisting of rehabilitation medicine, pharmacologic and nonpharmacologic interventions, behavior modification, and medically supervised diet, was accompanied by psychological evaluation to determine motivation and long-term perception of patient goals. This resulted, after roughly 1 year, in a functional improvement to 2 metabolic equivalents (METs) and weight loss to 204.12 kg, with a BMI of 61.0 kg per m^2, a roughly 25% decrease. Once the patient had been deemed optimized for surgery, and after at least 6 months, the preoperative workup is conducted and surgery was scheduled.

Preoperative evaluation includes a detailed history, review of systems, physical examination, and laboratory tests. Special attention is paid to circulatory, pulmonary, and hepatic functions. Circulatory evaluation includes signs and symptoms of left or right ventricular failure, history of hypertension, and electrocardiographic abnormalities. Respiratory evaluation includes smoking history, exercise tolerance, history of hypoventilation and somnolence, PFTs with spirometry and baseline arterial blood gases, and chest x-ray results. Hepatic function tests include serum albumin and globulin, serum aspartate aminotransferase, serum alanine aminotransferase, direct and total bilirubin, alkaline phosphatase, prothrombin time, and cholesterol levels.

A cardiology consultation was conducted, with a noninvasive assessment of cardiac function by echocardiogram. Patients

without an adequate echocardiographic window require radionucleotide ventriculography to assess ventricular function and morphology, as in this case. It is important to obtain a full assessment by the cardiologist to determine whether this patient is optimized and which invasive lines, if any, are appropriate. This patient was found to have mild right ventricular hypertrophy and mild pulmonary artery hypertension. Pertinent negatives were the absence of demonstrated coronary artery disease and left or right ventricular failure. In this case, it was determined that the patient was optimized, and that an arterial line would be helpful.

Physical examination focuses on the cardiovascular, pulmonary, and the upper airway. The upper airway assessment, in particular, should be thorough. In addition to the routine parameters, atlanto-occipital joint extension, modified Mallampati class (MMC), temporomandibular joint (TMJ) assessment with inter-incisor distance, mento-hyoid distance, and dentition, the following parameters should be checked: pretracheal adipose thickness, neck circumference, and hypertrophic tonsils and adenoids. Nonreassuring findings related to the latter three variables are a large neck, an abundance of anterior neck soft tissue, and obligate mouth breathing. Neck circumference is an independent predictor of DI; the odds ratio is 1.13 (The odds of a problematic intubation in a particular patient with a neck circumference 1 cm larger than that of another patient are 1.13 times the odds of the patient with a 1 cm smaller neck circumference.). At 40 cm (15.75 in.), there is a 5% chance of DI; at 60 cm (23.62 in.), this increases to 35%. Pretracheal adipose greater than 2.5 cm at the level of the vocal cords, determined by ultrasound is an independent predictor of DI. Obligate mouth breathing may be a clue that the patient has adenotonsillar hypertrophy, nasal septal blockage, or a craniofacial dysostosis. Factors that render mask ventilation

problematic, such as a heavy beard, should be noted.

Prior anesthetic records should be obtained. Patients with a history of heavy snoring should have a formal sleep study or PSG. Severity of OSAHS, AHI, home oxygen therapy with CPAP or BIPAP, response, and compliance should be noted.

The obesity surgery mortality risk score (OR-MRS) is a ratified tool consisting of BMI >50 kg per m^2, male gender, hypertension, pulmonary embolus risk (previous thrombus, inferior vena cava (IVC) filter, right-sided heart failure, OHS), and age >45 years old. The STOP-BANG questionnaire is a widely used ratified tool to screen patients for OSA. An acronym, it consists of response to the following questions:
Snoring: louder than talking, heard through closed doors
Tired: daytime hypersomnolence
Observed cessation of breathing during sleep
High Blood **P**ressure: with or without treatment
BMI: >35 kg per m^2
Neck circumference: >40 cm (15.75 in.)
Gender: male

Predictive value of the STOP-BANG questionnaire is as follows.
High risk of OSA: Yes, three or more out of eight items.
Low risk of OSA: Yes, less than three items.

The sensitivities of the STOP questionnaire with AHI greater than 5, greater than 15, and greater than 30 as cut-offs were 65.6%, 74.3%, and 79.5%, respectively. When incorporating BMI, age, neck circumference, and gender into the STOP questionnaire, sensitivities were increased to 83.6%, 92.9%, and 100% with the same AHI cut-offs.

In this case, of the STOP-BANG acronym, each letter is positive, except for age, so the score is *7*.

ASA has devised a ratified patient- and procedure-specific perioperative scoring system that measures OSA risk based on

points:

A. OSA severity based on clinical indicators (0 to 3)
B. Invasiveness of surgery and anesthesia (0 to 3)
C. Need for postoperative opioids (0 to 3)

Score is based on A + B versus A + C, whichever is greater. Expert consensus: Agree that patient is at increased perioperative risk of OSA complications if the score is >3. In this case, A. *3 − 1 = 2 (due to patient compliance)*, B. *2*, C. *0.* OSA risk: *4 (mild increase)*. Recommendation: *Continue CPAP/BIPAP*, no need for monitored bed. It is acceptable to be cautious and send a patient to a monitored bed, it just does not match the expert consensus.

American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. B.2. One of the recent developments in bariatric surgery is that many patients are receiving prebariatric screening procedures performed in the endoscopy suite. Describe the anesthetic considerations.

Sleeve gastrectomy has emerged over the last few years to be an

ideal bariatric procedure because it is simpler than the Roux-en-Y gastric bypass (RYGB), yet still highly effective. More than half of the annual bariatric surgical procedures performed in the United States in 2017 (228,000) are now sleeve gastrectomy (59.39%). Patients with severe, chronic GERD, however, may have worsening of symptoms after a sleeve gastrectomy. The RYGB is an alternate procedure that may improve symptoms of GERD.

Endoscopic prescreening for bariatric surgery is becoming more widely used, being used in roughly 50% of cases.

Upper endoscopy (esophagogastroduodenoscopy [EGD]) and Bravo (Bravo Reflux Testing System®; Medtronic, Minneapolis, MN) may help determine the appropriate surgical procedure, documenting lower esophageal pH and demonstrating signs of chronic severe GERD. The Bravo® pH testing system is usually placed via upper endoscopy: A capsule is imbedded into the mucosa of the lower esophagus, where it remains for 48 hours and then either falls out or is retrieved endoscopically. Continuous pH readings may be obtained via an external device using Bluetooth wireless technology.

Anesthesia for bariatric prescreening procedures is typically deep sedation via propofol bolus or infusion only. In all patients for upper endoscopy, the mortality rate is 0.03% and a serious morbidity rate is 0.54%, but it may be higher in the obese patient population.

The SuperNO_2VA® (Vyaire Medical, Mettawa, IL) nasal CPAP device facilitates spontaneous, assisted, or controlled ventilation for numerous indications. Among the possible oxygen sources (anesthesia circuit, wall supply, E-cylinder, flow-inflating resuscitator), the lightweight, highly complaint Mapleson F (Jackson Rees circuit) has been particularly successful. At Weill Cornell Medical Center, the SuperNO_2VA® has been used successfully in over 1,000

procedures as well as most bariatric screening procedures, for the provision of deep sedation in the Endoscopy Suite.

B.3. Summarize the evidence-based workup, risk, chance of various adverse outcome, and expected length of stay for this patient.

The American College of Surgeons National Surgery Quality Improvement Project (NSQIP) Surgical Risk Calculator provides the latest, nationally risk-adjusted database for tracking surgical outcomes and has an on-line risk calculator. The Calculator estimates adverse outcomes for a given surgical procedure and is based on their database. Our patient is having a *laparoscopic sleeve gastrectomy* (CPT code 43775, 2018/2019 ICD-10-CM Z.98.84) and has risk factors (*severe systemic disease, diabetes [oral], hypertension, class 3 obese*). A panel of expected outcomes is generated, which compares *case-specific risk* to average being risk and chance of outcome, as follows: serious complication *3.1%* (2.6%), *above average*; any complication *3.8%* (3.3%), *above average*; pneumonia *0.2%* (0.2%); cardiac complication *0.1%* (0.1%); surgical site infection *1.4%* (1.2%), *above average*; urinary tract infection *0.4%* (0.5%), *below average*; venous thromboembolism *0.5%* (0.4%), average; renal failure *0.4%* (0.2%), *average*;

readmission *3.8%* (3.2%), *above average*; return to OR *1.1%* (0.9%), *above average*; death *0.1%* (0.1%); discharge to nursing or rehabilitation facility *0.4%* (0.4%); and predicted length of hospital stay *2 days*.

B.4. What is the role of enhanced recovery after surgery (ERAS) in bariatric surgery? How does the public find a quality bariatric surgery team and surgical facility? What is the role of robotics in bariatric surgery?

ERAS is a multiprofessional and multidisciplinary approach to the care of the *surgical* patient. The multimodal approach to *recovery* was first outlined by a Danish surgeon, Henrik *Kehlet*, in 1995 for colorectal surgery.

ERAS quickly evolved from several perioperative elements into a cohesive multidisciplinary team approach and has been adopted into several surgical subspecialties, such as urology, obstetrics and gynecology, vascular surgery, orthopedics, spine surgery, cardiac surgery, and, most recently, bariatric surgery. Although originally used for laparoscopic procedures, ERAS has been used on open and robotic surgery. ERAS implementation has radically changed the surgical experience and results in net health care cost savings. Subsequently, this idea evolved into a multidisciplinary instrument integrating several perioperative elements which is now recognized as the ERAS protocol with a number of official ERAS Society Guidelines for Perioperative Care in Bariatric Surgery. ERAS for bariatric surgery has been

termed ENERGY, for *EN*hanc*E*d *R*ecovery *G*oals in Bariatric Surger*Y*.

In 2017, The American College of Surgery (ACS) launched a major surgical quality improvement initiative in collaboration with the Johns Hopkins Medicine Armstrong Institute for Patient Safety and Quality and the Agency for Healthcare Research and Quality (AHRQ). Separate programs of the ACS and the American Society for Metabolic and Bariatric Surgery (ASMBS) have since been combined into a single unified program to achieve one national accreditation standard for bariatric surgery centers, the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP). Participating medical centers are subjected to rigorous ongoing criteria, data registry, and reaccreditation surveys, and are high-quality. The ACS website, and their publication, *Bariatric Times*, provides timely information to the public.

Initial robotic bariatric surgery results are promising, for even the highest risk candidates. A recent review revealed that robotics led to a similar or lower complication rate compared with laparoscopic technique as well as shorter learning curve, lower leak rate, similar operative time, superior visualization, more degrees of freedom, and better ergonomics.

B.5. Would you premedicate the patient?

Current practice is not to give sedatives or hypnotics until these patients are on the OR table, as part of preparation for painful procedures (e.g., arterial line placement), or airway management (e.g., airway topicalization and cranial nerve blocks V, IX, and X). A well-conducted preoperative visit is more important than is sedation. This patient was not sedated before surgery.

Nonrespiratory depressant premedication may be used as part of multimodal analgesia in patients with MO; this has the potential to decrease preinduction anxiety, lower anesthetic requirements, and decrease immediate postoperative depressant effects of opioids in a high-risk population. A single loading dose of intravenous dexmedetomidine in the OR suite blunts the hemodynamic responses during laryngoscopy, reduces opioid and anesthetic requirements; it also decreases blood pressure and heart rate as well as the recovery time after the operation. Other pre- and perioperative medications that have been considered include acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) including ketorolac, lornoxicam, diclofenac, pregabalin, tramadol, ketamine, magnesium, and others. More research needs to be conducted in this area before a standard of care emerges; however, preemptive analgesia has not been

adopted as a standard in bariatric surgical population.

Other drugs that have been advocated as intravenous premedicants include the anticholinergic, drying agent glycopyrrolate, prokinetic, antiemetic metoclopramide, and H_2-blockers, such as famotidine. Aprepitant, a selective human substance P/neurokinin 1 receptor antagonist, has recently been advocated as prophylaxis of postoperative nausea and vomiting (PONV). PONV is often severe following bariatric surgery and requires polypharmacy, including oral preoperative medications, such as aprepitant. Nonsedative premedicants (e.g., glycopyrrolate, metoclopramide, famotidine) are rarely used because these patients are on a liquid diet for 2 days preoperatively.

At our institution, we follow the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) on all cases, unless contraindicated. Two hours prior to surgery, in the holding area, subcutaneous heparin 5,000 mg, and the ENERGY protocol medications: celecoxib 400 mg oral, acetaminophen 975 mg oral, gabapentin 300 mg oral, aprepitant 40 mg oral. Despite best practice, the incidence of PONV, the most common postoperative complication in bariatric surgery, is high.

B.6. Describe the mechanism of action of each premedication in the ENERGY protocol.

- The combination of a highly selective reversible inhibitor of the COX-2 isoform of cyclooxygenase, *celecoxib*, inhibits the transformation of arachidonic acid to prostaglandin precursors, exhibiting antipyretic, analgesic, and anti-inflammatory properties.
- *Acetaminophen*, a centrally acting cyclooxygenase inhibitor (COX-1 to 3), increases the pain threshold, decreasing opioid requirements.
- Gabapentinoid (*gabapentin* or pregabalin) is structurally related to the neurotransmitter GAB (gamma-aminobutyric acid), an anticonvulsant, works on the centrally located auxiliary subunit of the voltage-activated calcium channels, functioning as an anticonvulsant, treating neuropathic pain, and decreasing perioperative analgesic requirements.
- *Aprepitant* works as a selective human substance P/neurokinin 1 receptor antagonist and has been used as powerful antiemetic therapy to treat chemotherapy-induced nausea and vomit.

B.7. How would you adjust doses of anesthetics in the morbidly obese?

Anesthetizing MO patients requires careful consideration regarding changes in the pharmacokinetic and pharmacodynamic properties of numerous drugs used in anesthesia. Physiologic and anthropometric changes, such as increases in cardiac output, changes in regional blood flow, and increases in the body composition affect pharmacokinetic properties. In addition, respiratory pathophysiology such as the increased incidence of OSA and fat deposition in the oropharynx and chest wall alters pharmacodynamic properties of anesthetics.

Weight-based dosing scalars other than TBW must be considered when administering drugs to MO patients. Administration of drugs based on TBW can result in an overdose, whereas administration based on IBW can result in a subtherapeutic dose.

With the exceptions of succinylcholine (where TBW is appropriate) and the nondepolarizing neuromuscular blocking agents (where IBW is appropriate), LBW is the optimal dosing scalar for most anesthetic agents including opioids and anesthetic-induction agents, especially as cardiac output is significantly correlated to LBW, except in individuals with obesity cardiomyopathy (**Table 63.1**).

TABLE 63.1 Weight-Based Dosing Scalar Recommendation for Commonly Used Intravenous Anesthetics

Drug	Dosing Scalar	Comments
Thiopental	Induction: LBW Maintenance: TBW	Simulations showed a 60% decrease in peak plasma concentration in MO subjects compared with lean subjects after a 250 mg dose. Induction dose adjusted to LBW results in same peak plasma concentration as dose adjusted to CO. Volumes and clearances increase proportionally with TBW.

Propofol	Induction: LBW Maintenance: TBW	MO subjects given an induction dose based on LBW required similar amounts of propofol and similar times to loss of consciousness compared with lean subjects given propofol based on TBW. Volume of distribution and clearance at steady state increases with increasing TBW.
Fentanyl	LBW	Clearance increases linearly with 'PK mass', an arbitrary scalar highly correlated to LBW.
Remifentanil	LBW	An infusion based on LBW results in similar plasma concentrations as normal weight subjects were given an infusion based on TBW.
Succinylcholine	TBW	Administration of 1 mg kg^{-1} based on TBW resulted in a more profound block and better intubating conditions compared with doses based on IBW or LBW.
Vecuronium	IBW	Doses based on TBW result in a prolonged duration of action in obese *vs* non-obese subjects.
Rocuronium	IBW	There is an increased duration of action when the drug is given based on TBW *vs* IBW.
Atracurium, Cisatracurium	IBW	The duration of action is prolonged in obese subjects when given on the basis of TBW *vs* IBW.

CO, cardiac output; IBW, ideal body weight; LBW, lean body weight; MO, morbid obesity; PK, pharmacokinetic; TBW, total body weight.

Volatile anesthetics are sequestered in adipose tissue based on lipid solubility. Desflurane has faster washout and recovery than sevoflurane; sevoflurane is useful for short-duration titration of anesthetic depth and in selected patients (e.g., smokers, asthma).

C. Intraoperative Management

C.1. How would you monitor this patient?

In addition to the routine ASA-mandated monitors of ECG, noninvasive blood pressure, pulse oximetry, end-tidal CO_2, and temperature, an arterial line may be inserted for frequent assessment of blood gases for continuous blood pressure tracing in the patient with cardiac disease (as in our patient). An esophageal stethoscope with thermistor is placed in the tympanic membrane, or in the axilla, to monitor temperature because any device placed in the esophagus may be inadvertently included in the surgical anastomosis. Urinary drainage catheters are not typically placed. A peripheral nerve stimulator is used to monitor the effects of muscle relaxants. A processed EEG, such as the bispectral index or BIS® (Medtronic, Minneapolis, MN), was used to monitor depth of anesthesia. BIS monitoring has been shown to be useful in laparoscopic bariatric surgery, both because blood pressure and heart rate are inadequate surrogate proxies of anesthetic depth, due to patients positioned in the standing position with frequent sympathomimetic support (in this case, phenylephrine infusion), and because total intravenous anesthesia (TIVA) is frequently used. Obese patients are at higher risk of perioperative awareness under general anesthesia. Intraoperative spirometry and the use of flow–volume loops (GE Datex S/5 [System 5] series monitor [GE Datex Ohmeda, Helsinki, Finland]) are highly useful and will alert the anesthesiologist to change in surgical conditions and patient status. Automatic peripheral nerve stimulator (IntelliVue® NMT; Phillips, Amsterdam, The Netherlands) simplifies data acquisition and charting on the electronic medical record (EMR, CompuRecord®; Philips, Amsterdam, The Netherlands).

The advantages of invasive monitoring have to be weighed against the possible complications. Laparoscopic bariatric

surgeries have minimal blood loss (typically less than 100 to 200 mL) and fluid shifts. These are elective cases, and patients are optimized preoperatively. Invasive arterial monitoring is used for the super obese with severe cardiopulmonary disease or poor fit of the noninvasive blood pressure cuff because of the conical shape of the upper arms or unavailability of appropriately sized cuffs. Accurate blood pressure readings may be obtained from the wrist or the ankle. Central venous access is typically used when there are difficulties obtaining peripheral access. A pulmonary artery catheter is reserved for the rare patient with severe pulmonary hypertension, cor pulmonale, or LV failure.

C.2. The American Society of Anesthesiologists' (ASA) Difficult Airway Algorithm (DAA) provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?

The ASA DAA provides a guideline for management of the

difficult airway. It was created by a panel of experts under the direction of the ASA in 1993 and modified in both 2003 (to include the laryngeal mask airway [LMA]) and 2013 (to include the supraglottic airway [SGA] and videolaryngoscopes). Implementation of the algorithm will be altered in different patient populations, according to factors such as location, patient demographics, comorbidities, surgical requirements, equipment availability, presence of additional personnel, and, probably most importantly, the skill set of the anesthesiologist.

In the bariatric surgical population, with demonstrated or suspected OSA, considerations include bariatric surgical patients are considered "empty stomach" in most cases; they are generally vulnerable to precipitous apneic deoxygenation; the standard airway assessment may not be sufficient, there is a higher incidence of difficult mask ventilation and DI, and redundant adipose tissue may obstruct the line of sight on laryngoscopy. Each of these points deserves clarification.

First, bariatric surgical candidates typically receive an upper endoscopy. We therefore know whether they have conditions associated with the need for aspiration prophylaxis, such as GERD, hiatal hernia, a gastric hypersecretory state, or achalasia. Obesity produces a moderate increase in gastric accommodation and an increase in emptying rate. Foregut surgical patients are placed on a liquid diet for 2 days and should have an empty stomach. As part of the ERAS protocol for bariatrics, or ENERGY, patients receive an energy drink prior to midnight on the day prior to surgery and upon awakening. Studies have shown that gastric fluid volume and pH are unchanged after drinking a nonparticulate drink 2 hours prior to surgery.

Second, severely obese patients are at higher risk of early arterial apneic desaturation during induction of anesthesia. This is due to several factors, including derangement of pulmonary mechanics (decreased ERV and FRC) by cephalad displacement

of the diaphragm, increased incidence of atelectasis, airway modifications, and increased frequency of hypotensive events. This is discussed further in section C.3.

Third, the standard airway assessment may not be sufficient. Physical findings suggestive of peripheral OSA (such as pretracheal adipose thickness, neck circumference, and hypertrophic tonsils and adenoids) should be sought out. Craniofacial dysostoses (e.g., relative micrognathia) may be hidden behind facial adipose or hair. This is discussed further in section B.1. In consequence, there is a higher incidence of both difficult mask ventilation and unanticipated difficult airway. The latest guidance is from the Difficult Airway Society 2015 guidelines for management of unanticipated DI in adults. Videolaryngoscopes and alternative airway devices, including fiberoptic bronchoscopes (FOB), have been shown to improve laryngeal view during intubation. It is important, in this patient population, to have options when the primary airway management technique fails.

Fourth, and last, the importance of additional personnel needs to be stressed. The attending surgeon needs to be present at induction of anesthesia, and an unopened tracheostomy set should be available. When indicated, an additional anesthesia attending may be helpful. With the evolution of videolaryngoscopic devices, and our collective extensive experience, use of the FOB and awake techniques for securing the airway have become a rarity. The FOB remains an important part of our arsenal, however, and should be available as part of a backup plan.

C.3. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques. What is the importance of continuous positive airway pressure (CPAP) during the induction of general anesthesia? Describe use of the nasal CPAP mask in the induction of general anesthesia.

In this patient population, preoxygenation (pre-O_2) is essential due to precipitous apneic deoxygenation on induction of anesthesia. Pre-O_2 is optimized by semirecumbent position and a tight-fitting face mask. In the past, two techniques of pre-O_2 have been used: full, or "slow" (V_T breathing for 3 minutes), and "fast" (four-maximum-breath over 30 seconds). "Slow" pre-O_2 produces higher oxygen tension; the "fast" is to be discarded. When time is of the essence, however, a modified "fast" pre-O_2 technique (eight-maximum-breath over 60 seconds) compares

favorably with the "slow" pre-O_2, both in terms of fraction of expired oxygen (FEO_2) and duration of apnea without desaturation in seconds (DAWD). The vast majority of the oxygen reserve is in the FRC. The amount of time for onset of hypoxia (SpO_2 of 90%) has been calculated for a healthy nonobese adult when breathing room air and when breathing 100% oxygen both at onset of apnea. The subject could sustain a period of apnea of 0.9 minutes versus 9 minutes. The vast majority of the oxygen reserve is in the FRC, and the first 8.1 minutes are spent consuming the FRC reserve. For the MO patient, time to hypoxia will be significantly shorter.

Continuous positive pressure ventilation (CPAP) increases FRC and further raises the oxygen reserve, compared with nasal oxygen. This occurs both during sedation and induction of general anesthesia. CPAP works by tenting open the hypopharynx and increasing the FRC, both particularly important in the MO patient population. Recent meta-analysis of perioperative noninvasive ventilation in obese patients suggest that CPAP is well tolerated and effective before induction of general anesthesia and after extubation in improving CO_2 clearance and decreasing the risk of respiratory complications.

Recently, the SuperNO_2VA® (Vyaire Medical, Mettawa, IL), a modified nasal CPAP mask, has been favorably trialed during the induction of general anesthesia. Nasal positive pressure ventilation is conducted via the anesthesia ventilator during the induction sequence without steric hindrance, due to the low-profile mask, and patients may be effectively ventilated while being intubated, as was our patient. This may be helpful in the event of an unexpected difficult airway. This device requires further study but has the potential to be incorporated into the guidelines of the Difficult Airway Society for the unexpected difficult airway.

C.4. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?

In the 2013 iteration of the DAA, the SGA was introduced, in place of the LMA (Teleflex, Limerick, PA), to reflect further developments in the marketplace. Inclusion of the SGA into the algorithm emphasized that being able to ventilate through a temporary airway (1) returns the patient to the elective branch of the algorithm because they are being ventilated and oxygenated, (2) may often be all that is required for patient management, and (3) provides a bridge for insertion of a definitive airway. As used in the algorithm, “SGA” should not be interpreted as endorsement of any particular manufacturer or product. In addition, since publication of the first two DAAs, many new and diversified SGAs have been developed. Other types of airway devices have been developed as well. At the present time, there are no large prospective, randomized studies comparing the newer devices on the MO or OSA subject, and the choice of device on a given patient may be driven by the clinician. The

skill set of the clinician still appears to be the most relevant factor until the literature provides more guidance.

Several noteworthy advances in airway management devices have occurred. The first is the advent of affordable, high-quality video laryngoscopes (VL), mentioned in the 2013 DAA. Particularly promising of these for the MO/OSA patient appears to be the McGrath® MAC VL (Ambu, Ballerup, Denmark) and the C-MAC® (Karl Storz Endoskope, Tuttlingen, Germany). The McGrath® is totally portable, unchanneled, low profile (e.g., TMJ dysfunction), and both a DL, in which the operator looks in the mouth, or indirect laryngoscopy (IDL), in which the operator looks on the screen. It may therefore be referred to as a DL/IDL device. Complementary metal oxide semiconductor (CMOS) technology, similar to a cell phone camera, ensures high-quality optical resolution. Originally intended as a routine DL replacement, it may well be the first airway device capable of replacing DL. The C-MAC® (Karl Storz Endoskope, Tuttlingen, Germany) is also an unchanneled, DL/VL, CMOS device. Attached to a semiportable electronic module, and possessing the highest quality optical resolution, it is a true difficult airway device and may also be connected to a fiberoptic scope. Single-use or reusable blades come in different sizes; most MO/OSA patients may be intubated with either the no. 3 or the D (Doerges) blades. The D-blade is particularly suited to patients with increased neck circumference, who are prone to lateral pharyngeal collapse. The electronic module comes either mounted on an intravenous pole, freestanding, or totally portable (the C-MAC Pocket Monitor®). Digital photographs or video clips of a C-MAC® intubation may be taken by the laryngoscopist without advance preparation and uploaded to a memory card. The C-MAC® electronic module may be used for flexible, fiberoptic, and rigid (Storz Bonfils®; Karl Storz SE & Co. KG, Tuttlingen, Germany) or articulating (Videostylet®;

Karl Storz SE & Co. KG, Tuttlingen, Germany) scopes; in addition, a C-HUB adaptor serves as a CMOS-digital convertor for either a fiberoptic intubating tower or the surgeon's operative tower. Other unchanneled VL devices which have been used for the MO/OSA patient population include the GlideScope® Videolaryngoscope (GVL) suite of products. Most of the GVL products are IDL devices. Although glottic visualization is frequently successful with the GVL, intubation may be problematic, and right palatopharyngeal arch perforation has been reported secondary to blind insertion of the tracheal tube from the back of the pharynx to resurfacing within the camera's visual field at the laryngeal inlet. This complication is more likely to occur when lateral pharyngeal wall crowding occurs, as in MO with jowls, or severe OSA.

The second advance in airway management is the development of a new class of airway devices: the channeled, disposable optical laryngoscope. The Airtraq® (AT) (Prodol Systems, Viscaya, Spain) and the King Vision® (KV) (Ambu, Ballerup, Denmark) are in this category. These devices have been very successful in the MO/OSA patient. Advantages include portability, being able to intubate in unusual positions (such as semi-Fowler position or "face-to-face"), or with limited access. There is a high retention success rate for the novice or infrequent practitioner, and being an excellent conduit for FOB. Intubating is accomplished in a neutral neck position with little mouth opening, so TMJ limitation and cervical spinal pathology are indications. The KV has technical advantages over the AT. Both the KV and the AT are channeled devices, although they have different operating profiles. The advantages of KV include totally portable organic light-emitting diode (OLED) display (similar to the GVL), needing no special charger (three AAA batteries provide 1 hour of light), improved channel with J-curve sliding off tracheal tube easily, guiding channel with loaded

tracheal tube serving as an ideal fiberoptic ramp, absence of distal “tooth” at end of channel facilitating removal of tracheal tube, distal light and optical inlet with “fish-eye” lens with antifog lens, and wide angle of aperture. However, patients with a short jaw or TMJ dysfunction will benefit from the more compact profile of the original AT, an optical scope similar to a flashlight with two mirrors.

The third advance in airway management is the development of better airway “bridges” and short-term ventilatory support devices. The LMA Fastrach® (LMA-FT), or intubating LMA® and the LMA EVO® (Teleflex Medical, Research Triangle Park, NC; LMA, North America, San Diego, CA), provides a method of oxygenating and ventilating while obtaining a definitive airway. The I-Gel® (Intersurgical Complete Respiratory Systems, Berkshire, United Kingdom) provides an uncuffed perilaryngeal airway with a gastric decompression lumen. The LMA Supreme® (Teleflex Medical, Research Triangle Park, NC; LMA, North America, San Diego, CA) is an SGA salvage device with a gastric decompression port that incorporates features of the LMA Unique®, ProSeal®, and LMA-FT. In practice, these “bridges” are not utilized as often as they were before because the aforementioned devices (VL, channeled airway devices) rarely fail. Other than routine indications, they are useful for either airway salvage or as conduits for fiberoptic intubation. An airway salvage that has had success out-of-hospital by first responders and military medics, particularly in the event of gastrointestinal bleeding or for the difficult to manage airway (e.g., OSA), is the King Laryngo-Tracheal-Suction-Disposable® (King LTS-D®) (Ambu, Ballerup, Denmark).

The final advance in airway management is the development of high-quality, single-use metal laryngoscope blades, which appear to have superior success rates compared with their

reusable counterparts (both in terms of blade and handles and plastic) when used during the induction of anesthesia, due to a predictable degree of brightness.

For the MO/OSA patient with a challenging airway, FOB remains the gold standard. FOB has substantial limitations, however, such as limited availability, a long learning curve, a low retention rate, equipment fragility, longer setup time, longer intubation time, and few absolute indications (mostly lower airway pathology). As the advanced airway management devices improve, and clinician experience grows, the need for FOB should continue to decline.

C.5. How would you induce anesthesia? Describe the intubation technique.

The OR should be set up with appropriate alternative noninvasive and invasive airway devices.

On arrival in the OR, the patient is positioned on the OR table in a ramp position (Troop Elevation Pillow®; Sharn Anesthesia Inc, Tampa, FL), placed on monitors, and administered an F_{IO_2} of 100% nasal CPAP with the SuperNO_2VA® (Vyaire Medical, Mettawa, IL) for 3 to 5 minutes at a fresh gas flow (FGF) rate of 15 L per minute, in both the mask and the auxiliary oxygen port,

attached to the anesthesia circuit. General anesthesia is gradually induced with propofol 2 mg per kg TBW, after setting the anesthesia ventilator to pressure control, and assuring the ability to positive pressure ventilate. At this point in the induction, intraoperative spirometry (e.g., flow–volume loop) is helpful; look for an open loop without signs of obstruction or restriction. Failure to obtain a capnogram usually indicates upper airway obstruction requiring jaw thrust or an oral airway. The goal is to have an expired V_T of 3 to 5 mL per kg LBW while maximizing FRC and arterial oxygen and pulmonary oxygen reserve in preparation for induction of general anesthesia. Once it has been ascertained that mask ventilation is feasible, nondepolarizing neuromuscular blockade is induced.

This patient was considered to be a moderately DI and, possibly, difficult mask ventilation. A videolaryngoscope such as channeled King Vision Laryngoscope® (KVL_C) (Ambu, Ballerup, Denmark) was used for intubation. A C-MAC® (Karl Storz Endoskope, Tuttlingen, Germany) electronic module coupled with the Doerges®, or D-blade, and FOB was available as a backup. If needed, the FOB could either be used to "peer and steer" the channeled tracheal tube or, more rarely, to cannulate the upper trachea and advance the tracheal tube in a Seldinger maneuver over the KVL_C blade.

If the physical examination and past anesthetic record demonstrated easy orotracheal intubation or the patient was at high risk of aspiration, a rapid sequence intubation could be contemplated using propofol (2 mg per kg TBW) with succinylcholine (1 to 1.5 mg per kg TBW), with the patient positioned on a ramp. This was not the case with our patient.

perioperative airway management. *Anesthesiology*. 2009;110:908–921.

C.6. How would you maintain general anesthesia? What agents would you choose? How would you prepare for emergence?

The ideal maintenance anesthetic for morbidly obese patients undergoing laparoscopic surgical procedures is a matter of some discussion; there is support in the literature for a technique comprising insoluble anesthetic gases resistant to metabolic degradation and without lipid depot compartmentalization, combined with rapid return of airway reflexes, plus intravenous agents that are either hydrophilic, spontaneously degrade in vivo, or are ultrashort-acting. For the maintenance phase of general anesthesia, both inhalation and total intravenous techniques have been used successfully.

Of the potent inhalation agents, desflurane has several advantages; it is insoluble, has a faster wake-up, a faster return of airway reflexes, and a decreased amount of hepatic metabolism. Obesity increases the biotransformation of the inhalation anesthetics, resulting in increased serum toxic products of metabolism. Because of the frequent presence of coexisting liver dysfunction in the morbidly obese (75% have hepatic steatosis and 25% have severe hepatic dysfunction) and the absence of a clear correlation between LFTs and hepatic dysfunction, it would seem logical to use the agent with the lowest percentage of hepatometabolism, desflurane (0.02%), compared with isoflurane (0.2%) and sevoflurane (2% to 3%). An agent with a low blood–gas solubility coefficient also appears better because there will be a smaller body reservoir available for metabolism, and a faster time to steady state at the target organ, the brain. Of the inhaled agents, desflurane has the fastest wake-up, followed by sevoflurane and then by isoflurane. Desflurane also has the fastest return of airway reflexes,

followed by sevoflurane. All of the inhalational anesthetics will accumulate in the lipid compartment, creating a two-compartment model and lengthening the emergence. All of the inhalation agents, however, have been used successfully.

N_2O, a weak inhalation anesthetic, has a low blood–gas solubility coefficient (0.46) but is not recommended for maintenance use because it causes intestinal inflation; is emetogenic; and is contraindicated in the presence of severe pulmonary hypertension, a condition more common in the MO. Short duration use of N_2O, particularly during the surgical closure, facilitates offset of relatively lipid-soluble agents.

Of the intravenous anesthetics, remifentanil is an attractive choice because of its rapid onset, consistent profile, and rapid offset. Although it is lipophilic, it has a half-life of 5 minutes and therefore does not compartmentalize in the lipid compartment. The dose of remifentanil is therefore calculated by using LBW. It is dosed by infusion, in the range of 0.05 to 0.2 μg/kg/min LBW. The lipophilic opioids, fentanyl and sufentanil, that are dosed by LBW and may cause delayed respiratory depression in the high-risk patient, especially OSAHS, are less than ideal in larger doses. They may, however, be used in reasonable doses (fentanyl up to 5 μg per kg LBW). Dexmedetomidine, a centrally acting α_2-agonist, has also been used successfully in these cases. It decreases anesthetic and opioid requirements and may continue through the emergence phase and extubation because it only marginally raises the CO_2 apneic threshold.

For our patient, an inhalation technique was chosen with desflurane, and once a deep level had been reached (minimum alveolar concentration [MAC] of 1.2), low flow (FGF of 0.65 L per minute) was established. For this patient, we assessed anesthetic depth by end-tidal desflurane concentration,

hemodynamics, and a processed EEG (BIS®, Medtronic, Minneapolis, MN). Blood pressure was supported and maintained at the patient's baseline range with a phenylephrine infusion because operative position is steep reverse Trendelenburg. Roughly an hour from the end of the procedure, desflurane was discontinued, hydromorphone is administered, FGF is increased, and switched to oxygen/N_2O at 50%, and the BIS is maintained at acceptable levels (under 50) with small boluses of propofol for the remainder of the case. The ventilator was switched to a patient-assisted modality.

Recently, ENERGY, or ERAS for bariatric surgery (see section B.4), has changed both the surgical and anesthetic experience. More than half of the cases are sleeve gastrectomies (57% of 233,000 in 2017), a simpler surgical procedure with no anastomoses lasting about 2 to 3 hours. In consequence, anesthetic requirements are decreased, particularly for opioids. This patient received fentanyl 200 mcg, with a pain score of 0/10 on arrival in the PACU. TAP blocks decrease postoperative analgesic requirements, negating the need for postoperative opioid infusions (e.g., IV-PCA). Lighter anesthetics, consisting of less opioid, desflurane, and muscle relaxants, translate into less PONV and less opioid-induced nausea and vomiting (OINV) as well as a more awake patient who is less likely to require a NIPPV modality.

C.7. Which muscle relaxants would you use?

For intubation, a nondepolarizing muscle relaxant (NDMR) would be used. Patients presenting for bariatric surgery are generally on a liquid diet for a couple of days. The rate of gastric emptying is identical to that of the nonobese subjects, although MO patients have a larger gastric pouch. Cisatracurium has a predictable dose-response curve and no prolongation of recovery due to organ-independent recovery, or Hoffman elimination; dosage is by IBW. Cisatracurium is, however, relatively expensive. For this reason, rocuronium and vecuronium are more commonly used; both are dosed by IBW.

For the occasional subject requiring rapid sequence induction, succinylcholine or rocuronium are acceptable choices. Succinylcholine is dosed by TBW because the plasma cholinesterase activity increases in proportion to the BMI. When an awake technique is chosen for securing the airway, an NDMR may be administered, once tracheal intubation has been confirmed.

Dense muscle relaxation is required for laparoscopic bariatric surgical procedures to facilitate ventilation, to maintain adequate intraperitoneal space for visualization and manipulation of the surgical instruments, and to permit the introduction of surgical instruments and the removal of excised tissues.

Intraoperative contracture of the abdominal musculature, due to inadequate muscle relaxants, may increase intra-abdominal pressure during PNP, driving CO_2 out from the inflated abdominal cavity through the trocar sites. Adequacy of neuromuscular blockade is assessed by the anesthesiologist, by

following both peripheral nerve stimulation data and the inflation pressures necessary for excellent surgical conditions.

A peripheral nerve stimulator should be used to monitor the extent of relaxation and to avoid underdosing or overdosing. Extubation should only occur after documentation of full baseline train-of-four (T_4/T_1 >0.9) and return of extubation criteria. Reversal agents should be given in appropriate doses. Sugammadex, a modified γ-cyclodextrin, which was developed to reverse muscle relaxation by amino-steroid NDMRs, has had a huge impact on bariatric surgery, allowing dense anterior abdominal wall muscle relaxation until the end of surgery. It is dosed by TBW.

C.8. Is postoperative pain severe after bariatric surgery? What are the pain generators? What is the role of regional anesthesia to decrease opioid requirements for bariatric surgery? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?

Today, the majority of bariatric surgical procedures are performed laparoscopically. Postoperative pain is not usually severe and is of short duration, typically a few days.

Laparoscopic bariatric surgical procedures cause pain due to surgical portholes (somatic pain), from PNP (carbonic acid deposited on the parietal peritoneum) and from mild tugging on

the gastroesophageal junction (referred visceral pain). Porthole pain may be treated by intravenous opioids, infiltration of local anesthetics, and regional anesthesia. The other pain generators, described as a colitis-like cramping and a retrosternal "sticking" sensation, are milder and respond to intravenous NSAIDs.

Several regional anesthetic techniques may be used in bariatric surgery to decrease opioid requirements. Neuraxial techniques, used in the past, include thoracic epidurals for patient-controlled epidural analgesia (PCEA), the best studied of these, as well as continuous spinal anesthesia and analgesia (CSAA), and intrathecal opioids. Although they have a good side effect profile and reduce general anesthetic requirements, their use has been restricted to the rare open procedure. Until recently, IV-PCA was the standard of care. With the overwhelming majority of bariatric surgery being performed laparoscopically, analgesic postoperative analgesic requirements are decreased, and the emphasis is on getting patients out of bed, shortening hospital stay, and returning to baseline functional status. In consequence, neuraxial analgesic techniques are not currently used.

Techniques adopted from multimodal perioperative analgesia (MMPA) use nonopioid receptors (e.g., *N*-methyl-D-aspartate receptor antagonists [NMDA]) instead of, and synergistically with, the standard anesthetic pharmacopoeia. Nonopioid analgesia (NOA) has been used with varying agents such as dexmedetomidine, NSAIDs (e.g., ketorolac,) clonidine, lidocaine, ketamine infusion, and magnesium sulfate infusion in an attempt to decrease side effect profile and speed recovery.

The introduction of ENERGY (see section B.4) has changed the analgesic regimen for bariatric surgery. In the ENERGY protocol: *premedication* consists of a "cocktail" of oral nonopioid analgesics (e.g., COX-2 inhibitor, COX-3 inhibitor, gabapentinoid, an anticonvulsant, and a substance P/neurokinin

1 receptor antagonist); *intraoperative analgesics* consist of judicious opioids, with either infusions of intravenous lidocaine or the TAP block. In this technique, local anesthetics are deposited between the internal oblique and transversus abdominis muscles, blocking the anterior rami of spinal nerves T7–L1, which innervate the anterolateral abdominal wall. The TAP block has been hugely successful and has replaced other regional techniques. It is performed bilaterally with ultrasound guidance percutaneously by anesthesiologists and at the end of surgery with laparoscopic, or robotic, guidance by surgeons. Both techniques have been used successfully. Whether the TAP block is superior to surgical porthole infiltration is controversial. Our patient received surgical porthole infiltration. *Postoperative analgesics*, for both the PACU and the floor consist of oral acetaminophen (650-mg or a 975-mg tablet), an oxycodone (5-mg or 10-mg immediate release tablet), with dose-dose parenteral opioids (hydromorphone 0.2 mg) for breakthrough pain.

C.9. What is the pathophysiology of pneumoperitoneum (PNP)? What is the effect on the cardiopulmonary

system? How does it change perioperative care? What are the optimal ventilator strategies for morbidly obese patients undergoing bariatric surgery?

Currently, the vast majority of bariatric surgical procedures are performed laparoscopically and now robotically. Benefits of laparoscopy include much smaller surgical incisions, decreased postoperative pain requirements, shorter hospital stay, and faster recovery time to baseline level of activity. CO_2 is the universally accepted gas choice for abdominal insufflation during laparoscopy. CO_2 has documented advantages, including short half-life, due to high tissue diffusion across all tissue beds and less flammability and morbidity, compared with other agents trialed (oxygen, N_2O).

PNP with CO_2, however, alters physiology and complicates intraoperative anesthetic management. Altered physiology due to PNP is both primary (due to CO_2 absorption) and secondary (due to increased intra-abdominal pressure). Primary physiologic changes arise from acidification of tissues from CO_2 absorption (approximately 30 to 42 mL per minute), which increases ventilator requirements (approximately 30%).

Cerebral effects arise from changes in cerebral vasoregulation due to hypercarbia: increased intracranial pressure from increased intrathoracic pressure and cerebral vasodilation, decreased cerebral oxygen saturation, and initiation of a hormonal cascade, with catecholamine and vasopressin release.

Cardiovascular effects arise from CO_2, which mildly depresses myocardial contractility and sensitizes myocardium to the arrhythmogenic effects of catecholamines. Most of the pathophysiologic changes occur as a result of increased intra-abdominal pressure, which decreases venous return, decreasing

cardiac output and blood pressure. Other *cardiac effects* are those typical of increased sympathetic output from hypercarbia, although bradycardia may result from initial peritoneal insufflation.

Pulmonary effects are due to cephalad shift of the diaphragm, decreased FRC, increased physiologic dead space, greater ventilation/perfusion mismatch, decreased pulmonary compliance, and increased airway pressures especially peak airway pressure.

Renal effects are due to decreased renal perfusion; decreased urine output; and increased release of antidiuretic hormone, plasma renin, and aldosterone levels.

Hepatic effects are due to decreased portal venous flow, which may lead to hepatic hypoperfusion, acute hepatocellular injury, and increased transaminase levels. Increased intra-abdominal pressure causes decreased venous drainage of the abdominal viscera and the lower extremities, which may result in deep venous thrombosis.

Most of the intraoperative changes caused by PNP are well tolerated, provided that the insufflation pressure is maintained at the lowest acceptable level, approximately an intra-abdominal pressure of less than 20 mmHg, an intraoperative recruitment maneuver is provided when indicated, and the following precautions are taken: loading of intravenous fluids (typically 500 to 1,000 mL), use of sequential compression devices, optimal ventilator settings as described in the following text, and intraoperative spirometry to monitor flow– and pressure–volume loops, and plateau airway pressure. In comparison with volume control ventilation, pressure control ventilation appears to improve oxygenation, produce lower airway pressures, greater dynamic compliance, and better preserve ventilation/perfusion matching.

- *Management of ventilation in MO patients*

- CPAP during induction
- F_{IO_2} <0.8
- Recruitment maneuver after induction, then periodically
- Pressure control-volume guarantee (PC-VG)
- V_T = 6 to 10 mL per kg IBW
- PEEP 10 to 12 cm H_2O
- Inspiration : expiration (I:E) = 1:1 longer inspiratory time to minimize atelectasis and improve gas exchange
- Inspiratory pressure <30 cm H_2O
- CPAP or BIPAP after extubation, if used preoperative, or deemed high-risk (as our patient)

C.10. What are the devices that anesthesiologists place in the upper gastrointestinal canal during laparoscopic bariatric surgery? Are there risks associated with placement and management of these devices?

Various devices have been placed in the upper gastrointestinal canal during laparoscopic bariatric surgery. All of these devices are single use and are placed orally by the anesthesiologist. The surgeon laparoscopically visualizes transit of the device through the gastrointestinal tract by gut distension and may help guide passage. *Orogastric tubes* are used both to decompress the stomach at the beginning of surgery and for “a leak test” after

completion of the anastomosis, in which a vital dye, such as methylene blue, is injected, the stomach is inflated, and lack of "leak" documented. The amount of vital dye is documented and serves as a rough estimate of neogastric pouch size. Both *bougies* or *calibration tubes* serve as templates to delineate the feeding channel, identify landmarks for the anastomosis, and choose the staple line. Bougies come as either *graduated-tip*, which are easier to insert, or *blunt-tip*. Gastroesophageal *anvils*, OrVil® (Medtronic, Minneapolis, MN), are used to create the gastrojejunostomy anastomosis in RYGB.

The ViSiGi 3D® (Boehringer, Ingelheim, Germany) can perform all of these functions and is becoming the preferred device for the laparoscopic sleeve gastrectomy. Both the anesthesiologist who places these devices and the surgeon are responsible for monitoring proper function and lack of trauma at removal. When the anesthesiologist is unable to place the indicated device, there are three options: The surgeon may try, gastroscopy may be attempted, or surgery may be converted to an open procedure.

Some of the pooled specific procedural risks with these devices are as follows: improper disinfection, incidence 1 per 100,000 cases; accidental stapling of tubes, incidence 1 per 132 cases; esophageal perforation, incidence 1 per 810 cases. Single-use devices can eliminate the first of these. The OrVil® is composed of a curved metal section joined to a modified orogastric tube; as a fairly sharp device, it is easy to understand how it may traumatize the esophagus.

Clearly, placement of these devices is a crucial portion of the anesthetic and surgical risk. Regardless of which device is chosen, the attending anesthesiologist should be present at the time of placement and document his or her findings. Orogastric tubes and esophageal temperature probes are strictly prohibited for patient monitoring during bariatric surgery; they may be

stapled and left as foreign bodies, resulting in major morbidity or death.

C.11. When will you extubate this patient? Describe weight-based extubation criteria.

Bariatric surgery and anesthesia experience has evolved to the point where postoperative ventilatory support is rarely necessary, due to changing surgical technique (higher percentage of sleeve gastrectomies), with a simpler, shorter surgical time, and to the advent of ENERGY (see section B.4). Patients treated preoperatively with NIPPV should be returned to their therapy. Patients with an unfavorable OSA questionnaire response, STOP-BANG score of 4 or more (see section B.1) should be given consideration to NIPPV therapy. Our patient received BIPAP +12/5 cm H_2O at 40% oxygen via a full-face mask.

The vast majority of patients, however, are extubated in the OR at the conclusion of surgery as soon as the following extubation criteria are met:

- Intact neurologic status, fully awake and alert, with head lift >5 seconds
- Hemodynamic stability
- Normothermia, above 36°C
- Full reversal of neuromuscular blocking agents confirmed

with train-of-four (T_4/T_1 >0.9)

- Respiratory rate (breaths per minute) >10 and <30
- Baseline peripheral oxygenation, as judged by pulse oximeter (Spo_2 >95% on Fio_2 of 0.4)
- Acceptable blood–gas results, if available (Fio_2 of 0.4; pH, 7.35 to 7.45; Pao_2, >80 mmHg; $Paco_2$, <50 mmHg)
- Acceptable respiratory mechanics: negative inspiratory force (NIF) >25 to 30 cm H_2O; VC >10 mL per kg IBW; V_T >5 mL per kg IBW
- Acceptable pain control
- No demonstrated or suspected laboratory abnormalities

Patients with OSAHS, OHS, and PS have higher incidence of postoperative respiratory dysfunction. They require special attention during tracheal extubation, and occasionally, warrant a monitored bed for observation.

Extubation criteria should be used systematically in obese patients; in all cases, an attending anesthesiologist with advanced airway skills must be in attendance, in case tracheal reintubation becomes necessary, and the surgeon must be immediately available. Patients with documented difficult airway should be extubated per protocol of the individual institution. A significant percentage of settled malpractice cases in the ASA Closed Claims Database (67% upon induction, 15% during surgery, 12% at extubation, and 5% during recovery) occurred at the end of surgery. Death and brain damage decreased in the time periods of 1985–1992 and 1993–1999 during induction but not during extubation and recovery.

C.12. What is apneic oxygenation?

Draper and Whitehead conducted the pioneer study on apneic oxygenation in 1944. Apneic oxygenation (formerly known as diffusion respiration) is actually caused by mass movement oxygenation. When the lungs are completely denitrogenized with oxygen and the airway is connected to an oxygen source, continuous oxygenation takes place by mass movement. Normally, every minute, 250 mL of oxygen is removed from the alveoli for metabolism, and 200 mL of CO_2 is produced and eliminated from the lungs. When a person is apneic, only 10% of CO_2 accumulates in the alveoli, and 90% of CO_2 stays in the blood as bicarbonate. Consequently, 250 mL of oxygen is removed from the lungs and 20 mL of CO_2 accumulates in the lungs, creating a 230-mL vacuum effect and sucking in oxygen. CO_2 tension continues to rise because no elimination occurs during apnea. The total pressure in the alveoli is constant, so the decrease in P_{O_2} equals the rise in P_{CO_2}, ranging from 3 to 6 mmHg per minute. If the patient had been breathing 100% oxygen before respiratory arrest, the starting alveolar P_{O_2} would be about 650 mmHg, and therefore, the patient could theoretically maintain Pa_{O_2} above 100 mmHg for about 100 minutes of apnea provided that the airway remained clear and connected to 100% oxygen. However, patients will die of severe

respiratory acidosis (pH <6.80) before hypoxemia occurs. Moreover, as seen in suffocation, gross hypoxia supervenes after about 90 seconds if apnea with airway occlusion follows air breathing at the FRC. When the airway is patent and the ambient gas is air, gross hypoxia supervenes after about 2 minutes of apnea, as seen during intubation without pre-O_2. However, if the patient is preoxygenated for 3 minutes, gross hypoxia will not occur until 6 minutes of apnea for normal-weight patients and until about 3 minutes of apnea for morbidly obese patients. Apneic oxygenation is an older technique that is not recommended for obese patients. Aside from hypoxia and hypercarbia, it may lead to atelectasis or derecruitment of West Zone 3.

A much more useful maneuver in severely obese patients is to utilize 100% oxygen and PEEP, during both induction and emergence from general anesthesia. We did this with the SuperNO_2VA®, both on induction and on extubation.

C.13. What is diffusion hypoxia (DH)? How do you prevent

it?

Fink and colleagues in 1954 first reported DH during recovery from N_2O–oxygen anesthesia. A mild degree of hypoxia can develop for more than 10 minutes when N_2O–oxygen anesthesia is concluded and the patient is allowed to breathe room air. The arterial oxygen saturation can fall 5% to 10% and often reaches values less than 90% (Pa_{O_2} <60 mmHg). This occurs at the times when nitrous oxide is eliminated rapidly through the lungs. N_2O is 35 times more soluble in blood than nitrogen. Therefore, the amount of nitrous oxide diffused from blood to alveoli is much more than the amount of nitrogen diffused from alveoli to blood. Hence, alveolar oxygen is diluted by nitrous oxide.

DH, called the Fink effect, is explained by movement down a concentration gradient: Recovery from a high concentration of nitrous oxide leads to high partial pressure in the alveolus, which dilutes both the partial pressure of oxygen and CO_2 and may lead to hypoxia. Hypoxia is more likely in the presence of hypoventilation (e.g., residual anesthetics). DH may be prevented by simply increasing the inspired oxygen concentration prior to emergence, or by using, at most, a 50:50 mixture of N_2O:oxygen.

DH should not be allowed to occur in obese patients. There is no room for deep extubations in the MO/OSA patient. Patients should be fully awake, with baseline respiratory function. All anesthetics and analgesics should be stopped. Many of the newer anesthesia ventilators allow the use of pressure support ventilation during the emergence phase, which minimizes atelectasis. One hundred percent oxygen prior to, and during, extubation followed by a tight-fitting face mask with pressure support aids the patient in reestablishing ventilatory function, and assists in removal of trace anesthetic gas, until the patient is

fully recovered.

D. Postoperative Management

D.1. What are the early postoperative complications of bariatric surgical procedures?

All-cause mortality within 30 days of bariatric surgery is rare (0.3%), with the majority of causes being of nonanesthetic origin: Most common cause of death was sepsis (33% of deaths), followed by cardiac causes (28%) and pulmonary embolism (17%). Early surgical complications include anastomotic closure with bowel obstruction, anastomotic or staple line leak, intestinal obstruction, gastrointestinal bleeding, and wound infection. The most commonly quoted source of statistics is the LABS, a 10-center observational cohort study of bariatric surgical outcomes, consisting of 6,118 bariatric surgical patients from March 2005 to April 2009, at academic centers of excellence. Obesity cardiomyopathy was highlighted in this study, predisposing to congestive heart failure and arrhythmias and emphasizing the need to perform risk assessment on all bariatric candidates. The LABS revealed the relationship between surgical volume and adverse outcome, at least for the RYGB.

Anesthetic early postoperative complications are mostly

related to the pulmonary and cardiovascular systems. Postanesthetic hypoxemia is more common in the MO patient, with or without the presence of OSA, despite supplemental oxygen therapy. This may be due to atelectasis, or reversion to a restrictive breathing pattern, with increased use of accessory muscles, as well as decreased FRC from pain ("splinting"), residual PNP, parietal peritoneal irritation from carbonic acid, air in the stomach, as well as pain. Other potential early postoperative complications include respiratory depression from residual anesthetic or muscle relaxant, early ventilatory failure with need for reintubation, positional ventilatory collapse, hemodynamic instability, PONV, positional injury, and venous thromboembolism. PONV, the single most common postoperative patient complaint after bariatric surgery, is distinguished from OINV, which is more severe and more difficult to treat. Bariatric surgical procedures are highly emetogenic and frequently require prophylaxis with multiple agents. They are foregut surgical operations and interrupt peristalsis and the gastroesophageal antireflux mechanism. Severe, resistant, or recurrent PONV may be due to anastomotic kink, leak, or iatrogenic esophageal injury; the surgical team should be called to examine the patient. In-hospital postoperative ventilatory insufficiency is always a risk; patients should be triaged by the perioperative team for postsurgical care. Very high-risk patients include those with severe cardiopulmonary disease, or severe OSA, by either STOP questionnaire, or who are noncompliant with NIPPV (CPAP or BIPAP). They should be triaged from the PACU to a step-down unit postoperatively or rarely to an intensive care unit. These patients should be transported wide-awake, whenever possible, and with oxygen (nasal cannula or face mask), as well as a NIPPV device if needed. The SuperNO_2VA® nasal CPAP device was used to transport our patient to the PACU. Our

patient was placed on NIPPV and later transferred.

At any given weight, the perioperative risk is greater for central obesity than for peripheral obesity, and for patients with preexisting severe comorbidity, especially OSA. All OSA patients should be given OSA precautions. The major perioperative risk of death correlates statistically with BMI, preexisting hypertension, pulmonary embolus, and anastomotic leak. Etiology is surgical, anesthetic, mixed, or undetermined.

Although perhaps difficult to objectively measure, it may well be that blinded peer review of surgical skill is the most important determinant of bariatric surgical outcome.

Alvarez A, Brodsky JB, Lemmens HJM, et al, eds. *Morbid Obesity: Peri-operative Management*. 2nd ed. Cambridge, United Kingdom: Cambridge University Press; 2010:155–159, 161–170.

Varban OA, Reames BN, Finks JF, et al. Hospital volume and outcomes for laparoscopic gastric bypass and adjustable gastric banding in the modern era. *Surg Obes Relat Dis*. 2015;11(2):343–349.

D.2. What are the late complications of bariatric surgical procedures?

Late (after 30 days) complications of bariatric surgical procedures are mostly surgical and may occur in up to 40%. Some of these complications are general, and some procedure-specific, occurring with more complex procedures possessing one or more anastomosis, such as the RYGB or the biliopancreatic diversion duodenal switch. Some of the general complications are ventral incision hernia, internal hernia, hiatus hernia, marginal ulcers, small bowel obstruction, cholelithiasis, and metabolic and nutritional derangements. Some of the

procedure-specific complications are gastric remnant distension, stomal stenosis, marginal ulcers, nephrolithiasis and renal failure, gastric remnant distension, short bowel syndrome, dumping syndrome, postoperative hypoglycemia, failure to lose weight, weight regain, internal (usually gastro-gastric) fistulas, and others.

Lalor PF, Tucker ON, Szomstein S, et al. Complications after laparoscopic sleeve gastrectomy. *Surg Obes Relat Dis*. 2008;4:33–38.

D.3. What is the effect of position on respiratory function in the obese patient?

In the supine position, intra-abdominal contents shift the diaphragm rostrally, resulting in diaphragmatic dysfunction, decreased functional residual reserve (FRC), airway closure, increase in venous admixture (Q_S/Q_T), decreased Pa_{O_2}, and, possibly, positional ventilatory collapse. The FRC, the body's oxygen reserve, decreases 30% in the supine position. Pre-O_2 is more effective in the semi-Fowler position (head up 30 to 45 degrees) than in the supine position in severely obese patients, both for preinduction of general anesthesia, and for eventual postoperative reintubation. Recovery should take place in this position as soon as these patients are hemodynamically stable. Other benefits of a semi-sitting position are decreased superior vena cava pressure and decreased incidence of positional

injuries, which are more common in the MO, especially ulnar neuropathy. Patients recovered in the semi-Fowler position who are in need of eventual emergent mask ventilation or tracheal reintubation present better conditions for the laryngoscopist. There is a higher incidence of tracheal tube misplacement in the morbidly obese; care should be taken when positioning intubated morbidly obese patients in a semi-Fowler position.

Dixon BJ, Dixon JB, Carden JR, et al. Preoxygenation is more effective in the 25° head-up position than in the supine position in severely obese patients: a randomized controlled study. *Anesthesiology*. 2005;102:1110–1115.

Smetana G. Postoperative pulmonary complications: an update on risk assessment and reduction. *Cleve Clin J Med*. 2009;76(suppl 4):S60–S65.

D.4. How would you prevent postoperative atelectasis?

In the past, bariatric surgical procedures were often performed open, with an incidence of postoperative atelectasis of 45%. Approximately 90% are now performed laparoscopically, so the incidence would be expected to decline substantially.

Early ambulation, chest physical ambulation with incentive spirometry, and effective coughing are encouraged to improve respiratory function. Prolonged recumbency is avoided whenever possible because of its adverse effects on the $\dot{V}/\dot{Q}$ ratio and to minimize circulatory congestion of the recumbent lung. Careful titration of postoperative analgesics is emphasized to prevent splinting from pain and hypoventilation from excessive sedation.

A recruitment maneuver followed by PEEP before extubation does reduce atelectasis and improve oxygenation in morbidly obese patients.

Neligan PJ, Malhotra G, Fraser M, et al. Continuous positive airway pressure via the Boussignac system immediately after extubation improves lung function in morbidly obese patients with obstructive sleep apnea undergoing laparoscopic bariatric surgery. *Anesthesiology*. 2009;110(4):878–884.

Zoremba M, Dette F, Gerlach L, et al. Short-term respiratory physical therapy treatment in the PACU and influence on postoperative lung function in obese adults. *Obes Surg*. 2009;19(10):1346–1354.

D.5. How long would you prescribe supplementary oxygen postoperatively?

The incidence of postanesthetic hypoxemia (Pa_{O_2} <60 mmHg) is increased from a baseline of 25% to 30% in the nonobese to 75% in the obese. For a routine case on an otherwise healthy patient with simple obesity, supplemental oxygen in the PACU is probably sufficient. In most MO patients with comorbidities, oxygen should be prescribed for 24 to 72 hours. The MO patient with severe OSAHS on CPAP or BIPAP will usually have continuation of his or her therapy overnight, be recovered in a semi-Fowler position (30 to 45 degrees), and should have individualized care in an appropriate setting with continuous pulse oximetry and respiratory monitoring. At the New York-Presbyterian Hospital, the majority of these patients are discharged to home on the second or third postsurgical day.

Leykin Y, Brodsky JB, eds. *Controversies in the Anesthetic Management of the Obese Surgical Patient*. Milan, Italy: Springer-Verlag Italia; 2013:241–253.

D.6. How would you control postoperative pain?

Until recently, postoperative analgesia was provided by PCA in more than 90% of bariatric surgical procedures. PCA has been shown to be safe and effective in the MO patient population. It has many advantages: PCA is simple to use, saves nursing time,

and involves minimal time delay between patient perception of pain and therapy. There is less splinting and derangement of PFTs. PCA also facilitates early ambulation and shortens hospital stay. Hydromorphone is the gold standard. Morphine, once commonly used, has fallen out of favor due to histamine release, higher rates of nausea, and more interpatient variability. Dose regimens need to be individualized according to pain control and side effect profile. There have been rare cases of respiratory complications in the MO-OSAHS patient, so extra vigilance is needed in this group. PCA dosages for the MO in the opioid naive, based on IBW, are as follows:

- Morphine sulfate 20 μg per kg IBW
- Hydromorphone 4 to 5 μg per kg IBW
- Fentanyl 1 μg per kg IBW
- Methadone 20 μg per kg IBW

All settings are every 10 minutes, without continuous rate, at 80% of the calculated maximum doses. Although the opioids have different lipid solubilities, for IV-PCA, all have been dosed by IBW because the doses were originally formulated using IBW. Meanwhile, as we are titrating to individual patient satisfaction, there is room for posttreatment dose modification.

Intravenous infusions of opioids may also be administered in a monitored setting. In the past, opioids have been administered intramuscularly. Although this route has been shown to be effective, intramuscular injection is not advisable in the MO because of unpredictable pharmacodynamics, arising from inadvertent injection into lipid tissue.

There are three regional anesthetic/analgesic options: thoracic epidural analgesia and anesthesia/patient-controlled epidural analgesia (TEAA/PCEA), intrathecal opioids, and continuous spinal anesthesia/patient-controlled intrathecal analgesia (CSA/PCIA). All of these may be used with or without light general anesthesia. They offer similar side effect profiles and

will be described together. *PCEA*, the most commonly used of these, has numerous theoretical advantages. At a lower dose compared with parenteral opioids, there are few side effects and serious complications, effective analgesia, faster recovery, less respiratory complications, decreased total body oxygen consumption, improved cardiac function, and shorter hospitalization times compared with PCA. PCEA dosages in the MO should be decreased 75% to 80% due to decreased volume of the epidural space from increased intra-abdominal pressure. PCEA is strongly recommended when feasible yet remains underutilized. Patients should be positioned in a sitting position for epidural catheter insertion, and ultrasound guidance is recommended. Disadvantages include a higher rate of wound infection, possibly because of microdehiscence from faster return of gastrointestinal function, and the risk of neural injury. There is frequent technical difficulty with catheter insertion, which slows OR case flow. There is a higher rate of inadequate function, catheter migration and replacement, and variable block level. Side effects include excessive drowsiness, PONV, pruritus, and urinary retention. Respiratory depression occurs rarely and is more common with hydrophilic (e.g., preservative-free morphine sulfate [PFMS]) than with hydrophilic agents. With PFMS, it may occur from 1 hour until 18 hours. With fentanyl or sufentanil, it may occur from minutes until 2 hours. Neuraxial opioid respiratory depression risk factors include advanced age, excessive or repeated doses, lack of opioid tolerance, use of concomitant sedatives or hypnotics, increased intra-abdominal pressure (e.g., PNP), and severe OSAHS, which may precipitate massive pharyngeal collapse. *CSA/PCIA* with light general anesthesia has been used for gastroplastic surgery. It is technically easier to perform than TEAA/PCEA and produces a denser block with motor component, which is more predictable and controllable. *Intrathecal* opioids, with or without

local anesthetics, are technically easier to administer and offer an excellent alternative for appropriate surgical procedures. Other methods of controlling postoperative pain in bariatric surgery include preemptive analgesia via local anesthetic wound infiltration before and after surgery, pre- and intraoperative nonopioid drug combination (ketorolac, clonidine, lidocaine, ketamine, magnesium sulfate, and methylprednisolone), and perioperative dexmedetomidine.

Some bariatric patients will develop esophageal spasm-like pain in the postoperative period, which may mimic myocardial ischemic pain. These usually respond to antacids and H_2-receptor antagonists.

With the advent of Enhanced Recovery After Surgery (ERAS) techniques, postoperative pain is substantially less. In consequence, except for complex surgical cases or reoperations, no opioids are prescribed. The mainstay of postoperative analgesics today is non-opioid analgesics. Intravenous opioid analgesics are reserved for break-through pain. Aside from decreasing postoperative nausea and vomit, the most significant side effect after these cases, and decreasing respiratory depression, minimizing opioid exposure is associated with substantial societal benefits.

preoperative evaluation and preparation, 608, 616–619
Hypertensive hypervolemic hemodilution (HHH)
for cerebral aneurysm clipping, 488
for cerebral vasospasm, 497
Hyperthermia
drug-induced syndromes, 989–990
in head injury, prevention of, 479–480
malignant (*See* Malignant hyperthermia)
Hypertonic saline (HTS)
for awake craniotomy, 453
for head injury, 475–476, 477
for hyponatremia in TURP, 534
for intracranial hypertension, 394

for intracranial procedures, 407
Hypertrophic obstructive cardiomyopathy (HOCM), 106
Hyperventilation
in asthmatic attacks, 5
in cerebral aneurysm procedures, 491
in craniotomy, 405, 406
in head injury, 474
in intracranial hypertension, 394
in malignant hyperthermia, 993
in preterm infant, 842
Hypervolemia, in TURP, 532, 532*f*
Hypnosis, for cancer pain, 922, 922–923
Hypocalcemia
in crush injury, 1048
in head injury, 466
in liver transplantation, 381
in massive transfusion, 1036
in preterm infants, 842
in 22q11 deletion syndrome, 822–823
Hypocapnia/hypocarbia
in asthmatic attacks, 5
in cardiopulmonary bypass, 121
in cerebral aneurysm procedures, 491
and cerebral blood flow, 424–425
and electroconvulsive therapy, 1096
and intraocular pressure, 712
Hypochloremia, in pyloric stenosis, 791–794
Hypofibrinogenemia, 663, 678, 1038
Hypogastric plexus block, for cancer pain, 917
Hypoglycemia
in diabetes therapies, 512
in pheochromocytoma surgery, 509
in preterm infants, 841

Hypoglycemic shock, intraoperative, 520
Hypokalemia
diuretics and, 272
in head injury, 465
in massive transfusion, 1035–1036
in pyloric stenosis, 791–794
Hypomagnesemia
in head injury, 465–466
preoperative treatment of, 272
Hyponatremia
in cirrhosis, 371, 374–375
in head injury, 465
in MELD score, 368
preoperative management of, 374–375
in pyloric stenosis, 791–794
in scoliosis, postoperative, 1070
subarachnoid hemorrhage and, 498
in TURP, 533–534
Hypophosphatemia, in head injury, 465–466
Hypotension
ACE inhibitors and, 270
with aortic dissection, 210
in cardiac tamponade, 286
in cardiac tamponade surgery, 300
controlled
for cerebral aneurysm procedures, 492–493
for craniotomy, 409
drawbacks of, 493
for hypertension, 266–267
for scoliosis surgery, 1068–1069
in craniotomy, 402
in head injury, 475
in hypertensive patients, 274, 275

intraoperative, management of, 99, 117
in kidney transplantation, 553
malignant hyperthermia and, 984
maternal, in labor and delivery, neuraxial analgesia and, 621
postoperative
in carotid endarterectomy, 437, 438
in heart valve surgery, 177
in obstetric hemorrhage, 606–607
in pheochromocytoma surgery, 508
in protamine reaction, 131–132
in shock, 1029
in TURP, 534, 536
Hypotensive bradycardiac episodes (HBE), sitting position and, 871
Hypothermia
adverse effects of, 1037
in burn patients, 1019
in cardiopulmonary bypass, for CABG
acid–base regulatory strategies in, 123–125, 124*t*
blood viscosity change in, 120
glucose control in, 125
pump flow in, 119–121
rewarming time, 128
weaning temperature, 128
in cardiopulmonary bypass, for transposition of the great arteries repair, 784–787
in cleft lip/palate closure, 819
definition, 1036
deliberate (induced)
for cerebral aneurysm procedures, 493–494
for intracranial hypertension, 395
neuroprotective effects of, 493
in head injury, 476
in massive transfusion, 1035

in neonates, 741, 751, 839, 844
in patent ductus arteriosus ligation, 844
postoperative
and myocardial ischemia, 338
in TURP, 537
in thoracoabdominal aneurysm repair, 230
in trauma surgery, 1036–1037
treatment of, 1037
Hypothermic circulatory arrest
in aortic aneurysm repair, 219–222
in aortic dissection surgery, 224
in cerebral aneurysm procedures, 494
in transposition of the great arteries repair, 784–785
Hypoventilation
in asthmatic patients, 22
in burn patients, 1017
in COPD patients, 25
low SpO_2 reading in, 1087*t*
in morbidly obese patients, 1104, 1137–1138, 1142
postoperative, differential diagnosis of, 998
Hypovolemic ARF, 1021–1022
Hypovolemic shock, 1029–1031
acid–base disturbance in, 1030
burns and, 1014–1015
cardiovascular derangement in, 1029
dextran or hetastarch for, 1031
pathophysiology of, 1029–1030
Hypoxemia
in acute chest syndrome, 692, 697
in acute respiratory distress syndrome, 56, 58
in aortic aneurysm evaluation, 244
in apnea spells, 836
in asthmatic attacks, 4–5

in burn patients, 1017
in cerebral aneurysm procedures, 490, 491*f*
in cirrhosis, differential diagnosis of, 373
in congenital diaphragmatic hernia, 748
definition, 1074
intraocular pressure in, 712–713
maternal, after delivery, 647
in morbidly obese patients, 1142
physiologic causes of, 10–11
in Pickwickian syndrome, 1138
in pneumothorax, 1027
postanesthetic, in morbidly obese patients, 1162, 1164
postoperative, causes of, 1089
in refractory respiratory failure, 63–65
in respiratory distress syndrome, 835
in transposition of the great arteries, 776
in TURP syndrome, 529
Hypoxia
in ARDS, 1090–1091
in carbon monoxide poisoning, 1014
definition, 1074
diffusion, 1021, 1163
in equipment failure, 1073–1092
intraoperative management, 1073, 1086–1088
medical disease and differential diagnosis, 1073, 1074–1083
postoperative management, 1074, 1089–1092
preoperative evaluation and preparation, 1073, 1083–1086
in tetralogy of Fallot, 759
in traumatic brain injury, 479
Hypoxic gas mixture, 1087*t*
Hypoxic pulmonary vasoconstriction (HPV), 40–42, 82, 87
Hysterectomy
for placenta accreta syndrome, 589

robotic-assisted laparoscopic, 1073, 1086–1092

SECTION 1 The Respiratory System
1 Asthma and Chronic Obstructive Pulmonary Disease
A. Medical Disease and Differential Diagnosis
A.1. What is the differential diagnosis of dyspnea?
A.2. What is the prevalence of asthma and chronic obstructive pulmonary disease (COPD)?
A.3. What is the etiology of asthma?
A.4. Discuss the pathogenesis of asthma. How is asthma distinguished from COPD?
A.5. What are the triggers of bronchospasm?
A.6. What is the universal finding in ABGs during asthmatic attacks: hypoxemia or CO_2 retention?
A.7. Describe the abnormalities seen in spirometry, lung volumes, and lung capacities during an asthmatic attack.
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate the patient preoperatively? What preoperative workup would you order?
B.2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?
B.3. Define normal lung volumes and lung capacities. Give normal values for an average adult male.
B.4. What are flow–volume loops? Draw flow–volume loops for a healthy subject and patients with COPD, restrictive lung disease, fixed obstruction of the upper airway, variable extrathoracic obstruction, and variable intrathoracic obstruction.
B.5. Define closing volume (CV) and closing capacity (CC). What is the normal value of CV?
B.6. Why is the functional residual capacity (FRC) important in oxygenation?

B.7. How are FRC and CC affected by age and posture? How are they affected by anesthesia?
B.8. Give the equations for shunt (Qs/Qt) and dead space/tidal volume (Vd/Vt). What are their normal values?
B.9. Interpret the following ABG: pH, 7.36; PCO_2, 60 mmHg; PO_2, 70 mmHg; and CO_2 content, 36 mEq per L.
B.10. What are the common physiologic causes of hypoxemia?
Decreased pulmonary capillary oxygen tension
Increased shunting
Reduced venous oxygen content
B.11. How would you prepare this asthmatic patient with COPD for surgery?
B.12. The patient comes to your perioperative clinic 2 weeks before surgery. He wants to know if his smoking puts him at increased risk during surgery. What do you tell him? Should he quit now?
B.13. You discover that the patient had a recent upper respiratory infection (URI), would you postpone surgery? For how long?
B.14. What medications would you expect the patient to have taken in the past or be taking at the present time?
B.15. The patient was on 20 mg of prednisone per day for 5 days as part of the treatment of an asthma exacerbation 3 months ago. He is currently not on steroids. Should the patient receive stress-dose steroids?
B.16. Should patients with reactive airway disease receive preoperative steroids?
B.17. What is the onset of action of intravenous steroid therapy in asthma?
C. Intraoperative Management
C.1 If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?
C.2. The patient did not have an asthmatic attack in the operating room and you proceed with induction. How would you induce anesthesia? Would you use a supraglottic airway instead of an endotracheal tube?
C.3. Would you use propofol for induction of anesthesia?
C.4. Would you use thiopental, methohexital, etomidate, or

ketamine for induction?
C.5. Would you administer lidocaine for intubation?
C.6. If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?
C.7. Could a regional technique be used for this surgery? Discuss the advantages and disadvantages of neuraxial anesthesia in this patient for this surgery.
C.8. Would you choose an inhalational or an intravenous technique for maintenance of anesthesia?
C.9. What mechanisms produce bronchodilation from volatile anesthetics?
C.10. Which muscle relaxants would you use? Why?
C.11. How will you ventilate the patient? Will you use positive end-expiratory pressure (PEEP)? How can you detect the presence of auto-PEEP on your ventilator?
C.12. What is the differential diagnosis of intraoperative bronchospasm?
C.13. In the middle of surgery, peak inspiratory pressures (PIPs) suddenly increase. How do you manage this?
C.14. How would you give β_2-agonists? What is their mechanism of action on asthma?
C.15. If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?
C.16. The asthmatic attack was relieved with your treatment, and the surgery was completed. Following emergence, the patient was found to be hypoventilating. What are the common causes of hypoventilation? What will be your approach to treat hypoventilation?
C.17. Would you consider a deep extubation in this patient?
C.18. If the patient cannot be extubated, what measures can you take to reduce the likelihood of bronchospasm with an endotracheal tube in place?
D. Postoperative Management
D.1. In patients with asthma and COPD, are there special considerations for the use of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) for postoperative pain control?
D.2. Would you consider using a regional technique for analgesia?

D.3. The patient was breathing well and was extubated. Would you place this patient on supplemental oxygen in the recovery room? How much?
D.4. The patient is hypoventilating in postanesthesia care unit (PACU). Would you initiate noninvasive ventilation (NIV)?
2 Bronchoscopy, Mediastinoscopy, and Thoracoscopy
A. Medical Disease and Differential Diagnosis
A.1. How is the diagnosis of lung cancer made? What is your prediction for the most likely type of malignancy?
A.2. What are the less common manifestations of bronchogenic carcinoma?
A.3. The patient has a long history of cigarette smoking. What is the significance of this finding?
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate the patient prior to surgery?
B.2. What are the pulmonary function guidelines that indicate an increased risk for morbidity and mortality?
B.3. What are the preoperative concerns of induction immunotherapy?
C. Intraoperative Management
C.1. How would you premedicate, monitor, and anesthetize this patient?
C.2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?
C.3. What are the indications for cervical mediastinoscopy? Are there potential complications?
C.4. The decision was made to proceed with a robotic right middle lobectomy. How would this alter your management?
C.5. What are the indications for single-lung ventilation and how can it be accomplished?
C.6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?
C.7. Would you use a right- or left-sided DLT?
C.8. How do you know that the tube is in the correct position?
C.9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?
C.10. How will systemic oxygenation be monitored during single-

lung ventilation? What is the mechanism of pulse oximetry?
C.11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.
Respiratory Effects
C.12. What is hypoxic pulmonary vasoconstriction (HPV)?
C.13. What are the effects of anesthetic agents on HPV and their clinical implications?
C.14. Discuss pulmonary blood flow distribution, shunt flow, and partial pressure of oxygen in the arterial blood (PaO_2) (fractional inspired O_2 concentration [FIO_2] = 1.0) during single-lung ventilation in the lateral position.
C.15. How could you improve oxygenation during single-lung ventilation?
Ventilated Lung
Collapsed Lung
C.16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?
D. Postoperative Management
D.1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?
D.2. Why is it important to control postoperative pain? How would you achieve this goal?
Epidural, Paravertebral, and Intrathecal Analgesia
Peripheral Nerve Blocks
Systemic Opioids and Adjuvants
Oral and Transdermal Agents
Intrapleural Regional Analgesia
Cryoanalgesia
Transcutaneous Electrical Nerve Stimulation
Shoulder Pain after Lung Resection
3 Aspiration and Postoperative Respiratory Failure
A. Aspiration
A.1. What are the risk factors for perioperative aspiration?
A.2. How does large volume aspiration affect the respiratory system?
A.3. How should you manage the patient after an aspiration event?

A.4. How would you prevent aspiration during emergency surgery?
B. Postoperative Respiratory Failure
B.1. How can you predict which patients will develop postoperative respiratory failure?
B.2. How can intraoperative anesthesia management prevent respiratory failure?
B.3. What is the pathogenesis of postoperative respiratory failure?
B.4. What is the diagnostic approach to postoperative respiratory failure?
C. Indications for Ventilator Support
C.1. What are the indications for noninvasive positive pressure ventilation (NIPPV)?
C.2. What are the indications for emergency endotracheal intubation?
D. The Acute Respiratory Distress Syndrome
D.1. What is the definition and etiology of the acute respiratory distress syndrome (ARDS)?
D.2. Explain the pathophysiology of ARDS.
D.3. What role does ventilator-induced lung injury (VILI) play in ARDS?
E. Management of Mechanical Ventilation
E.1. Which mode of mechanical ventilation will you choose? Describe the features of that mode.
E.2. How should you set the fraction of inspired oxygen (FIO_2)?
E.3. How should you set the positive end-expiratory pressure (PEEP)?
E.4. What tidal volume and inspiratory pressure target should you set?
F. Management of Refractory Respiratory Failure
F.1. What else can promote additional lung recruitment?
F.2. What rescue strategies can you use for refractory ARDS?
G. Adjunctive Management of Respiratory Failure
G.1. What is the cause and treatment of the hemodynamic instability associated with mechanical ventilation?
G.2. What is the adjunctive medical therapy for ARDS?
H. Liberation of the Patient from Mechanical Ventilation
H.1. Explain the importance of the decision to extubate the patient

or continue mechanical ventilation.
H.2. How will you prepare the patient for liberation from the ventilator?
H.3. How will you recognize when the patient is ready for extubation?
4 Lung Transplantation
A. Medical Disease and Differential Diagnosis
A.1. What are the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?
A.2. What other end-stage lung diseases can also be treated with transplantation?
A.3. How many lung transplantations have been performed?
A.4. What are the selection criteria for recipients?
A.5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?
A.6. How does a single-lung transplantation (SLT) differ technically from a bilateral-lung transplantation (BLT)?
B. Preoperative Evaluation and Preparation
B.1. What preoperative evaluation is desirable?
B.2. Would you premedicate this patient? If so, how?
B.3. What vascular access is appropriate?
B.4. Is preoperative epidural catheter placement advantageous?
C. Intraoperative Management
C.1. What special equipment is necessary?
C.2. How would you monitor this patient?
C.3. How would you induce anesthesia in this patient?
C.4. How would you ventilate this patient? What kind of endotracheal tube would you use?
C.5. How does the physiology of single-lung ventilation influence the procedure?
C.6. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?
C.7. What problems are associated with the lateral position?
C.8. Should volatile anesthetics be avoided during single-lung ventilation?

C.9. At what specific points in the procedure are problems anticipated?
C.10. How would you deal with problems related to clamping of the pulmonary artery (PA)?
C.11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?
C.12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?
C.13. Should fluid administration be restricted, and are blood products commonly required?
C.14. Would you extubate the patient upon conclusion of the procedure?
D. Postoperative Management
D.1. What are the major complications after lung transplantation?
D.2. How is postoperative ventilation managed, and for how long is it required?
D.3. What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?
D.4. What are the long-term outcomes of lung transplantation?
D.5. Are there surgical alternatives to lung transplantation?
SECTION 2 The Cardiovascular System
5 Ischemic Heart Disease and Coronary Artery Bypass Grafting
A. Medical Disease and Differential Diagnosis
A.1. What is triple-vessel CAD? Name the branches of the coronary arteries.
A.2. What are the indications for CABG?
A.3. What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.
A.4. What are the expected results of CABG?
B. Preoperative Evaluation and Preparation
B.1. Which preoperative tests would you order?
B.2. How would you evaluate the patient’s left ventricular function?
B.3. Which factors determine myocardial oxygen supply?
B.4. What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?

B.5. Would you continue the β-blocker (metoprolol) on the day of surgery? Why/why not? What is its half-life? What is the role of β-adrenergic blockers in treating congestive heart failure (CHF)?
B.6. Would you continue the angiotensin-converting enzyme (ACE) inhibitor on the day of surgery? Why/why not?
B.7. If the patient who is on lisinopril develops hypotension intraoperatively, how would you manage it?
C. Intraoperative Management
C.I. Before Cardiopulmonary Bypass
C.I-1. What is your plan to monitor the patient?
C.I-2. What is the Allen test?
C.I-3. How would you monitor electrocardiogram (ECG)? Why lead V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?
C.I-4. Should you monitor temperature from multiple sites?
C.I-5. Is it necessary to monitor pulmonary artery (PA) pressure for coronary artery operations?
Diagnostic
C.I-6. What are the possible complications of PA catheterization?
Similar to Central Venous Catheter Insertion
From Pulmonary Artery Catheter
C.I-7. What is normal pulmonary artery occlusion pressure (PAOP)?
C.I-8. What are the hemodynamic consequences of myocardial ischemia? How can you detect myocardial ischemia? Is PAOP a sensitive indicator of myocardial ischemia?
C.I-9. Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.
C.I-10. How would you induce anesthesia? Is there any advantage/disadvantage to using propofol versus etomidate as the main induction agent? What kind of neuromuscular blocker (NMB) would you use? Why?
C.I-11. How would you maintain anesthesia? Volatile anesthetics or total intravenous anesthesia (TIVA)?
C.I-12. What are the cardiovascular effects of volatile anesthetics, morphine, and fentanyl?
C.I-13. What should you do during sternotomy?

C.I-14. Would you use prophylactic nitroglycerin during CABG to prevent intraoperative myocardial ischemia or perioperative MI?
C.I-15. If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative MI?
C.I-16. Discuss autologous transfusion and blood conservation for cardiac surgery.
C.I-17. What antifibrinolytic will you use to reduce blood transfusions?
C.I-18. How do you know that the tip of the PA catheter is in the right ventricle (RV) or the PA?
Pressure Contour
Ventricular Filling
C.II. During Cardiopulmonary Bypass
C.II-1. What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?
C.II-2. What is the half-life of heparin? How is it eliminated?
C.II-3. How do you monitor heparin dosage? What is the activated coagulation time (ACT) test?
C.II-4. What is total CPB? What is partial bypass?
C.II-5. What kinds of pumps are used in CPB? Are they pulsatile or not?
C.II-6. What is the purpose of venting the LV? How can it be done?
C.II-7. How many types of oxygenators are there? What are the advantages of each type?
Direct Gas Interface
Without Gas Interface
C.II-8. What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?
C.II-9. What are the advantages and disadvantages of hemodilution?
Advantages of Hemodilution
Disadvantages of Hemodilution
C.II-10. How do you monitor the patient during CPB?
Clinical Monitoring

Laboratory Monitoring at Least Once Every Hour
C.II-11. What should your target BP be during CPB?
C.II-12. How would you treat hypotension during CPB?
C.II-13. How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mmHg)?
C.II-14. How do you prepare an IV infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?
C.II-15. How much pump flow would you maintain during CPB? During hemodilution? During hypothermia?
C.II-16. How does blood viscosity change during hemodilution and hypothermia?
C.II-17. How is anesthesia provided during CPB?
C.II-18. Would you give muscle relaxants during CPB? How is the action of muscle relaxants affected during CPB?
C.II-19. How do you know the patient is well perfused during CPB?
C.II-20. How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?
C.II-21. What are the disadvantages of hypocapnia during CPB?
C.II-22. How would you preserve the myocardium during CPB?
C.II-23. What is cardioplegia? How much would you use?
C.II-24. The arterial blood gases and electrolytes during CPB are as follows: pH, 7.36; $PaCO_2$, 42 mmHg; PaO_2, 449 mmHg; CO_2 content, 24 mEq per L; sodium (Na), 128 mEq per L; potassium (K), 5.8 mEq per L; glucose, 180 mg/dL; and hematocrit, 20%. The patient's temperature is 27°C (80.6°F). At what temperature are blood gases measured? How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37°C (98.6°F) or at patient's body temperature?
C.II-25. How does the blood sugar level change during CPB? Why? What is optimal glucose control intraoperatively? Does hyperglycemia increase neurologic complications during CPB?
C.II-26. What are the effects of CPB on platelet and coagulation factors?
C.II-27. If the blood level of the venous reservoir is low, what

would you replace it with? Blood or balanced salt solution?
C.II-28. How do you estimate the fluid balance during CPB?
C.II-29. For how long a period can the aorta be cross-clamped?
C.II-30. Why does the urine turn pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?
C.II-31. Why does it take longer to rewarm than to cool the patient via the pump oxygenator?
C.II-32. At what temperature can the patient be weaned from CPB?
C.II-33. How would you defibrillate the heart internally during CPB?
C.II-34. If the HR is 40 beats per minute, what should you do?
C.II-35. How would you prepare for termination of CPB?
Laboratory Data
Anesthesia Machine
Monitors
Patient/Pump
Support
C.II-36. How would you decide the need for inotropic support?
C.III. After Cardiopulmonary Bypass
C.III-1. How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize heparin?
C.III-2. What is the action mechanism of protamine?
C.III-3. What are the complications of too much protamine?
C.III-4. What is a protamine reaction? How can you prevent this condition? How do you treat it?
C.III-5. What are the indications for intra-aortic balloon pump (IABP)?
Ischemic Heart Disease
Cardiac Surgery
C.III-6. What are the principles of IABP?
C.III-7. What are the complications of IABP?
D. Postoperative Management
D.1. Would you reverse the muscle relaxants? Why?
D.2. When will you wean the patient from the ventilator?
D.3. What criteria would you use in deciding when to wean the patient from the ventilator?

D.4. What are potential postoperative complications?
Cardiovascular
Pulmonary
Renal
Hemorrhage
6 Mechanical Circulatory Support
A. Medical Disease and Differential Diagnosis
A.1. What is an IABP?
A.2. How is an IABP placed and positioned?
A.3. Describe an IABP inflation and deflation timing.
A.4. How does the IABP help improve hemodynamics?
A.5. What are the indications for IABP placement?
A.6. What are the contraindications and potential complications of IABP placement?
A.7. What are the pitfalls of IABP timing?
A.8. What are the main advantages and disadvantages of IABP support?
A.9. What is mechanical circulatory support?
A.10. What is a ventricular assist device (VAD)?
A.11. What are the types of percutaneous/temporary VADs?
A.12. What are the types of permanent VADs?
A.13. How does VAD work?
A.14. When is circulatory support needed?
A.15. What are the physiologic considerations in patients requiring a VAD?
A.16. What are the reasons for suboptimal VAD support?
A.17. What are common complications from VAD?
A.18. How long can VADs remain in the patient?
B. Preoperative Evaluation and Preparation
B.1. What is the focus of the preoperative assessment of an LVAD patient?
C. Intraoperative Management
C.1. Detail the anesthetic management for a patient undergoing LVAD placement.
C.2. How is a VAD patient monitored during a general anesthetic?
C.3. Prescribe an anesthetic for a VAD patient.
C.4. What is ECMO? What are the indications for ECMO? What

are the different types of ECMO?
C.5. What are the contraindications of ECMO?
C.6. What are the main complications of ECMO?
C.7. What are the necessary equipment and teams required to place ECMO? What are the pros and cons of different venoatrial ECMO (VA-ECMO) cannula placement?
C.8. How are patients monitored and managed while on ECMO?
C.9. What are the complications of ECMO?
C.10. How frequently is VA-ECMO being used and how effective is it in cardiogenic shock?
D. Postoperative Management
D.1. When and how is a patient weaned off IABP support?
D.2. How is weaning from ECMO accomplished?
7 Valvular Heart Disease
A. Medical Disease and Differential Diagnosis
A.1. What are the major etiologies of AS, AI, mitral stenosis (MS), and MR?
A.2. What are the major changes in the loading conditions of the LV that result from the four different lesions? Why do they occur? What changes result from them?
A.3. What are pressure–volume (P–V) loops? What do the different inflection points represent?
A.4. What are representative P–V loops for the four valvular lesions?
A.5. Draw the pressure/time curves for the LV, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.
Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation
A.6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?
A.7. What are the three TEE vantage points for the comprehensive imaging of the LV? How are pressure gradients measured by echocardiography? How do the pressure gradients derived from

Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?
A.8. What is the role for three-dimensional (3D) echocardiography in the operating room?
A.9. What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?
Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation
B. Preoperative Evaluation and Preparation
B.1. What are the presenting signs and symptoms of the four valvular lesions listed previously?
Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation
B.2. What is the New York Heart Association classification of heart failure?
B.3. Discuss the role of premedication for patients with the four different valvular lesions.
B.4. How would you premedicate the patient with severe AS and MR?
C. Intraoperative Management
C.1. Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and contractility?
Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation
C.2. What are the hemodynamic goals for this patient with the combination of severe AS and MR?
C.3. How would you monitor this patient with severe AS and MR?
C.4. Should the patient have a pulmonary artery catheter placed before induction?
C.5. Is a pulmonary artery catheter with pacing capabilities

indicated?
C.6. What anesthetic technique would you employ? Why?
C.7. What muscle relaxant would you use for this patient?
C.8. What are the usual TEE findings in a patient with AS or MR? How do you grade the severity of AS by TEE? How do you quantify the severity of MR? What is the impact of AS on the severity of MR?
C.9. What special considerations particular to cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.
Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation
C.10. The patient cannot be weaned from CPB following an AV replacement and MV replacement. What are the possible causes?
C.11. How would you diagnose right-sided heart failure and pulmonary hypertension? How would you treat it?
C.12. How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?
C.13. What role does the IABP have in this setting?
C.14. What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?
C.15. How would you properly time the IABP cycle?
C.16. What are the contraindications to the use of an IABP?
C.17. What is the role for ventricular assist devices?
D. Postoperative Management
D.1. In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?
D.2. Would you extubate this patient early in the ICU? Why?
D.3. What are the advantages and disadvantages of early extubation?
E. Alternative Treatments
E.1. What are the percutaneous options for MV repair?

E.2. How is percutaneous MV repair performed?
E.3. What are the percutaneous options for AV repair and replacement?
E.4. How is percutaneous AV replacement performed?
E.5. What anesthetic techniques and monitors are used?
E.6. What is minimally invasive cardiac valve surgery?
8 Pacemakers, Implantable Cardioverter-Defibrillators, and Cardiac Resynchronization Therapy Devices
A. Medical Disease and Differential Diagnosis
A.1. What are the indications for PPMs?
A.2. What is sick sinus syndrome? What is chronotropic incompetence?
A.3. How would you diagnose first-, second-, and third-degree AV block; bifascicular block (right bundle branch block [RBBB] with left anterior fascicular hemiblock or left posterior fascicular hemiblock); and trifascicular block?
A.4. Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?
A.5. What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?
A.6. How many modes of pacing are available in modern PPMs? How do they work? What is the difference between DDD pacing and DDI pacing?
A.7. The patient was mechanically hyperventilated during surgery, and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?
A.8. What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of right ventricular pacing only?
A.9. What are the indications for and complications associated with AV sequential PPMs?
A.10. How would you know if the patient’s PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?
A.11. What is a biventricular PPM or CRT device? What are the indications for such a device?

A.12. What are the usual lifespans of PPMs and implantable cardioverter-defibrillators (ICDs)?
A.13. What is an ICD? How does it work? What is a subcutaneous ICD?
A.14. What are the indications for ICDs?
A.15. What is the NASPE and BPEG generic defibrillator (NBD) code?
B. Preoperative Evaluation and Preparation
B.1. How would you preoperatively evaluate the patient described earlier?
B.2. How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?
B.3. How do you determine whether the patient is dependent on the pacing from the CIED?
B.4. How do you know if the implanted PPM or ICD is working?
B.5. What information would you like to obtain from interrogating this device?
B.6. How do you preoperatively prepare the patient for surgery and anesthesia?
B.7. Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?
B.8. The patient requires an abdominal magnetic resonance imaging (MRI) prior to the surgery. What considerations should you make regarding her CIED?
C. Intraoperative Management
C.1. How would you monitor this patient?
C.2. What drugs and equipment would you like to have on hand in the operating room?
C.3. How would you set up the transcutaneous external pacer and defibrillator?
C.4. Had this patient’s ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?
C.5. Electromagnetic interference (EMI) from electrocautery results in significant noise on your cardiac monitor. You recall that EMI

also can inhibit pacing function from the PPM. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the PPM is occurring?
C.6. What are the potential responses of pacemakers and ICDs to electrocautery?
C.7. How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?
C.8. What are the effects of a magnet on pacemakers and ICDs?
C.9. In the middle of surgery, the patient developed ventricular tachycardia. What would you do?
C.10. What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?
C.11. Is electroconvulsive therapy (ECT) contraindicated in patients with pacemakers or ICDs?
C.12. What precautions should be taken during radiofrequency ablation for a patient with a CIED?
C.13. During surgery, the patient developed frequent premature ventricular complexes and some of these resulted in rapid ventricular pacing (see Fig. 8.8). What is accounting for the pacemaker's behavior?
D. Postoperative Management
D.1. How would you monitor this patient in the postanesthesia care unit?
D.2. How would you confirm that the CIED is functioning properly after surgery?
9 Thoracic and Thoracoabdominal Aortic Aneurysms
A. Pathophysiology and Differential Diagnosis
A.1. What is a thoracic aortic aneurysm (TAA) and TAAA, and how do they typically present?
A.2. How are TAAs and TAAAs classified?
A.3. What is the pathogenesis of aortic aneurysms and what genetic conditions predispose to their formation?
A.4. What are the risk factors for TAA rupture?
A.5. What is the natural history and medical management of thoracic aneurysms?
A.6. What is a thoracic aortic dissection, and how does it typically

present?
A.7. How are thoracic aortic dissections classified?
DeBakey Classification
Stanford Classification
Penn Classification
B. Preoperative Evaluation and Preparation
B.1. What are the indications and timing of surgical intervention for TAAs?
B.2. Which patients are candidates for endovascular aortic repair, and what are the advantages to this approach?
B.3. What are the preoperative considerations for the anesthesiologist before TAA repair?
Cardiovascular
Respiratory
Renal
Neurologic
B.4. What is the preoperative management of a patient presenting with an acute aortic dissection (AAD)?
B.5. What is the spinal cord blood supply?
C. Intraoperative Management
C.1. What are the surgical approaches to thoracic aneurysm repair?
Ascending and Arch Aortic Aneurysms
Thoracoabdominal Aneurysms
C.2. How is the open repair performed?
Ascending and Arch Aortic Aneurysms
Thoracoabdominal Aneurysms
C.3. How are endovascular repairs of TAAAs performed?
C.4. What are the surgical approaches to aortic dissections?
Type A Aortic Dissection
Type B Aortic Dissection
C.5. What are the specific considerations for anesthetic management of the patient presenting for open TAAA repair?
C.6. What are the specific considerations for anesthetic management of the patient presenting for endovascular TAAA repair?
C.7. What hemodynamic monitors should be used for the patient undergoing thoracic aneurysm repair?

C.8. What strategies are used for spinal cord protection during a TAAA repair?
Left-Heart Bypass
Intraoperative Neuromonitoring
Cerebrospinal Drainage
Hypothermia
C.9. What strategies are used for mesenteric and renal preservation?
C.10. What is the pathophysiology of aortic clamping and unclamping?
Aortic Clamping
Aortic Unclamping
C.11. Why does a coagulopathy ensue and how is it prevented/treated?
D. Postoperative Anesthetic Management
D.1. What are the postoperative complications after open TAAA repair?
Respiratory Failure
Renal Failure
Spinal Cord Injury
D.2. What are the postoperative complications after endovascular TAAA repair?
Left Upper Extremity Ischemia
Stroke
Spinal Cord Ischemia
Renal Failure
Postimplantation Syndrome
Endograft Collapse
Endoleaks
10 Abdominal Aortic Aneurysm Repair
A. Medical Disease and Differential Diagnosis
A.1. What risk factors are associated with an abdominal aortic aneurysm (AAA)?
A.2. What other diseases are commonly found in patients with aortic aneurysms?
A.3. What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the

natural history of the disease without surgical repair?
A.4. What should be done for smaller aortic aneurysms that are found in patients?
A.5. What is the risk of perioperative myocardial infarction (MI) in patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?
A.6. Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?
B. Preoperative Evaluation and Preparation
B.1. Which preoperative laboratory tests would you require for this patient?
B.2. What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what would they tell you?
B.3. Is it necessary to evaluate this patient's pulmonary status?
B.4. Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $PaCO_2$, 47 mmHg; and PaO_2, 68 mmHg on room air. What is the significance of this result?
B.5. How would you measure creatinine clearance in this patient, and what is its value in this case?
B.6. Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?
B.7. How do you detect spinal cord ischemia?
B.8. What are the various surgical approaches to repair an AAA?
B.9. How does the choice of surgical technique affect the anesthetic management?
B.10. How would you premedicate this patient?
C. Intraoperative Management
C.1. Would you use an arterial line? What are the complications of arterial line placement?
C.2. What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?
C.3. What additional monitors would you employ?
C.4. Is there a role for somatosensory evoked potential (SSEP) monitoring during aortic clamping?
C.5. How would you anesthetize this patient for an open repair of

the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.
C.6. This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?
C.7. What are your plans for fluid and blood replacement during surgery?
C.8. What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?
C.9. Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?
C.10. What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?
D. Postoperative Management
D.1. What are the parameters used to extubate this patient?
D.2. What are the anticipated changes in postoperative pulmonary function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?
D.3. How would you control postoperative pain? What are the alternatives in the management of this patient’s postoperative pain?
11 Hypertension
A. Medical Disease and Differential Diagnosis

A.1. Define hypertension and categorize its severity.
A.2. What is the prevalence of hypertension?
A.3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.
Etiology of Hypertension
A.4. What are the clinical patterns of hypertension encountered?
A.5. What is the pathophysiology of essential hypertension?
A.6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?
A.7. What are the end-organ damages caused by long-standing hypertension?
Cardiac Involvement
Eye Involvement
Renal Involvement
Cerebral Involvement
A.8. Are hypertensive patients at an increased risk for perioperative cardiac morbidity?
A.9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?
A.10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?
A.11. What are the BP goals for patients with hypertension and when should antihypertensive drugs be initiated?
A.12. What is the mechanism of action of antihypertensive drugs?
Diuretics
Antiadrenergic Agents
Direct Vasodilators
Dopaminergic Agonists
Calcium Channel Blockers
Angiotensin-Converting Enzyme Inhibitors
Angiotensin II Receptor Blockers
Other Vasodilators
A.13. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?
A.14. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

B. Preoperative Evaluation and Preparation
B.1. How would you evaluate this patient preoperatively?
B.2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?
B.3. Should all or any of the chronic medications be discontinued before the operation?
B.4. Should hypokalemia be treated before anesthesia? Why?
B.5. Should hypomagnesemia be treated before anesthesia? Why?
B.6. Does an asymptomatic carotid bruit increase the risk in these patients?
B.7. The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mmHg and potassium 4.0 mEq per L. How would you premedicate this patient?
B.8. If the patient is an untreated hypertensive patient with BP 170/70 mmHg, would you treat the patient preoperatively with an antihypertensive agent?
C. Intraoperative Management
C.1. How would you monitor this patient?
C.2. What are the anesthetic goals for hypertensive patients?
C.3. How would you induce anesthesia for the hypertensive patient?
C.4. How does tracheal intubation produce hypertension?
C.5. What happens to the left ventricular ejection fraction during and immediately following intubation?
C.6. What other measures can prevent hypertension and tachycardia at the time of intubation?
C.7. After induction and intubation, the BP decreased to 70/40 mmHg. What would you do?
C.8. What is your choice of agents for maintenance of anesthesia? Why?
C.9. How would you manage fluid therapy for hypertensive patients?
C.10. During the surgery, BP increased to 220/120 mmHg. How would you treat the hypertension?
C.11. What could you do to prevent hypertension during extubation and emergence?

C.12. Would you consider regional anesthesia for this patient?
D. Postoperative Management
D.1. The patient developed hypertension, BP 210/110 mmHg, in the postanesthesia care unit. What would you do?
12 Cardiac Tamponade
A. Medical Disease and Differential Diagnosis
A.1. What is the differential diagnosis of low CO following cardiac surgery?
A.2. Describe the pathophysiology of cardiac tamponade.
A.3. What are the common etiologies of cardiac tamponade?
A.4. What is the difference between acute and delayed cardiac tamponade?
A.5. What is regional cardiac tamponade?
A.6. Describe the ventricular interaction in cardiac tamponade.
A.7. How is coronary blood flow affected in cardiac tamponade?
A.8. What is the Beck triad? Describe the typical signs and symptoms of cardiac tamponade.
A.9. Define pulsus paradoxus and describe its pathophysiology.
A.10. What is Kussmaul sign? Is this finding consistent with tamponade physiology?
A.11. Which medical conditions mimic cardiac tamponade?
B. Preoperative Evaluation and Preparation
B.1. Interpret and explain the pathophysiologic basis for this patient's hemodynamic findings.
B.2. How would you optimize this patient's cardiovascular status prior to definitive diagnosis and treatment?
B.3. What are the radiographic findings in tamponade?
B.4. A limited bedside transthoracic echocardiogram is performed, demonstrating a layer of clotted blood anterior to the right atrium (RA) and ventricle. What echocardiographic findings support the diagnosis of tamponade?
B.5. What additional information should be obtained from a limited echocardiographic study?
B.6. Describe the procedures for treating cardiac tamponade. What are the clinical indications for each approach?
B.7. Having made the diagnosis of tamponade, what additional investigations are required prior to surgery?

B.8. Explain the technical and physiologic principles behind rotational thromboelastometry.
B.9. A rotational thromboelastometry was performed, and a 10-minute analysis reveals the following results (see Fig. 12.9 and Table 12.8). How do you interpret this information?
B.10. Given the ROTEM® findings and high clinical suspicion for occult postsurgical bleeding, what hemostatic products would you arrange to have in the operating room?
B.11. How would you organize and conduct the transport of this patient to the operating room?
C. Intraoperative Management
C.1. What are the cardiovascular effects of commonly used intravenous anesthetic and coinduction agents?
Propofol
Etomidate
Ketamine
Thiopental
Fentanyl
Midazolam
C.2. What is the effect of supine positioning and positive pressure ventilation on the hemodynamics of a patient with tamponade?
C.3. Describe the induction process for cardiac tamponade.
C.4. Following induction and intubation, the systemic blood pressure decreases to 55/30 mmHg. Describe your management.
C.5. What hemodynamic changes are frequently associated with opening the pericardial space?
C.6. Following the removal of approximately 500 mL of dark blood and clots from the mediastinum, the patient's CO remains low. What are your differential diagnoses?
C.7. What is pericardial decompression syndrome (PDS)?
D. Postoperative Management
D.1. A pericardial drain is placed following mediastinal decompression. How should this drainage tube be managed?
D.2. How would you manage hypertension in the intensive care unit?
13 Heart Transplantation and Subsequent Noncardiac Surgery
A. Medical Disease and Differential Diagnosis

A.1. What are the common diagnoses requiring adult heart transplantation?
A.2. What are the indications and relative contraindications for recipient selection?
A.3. What are the criteria for donor heart selection?
A.4. What is the role of donation after cardiac death (DCD) for heart transplantation?
A.5. What are the principles of perioperative donor management?
A.6. What are the risk factors associated with posttransplant mortality?
A.7. What is the difference between the biatrial and bicaval surgical techniques of heart transplant?
A.8. When is a combined heart/lung transplant indicated? What are the important differences?
A.9. What are the medical and surgical alternatives to cardiac transplantation?
A.10. What is the role of ventricular assist devices (VADs) in this type of patient?
A.11. What are the considerations in anesthetizing patients for LVAD insertion?
B. Preoperative Management
B.1. How would you assess this patient preoperatively?
B.2. How would you premedicate this patient? Why?
C. Intraoperative Management
C.1. What anesthetic equipment and monitors would you set up? Why?
C.2. What is the role of transesophageal echocardiography (TEE)?
C.3. Describe the induction and maintenance of anesthesia.
C.4. How would you manage this patient during cardiopulmonary bypass (CPB)?
D. Postoperative Management
D.1. What are the early postoperative complications?
D.2. What are the mechanisms of early right ventricular (RV) failure?
D.3. How would you treat RV failure following heart transplantation?
D.4. How does inhaled nitric oxide (NO) work as a selective

pulmonary vasodilator?
D.5. What is the pathophysiology of the denervated heart?
D.6. What are the common cardiac dysrhythmias following heart transplant?
D.7. What are the causes of posttransplant bleeding?
D.8. How would you treat posttransplant bleeding?
D.9. What are the causes of early graft failure?
D.10. How would you manage this patient in the intensive care unit?
E. Subsequent Noncardiac Surgery
E.1. How would you monitor this patient?
E.2. What type of anesthetic is best for the heart-transplanted patient?
E.3. What anesthetic technique would you choose for this patient?
E.4. Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle relaxant in heart-transplanted patients?
E.5. What are the anesthetic implications for heart-transplanted patients?
E.6. What is the significant implication of the denervated heart?
E.7. What is the significance of allograft rejection?
E.8. What is the significance of infection in these patients?
E.9. What are the significant implications of drug interactions?
E.10. What is cardiac allograft vasculopathy (CAV)? Why is this important?
E.11. What is the significant implication of posttransplant hypertension?
E.12. What is the significant implication of renal dysfunction?
E.13. What types of malignancy are found in recipients?
E.14. Is ambulatory surgery appropriate for heart transplant recipients?
14 Ischemic Heart Disease and Noncardiac Surgery
A. Medical Disease and Differential Diagnosis
A.1. What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?
A.2. What are the determinants of myocardial oxygen demand? How are they measured clinically?

A.3. What factors determine myocardial oxygen supply?
A.4. What is the mechanism of perioperative myocardial ischemia and MI?
A.5. What is the incidence of perioperative reinfarction for noncardiac surgery?
A.6. State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.
β-Adrenergic Antagonists (Esmolol, Atenolol, Metoprolol, Bisoprolol)
α_2-Adrenergic Agonist (Clonidine)
Nitrovasodilators (Nitroglycerin, Isosorbide Dinitrate)
Calcium Channel Blockers (Verapamil, Diltiazem, Nifedipine, Nicardipine)
Aspirin
Statins
A.7. Based on his MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?
A.8. Would you recommend that this elective colectomy be postponed if the patient underwent placement of a right coronary artery, second-generation DES, and is taking aspirin and clopidogrel (Plavix)?
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?
B.2. Would you recommend further cardiac testing or coronary revascularization before surgery?
B.3. How would you classify the cardiac risk according to the type of surgery?
B.4. What is the role of exercise or pharmacologic stress test for this patient?
B.5. Would you discontinue any medication before surgery?
B.6. How would you premedicate this patient?
B.7. Is there a role for α_2-agonist in premedication?
C. Intraoperative Management
C.1. What are the intraoperative predictors for perioperative MACE?
Intraoperative Predictors

C.2. How would you monitor the patient in the operating room?
C.3. What electrocardiogram (ECG) leads would you monitor? Why lead V_5?
C.4. Would you use a pulmonary artery catheter (PAC)?
C.5. Would you use transesophageal echocardiography (TEE) as a monitor?
C.6. Is regional anesthesia better than general anesthesia for patients with cardiac disease?
C.7. How will you induce general anesthesia?
C.8. Would you induce anesthesia with etomidate? Why?
C.9. What is the best choice of anesthetic agents for maintenance of anesthesia? Why?
C.10. You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?
C.11. Would you give prophylactic intravenous NTG to prevent myocardial ischemia?
C.12. What is the significance of tight control of the heart rate intraoperatively?
C.13. When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?
D. Postoperative Management
D.1. What are the postoperative predictors of perioperative MACE?
D.2. How would you control postoperative pain?
D.3. Is postoperative anemia associated with adverse cardiac outcome?
D.4. Is postoperative hypothermia associated with postoperative myocardial ischemia?
D.5. How would you make a diagnosis of perioperative MI (PMI)?
D.6. How would you manage the patient with a suspected PMI?
SECTION 3 The Gastrointestinal System
15 Intestinal Obstruction and Enhanced Recovery after Surgery
A. Medical Disease and Differential Diagnosis
A.1. What is the differential diagnosis of the acute abdomen?
A.2. What are the causes of intestinal obstruction of the small bowel and of the large bowel?
A.3. Differentiate between simple and strangulated bowel

obstruction.
A.4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why? How might the distinction be made?
A.5. What are the causes and effects of bowel distention?
A.6. Describe the fluid shifts during small bowel intestinal obstruction.
A.7. Discuss the systemic derangements that occur with intestinal obstruction.
A.8. What is an ileus? Discuss its causes and pathophysiology.
B. Preoperative Evaluation and Preparation
B.1. What is Enhanced Recovery after Surgery (ERAS)? What are the core tenants of these programs?
B.2. Can ERAS be used in this case?
B.3. What components of ERAS are applied in the preoperative phase of the care of colorectal surgery (CRS) patients?
B.4. Is it important to decompress the abdomen before induction of anesthesia? Why?
B.5. Describe the respiratory implications.
B.6. What are the implications of the tense abdominal wall?
B.7. Outline the methods of abdominal decompression.
B.8. Discuss the goals of fluid management.
B.9. What would you use as a guide to fluid volume replacement?
C. Intraoperative Management
C.1. What dangers are present during induction? How are they planned for?
C.2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?
C.3. In what position would you intubate this patient?
C.4. What is the best muscle relaxant to use for the rapid sequence induction?
C.5. Would you remove or leave the nasogastric tube (NGT) in place before inducing anesthesia?
C.6. Would you use nitrous oxide in this patient?
C.7. Are there any benefits to using a high concentration of inspired oxygen (FIO_2)?

C.8. What components of ERAS are applied in the intraoperative phase of the care of CRS patients?
C.9. What are the strengths, weaknesses, benefits, and challenges of ERAS?
Strengths
Weakness
Benefits
Challenges
C.10. What are the indications for ERAS?
D. Postoperative Management
D.1. What are the principles of postoperative care in this patient?
D.2. Are there any postoperative respiratory problems associated with factors other than aspiration?
D.3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?
D.4. What is gram-negative sepsis? Describe the clinical picture and treatment.
D.5. What components of ERAS are applied in the postoperative phase of the care of CRS patients?
16 Liver Transplantation
A. Medical Disease and Differential Diagnosis
A.1. What are the potential graft options for liver transplantation?
A.2. What are the indications and contraindications for liver transplantation?
A.3. What is acute liver failure (ALF)?
A.4. What is the MELD score, and how is it used in liver transplantation evaluation?
A.5. What is portal hypertension? What are the sequelae of portal hypertension?
A.6. Describe the cardiovascular system of patients with end-stage liver disease (ESLD).
A.7. What causes acute kidney injury (AKI) in patients with cirrhosis?
A.8. What causes hyponatremia in patients with cirrhosis?
A.9. Discuss the neurologic manifestations of acute and chronic liver disease.
A.10. Why do patients with ESLD have abnormalities of

hemostasis?
A.11. What is the differential diagnosis for hypoxemia in patients with cirrhosis?
A.12. What are the risk factors and treatment guidelines for spontaneous bacterial peritonitis (SBP)?
B. Preoperative Evaluation and Preparation
B.1. What preoperative workup is desirable?
B.2. How is ascites managed preoperatively?
B.3. How is hyponatremia managed preoperatively?
B.4. What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?
B.5. How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?
B.6. Should this patient be transfused with fresh frozen plasma prior to surgery?
C. Intraoperative Management
C.1. What monitors would you use? Why?
C.2. What are the considerations for the induction of anesthesia?
C.3. How does liver disease affect intraoperative medication management?
C.4. What happens during the first stage (preanhepatic phase) of the liver transplant operation?
C.5. What happens during the second stage (anhepatic phase) of the liver transplant operation?
C.6. What physiologic disturbances should be anticipated during the second stage (anhepatic phase) of the liver transplant operation?
C.7. What is venovenous bypass? What are the potential advantages and disadvantages of this procedure?
C.8. What surgical techniques anastomose the donor and recipient inferior vena cava (IVC)?
C.9. What are the potential advantages of the “piggyback” (vena cava preservation) technique?
C.10. What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome (PRS)?
C.11. How would you treat hyperkalemia?
C.12. Why should you anticipate hypocalcemia?

C.13. What happens during the third stage of the liver transplant operation?
C.14. What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What are thromboelastography (TEG) and rotational thromboelastography (ROTEM)?
C.15. What are the complications of massive transfusion?
C.16. How are the complications of massive transfusion prevented?
C.17. How is hyperfibrinolysis managed?
C.18. When is intraoperative renal replacement therapy indicated?
C.19. What intraoperative signs suggest that the hepatic graft is working?
D. Postoperative Management
D.1. What are the goals of immediate postoperative care of the liver transplant patient?
D.2. What postoperative findings suggest that the hepatic graft is functioning?
D.3. What coagulation disturbances should be anticipated in the postoperative period?
D.4. Can renal function change after liver transplantation?
D.5. What vascular and biliary complications occur after liver transplantation?
D.6. What immunosuppressive agents will be given after liver transplantation? What are the major side effects?
Acknowledgment
SECTION 4 The Nervous System
17 Brain Tumor and Craniotomy
A. Medical Disease and Differential Diagnosis
A.1. What is the pathology of intracranial tumors?
A.2. What is intracranial pressure (ICP), and what are its determinants?
A.3. How does the presence of a mass alter the ICP in this patient, and what are the clinical manifestations of these alterations?
A.4. What is cerebral blood flow (CBF), and what are its determinants?
A.5. What are the cerebral steal syndromes?
A.6. Are there any issues specific to posterior cranial fossa

pathology?
A.7. What is the role of preoperative embolization therapy?
B. Preoperative Evaluation and Preparation
B.1. What are the special considerations in preoperative evaluation of the patient scheduled for posterior fossa craniotomy?
B.2. In a patient who presents with intracranial hypertension, what management might have already been initiated preoperatively, and what are the implications for anesthetic management?
B.3. What are the types of intraoperative neurophysiologic monitoring (IOM) that would likely be used for this procedure, and how will they affect the anesthetic management plan?
B.4. What are the options for patient positioning during posterior fossa surgery?
B.5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?
B.6. How does the sitting position affect your preoperative assessment and planning?
B.7. How should the patient position ultimately be determined?
B.8. Should this patient receive premedication?
C. Intraoperative Management
C.1. What are the anesthetic goals for craniotomy?
C.2. What monitors should be used during craniotomy?
C.3. Would you monitor for venous air embolism (VAE)? What are the monitoring options?
C.4. What specific risks are associated with induction of anesthesia?
C.5. How would you induce anesthesia?
C.6. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRO_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?
Volatile Anesthetics
Nitrous Oxide
Intravenous Anesthetics
Opioids
C.7. How would you manage ventilation and maintain arterial carbon dioxide (CO_2)?
C.8. How would you approach diuretic therapy?

C.9. How would you manage serum glucose?
C.10. How would you approach fluid management?
C.11. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still “tight.” What would be your response?
C.12. If deliberate hypotension is indicated, how will you achieve it?
C.13. While the surgeon is resecting tumor from near the brainstem, the patient’s heart rate suddenly drops to 20 beats per minute. What is your assessment and management?
C.14. Are there any measures you can take to prevent VAE?
C.15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($EtCO_2$) drops from 31 to 13 mmHg, and the systemic pressure from 121/63 to 64/32 mmHg. What is your assessment and management plan?
C.16. What is your approach to emergence? What if the patient does not regain consciousness?
D. Postoperative Management
D.1. What postoperative complications are of greatest concern? What level of monitoring is required?
D.2. What is your approach to postoperative pain control?
D.3. In the ICU, the patient’s neurologic status deteriorates and ICP monitoring is instituted. What are the different methods of monitoring ICP, and what are their limitations?
18 Carotid Artery Disease
A. Medical Disease and Differential Diagnosis
A.1. What are the presenting symptoms of carotid stenosis?
A.2. What is the prevalence of carotid artery disease?
A.3. What is the natural course of carotid artery disease as it relates to stroke?
A.4. What in the patient’s history puts them at higher risk for having carotid atherosclerosis?
A.5. Do we screen patients for asymptomatic carotid stenosis?
A.6. What is the risk of stroke and cardiovascular events in asymptomatic carotid atherosclerosis?
A.7. What are the current medical options that the patient has for treating carotid atherosclerosis?

A.8. What are the indications for CEA and carotid artery stenting (CAS) in asymptomatic carotid atherosclerotic disease?
A.9. What are the indications for performing a CEA in symptomatic carotid stenosis?
A.10. Is there any role for CAS in symptomatic patients?
A.11. Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.
A.12. Discuss cerebral blood flow (CBF) in the presence of carotid artery disease.
A.13. Discuss the different surgical approaches to carotid revascularization.
A.14. Discuss the endovascular approaches to carotid stenting.
A.15. What is normal CBF?
A.16. What is critically low CBF as measured by the electroencephalogram (EEG)?
A.17. What is cerebral autoregulation?
A.18. How does $PaCO_2$ affect CBF?
A.19. What are the principal determinants of CBF?
A.20. What is meant by the term luxury perfusion?
A.21. What is meant by the term intracerebral steal?
B. Preoperative Evaluation and Preparation
B.1. What will you look for in your preoperative evaluation of this patient?
B.2. Is this patient's blood pressure too high for elective surgery?
B.3. What laboratory data are required preoperatively?
B.4. Will you treat this patients' blood glucose?
B.5. Will you premedicate this patient?
C. Intraoperative Management
C.1. How will you monitor this patient?
C.2. How will you know that the patient's cerebral perfusion is adequate during surgery?
C.3. Discuss the differences and relative advantages and disadvantages of unprocessed EEG and processed EEG monitoring.
C.4. How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique?
C.5. Describe the use of stump pressure and its limitations.
C.6. Describe the use of transcranial Doppler (TCD) and its

limitations.
C.7. Describe the use of jugular venous oxygen saturation ($SjvO_2$) and its limitations.
C.8. Describe the use of cerebral oximetry and its limitations.
C.9. Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during CEA.
C.10. What type of anesthesia will you choose for this patient if she chose to have an endarterectomy?
C.11. What type of anesthesia will you choose for this patient if she chose to have a carotid stent?
C.12. How will you induce and maintain general anesthesia in this patient for CEA?
C.13. How would you proceed if the patient were to receive regional anesthesia?
C.14. Discuss the effects of anesthetics on CBF.
C.15. Discuss the protective effects of anesthetic agents on cerebral function.
C.16. How will you manage this patient's ventilation under general anesthesia?
C.17. How will you manage this patient's blood pressure intraoperatively?
C.18. Discuss reperfusion injury following CEA and CAS.
C.19. What intravenous fluids will you give this patient intraoperatively?
D. Postoperative Management
D.1. The patient does not "wake up" from general anesthesia. Why?
D.2. Postoperatively, the patient's blood pressure is 170/96 mmHg. Will you treat this?
D.3. What immediate postoperative complications might you expect after a CEA?
D.4. What postoperative complications might you expect after a CAS?
D.5. Discuss postoperative neurocognitive dysfunction following uncomplicated carotid intervention.
19 Awake Craniotomy for Mapping and Surgery in the Eloquent Cortex

A. Medical Disease and Differential Diagnosis
A.1. What is the eloquent cortex?
A.2. What is the underlying pathology?
A.3. What determines intracranial pressure (ICP)?
A.4. How does a space-occupying mass alter ICP?
A.5. What is autoregulation, and why is it important?
A.6. How is cerebral blood flow (CBF) regulated?
A.7. What drug therapies may be associated with this pathology?
B. Preoperative Evaluation and Preparation
B.1. Why is the craniotomy performed awake?
B.2. What neurologic symptoms of the patient are important?
B.3. What is the status of their other comorbid conditions?
B.4. Are there anesthetic implications from current treatment drugs?
B.5. What laboratory data are required?
B.6. What radiology data should be reviewed?
B.7. How do you prepare the patient for an awake craniotomy?
B.8. Should this patient receive premedications?
B.9. What precautions should be made for airway management?
C. Intraoperative Management
C.1. How should this patient be monitored?
C.2. Does this patient require invasive monitoring?
C.3. Can current drug therapy alter eloquent cortex mapping?
C.4. Why use hypertonic fluids during a craniotomy?
C.5. What intravenous fluids (IVFs) are recommended?
C.6. Would a lumbar drain for cerebrospinal fluid (CSF) removal benefit this patient?
C.7. Venous air embolism (VAE): Is it a concern in this case?
C.8. How is the eloquent cortex mapped?
C.9. How are intraoperative seizures treated?
C.10. How will you conduct this anesthetic?
D. Postoperative Management
D.1. What are the major concerns following craniotomy?
Acknowledgments
20 Head Injury
A. Pathophysiology and Differential Diagnosis
A.1. What types of intracranial injuries are most likely to have

occurred in this patient?
A.2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?
A.3. What are the benefits and risks of administering mannitol?
Benefits
Risks
A.4. What is the effect of hyperglycemia on neurologic outcome following head trauma?
A.5. What alterations in sodium and potassium balance can occur in patients with head injury?
A.6. In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?
A.7. What are the neuroprotective effects of administering magnesium (Mg)?
A.8. What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?
A.9. What is the role of decompressive craniectomy (DC) as a treatment option for ICP control after head injury?
A.10. Do genetic factors play a role in the outcome after head injury?
B. Preoperative Evaluation and Preparation
B.1. What is the GCS? What is the significance of a GCS of 7T in this patient?
B.2. In addition to the GCS, what other assessments can be done to evaluate neurologic function?
B.3. What is the role of CT scanning in the initial evaluation of the patient with head injury? What are the management options in patients whose neurologic condition is deteriorating before obtaining a CT scan?
B.4. What is the role of ICP monitoring in the management of head injury?
B.5. How can you clear this patient's cervical spine?
B.6. What are the advantages of early endotracheal intubation in this patient?
B.7. What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling

of the head and neck?
B.8. What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?
B.9. What coagulation abnormalities are present after TBI? What modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?
C. Intraoperative Management
C.1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?
C.2. Should hyperventilation be used in this patient?
C.3. What are the implications of arterial hypertension in patients with head injury? How should BP be managed?
C.4. What should be done about intravenous (IV) fluid replacement? Should corticosteroids be given empirically?
C.5. Should hypertonic saline (HTS) be administered to this patient? How is HTS administered?
C.6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?
C.7. Should hypothermia be employed in this patient?
D. Postoperative Neurointensive Care Management
D.1. What are the postoperative ventilation concerns in this patient?
D.2. What specific measure should be used to control the patient's ICP? What type of monitoring devices can be used to measure ICP?
D.3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?
D.4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?
D.5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?
D.6. What methods can be used in the neurointensive care unit to prevent hyperthermia?
21 Cerebral Aneurysm
A. Medical Disease and Differential Diagnosis

A.1. What are the incidence, prevalence, and causes of subarachnoid hemorrhage (SAH), and what are the risk factors associated with rupture of intracranial aneurysms?
A.2. What are common sizes and locations of intracranial aneurysms?
A.3. What is the pathophysiology of aneurysmal rupture and SAH?
A.4. What are symptoms and signs of SAH?
A.5. How does one assess the severity of SAH?
A.6. What are the cardiovascular effects of SAH?
A.7. How is the diagnosis of SAH made?
A.8. What is the risk for rebleeding for a patient with SAH?
B. Preoperative Evaluation and Preparation
B.1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to be followed immediately with coiling of an aneurysm?
B.2. What type of anesthesia is required for coiling of an aneurysm?
B.3. Should one proceed with induction of general anesthesia under these circumstances?
B.4. What types of emergencies can occur during coiling of an aneurysm, and how should they be managed?
B.5. What other modalities of endovascular therapy are available?
B.6. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated troponin and CPK-MB fractions?
B.7. Would you premedicate this patient before craniotomy?
C. Intraoperative Management
C.1. What are the goals of the induction and maintenance of anesthesia for this patient?
C.2. Is placement of an arterial catheter necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?
C.3. How would you assess fluid status in this patient?
C.4. Would monitoring central venous pressure (CVP) be useful for craniotomy and aneurysm clipping in this patient?
C.5. What other forms of monitoring would you consider?
C.6. What are your specific concerns during induction of anesthesia in this patient?

C.7. How would you accomplish a smooth and safe induction and intubation in this patient?
C.8. Would you perform a rapid sequence induction and tracheal intubation for this patient?
C.9. What are the effects of hypoxemia and hypercapnia, such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?
C.10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?
C.11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was “tight.” What could you do to achieve better brain relaxation and facilitate surgical exposure?
C.12. How might transmural pressure be decreased to allow for aneurysm clip placement?
C.13. What is the purpose of controlled hypotension, and how is it achieved?
C.14. What are some of the drawbacks of controlled hypotension?
C.15. What methods of cerebral protection might you use during this operation?
C.16. Would you induce mild hypothermia as a means of cerebral protection?
C.17. What are the indications for deep hypothermic circulatory arrest?
C.18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?
C.19. How would you plan the emergence from an anesthetic for aneurysm clipping?
D. Postoperative Management
D.1. Would you extubate the patient postoperatively?
D.2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?
D.3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?
D.4. What is cerebral vasospasm, and what causes it?

D.5. What are pathophysiologic changes seen in cerebral vasospasm?
D.6. How is the diagnosis of cerebral vasospasm made?
D.7. What steps can be taken to prevent cerebral vasospasm?
D.8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?
D.9. What are other neurologic complications following SAH and aneurysm clipping?
D.10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?
SECTION 5 The Endocrine System
22 Pheochromocytoma
A. Medical Disease and Differential Diagnosis
A.1. What are some common differential diagnoses for arterial hypertension?
A.2. What is a pheochromocytoma?
A.3. Describe the anatomy of the adrenal gland.
A.4. What substances does the adrenal medulla secrete?
A.5. What are the mechanisms of action of epinephrine and norepinephrine?
A.6. What is the pathway for synthesis and breakdown of catecholamines?
A.7. What does the adrenal cortex secrete?
A.8. What are the metabolic actions of the glucocorticoids and the mineralocorticoids?
A.9. What are the clinical features associated with a pheochromocytoma?
A.10. What is the prevalence of pheochromocytomas and paragangliomas?
B. Preoperative Evaluation and Preparation
B.1. How can you diagnose and localize the tumor preoperatively?
B.2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?
B.3. What other aspects of preoperative management are important?
C. Intraoperative Management
C.1. What drugs should be avoided during the operation?

C.2. How would you monitor this patient?
C.3. Describe the anesthetic management of the patient with pheochromocytoma.
C.4. What drugs are used to control the effects of catecholamine stimulation during surgery?
C.5. What are some management concerns after the tumor is removed?
C.6. What are some of the concerns with laparoscopic adrenalectomy?
D. Postoperative Management
D.1. What is the significance of postoperative hypotension? How is it treated?
D.2. What other problems can arise in the postoperative period?
23 Diabetes Mellitus
A. Medical Disease and Differential Diagnosis
A.1. What is the epidemiology of DM in the general population?
A.2. What are the factors in the etiology of the disease?
A.3. How is DM classified?
A.4. What are the complications of DM?
A.5. How are the different forms of this illness treated?
A.6. How is control of the disease adequately monitored?
A.7. What are some of the factors that alter insulin requirements?
A.8. What are the principles of management of diabetic ketoacidosis (DKA)?
A.9. What is a hyperglycemic hyperosmolar state?
B. Preoperative Evaluation and Preparation
B.1. How should this patient be evaluated?
B.2. How would the stiff joint syndrome affect her airway management?
B.3. What are the signs and implications of autonomic neuropathy in the diabetic patient?
B.4. How should this patient be prepared for anesthesia and surgery?
B.5. For elective surgery, how are insulin and glucose requirements managed on the day of surgery?
B.6. How should this patient be premedicated?
C. Intraoperative Management

C.1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?
C.2. What anesthetic techniques should be considered?
C.3. How should this patient be monitored?
C.4. How is hyperglycemia treated intraoperatively?
C.5. How is hypoglycemic shock recognized and treated intraoperatively?
D. Postoperative Management
D.1. How is diabetes controlled in this patient postoperatively?
D.2. Does diabetes increase perioperative risk?
D.3. What are the common postoperative complications to be expected in a diabetic patient?
D.4. Is it necessary to achieve tight perioperative control of glucose?
SECTION 6 The Genitourinary System
24 Transurethral Resection of the Prostate and Geriatric Anesthesia
A. Medical Disease and Differential Diagnosis
A.1. What comorbidities are common in patients undergoing TURP?
A.2. What are the normal physiologic consequences of aging for the various organ systems?
A.3. How should drug dosages be adjusted for elderly patients? Should any particular medications be avoided?
A.4. Does a history of prior MI increase the patient's risk of perioperative reinfarction or stent thrombosis?
A.5. In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period?
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate the patient's cardiac condition? Does he need additional testing?
B.2. Would you discontinue any antihypertensives or any medications for angina?
B.3. For a patient with a cardiac implantable electronic device (CIED), what information should you know? What precautions should be taken?
B.4. What types of coronary stents are available? What is their perioperative relevance?

B.5. What is the conventional recommendation for dual antiplatelet therapy (DAPT) in a patient with previous percutaneous coronary intervention (PCI) undergoing elective noncardiac surgery?
B.6. What risk is associated with continuing perioperative antiplatelet therapy? What risk is there with stopping it?
B.7. How should patients with coronary stents undergoing noncardiac surgery be managed?
C. Intraoperative Management
C.1. What monitors would you use for this patient?
C.2. Is there a preferred anesthetic technique for patients undergoing TURP, and why?
C.3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia?
C.4. What intravenous fluid would you use during TURP?
C.5. Forty minutes after a sensory level of T10 was established with intrathecal anesthesia, and monopolar TURP (M-TURP) resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic is administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, and pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar (B-TURP) or laser TURP (L-TURP) resection?
C.6. What are the important characteristics of irrigation solutions used during TURP?
C.7. What is the effect on body temperature of continuous bladder irrigation during TURP?
C.8. What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?
Cardiopulmonary
Hematologic and Renal
Central Nervous System
C.9. How does the patient absorb irrigation solution during TURP?
C.10. What factors increase the incidence of TURP syndrome?
C.11. What is the effect on cardiopulmonary, renal, and central

nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?
C.12. What causes CNS dysfunction in patients who have undergone M-TURP?
C.13. How does acute hyponatremia affect the cardiovascular system?
C.14. What prophylactic measures may reduce the incidence of TURP syndrome?
C.15. What therapeutic measures are recommended for patients with TURP syndrome?
C.16. Is hypertonic saline administration necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?
C.17. What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic by-products of glycine?
C.18. What are the symptoms and clinical course of TURP-induced hyperammonemia?
C.19. What are the clinical characteristics, causes, and prognosis of TURP-related blindness?
C.20. What are the causes of excessive bleeding during TURP?
C.21. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?
C.22. What are the causes of hypotension during TURP?
D. Postoperative Management
D.1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?
D.2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?
D.3. Is postoperative hypothermia a risk factor for myocardial ischemia?
D.4. What is postoperative cognitive dysfunction (POCD)? How does this differ from delirium, and what is the time course to resolution?
D.5. What are the mechanisms and risk factors for POCD? How would you mitigate the risk of POCD? Does anesthesia type influence development of POCD?

E. Comparing M-TURP, B-TURP, and L-TURP
E.1. What differentiates M-TURP from B-TURP?
E.2. Are decreased morbidity and mortality associated more closely with M-TURP or with B-TURP?
E.3. What differentiates the technologies for L-TURP?
25 Kidney Transplant
A. Medical Disease and Differential Diagnosis
A.1. What are the causes of chronic renal disease that can progress to renal failure?
A.2. How is chronic kidney disease (CKD) diagnosed?
A.3. What are the indications for dialysis?
A.4. What are the common clinical manifestations of ESRD?
A.5. What electrolyte imbalances occur in patients with impaired renal function, and how are they treated?
A.6. How is metabolic acidosis managed in chronic renal failure?
A.7. Are patients with renal disease at increased risk of cardiovascular disease?
A.8. When is the best time to receive a kidney transplant?
A.9. How are immunosuppressive drugs managed in kidney transplant recipients?
A.10. How are kidneys allocated to recipients on the waiting list in the United States?
A.11. What is donation after cardiac death (DCD)?
A.12. What is a living donor transplant program?
A.13. What is a paired donor exchange transplant program?
A.14. What are some barriers to receiving a kidney transplant?
A.15. What surgical techniques are available for donor nephrectomy (DN)?
A.16. How is a donor kidney preserved?
A.17. Describe the operative procedure of kidney transplantation.
B. Preoperative Evaluation and Preparation
B.1. What preoperative workup would you order for a recipient?
B.2. How does the presence of obesity affect the outcome of a transplanted kidney?
B.3. How are routine medications and immunosuppressive medications managed in the perioperative period?
C. Intraoperative Management

C.1. Are a central venous pressure (CVP) monitoring line, an arterial line, and a pulmonary artery catheter required for the transplant procedure?
C.2. What type of intravenous fluid should be used during surgery?
C.3. How would you conduct the anesthesia induction?
C.4. Is succinylcholine contraindicated in renal failure patients?
C.5. How are the nondepolarizing muscle relaxants affected by renal failure?
C.6. How would you maintain anesthesia during the case?
C.7. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration (GFR), and urine output?
C.8. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?
C.9. How does renal failure affect the pharmacology of opioids?
D. Postoperative Management
D.1. How is the diagnosis of transplant rejection made?
D.2. What are immunosuppressive agents, and how do they affect anesthetic care?
26 Robotic-Assisted Laparoscopic Surgery
A. Medical Disease and Differential Diagnosis
A.1. What is the incidence of carcinoma of the prostate?
A.2. How is prostate cancer diagnosed?
A.3. How is prostate cancer treated?
A.4. Define laparoscopy.
A.5. Describe the development of robotic-assisted laparoscopy.
A.6. What are the advantages and disadvantages of minimally invasive surgery over open surgery?
A.7. What are the contraindications to laparoscopic or robotic-assisted laparoscopic surgery? Is pregnancy a contraindication to robotic surgery?
A.8. What other specialties commonly perform robotic surgery?
A.9. Why is carbon dioxide (CO_2) the gas of choice for robotic laparoscopy? What are its disadvantages?
A.10. How much endogenous CO_2 is produced at basal level and at maximal exercise?
A.11. How much CO_2 is stored in the body? Where is it stored? Of

what significance is this to laparoscopy?
A.12. Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.
A.13. Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?
B. Preoperative Evaluation and Preparation
B.1. What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for robotic surgery?
B.2. What factors increase this patient's risk of pulmonary complications?
B.3. What laboratory tests should be performed preoperatively?
B.4. What specific information should the patient be given about robotic surgery before obtaining informed consent?
B.5. What additional procedures should be done before surgery?
B.6. What are the three major forces that uniquely alter the patient's physiology during robotic laparoscopy?
C. Intraoperative Management
C.1. What is the anesthetic technique of choice for robotic-assisted laparoscopy? Why?
C.2. Can a laryngeal mask airway (LMA) be used?
C.3. What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic agents contraindicated?
C.4. Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?
C.5. Can laparoscopy be performed under local or regional anesthesia?
C.6. What monitors and devices would you apply to the patient? Why?
C.7. How is the patient to be positioned? What special precautions are required for robotic laparoscopy?
C.8. How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?

Respiratory
Circulatory
C.9. What techniques are available for initial access to the peritoneal cavity? What anesthetic problems can arise during insufflation?
C.10. What intravenous (IV) solution and how much fluid volume do you plan to infuse?
C.11. Under what circumstances should laparoscopy be converted to laparotomy?
C.12. What is the arterial to end-tidal CO_2 gradient ($PaCO_2$–$EtCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?
C.13. Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $EtCO_2$ exceed the $PaCO_2$? Why?
C.14. What are the possible causes of hypercarbia?
C.15. What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?
C.16. How rapidly does the $PaCO_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $PaCO_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?
C.17. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the cardiovascular system?
C.18. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the respiratory system?
C.19. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the central nervous system?
C.20. What are the neuroendocrine changes that occur during laparoscopy?
C.21. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the renal system?
C.22. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the bowel and gastrointestinal system?
C.23. How would you recognize a CO_2 embolism during

laparoscopy? How does this differ from an air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of CO_2 emboli?
C.24. What is the mechanism of increase in shunting resulting from embolization?
C.25. How is a gas embolism (CO_2 or air) treated?
C.26. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?
C.27. How would you decide when to extubate?
D. Postoperative Management
D.1. What are some of the unique complications of laparoscopy?
Injuries from Instruments
Complications of Pneumoperitoneum
Systemic Effects of CO_2 Absorption
Trendelenburg Position
Late Complications
D.2. In the postanesthesia care unit (PACU), our patient complains of numbness and weakness of the lower extremities after 6 hours of anesthesia for robotic prostatectomy. What tests will you order?
When would you remove the Foley catheter and arterial line?
Under what circumstances would you order a chest x-ray film?
D.3. What is the incidence of postoperative nausea and vomiting?
SECTION 7 The Reproductive System
27 Placenta Previa/Placenta Accreta Spectrum
A. Medical Disease and Differential Diagnosis
A.1. What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?
A.2. What is the differential diagnosis for an antepartum hemorrhage?
A.3. How would you diagnose the etiology of antepartum bleeding after midpregnancy?
A.4. What is the incidence of placenta previa, and what are the associated conditions?
A.5. What are the different types of placenta previa?
A.6. What is the usual obstetric management for placenta previa?

A.7. What is vasa previa? How is it diagnosed and managed?
A.8. What are the risk factors for the development of a placental abruption?
A.9. How is placental abruption diagnosed and managed?
A.10. What complications are associated with placental abruption?
A.11. Who is at risk for uterine rupture, and how is uterine rupture diagnosed?
A.12. What is the treatment for uterine rupture?
A.13. Is this patient at risk for postpartum bleeding?
A.14. What is the placenta accreta spectrum (PAS)?
A.15. How is the PAS diagnosed?
A.16. How is the PAS managed obstetrically?
A.17. What tests and/or interventions can improve neonatal outcome of a preterm birth?
B. Preoperative Evaluation and Preparation
B.1. How does pregnancy change respiratory function, and what impact does this have on anesthetic care?
B.2. What are the maternal cardiovascular changes of pregnancy?
B.3. What are the maternal gastrointestinal changes of pregnancy?
B.4. What hematologic changes occur during pregnancy?
B.5. What laboratory data do you need before taking this patient to the operating room?
B.6. What preoperative medications would you administer to this patient?
C. Intraoperative Management
C.1. What monitors would you use for this patient?
C.2. What anesthetic could be used in this patient?
C.3. What are the absolute and relative contraindications for neuraxial anesthesia?
C.4. How is postpartum hemorrhage (PPH) defined, and what are the etiologies of this bleeding?
C.5. After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this patient’s bleeding?
C.6. After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial contractility and

therefore decrease blood loss?
C.7. When should this patient receive tranexamic acid (TXA)?
C.8. If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?
C.9. What laboratory tests should be ordered during the resuscitation of this patient?
C.10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?
C.11. What is the role of recombinant activated factor VII (rFVIIa) in the hemorrhaging obstetric patient?
C.12. What is the role of type O Rh-negative (universal donor) uncrossmatched blood in emergency transfusions, and how does this change your future management?
C.13. What complications can occur from the transfusion of blood products?
C.14. What is the role of autologous transfusion in obstetric patients?
C.15. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?
C.16. What is disseminated intravascular coagulation (DIC)?
C.17. Define amniotic fluid embolism (AFE) syndrome and discuss treatment.
D. Postoperative Management
D.1. If the patient received epidural anesthesia and subsequently developed DIC, when should the epidural catheter be removed?
D.2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?
28 Hypertensive Disorders of Pregnancy
A. Medical Disease and Differential Diagnosis
A.1. What is the classification of hypertension disorders in pregnancy as defined by the American College of Obstetricians and

Gynecologists?
A.2. What is preeclampsia?
A.3. What is preeclampsia with severe features?
A.4. What is eclampsia?
A.5. What is HELLP syndrome?
A.6. What are the risk factors for developing preeclampsia?
A.7. What is the mortality associated with preeclampsia?
A.8. Discuss the pathogenesis of preeclampsia.
Immunologic Factors
Genetic Factors
Endothelial Factors
Platelet Factors
Calcium
Coagulation Factors
Fatty Acid Metabolism
Markers of Angiogenesis
A.9. Discuss the pathologic alterations of preeclampsia.
Cardiovascular Changes
Hemodynamic Changes
Hematologic Changes
Renal Changes
Endocrine Changes
Respiratory Changes
Hepatic Changes
Neurologic Changes
Uteroplacental Perfusion
A.10. What are some of the complications associated with preeclampsia?
B. Preoperative Evaluation and Preparation
B.1. What initial laboratory studies are recommended for patients with preeclampsia?
B.2. Discuss bleeding time and platelet count evaluation during preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.
B.3. What types of monitoring are important for patients with preeclampsia? When is a central venous pressure (CVP) monitor indicated?

B.4. Discuss the obstetric management of preeclampsia with severe features.
B.5. What are the antihypertensive agents of choice for preeclampsia?
B.6. What drug therapy is the treatment of choice for seizure prophylaxis?
B.7. Discuss the mechanism of action of magnesium sulfate.
B.8. What are the fetal effects of magnesium sulfate therapy?
B.9. Discuss the treatment of magnesium sulfate toxicity.
B.10. What conditions mandate immediate delivery, regardless of the gestational age?
B.11. Discuss the management of eclampsia.
C. Intraoperative Management
C.1. What is your choice of labor analgesia for patients with preeclampsia?
C.2. What is the advantage of prehydration prior to initiation of neuraxial analgesia?
C.3. What sensory level of analgesia is required for labor and delivery?
C.4. Discuss the commonly used local anesthetics for labor analgesia.
C.5. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?
C.6. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after neuraxial analgesia is instituted?
C.7. What would you do after an accidental dural puncture? How do you treat postdural puncture headache?
C.8. How would you manage total spinal anesthesia?
C.9. Should methylergonovine be given to preeclamptic patients?
C.10. When and how would you give spinal anesthesia?
C.11. Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.
C.12. What agents can you use to prevent hypertension during the induction of general anesthesia for cesarean delivery?
D. Postoperative Management
D.1. Discuss the postpartum management of preeclamptic patients.

D.2. Can nonsteroidal anti-inflammatory drugs (NSAIDs) be used to treat postpartum pain in preeclamptic patients?
29 Breech Presentation, Fetal Distress, and Mitral Stenosis
A. Medical Disease and Differential Diagnosis
A.1. How are fetal lie, presentation, and position defined and determined?
A.2. What is the approximate frequency of the various lies and presentations at or near term?
A.3. What are the different types of breech presentation, and what is their incidence?
A.4. What is the cause of breech presentation?
A.5. What are the delivery problems associated with breech presentation?
A.6. What is the usual obstetrical management for patients with breech presentation?
A.7. What is the incidence of heart disease in pregnancy and the mortality rate associated with maternal cardiac disease?
A.8. How is peripartum cardiomyopathy defined?
A.9. What classifications help predict an individual pregnant woman’s cardiac risk?
A.10. What are the cardiovascular changes of pregnancy?
A.11. What changes normally occur in heart sounds during pregnancy?
A.12. What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?
A.13. What causes rheumatic heart disease?
A.14. What are the physiologic consequences of mitral stenosis?
A.15. What are the auscultatory findings associated with mitral stenosis?
A.16. What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?
A.17. What are the echocardiographic findings associated with mitral stenosis?
A.18. What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?
A.19. If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?

A.20. What are the determinants of fetal oxygenation?
A.21. What are the determinants of uterine blood flow?
B. Preoperative Evaluation and Preparation
B.1. How is fetal well-being assessed during labor?
B.2. How are FHR and maternal contractions monitored?
B.3. What is the normal FHR with beat-to-beat variability?
B.4. What are FHR decelerations?
B.5. How accurate is FHR monitoring in predicting fetal well-being?
B.6. In a fetus with minimal FHR variability, what other modalities can be used to assess fetal well-being?
B.7. What is the significance of meconium-stained amniotic fluid?
B.8. What is meconium aspiration syndrome?
B.9. What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?
B.10. What preoperative medications, if any, would you give this patient?
C. Intraoperative Management
C.1. What monitors would you use in this functional New York Heart Association (NYHA) class II patient during her cesarean section?
C.2. When would you use invasive monitoring in a pregnant patient with cardiac disease?
C.3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?
C.4. What anesthetic technique would you use for this emergency cesarean section?
C.5. How would you manage local anesthetic systemic toxicity (LAST) in this patient?
C.6. If cardiac arrest were to occur prior to delivery, how would you proceed?
C.7. What technique could you use for general anesthesia in this patient?
C.8. If you are unexpectedly unable to intubate this patient, how would you manage the airway?
C.9. Would this patient benefit from the use of β-blockers?
C.10. What is the effect of the inhalation agents on uterine

contractility?
C.11. What is the Apgar scoring system?
C.12. What is the significance of Apgar scores?
C.13. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?
C.14. If the Apgar score of the newborn is 3 at 1 minute, how would you treat the newborn?
C.15. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?
D. Postoperative Management
D.1. Immediately after the baby is delivered, the mother's oxygen saturation decreases. What is the differential diagnosis?
D.2. Additional bleeding occurs in the postanesthesia care unit, and the obstetrician diagnoses retained placenta. What, if any, antibiotics are indicated to prevent endometritis after manual extraction of retained placenta?
30 Appendectomy for a Pregnant Patient 648
A. Medical Disease and Differential Diagnosis
A.1. What is the differential diagnosis for acute abdomen in the pregnant patient?
Medical Conditions
Obstetric Conditions
Gynecologic Conditions
Surgical Conditions
A.2. How would you make the clinical diagnosis of acute appendicitis?
A.3. What is the incidence of surgery during pregnancy? What is the incidence of appendicitis during pregnancy?
A.4. What is the incidence of gangrenous appendix/peritonitis during pregnancy, and is this incidence higher in pregnant than in nonpregnant women?
A.5. What are the main concerns associated with nonobstetric surgery in the pregnant patient?
A.6. What are the factors influencing teratogenicity from anesthetic agents in humans?
A.7. Are there any specific concerns regarding neurotoxicity and cognitive development in the developing fetus?

A.8. What factors influence fetal oxygenation, and how would you prevent intrauterine fetal asphyxia?
A.9. What is the incidence of trauma during pregnancy, and what are the risks to the mother and the fetus secondary to trauma?
A.10. What are other common surgeries performed during pregnancy?
B. Preoperative Evaluation and Preparation
B.1. Preoperatively, what would you discuss with this patient? Are any additional medical consultations warranted?
B.2. Is there a difference in the goal of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?
B.3. How would you premedicate this patient?
C. Intraoperative Management
C.1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?
Cardiovascular System
Respiratory System
Gastrointestinal System
Central Nervous System
Airway, Skin, and Mucous Membranes
C.2. If you choose epidural anesthesia, describe your technique and dosage.
C.3. If the patient needs supplemental analgesia, what would be your choice?
C.4. What vasopressor would you choose to improve uteroplacental perfusion?
C.5. When this patient arrived in the operating room, she desired a general anesthetic. Describe your technique.
C.6. Does any controversy exist surrounding the use of nitrous oxide?
C.7. Does any controversy exist surrounding operating room personnel, anesthetic exposure, and pregnancy outcomes?
C.8. What is the impact of nonobstetric surgery on maternal mortality, birth defects, and fetal loss? What factors influence it?
C.9. Should intraoperative fetal heart rate (FHR) monitoring be used? What would you expect to see on the electronic fetal monitor during anesthesia?

C.10. How would your anesthetic management differ if the patient were having upper extremity surgery?
C.11. The surgeon schedules the procedure to be performed laparoscopically. Does this pose any additional problems?
D. Postoperative Management
D.1. When would you extubate this patient?
D.2. Postoperatively, what monitors would you use?
D.3. What other postoperative precautions would you take? What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?
D.4. The next day, the patient went into premature labor and now needs a cesarean section for prematurity and breech presentation. She requires another general anesthetic. In what way would your technique differ from your previous anesthetic technique?

SECTION 8 The Hematologic System

31 Hemophilia and Disorders of Coagulation
A. Medical Disease and Differential Diagnosis
A.1. Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.
A.2. What is the difference between platelet adhesion, activation, and aggregation at sites of vascular injury?
A.3. Describe the physiologic events that occur following endothelial interruption in the blood vessel.
A.4. What factors prevent the extension of a clot beyond the site of injury?
A.5. Describe the factors involved in the extrinsic, intrinsic, and common coagulation cascade.
A.6. Describe the typical presentation history and pathophysiology associated with von Willebrand disease (vWD).
A.7. Explain the pathophysiology, frequency, and treatment of significant rare disorders of coagulation (factor VII [FVII], factor XII [FXII], and fibrinogen).
A.8. Differentiate between hemophilia A, B, and C.
A.9. What are the differences in factor replacement therapy between patients with hemophilia A and hemophilia B?
A.10. What is acquired hemophilia?

A.11. Which plasma protein is important in maintaining normal levels of factor VIII (FVIII)?
A.12. How are patients with severe hemophilia managed in the outpatient setting?
A.13. Describe the levels of FVIII necessary to maintain hemostasis in patients with spontaneous or surgical bleeding.
B. Preoperative Evaluation and Preparation
B.1. What steps would you take to normalize this patient's coagulation status before surgery?
B.2. What is meant by 1 unit of FVIII clotting activity, and how much does 1 unit of FVIII clotting activity per kilogram of body weight increase FVIII concentrations?
Approach 1
Approach 2
Plasma Volume Calculation
B.3. Would you administer FVIII using a bolus or infusion technique?
B.4. Can hemophiliac patients fail to mount an appropriate coagulation response following FVIII infusion?
B.5. If a patient with hemophilia does not respond to a bolus injection of FVIII, can an infusion technique be effective?
B.6. How much FVIII activity is present in plasma? What are the risks associated with plasma administration?
B.7. What are the indications for the administration of plasma?
B.8. What is cryoprecipitate, and how is it prepared? How much FVIII activity is present in cryoprecipitate? When is cryoprecipitate indicated?
B.9. Describe the advantages and disadvantages of the products that are available for repletion of FVIII activity.
B.10. What is the role of desmopressin (D-amino D-arginine vasopressin [DDAVP]) for hemostatic management in this patient?
B.11. What is the role of antifibrinolytic therapy in the perioperative period for the patient with hemophilia? What are examples of antifibrinolytics used in the treatment of hemophilia?
B.12. What are the options for operative treatment of patients with acquired hemophilia? Describe the mechanism of action and dosing considerations for each of these therapies.

C. Intraoperative Management
C.1. Is it safe to administer an intramuscular injection to this patient before surgery?
C.2. Would an axillary block be appropriate for this patient?
C.3. If general anesthesia is used, would it be safe to intubate the patient's trachea?
C.4. Would you use any special precautions for this patient who is positive for HIV?
C.5. What special considerations should be taken in choosing anesthetic drugs for this patient?
C.6. During an operative procedure, if the surgeon indicates that significant blood loss is occurring, would you transfuse this patient with packed red blood cells (RBCs) or whole blood?
C.7. During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8°C to 37.9°C (98.2°F to 100.2°F). What immediate steps should be taken by the anesthesiologist at this time?
C.8. Does giving blood intraoperatively increase the potential for the development of FVIII inhibitors?
C.9. Can FVIII be safely administered to patients who have developed circulating inhibitors?
C.10. The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?
C.11. Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?
D. Postoperative Management
D.1. What special consideration should be given to postoperative pain management for this patient?
D.2. What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?
D.3. Can this patient be treated with FVIII supplements using home infusion?
Acknowledgment
32 Sickle Cell Disease
A. Medical Disease and Differential Diagnosis
A.1. What was the most likely underlying medical condition in this

patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?
A.2. What is sickle cell disease (SCD)?
A.3. What is sickle cell trait (SCT)?
A.4. What are some of the other common hemoglobinopathies and what are their clinical features?
A.5. What are the clinical features of SCD?
A.6. Describe the different types of sickle cell crises.
A.7. Discuss the pathophysiologic effects of SCD.
A.8. What is acute chest syndrome?
B. Preoperative Evaluation and Preparation
B.1. What preoperative evaluation and testing would you perform on this patient prior to anesthesia? Would you ask for a hematology consult, and what question(s) would you ask?
B.2. What preoperative instructions would you give this patient prior to being admitted to the hospital? How would you prepare this patient for general anesthesia and regional anesthesia?
B.3. Discuss the indications for perioperative exchange transfusion in this patient.
B.4. What are the indications for blood transfusion in SCD?
Acute conditions
Chronic conditions
C. Intraoperative Management
C.1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.
C.2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.
C.3. What precautions should one take to prevent sickling in this patient?
C.4. Discuss what issues or concerns should be brought up by the team during the debrief at the conclusion of the case. What would you sign-out to the postanesthesia care unit (PACU) staff?
D. Postoperative Management
D.1. Discuss the postoperative management of this patient. What opioid sparing techniques can you use and discuss a multimodal analgesic plan?
D.2. What complications might occur in this patient in the

immediate postoperative period?
D.3. What is the treatment of sickle cell crisis?
D.4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?
SECTION 9 Eye, Ear, Nose, and Throat
33 Airway Trauma
A. Medical Disease and Differential Diagnosis
A.1. What variables mitigate injury from motorcycle collisions?
A.2. What other significant trauma may be present?
A.3. How is the initial assessment of a trauma patient organized?
A.4. How would you evaluate airway and breathing?
A.5. How would you evaluate the circulation?
A.6. How would you evaluate mental status and neurologic condition?
A.7. What diagnostic tests are indicated for this patient based on the mechanism of injury?
A.8. What are the zones of the neck, and what is their clinical significance?
A.9. What immediate treatment is necessary before diagnostic studies?
A.10. When and where should the impaling object be removed?
B. Preoperative Evaluation and Preparation
B.1. What laboratory tests would you want?
B.2. What x-ray studies are most important to the anesthesiologist?
B.3. Is an electrocardiogram (ECG) necessary?
B.4. Should this patient be intubated before going for computed tomography (CT) scanning?
B.5. When and where should this patient’s airway be managed?
B.6. Are any prophylactic medications indicated?
C. Intraoperative Management
C.1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?
C.2. What is the surgical approach to a zone I neck injury?
C.3. Is the patient likely to require tube thoracostomy? Should this be placed before managing the airway?
C.4. What are the options for managing this patient’s airway?
C.5. What are the risks of rapid sequence induction in this patient?

C.6. What anesthetic agents would you use for a rapid sequence induction?
C.7. How can you minimize the risk of exacerbating cervical spine trauma?
C.8. How can you minimize the risks of aspiration?
C.9. How would you anesthetize the airway for an awake intubation?
C.10. What are the risks of awake fiberoptic intubation?
C.11. If the patient cannot be ventilated, what options are available?
C.12. Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?
C.13. What surgical airway options are available in this case?
C.14. What maintenance anesthetics are indicated or contraindicated in this patient?
C.15. What complications will the surgical plan introduce?
D. Postoperative Management
D.1. What are the criteria for extubation?
D.2. What techniques may be used during extubation?
D.3. How does alcohol abuse affect postoperative management?
D.4. What pain medication should be used?
34 Open-Eye Injury and Cataract Surgery
A. Medical Disease and Differential Diagnosis
A.1. Why is this patient a particular challenge to the anesthesiologist?
A.2. What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?
A.3. How is aqueous humor formed and eliminated?
A.4. How is IOP affected by arterial PCO_2, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?
A.5. What is the role of the central nervous system (CNS) on IOP?
A.6. What is glaucoma?
A.7. Is atropine contraindicated in patients with glaucoma?
A.8. How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic agents decrease IOP?
A.9. Are carbonic anhydrase inhibitors or osmotic diuretics

indicated in open-globe injuries?
A.10. Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?
Atropine
Scopolamine
Cyclopentolate (Cyclogyl)
Tropicamide (Mydriacyl)
Phenylephrine Hydrochloride (Neo-Synephrine)
Epinephrine
Timolol Maleate (Timoptic)
Betaxolol Hydrochloride (Betoptic)
Acetylcholine
Echothiophate Iodide (Phospholine Iodide)
Cocaine
B. Preoperative Evaluation and Preparation
B.1. Is an open-globe injury always a surgical emergency?
B.2. What preoperative evaluation would you require?
B.3. The patient ate shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics to empty the stomach?
B.4. Could this case be done with topical anesthesia or a retrobulbar block?
B.5. How would you premedicate this patient?
C. Intraoperative Management
C.1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?
C.2. Will you intubate this patient? Would you consider a laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?
C.3. Would you consider an awake intubation?
C.4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?
C.5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?
C.6. How do nondepolarizing muscle relaxants affect IOP?

C.7. How will you perform a rapid sequence induction and intubation without using succinylcholine?
C.8. What are the effects of ketamine on the eye?
C.9. Would you consider the use of etomidate as an induction agent? What about propofol?
C.10. How do inhalation agents affect IOP and by what mechanism?
C.11. During the procedure, the patient's pulse suddenly dropped to 40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?
C.12. What are the afferent and efferent pathways of the OCR?
C.13. What factors contribute to the incidence of the OCR?
C.14. How do you diagnose and treat the OCR?
C.15. Is atropine useful for the OCR?
C.16. Can a retrobulbar block prevent the OCR? Is it appropriate in this patient?
D. Postoperative Management
D.1. Would you reverse the neuromuscular blockade in this patient?
D.2. Do reversal doses of atropine affect IOP?
D.3. What would you do before extubating this patient?
D.4. When would you extubate this patient?
D.5. The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?
D.6. Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?
D.7. What should you do when you suspect your patient might have a corneal abrasion?
D.7. A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?
E. Anesthesia for Cataract Surgery
E.1. What is a cataract?
E.2. What are the causes and risk factors of cataract formation?

E.3. How would you conduct the preoperative medical evaluation for a patient having cataract surgery?
E.4. What is the cardiac risk for this patient? If this patient is on anticoagulation and/or antiplatelet medications, should he stop or continue these medications?
E.5. What are the anesthetic options for cataract surgery?
E.6. What is the postoperative course after cataract surgery?
35 Laser Treatment for Laryngeal Lesions
A. Medical Disease and Differential Diagnosis
A.1. What is the cause of RRP?
A.2. What is the usual presentation of RRP?
A.3. How do you diagnose RRP?
A.4. What are the available treatment options for RRP?
A.5. What are common adverse effects of α-interferon therapy?
A.6. What is the differential diagnosis of hoarseness in this child?
B. Preoperative Evaluation and Preparation
B.1. What are the key points of the preanesthetic history and physical examination in this patient?
B.2. What preoperative laboratory tests are necessary?
B.3. How should this child be premedicated before coming to the operating room?
B.4. What are the special anesthetic considerations prior to inducing anesthesia in this patient?
C. Intraoperative Management
C.1. What is a laser, and how does it work?
C.2. What are the characteristics of laser radiation?
C.3. Discuss some advantages associated with the use of lasers for laryngeal surgery.
C.4. What are some disadvantages of lasers compared with microdebriders?
C.5. How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?
C.6. What special ETTs are available for laser surgery?
C.7. How would you manage an airway fire?
C.8. What is the Venturi effect?
C.9. What is Venturi jet ventilation?
C.10. How would you institute and maintain manual jet ventilation?

C.11. How is anesthesia maintained during jet ventilation?
C.12. What are the complications of jet ventilation?
C.13. Are there contraindications for the use of jet ventilation?
C.14. Discuss airway management options during laryngeal papilloma resection.
C.15. How would you plan to monitor this patient?
C.16. How would you induce anesthesia for an intermittent apnea technique?
D. Postoperative Management
D.1. What are the common postoperative complications?
SECTION 10 Pediatrics
36 Tracheoesophageal Fistula
A. Pathophysiology and Differential Diagnosis
A.1. What is the diagnosis? What are the clinical features of this disease?
A.2. What is the pathophysiology of this disease?
A.3. Describe the normal development of the trachea and esophagus.
A.4. How are tracheoesophageal fistula (TEF) and esophageal atresia (EA) inherited?
A.5. How are the different types of TEF/EA classified?
A.6. What other problems may this child have, and when should these be investigated?
A.7. What should the parents be told regarding perioperative risk? Risk of recurrence?
B. Preoperative Evaluation and Preparation
B.1. What laboratory workup should be obtained before surgery?
B.2. Describe management in the NICU before surgery.
B.3. How is severe lung disease managed before repair?
B.4. Should this patient be intubated preoperatively for airway protection?
C. Intraoperative Management
C.1. What invasive lines and monitoring are appropriate before induction? After induction?
C.2. Discuss fluid and temperature management for this baby.
C.3. What are the options regarding induction and intubation?
C.4. What is the role of rigid and fiberoptic bronchoscopy in this

patient prior to incision?
C.5. Describe the steps of an open repair of EA/TEF.
C.6. What are common intraoperative problems, and how can they be managed?
C.7. If the surgeon decides to proceed thoracoscopically, how will you perform your anesthetic? Is one-lung ventilation required? What are some complications unique to thoracoscopy in the newborn?
D. Postoperative Management
D.1. When should the baby be extubated?
D.2. What options are available for postoperative analgesia?
D.3. What are early and late complications of TEF repair?
37 Congenital Diaphragmatic Hernia
A. Medical Disease and Differential Diagnosis
A.1. What differential diagnoses are compatible with these signs and symptoms?
A.2. Describe the incidence and classification of congenital diaphragmatic hernia (CDH).
A.3. What are the causes of hypoxemia in patients with CDH?
A.4. How do you assess the severity of pulmonary hypoplasia?
A.5. How do you make a diagnosis of right-to-left shunting through the patent ductus arteriosus?
A.6. What other congenital anomalies are usually associated with CDH?
B. Preoperative Evaluation and Preparation
B.1. How would you interpret the following arterial blood gas analyses: pH, 7.20; $PaCO_2$, 55 mmHg; PaO_2, 35 mmHg; and CO_2 content, 19 mEq per L? How would you correct them?
B.2. What immediate treatment should be given to improve the newborn's respiratory status preoperatively?
B.3. Should CDH be repaired urgently once the diagnosis is made and confirmed?
B.4. What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?
B.5. What is the current role of extracorporeal membrane oxygenation (ECMO) in the management of CDH?
C. Intraoperative Management

C.1. What monitors would you use for this neonate during surgery?
Respiratory
Cardiovascular
Thermoregulatory
C.2. How would you induce and maintain anesthesia?
C.3. Would you use nitrous oxide for anesthesia? Why?
C.4. How would you ventilate the patient?
C.5. Is the infant with CDH more at risk from hypothermia?
C.6. The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mmHg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you immediately do?
C.7. Discuss fluid therapy in this patient.
C.8. At the conclusion of surgery, would you extubate the patient in the operating room?
D. Postoperative Management
D.1. What is the mortality rate in patients with CDH? What postoperative problems would you expect in this patient?
38 Tetralogy of Fallot
A. Medical Disease and Differential Diagnosis
A.1. What is TOF?
Tetralogy of Fallot with Pulmonary Stenosis
Tetralogy of Fallot with Pulmonary Atresia
Tetralogy of Fallot with Absent Pulmonary Valve
A.2. What is the pathophysiology of TOF/PS?
A.3. What is shunting, and how is Q_P:Q_S calculated?
A.4. What is the pathophysiology of TOF with pulmonary atresia?
A.5. How is SaO_2 determined in single ventricle physiology?
A.6. What is a “pink Tet”?
A.7. What are hypercyanotic spells? How are they treated?
A.8. What palliative surgical procedures are available for treating patients with TOF/PS?
A.9. What palliative catheter-based procedures are available for

patients with TOF?
A.10. What definitive surgical procedures are available for treating patients with TOF/PS?
A.11. What palliative and definitive surgical procedures are available for patients with TOF with pulmonary atresia?
A.12. What are the long-term outcomes of patients with TOF?
B. Preoperative Evaluation and Preparation
B.1. What preoperative history and physical examination information do you want?
B.2. Which other abnormalities need to be considered in this patient?
B.3. What premedication will you give to a child with congenital heart disease?
C. Intraoperative Management
C.1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?
C.2. Why would end-tidal carbon dioxide ($EtCO_2$) monitoring be of particular use in a patient with TOF/PS?
C.3. What is near-infrared spectroscopy (NIRS) and what does it measure?
C.4. What are the important management issues during creation of a palliative shunt?
C.5. What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?
C.6. What are the pre-cardiopulmonary bypass (pre-CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?
C.7. What interventions will reliably reduce PVR?
C.8. How does heparin administration and activated coagulation time (ACT) monitoring for CPB differ in children as compared with adults?
C.9. How is heparin reversed?
C.10. What is the incidence of protamine reactions in children?
C.11. What is the role of transesophageal echocardiography (TEE) in this patient?
C.12. What effect would a residual ventricular septal defect (VSD)

have in this patient following separation from CPB?
D. Postoperative Management
D.1. How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?
D.2. Following complete repair of TOF/PS in an infant, what SaO_2 is acceptable?
D.3. Following placement of a modified Blalock-Taussig shunt (MBTS) for TOF/PS in an infant, what SaO_2 is acceptable?
D.4. What is junctional ectopic tachycardia (JET)?
39 Transposition of the Great Arteries
A. Medical Disease and Differential Diagnosis
A.1. What defines the cardiac situs?
A.2. What is transposition of the great arteries (D-TGA)?
A.3. What additional cardiac lesions are associated with D-TGA?
A.4. What is the natural history of D-TGA?
A.5. What is the pathophysiology of D-TGA?
A.6. What determines the oxygen saturation in patients with D-TGA?
A.7. Why did this infant have reverse differential cyanosis?
A.8. What are the preoperative issues pertaining to the coronary arteries in D-TGA?
A.9. What are the clinical subsets of D-TGA?
A.10. What is the differential diagnosis of D-TGA and how is the diagnosis made?
A.11. What preoperative interventions can help stabilize a patient with D-TGA?
Intact Ventricular Septum
Ventricular Septal Defect
Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction
Pulmonary Artery Hypertension
A.12. What are the surgical options for repair? Why is one chosen over the others?
Arterial Anatomic Repair: Arterial Switch (Jatene) Operation
Intra-atrial Physiologic Repairs: Mustard and Senning Procedures
Rastelli, LeCompte, and Nikaidoh Procedures
B. Preoperative Evaluation and Preparation

B.1. What information is important to prepare for this case?
B.2. What are the anesthetic goals before cardiopulmonary bypass (CPB)?
B.3. What is the plan for glucose management in this patient?
C. Intraoperative Management
C.1. How would you monitor this infant?
C.2. What would be the best method of induction for this patient?
C.3. Is CPB in infants and children different from adults?
C.4. What is modified ultrafiltration (MUF)?
C.5. Briefly describe the surgical techniques of the Mustard/Senning, ASO, and Rastelli procedures.
Intra-atrial Physiologic Repairs: Mustard and Senning Procedures
Arterial Anatomic Repair: Arterial Switch (Jatene) Operation
Rastelli Procedure
C.6. What is hypothermia, and how is it classified? What is low-flow cardiopulmonary bypass (LFCPB)? What is deep hypothermic circulatory arrest (DHCA)?
C.7. Why is hypothermia beneficial to the brain during LFCPB and DHCA?
C.8. Explain the difference between α-stat and pH-stat blood gas management.
C.9. What are the immediate post-CPB issues following ASO?
D. Postoperative Management
D.1. How is myocardial ischemia addressed in the intensive care unit (ICU) following the ASO?
D.2. What immediate postoperative problems would be anticipated following the Rastelli procedure?
D.3. What intermediate and long-term surgical problems are seen after ASO?
D.4. What are the long-term outcomes after ASO?
D.5. What are the long-term outcomes after Rastelli repair for patients with D-TGA with left ventricular outflow tract (LVOT) obstruction?
D.6. What is long-term neurologic outcome like after ASO?
40 Pyloric Stenosis
A. Medical Disease and Differential Diagnosis
A.1. What is the diagnosis in this patient?

A.2. What is the differential diagnosis of pyloric stenosis?
A.3. What are the metabolic problems in this newborn secondary to his disease?
A.4. What are the adverse effects of metabolic alkalosis?
A.5. How would you treat this infant?
Supportive Therapy
Fluids
Electrolytes
Prevention of Aspiration
Diagnostic Tests
Surgery
A.6. How would you determine fluid replacement in a newborn, and what fluids would you use?
Maintenance Fluids
Electrolytes
Correction of Deficits
Replacement of Losses
A.7. How would you correct the metabolic alkalosis in this patient?
A.8. What causes a cardiac murmur?
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate this patient preoperatively?
History
Physical Examination
Laboratory Findings
B.2. How would you evaluate a heart murmur?
B.3. How would you differentiate between functional versus organic murmur?
B.4. What are the types of VSD? What type of shunt do they cause?
B.5. What are the risks of surgery and anesthesia in a patient with VSD?
B.6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?
B.7. How would you prepare this patient for anesthesia?
C. Intraoperative Management
C.1. What induction–intubation sequence would you use?
C.2. What are the anatomic characteristics of the airway in the newborn and how do they differ from those in the adult?

C.3. How do you determine the size of an endotracheal tube in a pediatric patient?
C.4. What anesthesia system would you use and why?
C.5. What are the advantages and the disadvantages of commonly employed nonrebreathing systems?
C.6. How would you monitor this patient intraoperatively?
C.7. How does the pulse oximeter function?
C.8. What factors affect the measurement of oxygen saturation by the pulse oximeter?
D. Postoperative Management
D.1. What are the complications that can occur in the postanesthesia recovery period?
D.2. How would you treat postextubation “croup” in this infant?
41 Inflammatory Airway Disease in Childhood: Laryngotracheobronchitis
A. Medical Disease and Differential Diagnosis
A.1. What portion of the airway is affected in the croup syndrome and why?
A.2. What is stridor?
A.3. How does stridor correlate with anatomic location?
A.4. Define croup. What is the clinical presentation of laryngotracheitis?
A.5. What is the differential diagnosis of acute upper airway obstruction in children?
A.6. What is bacterial tracheitis?
A.7. What congenital problems can mimic features of croup?
A.8. How is the severity of croup assessed?
A.9. What is the medical management of croup? Does this have implications for the anesthesiologist?
A.10. What is epiglottitis? What are its common causes? What is the incidence?
A.11. What are the clinical manifestations of epiglottitis?
A.12. How is the diagnosis of epiglottitis made?
A.13. What is postextubation croup? How is it managed?
A.14. What are the nonacute causes of partial airway obstruction in children?
Extrinsic Pathologies

Intrinsic Pathologies
B. Preoperative Evaluation and Preparation
B.1. Is intubation always required in children with epiglottitis?
B.2. Why is general anesthesia administered to a child with epiglottitis?
B.3. How would you prepare the patient for anesthesia?
C. Intraoperative Management
C.1. How is the airway of the child with epiglottitis best secured?
C.2. How would you induce anesthesia?
C.3. Should a child with epiglottitis undergo a rapid sequence induction?
C.4. Is awake intubation a practical alternative to secure the patient's airway?
C.5. What would you do if the airway cannot be secured with intubation?
C.6. Should this patient have a nasotracheal or orotracheal tube placed?
C.7. Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?
D. Postoperative Management
D.1. How long should this patient remain intubated? What criteria determine extubation time?
D.2. How would you make this patient comfortable during the course of intubation?
D.3. What outcome can one expect for the child with acute epiglottitis?
42 Cleft Palate
A. Medical Disease and Differential Diagnosis
A.1. Describe the anatomic concept of a cleft palate and a cleft lip.
A.2. What is the cause of a cleft lip or a cleft palate?
A.3. What is the incidence of a cleft lip and a cleft palate?
A.4. Discuss the pathophysiology of a cleft lip and palate in the neonate and the older child (e.g., age >5 years).
A.5. What other conditions are associated with a cleft lip and a cleft palate?
A.6. What is Pierre Robin syndrome?

A.7. What is Treacher Collins syndrome?
A.8. What kind of specialized team care would these patients need?
A.9. Discuss indications and timing of closure of cleft lip and palate.
A.10. What is velopharyngeal incompetence, and how can it be diagnosed?
A.11. What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?
B. Preoperative Evaluation and Preparation
B.1. What information do you need before closure of a cleft lip and palate?
B.2. What preoperative orders are needed?
C. Intraoperative Management
C.1. What monitors will you need for cheiloplasty and palatoplasty?
C.2. Discuss the induction and the anesthetic management for cleft lip and palate.
C.3. What positioning is recommended for cleft palate repair surgery?
C.4. What are the reported complications of this type of surgery and anesthesia?
C.5. Briefly describe the surgical techniques used to repair cleft defects.
C.6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?
C.7. What is an Abbe flap? What are its anesthetic implications?
C.8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?
C.9. What is laryngospasm? How would you make a diagnosis of laryngospasm?
C.10. How would you manage the patient with laryngospasm?
D. Postoperative Management
D.1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?
D.2. How do you protect the airway postoperatively?
D.3. How would you control postoperative pain in patients following a cleft lip and cleft palate repair?

43 Congenital Heart Disease with a Cervical Mass in Infancy
A. Medical Disease and Differential Diagnosis
A.1. What is 22q11 deletion syndrome?
A.2. What are the associated cardiovascular defects in 22q11 deletion syndrome?
A.3. What are the metabolic and endocrine abnormalities in patients with 22q11 deletion syndrome and the attendant manifestations?
A.4. What are the immunologic findings in 22q11 deletion syndrome?
A.5. What is the differential diagnosis of cervical masses in infancy?
A.6. What is a cystic hygroma? What are the complications? What is the treatment?
A.7. What is the IAA anomaly?
A.8. What is the pathophysiology of the IAA syndrome?
A.9. How is ductal patency maintained?
A.10. What are the side effects of prostaglandin infusion?
A.11. What is the hyperoxia test?
B. Preoperative Evaluation and Preparation
B.1. What preoperative studies should be obtained to evaluate the neck mass?
B.2. How would you categorize the difficult airway in children?
B.3. What features of the difficult airway can be noted on physical examination?
B.4. How would you preoperatively optimize the ability to secure the airway in the operating room?
B.5. What laboratory studies are necessary before surgery?
B.6. What are the causes of heart failure (HF) in the infant? How would you assess this infant in your preoperative evaluation for signs of HF?
B.7. How would you optimize the preoperative treatment of HF?
B.8. How would you premedicate this infant?
B.9. When is premedication useful in infants and children?
B.10. Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to ensure that the baby remains immobile for 20 minutes to perform the scan

adequately. How would you accomplish this?
C. Intraoperative Management
C.1. What anesthesia equipment, circuit, and monitors would you use?
C.2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this baby.
Infant Video Laryngoscope
Intubation through a Laryngeal Mask Airway
Retrograde Cricothyroid Wire
Blind Nasal Intubation
Nasal Intubation with Laryngoscope and Magill Forceps
Fiberoptic Intubation
C.3. How would you monitor blood loss in this patient?
C.4. What anesthetic technique should be used in a patient who may experience severe loss of blood intraoperatively?
C.5. How would you induce and maintain anesthesia in this neonate?
C.6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?
D. Postoperative Management
D.1. How would you manage this patient postoperatively?
44 Patent Ductus Arteriosus and Prematurity
A. Medical Disease and Differential Diagnosis
A.1. How would you classify prematurity? What are the common problems associated with prematurity?
A.2. What are the survival rates of preterm infants?
A.3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.
A.4. What is bronchopulmonary dysplasia (BPD)? How would you treat it?
A.5. What are apnea spells? What are the possible causes of apneic spells?
A.6. Discuss the incidence and pathophysiology of PDA in preterm infants.
A.7. How would you make a diagnosis of PDA? Describe its treatment.

A.8. Would you give digitalis to treat congestive heart failure in preterm infants? Why?
A.9. How does indomethacin close the ductus? What are the adverse effects of indomethacin?
A.10. When is surgical closure indicated? What are the complications associated with surgical ligation?
A.11. What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, prevention, and treatment.
A.12. Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate this patient preoperatively?
B.2. What are the normal values of arterial blood gases and pH in neonates and infants?
B.3. Interpret the arterial blood gases: pH, 7.30; $PaCO_2$, 60 mmHg; PaO_2, 49 mmHg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?
B.4. What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm infants?
B.5. What are the normal values of WBC, red blood cells (RBCs), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?
B.6. Would you transfuse blood to this patient preoperatively?
B.7. How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1+; and protein, 1+?
B.8. Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?
B.9. How would you premedicate this patient?
C. Intraoperative Management
C.1. Where should the procedure take place? In the neonatal intensive care unit (NICU) or the operating room?

C.2. What monitors would you use for this child during surgery?
C.3. How does the oxygen analyzer work?
C.4. What is the Doppler effect? How does the Doppler transducer measure blood pressure?
C.5. What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?
C.6. How would you maintain the patient's body temperature?
C.7. How do the anesthetic requirements of the preterm infant differ from those of the adult?
C.8. What size endotracheal tube would you have used if the patient had not been intubated?
C.9. How would you have induced anesthesia if the patient had not been intubated?
C.10. How would you maintain anesthesia?
C.11. How would you ventilate the patient? What tidal volume, respiratory rates, and FIO_2 would you set for the infant?
C.12. Discuss blood and fluid therapy in this preterm infant.
C.13. During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?
D. Postoperative Management
D.1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?
D.2. How can one minimize the risk of transporting the patient to the NICU after surgery?
D.3. The patient's condition deteriorated postoperatively in the intensive care unit (ICU). Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?
45 Post-tonsillectomy Hemorrhage
A. Medical Disease and Differential Diagnosis
A.1. Approximately how many pediatric tonsillectomies are performed in the United States each year? What are the indications for tonsillectomy?
A.2. What is the differential diagnosis for this patient?
A.3. What is the treatment for a patient with von Willebrand

disease?
A.4. Describe the vascular anatomy of the tonsils. What is the incidence of post-tonsillectomy hemorrhage?
A.5. What are the risk factors for post-tonsillectomy hemorrhage? Does age matter?
A.6. Describe the morbidity and mortality of post-tonsillectomy hemorrhage.
B. Preoperative Evaluation and Preparation
B.1. What is your approach to assessing this patient?
B.2. What will you set up in the operating room for this patient? How will your preparation be different from a routine general anesthetic set up?
B.3. Should you plan to use vasopressors?
B.4. The patient seems anxious. Will you administer a sedative to calm the patient down?
B.5. How do you plan on interpreting this patient's laboratory results?
B.6. What are your expectations of the surgeon, specifically as it relates to induction of anesthesia?
C. Intraoperative Management
C.1. What is your plan for induction of anesthesia? During the initial procedure, this patient underwent an uneventful inhalational induction, with postinduction intravenous (IV) placement. Would you perform an inhalational induction again? Why or why not?
C.2. What is your plan for management of blood in the oropharynx?
C.3. What is your plan for airway management?
C.4. Laryngoscopy and intubation prove challenging due to blood in the airway. What options do you have now?
C.5. What is your plan for maintenance of the anesthetic? What other medications might you want to give?
C.6. Assuming the surgical intervention is successful, what is your plan for emergence and extubation?
D. Postoperative Management
D.1. Is postoperative management in the pediatric intensive care unit (PICU) indicated?
D.2. What would you require for safe transport from the operating

room to the PICU?
D.3. Discuss potential postoperative complications for this patient.
D.4. What discharge instructions should be given post-tonsillectomy?
SECTION 11 Pain Management and Neuraxial Blocks
46 Brachial Plexus Block
A. Medical Disease and Differential Diagnosis
A.1. What are the presenting problems in this patient?
A.2. What additional medical history would you want to obtain?
A.3. What implications does the use of atenolol have on the patient's coexisting medical condition?
A.4. Why is immobilization of the arm important following humeral fracture?
A.5. What nerve is at particular risk for injury from humeral fracture?
B. Preoperative Evaluation and Preparation
B.1. What testing would be helpful to elucidate the cause of this patient's fainting spells?
B.2. What premedication would you order?
B.3. What are the respiratory effects of benzodiazepines?
C. Intraoperative Management
C.1. What anesthetic technique would you use?
C.2. Describe the relevant anatomy of the brachial plexus.
C.3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?
C.4. What regional technique would you choose to block the brachial plexus in this patient?
C.5. What are the advantages and disadvantages of the following blocks?
Interscalene Block
Supraclavicular Block
Infraclavicular Block
Axillary Block
C.6. Describe the landmarks and procedures for nerve stimulator and ultrasound-guided interscalene block.
C.7. Describe the landmarks and procedures for supraclavicular

block.
C.8. Describe the landmarks and procedures for infraclavicular block.
C.9. Describe the landmarks and procedures for axillary block.
C.10. The patient requests to have the brachial plexus block performed after you administer general anesthesia. Would you agree to this request?
C.11. What relevant respiratory complications or side effects are you concerned about in this patient?
C.12. What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by decreasing the volume or concentration of local anesthetic injected or by using ultrasound-guided supraclavicular block?
C.13. Describe the pulmonary function changes that occur after interscalene brachial plexus block.
C.14. What would you do if the patient complained of dyspnea after you performed an interscalene or supraclavicular block?
C.15. The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?
C.16. Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block? With all brachial plexus blocks?
C.17. What is the expected duration of brachial plexus block with 30 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?
C.18. What is the maximum safe dose of local anesthetic for brachial plexus block?
D. Postoperative Management
D.1. What regimen would you suggest for postoperative pain management?
D.2. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?
D.3. On the third postoperative day after removal of the brachial plexus catheter, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How would you manage neurologic dysfunction after

brachial plexus block that persists for 1 week?
47 Nerve Blocks of the Lower Extremity
A. Preoperative Evaluation
A.1. What is the Glasgow Coma Scale and its significance in this patient?
A.2. Should surgery be allowed to proceed in this patient who has a subdural bleed?
A.3. Does the patient's atrial fibrillation need to be addressed prior to surgery, and if so, how?
B. Preoperative Preparation
B.1. What is dabigatran (Pradaxa)? How is its effect measured? How far in advance of elective surgery should it be stopped? Can its effect be reversed?
B.2. What concerns do you have regarding neuraxial anesthesia in this patient who has a subdural hematoma?
B.3. What concerns do you have regarding neuraxial anesthesia in this patient who has prior back surgery?
B.4. The surgeon is willing to wait a few days prior to surgery while the swelling around the injury decreases. When would you feel comfortable proceeding with surgery in this patient?
C. Intraoperative Management
C.1. What two nerve plexuses need to be blocked in this case? What nerve roots contribute to each plexus? Name the major nerves that come from each plexus.
C.2. What is the innervation to the medial and lateral aspects of the ankle? What nerves need to be blocked for his surgery?
C.3. What nerves are blocked with an ankle block? Would you do an ankle block in this case?
C.4. Explain the posterior landmark technique to blocking the lumbar plexus. What motor response would be elicited with a nerve stimulator? At what stimulation level would you feel safe injecting the patient? Why not at a lower level of stimulation? Can ultrasound guidance be utilized for this injection?
C.5. What is a fascia iliaca block (three-in-one block)?
C.6. Describe the different ultrasound approaches to blocking the saphenous nerve above the knee.
C.7. What benefits might a saphenous nerve block above the knee

provide compared to a femoral nerve block?
C.8. How would pain from a midthigh tourniquet dictate which peripheral nerve blocks to use in this patient? Describe the landmark technique of sciatic nerve block in the gluteal region. What is seen while performing an ultrasound technique to block the sciatic nerve?
C.9. Why does a popliteal nerve block have a high failure rate if performed too proximate to the popliteal fossa when using a landmark/nerve stimulator technique? Describe how this can be avoided when using ultrasound-based popliteal block.
C.10. What is the IPACK block? In what situations would this block be useful?
D. Postoperative Pain Management
D.1. Describe compartment syndrome and how that risk would influence your postoperative plan for peripheral regional analgesia.
D.2. How would the addition of dexamethasone to your local anesthetic influence the duration of the blocks placed in the OR?
D.3. What is liposomal bupivacaine?
D.4. What benefit would a peripheral nerve catheter provide over a long-acting local anesthetic? Are there any downsides?
D.5. You were able to perform a continuous spinal epidural (CSE) at L3–L4 and used 0.125% bupivacaine via epidural route for postoperative pain control. The patient reports that he is comfortable regarding both his back pain and his ankle pain. What benefit would continuing the patient's methadone confer in this case?
D.6. How can regional analgesia aid in fast-track postoperative care?
48 Complex Regional Pain Syndromes
A. Medical Disease and Differential Diagnosis
A.1. What is the differential diagnosis of pain in this patient?
A.2. What is complex regional pain syndrome (CRPS)?
A.3. What are the two types of CRPS?
A.4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?
A.5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.
A.6. What are the stages of CRPS?

Stage I
Stage II
Stage III
A.7. What are the possible etiologies of CRPS?
A.8. Explain the pathophysiology of the development of CRPS.
A.9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).
A.10. How does CRPS differ from neuralgia?
A.11. What is central pain? How will you differentiate central pain from CRPS?
A.12. Is the social history of this patient relevant to the development of chronic pain syndrome?
B. Pain Management
B.1. How will you work up CRPS types I and II?
B.2. Describe the sympathetic nerve supply to the arm?
B.3. Where is the stellate ganglion located?
B.4. What are the anatomic landmarks used in the stellate ganglion block?
B.5. What are the clinical signs of stellate ganglion block?
B.6. What is Horner syndrome?
B.7. After a stellate ganglion block, this patient reports no significant change in the degree of pain despite developing Horner syndrome. Is the pain psychogenic in this patient?
B.8. What types of nerve fibers are interrupted in stellate ganglion block?
B.9. What is a differential block?
B.10. What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.
B.11. What factors determine the onset, potency, and duration of a local anesthetic block?
B.12. How does the addition of epinephrine to commercially available premixed solutions affect the efficacy of local anesthetics?
B.13. How will you treat this patient?
B.14. What is the pharmacologic management of CRPS?
B.15. What is the role of intravenous regional block (Bier method) in diagnosis and treatment of CRPS?

B.16. Compare and contrast the mechanism of actions of ketamine and methadone.
B.17. What roles does ketamine infusion play in the treatment of CRPS? Is there a guideline for ketamine infusion in treating CRPS?
B.18. What is neuromodulation? What is the role of spinal cord stimulation (SCS) in treating CRPS?
B.19. What is the role of surgical sympathectomy?
B.20. What role does intrathecal (IT) therapy play in managing CRPS?
B.21. If opioids are prescribed as treatment for CRPS patients, what is the Centers for Disease Control and Prevention (CDC) guideline of chronic opioid therapy?
C. Complications
C.1 What are the complications of stellate ganglion block?
C.2 What is the systemic toxicity of local anesthetics?
Central Nervous System Effects
Cardiovascular Effects
C.3 How do you treat the systemic toxicity of local anesthetic drugs?
C.4 What are the possible complications of SCS?
C.5. What are the possible complications of IT therapy?
49 Cancer Pain
A. Medical Disease and Differential Diagnosis
A.1. What is the definition of pain?
A.2. How significant is the problem of pain in patients with cancer?
A.3. What are the components of cancer pain?
A.4. How does the pain contribute to the suffering of patients with cancer?
A.5. How do psychological factors affect pain in patients with cancer?
A.6. What are the causes of pain in patients with cancer?
A.7. How do you classify pin in patients with cancer?
A.8. What are the characteristics of pancreatic cancer pain?
A.9. How do you assess pain in patients with cancer?
A.10. What is the differential diagnosis of abdominal pain?
B. Pharmacologic Treatment of Pain
B.1. What is the World Health Organization stepladder approach

for cancer pain management?
B.2. What class of drugs does morphine sulfate belongs to?
B.3. What is the difference between morphine and synthetic opioids?
B.4. How does mixed opioid agonist/antagonist differ from opioid agonist?
B.5. Describe the role of methadone in the management of cancer pain.
B.6. What are the advantages and disadvantages of methadone?
B.7. What is the mechanism of action of opioids?
B.8. What are the side effects of opioid therapy?
B.9. Define tolerance and physical dependence.
B.10. How would you treat the side effects of opioid therapy?
B.11. What is tramadol? Is it an opioid?
B.12. When would you consider adjuvant analgesics as part of the treatment plan?
B.13. The patient and his family are worried about addiction. How would you approach this problem?
B.14. Describe different routes of opioid administration.
B.15. Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?
B.16. What is meperidine? How is it different from other opioids?
B.17. What is rotation of opioids? When would you consider rotation of opioids?
C. Invasive Therapy
C.1. Describe the role of peripheral nerve blocks in cancer pain management.
C.2. Describe the role of celiac plexus block in cancer pain management.
C.3. What are the complications of celiac plexus block?
C.4. Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.
C.5. Which medications can be used intrathecally? What is ziconotide?
C.6. What is a Personal Therapy Manager (PTM), and what role does it play in neuraxial pain relief?

C.7. Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.
C.8. Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?
C.9. Describe the role of radiation therapy in cancer pain.
D. Nonpharmacologic Management
D.1. What are the various nonpharmacologic techniques of cancer pain management?
D.2. What physical modalities have been successfully tried in cancer pain management?
D.3. Describe the role of neuromodulation in cancer pain management.
D.4. What psychological techniques have been promoted for comfort care and pain relief?
D.5. What are distraction and reframing techniques? What is the role of hypnosis in cancer pain?
50 Low Back Pain and Sciatica
A. Medical Disease and Differential Diagnosis
A.1. How great an issue is low back pain in the general population?
A.2. What is the prevalence of low back pain?
A.3. What is the societal cost of low back pain?
A.4. What causes low back pain?
A.5. What are the risk factors for low back pain?
A.6. What are the potential sources of pain in the spine?
A.7. What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?
A.8. What is the anatomy of the spinal facets? How do the facet joints cause pain?
A.9. What are the important findings through history and physical examination?
A.10. What are the appropriate diagnostic studies for low back pain?
A.11. What is the differential diagnosis of low back pain?
A.12. What are the causes of persistent back pain after multiple spine surgeries?
B. Management of Low Back Pain and Sciatica

B.1. What are the noninterventional treatments available?
B.2. What traditional interventional treatments are available and how should they be used?
B.3. What are some of the recent safety improvements recommended for lumbar epidural steroid injection?
B.4. What are some of other approaches in minimally invasive interventions?
B.5. What are the concerns about magnetic resonance imaging (MRI) safety in patients with a spinal cord stimulator (SCS)?
B.6. When should surgery be considered?
B.7. What surgical options are available for the treatment of disc disease?
51 Perioperative Pain Management
A. Perioperative Pain Management for Thoracotomy
A.1. What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?
A.2. How will you decide about the choice of anesthetic technique?
A.3. What is chronic postsurgical pain (CPSP)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?
A.4. What would be your perioperative analgesic strategy?
A.5. Does the choice of analgesic technique influence postoperative outcome?
A.6. Does it matter if the epidural catheter is at the thoracic or lumbar level?
A.7. Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?
A.8. What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?
A.9. If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?
A.10. What are the alternatives to TEA?
A.11. What is the usual clinical regimen for intravenous patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?
A.12. What are the side effects and complications of epidural technique?

A.13. What recommendations for placement and removal of epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?
Prophylactic Unfractionated Heparin
Therapeutic Intravenous Unfractionated Heparin
Preoperative Low Molecular Weight Heparin (Enoxaparin)
Postoperative Low Molecular Weight Heparin
Oral Anticoagulants
Newer Agents
B. Chronic Opioid Therapy and Perioperative Pain Management
B.1. How does chronic opioid therapy influence postoperative pain management?
B.2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?
B.3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?
B.4. What issues need to be considered in the opioid-tolerant patient who is scheduled for surgery?
B.5. What would be your strategy regarding preoperative information and choice of anesthesia technique?
B.6. What are the choices for perioperative pain management in opioid-tolerant patients?
B.7. What issues need to be considered before discharging an opioid-tolerant patient?
C. Perioperative Pain Management for Ambulatory Surgery
C.1. What would be your preoperative considerations and advice to the patient?
C.2. What are the consequences of inadequate pain management after ambulatory surgery?
C.3. What is the role of premedication or preoperative analgesic?
C.4. Does the choice of anesthetic technique influence postoperative pain?
C.5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?
C.6. What is the role of surgical technique in influencing postoperative pain after a laparoscopic cholecystectomy?

C.7. What would be your strategy for pain control after discharge home?
D. The Role of an Acute Pain Service (APS)
D.1. What is the extent of the problem, and which patients are at greatest risk of undertreatment?
D.2. What are the consequences of inadequate postoperative pain relief?
D.3. What is the role of an APS in improving postoperative pain management?
D.4. Does an APS improve postoperative outcome?
52 Acupuncture
A. Acupuncture as a Complementary Medical Therapy
A.1. What is acupuncture?
A.2. How is acupuncture practiced? (Video 52.1)
A.3. What are the mechanisms of acupuncture analgesia?
A.4. What were the conclusions of the National Institutes of Health Consensus Conference about acupuncture?
A.5. Can acupuncture be a novel nonopioid alternative pain therapy?
B. Acupuncture for the Treatment of Chronic Conditions
B.1. What are the rationales in integrating acupuncture for the treatment of postoperative nausea and vomiting?
B.2. Can acupuncture be used for the treatment of chemotherapy-induced nausea and vomiting?
B.3. How effective is acupuncture for the management of chronic headache?
B.4. Can acupuncture be used for the treatment of chronic neck and back pain?
B.5. Can acupuncture be used for the treatment of osteoarthritis?
B.6. What role can acupuncture play in the care of patients with cancer?
B.7. Can acupuncture/acupressure be used to decrease anxiety?
B.8. What is ear acupuncture/acupressure? Can it be useful for alleviating anxiety and pain? (Video 52.2)
C. Complications
C.1. What are the possible complications of acupuncture treatment?
SECTION 12 Miscellaneous

53 Myasthenia Gravis
A. Medical Disease and Differential Diagnosis
A.1. What is MG?
A.2. What is the etiology and pathophysiology of MG?
A.3. Describe the clinical classification of MG.
A.4. How is the diagnosis of MG made?
A.5. What should be considered in the differential diagnosis?
A.6. How does myasthenic syndrome (Lambert-Eaton syndrome) differ from MG?
A.7. What treatments are available for a patient with MG?
Medical Therapy
Surgical Therapy
B. Preoperative Evaluation and Preparation
B.1. Describe the preoperative evaluation of this patient.
B.2. What preoperative laboratory data are required?
B.3. How should the patient's medications be managed preoperatively?
C. Intraoperative Management
C.1. What are your considerations in the choice of anesthetic technique?
C.2. How should this patient be monitored intraoperatively?
C.3. What anesthetic regimen would you choose for this patient?
C.4. Can neuromuscular blocking drugs be used safely in a patient with MG?
C.5. Should the MG patient who is in remission (i.e., symptom free without treatment) be managed differently?
D. Postoperative Management
D.1. What factors will help you predict this patient's need for continued intubation or other postoperative ventilatory support?
D.2. How will you determine if this patient's trachea can be safely extubated?
D.3. How will you manage postoperative analgesia?
D.4. How will you define and manage postextubation ventilatory failure in this patient?
54 Malignant Hyperthermia
A. Medical Disease and Differential Diagnosis
A.1. What was the problem of concern in this case?

A.2. What is malignant hyperthermia (MH)?
A.3. What are the clinical features of a susceptible patient?
A.4. Does the history of previous uneventful sevoflurane anesthesia reasonably exclude the patient's susceptibility to MH?
A.5. What are the clinical features of the syndrome?
Hyperkalemic Cardiac Arrest
A.6. What are the laboratory findings during an acute crisis of MH?
A.7. What is the incidence of this syndrome?
A.8. What is the mode of inheritance of the disease? Does MH "skip" generations?
A.9. What genetic disorder results in MH susceptibility?
A.10. What is the pathophysiology of the syndrome?
A.11. What laboratory tests can further substantiate the susceptibility of the patient to MH?
Molecular Genetic Testing for MH Susceptibility
A.12. What is neuroleptic malignant syndrome (NMS)?
B. Preoperative Evaluation and Preparation
B.1. How would you prepare this patient for anesthesia and surgery?
B.2. Is dantrolene prophylaxis indicated?
B.3. What laboratory tests would you obtain before surgery?
B.4. Is outpatient surgery appropriate for this patient?
B.5. In anticipation of general anesthesia, what preparations would you make?
C. Intraoperative Management
C.1. What anesthetic techniques and agents would you employ?
C.2. Should body (core) temperature be monitored during general anesthesia lasting more than a short time?
C.3. What anesthetic agents are contraindicated?
C.4. If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?
C.5. What is the significance of masseter muscle spasm occurring after succinylcholine administration?
C.6. Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?

C.7. What modalities would you monitor closely during management of the crisis?
C.8. What steps should be taken to avoid major morbidity from MH?
C.9. How does the new formulation of dantrolene (Ryanodex) compare with the existing formulation of dantrolene (Dantrium or Revonto)?
D. Postoperative Management
D.1. What complications may follow this syndrome?
D.2. What would be your follow-up in this case?
D.3. What would you advise the patient and the family?
D.4. What precautions should an MH-susceptible patient take outside of the operating room (OR)?
55 Postoperative Residual Neuromuscular Weakness and Prolonged Apnea
A. Medical Diseases and Differential Diagnosis
A.1. What is the differential diagnosis for postoperative hypoventilation?
A.2. How is residual neuromuscular blockade (NMB) diagnosed?
A.3. What is the order of recovery of voluntary muscle groups from nondepolarizing muscle relaxants?
A.4. What is the mechanism of action of succinylcholine, and how is it metabolized? What are the side effects of succinylcholine?
A.5. If succinylcholine were the only muscle relaxant used during the case and the patient did not exhibit a response to train-of-four (TOF) stimulation, what is the likely diagnosis? How would you confirm it?
A.6. What are acetylcholinesterase and serum cholinesterase? What is the clinical significance of heterozygosity for atypical pseudocholinesterase (PChE)?
A.7. What is the incidence of atypical cholinesterase activity?
A.8. What are some factors that can lower PChE levels?
B. Intraoperative Management
B.1. How is the choice among muscle relaxants made?
B.2. What factors can alter sensitivity to nondepolarizing neuromuscular blockers?
B.3. What are the characteristics of nondepolarizing block?

B.4. What is a TOF stimulus?
B.5. Why is the TOF ratio of clinical importance?
B.6. How do we define adequate recovery of neuromuscular function?
B.7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?
B.8. How accurate are subjective estimates of the TOF ratio, and what purpose do peripheral nerve stimulator (PNS) monitors serve?
B.9. What is double burst stimulation (DBS)?
B.10. What is the posttetanic count (PTC)?
B.11. How can the TOF ratio be measured quantitatively?
B.12. What are the limitations of acetylcholinesterase antagonists?
B.13. Is there anything wrong with administering neostigmine when the TOFC is less than 3?
B.14. Is reversal of blockade always necessary?
B.15. Is there any way to rapidly antagonize a profound nondepolarizing block?
C. Postoperative Management
C.1. What is the incidence of residual NMB in the PACU?
C.2. Does undetected postoperative residual neuromuscular block (PORB) have clinical consequences?
56 Burns
A. Medical Disease and Differential Diagnosis
A.1. How do you classify the burn injury?
A.2. How do you express the extent of the burn injury?
A.3. Should the “rule of nines” be used in children?
A.4. What functions does the skin perform?
A.5. What pathophysiologic changes accompany major thermal injury?
A.6. What is the prognosis for this patient? What major factors affect his prognosis?
A.7. What are the common causes of death in burn patients?
A.8. Does this patient have a smoke inhalation burn? How do you make the diagnosis?
A.9. What is carbon monoxide poisoning? How do you diagnose and treat carbon monoxide poisoning?
A.10. What resuscitative measure would you institute immediately

in this patient with 40% burns?
A.11. What fluid formula would you use?
Parkland Formula
A.12. What cardiovascular changes typify the burn injury?
A.13. What changes occur in hepatic function? What are the anesthetic implications of such changes?
A.14. What are Curling ulcers? How can they be prevented?
A.15. What complications are associated with electrical burns?
B. Preoperative Evaluation and Preparation
B.1. What preoperative preparations would you order? What are particular concerns in this patient?
B.2. What are the various operative and management options available for severely burned patients?
B.3. What are the advantages and disadvantages of early tangential excision split-thickness skin grafting (TE/STSG)?
B.4. What is this patient's mean arterial blood pressure? How do you calculate it?
B.5. Are you concerned about this patient's blood pressure? What treatment would you institute?
B.6. This patient was ventilated with respirator settings of tidal volume, 800 mL; respiratory rate, 20 breaths per minute; fraction of inspired oxygen (FIO_2), 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.24; PO_2, 56 mmHg; PCO_2, 60 mmHg; and oxygen saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high PCO_2 and low PO_2?
B.7. How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues?
C. Intraoperative Management
C.1. What monitors would you use in the operating room?
C.2. What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations performed?
C.3. If the patient had not been intubated, how would you proceed with the anesthetic induction?
C.4. Why is awake intubation considered the safest?
C.5. What anesthetic agents would you use? Discuss inhalation

versus intravenous agents.
C.6. Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?
C.7. How is temperature best maintained?
C.8. What derangements occur with hypothermia?
C.9. What muscle relaxant would you use?
C.10. Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?
C.11. What other adverse effects are associated with succinylcholine?
C.12. How are the doses of nondepolarizing muscle relaxants affected by burn injury?
C.13. How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?
D. Postoperative Management
D.1. How would you monitor this patient during transport?
D.2. What is meant by diffusion hypoxia? How do you prevent it?
D.3. Why do patients often shiver in the recovery room on emergence from anesthesia?
D.4. Discuss the causes of oliguria in the recovery room.
57 Trauma
A. Medical Disease and Differential Diagnosis
A.1. How is trauma classified?
A.2. What are the injuries associated with thoracic trauma?
A.3. What are the injuries associated with cardiac trauma?
A.4. What is the pathophysiology of acute pericardial tamponade?
A.5. What are the anesthetic implications for treating cardiac tamponade?
A.6. How is the initial assessment and management of the trauma patient performed?
A.7. What constitutes a primary survey, and what is its objective?
A.8. What constitutes a secondary survey, and what is its objective?
A.9. What is the definition of massive hemothorax? What are the signs and symptoms of a hemothorax?
A.10. What are the indications for a thoracotomy to treat a

hemothorax?
A.11. How are pneumothoraces categorized?
A.12. What is an occult pneumothorax?
A.13. If the patient has a widened mediastinum on chest radiograph, what are your concerns?
A.14. What are the most commonly injured organs in blunt abdominal trauma?
A.15. What is a focused abdominal sonography for trauma (FAST) examination?
A.16. What is diagnostic peritoneal lavage (DPL)?
A.17. Why was DPL not performed for this patient?
A.18. Define shock.
A.19. What are the four types of shock?
A.20. List the signs and symptoms of shock.
A.21. What is the pathophysiology of hypovolemic shock?
Cardiovascular Derangement
Acid–Base Disturbance
A.22. How would you classify hemorrhage?
A.23. What is the initial treatment of hemorrhagic shock?
A.24. Would you choose crystalloid, colloid, or blood products to treat hemorrhagic shock?
A.25. Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?
B. Preoperative Evaluation and Preparation
B.1. What premedication would you order?
B.2. What preoperative testing would you order?
C. Intraoperative Management
C.1. How would you monitor this patient?
C.2. How would you induce anesthesia?
C.3. What technique could you use if single-lung ventilation was indicated?
C.4. What agents would you choose to maintain anesthesia?
C.5. What muscle relaxant would you choose?
C.6. What can be done to decrease the incidence of intraoperative awareness?
C.7. Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?

C.8. How would you make a diagnosis of tension pneumothorax?
C.9. What is the treatment of tension pneumothorax?
C.10. The patient's blood loss was continuing, and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?
C.11. What precautions should be taken if more than 2 units of low titer type O uncrossmatched whole blood are given?
C.12. What are the complications associated with any blood transfusion?
Transfusion Reactions
Transmission of Disease
Microembolization
What is considered a massive transfusion (MT)? What is the Assessment of Blood Consumption (ABC) score?
C.14. What are the complications associated with an MT?
C.15. Can the shift of the oxygen–hemoglobin dissociation curve be quantified?
C.16. How is hypothermia defined?
C.17. What are the adverse effects of hypothermia?
C.18. What is the treatment of hypothermia?
C.19. What are the effects of blood transfusion on the immune system?
C.20. What are the guidelines for transfusion of blood products?
Red Blood Cell Transfusion Criteria
Platelet Transfusion Criteria
Fresh Frozen Plasma Transfusion Criteria
Cryoprecipitate Transfusion Criteria
What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in an MT?
C.22. If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?
C.23. If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?
C.24. What are the concentrated factors and hemostatic agents available for bleeding patients?
Recombinant Activated Factor VII (rFVIIa, NovoSeven)
Four-Factor Prothrombin Complex Concentrate

Fibrinogen Concentrates
Tranexamic Acid
What is thromboelastography (TEG) and thromboelastometry? How can they guide transfusion?
Rotation Thromboelastometry
Thromboelastography
D. Postoperative Management
D.1. What is acute respiratory distress syndrome (ARDS)? What is acute lung injury?
D.2. How is ARDS treated?
D.3. In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this patient?
Prerenal
Renal
Postrenal
D.4. If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?
58 Scoliosis
A. Medical Disease and Differential Diagnosis
A.1. What is scoliosis?
A.2. What is the most common type of scoliosis?
A.3. What are the other types of scoliosis?
Idiopathic
Neuromuscular
Myopathic
Congenital
Neurofibromatosis
Mesenchymal Disorders
Trauma
A.4. How is the severity of scoliosis assessed, and why is the severity important?
A.5. What are the nonoperative treatment options of scoliosis?
A.6. What abnormalities in pulmonary function tests (PFTs) are most commonly seen in scoliosis? What is the cause of these abnormalities?
A.7. What is the most common arterial blood gas abnormality seen

in scoliosis? What are possible causes for this abnormality?
A.8. What abnormalities of ventilatory drive may be associated with scoliosis?
A.9. How may the cardiovascular system be affected in patients with scoliosis?
A.10. What is the relationship between scoliosis and malignant hyperthermia?
B. Preoperative Evaluation and Preparation
B.1. What should the anesthesiologist know about the nature of the spinal curve?
B.2. What aspects of the history are most important?
B.3. What aspects of the physical examination are most important?
B.4. Why is a preoperative neurologic assessment important?
B.5. What tests would you order preoperatively?
B.6. What is an enhanced recovery after surgery (ERAS) pathway? How has it been applied to the recovery for pediatric patients undergoing posterior spinal instrumentation and fusion?
B.7. How will the surgical procedure influence the anesthetic management?
C. Intraoperative Management
C.1. What monitoring would you use?
C.2. What is the incidence of neurologic complications in scoliosis surgery, and which patients are at highest risk?
C.3. What monitoring techniques are used to minimize neurologic complication?
C.4. What are somatosensory evoked potentials (SSEPs), and how are they used?
C.5. How reliable are SSEPs for predicting spinal injury?
C.6. What are motor evoked potentials (MEPs), and how are they used?
C.7. How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?
C.8. What is the optimal anesthetic technique for scoliosis surgery?
C.9. What should be done if the SSEPs or MEPs become abnormal during surgery?
C.10. How is the “wake-up” test performed? What complications can occur during this test?

C.11. Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mmHg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?
C.12. How common is significant air embolism during scoliosis surgery?
C.13. What should be done if an air embolus is suspected?
C.14. What complications occur related to positioning the patient?
C.15. What is transfusion-related acute lung injury (TRALI)? How do you distinguish it from transfusion-associated circulatory overload (TACO)?
C.16. What techniques can be used to minimize transfusion requirements?
D. Postoperative Management
D.1. When would you extubate the patient?
D.2. What should be done to optimize pulmonary status?
D.3. What laboratory tests should be ordered postoperatively?
D.4. What fluid therapy would you use postoperatively?
D.5. What complications may occur following scoliosis surgery?
D.6. Upon arrival to the recovery room, you notice that the urine appears to be tea colored. What is your diagnosis, and how should this be managed?
D.7. How would you manage this patient's pain, nausea, and vomiting postoperatively?
59 Hypoxia and Equipment Failure
A. Medical Disease and Differential Diagnosis
A.1. What is hypoxia, and what is hypoxemia?
A.2. Is the partial pressure of oxygen in arterial blood (PaO_2) related to age?
A.3. Was this patient hypoxemic?
A.4. What is a pulse oximeter, and what is a hemoximeter?
A.5. How does a pulse oximeter work?
A.6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?

A.7. What may affect the accuracy of a two-wavelength pulse oximeter?
A.8. How do the dyshemoglobins, methemoglobin (metHb), and carboxyhemoglobin (HbCO) affect SpO_2 readings?
A.9. What is a capnometer, and what is capnography? Of what value are they in patient monitoring?
A.10. What is meant by the term end-tidal carbon dioxide ($EtCO_2$)?
A.11. What is the appearance of a normal capnogram, and what is its significance?
A.12. What are mainstream and sidestream capnometers?
A.13. Show some common capnograms and provide a differential diagnosis of each event.
A.14. What is the arterial–alveolar difference in carbon dioxide (CO_2)?
A.15. What are some of the important safety features of the contemporary anesthesia workstation?
Features Intended to Prevent Human Error
Features to Correct for Use Error
Monitoring Systems
Alarm Systems
A.16. What are the common sites for gas leakage?
A.17. How is the anesthesia machine checked for leaks?
B. Preoperative Evaluation and Preparation
B.1. What should be included in the equipment checkout in preparation for anesthesia?
Emergency ventilation equipment
High-pressure system
Low-pressure systems
Scavenging system
Breathing system
Manual and automatic ventilation systems
Monitors
Final position
B.2. What emergency equipment should be easily available to the anesthesiologist?
B.3. How should this patient be premedicated?
C. Intraoperative Management

C.1. How should this patient be monitored?
Oxygenation
Ventilation
Circulation
Body temperature
C.2. Following uncomplicated induction of anesthesia and endotracheal intubation, the procedure begins. Upon insufflation of the abdomen with CO_2, the SpO_2 decreases to 78%. What acute diagnostic and therapeutic interventions would you perform?
C.3. The endotracheal tube was withdrawn 2 cm. Squeezing the reservoir bag in the circle breathing system failed to generate positive pressure in the circuit. What are the common sites for gas leaks in the circle breathing system?
C.4. The patient was taken out of Trendelenburg position. Direct laryngoscopy revealed the endotracheal tube to be supraglottic. Additionally, green secretions were noted to be pooled in the posterior pharynx. What should be done next?
D. Postoperative Management
D.1. What criteria would you use for tracheal extubation?
D.2. What are the causes of postoperative hypoxemia?
D.3. What is the difference between shunt, ventilation/perfusion mismatch, and dead space?
D.4. Postoperatively, the patient developed hypoxia and pulmonary edema. What is the differential diagnosis of pulmonary edema? What is the most likely cause of pulmonary edema in this patient?
D.5. How should the ventilator be set if mechanical ventilation is required postoperatively?
D.6. If this patient had acute respiratory distress syndrome (ARDS) secondary to aspiration, besides low-tidal volume ventilation, what other changes in routine therapy should be considered?
D.7. What therapies routinely administered by the anesthesiologist may cause acute lung injury?
D.8. What methods of oxygen administration may be used postoperatively?
60 Electroconvulsive Therapy
A. Medical Disease and Differential Diagnosis
A.1. What are the indications for ECT?

A.2. Are there any contraindications to ECT?
A.3. What is the mechanism of action of ECT?
B. Preoperative Evaluation and Preparation
B.1. How would you assess the cardiac status of this patient?
B.2. How should his anticoagulation be managed during ECT?
B.3. What implications do his history of sleep apnea have on management of ECT?
B.4. How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?
B.5. Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardioverter-defibrillator?
B.6. Are there any psychiatric medications he is taking that would impact your anesthetic care?
C. Intraoperative Management
C.1. Describe the hemodynamic and cardiac response to ECT in a typical patient.
C.2. Is an arterial line warranted in this patient?
C.3. By what means would you attempt to maximize hemodynamic stability?
C.4. Describe the cerebral hemodynamic effects of ECT.
C.5. How would you proceed with an anesthetic induction for this procedure?
C.6. How do you intend to manage his airway during each treatment?
D. Postoperative Management
D.1. The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options.
D.2. After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?
61 Ambulatory Surgery
A. Medical Disease and Differential Diagnosis
A.1. Is this patient morbidly obese?
A.2. What medical conditions may be associated with obesity and morbid obesity?
A.3. Is there a link to a decline in memory and thinking with

anesthesia and surgery?
B. Preoperative Evaluation and Preparation
B.1. What advantages does outpatient surgery offer?
B.2. What are the goals of the preoperative evaluation of the surgical outpatient?
B.3. In order to thoroughly screen for disease, should one put all outpatients through a full battery of laboratory testing?
B.4. What preoperative laboratory testing is necessary for surgical outpatients?
B.5. Which outpatients should receive a preoperative chest roentgenogram?
B.6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?
B.7. Would age or physical status influence the decision to perform outpatient surgery?
B.8. What patients are considered inappropriate for ambulatory surgery?
B.9. What questions are critically important to ask this patient when obtaining her history?
B.10. What instructions should the patient be given with regard to continuing or discontinuing lisinopril in the perioperative period?
B.11. What is an enhanced recovery after surgery (ERAS) protocol, and how would you apply it in the outpatient setting?
B.12. How would you premedicate this patient?
B.13. Should every outpatient receive prophylaxis against aspiration pneumonitis?
B.14. Is an overnight fast justified for all outpatients?
C. Intraoperative Management
C.1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?
C.2. How would you monitor this patient?
C.3. What is the bispectral index (BIS) monitor, and what information does it convey?
C.4. What benefits might be derived from using a BIS monitor?
C.5. Is BIS monitoring applicable to children?
C.6. What are the major limitations of BIS monitoring?
C.7. What does a BIS reading of 56 mean?

C.8. What anesthetic agents would you use to induce and maintain general anesthesia in this patient?
C.9. Under what circumstances might spinal anesthesia be appropriate for outpatient surgery?
D. Postoperative Management
D.1. What are the common causes of nausea and vomiting in outpatients?
D.2. How would you pharmacologically prevent PONV in the susceptible ambulatory patient?
D.3. How is postoperative pain treated?
D.4. What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?
D.5. How would you decide when to discharge a patient after regional anesthesia?
D.6. What instructions should be given to an ambulatory surgical patients upon discharge?
62 Magnetic Resonance Imaging
A. Medical Disease and Differential Diagnosis
A.1. What is MRI, and how does it work?
A.2. What are some advantages of MRI?
A.3. What are some disadvantages associated with MRI? What are some safety concerns?
A.4. How do you manage patients with implanted devices?
A.5. What are the biologic effects of clinical MRI?
A.6. What are the anesthetic considerations for this procedure?
A.7. What is intraoperative MRI (iMRI)? What is real-time MRI, and in what setting can this be used?
B. Preoperative Evaluation and Preparation
B.1. What type of patients may require sedation or general anesthesia for MRI?
B.2. Do all children require sedation for MRI?
B.3. What preoperative laboratory testing would you require for this patient?
B.4. How would you premedicate this patient? What are some options that can be used to premedicate other patients for MRI?
C. Intraoperative Management
C.1. What are some of the anesthetic options for this patient?

C.2. How is an MRI conducted?
C.3. How would you monitor this patient?
C.4. What special considerations apply to monitoring equipment used during MRI?
C.5. How would you induce and maintain general anesthesia in this patient?
C.6. What are ways to maintain the airway during an MRI scan?
C.7. During the scan, you notice loss of end-tidal carbon dioxide. You immediately go into the scanner, remove the patient from the MRI scanner and initiate bag ventilation. However, you are still unable to ventilate the patient, and asystole follows. What do you do next?
C.8. What is the risk to the patient of gadolinium administration in the presence of acute renal insufficiency?
D. Postoperative Management
D.1. How will you recover the patient from anesthesia?
63 Morbid Obesity, Obstructive Sleep Apnea, and Bariatric Anesthesia
A. Medical Disease and Differential Diagnosis
A.1. What problems exist with this patient? The patient asks you if he is high risk. What is the evidence? Is surgical therapy a safe and viable alternative for this patient?
A.2. Define the terms overweight, obesity, MO, super obesity (SO), super-SO (SSO), normal weight, ideal body weight (IBW), and lean body weight (LBW). What is the impact of obesity on society?
A.3. What is OSA? What are the risk factors for OSA?
A.4. How is OSA diagnosed? What is a sleep study, or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the subtypes of OSA? Are there genetic disorders with a predisposition to OSA? What is the role of OSA screening tests in the preoperative setting?
A.5. How does OSA differ in the pediatric population in clinical presentation and pathogenesis?
A.6. What is the Pickwickian syndrome (PS)? What is obesity hypoventilation syndrome (OHS)? Describe the pathogenesis of severe OSA.
A.7. What is the association between obesity and OSA? What is the

etiology of OSA in severe obesity?
A.8. What are the anesthetic implications of OSA?
A.9. What type of metabolic problems would you expect to find in morbidly obese patients? What are the roles of leptin and ghrelin in obesity?
A.10. Describe the changes that occur in the following respiratory parameters in morbidly obese patients:
A.11. What changes occur in PaO_2 and $PaCO_2$ in morbidly obese patients?
A.12. What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in MO? Describe the Shunt equation and the physiologic dead space, or Bohr equation.
A.13. What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output, blood volume, blood pressure, and pulmonary arterial pressure.
A.14. Are there any other disease entities commonly associated with obesity? What is their relationship?
A.15. What anatomic changes that affect the airway are associated with MO and OSA?
A.16. What derangements of the gastrointestinal system are associated with MO?
B. Preoperative Evaluation and Preparation
B.1. How would this patient be optimized for surgery preoperatively? Would you use preoperative screening questionnaires to diagnose OSA? Summarize the workup for this patient.
B.2. One of the recent developments in bariatric surgery is that many patients are receiving prebariatric screening procedures performed in the endoscopy suite. Describe the anesthetic considerations.
B.3. Summarize the evidence-based workup, risk, chance of various adverse outcome, and expected length of stay for this patient.
B.4. What is the role of enhanced recovery after surgery (ERAS) in bariatric surgery? How does the public find a quality bariatric surgery team and surgical facility? What is the role of robotics in bariatric surgery?

B.5. Would you premedicate the patient?
B.6. Describe the mechanism of action of each premedication in the ENERGY protocol.
B.7. How would you adjust doses of anesthetics in the morbidly obese?
C. Intraoperative Management
C.1. How would you monitor this patient?
C.2. The American Society of Anesthesiologists' (ASA) Difficult Airway Algorithm (DAA) provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?
C.3. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques. What is the importance of continuous positive airway pressure (CPAP) during the induction of general anesthesia? Describe use of the nasal CPAP mask in the induction of general anesthesia.
C.4. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?
C.5. How would you induce anesthesia? Describe the intubation technique.
C.6. How would you maintain general anesthesia? What agents would you choose? How would you prepare for emergence?
C.7. Which muscle relaxants would you use?
C.8. Is postoperative pain severe after bariatric surgery? What are the pain generators? What is the role of regional anesthesia to decrease opioid requirements for bariatric surgery? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?
C.9. What is the pathophysiology of pneumoperitoneum (PNP)? What is the effect on the cardiopulmonary system? How does it change perioperative care? What are the optimal ventilator strategies for morbidly obese patients undergoing bariatric surgery?
C.10. What are the devices that anesthesiologists place in the upper gastrointestinal canal during laparoscopic bariatric surgery? Are there risks associated with placement and management of these

devices?
C.11. When will you extubate this patient? Describe weight-based extubation criteria.
C.12. What is apneic oxygenation?
C.13. What is diffusion hypoxia (DH)? How do you prevent it?
D. Postoperative Management
D.1. What are the early postoperative complications of bariatric surgical procedures?
D.2. What are the late complications of bariatric surgical procedures?
D.3. What is the effect of position on respiratory function in the obese patient?
D.4. How would you prevent postoperative atelectasis?
D.5. How long would you prescribe supplementary oxygen postoperatively?
D.6. How would you control postoperative pain?
Index
