In addition to these various presenting signs and symptoms, asymmetric supratentorial tumors can enlarge to the point of causing a midline shift of the intracranial contents, possibly leading to herniation. The brain can be displaced across the midline beneath the falx or compressed through the tentorial incisura into the posterior fossa. As these various areas of the brain are compressed against these dense fibrous structures,

stretching and shearing of the penetrating arteries can result in devastating neurologic injuries.

An area of cerebral edema surrounds most intracranial masses; secondary to the disruption of the blood–brain barrier (BBB) usually associated with a localized acidosis. Vasogenic edema reflects a shift of fluid from the intravascular to the extravascular space; the interstitial space of the brain. Cytotoxic edema represents a shift of fluid from the extracellular to the intracellular space. Vasogenic edema responds very well to corticosteroid treatment. Dexamethasone is frequently prescribed for this problem. This area of cerebral edema is known as the penumbral area and represents areas of autoregulatory dysfunction as well as BBB breakdown. The vasculature in this area of the brain is usually maximally vasodilated. Hypercapnia in surrounding normal brain causes vasodilation in the normal vasculature and may result in decreased flow to the ischemic area. Hypocapnia, on the other hand, causes vasoconstriction of the normal adjacent vascular beds, with the resultant redistribution of blood to the ischemic area. This has been referred to as the "Robin Hood" phenomenon. The formation of peritumoral edema increases the overall size of the tumor, which can lead to or exacerbate the same signs and symptoms as noted earlier. Such was the case in our patient (**Fig. 19.1**), a tumor with much vasogenic edema, who had a dramatic improvement in symptoms after initiation of dexamethasone.

Patients presenting for an awake craniotomy for excision of an epileptic foci have usually had a seizure disorder for many years and have been on numerous antiepileptic drugs (AEDs) in an attempt to control their disorder. Unfortunately, many of these patients develop adverse reactions or cannot tolerate the side effects of the AEDs and become, for practical purposes, medication failures. **Table 19.1** lists the more common AEDs

and the types of seizure disorder they treat.

TABLE 19.1 Commonly Used Drugs in Seizure Control

Type of Seizure	First-Line Drug	Second-Line Drug
Generalized tonic–clonic	Carbamazepine Phenytoin Valproate	Clobazam Clonazepam Lamotrigine Phenobarbital Vigabatrin Felbamate Acetazolamide
Generalized absence	Valproate Ethosuximide	Clonazepam Lamotrigine Acetazolamide
Tonic, atonic, atypical absences	Valproate Clobazam Clonazepam Lamotrigine Phenytoin	Carbamazepine Phenobarbital Felbamate Acetazolamide
Myoclonic seizures	Valproate Clonazepam	Phenobarbital Acetazolamide
Simple partial, complex partial, secondarily generalized	Carbamazepine Valproate Phenytoin	Clobazam Lamotrigine Gabapentin Vigabatrin Phenobarbital Felbamate Acetazolamide

Only patients with seizures in whom the foci are localized in an area of eloquent cortex require an awake craniotomy. Temporal lobe, hippocampal-localized foci are usually resected under general endotracheal anesthesia with intraoperative electrocorticography. Most of these patients have had preceding intracranial strips, grids, or electrodes placed to help localize the seizure foci.

A.3. What determines intracranial pressure (ICP)?

The adult skull is a rigid, bony box with a fixed volume. Neonatal and infant skulls have several noncalcified portions, called fontanels, which allow the skull to deform during passage through the birth canal. These noncalcified areas also allow the volume of the skull to increase in the presence of increased ICP such as congenital hydrocephalus. Once these areas have calcified, the pediatric skull is also a rigid, fixed-volume box.

The intracranial constituents are intravascular blood, CSF, and the brain. As liquids, the blood and CSF are noncompressible and can be physiologically redistributed outside of the intracranial space. Although water can be extracted from the brain by use of osmotic diuretics and other hypertonic fluids, this does not result in much change in brain volume, and its gel-like consistency also makes it virtually noncompressible, yet both movable and deformable, often resulting in irreversible damage. This can also be redistributed pathologically outside the intracranial vault with uncal herniation.

ICP is a relationship of the homeostatic balance of the noncompressible contents within a fixed-volume container, the skull. The normal value is 10 to 15 mmHg. In the early 19th century, the Monro-Kellie hypothesis was the first attempt to describe this relationship. Although several modifications of this doctrine have been made over the years as more has been learned, the basic principle still holds true: Because the intact skull is unyielding, an increase in volume of any one of the

normal contents or the addition of a space-occupying lesion must be accompanied by a reduction in one or more of the normal constituents to maintain normal ICP (also see Chapter 17, section A.2).

Mokri B. The Monro-Kellie hypothesis: applications in CSF volume depletion. *Neurology*. 2001;56:1746–1748.

A.4. How does a space-occupying mass alter ICP?

There are limits to the balanced relationship described by the Monro-Kellie hypothesis. **Figure 19.2** represents an idealized ICP–volume curve and diagrams these limitations.

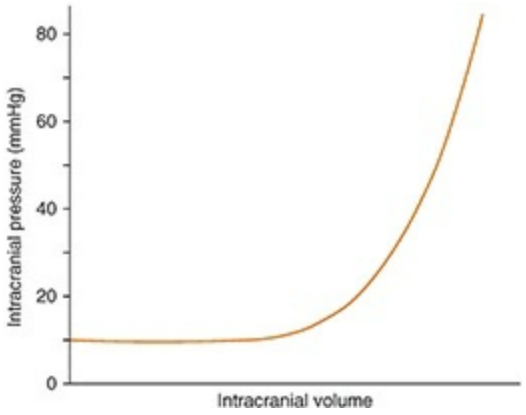

FIGURE 19.2. Idealized ICP volume curve. (*Reprinted with permission from Hou YJ, Kass IS. Physiology and metabolism of the brain and spinal cord. In: Newfield P, Cottrell JE, eds.* Handbook of Neuroanesthesia*. 5th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2012:16.*)

The flat portion of the curve represents increasing volume with no increase in ICP. Several compensatory mechanisms are at work to keep the ICP steady. The most effective of these mechanisms is the dynamic nature of CSF. The rate of absorption increases or the rate of production decreases in light of an increase in ICP. Cerebral blood volume (CBV) is decreased by a redistribution primarily of the intracranial venous blood volume. These mechanisms work to keep the ICP at its

normal value of 10 to 15 mmHg. As the volume continues to increase, these compensatory mechanisms become exhausted and ICP starts to rise as represented by the “knee” of the graph. It is important to note that at this area of the curve, small increases in volume give rise to a much larger increase in ICP. The sharp rise in the graph demonstrates rapidly increasing ICP with even smaller increases in volume. It is vitally important to understand that as the volume continues to rise and ICP continues to increase, the risk of cerebral herniation also increases. The acute rise in ICP is often a localized increase in intracranial volume associated with the underlying pathologic process with a corresponding localized increase in ICP producing a vectorial force and resulting in movement of the brain. Cerebral perfusion pressure (CPP) is also adversely affected with a rise in ICP. CPP is defined as: CPP = MAP − ICP or CVP (depending on which is higher), where MAP = mean arterial pressure and CVP = central venous pressure. MAP, for the purposes of calculating CPP, is measured at the tragus. Implicit in this measurement is that position of the head relative to the heart can dramatically affect these estimates. This equation also shows that an increase in ICP will lead to a decrease in CPP, if MAP does not increase to maintain CPP. However, an increase in MAP is one of the normal physiologic compensatory mechanisms to maintain CPP and hence brain perfusion. Yet, there are many common clinical situations where this compensatory response has been blunted by preexisting comorbid conditions, acute injury, or drugs (e.g., large doses of propofol).

Figure 19.3 shows that CBF is *independent* of MAP over a wide range of pressures from 50 to 150 mmHg. The magnitude of the CBF is determined by the metabolic demands of the brain. Here, the CBF is dynamically increased or decreased to accommodate the changing electrical activity of the brain and

the associated metabolic processes. Some have advocated that the lower threshold for autoregulation should be shifted toward 70 mmHg and the upper threshold shifted toward 180 mmHg. In the supine position, ICP is effectively zero when the dura is opened, making CPP directly related to MAP (at least for structures adjacent to the open dura).

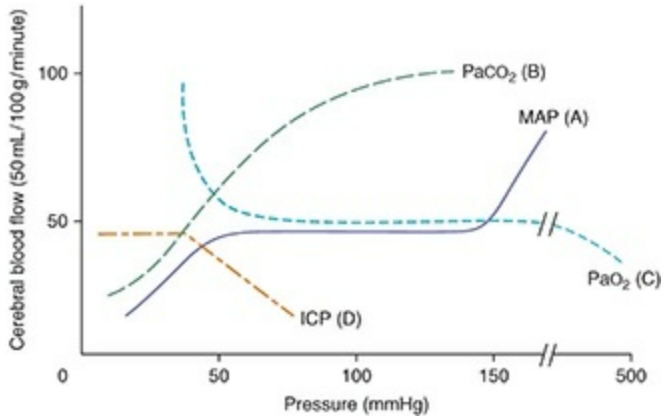

FIGURE 19.3. Pressure–CBF relationships. A, CBF autoregulation. CBF is maintained at 50 mL/100 g/min for mean arterial pressure (MAP) / cerebral perfusion pressure (CPP) = 50 to 150 mmHg; **B,** linear relationship between $PaCO_2$ and CBF for $PaCO_2$ = 20 to 80 mmHg; **C,** PaO_2 and CBF; **D,** intracranial pressure (ICP) and CBF. (*Reprinted with permission from Hou YJ, Ravussin PA. Anesthesia for supratentorial tumors. In: Newfield P, Cottrell JE, eds.* Handbook of Neuroanesthesia. *5th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2012:118.*)

A.5. What is autoregulation, and why is it important?

In its simplest form, autoregulation is a myogenic response of the vascular smooth muscle of the intracranial cerebral arterioles to dynamically maintain a nearly constant CBF in the face of changing CPP. Not all of the mechanisms controlling this action are fully understood.

When MAP becomes less than 50 mmHg or greater than 150 mmHg, CBF becomes pressure passive. This response is important to keep in mind when considering the use of deliberate hypotension. A MAP of less than 50 mmHg could theoretically cause a decrease in CPP and thereby decrease CBF to the point of causing cerebral ischemia. On the other side of the spectrum, MAPs greater than 150 mmHg can cause

disruption of the BBB and vasogenic edema throughout the brain, not only in the area of vasogenic edema surrounding the tumor.

The autoregulation curve is shifted to the right in the presence of chronic uncontrolled hypertension, as shown in **Figure 19.4**.

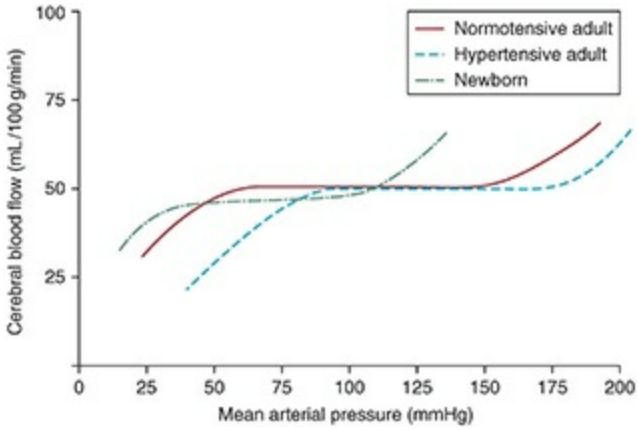

FIGURE 19.4. Autoregulatory curve of the cerebral vasculature in the normotensive adult, the hypertensive adult, and the newborn. (*Reprinted with permission from Hou YJ, Ravussin PA. Anesthesia for supratentorial tumors. In: Newfield P, Cottrell JE, eds.* Handbook of Neuroanesthesia. *5th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2012:15.*)

This is important because now the lower threshold for cerebral ischemia is higher than in the normal state. Although there is not a direct correlation between degree of hypertension and rightward shift of the autoregulatory curve, it is possible that where signs of cerebral ischemia might not have become obvious until the CPP was 30 to 40 mmHg in the normotensive person, these signs may now occur with the CPP at 80 to 90 mmHg, a usually normal CPP. Therefore, great care must be taken to keep MAP near the patient's usual levels in the uncontrolled or poorly controlled hypertensive patient. On the other end of the curve, it is possible that the rightward shift adds some form of cerebral protection against perfusion breakthrough at the higher CPPs. Chronic treatment with antihypertensive drugs modifies this rightward shift back toward the normal range. The degree to which this occurs depends both on the

length of time the hypertension has been treated and the resultant decrease in blood pressure.

The type of drug used to treat hypertension may also determine the effect on autoregulation. Systemic direct-acting vasodilators without action on cerebrovascular smooth muscle and α-adrenergic and ganglionic blocking drugs should have no effect on cerebrovascular autoregulation. Systemic direct-acting vasodilators that do have an action on the cerebrovascular smooth muscle, such as hydralazine, sodium nitroprusside, nitroglycerin, and calcium channel blockers may influence autoregulation. Treating congestive heart failure may also improve CPP by lowering CVP and thereby decreasing cerebral venous outflow pressure.

A.6. How is cerebral blood flow (CBF) regulated?

In addition to metabolic demand, CBF also responds to modulation by dissolved gases. **Figure 19.3** demonstrates these relationships in the arterial carbon dioxide partial pressure ($PaCO_2$) and arterial oxygen partial pressure (PaO_2) curves. Carbon dioxide (CO_2) concentration is the most potent modulator of CBF. Insonating the middle cerebral artery of a volunteer by means of transcranial Doppler device and asking the subject to hyperventilate will show an increase in cerebral blood velocity reflecting a decrease in CBF secondary to cerebral vascular constriction, usually within 3 to 4 breaths, a

very rapid response. This principle is utilized to treat increased ICP by decreasing CBV secondary to the hyperventilation. However, this mechanism is self-limited after approximately 6 to 10 hours and will no longer provide the decreased ICP.

As shown in **Figure 19.3**, there is a near-linear response in CBF at a $Paco_2$ between 20 and 80 mmHg, with CBF increasing about 2% to 4% for each millimeter of mercury change in $Paco_2$. In general, doubling $Paco_2$ from 40 to 80 mmHg doubles CBF and likewise halving $Paco_2$ from 40 to 20 mmHg halves CBF. This represents maximal vasodilation at extreme hypercapnia and maximal vasoconstriction at extreme hypocapnia, respectively.

CBF also responds to the oxygen partial pressure. As shown in **Figure 19.3**, when the Pao_2 reaches approximately 50 mmHg, a steep increase in CBF occurs, as the Pao_2 continues to fall. At normal Pao_2 levels, CBF is not affected. Hyperoxia can actually cause a 10% to 15% decrease in CBF at 1 atm. Temperature can also affect CBF: For each 1°C decrease in body temperature, the cerebral metabolic rate for oxygen consumption ($CMRO_2$) decreases by approximately 7%. The regulation of CBF is closely coupled to the cerebral metabolism and is reflected by a parallel decrease. These changes are not homogeneous, with more changes seen in the cerebral and cerebellar cortices; less so in the thalamus and no difference in the hypothalamus and brainstem. During hypothermic cardiopulmonary bypass, lowering the body temperature to 26°C results in a 56% calculated reduction in $CMRO_2$ and a 55% reduction in CBF.

The potent inhalational anesthetics can also increase CBF in the presence of decreasing $CMRO_2$, thus uncoupling their relationship. Increasing doses can also blunt the CO_2 response or render CBF pressure passive. CO_2 reactivity is preserved during

intraoperative use of opioids such as fentanyl and remifentanil.

A.7. What drug therapies may be associated with this pathology?

Patients can present with intracranial pathology at any age. Patients with comorbidities may be taking medications for hypertension, diabetes mellitus, congestive heart failure, atrial fibrillation, prior myocardial infarction (MI), and reactive airway disease with and without frank chronic obstructive pulmonary disease (COPD) as examples. It is not uncommon today for many patients with cardiac comorbidities to be on anticoagulation and also some form of antiplatelet drug whether they have suffered an MI or not. These chronic comorbid conditions should be well treated and relatively stable, with the coagulation system reconstituted prior to undertaking any awake procedure. The success of the procedure is critically dependent on a compensated and stable cardiopulmonary system and an expectation of relatively small blood loss (<500 ml). The effects of some of these drugs can be reversed with fresh frozen plasma, whereas others are not immediately reversible and need 7 to 10 days before their effect is gone.

Patients with epilepsy may be on several medications in an attempt to control their seizures. These drugs are listed in **Table 19.1**. Presenting signs and symptoms have been described earlier. AEDs are indicated in 26% of patients presenting with seizures who are later diagnosed with a brain tumor.

Another 20% to 45% of patients with brain tumors will eventually develop a seizure after diagnosis. The current

standard (2016) is that prophylactic AEDs should not be started in this group of patients. As a guideline, in patients with brain tumors undergoing craniotomy, prophylactic AEDs may be used, and if there is no seizure activity, they may be tapered, starting 1 week postoperatively. If initiated at the time of surgery, they should be administered early in the procedure because they often have sedating properties and can delay awakening.

As previously discussed, most intracranial mass lesions are surrounded by an area of vasogenic edema to varying extents. The use of steroids, in particular dexamethasone, is commonly employed to help alleviate the problems associated with this. Dexamethasone is more beneficial, and the effect of reducing the area of edema often much more dramatic in metastatic tumors than primary tumors. The usual dosage in the corticosteroid-naive patient is a loading dose of 10 mg IV and then 4 to 6 mg by mouth or IV every 6 hours. Doses of up to 10 mg every 4 hours have been given for severe vasogenic edema. For the patient previously diagnosed and on corticosteroids, the current dose is doubled for acute deterioration.

Greenberg MS. General information, classification and tumor markers. In: Greenberg MS, ed. *Handbook of Neurosurgery*. 8th ed. New York: Thieme; 2016:584–602.

B. Preoperative Evaluation and Preparation

B.1. Why is the craniotomy performed awake?

An awake craniotomy is performed when the pathologic lesion, be it a tumor or an epileptic focus, is in or near an area of eloquent cortex, as defined earlier, in an effort to preserve neurologic function.

The extent of the craniotomy is variable. Some neurosurgeons advocate a carefully planned, limited-exposure craniotomy

defined with neuronavigational devices to encompass primarily the area of the lesion and immediate surrounding brain. Others advocate a large craniotomy exposing a wide cortical area for mapping. In either case, the primary goal of the surgical procedure is to obtain the greatest degree of tumor resection with as little damage to the eloquent cortex as possible and hence the least postoperative neurologic deficit.

Even with the cortex exposed, there are many challenges in identifying these areas of eloquent cortex that demand an awake and cooperative patient. As a tumor within or near the eloquent cortex grows and expands, the various neuronal pathways can become distorted from their normal anatomic locations. Ultrasonography may assist the neurosurgeon in identifying the lesion borders so testing can proceed in the surrounding areas of the cortex. Areas that do not elicit a response, respective of the area being tested, are also identified as areas of negative mapping and may serve as an entrance site for both cortical and subcortical resection as needed. Several studies have indicated that surgery through these areas of absolute negative mapping have a significantly lower incidence of both intraoperative and postoperative neurologic deficits. There is also increasing realization that there are more cortical areas that relate to an acceptable quality of life other than the areas of eloquent cortex. Nonlanguage areas that have to do with visual and/or vestibular functions, spatial awareness, cognitive function, understanding and judgment, memory, calculation, and emotion can be mapped both cortically and subcortically to help prevent postoperative complications that are usually not discussed or described.

B.2. What neurologic symptoms of the patient are important?

In order to successfully complete an awake craniotomy, the patient must be motivated to undergo the demanding procedure and able to effectively communicate with the neurosurgeon, the neurologist or the speech pathologist and the neuroanesthesiologist. The patient's ability to understand and execute a myriad of tasks, depending on the tumor's location, remains of paramount importance. In many cases, the patient must also be able to read short phrases, identify various objects, and describe pictures.

A patient who presents with some form of dysphasia may not be able to participate at all. Expressive dysphasia and global dysphasia are extreme examples but not uncommon presentations. At times, a short course of corticosteroids will decrease the penumbral area enough that verbal testing is practical. Some patients will present greatly agitated. Although this is usually their presenting symptom, they cannot cooperate in any fashion, even with minimal commands, and other means are necessary to care for these patients.

Areas of muscular weakness or paralysis, either from the current problem or past injury, must be identified preoperatively to differentiate between postoperative worsening and new neurologic deficits. Rarely will the patient show improvement in the immediate postoperative period; however, preexisting problems can actually be accentuated in the postoperative period.

Overall, patients who cannot communicate effectively or cooperate do not make good candidates for an awake

craniotomy.

In those patients with an ongoing seizure disorder associated with their tumor or epilepsy, the frequency and character of their ictal and postictal periods should be well understood. Limited seizures during mapping procedures are usually well tolerated if treated promptly. Patients with worsening seizures or generalized tonic–clonic seizures that are frequent are not ideal candidates for an awake procedure. The movements of the body while fixed in a rigid Mayfield frame, hemodynamic derangements, and altered control of the upper airway and ventilation associated with tonic–clonic seizures are potentially life-threatening. In fact, retrospective analysis of failed awake procedure was associated with increased postoperative morbidity and reduction of gross-total resection. Thus, the success of these procedures is critically dependent of good patient selection and the experience of the anesthesia and surgical teams with the nuances of these procedures.

B.3. What is the status of their other comorbid conditions?

Aside from the symptoms associated with their neurologic condition, those associated with the patient's other comorbid conditions can significantly limit the potential success of, and are a relative contraindication to, an awake procedure. This procedure requires the patient to lie in one position with little ability to move and "get-comfortable" for a period of wakefulness of 2 to 4 hours and to remain "motionless" for the remainder of the procedure, typically requiring about 6 to 8 hours of stable hemodynamics and adequate ventilation with an unsecured airway. This represents both a psychological and physiologic stress of significance. There are five common areas of comorbidity to consider when evaluating the relative fitness of the patient for this procedure: morbid obesity, pulmonary,

cardiac, chronic pain, and psychiatric disorders. The morbidly obese patient, body mass index (BMI) >40, presents significant challenges in positioning without incurring skin breakdown and maintenance of upper airway patency in a patient with functional obstructive sleep apnea or hypoventilation syndromes. Poor upper airway control, rocking-shaking ventilatory effort and inability to maintain normocarbia all pose significant challenges. Much of this can be ameliorated with judicious use of airway adjuncts while sedated, in particular, a nasal trumpet. Similarly, COPD particularly with CO_2 retention also complicates CO_2 management. Together, these conditions lead to cerebral vasodilatation and increased CBV. Elevations of CO_2 are particularly detrimental for patients with pulmonary hypertension, especially those with right heart strain. Thus, monitoring of end-tidal CO_2 to help ensure adequacy of ventilation and to minimize CO_2 rebreathing during the initial stages of the procedure is important.

Cardiac arrhythmias such as atrial fibrillation with poor ventricular rate control and poorly or uncontrolled hypertension both place the patient at increased risk for untoward hypotension and hypertension, respectively. Exacerbations of congestive heart failure or ischemic heart disease require further treatment prior to the procedure. Patients with chronic pain pose a special dilemma, especially those on chronic opioid therapy. The short-term management of their chronic pain during the procedure remains problematic because opioids are usually spared to avoid oversedation and hypoventilation. However, this can be addressed with low-dose remifentanil infusion. Paramount to the success of the procedure is the awake and communicative patient; preexisting psychiatric conditions that impair calm and focused attention will most assuredly not improve under the conditions of this procedure and should not be attempted unless

the conditions have been well controlled.

B.4. Are there anesthetic implications from current treatment drugs?

Many of the AEDs currently available for treating patients with seizure disorders or those secondary to a brain tumor are listed in **Table 19.1**. Many of these drugs, such as the benzodiazepines, hydantoin analogs, and phenytoins, can interfere with drug metabolism in the liver, requiring increased dosages of IV anesthetic agents and opioids.

Potential side effects associated with corticosteroid use include, but are not limited to, increased white blood cell (WBC) count, glucose intolerance, corticosteroid "stress ulcers," corticosteroid-induced psychosis, hypertension, water and electrolyte imbalance, suppression of the hypothalamic–pituitary–adrenal axis, weight gain, infection, and impaired wound healing.

B.5. What laboratory data are required?

Although the current practice is to minimize the number of preoperative laboratory tests obtained, several are necessary in the patient undergoing a craniotomy, awake or under general anesthesia, for tumor or epileptic foci resection.

Coagulation studies are a must. Although some tumors can have a significant amount of blood loss associated with their resection (meningioma), bleeding from an abnormal coagulation system into a tumor bed can pose very serious and at times life-threatening problems. Partial thromboplastin time, prothrombin time, international normalized ratio, and fibrinogen and platelet counts are routinely obtained. If patients have been on novel oral anticoagulation (e.g., dabigatran, rivaroxaban, apixaban), there are no routine standardized laboratory studies to quantify drug levels. Institution-specific approaches to monitoring anticoagulation with these drugs should be available in

consultation with a hematologist. In patients who are or have recently taken clopidogrel or other antiplatelet, adenosine diphosphate inhibitors, a platelet activity test is beneficial. This test requires specialized equipment and may be done only at certain times of the day; it may require some form of prenotification to the laboratory to ensure that pretesting preparation is completed before the blood sample arrives. Some AEDs may cause thrombocytopenia, but leukopenia is more common.

Electrolyte studies are necessary. This patient population can have imbalances from substances secreted by the tumor, such as atrial natriuretic factor, or secondary to drug effects, such as hyponatremia or hypokalemia. Blood glucose levels are also included and should be controlled to 120 to 180 mg per dL or less, but hypoglycemia (less than 55 mg per dL) should be avoided. Complete blood count with differential will give information about the hematocrit and WBC count. The differential will be normal if the WBC count is elevated from degranulation of WBCs caused by preoperative corticosteroids. If not, an infection may be present and must be addressed. A routine urinalysis will rule out an asymptomatic urinary tract infection.

Blood type, antibody screen, and crossmatch are also required. In the case of a positive antibody screen, at least 4 units of crossmatched blood are recommended to be available before starting the procedure. Imagine a worst case scenario: a patient with several major antibodies, compatible with 1 in 10,000 blood donors per the blood bank. It could take several days to find acceptable blood. Transfusion during an awake craniotomy is uncommon because these lesions are usually small. Nevertheless, if it does become necessary, the need will be immediate. For a negative antibody screen, 2 units of blood readily available is acceptable.

Depending on comorbidities, an electrocardiogram (ECG) can be obtained.

B.6. What radiology data should be reviewed?

Reviewing the most recently obtained MRI or computed tomography (CT) scans can provide a great deal of insight about the intracranial pathology. Characteristics of the tumor such as ring enhancement, cystic or lobulated nature, or variously weighted CT studies may give the neuroradiologist and neurosurgeon some insight regarding the diagnosis of the tumor as well as the location of the lesion. The location of the lesion may confirm the presenting symptoms. Vasogenic edema is readily seen, and the progress of resolution with corticosteroids is possible by reviewing a series of CT scans since presentation. Additional information can be gained but is not always present for the smaller lesions usually associated with the awake craniotomy. A midline shift would be evidence of increased ICP, as would loss of sulci and gyri, not to mention the presence of uncal or falcine herniation (**Fig. 19.5**). The presence of hydrocephalous from blockage of CSF pathways is also readily seen and could be a source of increased ICP. Previous areas of stroke are usually easily visualized and need to be noted. This is a very rapidly changing field, so there should be no hesitation in calling on the neuroradiologist or neurosurgeon to point out the pathology and their major concerns. Important considerations are how big is the lesion, and how much work needs to be done to provide for safe and effective brain relaxation. A neuroanesthesiologist can never overcommunicate with the neurosurgeon.

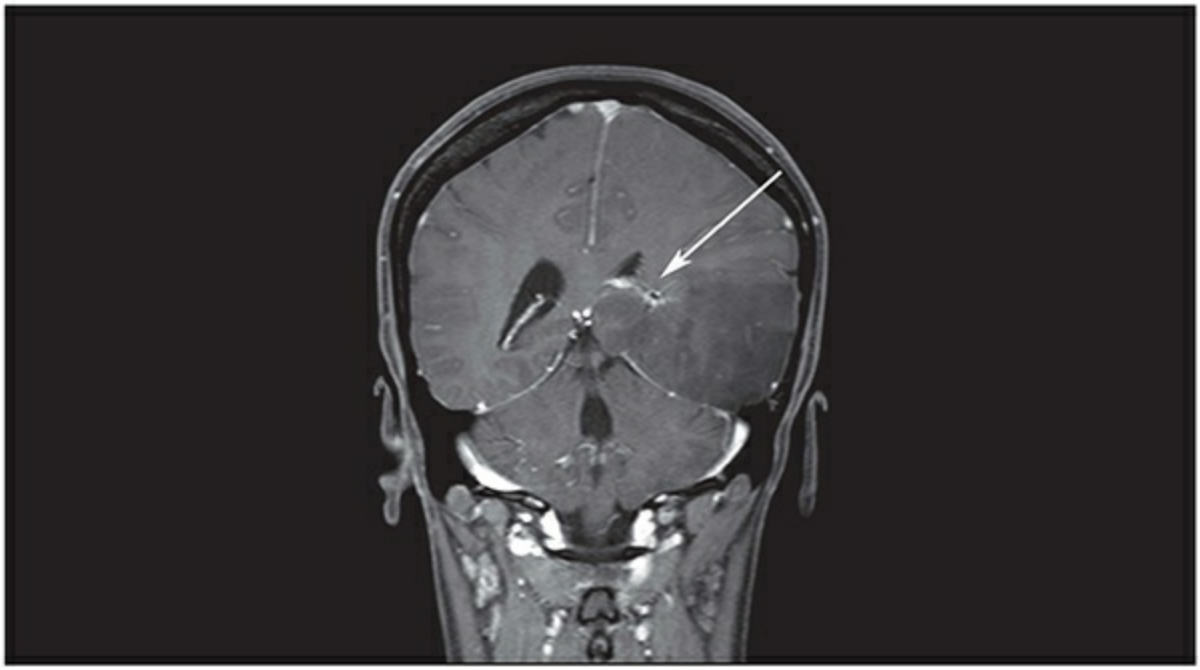

FIGURE 19.5. MRI scan of a 29-year-old female with a 2-week history of word-finding difficulty and no other symptoms. Note the rather significant uncal herniation (*arrow*). The patient underwent an uneventful left, awake craniotomy with language area mapping and was discharged to home the next day. Final pathology revealed a WHO grade III anaplastic oligoastrocytoma.

B.7. How do you prepare the patient for an awake craniotomy?

The most important preparation is proper patient selection, as alluded to earlier. A patient who cannot effectively communicate and cooperate will not do well with this procedure regardless of how well everything else is done.

The need for an awake craniotomy is usually first broached by the neurosurgeon during the workup. It is not unusual then to have a rather concerned and anxious patient arrive in the preanesthetic clinic. Ideally, the neuroanesthesiologist who will handle the case will conduct the interview, although this is not frequent. If not, the neuroanesthesiologist must make every effort to see the patient well before the patient arrives in the operating room. In either case, a direct and detailed explanation of what will happen should be provided. Assure the patient that adequate means will be taken to control any pain, that he or she

can ask for more medications if needed given the limitations secondary to needing the patient awake and cooperative. Discuss additional IV lines, invasive monitors if deemed necessary and why they are used, and when they will be placed.

A discussion about the anesthetic itself is essential. Usually, if patients have a good understanding of the sequence of the procedure and that they may not be exactly fully awake for the entire time they are in the operating room, they are more at ease. Describe everything in detail. This may be the first surgical procedure they have had.

B.8. Should this patient receive premedications?

Any premedications that might affect the intraoperative ability to adequately map the cortex are contraindicated. This includes medications that might not only cause prolonged sedation but, in the case of epilepsy surgery, interfere with intraoperative intracranial electrocorticography to define epileptic foci; benzodiazepines and barbiturates should be avoided for these reasons. A calm and reassuring neuroanesthesiologist is usually the best "premedication."

The *other* premedications are those taken for preexisting comorbidities. Typically, patients should receive medications for their chronic conditions, including (but not limited to) antihypertensive, antiarrhythmics, bronchodilators, as would be the standard practice of the institution, with the exception of anxiolytics, short- and long-acting opioids, aspirin, and nonsteroidal anti-inflammatory drugs. Patients on AEDs for tumor-related seizures should take their AED prior to the procedure. Patients with epilepsy as their primary diagnosis should follow the neurosurgeon's instruction on taking their AED. Often, these medications are held prior to surgery to help with intraoperative electrocorticography.

B.9. What precautions should be made for airway

management?

Airway evaluation is extremely important in this patient population. The head will most likely be fixed in a three-pronged device, making the ability to intubate the patient via direct laryngoscopy virtually impossible. Further limitations include the surgical drapes and the instrument table, which often extend over the patient completely. The patient is often positioned in the lateral decubitus position, making moving the patient to a flat position time-consuming, if possible at all. Patient body habitus can also make tracheal intubation challenging in the nonsupine position. Obese and morbidly obese patients present exceptionally difficult challenges; edentulous patients have bone erosion of both the maxilla and mandible that could make mask ventilation difficult in any position. Patients on phenytoin can have rather impressive gingival hypertrophy and associated bleeding that can interfere with intubation if required; teeth can be loose and easily displaced. These problems can make placement of an airway or laryngeal mask airway (LMA) difficult at best, impossible at worst. The next section suggests that use of an LMA or even endotracheal intubation for these cases is for some the preferred method.

Having an airway cart immediately available and prepared for a fiberoptic intubation with an assorted and readily available selection of LMAs is recommended. At baseline, a nasal cannula for oxygen delivery and CO_2 measurement should be placed before starting sedation. The maintenance of a patent airway is often facilitated by placement of a nasal trumpet. This is placed after sedation has started and may be removed while the patient is awake for testing.

C. Intraoperative Management

C.1. How should this patient be monitored?

Monitoring should be in accordance with the guidelines of the American Society of Anesthesiologists. These include pulse oximetry, electrocardiography, noninvasive blood pressure monitor, capnography, and temperature measurement as a minimum.

American Society of Anesthesiologists. Standards for basic anesthetic monitoring. https://www.asahq.org/standards-and-guidelines/standards-for-basic-anesthetic-monitoring. Accessed November 12, 2019.

C.2. Does this patient require invasive monitoring?

In general, for awake craniotomy, invasive blood pressure monitoring is not a requirement but should be placed in patients with comorbid conditions who would regularly receive invasive arterial monitoring. Nevertheless, many circumstances might be better served with an arterial line. Blood pressure measurement with an oscillometric device can be problematic in patients with atrial fibrillation; it also overestimates both systolic and diastolic blood pressure readings in patients with stiff arteries, such as diabetics. The diabetic patient may also require frequent blood glucose measurements, and the presence of an arterial line facilitates this and avoids multiple venous blood draws in the operating room. In several of the comorbid diseases of particular concern (e.g., obesity, COPD, pulmonary hypertension), the objective data of interest is the $PaCO_2$ and arterial sampling offers the most reliable method, although this could be accomplished with measurement of venous CO_2. Lastly, an arterial line may be placed for comfort as a regular inflation of a blood pressure cuff can be very distracting to some patients. In this, we try to place a radial arterial line in an arm that will not be involved in testing. A central venous line (CVL) for pressure measurement is not required in the awake patient. Nevertheless, at times, venous access is so poor that one needs to be placed

merely for that purpose. The best monitoring system for this case is the awake, cooperative patient.

C.3. Can current drug therapy alter eloquent cortex mapping?

For mapping of the language areas, any drug that would cause long-lasting, deep sedation, as discussed earlier, would be contraindicated. Patients presenting with new onset of seizures associated with the new diagnosis of brain tumor may have been started on any one or several of the AEDs listed in **Table 19.1**. These drugs may interfere with mapping of the eloquent cortex. In patients undergoing epilepsy surgery, the surgeon has usually stopped these drugs several days in advance so as not to interfere with intraoperative electrocorticography or placing of electrodes directly on the surface of the exposed brain. Corticosteroids and opioids do not interfere, but propofol can produce a pattern of high-frequency, high-amplitude β activity on the electroencephalogram for at least 20 minutes, which can cloud the abnormal activity being sought and should be stopped appropriately.

C.4. Why use hypertonic fluids during a craniotomy?

The intact brain, primarily the BBB, acts as an osmometer. Water can freely cross this semipermeable membrane in response to osmotic pressures created by dissolved solutes until there is an equal water pressure across the membrane. This is a function of the number of osmotically active, dissolved solutes (osmoles) present in a solution: The greater the number of osmoles, the greater is the osmolarity or osmotic activity of the

solution. At times, this is also called the *osmolality*. This term describes the same principle but does have several differences. *Osmolarity* is defined as osmoles per liter of fluid and is a calculated value. Osmolality is one of the four colligative properties of a solution. It is defined as osmoles per kilogram of fluid and is a measured value, usually by a freezing point depression method.

Table 19.2 lists several commonly used IV fluids and compares their osmolarity and osmolality. The osmolality is lower secondary to the presence of undissociated solutes in the solution. When solutes are given intravenously, the intact BBB prevents polar solutes from crossing into the brain, thus sequestering them to the intracranial intravascular space and creating a high vascular osmotic pressure, with resultant movement of water from the brain into the vascular space. This reduces brain bulk, which may provide better visualization of the tumor by the surgeon and hopefully decreases the need to apply retractors to the brain surface to enhance visualization. This in turn may help decrease ischemic injury to the brain directly under the retractors. It also decreases ICP in the intact brain. Intravascular proteins create a much smaller oncotic pressure in the intracranial vasculature than do the dissolved solutes, secondary to the intact BBB, and play a lesser role than they do in the peripheral circulation, where they are the primary determinant of fluid moving extravascular to intravascular.

TABLE 19.2 Osmotic Values of Common Intravenous Fluids

Fluid	Osmolarity (mOsm/L)	Osmolality (mOsm/kg)
Water	0	0
5% dextrose (D_5W)	252	259
Normal saline	308	282
Lactated Ringer's	273	250
3% Saline	1,027	921
6% Hetastarch	310	307

20% Mannitol	1,098	1,280
5% Albumin	290	283
Normosol–R	294	281
D_5W/0.2 NaCl	325	321

D_5W, 5% dextrose in water; D_5W/0.2 NaCl, 5% dextrose and 0.2% sodium chloride.

Hall JE, ed. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia, PA: Saunders; 2016:787–794.

C.5. What intravenous fluids (IVFs) are recommended?

Commonly used IVFs during craniotomy, awake or under general anesthesia, include 0.9% saline, 3% saline, 20% mannitol, and 5% albumin.

Normal plasma osmolality is 285 to 295 mOsm per kg. Therefore, any solution with a higher osmolality could act to extract water from the brain. The exception to this is any solution containing 5% dextrose. These solutions have an effective osmolality 259 mOsm less than the measured osmolality because glucose (osmolality 259 mOsm per kg) is rapidly transported intracellularly into neurons and glia and subsequently metabolized. Five percent dextrose in water (D_5W) thus has an effective osmolality of zero and D_5W/0.2 NaCl has an effective osmolality of 62 mOsm per kg as examples. These dextrose-containing solutions would present a very high concentration of free water within the intracranial intravascular space and result in water movement into the brain causing an increase in ICP or brain bulk.

It is now accepted that hyperglycemia before or during an episode of cerebral ischemia worsens outcomes. The mechanisms are not clear. One hypothesis is that during a hyperglycemic episode, increased intraparenchymal glucose leads to lactic acid production during the ischemic period, which is thought to have a negative effect enhancing neuronal death.

This being said, solutions containing dextrose are not routinely used during intracranial surgery.

Mannitol 20% is the most widely used IVF for treatment of elevated ICP. It also acts to decrease CSF production and as a scavenger of oxygen free radicals. Mannitol should be given intravenously over 10 to 15 minutes to prevent a sudden exposure of the cerebral circulation to extreme hyperosmolality (mannitol has an osmolality of 1,280 mOsm per kg), which could lead to a vasodilatory effect with resultant increased CBV, possible brain engorgement, and increased ICP. Increased urine output secondary to osmotic diuresis should be replaced with normal saline. The usual mannitol dose is 0.25 to 1 g per kg. Mannitol use in renal failure is contraindicated because it can exacerbate renal insufficiency and in cases of severe oliguric renal failure accumulate in the intravascular space leading to volume overload and pulmonary edema.

Hypertonic saline comes in a range of concentrations, with 3% being the most commonly used during intracranial surgery. A recent study has shown no difference between equiosmolar mannitol and hypertonic saline infusions for providing brain relaxation.

Normal saline has been the fluid of choice for intracranial procedures and is used to cover fluid requirements and replace blood loss until red blood cells are required. A drawback to its use is that a hyperchloremic, hypokalemic nonanion gap metabolic acidosis can occur when large volumes are given. This can mask other forms of acidosis and cloud the diagnostic picture. Lactated Ringer's solution (osmolality 250 mOsm per kg) would not theoretically, based on the prior discussion, be an ideal replacement for blood loss, insensible loss, or third-space losses. The crystalloid versus colloid debate seems to be never ending and is usually centered on head injury. Colloid, in the form of 5% or 25% albumin is rarely, if ever, needed in an

awake craniotomy.

C.6. Would a lumbar drain for cerebrospinal fluid (CSF) removal benefit this patient?

The lesions in the eloquent cortex are usually small, so a lumbar drain is not indicated. Historically, neurosurgeons have placed a lumbar drain before the start of the surgery to allow CSF to be drained slowly, usually 10 mL per hour, to decrease brain bulk. This might have been placed in an "open" position when the time came to open the dura, allowing for maximal brain relaxation and visualization in addition to preventing any intracranial contents from herniating through the craniotomy site.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:189–208.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1868–1910.

C.7. Venous air embolism (VAE): Is it a concern in this case?

VAE is the entrainment of air into open, noncollapsible vascular structures located above the level of the heart. Therefore, the short answer is yes, because the level of the surgical site meets this definition. VAE is usually associated with posterior fossa craniotomies and cervical spine surgery in the sitting position. Fatal VAE has been described with as little as 3 to 5 cm of surgical site elevation above the heart during lumbar spinal surgery using a four-poster support device in the prone position.

In this case, tumors are usually small and within the cortex, and the patient is either supine or in a nearly horizontal lateral decubitus position. Parasagittal and falcine meningiomas encroaching on the posterior portion of the sagittal sinus are the most common situations for VAE. Fortunately, the eloquent cortical areas are not in this location. Nonetheless, VAE has been reported after pin head holder placement and after craniotomy but before dural opening. This implies that free air can be entrained through the diploic space of the skull unless adequately sealed during the cranial opening. This is usually done with wax. Therefore, as stated earlier, VAE is a possibility during awake craniotomy.

Although transesophageal echocardiography is the most sensitive means of detecting VAE, it is impractical in the setting of awake craniotomy. The precordial Doppler device is the monitor of choice for this particular scenario if the head will be elevated above the level of the heart. When placed in the right or left parasternal region between the third and fourth ribs, Doppler has a high detection rate for VAE. Often, the awake patient may experience an episode of paroxysmal coughing with entrainment of air. The best chance of aspirating a VAE is through a properly placed, multiorificed central line that is positioned 2 cm below the superior vena caval–atrial junction by using intravascular ECG. Lead II is observed while the electrode of the CVL is attached to the leg lead. An equibiphasic P wave indicates that

the tip of the catheter is in the midatrial position.

Treatment for VAE is supportive. If VAE is suspected, the surgeon must be immediately informed and the surgical field flooded with saline to help prevent further air entrainment. Jugular compression and lowering the head are also maneuvers to help stop air entrainment. If it is present, an attempt should be made to aspirate air through the CVL simultaneously with the surgeon addressing the surgical field. Vasopressors or inotropes as needed are given to support hemodynamics and cardiopulmonary resuscitation initiated for cardiac arrest.

C.8. How is the eloquent cortex mapped?

Before the start of the case, the neurologist and or a speech pathologist, will go over the intraoperative testing procedure with the patient. This usually consists of various confrontational type testing in which the patient may be asked to simply count. At other times, the patient may be asked to name items on a card preceded with the phrase "that is a . . . ." Patients are sometimes asked to do simple math problems. It is important to realize that a patient who speaks multiple languages may need to have each of those languages tested separately. Not all learned languages are "laid down" in the same cortical area. This requires extensive preoperative planning to have the needed interpreters available to help with this testing.

Once the craniotomy is completed, the dura opened, and the patient awakened, testing can begin. The tumor surface is often

visible and helps guide the surgeon as to where to start the mapping. A handheld wand with two probes, separated by 5 mm, is gently placed on the brain surface about 2 cm from the tumor edge. This is connected to a constant-current, biphasic stimulator. Neurologists or speech pathologists usually stimulate for 2 to 5 seconds with a frequency of 50 Hz and a pulse width of 200 milliseconds. Responses are usually noted with a constant current range of 4 to 6 mA. After each test, the surgeon moves the wand freely to other areas of the cortex, repeating this procedure until satisfied that functional areas of the cortex have been localized and marked and that an area of negative mapping has been identified through which the tumor or epileptic foci can be resected.

In the case of seizure focus resection, there are no visible signs to follow. Often, the areas of eloquent cortex in danger will have been mapped out by magnetoencephalography (MEG). This is a noninvasive technique for mapping brain activity by recording the magnetic fields produced by the electrical currents of the brain. These studies can then be "laid over" an MRI study and appear as colored squares representing areas of the eloquent cortex tested and can be used for tumor or epilepsy surgery to help identify the functional areas. Mapping can then start outside of these designated areas looking, again, for a quiet area.

Moore TA II, Markert JM, Knowlton RC. Dexmedetomidine as a rescue drug during awake craniotomy for cortical mapping and tumor resection. *Anesth Analg*. 2006;102:1556–1558.

C.9. How are intraoperative seizures treated?

Intraoperative seizures can be either the baseline type, for which the patient presented, or they can be caused by the cortical surface stimulation used to map the cortex. The surgeon usually will not stimulate the same area more than two consecutive times to avoid this complication. If a seizure should occur, it

usually will take the form of the patient no longer answering questions, but maintaining their airway, and at times maybe a slow moaning sound will be made. This usually responds rapidly to application of cold irrigation solution, usually lactated Ringer's solution, to the cortex by the surgeon. If this fails, small doses of propofol, 10 to 20 mg, will usually suffice to stop the seizure. An uncontrolled seizure that is not terminated with these measures can progress into a surgical emergency. The spreading electrical activity will dramatically increase the CBF and blood volume in the cortex exposed beneath the cranial defect. Here, the rapid increase in blood volume pushes the exposed cortex up through the craniotomy defect, a process which can tear delicate cortical veins and result in a cortical venous infarction.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:296–316.

C.10. How will you conduct this anesthetic?

The conduct of this type of anesthetic actually begins long before the patient enters the operating room. The patient must be very motivated for this experience to be successful. The patient must realize fully that this is a lengthy procedure, and 4 to 8 hours is not unusual for being in the operating room. The patient's family must also be involved and have the same understanding. Most important is a motivated and experienced neurosurgeon, neurologist or speech pathologist, and neuroanesthesiologist. Each must realize that time is of the essence and the procedures must be completed as quickly as is safely possible.

The neurosurgeon will be the first person to suggest or inform the patient that this form of surgery is necessary to preserve the language or motor-sensory function. Ideally, the neurosurgeon and the neuroanesthesiologist have a successful history of

performing this procedure. They have developed a technique that has allowed them to have an awake, cooperative patient when the time comes for cortical or subcortical mapping and resection.

In the operating room, before patient arrival, several steps are taken to make the patient as comfortable as possible during this long and demanding procedure. A full-length gel pad is placed on the operating room table under the sheets, an underbody warmer is placed and in some cases the room temperature is set at 70°F or higher. Additional gel pads and foam sheets are available as needed as well as warm blankets.

Following the preoperative visit and IV line placement, the patient is brought to the operating room. Premedications that interfere with ability to cooperate and follow instructions are contraindicated. Standard intraoperative monitors are placed, and a CO_2 monitoring nasal oxygen cannula is placed.

The literature is replete with reports of various anesthetic techniques for awake craniotomy. The common theme is a triphasic “asleep-awake-asleep” technique utilizing a combination of moderate reversible sedation and regional scalp blocks. Some of these techniques use intubation of the trachea and potent inhalational agents until approximately 20 to 30 minutes before cortex mapping when the anesthetic is discontinued and the patient extubated. Others, use a supraglottic airway in the same fashion. Use of propofol, fentanyl, remifentanil, dexmedetomidine, and combinations of these drugs is added to these approaches as a means of transitioning the patient from a general anesthetic to the awake state for mapping and surgery within the eloquent cortex. The use of total IV anesthesia using the same drugs has also been described with the airway controlled by a supraglottic airway with controlled or spontaneous breathing or an unprotected airway (sometimes supported with a nasal trumpet) with

spontaneous respirations.

The literature describes cases in which similar, but not identical, approaches for mapping or other tasking has been successful for one group and not for another. This can lead to frustration in trying to decide how to administer this anesthetic. Many times, the technique is institutionally defined and has worked well for many years. One of the most important things is to fully understand the pharmacology of the anesthetic regimen chosen.

Our institution uses a triphasic total IV anesthesia technique with spontaneous breathing without LMA or tracheal intubation. After standard monitors are placed, two separate infusions are started. Dexmedetomidine is started at 1.0 μg/kg/hr and continued for 10 minutes and reduced to 0.5 to 0.75 μg/kg/hr. Propofol is started at 50 to 100 μg/kg/min. These drugs are titrated as needed to achieve a sedated yet spontaneously breathing patient; corresponding to an Observer's Assessment of Alertness/Sedation scale (OAA/S) of 3 to 4 or a Richmond Agitation-Sedation Scale (RASS) of −2 to −3. Patients on multiple AEDs often require higher doses of sedatives to achieve an adequately sedated patient for this procedure. When the patient no longer responds to name call, a urethral catheter, additional IV lines, and an arterial line, as deemed necessary, are placed. Small bolus doses of propofol 10 to 20 mg are given depending on patient response to these procedures. A loading dose of dexmedetomidine can be given at the discretion of the attending neuroanesthesiologist. The recommended dose is 1 μg per kg over 10 minutes, followed by a maintenance infusion. Reports of persistent bradycardia and hypotension have been reported with this approach versus starting the infusion without a loading dose. Bradycardia is treated with small doses (0.2 to 0.4 mg) of glycopyrrolate, and hypotension is easily treated with a low-dose (0.1 to 0.3 μg/kg/min) phenylephrine infusion. The

dexmedetomidine and propofol combination provides good sedation, anxiolysis, and some amnesia without causing significant respiratory depression.

The success of this procedure lies almost entirely with the precision and adequacy of the scalp blocks performed by the anesthesiologist or neurosurgeon. No amount of sedation will compensate for poorly performed blocks. The scalp block addresses the supratrochlear, supraorbital, zygomaticotemporal, auriculotemporal, greater auricular, and the lesser and greater occipital nerves. A combination of equal volumes of 2% lidocaine with epinephrine 1:100,000 and 0.5% bupivacaine with epinephrine 1:200,000 provides a rapid onset and longer duration than either component separately, although no convincing data support this practice. Use of ropivacaine alone for the same purpose is also described. Following the individual nerve blocks, an intradermal ring of the local anesthetic solution is placed around the operative side of the scalp. Each pin site for the pin head holder device is injected. The surgical incision site is also infiltrated by the surgeon after the patient is prepped and draped.

The dexmedetomidine and propofol infusions are continued as cranial opening proceeds. When the surgeon has made the final burr hole, propofol infusion is terminated and dexmedetomidine dose is reduced to 0.2 μg/kg/hr. The cranial opening continues, and approximately 15 to 20 minutes later, the patient is awake and conversant. The neurosurgeon and neurologist or speech pathologist begin the mapping process, which can take several hours, but usually about 1 hour. Dexmedetomidine is continued at 0.2 μg/kg/hr throughput the mapping process. When satisfied that areas of the eloquent cortex adjacent to the tumor have been localized and an area of negative mapping have been demonstrated, the surgeon proceeds with tumor resection. If the patient is resting comfortably, no

changes in the anesthetic are necessary. For deeper sedation, dexmedetomidine is increased to 0.35 μg/kg/hr; this usually keeps the patient comfortable for the remainder of the procedure. From time to time, the surgeon may ask to remap certain areas, and the dexmedetomidine is again lowered to 0.2 μg/kg/hr. The dexmedetomidine is stopped with skin stapling. The pin head holder is removed, dressings are placed, and preparations are made for leaving the operating room and transferring to the neurosurgery intensive care unit.

A transport monitor capable of providing pulse oximetry, blood pressure measurements, and ECG tracing is attached, and nasal cannula oxygen is continued during the transport.

D. Postoperative Management

D.1. What are the major concerns following craniotomy?

Several problems can occur in the immediate postoperative period following craniotomy. In general, the patient is transported to the neurosurgical intensive care unit and monitored as described. The head of the bed is usually elevated 20 to 30 degrees to maximize cerebral venous drainage with care of the patient transferred to the neurointensivist and the neurosurgical service.

The key feature of a good neuroanesthetic is the ability to quickly awaken the patient following the procedure so that a neurologic exam can be performed. Typically, with the current regimen the patient will awaken within 5 minutes after the end of the procedure. However, awakening in patients who have required larger doses of medication to achieve an adequate level of sedation (OAA/S 3 to 4) may take 10 to 20 minutes until a suitable neurologic exam can be obtained. Not infrequently, the patient may have a subtle diminution of the neurologic exam compared to the end of the tumor resection. These small differences are likely due to residual anesthetics and progressive edema around the resection site. The former will usually improve over the next 1 to 2 hours and the latter can take several days to resolve completely.

Emergence hypertension is not uncommon in the perioperative period. The incidence of postcraniotomy hypertension has been reported to be 57%. In this series of 11,214 craniotomies, perioperative systemic hypertension was associated with postoperative intracranial hematoma, with resultant increased mortality and increased length of hospital stay. Other possible causes are pain, hypercapnia, and shivering. Eighty-five percent of postoperative intracranial hematomas become evident within 6 hours of surgery and usually present as

a progressive decrease in level of consciousness. Up to 17% of these hematomas present at sites remote to the surgical site. Aggressive efforts at controlling this hypertension are required to prevent possible devastating complications such as bleeding into the tumor bed, requiring a second surgical procedure to evacuate that clot.

Systolic blood pressure goals in a normotensive patient are typically 120 to 140 mmHg and for a chronically poorly controlled hypertensive patient 140 to 160 mmHg. In both cases, aggressive measures to maintain blood pressures at the lower end of the range are warranted if the resection site was large and/or hemostasis was difficult. Often, if not contraindicated, bolus doses of labetalol 5 to 10 mg IV (to a total of 60 mg) is effective. Persistent hypertension, without signs of intracranial hypertension, may require additional treatment. Given the strict blood pressure parameters, failing suitable control with labetalol or hydralazine 5 to 10 mg IV, patients are usually transferred to the intensive care unit on an infusion of nicardipine 5 to 15 mg per hour or clevidipine 1 to 2 mg per hour rapidly titrated up to 16 mg per hour. Alternatively, depending on the patient's comorbid conditions, infusions of sodium nitroprusside or nitroglycerin are possible. A combination of enalapril and labetalol versus nicardipine alone has been reported, with little difference in the ability to control emergence hypertension.

Acute pain control is essential in the postoperative period. Not only are patients more comfortable with adequate pain relief but this also helps control postoperative hypertension and decreases the possibility of intracranial hematomas. Pain following craniotomy has probably been vastly understated secondary to concern about respiratory depression and sedation as well as the traditional thought that craniotomies are less painful than other operations. The incidence of postcraniotomy pain may be as high as 70%. However, our experience is that

pain following an awake procedure is much less common as the duration of the scalp blocks can extend well into the postoperative period. Another helpful adjunct is IV acetaminophen either given during the operative course or at the end of the procedure.

In the immediate postoperative period, almost all pain control medications are given intravenously. Morphine sulfate patient-controlled analgesia has been reported with good results and without respiratory depression or need for reintubation. One regimen consists of morphine 1.5 mg with a lockout period of 8 minutes and a total dose not to exceed 40 mg in 4 hours.

Nonsteroidal anti-inflammatory drugs have been associated with postoperative intracranial hematoma. Administration of antiplatelet agents (aspirin and nonsteroidal anti-inflammatory drugs) was the most common risk factor. Therefore, this class of analgesics should be avoided in the immediate postoperative period.

Postoperative nausea and vomiting is common following craniotomy and can cause hypertension and an increase in ICP. Infratentorial surgery, female sex, and a young age are associated risk factors. Ondansetron 4 to 8 mg IV can provide effective treatment.

Seizures can occur following intracranial tumor resections and can cause serious complications such as secondary intracranial bleeding, hypoxemia, and possibly aspiration. An intracranial mass, such as a hematoma (**Fig. 19.6**), should be suspected if the patient does not regain consciousness within a short period after the seizure has ceased. Small doses of midazolam, 1 to 2 mg, or other benzodiazepines can treat seizures effectively without compromising the airway.

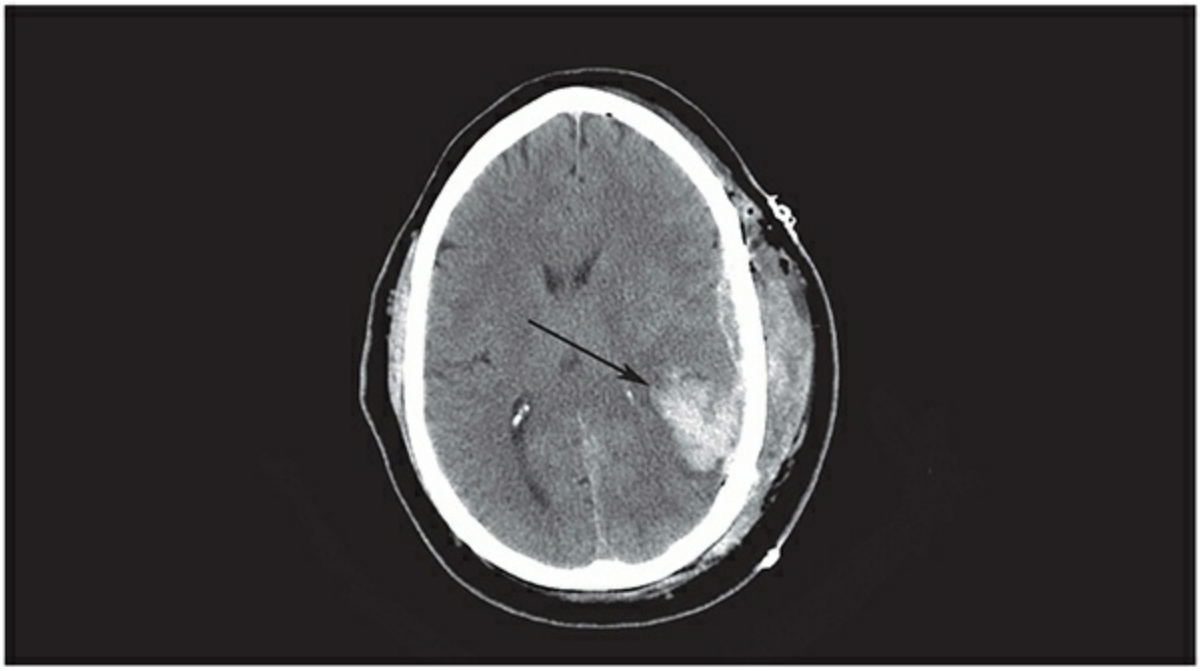

FIGURE 19.6. CT scan of a 73-year-old man who underwent an uneventful left awake craniotomy with motor and language area mapping. On postoperative day 2, he suffered a generalized tonic–clonic seizure and was extremely slow to awaken. CT scan revealed the presence of a large intracranial hematoma (*arrow*) in the operative site requiring return to the operating room for evacuation. Also note the small epidural and subgaleal hematomas. Coagulation studies were normal. The patient was placed on AEDs and did well on follow-up visits without further seizure activity. AEDs were successfully weaned over several weeks. Final pathology revealed glioblastoma multiforme.

Increased ICP commonly occurs after intracranial surgery, with the most common finding on CT scan being brain edema. Maximum pressures are usually recorded within 16 hours of surgery. Associated risk factors are glioblastoma resection and surgery lasting more than 6 hours. Continuing corticosteroids, such as dexamethasone 4 to 10 mg every 6 hours, usually controls this problem.

Peripheral nerve injuries are uncommon after awake craniotomy because patient comfort or discomfort can easily be assessed, and minor movements made if needed. Blister formation along the down side of morbidly obese patients' upper leg can occur after about 5 hours in the lateral decubitus position despite gel pads beneath the thigh.

Acknowledgments

We would like to thank the following people for their assistance in making this endeavor possible: Drs. Mark R. Harrigan and James M. Markert, chairman, University of Alabama School of Medicine (UABSOM), Department of Neurosurgery, for their

assistance in the acquisition and preparation of the radiographs used in this chapter; and Drs. David Miller and Richard C. Cross, UABSOM, Department of Anesthesiology and Perioperative Medicine, for their critical reading, suggestions, and encouragement.

20 Head Injury

Chris C. Lee , Susan A. Ironstone, and M. Angele Theard

A 52-year-old woman with an unknown past medical history, who was involved in a high-speed motorcycle collision, was airlifted to a trauma center. On the scene, she was combative, unresponsive, and intubated. She was found to have a left small pneumothorax, rib fractures, and an open tibial/fibular fracture that was reduced and fixed with return of pulses after an initial pulseless left leg. She had a skull fracture extending to the left parietal bone, occipital bone, clivus sphenoid sinus fracture, and temporal bone that was diagnosed at an outside hospital.

On admission, the patient had a Glasgow Coma Scale (GCS) of 7T, and her vital signs were a blood pressure (BP) of 69/40 mmHg, heart rate 150 beats per minute, respiratory rate 20 breaths per minute, and oxygen saturation 100% on 60% fraction of inspired oxygen (F_{IO_2}). The patient was aggressively resuscitated with packed red blood cell transfusions, 0.9% normal saline (NS), and placed on a norepinephrine infusion.

Head computed tomography (CT) scans showed bilateral traumatic subarachnoid hemorrhage (tSAH) and subdural hematomas (**Figs. 20.1** and **20.2**). Her laboratory values were as follows: hemoglobin, 9.8 g per dL/hematocrit, 29.5%; platelets, 137,000 per μL; lactate, 6.5

mmol per L; international normalized ratio (INR), 1.73; troponin-I, 1.27 ng per mL; glucose, 418 mg per dL; sodium (Na), 141 mEq per L; potassium (K), 3.6 mEq per L; and creatinine, 1.36 mg per dL. Fresh frozen plasma (FFP) and prothrombin complex concentrate (PCC) were given immediately to correct the coagulopathy.

The patient was GCS 7T; therefore, a right frontal external ventriculostomy drain (EVD) was emergently placed for intracranial pressure (ICP) monitoring and cerebrospinal fluid (CSF) drainage because her CT scan showed tSAH and early sings of cerebral swelling. The patient was managed conservatively for her ICP but required increasing medical treatment, including maximal hyperosmolar therapy, adequate pain control, sedation, and paralysis. Her ICP readings remained in the 30 mmHg range after initially low ICP readings. The patient was taken to the operating room for a bifrontal craniectomy for emergency decompression secondary to severe bifrontal contusions with malignant cerebral edema (**Figs. 20.3** and **20.4**).

A. Pathophysiology and Differential Diagnosis

1. What types of intracranial injuries are most likely to have occurred in this patient?
2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?
3. What are the benefits and risks of administering mannitol?
4. What is the effect of hyperglycemia on neurologic outcome following head trauma?
5. What alterations in sodium and potassium balance can occur in patients with head injury?
6. In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?
7. What are the neuroprotective effects of administering magnesium (Mg)?
8. What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?
9. What is the role of decompressive craniectomy (DC) as a treatment option for ICP control after head injury?
10. Do genetic factors play a role in the outcome after head injury?

B. Preoperative Evaluation and Preparation

1. What is the GCS? What is the significance of a GCS of 7T in this patient?
2. In addition to the GCS, what other assessments can be done to evaluate neurologic function?
3. What is the role of CT scanning in the initial evaluation of the patient with head injury? What are the management options in patients whose neurologic condition is deteriorating before obtaining a CT scan?
4. What is the role of ICP monitoring in the management of head injury?
5. How can you clear this patient's cervical spine?
6. What are the advantages of early endotracheal intubation in this patient?
7. What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling of the head and neck?
8. What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?
9. What coagulation abnormalities are present after TBI? What modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?

C. Intraoperative Management

1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?
2. Should hyperventilation be used in this patient?
3. What are the implications of arterial hypertension in patients with head injury? How should BP be managed?
4. What should be done about intravenous (IV) fluid replacement? Should corticosteroids be given empirically?
5. Should hypertonic saline (HTS) be administered to this

patient? How is HTS administered?

6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?
7. Should hypothermia be employed in this patient?

D. Postoperative Neurointensive Care Management

1. What are the postoperative ventilation concerns in this patient?
2. What specific measure should be used to control the patient's ICP? What type of monitoring devices can be used to measure ICP?
3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?
4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?
5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?
6. What methods can be used in the neurointensive care unit to prevent hyperthermia?

A. Pathophysiology and Differential Diagnosis

A.1. What types of intracranial injuries are most likely to have occurred in this patient?

The common causes of TBI include falls, motor vehicle accidents (MVA), assaults, and gunshots. TBI is a leading cause of death and disability after injury in the United States. The following types of intracranial injuries are most likely to have occurred in this patient:

- **Concussion** is both the most common type of TBI and the least apparent on imaging. It is often completely invisible to

any type of imaging and must be assessed and diagnosed clinically. It is also the most common type of TBI to result in ongoing morbidity, causing decreased job and school performance from lasting cognitive symptoms. This is a very complex type of injury and is a big focus of professional sports team injury experts. There is currently a social movement occurring now to raise awareness of these injuries, particularly in young athletes.

- **Diffuse axonal injury (DAI)** is difficult to see on CT of the brain, although small punctate hemorrhages in white matter tracts can be seen. Magnetic resonance imaging (MRI), particularly susceptible weighted imaging, is a more sensitive way to detect it. DAI can produce severe neurologic impairment with a poor prognosis.
- **tSAH** is the most common type of posttraumatic intracranial hemorrhage and the least severe indicator of injury. Although this finding often signals the presence of significant concussion injury, it does not require surgical intervention. tSAH resolves within days and carries a far lower risk of the secondary consequences than those associated with spontaneous aneurysmal subarachnoid hemorrhage (e.g., hydrocephalus and stroke from intracerebral vasospasm). Follow-up CT scans are usually not necessary due to this low risk of secondary neurologic injury.
- **Epidural hematoma** (located between the skull and dura mater) is classically associated with displaced temporal bone skull fractures causing a laceration of the middle meningeal artery. This arterial pressure hemorrhage results in a rapidly expanding hematoma lateral to the temporal lobe, which can lead to death from herniation if it is not emergently surgically evacuated. Injury to large venous structures including dural sinuses or venous bleeding from fractured bone can lead to a so-called venous epidural hematoma. Due to the fact that

these hemorrhages occur at venous pressure, they are thought to be less likely to expand to dangerous volume, but sometimes surgical treatment is required. Patients with acute epidural hematoma often exhibit a lucid interval after the initial impact before deteriorating. The signs of this deterioration can include depressed mental status, an ipsilateral fixed and dilated pupil, contralateral hemiplegia, and imaging demonstrating uncal herniation due to the rapidly expanding hematoma. Arterial epidural hematomas are almost always a true neurosurgical emergency; rapid intervention makes the difference between a good prognosis and death.

- **Subdural hematomas** (located between the brain and dura) arise from a tear in the dural sinuses or bridging veins and may accumulate more insidiously than an epidural hematoma. They are classified as acute (up to 48 hours), subacute (48 hours to 12 days), and chronic (more than 12 days) according to the interval of time between the TBI and the onset of symptoms. Subdural hematomas greater than 1 cm in thickness or causing more than 1 cm of midline shift are generally associated with significant lateralizing neurologic symptoms and often constitute a surgical emergency. Small subdural hematomas can expand in volume as they grow more chronic and can produce delays in onset of significant neurologic signs and symptoms.
- **Intracerebral hematomas and hemorrhages** arise from the tearing of small vessels in the white matter and are due to penetrating head injury or caused by acceleration-deceleration injuries that involve laceration of cortical arteries. These hemorrhages and hematomas can often be managed medically with serial follow-up head CT scans. Surgical evacuation of intracerebral hematomas is rarely indicated due to the deep location of many of these

hemorrhages. Although they can be associated with trauma, hypertension, amyloid angiopathy, and/or profound coagulopathy are more common causes.

- **Cerebral contusions** are superficial hemorrhages that occur mainly when the anterior temporal and frontal lobes strike the rough edges of the tentorium (contrecoup contusion). In a patient without focal neurologic deficits, the most probable intracranial injury is a cerebral contusion after ruling out other focal brain injuries. This type of injury is often associated with cerebral edema and can require aggressive management with hyperosmolar therapies or surgical craniectomy for decompression.

A.2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?

Primary injury refers to the direct injury of tissue at the moment of head trauma.

Secondary injury occurs minutes, hours, and even days after the initial head trauma and is the consequence of ischemic insults to the brain. The factors contributing to secondary injury include systemic causes (i.e., hypoxia, hypotension, hypo- or hypercarbia, fever, and hypo- or hyperglycemia) and intracranial

causes (i.e., intracranial hypertension, elevated ICP, and herniation). Systemic hypotension and intracranial hypertension are factors related to increased morbidity and mortality in patients with severe TBI. Mental status changes suggest inadequate cerebral perfusion, either from decreased systemic BP or elevated ICP. Cerebral perfusion pressure equals mean arterial pressure minus either ICP or central venous pressure, whichever is greater (CPP = MAP − ICP or CVP). Achieving a CPP between 60 and 70 mmHg requires maintaining an adequate BP, oxygenation, and a normal $PaCO_2$ in order to decrease the chance of mortality, morbidity, or any deleterious sequelae caused by secondary injury.

A.3. What are the benefits and risks of administering mannitol?

Benefits

Mannitol (20%) 0.25 to 1.0 g per kg body weight is effective in acutely reducing cerebral edema, brain volume, and ICP by increasing serum osmolality to 305 to 320 mOsm per L to improve CPP, which also facilitates surgical exposure and reduces tissue trauma from surgical retraction. The use of hyperosmolar agents is theoretically limited by an upper acceptable osmolality limit of about 320 mOsm per L. Its osmotic diuresis takes effect in 5 to 15 minutes, achieves a peak effect in 30 minutes, and lasts for 2 to 3 hours. For decades, mannitol has been commonly accepted as an acute treatment for

cerebral edema.

Risks

- After TBI, the possibility of loss of the blood–brain barrier (BBB) integrity leading to leak of mannitol into cerebral interstitial tissue may actually worsen cerebral edema.
- Osmotic diuresis can cause hypovolemia and the consequent hypotension can aggravate cerebral ischemia.
- It can transiently cause hypervolemia and may worsen or result in congestive heart failure in those patients who have borderline cardiopulmonary function.
- Electrolyte abnormalities (e.g., hypernatremia) due to diuresis can occur.
- A serum osmolality above 320 mOsm per L can cause renal failure.
- It could cause intracranial rebleeding in patients with expanding hematoma by removing a tamponading effect on the hematoma if mannitol is administered before the dura is opened.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1874–1875.

A.4. What is the effect of hyperglycemia on neurologic outcome following head trauma?

Hyperglycemia resulting from the nervous system response to injury following moderate to severe head trauma has been associated with an increased odds ratio for an unfavorable neurologic outcome and an increased risk of mortality. Additionally, persistent hyperglycemia has been found to be an independent predictor of an unfavorable outcome in patients with severe TBI. The degree of stress-induced hyperglycemia

(SIH) has been found to correspond to the severity of TBI.

Although there is a possibility that intensive glucose control with blood glucose targets of <126 mg per dL may be associated with improved neurologic outcome, it has not been shown to reduce mortality and does appear to increase the risk of severe hypoglycemia. In critically ill patients, hypoglycemia is strongly correlated with increased morbidity and mortality. Therefore, moderate glucose control targets with a range of 144 to 180 mg per dL are still currently recommended so that hyperglycemia and hypoglycemia can be avoided.

A.5. What alterations in sodium and potassium balance can occur in patients with head injury?

Electrolyte abnormalities such as hyponatremia and hypokalemia are commonly seen following head trauma. Hyponatremia may result via several mechanisms, including hypothalamus–pituitary dysfunction, cerebral salt-wasting syndrome, and syndrome of inappropriate antidiuretic hormone (SIADH). Additionally, sodium loss may be exacerbated by medications used to treat cerebral edema. Hyponatremia has been strongly correlated with poor outcomes. Severe hypokalemia has been found to be an independent mortality risk factor in patients with TBI and is likely related to trauma and stress-related catecholamine surge. Hypernatremia, resulting from mannitol use, HTS, or diabetes insipidus, is also frequently

seen in association with severe TBI. Hypernatremia may itself be an independent risk factor for postoperative death in patients with severe TBI.

A.6. In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?

Multiple electrolyte abnormalities, including hypomagnesemia and hypophosphatemia, are often associated with TBI and can be challenging to treat.

Symptoms of hypomagnesemia include ventricular arrhythmias, widened QRS, prolonged PR interval, weakness, and seizures. Symptomatic hypomagnesemia, or magnesium (Mg) level of less than 0.8 mEq per L, should be treated with IV Mg, although oral Mg should be used for asymptomatic patients. Mg repletion may also be required for successful correction of hypokalemia or hypocalcemia.

Patients with hypophosphatemia can present with hypotension, seizures, as well as cardiac or respiratory failure. Treatment of hypophosphatemia can result in severe hypocalcemia and so should only be considered in moderate to severe hypophosphatemia or symptomatic patients.

Wu X, Lu X, Lu X, et al. Prevalence of severe hypokalaemia in patients with traumatic brain injury. *Injury*. 2015;46(1):35–41.

A.7. What are the neuroprotective effects of administering magnesium (Mg)?

N-methyl-D-aspartate (NMDA) receptors are stimulated by excitatory amino acids, like glutamate, in the central nervous system. Once stimulated, the NMDA receptor ion channels will facilitate calcium entry into the cell. In the face of ischemia (TBI), Mg levels in the brain are reduced, and this has been associated with excess glutamate causing excitotoxicity and consequent increased intracellular calcium and cell death. Mg, a noncompetitive inhibitor of the NMDA receptor ion channel, will limit the influx of calcium, thereby decreasing cell death. Other effects of Mg include down regulation of the membrane protein, aquaporin 4, which is known to increase cerebral edema and decrease upregulation of the tumor suppressor gene *TP53*, which causes apoptosis. The benefits of Mg have been translated into decreased cortical damage noted in the rat brain after brain injury.

Despite encouraging preclinical data of the benefits of Mg as well as established safety studies, human outcome studies on the impact of Mg after TBI are varied. Mg administered 12 hours after TBI led to a significant decrease in mortality at 3 months: 13% mortality for patients treated with Mg versus 47% in the placebo group. Of those who survived, good recovery (Glasgow outcome score) was observed in 54% of the patients treated with Mg and 38% of patients treated with placebo. In another study, however, Mg administered to patients within 8 hours of brain injury had no beneficial effect based on mortality, seizures, functional status, or neuropsychological testing at 6 months postinjury. Study design problems, such as missing baseline vital signs, glucose values, concurrent injuries, and neurologic

scores at discharge, contributed to the mixed results. Another challenge in translating the benefit of Mg seen in preclinical studies to human research is the notably small, possibly inadequate, increase in ionized Mg in CSF affected by increasing serum Mg levels. This finding may relate to the integrity of the BBB. Finally, the multifactorial etiology of TBI may necessitate research examining combination therapy (e.g., combinations of hypothermia and/or hyperoxia that restore mitochondrial function with Mg administration) in order to achieve more consistent and favorable outcomes.

A.8. What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?

The estimated cost of care for the 3.5 million TBI victims in the United States annually is between $60 and $221 billion dollars. Unwavering efforts to improve TBI outcomes have compelled consideration of evidence, which suggests that women less than 50 years old suffering TBI have a decreased mortality risk compared to men. Additionally, preclinical data suggesting less severe sequelae and reduced mortality from TBI in pubescent compared to prepubescent females has served as the impetus for exploring the influence of sex hormones on outcomes after TBI.

Atella et al. demonstrated improved functional outcome in

pseudopregnant rats (higher progesterone levels) after TBI compared to normal cycling female rats with similar injuries. Other mechanisms by which progesterone may improve outcome after TBI include an anti-inflammatory action by reducing microglia activation and proinflammatory cytokines and stimulation of postinjury remyelination and repair. Estrogen may also be beneficial in cerebral ischemia by stabilizing the BBB and increasing blood flow during and after ischemia as well as improving regeneration and plasticity of new neurons.

Small clinical studies, which demonstrated a more favorable outcome with administration of progesterone 8 hours after injury while encouraging, did not translate into positive findings in two published major progesterone trials. In these two separate randomized controlled trials (RCTs) (SYNAPSE and PRoTECT III trial), progesterone administered to TBI patients did not produce a favorable outcome at 6 months as assessed by Extended Glasgow Outcome Scale (includes an assessment of ability to participate in activities of daily living) or other secondary outcomes. Conclusions from a recent meta-analysis of RCT comparing progesterone to placebo for TBI suggest that although exploration of the neuroprotective potential of progesterone should continue, routine administration of progesterone for TBI is not recommended.

A.9. What is the role of decompressive craniectomy (DC) as a treatment option for ICP control after head injury?

In TBI, DC has historically been reserved for those patients with increasing ICP refractory to medical therapy (e.g., sedation, hyperventilation, osmotic diuretics, HTS, paralysis, and/or ventriculostomy). A skull flap is removed to make room for the expanding traumatized brain thereby effecting a decrease in ICP and improved cerebral blood flow (CBF). However, this procedure is associated with a 26% mortality rate and is not without risk; contusion expansion, contralateral subdural hematoma or epidural hematoma, CSF leakage, herniation, and infection can occur. Consequently, translating the benefits of DC (i.e., decreased ICP and increase CBF) into a better neurologic outcome in this patient population has been challenging. TBI patients who underwent bifrontal craniectomy as an *early intervention* for increased ICP after failed medical therapy in the DECRA trial had poorer outcomes (worse scores on the Extended Glasgow Coma Scale) compared to patients who received standard care. Rates of death at 6 months were similar between the DC group and the standard care managed group. More recently, the RESCUEicp researchers investigated DC as a *last-tier* treatment for refractory increased ICP in TBI patients. At 6 months, DC for refractory increased ICP conferred an increased survival in TBI patients over patients managed medically; however, more patients in the DC group were in a vegetative state compared to medically managed patients. More investigation is needed to better identify which patients might benefit from DC, with consideration given to patient's quality of

life.

A.10. Do genetic factors play a role in the outcome after head injury?

Genetic factors as modulators of neurologic outcome while far from conclusive are worthwhile considering in order to elucidate varied TBI outcomes and to facilitate more effective treatment strategies. Evidence to date has suggested a role for genetic polymorphism (alterations in the DNA sequence within a given gene) as a contributor to the interindividual variability in outcomes after TBI. Polymorphisms along the coding region of tumor necrosis factor (TNF)-α at position -308 *A* allele (allele 2) may play a role in this proinflammatory cytokine's influence on TBI. In one study, individuals identified with -308 A-allele were more likely to have less favorable outcomes after TBI than noncarriers.

A change from proline to arginine due to a coding polymorphism in the p53 protein (involved in cell death) encoded by total protein 53 on chromosome 17 may help to explain poor outcomes in some TBI patients. Poor neurologic outcome has been associated with a greater rate of individuals homozygous for the arginine allele.

Another genetic polymorphism that may play a role in damage from TBI as well as recovery afterward is the angiotensin-converting enzyme (ACE) gene on chromosome 17. The ACE D (deletion) polymorphism in TBI patients appears to confer worse cognitive performance when compared to patients with the I (insertion) allele. Altered CBF due to increasing levels of ACE in the ACE D/D genotype may be responsible for cerebral ischemia affecting poor outcome.

Polymorphism in the proinflammatory cytokine interleukin (IL)-1 has been associated with more hemorrhagic events after TBI.

Genetic variation in the neurotrophin, brain-derived neurotrophic factor (BDNF), critical to memory and learning may affect processing speed suggesting an influence of the BDNF gene on cognitive performance after TBI.

Apolipoprotein E (APOE), a well-studied gene implicated in neurotrauma outcomes, is synthesized by astrocytes, microglia, and neurons under conditions of stress. This gene plays a role in neuronal repair and growth, maintains synaptodendritic connections, and is a mediator in brain inflammatory responses. Chromosome 19 carries the APOE gene, which has three major alleles. Research has linked the $\varepsilon 4$ allele, arginine/arginine, which differs from the other two major alleles, $\varepsilon 2$ (cysteine/cysteine) and $\varepsilon 3$ (cysteine/arginine), to poor outcomes in patients 6 months after brain injury. Women over 55 years with this polymorphism who suffer TBI have poorer outcomes when compared to men with TBI, and APOE4 has been identified as a risk factor for development of chronic traumatic encephalopathy (CTE).

B. Preoperative Evaluation and Preparation

B.1. What is the GCS? What is the significance of a GCS of 7T in this patient?

The GCS is an assessment tool in use since 1974 that uses eye opening as well as verbal and motor responses to evaluate neurologic status and severity of TBI (**Table 20.1**). It was initially developed to assess head trauma patients, although its use has expanded to many other patient populations. In this patient, a GCS of 7T signifies that she has a severe TBI and is intubated.

Patients with a GCS score of 13 to 15 are considered to have a mild TBI; moderate TBI is classified by a GCS score of 9 to 12, whereas a GCS score of 8 and below corresponds with severe TBI. Compared to patients with other types of traumatic injury, mortality risk is significantly increased with severe TBI. Even with isolated TBI, these patients are also at high risk of failure of nonneurologic organs. Guidelines published for the management of severe head injury by the American Society of Neurological Surgeons (ASNS) and Brain Trauma Foundation recommend early therapy directed toward avoiding hypotension and hypoxia as well as ICP monitoring in order to guide therapy for maintenance of cerebral perfusion. Adherence to these guidelines has been associated with improved survival following severe head injury.

in severe head injury: compliance with Brain Trauma Foundation guidelines and effect on outcomes: a prospective study. *J Neurosurg*. 2013;119:1248–1254.

TABLE 20.1 Glasgow Coma Scale

Eye opening:	None	1
	To pain	2
	To verbal command	3
	Spontaneous	4
Best verbal response:	No verbal response	1
	Incomprehensible sounds	2
	Inappropriate words	3
	Disoriented, conversing	4
	Oriented, conversing	5
Best motor response:	No response (flaccid)	1
	Extension (decerebrate)	2
	Abnormal flexion (decorticate)	3
	Flexion/withdrawal	4
	Localizes to pain	5
	Obeys verbal commands	6

B.2. In addition to the GCS, what other assessments can be done to evaluate neurologic function?

Although the GCS is the most commonly used assessment tool, there are other methods available to assess neurologic function. Abnormalities in pupillary size, symmetry, and light reflex may reveal conditions requiring immediate intervention such as uncal or cerebellar herniation. The World Federation of Neurological Surgeons scale is a modified GCS which grades patients according to GCS score and presence or absence of motor deficits. The Hunt and Hess scale is a grading system that predicts mortality in patients with subarachnoid hemorrhage based on clinical presentation and may also be useful for evaluation of TBI patients. The Abbreviated Injury Scale (AIS) is an anatomic scale for assessing the severity of traumatic injuries. It may be useful in conjunction with the GCS in more

accurately evaluating TBI in elderly patients.

B.3. What is the role of CT scanning in the initial evaluation of the patient with head injury? What are the management options in patients whose neurologic condition is deteriorating before obtaining a CT scan?

Following head trauma, CT scan can be very useful for revealing acute brain injury. An early CT scan is indicated for a GCS of 9 to 12 (moderate head injury) as well as severe head injury. Any patient with a deteriorating GCS score requires an immediate CT scan.

The Canadian CT Head Rule is a clinical decision-making tool that was developed to guide the use of CT scans in head injury because the vast majority of CT scans performed in the context of head trauma are negative for significant brain injury. The rule is used to assess risk level for neurosurgical intervention and brain injury on CT in patients with minor head injury and GCS of 13 to 15. Patients considered to be at high risk for neurologic intervention have any one of the following findings:

a. GCS score less than 15 at 2 hours beyond the time of injury
b. Any suspected open or depressed skull fracture
c. Signs of basal skull fracture (hemotympanum, Battle sign, raccoon eyes, otorrhea, or rhinorrhea of CSF)
d. Two or more episodes of vomiting
e. 65 years of age or older

Patients with injury resulting from any dangerous mechanism, such as ejection from a motor vehicle, fall from a height of 3 feet or more, or any patient who exhibits amnesia of 30 minutes or more prior to injury are considered to be at medium risk for brain injury findings on CT.

It is important to note that the Canadian CT Head Rule does not apply to trauma patients with GCS <13, obvious open skull fracture, age less than 16 years, or in patients with a bleeding disorder or taking anticoagulant medications.

The airway should be secured with an endotracheal tube as soon as possible in patients with deterioration in neurologic function or in those who are likely to have such changes prior to obtaining a CT scan.

B.4. What is the role of ICP monitoring in the management of head injury?

ASNS/Brain Trauma Foundation (BTF) guidelines recommend early ICP monitoring and concomitant goal-directed therapy for maintenance of cerebral perfusion in patients with severe head injury. Adherence to these guidelines may improve outcome in this patient population, primarily through guiding therapy to minimize secondary insults following the initial injury.

Because of impaired CBF and autoregulation in the injured brain, cerebral perfusion is highly dependent on cranial perfusion pressure for oxygen delivery and the prevention of cerebral ischemia.

Systemic hypotension and intracranial hypertension are

factors related to increased morbidity and mortality in severe TBI. Because CPP values of less than 50 mmHg are correlated with poor outcomes, continuous monitoring of ICP should be used to guide therapy in patients with severe TBI. The target range for CPP is 60 to 70 mmHg according to the most recent ASNS/BTF guidelines.

Currently, recommendations for ICP monitoring include (1) patients with GCS 3 to 8 following resuscitation and abnormal CT scan related to the injury (contusion, swelling, compressed basal cisterns, or hematoma seen on CT) and (2) patients with severe TBI if two or more of the following features are present: age over 40, motor posturing, or systolic BP (SBP) less than 90 mmHg, even if the CT scan is normal. Current recommendations include treating an ICP >22 mmHg, although treatment decisions may also depend on CT findings and clinical presentation.

ICP monitoring can be performed using ventricular catheters or intraparenchymal fiberoptic monitors. Ventricular catheters have the advantage of allowing CSF drainage, although they do carry a higher infection risk. In the setting of a coagulopathy, placing an ICP monitor is contraindicated.

B.5. How can you clear this patient's cervical spine?

The National Emergency X-Radiography Utilization Study (NEXUS) low-risk criteria are commonly used to determine the need for radiographic imaging in the clinical evaluation of cervical spine injury. A patient is considered to be low risk for cervical spine injury if they meet all of the following criteria:

1. No posterior midline cervical spine tenderness
2. No evidence of intoxication
3. GCS score of 15—normal level of alertness
4. No focal neurologic deficit
5. No painful distracting injuries

However, there is evidence that patients with clinically significant cervical spine injuries, such as ligamentous injury, cervical spine fracture, or dislocation, may be considered low risk according to the NEXUS criteria, particularly elderly patients. This may be a result of variation in determining the extent or presence of distracting injuries.

The Canadian C-spine Rule is another clinical decision-making tool that may be used in evaluating the need for further imaging in cervical spine injury. The criteria take into account the mechanism of injury, midline neck tenderness, and the ability to rotate the neck more than 45 degrees without pain (if it is safe for the patient to do so). A recent comparison of the Canadian C-spine and NEXUS rules indicated that the Canadian C-spine Rule may have greater reliability.

Nevertheless, CT evaluation is still recommended in the case of major trauma because of the possibility of misdiagnosis of a clinically significant cervical spine injury.

B.6. What are the advantages of early endotracheal intubation in this patient?

Endotracheal intubation is indicated in this patient with a severe TBI and a strong probability of further neurologic deterioration. Choosing early endotracheal intubation provides the advantage of securing the airway under more controlled and optimized circumstances as well as providing safer conditions for further evaluation and treatments.

Guidelines published by the Eastern Association for the Surgery of Trauma recommend early endotracheal intubation for all patients with a GCS score of 8 or less (level 1 indication). Other level 1 indications include airway obstruction, persistent hypoxemia, hypoventilation, hemorrhagic shock, and cardiac arrest.

Mayglothling J, Duane TM, Gibbs M, et al. Emergency tracheal intubation immediately following traumatic injury: an Eastern Association for the Surgery of Trauma practice management guideline. *J Trauma Acute Care Surg*. 2012;73:S333–S340.

B.7. What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling of the head and neck?

The practitioner considering airway management in a trauma patient should take into account his or her own skill level and experience with different approaches to intubation. Although

fiberoptic intubation could minimize manipulation of the cervical spine, difficulty is increased substantially under emergent conditions, especially in the presence of bleeding or secretions. Additionally, in a combative, uncooperative patient, attempting an awake or lightly sedated fiberoptic intubation would be inadvisable. Rapid sequence induction (RSI) may provide the best intubating conditions in the trauma patient, who should be considered a full stomach and at high risk for aspiration of gastric contents.

There is some controversy among practitioners regarding the use of both ventilatory breaths and cricoid pressure during RSI of the trauma patient. The risks of oxygen desaturation and hypercarbia for each patient must be taken into consideration when deciding whether ventilation should be used. If ventilatory breaths are necessary, cricoid pressure could limit gastric inflation caused by positive pressure ventilation, although it may also reduce tidal volumes. There is also some evidence that cricoid pressure could degrade laryngoscopic view in up to 30% of patients and should therefore be discontinued if required to improve intubating conditions and expedite securing the airway.

A recent large study conducted in 10 academic centers suggests that the risk of pulmonary aspiration does not increase if cricoid pressure (i.e., Sellick maneuver) is not applied during RSI induction of anesthesia. It is important to note, however, that this trial did not extend to patients outside of the operating room or to pregnant patients.

In-line stabilization (facilitated by removal of the front of the cervical collar if needed) is still recommended in the setting of cervical spine injury. Assistance from one or more individuals will be required in this endeavor, particularly with a combative patient.

Videolaryngoscopy would most likely be highly beneficial under these circumstances (depending on clinician experience)

for facilitation of intubation while reducing stress on the cervical spine. Difficult airway equipment should also be immediately accessible should the need to follow the difficult airway algorithm arise.

If an extremely difficult airway is anticipated, very cautious use or avoidance of neuromuscular blocking drugs (NMBDs) should be exercised, and alternative methods for securing an airway, such as cricothyroidotomy, should be considered.

A primary concern in a patient with facial fractures is the ability to provide adequate ventilation and preoxygenation prior to induction. Additionally, there is also a substantial probability that swelling, blood, and secretions will limit visibility and markedly increase difficulty in securing the airway. Light palpation of the facial bones can help to ascertain the presence of facial fractures.

Oral intubation is highly preferred in trauma situations. Nasal intubation should be avoided in head injury because of the possibility of fractures of the basilar skull and cribriform plate and concerns over entering the cranial vault as well as failed intubation.

B.8. What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?

The rapid onset and short duration of succinylcholine make it a suitable NMBD for facilitating intubation in trauma patients. Succinylcholine has been shown to transiently increase ICP, but this effect should be weighed against the potential detrimental effects of hypercarbia and hypoxia in patients with severe head

injury and is not a contraindication to its use. The rise in ICP may be attenuated by pretreatment with a small dose of a nondepolarizing NMBD; however, the benefits of this practice have not been proven.

In cases where succinylcholine is not considered to be suitable, high-dose rocuronium (1.2 mg per kg) is an alternative for RSI, particularly when sugammadex is available.

The cyclodextrin sugammadex (Bridion©) is a neuromuscular blockade reversal drug for use with the aminosteroid nondepolarizing agents, rocuronium and vecuronium, that has recently become widely available in the United States. In high doses (16 mg per kg), sugammadex may be considered for emergency reversal of rocuronium. It should be noted, however, that bradycardia and dose-dependent transient elevated activated partial thromboplastin time (aPPT) and prothrombin time/international-normalised-ratio (PT/INR) have been reported with sugammadex.

B.9. What coagulation abnormalities are present after TBI? What modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?

Coagulopathy, particularly in the first 24 to 72 hours following severe TBI, is associated with a high risk of mortality and may occur in greater than 60% of these patients. The risk of poor outcome may be increased up to 30 times in TBI patients presenting to the emergency room with abnormal coagulation. Therefore, the initiation of early coagulation monitoring is recommended.

Both hypo- and hypercoagulable states may be present and include disorders of coagulation enzymes, platelet function, thrombocytopenia, and impaired fibrinolysis. Although no specific mechanism has been established, release of tissue factor leading to a consumptive coagulopathy as well as hyperfibrinolysis and abnormal activation of the protein C pathway have been proposed.

Acute coagulopathy following severe head injury is complex and may not be differentiable from coagulopathy associated with other types of trauma. Treatment should address the primary cause with correction of the coagulation abnormality and a focus on controlling bleeding. Although FFP could be useful when there is evidence of a coagulopathy, prophylactic early use in head trauma has not proven to be beneficial and is related to adverse events. Conflicting information exists with respect to platelet administration. Goal-directed platelet use may be effective in reversing platelet dysfunction, particularly in reversal of aspirin therapy, but may not be as effective with other antiplatelet medications. Nevertheless, it is still recommended that an INR above 1.4 and a platelet count at or below 75,000 per μL be corrected.

Recombinant factor VIIa rapidly corrects INR and possibly allows earlier neurosurgical intervention, although a higher incidence of asymptomatic deep vein thrombosis has also been observed. Additionally, administration of recombinant factor VIIa has not been found to improve clinical outcomes and may

be associated with lower GCS at discharge. Four factor prothrombin complex concentrate has been recommended for Vitamin K antagonist reversal, as well as for reversal of Novel Oral Anticoagulants that inhibit Factor Xa, in TBI patients with ICH.

Tranexamic acid has also been investigated and may show some benefit with reduction in intracranial hemorrhage progression particularly in the first 1 to 3 hours following injury. Idarucizumab is a specific antibody now available for the reversal of dabigatran.

C. Intraoperative Management

C.1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?

First, the patient should be stabilized prior to CT scanning or

any other diagnostic studies. When a patient, who has sustained a TBI, is uncooperative, combative, or comatose and requires airway control, an emergent endotracheal intubation is necessary to protect airway, facilitate diagnostic procedures, such as head CT scan or MRI, and prevent hypoxia and hypercarbia which are two important secondary insults. Hemodynamic monitoring should include standard American Society of Anesthesiologists (ASA) monitors: noninvasive BP, electrocardiography (ECG), pulse oximetry, capnography (end-tidal carbon dioxide [$EtCO_2$]), and temperature. Patent airway, adequate ventilation, and stable circulation are initial priorities.

If the patient with TBI shows signs of intracranial hypertension (defined as sustained ICP greater than 20 mmHg), such as headache, nausea/vomiting (N/V), papilledema, focal neurologic deficits, altered consciousness, or Cushing triad (reflex arterial hypertension, bradycardia, and bradypnea), hyperosmolar therapy (e.g., mannitol) should be started immediately to lower ICP without direct ICP measurement during CT scanning.

In addition to the aforementioned standard ASA monitors, during the craniotomy for evacuation of a subdural hematoma, which is much more common than epidural hematoma and carries a worse prognosis, an intra-arterial catheter for continuous BP monitoring and urine output monitoring are appropriate in this patient. Central line placement should be considered if the patient has difficult peripheral IV access, the injury is extensive or unknown, or the patient is unstable requiring norepinephrine infusions. ICP monitoring is indicated in this patient because she has severe TBI and abnormal findings on her head CT scans. Important objectives in the management of the patient with TBI are to maintain adequate MAP, keep ICP less than 20 mmHg, prevent or reverse herniation, minimize retractor pressure, and facilitate surgical access. Furthermore,

CPP monitoring and novel techniques, such as jugular venous oxygen saturation ($SjvO_2$) for advanced cerebral monitoring (ACM), may help guide management and improve outcome. Normal $SjvO_2$ threshold is 55% to 75% (see section D.5 for additional information). Medical treatment and surgical intervention decisions are ideally driven by multiple monitoring approaches and ongoing clinical assessment. In addition, monitoring for venous air embolism is reasonable if the patient's head is elevated above the heart.

C.2. Should hyperventilation be used in this patient?

The 2017 BTF guidelines recommend that hyperventilation be avoided during the first 24 hours after TBI when CBF is often critically reduced during the stage of primary brain injury. Hyperventilation with maintenance of $PaCO_2$ 30 to 35 mmHg is an acceptable temporizing measure to reduce elevated ICP unresponsive to sedation, neutrally positioned head elevated to 15 to 30 degrees, osmotic diuretics, and/or CSF drainage but should be as brief as possible. When prolonged hyperventilation is required, monitoring cerebral oxygenation with $SjvO_2$ and CBF with transcranial Doppler should be considered.

$PaCO_2$ is a powerful determinant of CBF. The target $PaCO_2$ is 35 to 45 mmHg. Generally speaking, alterations of $PaCO_2$ within

the range of 20 to 80 mmHg cause changes in CBF accordingly, that is, a decreased $PaCO_2$ or hypocapnia results in decreased CBF and ICP. Moderate hyperventilation ($PaCO_2$ 30 to 33 mmHg), therefore, is often very helpful in reducing CBF and normalizing ICP. A modest decrease in $PaCO_2$ is valuable to counteract the vasodilating effects of volatile anesthetics. However, hypocapnia with resultant vasoconstriction can cause cerebral ischemia, which may worsen cerebral injury in patients with focal ischemia, particularly in a recently injured brain and in a brain beneath a retractor. The most recent BTF guidelines are that hyperventilation should be employed selectively rather than routinely in the management of patients with TBI. Prolonged prophylactic hyperventilation with $PaCO_2$ of ≤25 mmHg is not recommended. Hyperventilation should be reserved for patients in which herniation is imminent.

C.3. What are the implications of arterial hypertension in patients with head injury? How should BP be managed?

Hypertension is common in head injury patients who do not have other injuries associated with massive blood loss. There are at least four important implications of arterial hypertension in patients with head injury. (1) Higher SBP may be required to achieve adequate CPP (CPP = MAP − ICP or CVP), particularly in patient with severely elevated ICP. This may be the body's compensatory mechanism. MAP and CPP must be considered in

addition to SBP. Efforts to optimize CPP should first lower ICP. (2) Because autoregulation of CBF is usually impaired in areas of brain injury, arterial hypertension can worsen cerebral edema, leads to secondary hemorrhage, and increases ICP because of the increased cerebral blood volume and hyperemia ("pressure-passive" in TBI patients with impaired cerebral autoregulation). Intra-arterial BP monitoring is necessary. (3) Cushing triad is reflex systemic hypertension, bradycardia, and bradypnea in association with elevated ICP. It is a late and unreliable sign that usually precedes brain herniation. (4) Other etiologies of arterial hypertension might be related to pain or catecholamine surge and can be treated with opioids and deepening anesthesia only after hypoxemia and hypercarbia are ruled out as causes.

It is prudent to maintain SBP ≥100 mmHg for patients 50 to 69 years old or at ≥110 mmHg for patients 15 to 49 or over 70 years old. Recent guidelines recommend keeping CPP between 60 and 70 mmHg to ensure adequate brain perfusion and avoid secondary brain injury in order to improve outcomes. However, patients with TBI associated with multiple trauma injuries are at risk for arterial hypotension (SBP <90 mmHg) related to bleeding, especially when combined with tachycardia. Avoiding hypotension in patients with severe TBI is a primary perioperative goal. Hypotension can cause cerebral ischemia and is related to poor neurologic outcome in TBI patients; treatment includes the judicious use of IV fluids, blood transfusion, and vasopressors. Interventions to stop bleeding and restore intravascular volume should precede surgical management of TBI. Attention to fluid resuscitation is in order because aggressive IV fluids to maintain CPP >70 mmHg may lead to acute respiratory failure.

C.4. What should be done about intravenous (IV) fluid replacement? Should corticosteroids be given empirically?

Hypotension (SBP <90 mmHg) after head injury is associated with a greater than 70% increased incidence of morbidity and mortality when compared to patients with higher SBPs. Fluid resuscitation should be initiated prior to induction of anesthesia. IV fluids are replaced in trauma patients to restore circulation secondary to blood loss and to maintain MAP and CPP. The important principles are that the chosen fluids should be able to prevent decreases in serum osmolality and colloid oncotic pressure. The choice of the best resuscitation fluids for patients with severe TBI is still controversial. The SAFE-TBI study (2007) indicated that resuscitation with 4% albumin (vs. saline) may be linked with greater mortality in TBI; therefore, 0.9% NS is preferable. Lactated Ringer's solution should be avoided because it was associated with increased mortality compared with NS in patients with TBI.

Corticosteroids should not be given empirically in the operating room because there are no benefits in these patients. In patients with severe TBI, high-dose methylprednisolone was associated with increased mortality and is contraindicated; this is unlike the beneficial role they play in mitigating the swelling and edema that can occur with brain tumors, subdural hematomas, postoperative swelling, and acute spinal cord injury.

Semler MW, Self WH, Wanderer JP, et al. Balanced crystalloids versus saline in critically ill adults. *N Engl J Med*. 2018;378(9):829–839.

C.5. Should hypertonic saline (HTS) be administered to this patient? How is HTS administered?

Even though mannitol is used most commonly intraoperatively because of its rapid onset, efficacy in decreasing ICP, and improvement in brain relaxation, HTS has been used as an alternative agent for the effective treatment of elevated ICP. HTS can be administered if this patient is refractory to mannitol or if repeated administration of mannitol results in the adverse effects such as renal injury, hypovolemia, or electrolyte disturbances from profound diuresis.

HTS (3% most commonly used), like mannitol, creates a hyperosmotic state in the intravascular compartment but does not cross the intact BBB. As a result of the osmotic gradient formed across the BBB, water flux from the extravascular to the intravascular compartment occurs. At this time, however, there is insufficient evidence to support the use of one rather than the other to improve outcomes such as mortality or functional recovery. Three percent HTS is typically administered via a central venous catheter as a continuous infusion with careful attention to serum sodium (keep between 145 and 155 mEq per L). Slow administration is helpful in preventing central pontine myelinolysis.

Hyperosmolar agents (mannitol and HTS) are more widely used in neurosurgery to decrease the brain volume of the intra- and extracellular fluid compartments and ICP. However, loop diuretics help promote diuresis.

C.6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?

The three important principles in providing anesthesia for craniectomy for evacuation of an intracerebral hematoma in this patient are to maintain adequate MAP, control cerebral edema, and reduce ICP in order to maintain CPP and provide brain relaxation for surgical access. All inhaled anesthetics (all of the volatile anesthetics and nitrous oxide [N_2O]) have some cerebral vasodilatory effect, increase CBF and ICP, and are best avoided. Volatile anesthetics often uncouple CBF and cerebral metabolic rate for oxygen ($CMRO_2$); they produce a dose-dependent increase in CBF but decrease $CMRO_2$. However, all of the IV anesthetic agents, except ketamine, are cerebral vasoconstrictors and cause coupled decrease in CBF and $CMRO_2$ in dose-dependent manner. The IV anesthetic agents such as propofol and narcotics are preferred in this patient. Even though propofol is most commonly used to help reduce ICP, high-dose propofol

is associated with significant hypotension, which can be prevented as long as you support the patient with vasoactive agents. It is critical to keep in mind that hemodynamic stability is essential before and during high-dose propofol. Like N_2O, ketamine increases both CBF and $CMRO_2$ and should also be avoided.

C.7. Should hypothermia be employed in this patient?

Mild hypothermia (32°C to 34°C) may be the most effective method for protecting the brain during focal and global ischemia because it can reduce both basal and electrical metabolic requirements throughout the brain. Induced hypothermia can be employed if this patient is at high risk of intraoperative ischemia and her elevated ICP is refractory to other therapies after discussion with her family or surrogates. However, early (within 2.5 hours), short-term (48 hours postinjury), routine prophylactic hypothermia in neurosurgery is not recommended to improve clinical outcomes in patients with diffuse injuries. An international multicenter trial of mild hypothermia did not show neurologic improvement in patients with TBI. Clinicians should keep in mind that hypothermia may cause cardiac arrhythmias and coagulopathies (platelet dysfunction) and may worsen acidosis, which are deleterious to patients with TBI. Fever worsens clinical outcomes after severe TBI, presumably by aggravating secondary brain injury. Hyperthermia should be treated aggressively and avoided. Intraoperative normothermia is the goal for temperature management. In witnessed cardiac arrest, mild hypothermia has been shown to improve neurologic outcome in these patients.

D. Postoperative Neurointensive Care Management

D.1. What are the postoperative ventilation concerns in this patient?

This patient will undoubtedly remain intubated after DC due to a presenting GCS of 7, acidosis, hyperglycemia, diabetes insipidus, probable lung injury, and pain due to rib fractures. Necessary fluid resuscitation may exacerbate respiratory failure in a patient who is at risk for cardiac dysfunction due to neurogenic pulmonary edema. ICP monitoring is helpful in managing ventilation in the postoperative period because controlling $Paco_2$ and ensuring adequate oxygenation are critical to limiting secondary brain injury. Additionally, CPP (maintained between 60 and 70 mmHg) and MAP should also be monitored to avoid secondary brain injury. To maintain a favorable balance between decreasing ICP and minimizing the decrease in CBF, hyperventilation to no lower than a $Paco_2$ 35 to 40 mmHg is the goal. A low $Paco_2$ will result in low CBF and consequent cerebral ischemia, whereas high $Paco_2$ levels can result in cerebral hyperemia and high ICP. Prolonged prophylactic hyperventilation with $Paco_2 \leq 25$ mmHg is not recommended (level IIB evidence). A muscle relaxant will be helpful in controlling ventilation and preventing unacceptable spontaneous increases in ICP (e.g., during suctioning). Attention

to avoiding high tidal volumes (<6 mL per kg if possible) in order to avoid barotrauma and positive end expiratory pressure (PEEP ≤15 cm H_2O) as needed to maintain adequate oxygenation (PaO_2 >60 mmHg) is important for limiting additional pulmonary damage. Close hemodynamic and ICP monitoring are essential to avoid increases in ICP and/or decreased venous return with institution of PEEP. Other ventilatory strategies including high-frequency percussive ventilation (HFPV) and extracorporeal membrane oxygenation (ECMO) should also be considered if oxygenation continues to be a problem.

D.2. What specific measure should be used to control the patient's ICP? What type of monitoring devices can be used to measure ICP?

Controlling ICP (normal range: 0 to 10 mmHg) is essential to maintaining cerebral perfusion and improving outcome after TBI. ICP should be monitored in patients with severe TBI (GCS 3 to 8) and a CT scan showing hematomas, contusions, swelling, herniation, or compressed basal cisterns. In the case of a normal CT scan, if that patient has two or more of the following features, then ICP monitoring is indicated: >40 years of age, unilateral or bilateral motor posturing, and/or an SBP <90 mmHg. Surgery is often required initially in order to evacuate a

subdural or epidural hematoma causing ICP. The neurosurgical service will often place a ventricular drain in the patient to drain CSF. The head of the bed is typically elevated 15 degrees to promote venous drainage. Keeping the patient sedated, controlling the pain, and avoiding hyperthermia also help to ensure decreased brain cerebral metabolic requirements for oxygen. Selective hyperventilation, as mentioned earlier, may be necessary to control ICP; however, this maneuver will also decrease CBF. Hyperventilation to a $Paco_2$ of <35 mmHg as a temporizing measure is avoided unless transtentorial herniation is suspected. Assuming that the BBB is intact, hyperosmolar therapy with mannitol or HTS will help increase serum osmolarity so that fluid is mobilized from the brain; the serum osmolarity should be no higher than 320 mOsm per L. Electrolyte abnormalities and changes in fluid status require regular blood sampling, close attention to fluid balance, hemodynamic monitoring, and the availability of vasoactive agents. Induction of a barbiturate coma to decrease cerebral metabolism in a patient whose ICP is refractory to treatment will require continued ventilator support, cardiovascular monitors, hemodynamic support, and electroencephalogram (EEG) monitoring. The decrease in ICP caused by mild hypothermia has not translated into improved outcome in TBI patients.

The intraventricular catheter or ventriculostomy connected to a transducer is the most accurate, reliable, and low-cost method for monitoring ICP and guiding therapy. It can be recalibrated in situ. Intraparenchymal ICP monitors using microstrain pressure transducers have negligible drift but cannot be recalibrated in situ. Furthermore, unlike ventricular catheters these catheters cannot be used for draining CSF to decrease ICP. Subdural, subarachnoid, and epidural monitors are less accurate than the aforementioned devices.

D.3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?

Neurogenic pulmonary edema occurs suddenly as a consequence of sympathetic nervous system stimulation from the hypothalamus and medulla after severe neurologic injury. Patients are dyspneic and tachypneic with pink, frothy sputum. They are often hypoxic, tachycardic, and hypertensive. Crackles and rales can be heard on lung auscultation. The chest x-ray is often significant for bilateral infiltrates and the Pa_{O_2}/F_{IO_2} ratio <200.

Theories explaining the pathophysiology of this consequence of TBI are varied. One theory is that myocardial injury from a surge in catecholamines causes pulmonary edema due to cardiac dysfunction, similar to that seen in reversible Takotsubo cardiomyopathy. Neurohemodynamic neurogenic pulmonary edema occurs secondary to an acute rise in systemic and pulmonary pressures leading to left ventricular failure; fluid then shifts to the low-resistance pulmonary circulation causing pulmonary edema. Damage to the alveolar-capillary membrane from the rise in capillary pressure with a consequent transudative pulmonary edema describes the "blast theory."

Finally, trauma to the pulmonary capillary bed secondary to sympathetic discharge may occur without any systemic changes according to the "pulmonary venule adrenergic hypersensitivity theory." After ruling out other causes of respiratory distress (i.e., congestive heart failure, aspiration, acute respiratory distress syndrome, sepsis, and/or transfusion overload), treatment is supportive while addressing the underlying neurologic cause.

Adequate oxygenation of the patient is essential to ensuring cerebral perfusion. If ventilator support with an increased F_{IO_2} is not effective in maintaining a Pa_{O_2} >60 mmHg, then PEEP may help to improve oxygenation. The unwanted consequences of PEEP may be successfully addressed by regular blood sampling and appropriate monitoring. Avoiding hypercarbia from overdistention of alveoli and increased dead space is essential to managing this patient. Elevation of the head of the bed helps to combat the transient increase in right atrial pressure from PEEP-induced impairment of cerebral venous drainage. Monitoring the central circulation to keep the patient euvolemic and close attention to cardiac function will help avoid decreases in venous return from high PEEP and maintain CPP.

Davison DL, Terek M, Chawla LS. Neurogenic pulmonary edema. *Crit Care*. 2012;16(2):212.

D.4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?

Approximately 30% of patients with severe TBI are at risk for posttraumatic seizures (PTS) in the first 7 days after their trauma (early seizures). These patients may also be at risk for late seizures (after the seventh day after TBI). Penetrating trauma carries with it the greatest risk of PTS; however, patients presenting with a GCS <8, subdural or intracerebral hematoma,

posttraumatic amnesia, immediate seizures, depressed skull fractures, age <65 years, or chronic alcoholism are also at risk for PTS.

The risk of chronic epilepsy, increased cerebral metabolism, and increased ICP makes seizure prophylaxis a serious consideration. Antiepileptic drugs (AEDs) help prevent seizures in patients with early PTS but have little effect on late PTS. Consequently, prophylactic AED is recommended for the first week after head trauma or surgery. Levetiracetam is beneficial and commonly used for early PTS. This drug does not require serum concentration monitoring as with phenytoin and has favorable pharmacokinetic properties.

D.5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?

Brain hypoxia from ischemia due to BBB disruption and cerebral edema, anemia, hypoxemia, and hyperventilation will worsen secondary brain injury. Monitoring of partial pressure of oxygen in brain tissue ($PbrO_2$) is appealing as a guide for managing TBI patients by helping determine the optimal cerebral perfusion pressure (CPP) for adequate brain tissue oxygen. The parenchymal brain oxygen ($PbrO_2$) monitor is inserted into the brain parenchyma typically at the time of ICP monitor placement and measures tissue oxygen in the immediate area. According to the BTF, evidence of a benefit in using this monitoring device to manage TBI patients is inconclusive. In a retrospective study, 123 TBI patients who had ICP and $PbrO_2$

monitoring had a similar mortality rate to the other 506 patients whose treatment was guided by ICP monitoring only. Although hypoxia detected by brain tissue oxygen monitoring was associated with worse outcomes in this study, these researchers were unable to link treatment in response to $PbrO_2$ monitoring to outcome. Several class 3 studies (low-quality RCTs and noncomparative designs) examining $PbrO_2$ monitoring for TBI patients revealed conflicting results regarding mortality and outcome, which has effectively removed the level III recommendation for this advanced monitor for the management of TBI.

Jugular bulb catheters for $SjvO_2$ monitoring provide information regarding global cerebral oxygenation because arteriovenous difference of oxygen content ($AVDO_2$) is an indicator of cerebral oxygen extraction. A cervical spine x-ray is helpful in confirming placement into the dilated portion of the jugular vein just below the base of the skull. Like $PbrO_2$, there is insufficient evidence to support a level I or II recommendation for the use of $AVDO_2$ in managing TBI patients (level II evidence demonstrated no improvement in outcome for monitored patients). Nonrandomized, nonblinded observational studies suggest that jugular bulb monitoring in TBI patients may effect reduced mortality and improved outcomes at 3 and 6 months postinjury (level III evidence).

Regarding threshold values to target or avoid specific to these advanced cerebral monitors, the BTF reports that there is insufficient evidence to inform level I or II recommendations. However, there is level III evidence to support a jugular venous saturation of <50% as a threshold to avoid in the management of TBI.

D.6. What methods can be used in the neurointensive care unit to prevent hyperthermia?

Fever (>38.3°C) occurs in approximately 70% of patients with brain injury and may last weeks after injury. After ruling out infections, approximately one-third of patients will require treatment for a central fever due to their injured brain. Damage to or irritation of the hypothalamus, the center for thermoregulation, and increased sympathetic tone are responsible for this elevation in temperature. The elevated temperature exacerbates secondary brain injury by increasing neurotransmitter release, oxygen free radicals, high glutamate concentrations, ischemic damage in the penumbra, and BBB breakdown. Fever after TBI is associated with poor long-term outcome.

Antipyretic agents (e.g., acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs) inhibit cyclooxygenase-mediated prostaglandin synthesis in the brain and lower the hypothalamic set point. The limited benefit of this mode of treatment relates to damage of the thermoregulatory center in head trauma patients.

Nonpharmacologic interventions include external and intravascular cooling. External cooling includes four modes of promoting heat loss: evaporation via sponge baths, conductive heat loss with water-circulating cooling blankets, convective heat loss using fans and air-circulating cooling blankets, and radiation or exposure of the patient's skin. Combining these modalities appears to be more effective than any single method for decreasing temperature in patients without brain injury. A new system of surface cooling includes tightly wrapped pads

that circulate cold water to promote conductive heat loss. This mode of conductive heat loss reduces fever better and faster than the conventional water-circulating cooling blanket.

Intravascular cooling works by infusing cooled saline intravascularly. This method is more effective at cooling than other nonpharmacologic methods. The solution extracts heat from the blood thereby lowering body temperature. Infusion of NS at 4°C will decrease core temperature by 2.5°C within an hour after the infusion is started with no untoward effects on the patient.

The hyperthermic patient must be continuously monitored for any signs of infection and hypothermia. At temperatures less than 35°C, the risk for dysrhythmias, coagulopathy, electrolyte abnormalities, and hypovolemia will increase. Shivering and vasoconstriction (<36°C) may complicate the cooling process with a significant increase in metabolic demand and unwanted tachycardia and hypertension. Attention when caring for these patients is in order because the injured hypothalamus may reset so that these effects may manifest at normothermia.

Cerebral Aneurysm

Patricia Fogarty Mack

21

A 43-year-old woman presented to the emergency room 2 days ago, complaining of severe headache, nausea, and vomiting, followed by a witnessed 3-minute loss of consciousness. On regaining consciousness, she was noted by her family to be confused. A computed tomography (CT) scan showed subarachnoid bleeding. You are called to the angiography suite because four-vessel angiography has revealed an 18-mm basilar tip aneurysm and a 10-mm right middle cerebral artery aneurysm. The interventional neuroradiologist wishes to coil the basilar tip aneurysm but believes the middle cerebral artery aneurysm will require a craniotomy and clipping. At present, she was oriented only to person. She had no previous medical history; however, she has smoked one pack of cigarettes per day for the last 20 years. Her blood pressure was 130/80 mmHg, pulse 90 beats per minute, and respiration 18 breaths per minute. She had no focal neurologic deficits. Laboratory examination revealed normal electrolytes and complete blood count but elevated creatine phosphokinase myocardial-bound (CPK-MB) and troponin. Electrocardiogram demonstrated normal sinus rhythm with flipped T waves throughout the precordium.

A. Medical Disease and Differential Diagnosis

1. What are the incidence, prevalence, and causes of

subarachnoid hemorrhage (SAH), and what are the risk factors associated with rupture of intracranial aneurysms?
2. What are common sizes and locations of intracranial aneurysms?
3. What is the pathophysiology of aneurysmal rupture and SAH?
4. What are symptoms and signs of SAH?
5. How does one assess the severity of SAH?
6. What are the cardiovascular effects of SAH?
7. How is the diagnosis of SAH made?
8. What is the risk for rebleeding for a patient with SAH?

B. Preoperative Evaluation and Preparation

1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to be followed immediately with coiling of an aneurysm?
2. What type of anesthesia is required for coiling of an aneurysm?
3. Should one proceed with induction of general anesthesia under these circumstances?
4. What types of emergencies can occur during coiling of an aneurysm, and how should they be managed?
5. What other modalities of endovascular therapy are available?
6. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated troponin and CPK-MB fractions?
7. Would you premedicate this patient before craniotomy?

C. Intraoperative Management

1. What are the goals of the induction and maintenance of anesthesia for this patient?
2. Is placement of an arterial catheter necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?

3. How would you assess fluid status in this patient?
4. Would monitoring central venous pressure (CVP) be useful for craniotomy and aneurysm clipping in this patient?
5. What other forms of monitoring would you consider?
6. What are your specific concerns during induction of anesthesia in this patient?
7. How would you accomplish a smooth and safe induction and intubation in this patient?
8. Would you perform a rapid sequence induction and tracheal intubation for this patient?
9. What are the effects of hypoxemia and hypercapnia, such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?
10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?
11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was "tight." What could you do to achieve better brain relaxation and facilitate surgical exposure?
12. How might transmural pressure be decreased to allow for aneurysm clip placement?
13. What is the purpose of controlled hypotension, and how is it achieved?
14. What are some of the drawbacks of controlled hypotension?
15. What methods of cerebral protection might you use during this operation?
16. Would you induce mild hypothermia as a means of cerebral protection?
17. What are the indications for deep hypothermic circulatory arrest?
18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?
19. How would you plan the emergence from an anesthetic for

aneurysm clipping?

D. Postoperative Management

1. Would you extubate the patient postoperatively?
2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?
3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?
4. What is cerebral vasospasm, and what causes it?
5. What are pathophysiologic changes seen in cerebral vasospasm?
6. How is the diagnosis of cerebral vasospasm made?
7. What steps can be taken to prevent cerebral vasospasm?
8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?
9. What are other neurologic complications following SAH and aneurysm clipping?
10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?

A. Medical Disease and Differential Diagnosis

A.1. What are the incidence, prevalence, and causes of subarachnoid hemorrhage (SAH), and what are the risk factors associated with rupture of intracranial aneurysms?

The prevalence of SAH is 2% to 5% with an incidence of 10 to 15 per 100,000 people. Each year, 25,000 cases of SAH occur in the United States, comprising 5% to 10% of all cases of stroke. In China and South America, the incidence is only 2 to 4 cases per 100,000 people, whereas higher rates of 19 to 23 per

100,000 are reported in Finland and Japan. Sixty percent of the cases occur in young individuals between the ages of 40 and 60 years. Therefore, a poor neurologic outcome is a devastating condition to be endured over a potentially long period.

Approximately one-third of patients die as a result of the acute bleed. Of the two-thirds who survive the acute bleed, one-half (one-third of total) later die or are severely disabled and half (one-third of total) have an acceptable outcome.

Cerebral aneurysms account for 75% to 80% of SAH; arteriovenous malformations are the cause in 4% to 5%, whereas no specific cause can be found in 15% to 20% of SAH. Other causes of SAH include trauma, mycotic aneurysm, sickle cell disease, cocaine use, and coagulation disorders.

According to a Danish study of 250 patients with SAH compared to 250 control patients, the four strongest independent predictors of aneurysmal SAH are current smoking (odd ratio [OR] 5.9; 95% confidence interval [CI] 4.1 to 8.6), family history of aneurysmal SAH (OR, 4.3; 95% CI 2.4 to 7.5), hypertension (OR, 2.3; 95% CI 1.5 to 3.7), and excessive alcohol use (>/=18 units per week) (OR, 1.2; 95% CI 1.0 to 2.8). Other risk factors include pregnancy and vascular abnormalities (e.g., type III collagen deficiency and elastase abnormalities). One-third of patients with polycystic kidney disease have been found to have intracranial aneurysms at autopsy. Genetic predisposition plays a role: Seven percent of berry aneurysms are familial, and 5% to 10% of patients with a ruptured aneurysm have a first-order relative with a ruptured aneurysm. The rupture rate for aneurysm has been estimated at 0.14% per year for a 5-mm lesion to 1.1% per year for a 10-mm lesion.

Smoking and alcohol abuse also appear to predispose to aneurysm formation and rupture. Smoking at any time and female sex are related to the presence of multiple intracranial aneurysms as well as accelerated aneurysm growth. Cocaine

abuse and resultant episodic hypertension may predispose to aneurysmal rupture at an early age.

Death and disability are primarily due to the initial bleed, vasospasm, and rebleeding. Other causes include surgical complications, parenchymal hemorrhage, hydrocephalus, and complications of medical therapy.

Yoshimoto Y. A mathematical model of the natural history of intracranial aneurysm: quantification of the benefit of prophylactic treatment. *J Neurosurg*. 2006;104:195–200.

A.2. What are common sizes and locations of intracranial aneurysms?

Small (less than 12 mm) aneurysms make up 78% of the total, whereas large (12 to 24 mm) are 20%, and giant (greater than 24 mm) comprise 2%. Most aneurysms are located in the anterior circulation, with the junction of the anterior communicating and anterior cerebral arteries being the most common (39%). Thirty percent of aneurysms occur in the internal carotid artery, 22% in the middle cerebral artery, and 8% in the posterior circulation (posterior cerebral, basilar, and vertebral arteries).

Kassell NF, Torner JC, Haley EC Jr, et al. The international cooperative study on the timing of aneurysm surgery. Part 1: overall management results. *J Neurosurg*. 1990;73:18–32.

A.3. What is the pathophysiology of aneurysmal rupture and SAH?

On the basis of experimental models, aneurysmal rupture leads to the leakage of arterial blood and a rapid increase in intracranial pressure (ICP), approaching diastolic blood pressure in the proximal intracerebral arteries. This increase in ICP causes a decrease in cerebral perfusion pressure (CPP) and a fall in CBF, leading to a loss of consciousness. The decrease in CBF diminishes bleeding and the SAH. A gradual reduction in ICP and an increase in CBF indicate improved cerebral function and possibly a return to consciousness. A persistent increase in ICP (perhaps resulting from thrombi in the cranial cisterns), however, results in a persistent no-flow pattern with acute vasospasm, cell swelling, and death.

A.4. What are symptoms and signs of SAH?

Headache occurs in 85% to 95% of patients. Often, a brief loss of consciousness occurs, followed by diminished mentation; consciousness may be impaired to any degree or may be unaffected at the time of presentation. Symptoms secondary to subarachnoid blood may be similar to those of infectious meningitis (nausea, vomiting, and photophobia). The patient may also experience motor and sensory deficits, visual field disturbances, and cranial nerve palsies. Finally, blood in the subarachnoid space may cause an elevated temperature.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

A.5. How does one assess the severity of SAH?

Two grading scales are commonly used to assess neurologic status following SAH, the Hunt and Hess grade (**Table 21.1**) and the World Federation of Neurologic Surgeons' grade (**Table 21.2**), based on the Glasgow Coma Scale. The scales are useful

in identifying a baseline neurologic status from which any acute changes should be assessed. In addition, the scales may correlate with physiologic status. Patients who are Hunt and Hess grades I and II have near-normal cerebral autoregulation and ICP.

TABLE 21.1 Modified Hunt and Hess Clinical Grades

Grade[a]	Criteria
0	Unruptured aneurysm
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, but no neurologic deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, mild to severe hemiparesis, possible early decerebrate rigidity, vegetative disturbance
V	Deep coma, decerebrate rigidity, moribund appearance

[a]Serious systemic disease such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography result in placement of the patient in the next less favorable category.

TABLE 21.2 World Federation of Neurological Surgeons (WFNS) Grading Scale

WFNS Grade	Glasgow Coma Scale	Motor Deficit
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	6–3	Present or absent

A.6. What are the cardiovascular effects of SAH?

Injury to the posterior hypothalamus from SAH causes the release of norepinephrine from the adrenal medulla and cardiac sympathetic efferents. Norepinephrine can cause an increase in afterload and direct myocardial toxicity, leading to subendocardial ischemia. Pathologic analysis of the myocardium of patients who have died of acute SAH has revealed microscopic subendocardial hemorrhage and myocytolysis.

Electrocardiographic abnormalities are present in 50% to 80% of patients with SAH. Most commonly, these involve ST-segment changes and T-wave inversions but also include prolonged QT interval, U waves, and P-wave changes. ST-T wave changes are usually scattered and not related to a particular distribution.

Dysrhythmias occur in 80% of patients, usually in the first 48 hours. Premature ventricular contractions are the most common abnormality, but any type of dysrhythmia is possible. They include severely prolonged QT interval, torsades de pointes, and ventricular fibrillation. In one series, 66% of arrhythmias were considered mild, 29% moderate, and 5% severe. In addition to increased catecholamine secretion, hypercortisolism and hypokalemia have been suggested as causes for the dysrhythmias seen with SAH.

Ventricular dysfunction, possibly leading to pulmonary edema, is present in approximately 30% of patients with SAH.

Cardiac troponin I predicts myocardial dysfunction in SAH with a sensitivity of 100% and a specificity of 91%. This compares with a sensitivity and specificity of 60% and 94% for CPK-MB in predicting myocardial dysfunction. In order to plan optional anesthetic management, it is important to determine if any cardiac dysfunction is due to a myocardial infarction or reversible neurogenic left ventricular dysfunction. A retrospective study found that reversible neurogenic cardiac dysfunction was associated with a troponin level of 0.22 to 0.25

ng per mL and an ejection fraction of less than 40% by echocardiography.

Bulsara KR, McGirt MJ, Liao L, et al. Use of the peak troponin value to differentiate myocardial infarction from reversible neurogenic left ventricular dysfunction associated with aneurysmal subarachnoid hemorrhage. *J Neurosurg*. 2003;98:524–528.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

A.7. How is the diagnosis of SAH made?

Noncontrast CT scan can determine the magnitude and location of the bleed. It may also be useful in assessing ventricular size and aneurysm location. High-resolution CT (CT angiogram) with contrast can more precisely determine the location of the aneurysm.

Lumbar puncture can be used to diagnose SAH if CT is negative, especially when the patient presents more than 1 week after an initial bleed. Xanthochromia, a yellow discoloration of the cerebrospinal fluid (CSF) after centrifugation, is present from 4 hours to 3 weeks after SAH. A lumbar puncture can cause herniation or rebleeding. Therefore, a CT scan should be performed first if the patient presents within 72 hours of suspected SAH.

Four-vessel angiography (right and left carotid and vertebral arteries) has been considered the gold standard in the diagnosis of a intracranial aneurysm; however, CT angiography has been used with increasing frequency and currently is used to determine whether an aneurysm is amenable to coiling or requires surgical clip placement. The goal is to visualize all of the intracranial vessels, to localize the source of bleeding, and to rule out multiple aneurysms (5% to 33% of patients). Three-dimensional reconstructive angiograms and magnetic resonance angiography also may be used to further delineate the intracranial vasculature.

Guy J, McGrath BJ, Borel CO, et al. Perioperative management of aneurysmal subarachnoid hemorrhage: part 1. Operative management. *Anesth Analg*. 1995;81:1060–1072.

A.8. What is the risk for rebleeding for a patient with SAH?

The risk of rebleeding from a ruptured aneurysm is highest, 4%, in the first 24 hours after the initial bleed and 1.5% per day thereafter. The cumulative risk is 19% in 14 days and 50% at 6 months. After 6 months, the rebleeding risk is 3% per year.

Kassell NF, Torner JC. Aneurysmal rebleeding: a preliminary report from the Cooperative Aneurysm Study. *Neurosurgery*. 1983;13:479–481.

B. Preoperative Evaluation and Preparation

B.1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to be followed immediately with coiling of an aneurysm?

Whenever an anesthesiologist assumes care of a patient when the patient is already sedated, it may be more difficult to obtain an accurate medical history. In addition, the physical examination will be limited by the patient's position for the diagnostic study. Finally, the patient's capacity to consent may also be impaired by previous sedation.

B.2. What type of anesthesia is required for coiling of an aneurysm?

Although there is a case series of aneurysm coiling under

monitored anesthesia care with dexmedetomidine infusion without loading dose, in most institutions, general anesthesia is required for coiling of an intracranial aneurysm. First, intraoperative neurologic testing is generally not required. Second, immobility is very important not only when the coils or stent are actually deployed but also while the interventionist is navigating the intracranial vessels to reach the aneurysm.

Lee H-H, Jung Y-J, Choi B-Y, et al. Usefulness of dexmedetomidine during intracerebral aneurysm coiling. *J Korean Neurosurg Soc*. 2014;55:185–189.

B.3. Should one proceed with induction of general anesthesia under these circumstances?

Obliteration of the aneurysm with coils has become the standard of care for basilar tip aneurysm, and it would be best for the patient to have this done in the same setting as the angiography, provided there were no contraindications to induction of general anesthesia (e.g., hemodynamic instability).

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

Lee CZ, Young WL. Anesthetic considerations for interventional neuroradiology. *ASA Refresher Course Anesthesiol*. 2005;33:145–154.

B.4. What types of emergencies can occur during coiling of an aneurysm, and how should they be managed?

Intraoperative emergencies can be divided into two categories—hemorrhage and thrombosis. Appropriate management requires constant communication between the radiologist, surgeon, and anesthesiologist. If an intracranial hemorrhage occurs, the interventionalist may try to "glue" the hole in the aneurysm or embolize the parent vessel. If this is not possible, heparin should be rapidly reversed with protamine, and a ventriculostomy will generally be placed by the surgical team. Management of arterial carbon dioxide partial pressure ($PaCO_2$) can then be guided by

the ICP.

As the technology of endovascular therapy has advanced to include balloon- or stent-assisted coiling, treatment of more complex aneurysms has increased. The rate of intraprocedural rupture (IPR) has increased as well. The rate of IPR may be as high as 7.5% in ruptured aneurysms and 2.5% in unruptured aneurysms. IPR may lead to significant clinical deterioration in previously unruptured aneurysms but does not appear to have a severe an impact in patients undergoing endovascular treatment for SAH.

In the case of catheter-induced thrombosis, induced hypertension is usually desirable while tissue plasminogen activator or antiglycoprotein IIb/IIIa therapy is considered.

If a coil was malpositioned, anticoagulation would be continued while the interventional radiologist attempts to snare the coil. As with thrombosis, it may be desirable to augment the blood pressure.

B.5. What other modalities of endovascular therapy are available?

Flow diverting devices (stents) have been utilized as an endovascular treatment for wide necked and fusiform aneurysms, which are otherwise not amenable to coiling. When these procedures are planned, the patient is prepared with acetylsalicylic acid (ASA) and clopidogrel to prevent stent

thrombosis. A recent meta-analysis found that the complication rate for flow diverting stents is greater in ruptured versus unruptured aneurysms with an overall complication rate of 17% and mortality of 2.8%.

Several additional devices to stent bifurcations as well as wide necked aneurysms have been developed and approved for use in specific circumstances. Assessments of efficacy and complication rates are ongoing.

Finally, in the case of cavernous carotid or otherwise non-clippable aneurysms without the possibility of tradition coil or stent embolization the internal carotid artery might be occluded itself if sufficient cerebral blood flow can be maintained.

B.6. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated troponin and CPK-MB fractions?

Fifty percent of patients will have an increase in CPK-MB fraction; however, CPK-MB per total CPK fraction is usually not consistent with a transmural myocardial infarction. As

discussed previously, troponin I levels are more sensitive. In addition, although some patients (0.7%) do sustain a myocardial infarction in the setting of SAH, little correlation is found between electrocardiographic abnormalities and ischemia in this population.

An echocardiogram may be useful in determining the severity of reversible neurogenic left ventricular dysfunction. If left ventricular function is found to be depressed, a pulmonary artery catheter, noninvasive cardiac output monitor, or intraoperative transesophageal echocardiography may be helpful for intraoperative management.

The desire to delay surgery because of cardiac abnormalities must be weighed against the risk of rebleeding and vasospasm. In most cases, the risk of recurrent hemorrhage outweighs the risk of perioperative myocardial infarction. Furthermore, even if coronary artery disease is present, these patients are not candidates for angioplasty or myocardial revascularization, which requires heparinization. If pulmonary edema or malignant dysrhythmias are present, it may be prudent to postpone surgery until such problems are controlled medically. However, if these problems are not present, then clipping of the aneurysm may be indicated. In a study by Bulsara et al., 2.9% of patients had severe cardiac dysfunction, and neurogenic left ventricular dysfunction resolved over 4 to 5 days.

Bulsara KR, McGirt MJ, Liao L, et al. Use of the peak troponin value to differentiate myocardial infarction from reversible neurogenic left ventricular dysfunction associated with aneurysmal subarachnoid hemorrhage. *J Neurosurg*. 2003;98:524–528.

B.7. Would you premedicate this patient before craniotomy?

No. When the patient is in a Hunt and Hess grade III to V state, anxiety is unlikely. Furthermore, heavy sedation may decrease

ventilation, raising $PaCO_2$ and increasing CBF and ICP, which, at the very least, may hinder preoperative and postoperative neurologic evaluation. If patients are Hunt and Hess grade I to II and it appears that preoperative anxiety might lead to hemodynamic instability, a small dose of a benzodiazepine may be appropriate.

Medications such as calcium channel blockers (nicardipine), anticonvulsants, and corticosteroids should be continued preoperatively on the day of surgery.

If the patient is at risk for aspiration, medications to decrease gastric acidity and volume are appropriate. Most patients will already be receiving a histamine-2 blocker or proton pump inhibitor if they are receiving a glucocorticoid.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

C. Intraoperative Management

C.1. What are the goals of the induction and maintenance of anesthesia for this patient?

The primary goal is to prevent aneurysm rupture, either on induction or intraoperatively, while maintaining adequate CPP. The goal of matching anesthetic depth to surgical stimulation is more important than the specific drugs used. In general, the anesthesiologist should provide for rapid and reversible titration of blood pressure, maintain CPP, and protect against cerebral ischemia. An additional goal is to provide a relaxed brain for ease of surgical exposure with minimal brain retraction. Finally, the anesthetic should be planned to achieve a rapid, smooth emergence, allowing prompt neurologic assessment. This can be accomplished with a combination of balanced anesthesia, muscle relaxation, and sympathetic blockers as well as with total

intravenous anesthesia.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

C.2. Is placement of an arterial catheter necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?

In this case, because a femoral sheath is in place at the time that anesthesia is induced, one may transduce femoral arterial pressure during induction. However, because the patient has two aneurysms and because the sheath will be removed at the end of the procedure, an additional arterial catheter should be placed before the removal of the sheath. When a large coaxial catheter is placed through the femoral sheath, systolic pressure is underestimated, but mean pressure should be accurate. Studies have suggested that the placement of an arterial catheter prior to induction is not essential when an unruptured aneurysm is to be coiled.

Lai YC, Manninen PH. Anesthesia for cerebral aneurysms: a comparison between interventional neuroradiology and surgery. *Can J Anaesth*. 2001;48:391–395.

C.3. How would you assess fluid status in this patient?

Several issues in interventional radiology complicate fluid management. First, contrast material acts as an osmotic diuretic. Often, these patients have had a CT scan with contrast in addition to an angiogram and may become intravascularly depleted. Second, the femoral sheath and other catheters are constantly flushed with a heparinized saline solution. It is not uncommon for a patient to receive 1,000 mL or more of flush

fluid during the case. This must be taken into account when calculating fluid balance.

C.4. Would monitoring central venous pressure (CVP) be useful for craniotomy and aneurysm clipping in this patient?

Many have suggested that CVP monitoring is essential in assessing volume replacement needs because urine output will be affected by osmotic or loop diuretics administered to facilitate surgical exposure. In addition, should vasoactive medication become necessary, it may be most effectively administered through a central venous catheter.

One disadvantage of CVP monitoring in the neurosurgical patient is catheter placement. Some clinicians are concerned that placement of an internal jugular venous CVP will compromise venous outflow of the head, thereby predisposing to bleeding or brain swelling, although this remains controversial. A "long-arm" or peripheral antecubital CVP catheter may be more difficult to insert and have a higher incidence of thrombophlebitis. Multiple studies have shown the complication rate of central catheter placement to be as high as 14%. When including failure to place the catheter, the complication rate rises to 54%. Nevertheless, use of an ultrasound-guided approach to placement of central venous catheters reduces the complication rates to less than 2% to 5% and should be the standard of care whenever possible.

Finally, a poor correlation between CVP and left ventricular end-diastolic pressure has been documented in SAH, so a pulmonary artery catheter may be more useful in assessing volume status as well as providing a monitor of cardiac output in those patients who have had preoperative cardiac problems. Patients who are expected to be candidates for hypertensive hypervolemic hemodilution (HHH) therapy for vasospasm or for

drug-induced coma may also benefit from placement of a pulmonary artery catheter.

Central pressure monitoring is usually instituted after the patient is anesthetized to minimize patient stress. One should be careful to use the minimal degree of head-down tilt necessary to access the central circulation because the Trendelenburg position can increase ICP and thereby decrease CPP.

Based on the risk and benefits of central venous and pulmonary artery access, placement of CVP and pulmonary artery catheters is reserved for patients who have documented cardiac dysfunction, cerebral vasospasm or poor peripheral intravenous access. Volume status may be assessed by noninvasive monitors that calculate stroke volume or by careful assessment of the arterial waveform utilizing calculated pulse pressure variation available on many monitoring systems.

C.5. What other forms of monitoring would you consider?

Electroencephalography (EEG) and somatosensory evoked potentials (SSEPs) have been advocated by some, although they are not standard monitoring in most hospitals. Although EEG has been used to monitor cerebral ischemia, scalp electrodes may not reflect activity of brain areas most at risk. Cortical electrodes, such as those used in epilepsy surgery, may avoid the problem of attenuation of the scalp electroencephalographic signal by CSF drainage and air between scalp electrodes and brain surface during surgery. EEG is useful in a titrating intravenous anesthetic infusion if burst suppression is desired

during temporary clipping.

SSEPs may detect reversible ischemia during temporary vessel occlusion, but they may not detect ischemia in subcortical structures and motor cortex. Furthermore, SSEPs have relatively high false-positive (38% to 60%) and false-negative (5% to 34%) rates. Brainstem auditory evoked responses may be useful for monitoring during posterior circulation aneurysm clipping. Motor evoked potentials may be superior in detecting subcortical ischemia. The use of SSEP and motor evoked potential monitoring usually warrants use of total intravenous anesthesia and avoidance of muscle relaxants.

Microvascular Doppler ultrasound evaluation may detect inadvertent vessel occlusion, but it cannot assess the adequacy of collateral perfusion.

Monitoring of ICP is common, with the probability of increased ICP being greatest 24 to 48 hours after SAH. An intraventricular catheter not only allows for ICP monitoring but also allows for CSF drainage to improve operating conditions. If an intraventricular catheter is not present, lumbar spinal drain may be placed. One must be careful not to allow substantial CSF drainage before dural opening because this may decrease ICP leading to an increase in transmural pressure and possible rupture.

Intraoperative angiography is one means to assess complete obliteration of the aneurysm without clip occlusion of the parent artery or perforating branches. Its use has increased with the installation of hybrid operating rooms that are fully equipped with advanced angiography equipment.

C.6. What are your specific concerns during induction of anesthesia in this patient?

If an aneurysm ruptures during anesthetic induction, mortality is high (approximately 75%). Therefore, precise control of transmural pressure is important in preventing aneurysm rupture.

Transmural pressure = CPP = MAP – ICP or CVP (whichever is greater), where MAP = mean arterial pressure

On the other hand, one does not want CPP to be so low that ischemia develops, especially in areas of vasospasm.

Chowdhury T, Cappellani RB, Sandu N, et al. Perioperative variables contributing to the rupture of intracranial aneurysm: an update. *ScientificWorldJournal*. 2013;2013:396404.

Tsementzis SA, Hitchcock ER. Outcome from "rescue clipping" of ruptured intracranial aneurysms during induction of anesthesia and endotracheal intubation. *J Neurol Neurosurg Psychiatry*. 1985;48:160–163.

C.7. How would you accomplish a smooth and safe induction and intubation in this patient?

Assuming that evaluation of the airway indicated that tracheal intubation is unlikely to be difficult, induction would begin with preoxygenation followed by propofol 1.5 to 2.5 mg per kg, thiopental 3 to 5 mg per kg, or etomidate 0.5 to 1 mg per kg, which have similar effects on CBF and cerebral metabolic rate. Given that this patient had no other medical problems, propofol is a reasonable choice. One may want to avoid ketamine for induction because of its potential to increase in CBF and ICP. Thiopental is not presently available in North America but may be available elsewhere.

After loss of consciousness and apnea, care must be taken to

maintain a normal $Paco_2$. Vigorous hyperventilation will lower $Paco_2$, decreasing CBF. This may lower ICP to such a degree that if MAP is maintained or increased, transmural pressure may be increased, leading to rupture of the aneurysm.

A nondepolarizing muscle relaxant, which has no effect on ICP or CBF, should be given to facilitate tracheal intubation. The neuromuscular junction should be monitored to ensure that paralysis is adequate to avoid coughing with intubation.

Fentanyl 3 to 5 μg per kg, sufentanil 0.5 to 1 μg per kg, or remifentanil 0.25 to 1 μg per kg can be given 3 to 5 minutes before laryngoscopy to blunt the hemodynamic response. Isoflurane, desflurane, or sevoflurane can be used to deepen the anesthetic. Finally, approximately 90 seconds before laryngoscopy, lidocaine 1.5 to 2 mg per kg or esmolol 0.5 mg per kg can be given to blunt the hemodynamic response to intubation.

Lidocaine decreases both CBF and cerebral metabolic rate for oxygen ($CMRO_2$), and at high concentrations can cause seizures. Esmolol and labetalol have no effect on CBF and ICP, even in brain areas where autoregulation may not be intact. Extreme reductions in MAP (greater than 35%) may compromise CPP in patients with increased ICP.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

C.8. Would you perform a rapid sequence induction and tracheal intubation for this patient?

No indication is seen for a rapid sequence induction and intubation in this patient. Overall risk of aspiration during general anesthesia has been estimated at 0.05%; however, the risk of aneurysm rupture during induction is 1% to 2%. Therefore, unless a clear indication exists for rapid sequence

induction, it is best avoided.

If a rapid sequence induction is indicated, one may consider using vecuronium 0.15 to 0.20 mg per kg or rocuronium 0.9 to 1.2 mg per kg rather than succinylcholine. Succinylcholine may increase in ICP, although some recent studies have noted no increase in ICP with administration of succinylcholine, but rather with intubation. The increase in ICP can be attenuated or eliminated by deep anesthesia or prior defasciculation. Succinylcholine, more importantly, may lead to hyperkalemia and possibly ventricular fibrillation in those patients presenting with motor deficits following SAH or in those patients who have been bedridden for some time.

In the case of a full stomach or an anticipated difficult airway, an awake fiberoptic intubation, with the use of appropriate sedation and topical application of local anesthesia, may be an appropriate alternative. Under such circumstances, it is useful to have an assistant so that while one person is securing the airway, the other is solely focused on controlling the hemodynamics with titration of appropriate medication. Videolaryngoscopy may reduce the need for awake fiberoptic intubation. In addition, the use of a supraglottic devices to maintain an airway during a difficult intubation may be useful in patients with an unanticipated difficult airway.

C.9. What are the effects of hypoxemia and hypercapnia,

such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?

Each millimeter of mercury increase in $PaCO_2$ increases CBF 3% to 4%, when $PaCO_2$ is in the range of 20 to 80 mmHg. In addition, hypoxemia will ensue if the airway is not secured in a timely manner and will also cause an increase in CBF once arterial oxygen partial pressure (PaO_2) is less than 60 mmHg (**Fig. 21.1**).

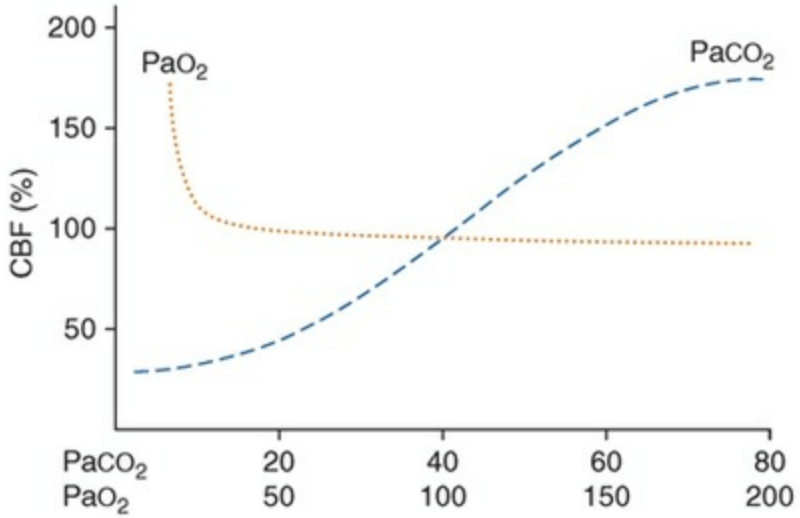

FIGURE 21.1. Change in CBF as a function of $PaCO_2$ and PaO_2 tension. (*From Albin MS, ed.* Textbook of Neuroanesthesia: With Neurosurgical and Neuroscience Perspectives. *1st ed. New York, NY: McGraw-Hill; 1997:30. Copyright © 1997 McGraw-Hill. With permission.*)

C.10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?

Maintenance fluid requirements and blood loss should be replaced. One wants to avoid profound hypovolemia not only for its detrimental cardiovascular effects but also because it is associated with cerebral ischemia and perioperative neurologic deficits resulting from vasospasm. Some authors advocate mild hypervolemia to maximize cerebral CBF and minimize vasospasm; however, one must keep in mind the possibility of

cerebral edema as well as acute congestive heart failure.

In general, dextrose-containing solutions should be avoided because an increased incidence of neurologic deficits associated with glucose administration has been found in experimental models of focal cerebral ischemia. Blood glucose should be maintained less than 180 mg per dL.

Use of crystalloid versus colloid for fluid management and which type of crystalloid solution has long been a matter of controversy. Although some authors advocate colloid solutions to diminish the risk of brain swelling, evidence exists that the solution may predispose to brain edema and contribute to hyponatremia, which may increase the incidence of delayed ischemic neurologic deficits. Hypotonic crystalloid solutions are avoided in the neurosurgical patient; acceptable solutions include normal saline and balanced electrolyte solutions such as Normosol® and Plasma-Lyte®.

A moderate degree of hemodilution to a hematocrit of 30% to 35% usually lowers blood viscosity, thereby increasing CBF. The goal is to increase oxygen delivery by increasing CBF, without allowing the hematocrit to decrease to a degree that reduction in oxygen content negates the increase in CBF. Hematocrit, serum sodium, and serum osmolality measurements may be used to guide fluid therapy. Serum sodium should be maintained within normal limits, both to maintain serum oncotic pressure and to avoid the hyponatremia associated with cerebral salt wasting.

C.11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was "tight." What could you do to achieve better brain relaxation and facilitate surgical exposure?

Any method that rapidly decreases ICP before dural opening may suddenly increase transmural pressure and lead to aneurysm rupture. After dural opening, one of the fastest ways to decrease cerebral blood volume and improve exposure is through hyperventilation. Mild hypocarbia ($PaCO_2$ = 30 to 35 mmHg) can usually be established before dural opening, with moderate hypocarbia ($PaCO_2$ = 25 to 30 mmHg) after dural opening. Because of the risk of cerebral ischemia secondary to diminished CBF, normocarbia should be maintained whenever possible in patients with vasospasm.

Mannitol is the most frequently used diuretic to reduce brain swelling. It is given as an infusion to a total dose of 0.7 g per kg (0.25 to 1 g per kg). Its immediate effect is a transient rise in intravascular volume, which may pose problems in patients with impaired ventricular function. In addition, too rapid infusion can lead to decreases in systemic vascular resistance. Its onset of diuretic action is in 10 to 15 minutes, with peak effect occurring at 60 to 90 minutes. If mannitol does not produce the desired brain relaxation and the serum osmolality is greater than 320 mOsm, additional mannitol is unlikely to produce additional effect. In those patients who may not tolerate the initial effects of mannitol, intravenous furosemide 0.1 to 0.3 mg per kg can be

substituted. Both medications can cause derangements in fluid status and serum electrolytes that require close monitoring.

Drainage of CSF from either a lumbar drain or an intraventricular catheter is usually effective in optimizing surgical exposure. One must be careful to avoid significant CSF drainage before dural opening to prevent either brainstem herniation or a sudden decrease in transmural pressure. Similarly, hemodynamic instability can ensue if CSF is drained too rapidly at any point in the operation.

If tight brain remains a problem, one must ascertain that there is no hypoxemia or hypercarbia. In addition, one should consider eliminating nitrous oxide (N_2O) and reducing the amount of volatile anesthetic because all inhalational agents are cerebral vasodilators and may potentially increase ICP. Of course, if inhaled agents are reduced, appropriate intravenous agents should be substituted to ensure adequate anesthesia. Total intravenous anesthesia may be useful in this situation.

One may give a bolus of propofol or thiopental to decrease $CMRO_2$ and CBF; nevertheless, one must maintain MAP to maintain CPP. At the time of patient positioning, one must ensure that no impediment exists to venous outflow of the brain (i.e., extreme flexion or rotation of the head should be avoided and no monitor cables [electrocardiogram] should be draped across the neck). Even 10 degrees of head-up positioning has been found to be effective at reducing ICP.

C.12. How might transmural pressure be decreased to allow for aneurysm clip placement?

The most widely accepted method for producing a slack

aneurysm to allow for clip placement is the use of temporary clip occlusion of one or more parent vessels. For example, to place a permanent clip on an anterior communicating artery aneurysm, a temporary clip can be placed on either the right or left anterior cerebral artery or both. Advantages of temporary clip use include a greater reduction in transmural pressure, a greater ease in clipping, a decreased incidence of intraoperative rupture, and the avoidance of controlled hypotension.

The maximal duration of temporary clip application before a neurologic deficit occurs is unknown, but it is probably related to the location of the aneurysm and distribution of perforating vessels distal to the temporary clip. White matter and major deep nuclei are likely to be more susceptible than gray matter to temporary ischemia. Risk factors for neurologic deficit following temporary clip placement include poor preoperative neurologic condition, age older than 61 years, and distribution of perforating arteries in distal basilar and horizontal segments of middle cerebral artery. Recent studies suggest that there are regional differences in brain oxygenation during temporary clip occlusion, with the middle cerebral artery distribution being more susceptible to ischemia than the anterior cerebral artery distribution. In addition, patients who underwent multiple brief periods of temporary occlusion had less ischemia than those who underwent a single temporary artery occlusion of greater than 10 minutes.

Adenosine-induced temporary flow arrest has also been reported as a mechanism to produce a slack aneurysm to facilitate clipping.

Bendok BR, Gupta DK, Rahme RJ, et al. Adenosine for temporary flow arrest during intracranial aneurysm surgery: a single-center retrospective review. *Neurosurgery*. 2011;69:815–821.

C.13. What is the purpose of controlled hypotension, and how is it achieved?

In the past, controlled hypotension was used to decrease transmural pressure, making the aneurysm neck slack enough to allow placement of a clip without vessel rupture. Various agents were used to achieve controlled hypotension, including volatile agent, nitroprusside, esmolol, labetalol, nitroglycerin, and trimethaphan. Specific agents were selected based on the patient's preexisting medical conditions, especially coronary ischemia or poor ventricular function. In an otherwise healthy patient, sodium nitroprusside infusion may be used for its rapid onset, easy titratability, and quick offset. An esmolol infusion can be added to augment hypotension and counteract the reflex tachycardia; by decreasing the amount of nitroprusside needed to induce hypotension, the likelihood of cyanide toxicity diminishes. Side effects of nitroprusside include cyanide toxicity, rebound hypertension, and intrapulmonary shunting. Direct measurement of CVP is useful when planning to use controlled hypotension in these patients.

During controlled hypotension, MAP is usually maintained at a minimum of 50 mmHg in previously normotensive individuals. Neurologic function monitors (EEG, SSEP, brainstem auditory evoked response, and cerebral oximetry) may be useful in guiding target level of MAP.

C.14. What are some of the drawbacks of controlled hypotension?

The main drawback of controlled hypotension is that it leads to a global decrease in CPP. CPP is then further diminished in the presence of vasospasm or in areas of brain retraction. In a retrospective study, multiple regression analysis indicated that patients who underwent even limited periods of controlled hypotension had a worse outcome, both in terms of Glasgow Outcome Scale (multiple regression) and higher incidence and severity of vasospasm. Although further studies indicated that this effect was not seen when corrected for age, controlled hypotension usually is avoided in neurosurgery.

C.15. What methods of cerebral protection might you use during this operation?

Cerebral protection has long been a matter of much investigation and controversy. Barbiturate loading has been shown in animals to be protective against focal ischemia, although no controlled human studies have been performed. Barbiturates decrease cerebral metabolic rate for glucose and oxygen and lower CBF and ICP. The dose is usually titrated to electroencephalographic silence or burst suppression. At doses used to suppress electroencephalographic activity, the patient may experience cardiovascular depression. The dose of barbiturate traditionally used for cerebral protection may also prolong emergence and hinder postoperative neurologic evaluation. Although barbiturates were originally thought to protect against ischemia through metabolic depression, other factors such as redistribution of blood flow to ischemic areas, blockade of

sodium channels and glutamate receptors, attenuation of *N*-methyl D-aspartate (NMDA), and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor-mediated glutamate toxicity all play a role.

Propofol has also been used as an alternative to thiopental sodium. Cerebral protection from propofol is thought to result from scavenging of free radicals, inhibition of glutamate release, and prevention of lipid peroxidation. In studies involving both volatile anesthetics and propofol, apoptotic cell death was delayed, but not prevented, if the ischemic result is mild. Propofol may be titrated to burst suppression on EEG monitoring.

Etomidate decreases cerebral metabolic rate at electroencephalographic burst suppression and prevents an increase in excitatory neurotransmitters during cerebral ischemia in animal models; nevertheless, it has been associated with a greater volume of injured brain than thiopental and control groups in focal ischemia in hypertensive rats.

Deliberate mild hypothermia (32.5°C to 35.5°C), although promising in animal models, did not demonstrate efficacy with patients with good-grade aneurysm in the Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) 2, although there was a suggestion of a trend toward benefit in subgroup analysis.

Although many pharmacologic targets for cerebral protection, including magnesium, lidocaine, and others, have shown promising results in laboratory analysis, none have consistently proven effective in the clinical setting.

C.16. Would you induce mild hypothermia as a means of cerebral protection?

Hypothermia causes a greater reduction in cerebral metabolic rate for glucose and oxygen than the level attained at electroencephalographic silence because its reduction of metabolism is caused by a reduction in both neuronal electrical activity and enzyme activity related to maintenance of cellular function. Hypothermia also reduces the release of excitatory neurotransmitters. Significant reduction in infarct size after global and focal ischemia has been demonstrated in several animal studies. Unfortunately, these advantages have not been documented in clinical trials. The IHAST study showed no differences in Glasgow Outcome Scale at 3 months in patients who present with good neurologic grade.

Disadvantages of unintentional hypothermia documented in the literature include an increased incidence of myocardial ischemia in peripheral vascular surgery, increased incidence of postoperative wound infection in abdominal surgery, coagulopathy, prolonged drug clearance, and hyperglycemia. In the IHAST study, the hypothermic group had a small increase in infection rate. The effect of hypothermia in poor clinical grade patients is unknown.

C.17. What are the indications for deep hypothermic circulatory arrest?

Hypothermic circulatory arrest at body temperature less than 22°C (71.6°F) is reserved for giant aneurysms, difficult basilar artery aneurysms, and anatomically complex aneurysms that are not clippable without complete cessation of blood flow and are not amenable to the use of temporary clips. Deep hypothermic circulatory arrest requires cooperation between several services, including anesthesiology, neurosurgery, cardiac surgery, and perfusionists. In addition to the concerns mentioned regarding anesthesia for the person with an intracranial aneurysm and the need for prompt awakening for ease of neurologic assessment, deep hypothermic circulatory arrest adds concerns regarding institution of and separation from cardiopulmonary bypass, systemic heparinization and protamine reversal, and, of course, rewarming from profound hypothermia. This is rarely performed now that coil embolization is possible for many of these aneurysms. Giant and complex aneurysms that are not amenable to coiling may be managed with flow diversion endovascular therapy.

Young WL, Lawton MI, Gupta DK, et al. Anesthetic management of deep hypothermic circulatory arrest for cerebral aneurysm clipping. *Anesthesiology*. 2002;96:497–503.

C.18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?

The incidence of intraoperative rupture is 2% to 19%. The stage

of the operation at which rupture occurs affects outcome, with rupture at induction being the worst. After induction, the most common times for rupture are when the dura mater or arachnoid mater are being opened, during intracranial hematoma removal, and, of course, during dissection exposure of the aneurysm. At any point in the operation, a sudden sustained increase in blood pressure with or without bradycardia is suggestive of rupture. If rupture is suspected on induction, one must institute measures to control ICP while maintaining CPP.

If rupture occurs during surgical dissection, mortality is lower. The primary concern is to control bleeding while maintaining systemic perfusion. Bleeding is controlled by placement of temporary clips or by clamping or compression of the ipsilateral carotid artery in the neck if the aneurysm is too proximal. If bleeding is not controlled in a timely manner and a significant amount of blood accumulates in the subarachnoid space, severe brain swelling that is refractory to all treatment may develop.

Lin BF, Kuo CY, Wu ZF. Review of aneurysmal subarachnoid hemorrhage—focus on treatment, anesthesia, cerebral vasospasm prophylaxis, and therapy. *Acta Anaesthesiol Taiwan*. 2014;52:77–84.

C.19. How would you plan the emergence from an anesthetic for aneurysm clipping?

The goal is to have a patient comfortable and not coughing or straining or subject to hypercarbia or wide variations in blood pressure.

After discontinuing all anesthetic agents and reversing neuromuscular blockade, the use of a lidocaine 1.5 mg per kg bolus may minimize coughing and reaction to the endotracheal tube. Strict control of blood pressure must be observed

especially in the presence of ischemic heart disease or in patients suspected of having multiple aneurysms. One should keep the blood pressure within 20% of the patient's normal measurement.

D. Postoperative Management

D.1. Would you extubate the patient postoperatively?

Most patients who are in Hunt and Hess grades I and II can be extubated postoperatively with no need for airway support. Patients in grades IV and V usually require mechanical ventilation postoperatively, whereas grade III patients may or may not require intubation and mechanical ventilation. Patients with vertebral or basilar artery aneurysms may require airway protection secondary to cranial nerve damage and loss of protective reflexes.

If this patient is able to follow commands, is clinically recovered from the effects of muscle relaxants, and has established an adequate ventilatory pattern with return of protective airway reflexes, extubation would be appropriate.

Bendo AA. Intracranial vascular surgery. *Anesthesiol Clin North Am*. 2002;20:377–388.

D.2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?

If the patient had a focal neurologic deficit on awakening in the operating room, the cause most likely would be a surgical one, although new-onset vasospasm is also a possibility.

If the patient failed to regain consciousness, the first step would be to ensure that all inhalational and infused anesthetics had been discontinued. Second, one should make sure that neuromuscular blockade was fully reversed. In addition, ensure that the patient is not hypothermic as hypothermia can prolong

the duration of action of intravenous medications. While considering reversal of benzodiazepines and opioids, one should rule out other causes such as hypoxia, hypercarbia, hyponatremia, and hypoglycemia. One should consider the possibility of intraoperative seizure, with delayed emergence resulting from a postictal state. If after reversal of all anesthetic agents, the patient has not awakened, a CT scan should be obtained to rule out subdural hematoma, intracranial hemorrhage, hydrocephalus, and pneumocephalus. An angiogram may also be obtained to rule out vascular occlusion. An electroencephalogram might be appropriate to rule out subconvulsive status epileptics.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

D.3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?

If transcranial Doppler is available, an increased value for cerebral arterial flow velocity would be suggestive for vasospasm, leading to delayed cerebral ischemia/infarction. Tissue oximetry may also be useful as a monitor for vasospasm. Angiography is the gold standard for diagnosis of cerebral vasospasm and should be performed to confirm the diagnosis and characterize the number and location of the vessels involved.

Cerebral vasospasm may be localized to the area of aneurysm rupture or in an area of the brain remote from SAH. The worst prognosis is in those patients in whom vasospasm is diffuse. Of course, as these studies are being done, laboratory values should

be checked to make sure no new or worsening metabolic derangement is contributing to the neurologic deterioration.

D.4. What is cerebral vasospasm, and what causes it?

Vasospasm, which occurs in 35% of patients with SAH, is a segmental or diffuse narrowing of the lumen of one or more intracranial arteries. It is the most common cause of delayed cerebral ischemia/infarction and may be seen angiographically in 60% of patients, even if clinical manifestations are not apparent. The severity of vasospasm may be related to the amount and location of subarachnoid blood. Injection of blood into the subarachnoid space causes vasospasm in experimental animals and antifibrinolytics apparently worsen the spasm. On a molecular level, one theory is that oxyhemoglobin causes the production of superoxide radicals that lead to a decrease in nitric oxide levels in endothelial cells. This decrease in nitric oxide increases protein kinase C and intracellular calcium, resulting in myofilament activation and vasospasm. Other theories involve prostaglandins and lipid peroxidases. There may also be a genetic predisposition to development of vasospasm. Preliminary studies suggest that patients with the polymorphism of haptoglobin ($\alpha_1\alpha_1$) may be protected against vasospasm compared to patients with haptoglobin $\alpha_2\alpha_2$, which is less effective at neutralizing free radical formation by free hemoglobin. It is clear that endothelial dysfunction is present, particularly in the microcirculation. The risk of vasospasm decreases with advancing age, with patients younger than 50 years old at a fivefold greater risk than older patients.

Kale SP, Edgell RC, Alshekhlee A, et al. Age-associated vasospasm in aneurysmal subarachnoid hemorrhage. *J Stroke Cerebrovasc Dis*. 2013;22:22–

27.

D.5. What are pathophysiologic changes seen in cerebral vasospasm?

Structurally, leukocytes, red blood cells, and macrophages are seen in arterial walls. Inflammatory mediators, such as eicosanoids, interleukin 1, and immune complexes, are increased. Eventually, the vessel wall thickens, and smooth muscle proliferation and collagen deposition accompany degenerative changes in the tunica intima and media.

Functionally, carbon dioxide reactivity is impaired, and autoregulation is often impaired, perhaps correlating to the degree of delayed cerebral ischemia/infarction. CBF in some areas appears to be pressure dependent, hence the reasoning behind hypertensive therapy.

Weyer GW, Nolan CP, Macdonald RL. Evidence-based cerebral vasospasm management. *Neurosurg Focus*. 2006;21:E8.

D.6. How is the diagnosis of cerebral vasospasm made?

The clinical diagnosis of cerebral vasospasm is made when the patient experiences an altered level of consciousness (drowsiness, disorientation) or a new focal neurologic deficit. These may be accompanied by increasing headache, meningismus, and fever. Vasospasm is rare in the first 3 days following SAH. It reaches peak incidence at 3 to 10 days and usually resolves by 10 to 14 days after SAH. In this patient, the new onset of hemiplegia suggests that the middle cerebral artery is involved. If vessels in the posterior fossa are involved, respiratory and hemodynamic abnormalities may develop.

The differential diagnosis includes rebleeding, hydrocephalus, seizure, hyponatremia, and drug effects. Transcranial Doppler CBF velocity greater than 120 cm per second in association with a new focal neurologic deficit are usually sufficient to make the diagnosis of cerebral vasospasm; however, a change in

transcranial Doppler values over time may be more useful than an absolute value. CBF velocity greater than 200 cm per second is associated with a high risk of cerebral infarct, whereas a velocity less than 100 cm per second indicates that cerebral vasospasm is unlikely. Recent evidence shows that transcranial Doppler had only 63% sensitivity in identifying delayed cerebral ischemia/infarction, with a positive predictive value of only 22% in grade II and III patients. Cerebral perfusion imaging may be necessary in patients of poor grade who are unable to participate in neurologic examination.

Angiographic cerebral vasospasm can be found in 60% of patients following SAH, but only 50% of these patients develop clinical focal neurologic deficits.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

D.7. What steps can be taken to prevent cerebral vasospasm?

Calcium channel blockers are standard prophylactic therapy to prevent vasospasm. The mechanism is unknown, but presumably, calcium channel blockers aid in maintaining cellular integrity by preventing calcium entry into ischemic cells. Nimodipine, taken orally, improves neurologic outcome. Patients given nimodipine have no change in overall incidence of vasospasm, but they have a lower incidence of severe narrowing. In addition, although no improvement is found in mortality, there is improvement in outcome for survivors.

Use of nicardipine, an intravenous agent, showed a lower incidence of vasospasm, but no improvement in outcome versus a placebo group; both groups received HHH therapy. The main

complication of calcium channel blocker therapy is hypotension (0% to 8%), which may make this therapy difficult to achieve.

Intravenous nimodipine is not available in the United States, although patients are given nimodipine orally or via nasogastric tube every 4 hours. The incidence of vasospasm does not differ significantly from open surgical repair to endovascular procedures. In addition, although calcium channel blockers cross the blood–brain barrier, the dose needed to achieve significant levels at the site necessary may be limited by systemic hypotension. Prolonged-release nicardipine implants placed at the time of surgical clipping were shown to reducing the incidence of vasospasm, improving outcome. In order to deliver calcium channel blockade intrathecally, nicardipine nanoparticles administered via external ventricular drains reduced delayed cerebral ischemia and improved clinical outcome. The microparticles appeared safe and there was no significant hypotension. In addition, there was a reduction in delayed cerebral ischemia/infarction and an improvement in clinical outcome.

Other steps to limit cerebral vasospasm include the removal of subarachnoid blood as quickly as possible, instillation of thrombolytic agents (e.g., tissue plasminogen activator), and use of pharmacologic agents to reduce inflammatory response (high-dose glucocorticoids, ibuprofen). In Europe and Japan, protease inhibitors have been used in the treatment of vasospasm.

D.8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?

Treatment for cerebral vasospasm is multifactorial and includes continuation of prophylactic measures. In the past, HHH therapy was used to augment CBF past the stenotic areas. It begins with hypervolemic hypertension, with intravascular volume expansion with crystalloid or colloid to increase cardiac output. Some recommended target values are CVP of 10 to 12 mmHg, pulmonary artery occlusion pressure of 15 to 18 mmHg, cardiac index of 3.0 to 3.5 L/min/m^2, and hematocrit of 30% to 35%. Various blood pressure targets have been reported, but a reasonable plan is systolic blood pressure 160 to 200 mmHg if the aneurysm is clipped and 120 to 150 mmHg if unclipped. Vasoactive infusions are added if hypervolemia alone is inadequate. End points of therapy are resolution of neurologic deficits or occurrence of complications of therapy, such as pulmonary edema (26%), myocardial ischemia, and rebleeding or rupture of a secondary aneurysm. A pulmonary artery catheter is often indicated. Fluid used for HHH should be isotonic and have enough sodium to avoid hyponatremia. Vasopressin, fludrocortisone, or hydrocortisone can be administered to counteract excessive sodium and fluid loss. Recent literature has proven the benefit of maintenance of euvolemia with induced hypertension in contrast to strict HHH.

Other treatments for vasospasm, including intra-arterial vasodilators or angioplasty, are utilized if the patient does not demonstrate prompt improvement with hypertensive therapy.

In spite of all attempted therapy, the outcome in patients with

significant vasospasm is often poor. Most medications investigated to ameliorate the devastating consequences of vasospasm have limited efficacy. Nimodipine has been found to have some efficacy in treating vasospasm and improving outcome. A recent target of pharmacologic therapy has been endothelin, a potent long-lasting vasoconstrictor. Clazosentan, an endothelin receptor antagonist, reduced angiographic vasospasm but did not improve clinical outcome in two appropriately powered trials.

D.9. What are other neurologic complications following SAH and aneurysm clipping?

Hydrocephalus, manifesting with a gradual decrease in level of consciousness, occurs in 25% of patients surviving SAH. Diagnosis is confirmed by CT scan. Treatment is by ventricular drainage.

Seizures occur in 13% of patients with SAH and may herald rebleeding or vasospasm. Seizures can increase MAP, CBF, ICP, and lactate production, predisposing to rebleeding in those patients with unclipped aneurysms and cerebral ischemia in those patients with vasospasm. Most patients receive prophylactic anticonvulsants.

Hyponatremia occurs in 10% to 34% of patients with SAH over a time course that parallels that of vasospasm. It may be due to syndrome of inappropriate antidiuretic hormone secretion, "cerebral salt wasting," or prolonged or excessive mannitol use. Cerebral salt wasting syndrome is thought to be mediated by release of atrial natriuretic factor by the hypothalamus secondary to distention of the cerebral ventricles from hydrocephalus. After SAH, patients also have elevated plasma volume. In these patients, fluid restriction is not the treatment of choice because hypovolemia may predispose to vasospasm. Serum brain natriuretic peptide, which causes diuresis and natriuresis, is elevated after SAH, and patients may require treatment with an isotonic or hypertonic salt-containing fluid. In addition, treatment with hydrocortisone may be considered. Finally, patients may experience brain swelling or edema, which is treated with hypertonic saline, mannitol, and/or dexamethasone.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Philadelphia, PA: Elsevier; 2017:222–247.

D.10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?

The lungs can be affected by pneumonia or neurogenic

pulmonary edema, in which disruption of the pulmonary capillary membrane occurs secondary to increased sympathetic nervous system activity. Because of inactivity, patients may be predisposed to developing deep venous thrombosis (DVT) and pulmonary embolism. Patients (approximately 5%) may develop heparin-induced thrombocytopenia, possibly due to heparin exposure during angiography. These patients tend to have increased rates of both vasospasm and DVT. In general, heparin prophylaxis is often avoided in patients after SAH due to concerns for aneurysmal rebleeding, surgical site bleeding or new bleeding around a ventriculostomy catheter. The incidence of venous thromboembolism in neurocritical care patients may be as high as 14%.

There appears to be a relationship between the use of hypertonic saline in the SAH patient and the incidence of acute kidney injury. Patients may have a fever secondary to subarachnoid blood, which may make the workup of postoperative infection more difficult. Finally, as in most patients with head injury, those with SAH may have increased metabolic rate.

SECTION 5 The Endocrine System

22 Pheochromocytoma

Anup Pamnani and Vinod Malhotra

A 39-year-old man has a history of recurrent headaches, diaphoresis, and severe hypertension for several weeks. During a physical examination, he was found to have an exceptionally high blood pressure (BP) of 230/150 mmHg with a heart rate of 112 beats per minute. Prior to this, the patient claims to have been in good health. Further studies were obtained to evaluate the etiology of his arterial hypertension and headaches.

A. Medical Disease and Differential Diagnosis

1. What are some common differential diagnoses for arterial hypertension?

9. What are the clinical features associated with a pheochromocytoma?
10. What is the prevalence of pheochromocytomas and paragangliomas?

B. Preoperative Evaluation and Preparation

1. How can you diagnose and localize the tumor preoperatively?
2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?
3. What other aspects of preoperative management are important?

C. Intraoperative Management

1. What drugs should be avoided during the operation?
2. How would you monitor this patient?
3. Describe the anesthetic management of the patient with pheochromocytoma.
4. What drugs are used to control the effects of catecholamine stimulation during surgery?
5. What are some management concerns after the tumor is removed?
6. What are some of the concerns with laparoscopic adrenalectomy?

D. Postoperative Management

1. What is the significance of postoperative hypotension? How is it treated?
2. What other problems can arise in the postoperative period?

A. Medical Disease and Differential Diagnosis

A.1. What are some common differential diagnoses for arterial hypertension?

The following is a partial list of differential diagnosis of hypertension:

- *Essential hypertension* of unknown etiology
- *Primary renal disease*: nephritis, renal artery stenosis, and renal infarction
- *Endocrine*: adrenocortical *hyperfunction*, hyperthyroidism, pheochromocytoma, acromegaly
- *Sympathetic stimulation*: hypoxia, hypercarbia, pain
- *Neurogenic*: seizure activity, elevated intracranial pressure, and denervation of the carotid sinus
- *Miscellaneous*: malignant hyperthermia, neuroleptic malignant syndrome, carcinoid syndrome, and toxemia of pregnancy

Longo DL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:2962–2968.

A.2. What is a pheochromocytoma?

Pheochromocytomas are catecholamine-secreting tumors of chromaffin tissue. The precise etiology of these tumors is unknown. They are usually located in the adrenal medulla or sympathetic paraganglia but may be found anywhere chromaffin tissue exists. These locations extend from the base of the skull to the anus. Traditionally, it was thought that 90% of pheochromocytomas were found in the adrenal medulla and 10% occurred elsewhere. Prevalence of extra-adrenal tumors is now thought to be as high as 20%. These are commonly called *paragangliomas*.

Pheochromocytomas account for only 0.1% of all cases of arterial hypertension. They are prevalent in 0.005% to 0.01% of the population. When unsuspected or improperly managed during surgery, the hemodynamic effects of the released

catecholamines can be profound.

A.3. Describe the anatomy of the adrenal gland.

The adrenal glands are paired, mustard-colored structures positioned superior and slightly medial to the kidneys in the retroperitoneal space. Each gland is supplied by three arteries: the superior adrenal arteries derived from the inferior phrenic artery, the middle adrenal arteries derived from the aorta, and the inferior adrenal arteries derived from the renal artery. In contrast to the arterial supply, each adrenal gland usually is drained by a single, major adrenal vein. The right adrenal vein is usually short and drains into the inferior vena cava (IVC), whereas the left adrenal vein is longer and empties into the left renal vein. Accessory veins occur in 5% to 10% of patients and are an important consideration during pheochromocytoma resection.

In most respects, the cortex and medulla of the adrenal gland can be considered as two completely distinct organs that happen to colocalize during development. They are of separate embryologic origin; the medullary portion is derived from the chromaffin ectodermal cells of the neural crest and develops in parallel with the sympathetic system during development, and the cortex originates around the fifth week of gestation from mesodermal tissue near the gonads on the adrenogenital ridge.

The chromaffin cells become enclosed within the cortex to form the medulla. The organs of Zuckerkandl are paraganglia

around the aorta at the level of the kidney anterior to the inferior aorta. Accessory areas for the occurrence of pheochromocytoma are in the mediastinum, in the bladder, occasionally in the neck, in the sacrococcygeal region, or in the anal or vaginal areas.

Brunicardi FC, Andersen DK, Billiar TR, et al, eds. *Schwartz's Principles of Surgery*. 10th ed. New York: McGraw-Hill; 2015:1343–1407.

Townsend CM, Beauchamp RD, Evers MB, et al, eds. *Sabiston Textbook of Surgery*. 20th ed. Philadelphia, PA: WB Saunders; 2016:963–995.

A.4. What substances does the adrenal medulla secrete?

The adrenal medulla primarily secretes three catecholamines: epinephrine, norepinephrine, and dopamine. These three compounds are found in all the chromaffin cells of the sympathetic nervous system, which includes the adrenal medulla, aberrant tissue along the sympathetic chain, and paraganglia. Both norepinephrine and dopamine are found at the endings of the postganglionic fibers of the sympathetic nervous system and in the central nervous system.

Brunicardi FC, Andersen DK, Billiar TR, et al, eds. *Schwartz's Principles of Surgery*. 10th ed. New York: McGraw-Hill; 2015:1343–1407.

Townsend CM, Beauchamp RD, Evers MB, et al, eds. *Sabiston Textbook of Surgery*. 20th ed. Philadelphia, PA: WB Saunders; 2016:963–995.

A.5. What are the mechanisms of action of epinephrine and norepinephrine?

These catecholamines exert their effects by acting on β-adrenergic and α-adrenergic receptors. β-Receptor stimulation results in G protein–mediated activation of adenylate (adenylyl) cyclase, which increases cyclic adenosine monophosphate (cAMP) levels.

Stimulation of the α_1 subtype of the α-receptor results in G protein–mediated hydrolysis of phospholipid membranes, which cause an increase in cytoplasmic Ca^{2+} levels and subsequent

smooth muscle contraction. The stimulation of α_2 receptors, conversely, inhibits the action of adenylate cyclase and decreases cAMP.

The pharmacologic response is dependent on the location of the catecholamine receptors throughout the body. The distribution and density of the receptors will determine the predominant response to each catecholamine.

A.6. What is the pathway for synthesis and breakdown of catecholamines?

The synthesis of endogenous catecholamines begins with the active transport of the amino acid tyrosine from the circulation into postganglionic sympathetic nerve endings. The hydroxylation of tyrosine is regarded as the rate-limiting step of the pathway (**Fig. 22.1**). The termination of the action of catecholamines occurs primarily through reuptake at nerve terminals. Diffusion and metabolism, by the enzymes catechol-*O*-methyltransferase (COMT) and monoamine oxidase (MAO), also play a role in termination of action.

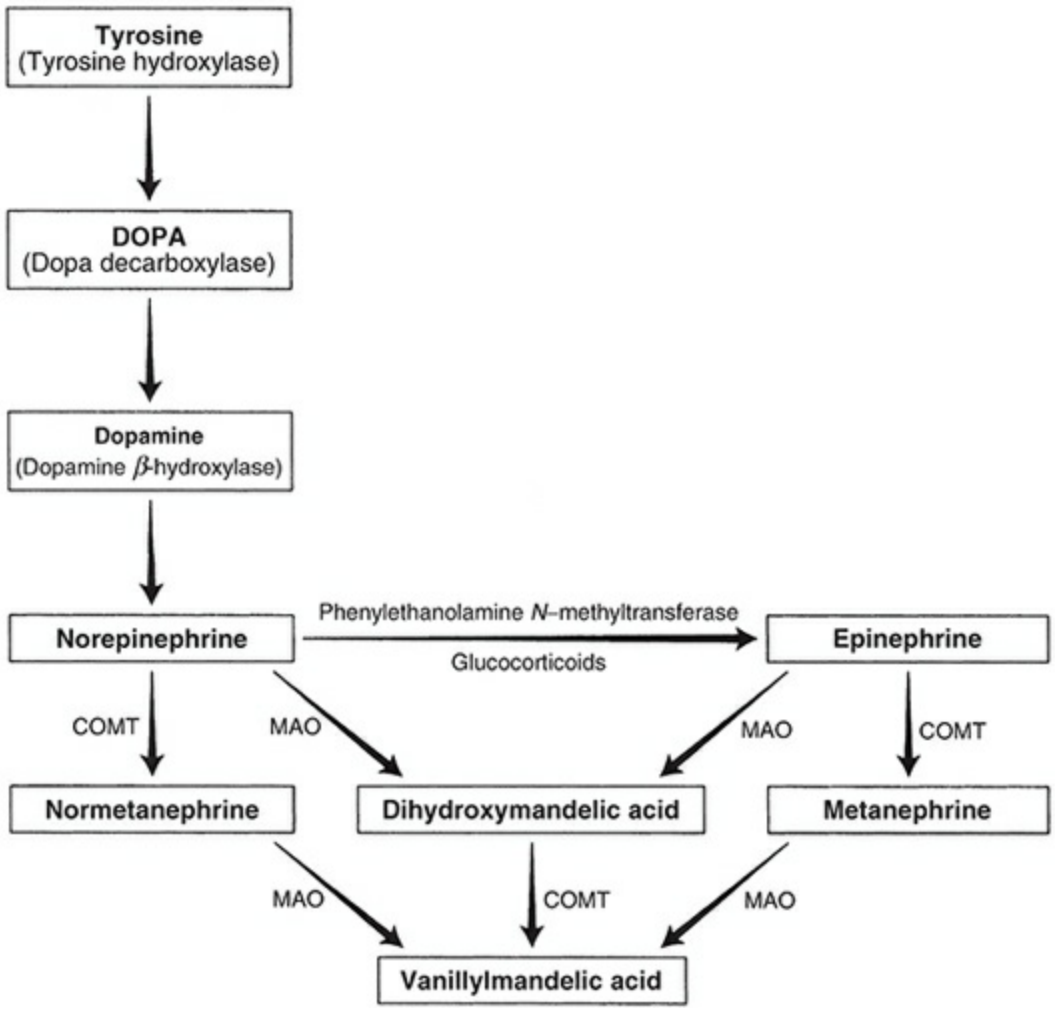

FIGURE 22.1. Synthesis and metabolism of endogenous catecholamine. COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase. (*Reprinted by permission from Springer: Pullerits J, Ein S, Balfe JW. A.7. What does the adrenal cortex secrete?

The adrenal cortex secretes more than 30 different corticosteroids. These can be divided into three major classes: mineralocorticoids, glucocorticoids, and sex steroids (the androgens and estrogen).

The precursor of all corticosteroids is cholesterol.

Aldosterone is the most important mineralocorticoid secreted by the adrenal cortex, whereas cortisol is the most important glucocorticoid secreted. The adrenal cortex is also responsible for secreting sex steroids.

Each of these substances is secreted by different zones. The mineralocorticoids are secreted by the zona glomerulosa, glucocorticoids are secreted by the zona fasciculata, and sex steroids are secreted by the zona reticularis.

Brunton LL, Knollmann BC, Dandan R, eds. *Goodman and Gillman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2017:191–224.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:449–476.

A.8. What are the metabolic actions of the glucocorticoids and the mineralocorticoids?

The glucocorticoids have their predominant mechanism of action on intermediary metabolism. These effects include increased gluconeogenesis, fatty acid mobilization, protein catabolism, and anti-inflammatory effects. Cortisol may improve cardiac function by improving responsiveness of β-adrenergic receptors. Approximately 95% of the glucocorticoid activity is from the secretion of cortisol.

The mineralocorticoids predominantly act on the body minerals, such as sodium and potassium. By conserving sodium ions, they sustain extracellular fluid volume. They also help maintain normal potassium plasma concentrations.

Pharmacokinet. 2005;44(1):61–98.

A.9. What are the clinical features associated with a pheochromocytoma?

The classic triad is severe headache, diaphoresis, and palpitations. One or more of the following often signal the presence of a pheochromocytoma: sudden severe headaches, perspiration, weight loss, paroxysmal hypertension, pallor, palpitations, diabetes-like syndrome with elevated fasting blood sugar, nausea, vomiting, fever, encephalopathy, anxiety, myocardial infarction, stroke, or acute renal failure. The aforementioned symptoms are usually paroxysmal in nature. These "attacks" may last from a few moments to hours. Although hypertension can be paroxysmal, 65% of adults demonstrate sustained hypertension.

A pressor response to particular drugs suggests the presence of this tumor. These drugs include histamine, glucagon, droperidol, tyramine, metoclopramide, cytotoxic drugs, saralasin, tricyclic antidepressants, and phenothiazines.

Townsend CM, Beauchamp RD, Evers MB, et al, eds. *Sabiston Textbook of Surgery*. 20th ed. Philadelphia, PA: WB Saunders; 2016:963–995.

A.10. What is the prevalence of pheochromocytomas and paragangliomas?

Pheochromocytomas occur in both sexes with peak incidence in the third to fifth decades of life. Advances in diagnosis and genetics now challenge the traditional "rule of 10" for pheochromocytomas (10% bilateral, 10% extra-adrenal, 10% familial, 10% malignant). Prevalence of bilateral adrenal tumors is higher than 10% in some familial pheochromocytoma syndromes such as multiple endocrine neoplasia type 2 and von Hippel-Lindau syndrome (see **Table 22.1** for complete list).

Prevalence of extra-adrenal tumors (paragangliomas) is thought to reach as high as 20%. Nearly 25% of these tumors are thought to be hereditary.

TABLE 22.1 Syndromes Associated with Pheochromocytoma

MEN type IIa (Sipple syndrome)	Parathyroid adenoma/hyperplasia
	Medullary carcinoma of thyroid
	Pheochromocytoma
MEN type IIb	Medullary carcinoma of the thyroid
	Mucosal adenomas
	Marfanoid appearance
	Pheochromocytoma
von Hippel-Landau syndrome	Hemangioblastoma of the retina, cerebellum, or other parts of the CNS, pheochromocytoma
Neurofibromatosis	Neurofibromas, café-au-lait spots, axillary or inguinal freckling, optic nerve glioma, pheochromocytoma

CNS, central nervous system; MEN, multiple endocrine neoplasia.

Metastases are low for adrenal pheochromocytomas (up to 5%). The prevalence of malignant disease is about 33% for extra-adrenal pheochromocytomas and even higher in patients with specific mutations such as those causing some forms of familial paragangliomas.

B. Preoperative Evaluation and Preparation

B.1. How can you diagnose and localize the tumor preoperatively?

The laboratory tests for pheochromocytoma are shown in **Table**

22.2. Biochemical diagnosis is based on the excess catecholamines and their metabolites released by the tumor.

TABLE 22.2 Biochemical Tests for Diagnosis of Pheochromocytoma

Urine Tests
Norepinephrine
Epinephrine
Dopamine
Total metanephrines
Fractionated metanephrines
Vanillylmandelic acid
Plasma Tests
Norepinephrine
Epinephrine
Dopamine
Plasma-free metanephrines
Clonidine suppression of norepinephrine secretion

In theory, the hydroxy-methoxy-mandelic acid (often misnamed as vanillylmandelic acid [VMA]) level should be the most reliable laboratory test because it is the final common product of both catecholamine metabolic pathways. In practice, however, the intermediate metanephrines have proved to be better discriminators of pheochromocytomas. Hydroxy-methoxy-mandelic acid is often used as an initial "case-finding" test because it has "acceptable" specificity and sensitivity and is relatively inexpensive.

Historically, 24-hour urine tests were generally considered superior to plasma tests in the diagnosis of pheochromocytomas because the tumor secretes catecholamines only intermittently and the catecholamines have a short half-life. These combined factors could result in relatively normal plasma catecholamine levels in the presence of an active tumor.

Measurement of total metanephrines gives the highest true-positive results, approximately 98% to 99%. Compelling

evidence now indicates that initial screening for pheochromocytomas and paragangliomas can include measurements of plasma-free metanephrines or urine-fractionated metanephrines. The plasma test offers advantages over the urine test in that it can additionally help predict size and adrenal versus extra-adrenal locations of tumors as well as presence of metastases and underlying germline mutations of tumor susceptibility genes. However, the plasma test is difficult to implement correctly, rendering the urine test preferable for mainstream use and the plasma test more appropriate for specialized endocrine centers.

Computed tomography (CT) with or without iodine 131 (^{131}I)–labeled metaiodobenzylguanidine (MIBG) is extremely accurate in diagnosing and localizing the tumor. Use of arteriography, once popular, should be performed cautiously because dye can stimulate catecholamine release. CT scanning and magnetic resonance imaging (MRI) scanning are excellent imaging techniques that visualize normal adrenal glands when the diagnosis is equivocal. For extra-adrenal locations and in pregnant patients, MRI scanning may be a more desirable choice.

B.2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?

The major goals of pharmacologic therapy in the preoperative period are to control hypertension and to facilitate intravascular volume expansion.

Administration of α-adrenergic blockers has been the cornerstone of preoperative management. Phenoxybenzamine, prazosin, terazosin, and doxazosin may all be employed to facilitate preoperative α-blockade. Phenoxybenzamine is most commonly used due to its relatively long duration of action and ease of administration. It irreversibly and nonselectively alkylates α-adrenergic receptors, including α_1-receptors on vascular smooth muscle, rendering them nonfunctional. Preoperative medical therapy is started 1 to 3 weeks prior to surgery. Therapy is titrated to resolution of symptoms and decrease of BP to low normal values for age. During this period, the patient is encouraged to liberally imbibe fluids and salt in order to facilitate volume replacement and minimize postural hypotension.

Reflex tachycardia is a frequent side effect of preoperative α-blockade. Tachycardia can be managed by subsequent addition of β-blocker therapy. It is worth noting, however, that β-blockade is best avoided in the initial phases of treatment. In the absence of adequate α-blockade, inhibition of β-receptor–mediated vasodilation can result in unopposed α-receptor–mediated vasoconstriction due to catecholamines secreted by the tumor. This can precipitate a hypertensive crisis, heart failure, and possibly end-organ damage.

α-Methyl-para-tyrosine (α-metyrosine) is also an option for preoperative management of pheochromocytoma. This agent decreases the biosynthesis of catecholamines through competitive inhibition of the enzyme tyrosine hydroxylase. The significant depletion of catecholamine stores reduces hemodynamic fluctuations during tumor manipulation. For maximal effect, α-metyrosine must be administered a minimum

of 2 to 3 days before surgery.

Recently, the calcium channel blocker nicardipine has been used as an alternative to phenoxybenzamine for preoperative management. Preoperative use of phenoxybenzamine can often be limited by its frequent and sometimes severe side effect profile (postural hypotension, reflex tachycardia, nasal stuffiness, syncope, etc.) as well as its uncommon use and high cost. Oral nicardipine therapy appears to be an equivalent alternative to phenoxybenzamine therapy and may be better tolerated, cheaper, and more accessible.

Brunaud L, Boutami M, Nguyen-Thi PL, et al. Both preoperative alpha and calcium channel blockade impact intraoperative hemodynamic stability similarly in the management of pheochromocytoma. *Surgery*. 2014;156(6):1410–1417.

Siddiqi HK, Yang HY, Laird AM, et al. Utility of oral nicardipine and magnesium sulfate infusion during preparation and resection of pheochromocytomas. *Surgery*. 2012;152(6):1027–1036.

B.3. What other aspects of preoperative management are important?

The circulating blood volume is frequently decreased in these patients due to vasoconstriction from high levels of circulating catecholamines. Patients are encouraged to consume fluid and salt in order to facilitate volume expansion once α-blocker therapy is initiated. However, volume expansion should be undertaken with caution in those with decreased myocardial function to avoid precipitating congestive heart failure.

Sedation in the immediate preoperative period can be

particularly helpful to attenuate catecholamine release secondary to anxiety. It may also help reduce vasodilator requirement subsequently in the intraoperative phase. Adequate sedation and analgesia should also be provided during invasive procedures such as arterial line access. Preoperative treatment of the airway with nebulized lidocaine can help significantly attenuate the tracheal response to intubation.

Lenders JW, Duh QY, Eisenhofer G, et al. Pheochromocytoma and paraganglioma: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2014;99(6):1915–1942.

Pacak K. Preoperative management of the pheochromocytoma patient. *J Clin Endocrinol Metab*. 2007;92(11):4069–4079.

C. Intraoperative Management

C.1. What drugs should be avoided during the operation?

Some of the commonly administered drugs that should be avoided in patients with pheochromocytoma are listed in **Table 22.3**. Many of these agents release histamine (e.g., morphine, atracurium), which is a potent catalyst of catecholamine release from the tumor. Agents that cause indirect increase of catecholamine levels (e.g., ketamine, ephedrine) should also be avoided. It should be noted, however, that these are not absolute contraindications and many of these agents can be used if clinically necessary, provided they are used judiciously with close monitoring.

TABLE 22.3 Suggested Drugs to Avoid in Patients with Pheochromocytoma

Droperidol
Morphine
Atracurium
Pancuronium
Ketamine

Ephedrine
Halothane
Cocaine
Metoclopramide

Connery LE, Coursin DB. Assessment and therapy of selected endocrine disorders. *Anesthesiol Clin North America*. 2004;22(1):93–123.

Kinney MA, Narr BJ, Warner MA. Perioperative management of pheochromocytoma. *J Cardiothorac Vasc Anesth*. 2002;16(3):359–369.

C.2. How would you monitor this patient?

Monitoring in these patients generally includes an electrocardiogram with a V_5 lead, core temperature, pulse oximetry, intra-arterial BP monitoring, central venous pressure monitoring, and a urinary catheter. For patients with known or suspected myocardial dysfunction, a pulmonary artery catheter or transesophageal echocardiography should be considered. Devices that measure cardiac output and stroke volume variation noninvasively can be particularly helpful in titrating fluid therapy.

Most tumors nowadays are excised using laparoscopic technique with minimal blood loss. With the increasing availability of noninvasive monitors of cardiac function, patients who are adequately optimized in the preoperative period and display minimal hemodynamic perturbation do not require central venous pressure monitoring.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:449–476.

Kinney MA, Narr BJ, Warner MA. Perioperative management of pheochromocytoma. *J Cardiothorac Vasc Anesth*. 2002;16(3):359–369.

C.3. Describe the anesthetic management of the patient with pheochromocytoma.

General anesthesia is frequently employed for tumor resection because most resections are performed by laparoscopic

technique. Neuromuscular relaxation and controlled ventilation allow for adequate gas exchange during CO_2 insufflation for pneumoperitoneum.

The anesthetic induction technique should minimize hemodynamic changes and allow for adequate depth of anesthesia during tracheal intubation. Lidocaine 4% solution administered prior to intubation, via mucosal atomizer device, or 1.5 mg per kg intravenously 2 minutes before laryngoscopy can significantly attenuate the response to tracheal intubation. Other measures to attenuate hemodynamic responses to intubation are described in Chapter 11, sections C.5 and C.6. Most of the inhaled agents can be employed during the maintenance phase. However, caution should be used when desflurane is utilized because it may provoke sympathetic stimulation and subsequent catecholamine release. Halothane, now infrequently used in most clinical settings, should be avoided because it has the potential to incite arrhythmias in the presence of high levels of circulating catecholamines.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:449–476.

C.4. What drugs are used to control the effects of catecholamine stimulation during surgery?

Drugs used to control intraoperative hypertension are listed in **Table 22.4**.

TABLE 22.4 Intravenous Drugs to Control Intraoperative Hypertension

Drug	Dose
Nicardipine	Infusion of 5–15 mg/hr. Increase by 2.5 mg/hr every 15 min to effect.
Phentolamine	1-mg IV boluses every 5–10 min. Start infusion 0.1–2 mg/min and titrate to effect.
Nitroglycerin	20–40 μg boluses every 5–10 min to effect. Infusion 5–20 μg/min initial (maximum dose 400 μg/min)

Nitroprusside	Infuse initially with 0.5–1.5 μg/kg/min to maximum of 8 μg/kg/min over 1–3 hr.
Propranolol	1-mg boluses to total 10 mg
Esmolol	Load with 5–10-mg boluses and infuse at 0.25–0.5 μg/kg/min.
Labetalol	5–10-mg boluses every 20–30 min to maximum dose 150 mg

IV, intravenous.

Nicardipine infusion can be easily titrated and is particularly effective at achieving systemic vasodilation. It is a good choice in patients that have already been started on oral nicardipine in the preoperative period. Sodium nitroprusside was used extensively previously. Concerns over toxic metabolites and handling precautions to prevent its degradation by light have largely resulted in nicardipine replacing it as a first-line agent. Phentolamine, a short-acting α-blocking agent, can also be given as a bolus medication or a continuous infusion to control BP.

Magnesium sulfate ($MgSO_4$) has been occasionally used in selected cases as an adjunct vasodilator. Data is still being gathered on its efficacy. Administration of $MgSO_4$ should be accompanied by close monitoring of plasma magnesium levels and other clinical signs of hypermagnesemia.

β-Blockers can be a useful adjunct to control BP in the intraoperative phase, particularly if tachycardia accompanies use of systemic vasodilators. They should, however, not be used as the first-line agent for treatment of intraoperative hypertension due to the concern about unopposed α-agonism.

Hodin R, Lubitz C, Phitayakorn R, et al. Diagnosis and management of pheochromocytoma. *Curr Probl Surg*. 2014;51(4):151–187.

Kinney MA, Narr BJ, Warner MA. Perioperative management of pheochromocytoma. *J Cardiothorac Vasc Anesth*. 2002;16(3):359–369.

C.5. What are some management concerns after the tumor is removed?

It is important to be aware of the fact that BP may decrease very quickly after venous drainage of the tumor is interrupted. Any vasodilators being administered should be discontinued. BP support may be maintained by administering vasopressors, such as norepinephrine and vasopressin, and administering fluids. Norepinephrine requirements can be substantial in the post–tumor resection period due to receptor insensitivity from chronic catecholamine exposure. Additional vasopressors, such as vasopressin, may also need to be initiated.

Close communication between the anesthesia and surgical teams is essential during this period. Continued vasodilator support may indicate inadequate resection or previously undiagnosed extra-adrenal tumor.

Hodin R, Lubitz C, Phitayakorn R, et al. Diagnosis and management of pheochromocytoma. *Curr Probl Surg*. 2014;51(4):151–187.

C.6. What are some of the concerns with laparoscopic adrenalectomy?

Insufflation of CO_2, to facilitate pneumoperitoneum, is typically associated with an elevation in catecholamine levels in patients undergoing laparoscopic adrenalectomy, resulting in an associated increase in cardiac output and BP. Close monitoring of vital signs is essential once pneumoperitoneum is initiated. Use of lower intra-abdominal pressures during laparoscopy has been associated with decreased release of catecholamines and less hemodynamic fluctuation. If hemodynamic instability is sustained or refractory, insufflation should be terminated.

D. Postoperative Management

D.1. What is the significance of postoperative hypotension? How is it treated?

Postoperative hypotension can be due to reduced circulating catecholamine levels post–tumor resection, hypovolemia, or residual effects of phenoxybenzamine (which has a long half-life). In addition, downregulation of catecholamine receptors, due to chronically elevated levels of catecholamines, renders administered catecholamines less effective. Post–adrenalectomy hypotension should be treated with volume administration and, if needed, norepinephrine. Vasopressin can be used to treat catecholamine-resistant hypotension. It is important that the clinician rule out other etiologies of hypotension, such as postoperative bleeding as well.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:449–476.

D.2. What other problems can arise in the postoperative period?

Occasionally, patients may be somnolent in the postoperative period. This is possibly due to the sudden removal of activating catecholamines. Narcotic requirement may also be decreased.

Hypoglycemia is another significant concern. Severe hypoglycemia may cause loss of consciousness and respiratory arrest. Hypoglycemia is the result of decreased catecholamine levels (particularly when the tumor is epinephrine-secreting). Neoglycogenesis and glycogenolysis, the result of chronic β-agonism, are no longer present, and chronically elevated insulin

plasma level may decrease more gradually. Close monitoring of plasma glucose levels is essential in the first 24-hours post–tumor resection.

Persistent hypertension after removal of a pheochromocytoma occasionally signifies that a residual pheochromocytoma tumor is present. Be aware that plasma catecholamine levels (norepinephrine) may not decrease to normal levels for many days after removal of the tumor.

23 Diabetes Mellitus

Mark E. Nunnally and Vinod Malhotra

A 59-year-old woman presents for vaginal hysterectomy for cervical cancer. She is obese (body mass index 32 kg per m^2) and has had diabetes mellitus (DM) type 2, hypertension, and dyslipidemia for 20 years. She takes enalapril; metoprolol; atorvastatin; metformin; sitagliptin; and recently, insulin glargine, 20 units subcutaneous, daily for refractory hyperglycemia. She measures her serum glucose intermittently at home. Values are generally 150 to 220 mg per dL. She experiences an early and a prolonged sense of fullness after meals and an unpleasant sour taste at night two or three times per week. Laboratory values are notable for a serum creatinine of 2.2 mg per dL and a serum glucose of 206 mg per dL. She has not taken any medications today and has had nothing to eat since midnight.

A. Medical Disease and Differential Diagnosis

1. What is the epidemiology of DM in the general population?
2. What are the factors in the etiology of the disease?
3. How is DM classified?
4. What are the complications of DM?
5. How are the different forms of this illness treated?
6. How is control of the disease adequately monitored?
7. What are some of the factors that alter insulin requirements?

8. What are the principles of management of diabetic ketoacidosis (DKA)?
9. What is a hyperglycemic hyperosmolar state?

B. Preoperative Evaluation and Preparation

1. How should this patient be evaluated?
2. How would the stiff joint syndrome affect her airway management?
3. What are the signs and implications of autonomic neuropathy in the diabetic patient?
4. How should this patient be prepared for anesthesia and surgery?
5. For elective surgery, how are insulin and glucose requirements managed on the day of surgery?
6. How should this patient be premedicated?

C. Intraoperative Management

1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?
2. What anesthetic techniques should be considered?
3. How should this patient be monitored?
4. How is hyperglycemia treated intraoperatively?
5. How is hypoglycemic shock recognized and treated intraoperatively?

D. Postoperative Management

1. How is diabetes controlled in this patient postoperatively?
2. Does diabetes increase perioperative risk?
3. What are the common postoperative complications to be expected in a diabetic patient?
4. Is it necessary to achieve tight perioperative control of glucose?

A. Medical Disease and Differential Diagnosis

A.1. What is the epidemiology of DM in the general population?

DM, literally "sweet urine," is a group of metabolic disorders defined by elevated serum glucose. Data from the National Health and Nutrition Examination Survey from 2010 to 2014 suggest a prevalence of DM in the adult population of 11.9%, with about a quarter of those undiagnosed. For patients 65 years or older, the prevalence is 26.3%. National Health Interview Survey (NHIS) data suggest a doubling of prevalence between 1990 and 2008, but no significant change between 2008 and 2012.

A majority of patients with diabetes (approximately 90%) have type 2 diabetes (DM2); a minority (approximately 10%) have type 1 diabetes (DM1). Finally, 1% to 14% of pregnant women develop gestational diabetes. DM1 and DM2 are very different diseases. In DM1, exogenous insulin is essential for cellular metabolism. Untreated, DM1 is a wasting disease associated with ketoacidosis and severe cumulative organ failure. DM2 is a metabolic disorder associated with resistance to insulin effects. Because of the presence of circulating insulin, ketoacidosis is rare in DM2. However, a hyperglycemic hyperosmolar state is a risk in the inadequately treated patient.

Hillier TA, Vesco KK, Pedula KL, et al. Screening for gestational diabetes mellitus: a systematic review for the U.S. Preventive Services Task Force. *Ann Intern Med*. 2008;148:766–775.

A.2. What are the factors in the etiology of the disease?

Because hyperglycemia defines DM, it is too easy to focus on elevations in serum glucose, ignoring other effects. Lipid and protein metabolism are deranged in both varieties of DM. Tissue growth, signaling, and function are likewise impaired. Simple control of blood sugar may not adequately treat the complex hormonal and metabolic derangements of DM. Inflammation and immune dysfunction are also components of the disease.

In DM1, the immune system destroys insulin-secreting pancreatic β cells. The diagnosis of DM1 is frequently made in childhood. DM2 manifests in a variety of conditions that decrease the hypoglycemic effects of insulin. Among these are obesity and endocrine and inflammatory conditions. In both cases, genetic association is incomplete and there is association with other diseases, including autoimmune disorders, hypertension, and dyslipidemias. Gestational diabetes reflects insulin resistance exacerbated by the effects of pregnancy. It likely signals patients who are at risk of developing DM2.

Cowie CC, Rust KF, Byrd-Holt DD, et al. Prevalence of diabetes and impaired fasting glucose in adults in the U.S. population: National Health and Nutrition Examination Survey 1999-2002. *Diabetes Care*. 2006;29(6):1263–1268.

A.3. How is DM classified?

Table 23.1 lists the criteria for the diagnosis of DM1, DM2, and gestational diabetes. Elevated (≥6.5%) hemoglobin A_1C (Hgb A_1C) or fasting hyperglycemia (≥126 mg per dL) are useful means to confirm metabolic derangement, but random hyperglycemia accompanied by classic symptoms (such as polyuria and polydipsia), or the inability to manage a glucose load, are sufficient to make the diagnosis. Ketoacidosis and the need for insulin reflect DM1, whereas obesity, gradual symptom

onset (usually at an older age), and hyperosmolality without ketosis suggest DM2. Gestational diabetes resembles DM2 only in the setting of pregnancy.

TABLE 23.1 American Diabetes Association Diagnostic Criteria for Diabetes Mellitus

1.	Symptoms of diabetes plus random plasma glucose level >200 mg/dL (11.1 mmol/L)
2.	Hemoglobin A_1C ≥6.5%
3.	Fasting plasma glucose level ≥126 mg/dL (7.0 mmol/L)
4.	Two-hour plasma glucose level ≥200 mg/dL (11.1 mmol/L) during oral glucose tolerance test

From American Diabetes Association. Classification and diagnosis of diabetes: standards of medical care in diabetes—2018. *Diabetes Care*. 2018;41(suppl 1):S13–S27. Copyright © 2017 by the American Diabetes Association. Used with permission of American Diabetes Association.

Therapy for DM varies by type. Insulin is essential in DM1. In DM2 and gestational diabetes, diet, exercise, and drugs that modify insulin secretion or sensitivity can help correct hyperglycemia, although exogenous insulin may be necessary.

American Diabetes Association. Classification and diagnosis of diabetes: standards of medical care in diabetes—2018. *Diabetes Care*. 2018;41(suppl 1):S13–S27.

A.4. What are the complications of DM?

Acute complications of DM include DKA and a hyperglycemic hyperosmolar state. Both are associated with severe systemic illness and a high mortality and will be discussed separately. Hypoglycemia is a serious risk of several diabetes therapies.

Chronically, DM impacts virtually every organ system. Of most concern to the anesthetist are macrovascular disease, including accelerated atherosclerosis, and microvascular nephropathy, neuropathy, and cardiomyopathy. Tissues fail from a combination of advanced glycation end products, inflammation, connective tissue proliferation, and impaired perfusion. Renal failure; neuropathy; and accelerated coronary, cerebral, and peripheral vascular disease are common.

Autonomic neuropathy and the stiff joint syndrome are both factors for preoperative evaluation (see later discussion). Hypertension frequently accompanies DM, exacerbating organ failure. Impaired immune function predisposes to infection. Hypercoagulability exacerbates macrovascular disease. Dyslipidemias accelerate atherosclerotic lesions and may directly contribute to metabolic toxicities.

Cumulatively, the systemic lesions caused or exacerbated by DM reduce life expectancy. When diagnosed before the age of 35 years, DM causes an estimated mean of 25.9 years of lost life. Because complications worsen with time, this effect decreases. About 50% of mortality in diabetic patients comes from cardiovascular disease.

Although it would be helpful to stratify diabetic patients according to their risk of complications, the complexity of the disease and its management makes risk stratification difficult. The safest assumption is that a diabetic is at high risk for coronary and other macrovascular disease, congestive heart failure, and renal insufficiency.

A.5. How are the different forms of this illness treated?

Diabetes care is different in chronic and acute settings. It is essential to differentiate between the agents used chronically and those used during acute perioperative stress.

Care of DM1 requires exogenous insulin. **Figure 23.1** illustrates the pharmacodynamics of several insulin preparations. A combination of a short- and a long-acting insulin preparation can help achieve the goals of resting and postprandial glycemic control. In contrast, DM2 responds to insulin, oral insulin

secretagogues, insulin sensitizers, glucose uptake inhibitors, gastrointestinal hormones, weight loss, dietary management, and exercise. **Table 23.2** lists the major classes of drugs for the treatment of DM2, their mechanisms of action, pharmacokinetics, and particular concerns for the anesthetist.

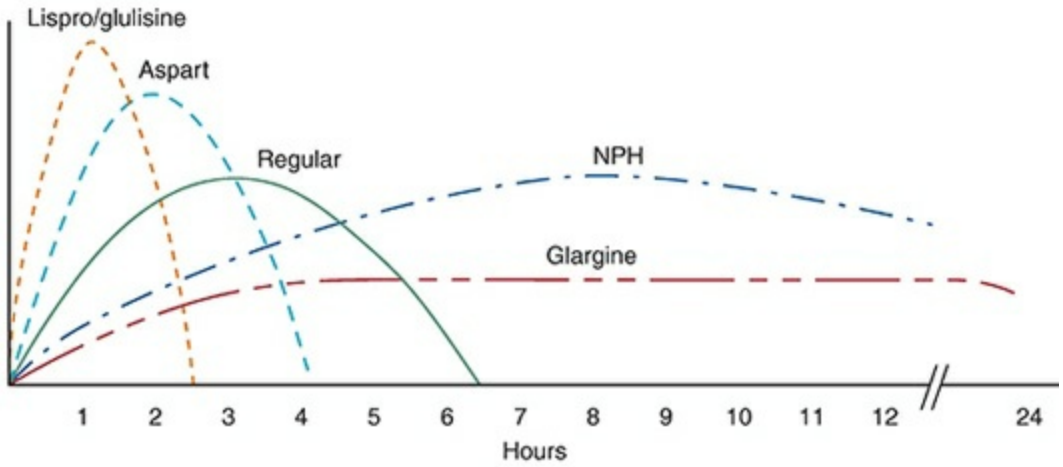

FIGURE 23.1. Onset and duration of action graphic for common subcutaneous insulin preparations. Regular insulin given intravenously fits the best profile for a titratable drug in the operating room, as onset peak and offset all occur within an hour. NPH, neutral protein hagedorn.

TABLE 23.2 Common Therapies for Type 2 Diabetes[a]

Drug Name/Class	Mechanism	Route	Onset	Duration	Important Considerations
First-generation sulfonylureas	↑ β cell insulin secretion	PO			Hypoglycemia
Acetohexamide			3 hr	24 hr	
Chlorpropamide			2 hr	24 hr	
Tolazamide			4 hr	16 hr	
Tolbutamide			1 hr	12 hr	
Second-generation sulfonylureas	↑ β cell insulin secretion	PO			Hypoglycemia
Glimepiride (Amaryl)			2–3 hr	24 hr	
Glipizide ER (Glucotrol XL)			2–4 hr	24 hr	
Glipizide IR (Glucotrol)			30 min	24 hr	
Glyburide			30 min	24 hr	

(Micronase)					
Biguanides	↑ Peripheral glucose uptake in response to insulin	PO			Lactic acidosis risk may extend up to 72 hr after administration.
Metformin (Glucophage)			1–3 hr	17 hr	
α-Glucosidase inhibitors	↓ Digestive carbohydrate breakdown	PO			No known adverse effects
Acarbose (Precose)			2 hr	NA	
Miglitol (Glyset)			2–3 hr	NA	
Thiazolidinediones (PPAR-γ mediators)	↑ Peripheral glucose uptake	PO			Risk for hepatic injury, fluid retention; congestive heart failure; ongoing concerns about myocardial ischemia
Pioglitazone (Actos)			Hours	$T_{1/2}$ 3–7 hr	
Rosiglitazone (Avandia)			Hours	$T_{1/2}$ 3–4 hr	
Meglitinides (glinides)	↑ β cell insulin secretion	PO			Hypoglycemia
Mitiglinide (Glufast)			Minutes	Hours	
Nateglinide (Starlix)			20 min	$T_{1/2}$ 1.5 hr	
Repaglinide (Prandin)			15–60 min	4–6 hr	
Incretin-mimetics (glucagon-like peptide-1 agonists)	↑ Insulin, ↓ glucagon, hepatic glucose production, gastric emptying, and appetite	SC			Observational data associated with renal failure, delayed gastric emptying, hypoglycemia, pancreatitis
Albiglutide (Tanzeum)			Days	$T_{1/2}$ 5 days	
Dulaglutide (Trulicity)			Hours (48 hr median)	$T_{1/2}$ 5 days	
Exenatide (Byetta, Bydureon)			10 min	6–8 hr	
Liraglutide (Saxenda, Victoza)			Minutes	$T_{1/2}$ 13 hr	
Lixisenatide (Adlyxin)			Hours	$T_{1/2}$ 3 hr	

Semaglutide (Ozempic)			Days	$T_{1/2}$ 1 week	
Dipeptidyl peptidase-4 (DPP-IV) inhibitors	Inhibits incretin breakdown	PO			May have effects on immune function and heart failure
Alogliptin (Nesina)			1–2 hr	$T_{1/2}$ 21 hr	
Linagliptin (Tradjenta)			1.5 hr	$T_{1/2}$ 12 hr	
Saxagliptin (Onglyza)			Hours	24 hr	
Sitagliptin (Januvia)			Hours	Days	
Amylin analogues	↑ Satiety, ↓ glucagon, and appetite, indication for DM1	SC			Hypoglycemia
Pramlintide (Symlin)			Minutes	Hours	
Sodium glucose cotransporter-2 (SGLT-2) inhibitors	Inhibit renal reabsorption of glucose	PO			Hypoglycemia, urinary tract infections. Bladder cancer. Antihyperglycemic effects may mask diabetic ketoacidosis.
Canagliflozin (Invokana)			Hours	$T_{1/2}$ 13 hr	
Dapagliflozin (Farxiga)			Hours	$T_{1/2}$ 13 hr	
Empagliflozin (Jardiance)			Hours	$T_{1/2}$ 12 hr	
Ertugliflozin (Steglatro)			1 hr	$T_{1/2}$ 17 hr	
Dopamine agonist	↓ Sympathetic tone, ↓ hepatic glucose production, ↓ postmeal free fatty acid levels	PO			Hypotension
Bromocriptine (Cycloset)			Minutes	$T_{1/2}$ 6 hr	
Bile acid sequestrant	Binds bile acids in GI tract, preventing reabsorption.	PO			May increase serum triglycerides, transaminases. GI discomfort

	Mechanism for controlling blood sugar unknown		
Colesevelam (Welchol)		Minutes	Works concurrently with meals

[a]Onset and duration data are approximate only and subject to variability.
DM1, type 1 diabetes; ER, extended release; GI, gastrointestinal; IR, immediate release; NA, not applicable; PO, per os (by mouth); PPAR-γ, peroxisome proliferator-activated receptor gamma; SC, subcutaneous; $T_{½}$, half-life.

Certain medications have adverse effects that deserve consideration. Biguanides, such as metformin, increase peripheral glucose uptake but also predispose patients to greater production of lactic acid and acidosis. The significance of this finding is not clear, but many recommend discontinuing these drugs perioperatively because they might increase the risk of lactic acidosis with hypoperfusion during surgery. Because of its long half-life, metformin may take up to 72 hours to clear from the bloodstream, so discontinuation on the day of surgery does not minimize the risk of acidosis. Thiazolidinediones have been associated with hepatic injury and congestive heart failure. Exenatide is associated with reports of kidney dysfunction. Sulfonylureas, pramlintide, and sitagliptin may be associated with hypoglycemia. Glucose transporter type 2 inhibitors, such as dapagliflozin, may be associated with urogenital infections. Long-term risks remain poorly characterized for this and other new agents, such as glucagon-like peptide agonists and inhaled insulin preparations.

For these reasons, as well as unreliable pharmacokinetics, the best option for acute treatment of all types of diabetic hyperglycemia is insulin. Although subcutaneous dosing is often used in the hospital setting, intravenous insulin best meets the profile of an ideal titratable agent. It has a short time to onset (10 to 15 minutes), peak effect (less than 30 minutes), and duration

of action (45 minutes). Frequent glucose monitoring is essential to titrate the therapy.

Although serum glucose or other markers of chronic hyperglycemia, such as Hgb A_1C, are currently standard end points for chronic therapy, other factors such as serum lipid and blood pressure management may be just as important. Anesthesiologists should inquire about agents treating these conditions during preoperative evaluation.

A.6. How is control of the disease adequately monitored?

Self-monitoring of blood glucose is possible in all forms of diabetes, usually by using finger-stick blood samples and portable monitors. This method is the established standard of care in DM1 for carefully titrated control to prevent hypoglycemia and ketoacidosis. Many advocate self-monitoring for patients with DM2, especially if they take insulin, but compliance varies, and self-monitoring may not be beneficial in all patients. Hgb A_1C, the product of Hgb exposure to hyperglycemic conditions, is a marker of long-term glycemic control. It may help identify subgroups of patients for whom the risk for complications is higher and can be a marker of disease control. The relationship between levels of glycemic control and Hgb A_1C is not linear, so a single laboratory value does not completely reveal the glycemic profile over time. Patients with

DM have blood pressure and serum lipid profiles monitored as part of their long-term care because these factors increase the risk of lifetime complications.

In the operating room, serum glucose can be measured by pinprick or vascular blood sample. Samples from a venous or arterial line offer greater reliability during low perfusion. If insulin is being used, monitoring is recommended every hour.

Moitra V, Sladen RN. Monitoring endocrine function. *Anesthesiol Clin*. 2009;27:355–364.

A.7. What are some of the factors that alter insulin requirements?

Insulin responsiveness is dynamic during stress or illness. Tissue injury from surgery, trauma, or inflammatory states, such as infection, decreases glycemic responsiveness to insulin as part of the stress response. Under ideal circumstances, these effects are maximal 2 to 3 days after injury and resolve over the course of a week, but there is substantial variability. Besides stress, any other condition that increases counter-regulatory hormones such as glucagon, cortisol, and catecholamines decreases insulin sensitivity and increases insulin requirements. Cushing disease and pheochromocytoma are examples of conditions that cause insulin resistance. Several medications, including corticosteroids, thyroid replacement preparations, oral contraceptives, and thiazide diuretics, also increase insulin resistance. In solid organ transplant recipients, steroids and the calcineurin inhibitors tacrolimus and cyclosporine have been associated with insulin resistance or onset of diabetes. Exercise and ethanol can decrease insulin requirements.

Thorell A, Nygren J, Ljungqvist O. Insulin resistance: a marker of surgical stress. *Curr Opin Clin Nutr Metab Care*. 1999;2(1):69–78.

A.8. What are the principles of management of diabetic ketoacidosis (DKA)?

A hyperglycemic patient should be assessed for DKA before surgery. Because DKA is associated with higher perioperative mortality, patients should be monitored for intravascular volume and electrolyte abnormalities.

Withholding insulin contributes to DKA. Infection or tissue injury exacerbates diabetes and sets off a chain of events that can result in DKA. Because of increased risk to the patient, DKA is corrected before surgery. When it is triggered by a surgical condition, time to correct it may be limited by the urgency of the surgery.

Patients with DKA have an anion gap metabolic acidosis in addition to hyperglycemia. Elevated serum ketone levels can help confirm the diagnosis, but urine ketones are frequently easier to assay. Commonly, a patient will be hypovolemic from polyuria and incomplete hydration, and resuscitation with isotonic fluids is appropriate. Lactate and acetate are converted to glucose by the liver, and this fact should be considered in selecting solutions for the initial resuscitation and weighed against the risks of hyperchloremic acidosis. Ketosis is corrected with insulin, which is best as an intravenous infusion. Because glucose levels frequently normalize before ketosis clears, insulin therapy is continued even after hyperglycemia corrects. Dextrose is administered simultaneously to avoid hypoglycemia. During acidemia, hyperkalemia is common, resulting from shifts in body stores. However, a patient will frequently have a net

potassium deficit. Hypokalemia during correction, which can reflect a deficit of up to 10 mEq potassium per kg body mass, should be treated aggressively. Likewise, hypocalcemia and hypomagnesemia should be anticipated and treated.

Kitabchi AE, Murphy MB, Spencer J, et al. Is a priming dose of insulin necessary in a low-dose insulin protocol for the treatment of diabetic ketoacidosis? *Diabetes Care*. 2008;31:2081–2085.

Kitabchi AE, Nyenwe EA. Hyperglycemic crises in diabetes mellitus: diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Endocrinol Metab Clin North Am*. 2006;35:725–751.

A.9. What is a hyperglycemic hyperosmolar state?

Any hyperglycemic patient should be evaluated for a hyperglycemic hyperosmolar state, another potentially fatal condition. The syndrome is more frequent in DM2. It includes hyperglycemia, hyperosmolarity, volume depletion, and changes in mental status. Adverse effects result from hyperosmolarity and hypovolemic shock. Glucose levels exceeding 1,000 mg per dL have been described. Mortality can be high. Glycosuria and inadequate fluid intake contribute to the condition. Treatment consists of fluid resuscitation and intravenous insulin to correct the hyperglycemia. Sodium, potassium, calcium, and magnesium levels should be evaluated and normalized.

Kitabchi AE, Nyenwe EA. Hyperglycemic crises in diabetes mellitus: diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Endocrinol Metab Clin North Am*. 2006;35:725–751.

B. Preoperative Evaluation and Preparation

B.1. How should this patient be evaluated?

The goals of preoperative evaluation are to stratify perioperative risk, ensure optimal management of concurrent illness, and screen for specific anesthetic-related problems. A diabetic patient is evaluated for cardiovascular disease, renal function,

stiff joint syndrome, autonomic neuropathy, aspiration risk, and acute diabetic emergencies.

Both DM1 and DM2 increase the risk of coronary artery disease. The 2014 American College of Cardiology (ACC)/American Heart Association (AHA) Guideline on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery recommends the use of the Revised Cardiac Risk Index (RCRI). This index uses a history of diabetes, ischemic heart disease, heart failure, cerebrovascular disease, and renal insufficiency to predict perioperative cardiovascular risk. According to the 2014 guidelines, patients are triaged based on risk for major adverse cardiac events (MACE). The RCRI, the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) Surgical Risk Calculator, and the Myocardial Infarction and Cardiac Arrest (MICA) calculators are three tools to measure this risk. In the case of the RCRI, diabetes requiring insulin is one of six criteria used in the score. In the Surgical Risk Calculator, risk is calculated from a larger group of factors, including surgery type and a diagnosis of diabetes. The MICA calculator risk is calculated based on surgery type, American Society of Anesthesiologists patient classification, serum creatinine, and patient age. If MACE risk from these indices is greater than or equal to 1%, poor or unknown exercise tolerance and whether the results will change perioperative care determine the need for stress testing. A diagnosis of diabetes is thus a major factor for deciding whether to supplement a patient assessment preoperatively because of cardiovascular risk. Preoperative β-blocker therapy is recommended (level of evidence: B) in diabetic patients with three or more RCRI risk factors, although starting these agents on the day of surgery in patients who have never had the therapy is discouraged.

Optimizing the patient's medical status is a consideration for

all patients but particularly for diabetics who have many comorbidities. Optimal management of coexisting hypertension and congestive heart failure can minimize perioperative risk. The decision to proceed or delay a procedure for medical management depends on the urgency of the surgery and the potential for improving the patient's medical condition.

Diabetes is a leading cause of renal insufficiency and failure. Because this patient already has an increased serum creatinine, she should be screened for renal insufficiency and any fluid and metabolic derangements should be corrected. A metabolic panel, including serum creatinine, blood urea nitrogen, potassium, sodium, chloride, bicarbonate, and base deficit can be useful, especially because angiotensin mediators, β-blockers, and insulin itself can affect serum potassium levels. Joint stiffness is assessed with a comprehensive airway examination and the "prayer sign," in which a patient's hands are placed against each other at the palmar surface to see whether the fingers touch. Other considerations in the diabetic include the risks of aspiration and autonomic instability. Although Hgb A_1C levels correlate with perioperative risk, the test does not add any information to the decision paradigm.

In addition to its chronic consequences, diabetes may produce a hyperglycemic hyperosmolar state and DKA. Both syndromes reflect severe metabolic abnormalities, most commonly resulting from infection. Because these syndromes may manifest as a result of a surgical emergency, patients with these conditions will present for perioperative management. Ideally, metabolic derangements should be corrected before anesthetic induction, but sometimes, patients must go to surgery urgently or emergently. Anesthesia providers should be prepared for hemodynamic instability, rapid fluid infusion, electrolyte repletion, and frequent monitoring of serum glucose and electrolytes. In both conditions, intravenous insulin infusion is

indicated, titrated to normoglycemia in the hyperglycemic hyperosmolar state and the clearance of ketones in DKA. Supplemental dextrose is usually necessary to maintain insulin infusion in DKA.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management for patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100(10):1043–1049.

B.2. How would the stiff joint syndrome affect her airway management?

The stiff joint syndrome is thought to result from glycation of connective tissue with chronic exposure to hyperglycemia. This collagen glycation starts in the fourth and fifth interphalangeal joints resulting in the patient not able to completely appose the palms and fingers of the hands—the "prayer sign." The degree of interphalangeal involvement can also be assessed by scoring the ink impression made by the palm of the dominant hand "palm print (PP) sign." These are good screening tests for joint stiffness and indicate a reduced range of motion in the cervical spine, temporomandibular, arytenoid joints, and glottic structures making endotracheal intubation difficult. The PP test and the prayer sign are sensitive and specific predictors of difficult airway that may likely require a smaller endotracheal tube and difficult airway adjuncts.

Salzarulo HH, Taylor LA. Diabetic "stiff joint syndrome" as a cause of difficult endotracheal intubation. *Anesthesiology*. 1986;64:366–368.

B.3. What are the signs and implications of autonomic neuropathy in the diabetic patient?

Diabetic neuropathy involves both the peripheral and autonomic nervous system. In the autonomic system, gastric motility, heart rate, and vasomotor tone may be impaired. Cardiac ischemia can be asymptomatic. This patient is at risk for pulmonary aspiration of gastric contents and hemodynamic instability. A history will elicit early satiety, prolonged postprandial fullness, and significant reflux symptoms. Potential difficulties with mask ventilation and intubation are assessed. Heart rate variability, best seen on an electrocardiogram (ECG) tracing in response to deep breathing, Valsalva maneuver, or position changes, identifies patients at risk for hemodynamic instability. Preparation is made to control hemodynamic instability, especially because this patient is taking an angiotensin-converting enzyme inhibitor. Angiotensin-receptor blocking agents also increase the risk of postinduction hypotension. Because of a high likelihood of hemodynamic instability, the anesthesiologist should prepare to use slow titration of anesthetic agents, frequent blood pressure monitoring, and vasoactive agents, if necessary.

Huang CJ, Kuok CH, Kuo TB, et al. Pre-operative measurement of heart rate variability predicts hypotension during general anesthesia. *Acta Anaesthesiol Scand*. 2006;50:542–548.

B.4. How should this patient be prepared for anesthesia and surgery?

This patient's cardiovascular risk is elevated. Her RCRI puts her

risk for MACE between 6% and 11%, but the NSQIP Surgical Risk Calculator puts it at 0.2%. If her exercise tolerance is below 4 metabolic equivalents (METs), about the equivalent of climbing a flight of stairs with a bag of groceries or performing heavy work around the house, noninvasive stress testing may be considered. Insulin therapy is given for hyperglycemia. Because of her elevated serum glucose, she is asked about polyuria, a sign that she might be dehydrated from hyperglycemic diuresis. DKA is unlikely because she has DM2, but a metabolic panel is indicated to rule out electrolyte abnormalities. The presence of an elevated anion gap should provoke further investigation for the possibility of ketoacidosis. An ECG may be indicated based on her risk factors for cardiovascular disease.

Her symptoms, consistent with gastroparesis and gastroesophageal reflux, will influence premedication and airway management. Results from a comprehensive airway examination, including assessment of neck and jaw mobility and a check for the prayer sign, affect anesthetic management decisions. A rapid sequence intubation could minimize aspiration risk but only if intubation is easy. If a difficult airway is suspected, awake intubation techniques should be considered.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management for patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

B.5. For elective surgery, how are insulin and glucose requirements managed on the day of surgery?

The risk of hypoglycemia is balanced against the benefit of glycemic control. Anesthetized patients can have occult hypoglycemia, so serum glucose is checked frequently. Intravenous insulin is titrated for glycemic control. When administered intravenously, either as an infusion or as

intermittent boluses, insulin has a fast onset and a short duration of action. Subcutaneous insulin, with longer lasting effects, is less predictable, especially during the hemodynamic changes of anesthesia and surgery. Subcutaneous insulin pumps should be turned down or off for all but the most minor procedures. Similarly, oral agents should be withheld on the day of surgery, except for minor procedures. Ideally, metformin should be withheld for 72 hours to minimize the risk of lactic acidosis.

Initial enthusiasm for tight glycemic control in critically ill patients has given way to a much more cautious approach. Perioperatively, hyperglycemia is associated with worsened neurologic and cardiac ischemia and poor wound healing. Even though tight control of serum glucose has been associated with better outcomes in some settings, there is risk associated with insulin therapy. Hypoglycemia is a serious risk, and insulin has multiple other effects that remain poorly described.

Evidence is limited to support glycemic control to a "normal" range of 80 to 110 mg per dL in the operating room. Higher targets minimize hypoglycemia. Levels higher than 180 mg per dL may cause protein glycation and osmotic diuresis. Targets within the range of 100 to 180 mg per dL are considered satisfactory.

Preoperative infusion of dextrose minimizes peripheral insulin resistance and reduces the risks of hypoglycemia. When dextrose causes hyperglycemia, the amount of insulin needed is increased. Given that insulin resistance and hyperglycemia are parts of the stress response to surgery, hyperglycemia may be a sign that exogenous carbohydrate infusion is not necessary.

Lipshutz AK, Gropper MA. Perioperative glycemic control: an evidence-based review. *Anesthesiology.* 2009;110:408–421.

B.6. How should this patient be premedicated?

Concerns with premedication include sensitivity to sedatives and aspiration risk. Preexisting cardiovascular, cerebrovascular, and renal disease temper the aggressiveness of administration of benzodiazepines and opioids. Because of the symptoms of gastroesophageal reflux and gastroparesis, histamine blockers, liquid antacids, or metoclopramide may be given. Metoclopramide, famotidine, and a liquid antacid like sodium citrate may minimize aspiration risk in this patient.

C. Intraoperative Management

C.1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?

As part of the stress response to surgery, metabolism increases and resistance develops to the hypoglycemic effects of insulin. The response includes the mobilization of protein stores (mostly muscle), more hepatic gluconeogenesis, and greater breakdown and synthesis of triglycerides. Hormones, including catecholamines, cortisol, glucagon, and even insulin, contribute to the metabolic changes. Although glucose metabolism increases, so too does glucose production, adding to the risk of hyperglycemia. Administration of exogenous dextrose can exacerbate hyperglycemia in diabetic patients.

Anesthetic techniques influence metabolism but generally to a lesser extent than the stress from surgical injury. Techniques that mitigate stress hormones, such as neuraxial anesthesia, also may mitigate hyperglycemia. Some drugs affect regulatory hormones directly. Etomidate blocks cortisol synthesis. Benzodiazepines can decrease cortisol secretion. Halogenated agents have in vitro effects on insulin secretion. However, none of these effects impact postoperative glycemic control as much as will the

surgery itself.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth*. 2000;85(1):80–90.

C.2. What anesthetic techniques should be considered?

Factors other than glycemic control may influence the choice of anesthetic technique in the patient with diabetes. Regional techniques are chosen based on provider skill, patient preferences, and postoperative pain control. Techniques that speed the time to oral intake by reducing nausea or minimizing ileus make glycemic management easier postoperatively. For this reason, antiemetics and the spare use of opioids might be beneficial. Although not a contraindication to nerve blockade, peripheral neuropathy should be documented in a preoperative neurologic examination. Nerve injury from local anesthetics or abnormalities on neurologic examination may complicate postoperative management. Infection risk from regional techniques may be increased in patients with diabetes.

Sedated or anesthetized patients cannot complain of hypoglycemic symptoms the same way unsedated patients can. Serum glucose is monitored regularly in all but the shortest cases.

In this patient, general endotracheal anesthesia with precautions to prevent aspiration, intravenous insulin titrated to a serum glucose of less than 180 mg per dL, and frequent blood glucose monitoring is a satisfactory choice.

Ljungqvist O, Nygren J, Soop M, et al. Metabolic perioperative management: novel concepts. *Curr Opin Crit Care*. 2005;11:295–299.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth*. 2000;85(1):80–90.

C.3. How should this patient be monitored?

If preoperative evaluation reveals a risk of hemodynamic

instability, cardiac ischemia, or congestive heart failure, added cardiovascular monitoring should be considered, depending on the procedure. Peripheral vascular disease can complicate placement of an arterial catheter but is not a contraindication because in patients who have cardiovascular comorbidities, the benefits of monitoring outweigh the risks.

Frequent glucose monitoring is recommended in cases lasting longer than an hour or when hypoglycemic agents are being used. Serum glucose by finger stick or, ideally, venous or arterial sample should be measured at least every hour when giving intravenous insulin.

In this patient, pulse oximetry, continuous ECG monitoring, end-tidal carbon dioxide and gas analysis, and noninvasive blood pressure monitoring are satisfactory, if no further concerns arise from cardiovascular evaluation or surgical complexity.

McAnulty GR, Robertshaw HJ, Hall GM. Anaesthetic management of patients with diabetes mellitus. *Br J Anaesth*. 2000;85(1):80–90.

C.4. How is hyperglycemia treated intraoperatively?

The high end of a normal range for fasting serum glucose is 110 mg per dL; however, hyperglycemia in inpatients need not be treated until it reaches a higher level.

The one good agent for treating intraoperative hyperglycemia is intravenous insulin. Onset takes minutes, peak effect is achieved in 15 to 30 minutes, and duration of effect is less than an hour, facilitating titration. Insulin may be administered by continuous infusion or as intermittent boluses; the bolus consumes less lead time and eliminates the risk of pump misprogramming or malfunction. Subcutaneous insulin is less ideal for use during general anesthetics or complex procedures because variable peripheral blood flow will alter the uptake and duration of action. Most other therapies for DM2 are not fit for

intraoperative use. Oral agents cannot be easily administered, are not reliably absorbed, and have too long a duration of action to be practical perioperatively. They may be taken on the day of surgery before minor procedures. In this case, sitagliptin should be discontinued to avoid hypoglycemia. Metformin, a biguanide, increases the risk of lactic acidosis during periods of hypoperfusion. Metformin is discontinued for 3 or more days before extensive procedures when a large-volume blood loss is possible.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J*. 2006;99(6):580–589.

C.5. How is hypoglycemic shock recognized and treated intraoperatively?

Hypoglycemia can lead to tissue energy failure and has been associated with hemodynamic collapse and brain injury. Any patient receiving insulin, pramlintide, sitagliptin, or sulfonylureas is at risk for hypoglycemia. Because risk is usually known beforehand, hourly or more frequent monitoring of serum glucose should detect hypoglycemia. If glucose levels are low or decrease rapidly, the fastest treatment is a bolus of intravenous dextrose, 50% solution, administered slowly. In an emergency, one full ampule is the starting dose. In less urgent settings when the serum glucose level is low but not critical, smaller doses can be titrated to serum glucose values.

Dierdorf SF. Anesthesia for patients with diabetes mellitus. *Curr Opin Anaesthesiol*. 2002;15:351–357.

D. Postoperative Management

D.1. How is diabetes controlled in this patient postoperatively?

Unless there is a change in disease status as a consequence of surgery or preoperative care was inadequate, this patient should be transitioned back to her preoperative regimen. Before transitioning, she must recover from the stress response to the surgery. If this were a simple outpatient procedure, such as a cataract extraction, she could return home on her outpatient medication regimen. In this case, however, the effects of tissue injury may not peak for days; diabetes control is thus a dynamic challenge. Regular monitoring of glucose is required (at a minimum, checks should be made every 6 hours).

She is monitored for hyperglycemia, and her nutrition regimen is adjusted to serum glucose measurements. Hourly glucose measurements and insulin infusion can control hyperglycemia. Most patients can be effectively managed with subcutaneous insulin and less frequent measurements. Insulin dose should take into account preoperative requirements, insulin resistance from the stress response, and caloric intake. Many patients receive intravenous dextrose postoperatively; if they are hyperglycemic on this regimen, dextrose is discontinued.

Oral diabetes medications can be reintroduced once the acute stress response begins to wane and the patient is cleared for a normal diet. Resumption of an oral diet can increase the risk of hyperglycemia, so ongoing monitoring is essential.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J*. 2006;99(6):580–589.

D.2. Does diabetes increase perioperative risk?

Because patients with diabetes are at a greater risk of atherosclerosis, infection, autonomic and cardiovascular instability, and metabolic abnormalities than those without diabetes, perioperative risk is higher in this patient population. After surgery, the diabetic patient is monitored for hyperglycemia and hypoglycemia, ischemic complications,

circulatory compromise, and wound and nosocomial infection. As a group, patients with diabetes have an increased risk for complications and poor outcomes from complications.

Lipshutz AK, Gropper MA. Perioperative glycemic control: an evidence-based review. *Anesthesiology*. 2009;110:408–421.

D.3. What are the common postoperative complications to be expected in a diabetic patient?

Hyperglycemia and hypoglycemia, wound infections, and organ ischemia are the most common and worrisome postoperative complications in patients with diabetes. Following myocardial infarction or cerebrovascular accident, hyperglycemia is associated with a worse prognosis.

Smiley DD, Umpierrez GE. Perioperative glucose control in the diabetic or nondiabetic patient. *South Med J*. 2006;99(6):580–589.

D.4. Is it necessary to achieve tight perioperative control of glucose?

In the critical care setting, there is evidence for improved outcomes with tight glycemic control, variably defined as serum glucose between 80 and 120 mg per dL or higher; other evidence has shown no benefit or even harm. Some advocate for tight glycemic control in cardiac and noncardiac surgery; however, the risks of hypoglycemia and data from more recent studies have tempered the enthusiasm for tight glycemic control.

Potential benefits from tight glycemic control include improvement in metabolic, anti-inflammatory, organ, and circulatory function. Unfortunately, there is little evidence to suggest these benefits are substantial perioperatively. Unresolved details include the best time for tight control, the goals of therapy, the effect of nutrition, and the magnitude and factors in the potential for significant hypoglycemia. The patient is transitioned to her preoperative level of control during

recovery, and severe hyperglycemia is prevented by monitoring glucose closely. Glucose levels above 180 mg per dL increase the risk of protein glycation and osmotic diuresis; targeting serum glucose below this value makes physiologic sense.

SECTION 6 The Genitourinary System

24 Transurethral Resection of the Prostate and Geriatric Anesthesia

Anuj Malhotra, Vinod Malhotra, and Fun-Sun F. Yao

A 79-year-old man with benign prostatic hypertrophy is scheduled for transurethral resection of the prostate (TURP). His past medical history includes myocardial infarction (MI) 7 months ago requiring drug-eluting coronary stent (DES) placement and an implantable cardioverter-defibrillator (ICD) inserted for episodes of ventricular tachycardia. His current left ventricular ejection fraction is 25%. The patient is taking diuretics, a β-blocker, clopidogrel, aspirin, and an angiotensin-converting enzyme (ACE) inhibitor.

A. Medical Disease and Differential Diagnosis

1. What comorbidities are common in patients undergoing TURP?
2. What are the normal physiologic consequences of aging for the various organ systems?
3. How should drug dosages be adjusted for elderly patients? Should any particular medications be avoided?
4. Does a history of prior MI increase the patient's risk of perioperative reinfarction or stent thrombosis?
5. In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient's cardiac condition? Does he need additional testing?
2. Would you discontinue any antihypertensives or any medications for angina?
3. For a patient with a cardiac implantable electronic device (CIED), what information should you know? What precautions should be taken?
4. What types of coronary stents are available? What is their perioperative relevance?
5. What is the conventional recommendation for dual antiplatelet therapy (DAPT) in a patient with previous percutaneous coronary intervention (PCI) undergoing elective noncardiac surgery?
6. What risk is associated with continuing perioperative antiplatelet therapy? What risk is there with stopping it?
7. How should patients with coronary stents undergoing noncardiac surgery be managed?

C. Intraoperative Management

1. What monitors would you use for this patient?
2. Is there a preferred anesthetic technique for patients undergoing TURP, and why?

3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia?
4. What intravenous fluid would you use during TURP?
5. Forty minutes after a sensory level of T10 was established with intrathecal anesthesia, and monopolar TURP (M-TURP) resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic is administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, and pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar (B-TURP) or laser TURP (L-TURP) resection?
6. What are the important characteristics of irrigation solutions used during TURP?
7. What is the effect on body temperature of continuous bladder irrigation during TURP?
8. What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?
9. How does the patient absorb irrigation solution during TURP?
10. What factors increase the incidence of TURP syndrome?
11. What is the effect on cardiopulmonary, renal, and central nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?
12. What causes CNS dysfunction in patients who have undergone M-TURP?
13. How does acute hyponatremia affect the cardiovascular system?
14. What prophylactic measures may reduce the incidence of TURP syndrome?
15. What therapeutic measures are recommended for patients with

TURP syndrome?

16. Is hypertonic saline administration necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?
17. What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic by-products of glycine?
18. What are the symptoms and clinical course of TURP-induced hyperammonemia?
19. What are the clinical characteristics, causes, and prognosis of TURP-related blindness?
20. What are the causes of excessive bleeding during TURP?
21. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?
22. What are the causes of hypotension during TURP?

D. Postoperative Management

1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?
2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?
3. Is postoperative hypothermia a risk factor for myocardial ischemia?
4. What is postoperative cognitive dysfunction (POCD)? How does this differ from delirium, and what is the time course to resolution?
5. What are the mechanisms and risk factors for POCD? How would you mitigate the risk of POCD? Does anesthesia type influence development of POCD?

E. Comparing M-TURP, B-TURP, and L-TURP

1. What differentiates M-TURP from B-TURP?
2. Are decreased morbidity and mortality associated more closely

with M-TURP or with B-TURP?

3. What differentiates the technologies for L-TURP?

A. Medical Disease and Differential Diagnosis

A.1. What comorbidities are common in patients undergoing TURP?

TURP patients often are elderly and suffer from cardiac, pulmonary, vascular, and endocrine disorders. The incidence of cardiac disease is 67%; vascular disease, 50%; chronic obstructive pulmonary disease, 29%; and diabetes mellitus, 8%.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

Malhotra V, Malhotra A, Pamnani A. Anesthesia and the renal and genitourinary systems. In: Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

A.2. What are the normal physiologic consequences of aging for the various organ systems?

- CNS changes include decreases in brain size, neuronal density, regional neurotransmitters, and neuroreceptors. Pharmacodynamic sensitivity increases with age for all intravenous agents (e.g., propofol, fentanyl, and midazolam). The minimal alveolar concentration (MAC) of inhalational anesthetics decreases by approximately 6% per decade after age 40 years. Also, a decrease in cholinergic receptor activity may explain the geriatric patient's vulnerability to the anticholinergic side effects of medications such as diphenhydramine, meperidine, and scopolamine.
- In the cardiovascular system, loss of arterial compliance increases afterload. Systolic function remains relatively preserved, but diastolic dysfunction is common, making patients dependent on adequate filling and atrial kick.

Valvular dysfunction and particularly aortic stenosis is common, occurring in >10% of patients older than 75 years.

- Total lung capacity remains unchanged, but residual volume increases, leading to an overall decrease in vital capacity. Closing capacity also increases with age and can exceed functional residual capacity, resulting in atelectasis. Decreased gas exchange and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch also occur.
- The glomerular filtration rate (GFR) decreases by 1 mL/min/1.73 m^2 per year starting at 40 years of age, which can slow clearance of renally excreted medications. Creatinine clearance is a good estimate of GFR, whereas urine output is not.
- Hepatic blood flow also decreases, particularly affecting drugs that undergo phase I but not phase II metabolism.
- Lean muscle mass decreases, as does subcutaneous (but not total body) fat, predisposing to temperature dysregulation and hypothermia.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2102–2114.

Nickalls RW, Mapleson WW. Age-related iso-MAC charts for isoflurane, sevoflurane and desflurane in man. *Br J Anaesth*. 2003;91:170–174.

Peters R. Ageing and the brain. *Postgrad Med J*. 2006;82:84–88.

A.3. How should drug dosages be adjusted for elderly patients? Should any particular medications be avoided?

Decreased GFR and decreased hepatic blood flow result in prolonged effect of drugs metabolized and excreted through these pathways. It is important to note that normal creatinine or liver synthetic function alone are not indicative of GFR or hepatic blood flow because the former can reflect decreased muscle mass rather than preserved renal function and the latter is

often preserved despite significant decrease in liver mass with aging.

In general, geriatric patients are more sensitive to the effects of all intravenous and inhalational anesthetics due to age-related physiologic changes in organ systems as discussed aforementioned and in section A.2. Initial doses of intravenous anesthetic agents should be reduced, with a longer interval between repeat doses. It is safer to start with 50% of the regular doses and then titrate to the desired effect. The dose of all inhalational agents should also be reduced by approximately 6% per decade after age 40 years.

In addition, the American Geriatrics Society Beers Criteria for Potentially Inappropriate Medication Use in Older Adults identifies medications that are likely to cause cognitive issues for elderly patients, many of which are commonly used as part of an anesthetic (**Table 24.1**).

TABLE 24.1 Common Medications in the Perioperative Period with Potential Neurological Effects

Drug	Rationale
Diphenhydramine	Highly anticholinergic; may increase confusion
Hydroxyzine	Highly anticholinergic; may increase confusion
Scopolamine	Highly anticholinergic
Amitriptyline	Highly anticholinergic; sedating
Antipsychotics	Increased risk of stroke and mortality in persons with dementia
Benzodiazepines	Older adults have increased sensitivity and decreased metabolism. Risk of cognitive impairment, delirium, and falls
Metoclopramide	Extrapyramidal side-effects; risk may be increase in older adults
Pethidine	Not effective analgesic; may cause neurotoxicity
Pentazocine	May cause central nervous system adverse events, including confusion and hallucinations
Neuromuscular blocking drugs	Poorly tolerated by older adults, with anticholinergic adverse effects

A.4. Does a history of prior MI increase the patient's risk of perioperative reinfarction or stent thrombosis?

Yes, a history of prior MI or ischemic heart disease is considered an intermediate predictor of perioperative cardiac morbidity and is part of the revised cardiac risk index. MI, as indication for initial stent placement also yields a higher risk for subsequent stent thrombosis.

A.5. In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period?

An acute MI (<7 days) or a recent MI (>7 days but <30 days) is considered an unstable coronary syndrome requiring additional evaluation and delay of elective noncardiac surgery. It is advocated to wait >60 days after an MI without revascularization before elective surgery is performed. Also see

Chapter 14, section A.7.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:e278–e333.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient's cardiac condition? Does he need additional testing?

The American College of Cardiology/American Heart Association guidelines suggest a stepwise approach that takes into account the clinical markers of cardiac risk, surgery risk, and functional capacity. The patient's medical history should focus on information about previous cardiac evaluations and interventions (coronary stent and automatic ICD [AICD] placement). Active cardiac conditions such as unstable coronary syndromes (recent MI or unstable angina), decompensated congestive heart failure (CHF), significant arrhythmias, or severe valvular disease warrant additional work up prior to surgery. If the patient has stable coronary artery disease (CAD), then risk for major adverse cardiac event (MACE) can be determined using combined clinical/surgical risk score. If risk for MACE is low (<1%), no additional information is required. If MACE is elevated, the functional capacity of the patient is best evaluated by the activity history and assessment of metabolic equivalents (METs), with >4 to 10 METs being suggestive of sufficient cardiac reserve. Stress testing may be indicated for patients with poor exercise tolerance or unable to assess METs, if this would affect the choice to proceed with surgery. Electrocardiogram (ECG) is reasonable in a patient with cardiac history undergoing greater than low-risk surgery

but is not required. Assessment of left ventricular function is reserved for cases of active CHF or known history without reassessment within 1 year. Also see Chapter 14, section B.1.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:e278–e333.

B.2. Would you discontinue any antihypertensives or any medications for angina?

Antianginal agents and β-blockers should be continued perioperatively including the day of surgery to prevent rebound hypertension and tachycardia that may result from sudden withdrawal of these drugs. Patients taking ACE inhibitors or angiotensin II receptor blockers (ARBs) can be predisposed to refractory intraoperative hypotension due to blunting of the sympathetic effect on vascular tone by anesthesia, increasing reliance on the renin–angiotensin–vasopressin system to maintain blood pressure and renal perfusion. It is recommended that these medications be held 24 hours before surgery.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:e278–e333.

Withholding versus continuing angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers before noncardiac surgery: an analysis of the vascular events in noncardiac surgery patients cohort evaluation prospective cohort. *Anesthesiology*. 2017;126:16–27.

B.3. For a patient with a cardiac implantable electronic device (CIED), what information should you know? What precautions should be taken?

Patients undergoing surgery with a CIED need to have the device interrogated prior to surgery to determine the device's features, settings, pacer function, pacing dependency, baseline rhythm and rate, ICD function, tachyarrhythmia history, effect of magnet, and battery status. Intraoperative management will be determined by risk for electromagnetic interference. If there is risk, pacer function can be programmed to asynchronous mode if pacemaker dependent and the antitachycardia algorithm of the ICD should be turned off (via magnet or programming, depending on settings) and external cardioversion paddles placed. Postoperatively, reprogram to baseline settings if programming changes were made. Also see Chapter 8, section C.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

B.4. What types of coronary stents are available? What is their perioperative relevance?

Coronary stent placement was introduced in order to reduce the risk of thrombosis, dissection, and restenosis after angioplasty. Two types of coronary stents have been used: bare metal stents (BMS) and DES. DES have been used extensively to reduce the neointimal hyperplastic reaction seen with the use of BMS, which is the main cause of restenosis; however, by delaying endothelialization of coronary stent struts, DES predispose to stent thrombosis if DAPT is stopped early. First-generation DES required 12 months minimum DAPT before cessation or interruption in therapy; however, second-generation DES appears to endothelialize faster and may be safe to stop at 6 months. Also see Chapter 10, section A.5, **Fig. 10.1**).

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:2215–2245.

Levin GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines: an update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention, 2011 ACCF/AHA guideline for coronary artery bypass graft surgery, 2012 ACC/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease, 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes, and 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2016;134:e123–e155.

B.5. What is the conventional recommendation for dual antiplatelet therapy (DAPT) in a patient with previous percutaneous coronary intervention (PCI) undergoing elective noncardiac surgery?

Therapy with thienopyridines (ticlopidine or clopidogrel) and aspirin, DAPT, is recommended after PCI. However, due to increased risk for bleeding, discontinuation is often required prior to surgery. DAPT is recommended for 2 to 4 weeks after dilatation without stenting (angioplasty); elective surgery should be postponed for 2 to 4 weeks. After BMS, antiplatelet therapy for 4 to 6 weeks is recommended; elective surgery should be postponed for 4 to 6 weeks, minimum 30 days. After the implantation of newer generation DES, at least 6 months of antiplatelet therapy is required, although if risk of delaying surgery would outweigh stent thrombosis, consideration can be given to proceeding at 3 months. In patients with an indication for PCI and a projected need for surgery within the next 6 months, a balloon angioplasty or BMS may be considered. Daily

aspirin should be continued during the perioperative period and DAPT should be resumed as soon as possible postoperatively. Also see Chapter 14, section A.8 and **Figure 14.1**.

Levin GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines: an update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention, 2011 ACCF/AHA guideline for coronary artery bypass graft surgery, 2012 ACC/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease, 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes, and 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2016;134:e123–e155.

B.6. What risk is associated with continuing perioperative antiplatelet therapy? What risk is there with stopping it?

In meta-analysis of perioperative aspirin withdrawal versus low-dose aspirin, the low-dose group's relative risk of bleeding increased by a factor of 1.5, but there was no increase in bleeding complications or in perioperative mortality, with the possible exceptions of intracranial surgery and prostatectomy. Studies with ticlopidine or clopidogrel demonstrate a small increased risk of major perioperative bleeding with DAPT (0.4% to 1%). The risk of stopping antiplatelet therapy is stent thrombosis with resulting acute MI and a high mortality rate, so whether bleeding risks outweigh the benefit of protection from stent thrombosis must be considered.

Burger W, Chemnitius JM, Kneissl GD, et al. Low-dose aspirin for secondary cardiovascular prevention—cardiovascular risks after its perioperative withdrawal versus bleeding risks with its continuation—review and meta-analysis. *J Intern Med*. 2005;257(5):399–414.

Oscarsson A, Gupta A, Fredrikson M, et al. To continue or discontinue aspirin

in the perioperative period: a randomized, controlled clinical trial. *Br J Anaesth*. 2010;104:305–312.

B.7. How should patients with coronary stents undergoing noncardiac surgery be managed?

The preoperative evaluation of patients with coronary stents should include information regarding the date of stent placement, the coronary anatomy, the type of coronary stent, and the antiplatelet strategy. Multidisciplinary discussions regarding how the risk of bleeding for the particular surgery compares with the risk of coronary stent thrombosis are strongly encouraged. When possible, continuing double antiplatelet therapy is recommended in patients with DES for surgery with minor or intermediate risk of perioperative bleeding. Discussion between the anesthesiologist, the surgeon, and the treating cardiologist is recommended.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:2215–2245.

Levin GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines: an update of the 2011 ACCF/AHA/SCAI guideline for percutaneous coronary intervention, 2011 ACCF/AHA guideline for coronary artery bypass graft surgery, 2012 ACC/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease, 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes, and 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2016;134:e123–e155.

C. Intraoperative Management

C.1. What monitors would you use for this patient?

The following monitors would be used for this patient:

- American Society of Anesthesiologists standard monitors, including multiple-lead ST-segment analysis
- Temperature
- Consider invasive arterial blood pressure.

C.2. Is there a preferred anesthetic technique for patients undergoing TURP, and why?

The choice of anesthetic technique should be guided by the requirements of the surgical procedure, coexisting diseases, need to prevent postoperative complications, and patient preferences.

Regional anesthesia has advantages for patients undergoing M-TURP for the following reasons:

- It allows monitoring of the patient's mentation, thereby facilitating early detection of signs of TURP syndrome.
- It can allow for earlier detection of prostate capsular tears or bladder perforation via patient reports of peritoneal or diaphragmatic (referred shoulder) pain.
- It promotes vasodilation and peripheral pooling of blood, thereby reducing the severity of circulatory overloading.
- It reduces blood loss by lowering arterial and venous blood pressure during surgery.
- However, less emphasis is placed on regional anesthesia for TURP now because of the increased use of bipolar electrode and laser resection surgical techniques.
- Regional anesthesia may not be a safe option in an anticoagulated patient.

prostrate. *Contin Educ Anaesth Crit Care Pain*. 2009;9(3):92–96.

C.3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia?

Although spinal anesthesia offers distinct advantages over general anesthesia for TURP surgery, mortality and many markers of patient outcome are similar for both groups, in large part because the safety of the procedure itself has advanced. The 30-day mortality rate associated with TURP has steadily declined from 2.5% in 1962 to current estimates of 0.2% to 0.8%. Mortality rates are similar in patients receiving regional anesthesia or general anesthesia. Increased morbidity is more associated with surgical and patient factors than anesthesia type and has been found in patients with resections exceeding 90 minutes, gland size greater than 45 g, acute urinary retention, and age older than 80 years. The incidence of postoperative complications, specifically MI, pulmonary embolism, cerebrovascular accidents, transient ischemic attacks, renal failure, hepatic insufficiency, and the need for prolonged ventilation is similar in patients receiving regional anesthesia and those receiving general anesthesia. With the increased use of L-TURP resection surgical techniques, even less emphasis has been placed on regional anesthesia as the preferred anesthetic technique given minimal absorption of irrigating fluid.

C.4. What intravenous fluid would you use during

TURP?

Because dilutional hyponatremia commonly occurs in patients undergoing M-TURP, the intravenous fluid of choice perioperatively is normal saline that contains sodium, 154 mEq per L. Circulatory overloading from absorbed irrigant is common in patients undergoing M-TURP or B-TURP (but not L-TURP); therefore, the amount of intravenous fluid administered during surgery should be carefully monitored.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.5. Forty minutes after a sensory level of T10 was established with intrathecal anesthesia, and monopolar TURP (M-TURP) resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic is administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, and pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar (B-TURP) or laser TURP (L-TURP) resection?

Restlessness and incoherence during TURP are particularly ominous signs of TURP syndrome. These are caused by pulmonary edema, hypoxemia, and cerebral edema. These signs must not be misinterpreted as signs of inadequate anesthesia. The administration of sedatives or general anesthesia in the

presence of TURP syndrome has been associated with severe complications including death. In B-TURP and L-TURP, normal saline can be used as the bladder irrigating solution and hyponatremia is not expected. In B-TURP, absorption of the intravascular bladder irrigating solution can still occur via the prostatic venous sinuses, resulting in circulatory overload. This is not expected in L-TURP because the treatment zone is rapidly coagulated.

O'Hara J. Anesthesia for select urologic procedures. In: *ASA Refresher Courses in Anesthesiology*. 2011;39(1):115–119.

C.6. What are the important characteristics of irrigation solutions used during TURP?

Ideal TURP irrigation solutions would be either isotonic or nearly isotonic, electrically inert, nontoxic, and transparent. Electrolyte-containing solutions such as normal saline are avoided in M-TURP because they can conduct electrical current to surrounding tissues and cause burns. Instead, solutions with nontoxic solutes are used for M-TURP; however, the need for transparency necessitates a hypotonic solution. If intravascular hypotonic bladder irrigating solution is absorbed, absorption can lead to hyponatremia, hypoosmolality, and, in severe cases, hemolysis. These complications are avoided when normal saline is used with B-TURP and L-TURP resection.

Over the years, a number of irrigation solutions have been introduced. The most commonly used solution for M-TURP is glycine (1.2% and 1.5%). Mannitol (3%), glucose (2.5% to 4%),

Cytal (a mixture of sorbitol 2.7% and mannitol 0.54%), and urea (1%) solutions are also occasionally used.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

C.7. What is the effect on body temperature of continuous bladder irrigation during TURP?

Several liters of irrigation solution pass through the bladder during TURP. This can reduce body temperature at the rate of 1°C per hour (**Fig. 24.1**). Approximately half of patients undergoing TURP become hypothermic and shiver at the conclusion of surgery.

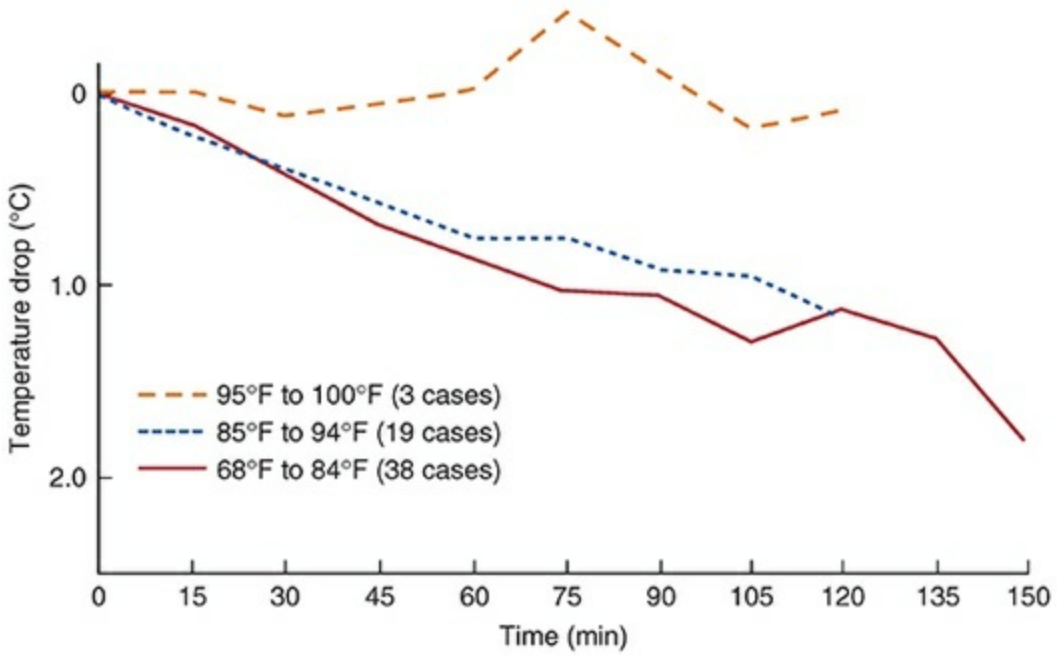

FIGURE 24.1. The decrease in body temperature during TURP is related to the temperature of the irrigating solution and to the duration of surgery. (*Modified with permission from Allen TD.*

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

C.8. What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?

Rapid absorption of a large-volume, hypotonic bladder irrigation solution during TURP can lead to TURP syndrome. TURP syndrome is characterized by intravascular volume shifts and plasma-solute (osmolarity) effects. The signs and symptoms of TURP syndrome are as follows:

Cardiopulmonary

- Hypertension
- Bradycardia
- Dysrhythmia
- Respiratory distress
- Cyanosis
- Hypotension
- Shock
- Death

Hematologic and Renal

- Hyperglycinemia
- Hyperammonemia
- Hyponatremia
- Hypoosmolality
- Hemolysis/anemia
- Acute renal failure
- Death

Central Nervous System

- Nausea/vomiting
- Confusion/restlessness
- Blindness
- Twitches/seizures
- Lethargy/paralysis
- Dilated/nonreactive pupils
- Coma
- Death

TURP syndrome can occur as early as 15 minutes after surgery has started and as late as 24 hours after surgery. Patient complaints of dizziness, headache, nausea, chest or throat tightness, and shortness of breath are often early clinical signs. Then the patient becomes restless, confused, and nauseated. Some patients complain of abdominal pain. The blood pressure often rises (both systolic and diastolic), and the heart rate decreases (Fig. 24.2). If not treated promptly, the patient becomes cyanotic and hypotensive and ultimately sustains cardiac arrest.

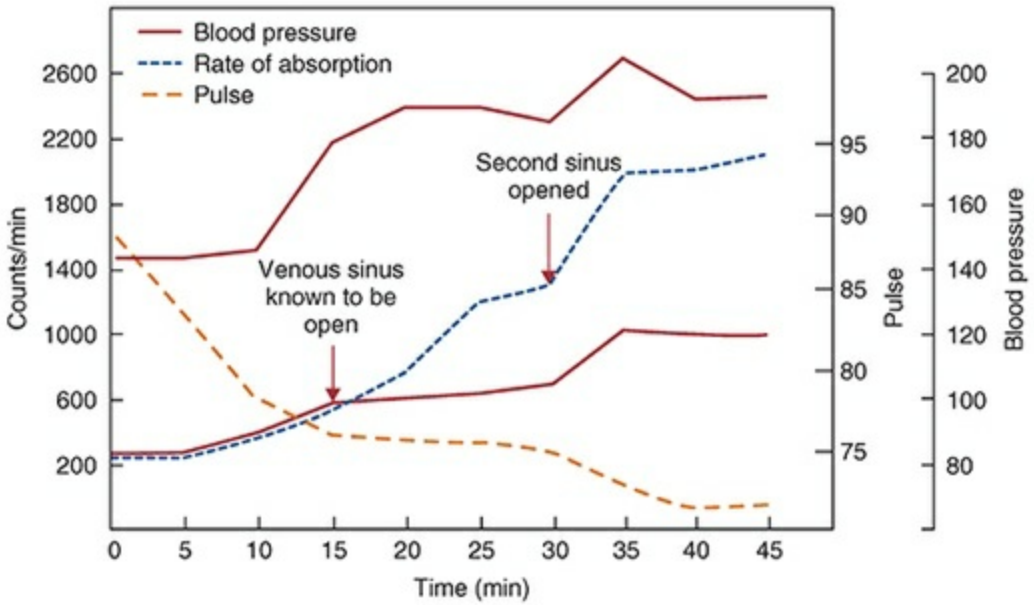

FIGURE 24.2. The blood pressure, heart rate, and absorption rate of radioactively tagged

irrigation solution during TURP. (*Modified with permission from Taylor RO, Maxson ES, Carter FH, et al. Volumetric gravimetric and radioisotopic determination of fluid transfer in transurethral prostatectomy.* J Urol. *1958;79[3]:490–499*.)

Occasionally, TURP syndrome manifests as neurologic signs. The patient becomes lethargic and then unconscious, and pupils dilate, reacting sluggishly to light. These signs may be followed by short episodes of tonic–clonic seizures and then coma lasting from minutes to hours.

If the patient is under general anesthesia, the presenting signs of TURP syndrome are typically a rise and then a fall in blood pressure, decreasing oxygen saturation, and severe refractory bradycardia. The ECG may show nodal rhythm, ST-segment changes, U waves, and widening of the QRS complex. Recovery from general anesthesia is delayed.

Gravenstein D. Transurethral resection of the prostate (TURP) syndrome: a review of the pathophysiology and management. *Anesth Analg*. 1997;84:438–446.

C.9. How does the patient absorb irrigation solution during TURP?

The bladder irrigation solution enters the bloodstream directly through open prostatic venous sinuses created during monopolar and bipolar resection techniques, particularly if the prostatic capsule is violated during surgery.

If the complication of bladder perforation occurs, significant accumulation of irrigating fluid in the intraperitoneal or retroperitoneal space can occur regardless of technique, resulting in significant intravascular absorption.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic*

Surgery. New York: Springer; 2014:35–51.

Geavlete B, Multescu R, Dragutescu M, et al. Transurethral resection (TUR) in saline plasma vaporization of the prostate vs standard TUR of the prostate: 'the better choice' in benign prostatic hyperplasia? *BJU Int*. 2010;106(11):1695–1699.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.10. What factors increase the incidence of TURP syndrome?

TURP syndrome is more likely to occur if the prostatic gland is atypically large, the prostatic capsule is violated during surgery, or the hydrostatic pressure of the irrigation solution is excessively high. Large prostatic glands have rich venous networks that promote intravascular absorption of irrigation solution. The violation of the prostatic capsule during surgery promotes entry of irrigation solution into the periprostatic and retroperitoneal spaces. The hydrostatic pressure of the irrigation solution is an important determinant of the rate at which the patient will absorb the solution. This pressure depends primarily on the height of the irrigation solution pole. When the height of the pole exceeds 60 cm (approximately 2 ft), the absorption of irrigation solution is greatly enhanced. Also, an excessively distended bladder during surgery facilitates absorption.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gravenstein D. Transurethral resection of the prostate (TURP) syndrome: a review of the pathophysiology and management. *Anesth Analg*. 1997;84:438–446.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.11. What is the effect on cardiopulmonary, renal, and central nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?

Excessive absorption of irrigation solution during TURP causes hypervolemia and hypertension with bradycardia and may induce angina and pulmonary edema (**Fig. 24.3**). It may also have an adverse effect on renal function. An inverse relation has been observed between the amount of irrigation solution absorbed during surgery and postoperative urinary output.

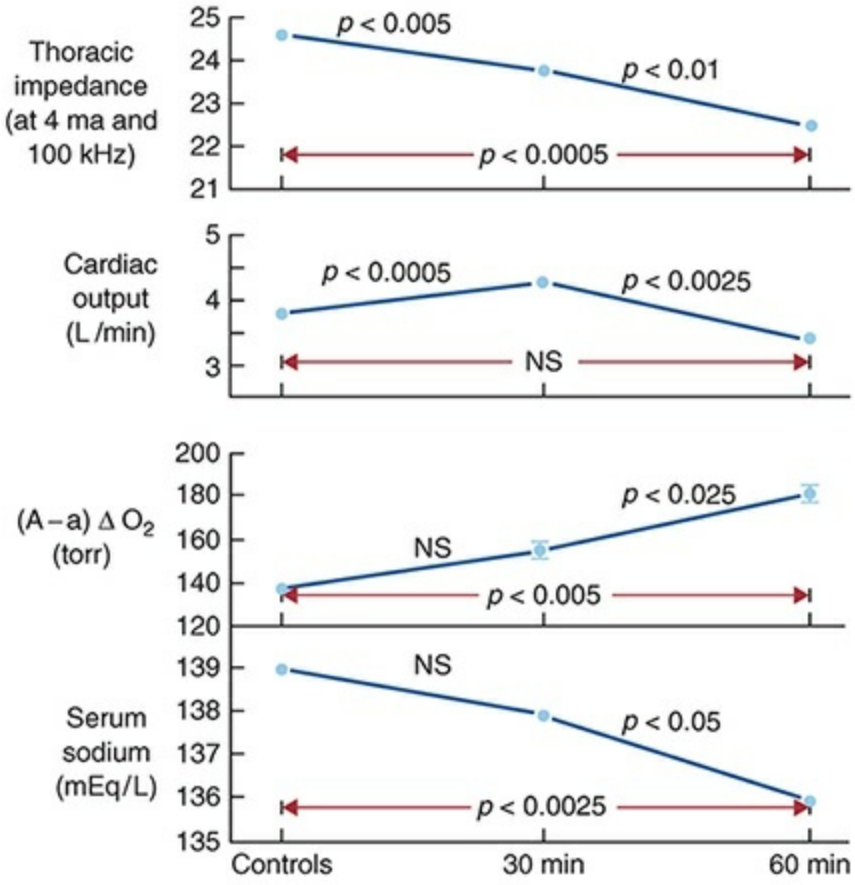

FIGURE 24.3. Mean changes in thoracic impedance, cardiac output, alveolar–arterial oxygen tension difference, and serum sodium level during TURP. NS, nonsignificant. (*Modified with permission from Casthely P, Ramanathan S, Chalon J, et al. Decreases in electric thoracic impedance during transurethral resection of the prostate: an index of early water intoxication.* J Urol. *1981;125[3]:347–349.*)

Some patients with TURP syndrome exhibit neurologic signs resulting from water intoxication if a hypotonic irrigating solution is used. They assume a decerebrate posture, exhibit clonus and positive Babinski reflex, and eventually convulse and

lapse into coma. Examination of the eyes reveals papilledema and dilated and sluggishly reacting pupils. The electroencephalogram shows low voltage bilaterally. The patients may remain in a coma from a few hours to several days.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gravenstein D. Transurethral resection of the prostate (TURP) syndrome: a review of the pathophysiology and management. *Anesth Analg*. 1997;84:438–446.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.12. What causes CNS dysfunction in patients who have undergone M-TURP?

The physiologic derangement of CNS function in TURP syndrome is not hyponatremia but acute hypoosmolality, which is predictable because the blood–brain barrier is essentially impermeable to sodium but freely permeable to water, leading to cerebral edema. The primary factor governing the manifestation of symptoms is the rate at which the serum sodium level falls rather than the total fall itself; the faster the fall in serum sodium level, the greater the incidence of neurologic symptoms. However, under 120 mEq per L, all patients are symptomatic. Cerebral edema caused by acute hypoosmolality can increase intracranial pressure, which results in bradycardia and hypertension by the Cushing reflex. The rise in intracranial pressure is directly correlated to the gain in body weight during TURP.

Fujiwara A, Nakahira J, Sawai T, et al. Prediction of clinical manifestations of transurethral resection syndrome by preoperative ultrasonographic estimation of prostate weight. *BMC Urol*. 2014;14:67.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gravenstein D. Transurethral resection of the prostate (TURP) syndrome: a

review of the pathophysiology and management. *Anesth Analg*. 1997;84:438–446.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.13. How does acute hyponatremia affect the cardiovascular system?

When serum sodium level falls to less than 120 mEq per L, signs of cardiovascular depression can occur. A decrease of less than 115 mEq per L causes bradycardia, widening of the QRS complex, ST-segment elevation, ventricular ectopic beats, and T-wave inversion. Patients with a serum sodium level of less than 110 mEq per L can develop respiratory and cardiac arrest.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

C.14. What prophylactic measures may reduce the incidence of TURP syndrome?

The most important preventive measure during surgery is preservation of the prostatic capsule. Another preventive measure is restriction of the hydrostatic pressure of the irrigation solution to 60 cm H_2O. This can be accomplished by limiting the height of the irrigation pole to 60 cm (approximately 2 ft) above patient level. Also, the bladder should not be allowed to overdistend and the duration of surgery should be restricted.

Serial serum sodium and osmolality are advisable in order to detect a decreasing trend in M-TURP. If clinical signs of TURP syndrome present, the surgeon should be informed and therapeutic measures immediately instituted. If serum sodium level approaches 120 mEq per L, surgery should be terminated as soon as possible.

Intravenous fluids should be cautiously administered during

M-TURP and B-TURP. A microdrip is recommended particularly for patients with cardiac or renal disease. If regional anesthesia causes hypotension, a small dose of a vasoconstrictor is recommended to raise the blood pressure rather than rapid infusion of intravenous fluids.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020.

C.15. What therapeutic measures are recommended for patients with TURP syndrome?

When symptoms of TURP syndrome appear, the following therapeutic measures are recommended:

- Terminate surgery as soon as possible.
- Administer furosemide, 20 to 40 mg intravenously. Although furosemide results in natriuresis, this effect is negligible relative to the desired acute diuresis and volume offloading of free water.
- Administer oxygen by nasal cannula or face mask to maintain oxygen saturation and consider intubation.
- Obtain arterial blood gas, serum osmolality, and sodium analysis.
- If the serum sodium level is abnormally low and clinical signs of hyponatremia are evident, intravenous administration of hypertonic saline (3% to 5%) may be recommended. The hypertonic solution should be given at a rate no faster than 100 mL per hour. In most cases, no more than 300 mL of hypertonic saline is needed to correct the hyponatremia.
- If the patient develops seizures, a short-acting anticonvulsant such as diazepam (5 to 20 mg) or midazolam (2 to 10 mg) can be administered intravenously. If these drugs do not arrest the seizures, a barbiturate or phenytoin can be added.

- If pulmonary edema or hypotension develops, invasive hemodynamic monitoring is recommended. This will serve as a guide for pharmacologic support and fluid administration.
- If significant blood loss is suspected, the administration of packed red blood cells should be considered. In general, intravenous fluids should be administered cautiously because of the propensity of these patients to develop pulmonary edema.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020.

C.16. Is hypertonic saline administration necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?

The administration of hypertonic saline to correct hyponatremia is not always necessary and sometimes can be detrimental. Unless the patient develops severe clinical signs of hyponatremia, hypertonic saline administration is not recommended. Spontaneous or induced diuresis usually corrects the hyponatremia within a few hours.

Patients who have undergone TURP often sustain circulatory overloading during surgery; consequently, hypertonic saline administration in these patients can induce pulmonary edema. In addition, rapid administration of hypertonic saline has been associated with central pontine myelinolysis (osmotic demyelination syndrome)—a poorly understood and fatal neurologic complication.

To reduce the hazards of hypertonic saline administration, serum osmolarity should be monitored and corrected aggressively only until symptoms substantially subside and then hyponatremia should be corrected at a rate no faster than 1.5

mEq/L/hr.

Sterns RH, Riggs JE, Schochet SS Jr. Osmotic demyelination syndrome following correction of hyponatremia. *N Engl J Med*. 1986;314:1535–1542.

C.17. What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic by-products of glycine?

Glycine is an inhibitory neurotransmitter similar to γ-aminobutyric acid in the spinal cord and brain. When absorbed by the patient in large amounts, glycine has direct toxic effects on the heart and retina. In patients who have undergone M-TURP with glycine absorption, it has been shown to cause an average decrease of 17.5% in cardiac output. In animal studies, the administration of the amino acid arginine reversed the myocardial depressing effect of glycine. The mechanism by which glycine depresses cardiac function and the mechanism by which arginine protects the heart is unknown.

Hyperglycinemia may cause transient visual disturbance (blindness) during TURP. However, glycine toxicity in patients who have undergone TURP is uncommon, probably because most of the absorbed glycine is retained in the periprostatic and retroperitoneal spaces, where access to the circulation is limited.

The most common metabolites of glycine are ammonia and glyoxylic and oxalic acids (**Fig. 24.4**). In some patients, excessive absorption of glycine during TURP leads to hyperammonemia. Hyperoxaluria could compromise renal function in patients with coexisting renal disease, which is often present in elderly patients undergoing TURP.

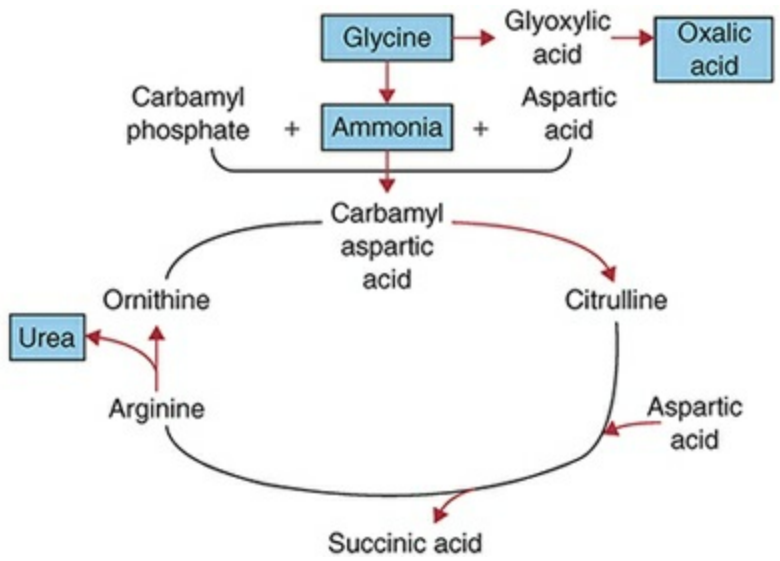

FIGURE 24.4. Metabolic pathways of glycine. (*Modified from McGilvery RW, Goldstein GW.* Biochemistry: A Functional Approach. *3rd ed. Philadelphia, PA: WB Saunders; 1983:584. Copyright © 1983 Elsevier. With permission.*)

Ovassapian A, Joshi CW, Brunner EA. Visual disturbances: an unusual symptom of transurethral prostatic resection reaction. *Anesthesiology*. 1982;57:332–334.

C.18. What are the symptoms and clinical course of TURP-induced hyperammonemia?

The signs and symptoms of hyperammonemia usually appear within 1 hour of surgery. Typically, the patient becomes nauseated, vomits, and then becomes comatose. Blood ammonia level can rise to more than 500 mmol per L. The patient remains comatose for 10 to 12 hours and eventually awakens when ammonia blood level decreases to less than 150 mmol per L. The hyperammonemia tends to linger postoperatively, probably because glycine absorption from the periprostatic space continues after surgery.

Roesch RP, Stoelting RK, Lingeman JE, et al. Ammonia toxicity resulting from glycine absorption during a transurethral resection of the prostate. *Anesthesiology*. 1983;58:577–579.

C.19. What are the clinical characteristics, causes, and prognosis of TURP-related blindness?

Transient blindness is one of the more alarming complications of TURP. The patient complains of blurred vision and of seeing halos around objects. This can occur either during surgery or later in the recovery room. Although it is sometimes accompanied by other TURP-related complications, blindness can occur as an isolated symptom. Examination of the eyes reveals dilated and unresponsive pupils. Postoperatively, TURP-related blindness gradually recedes and eyesight returns to normal within 8 to 48 hours of surgery.

The cause of TURP-related blindness is unclear. The intraocular pressure and optic discs remain normal. In the past, edema of the cerebral optical cortex was suspected; however, the clinical signs of TURP-related blindness are consistent with retinal rather than cortical dysfunction. Unlike cortical blindness, TURP-related blindness allows perception of light and the blink reflex is preserved. TURP-related blindness is most likely caused by a toxic effect of glycine on the retina. This theory is supported by the fact that glycine is a known inhibitory neurotransmitter. In animals, glycine has been shown to inhibit neuronal visual pathways. Also, the severity of TURP-related blindness is directly related to glycine blood level. Postoperatively, vision gradually improves as the glycine blood level declines.

C.20. What are the causes of excessive bleeding during TURP?

Patients undergoing TURP commonly bleed perioperatively, with 2.5% of patients undergoing M-TURP requiring transfusion. One possible cause is dilutional thrombocytopenia resulting from excessive absorption of irrigation solution. Another possible cause is local release of fibrinolytic agents (plasminogen and urokinase) from the mucosa of the lower urinary tract. During and immediately after TURP, these agents cause local fibrinolysis and promote bleeding from the raw surfaces of the prostatic gland. The existence of a local fibrinolytic mechanism is supported by the observation that prophylactic administration of ε-aminocaproic acid (an antifibrinolytic agent) reduces bleeding from the prostatic bed.

Systemic coagulopathy can also occur during TURP. The coagulopathy is caused by disseminated intravascular coagulation (DIC) rather than by primary fibrinolysis. DIC is triggered during TURP by prostatic particles rich in thromboplastin that enter the bloodstream during surgery. Characteristically, the platelet count and fibrinogen blood level are abnormally low. At autopsy, multiple microthrombi are observed in various parts of the body. The high level of fibrin-degradation products found in the blood of these patients is caused by secondary fibrinolysis, which commonly accompanies DIC.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

C.21. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?

The incidence of bladder perforation during TURP is approximately 1% and stems from trauma by surgical instrumentation, overdistention of the bladder, and, rarely, explosion of traces of hydrogen gas inside the bladder.

An early sign of bladder perforation is a sudden decrease in the return of irrigation solution from the bladder. This sign often goes unnoticed until a significant amount of irrigation solution accumulates in the abdomen, causing abdominal distress. Other clinical signs are hypotension, followed by hypertension and nausea. Reflex-type movements of the limbs have been observed under both general and regional anesthesia. When the perforation is intraperitoneal, symptoms develop faster and include severe shoulder pain caused by diaphragmatic irritation.

Diagnosis of bladder perforation is confirmed by cystourethrography. Treatment is immediate suprapubic cystotomy.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

C.22. What are the causes of hypotension during TURP?

The more common causes of hypotension during TURP are

circulatory overloading with resulting CHF, MI or myocardial ischemia, severe anemia resulting from blood loss, severe hyponatremia, and bacteremia.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

D. Postoperative Management

D.1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?

The prostatic gland often harbors large amounts of bacteria. TURP facilitates the entry of these bacteria into the bloodstream by opening of venous sinuses, leading to postoperative bacteremia. Approximately 30% of patients undergoing TURP have infected urine preoperatively, and half of them have transient bacteremia postoperatively, although most are asymptomatic; 6% to 7%, however, will develop signs of sepsis.

Surgical disruption of the prostatic venous sinuses and excessive hydrostatic pressure of the irrigation solution facilitate the entry of bacteria into the bloodstream. Also, a preoperative indwelling catheter promotes bacterial growth in the urethra.

Gainsburg DM, Bryson EO, Frost EAM, eds. *Anesthesia for Urologic Surgery*. New York: Springer; 2014:35–51.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1959.

D.2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?

The signs of septicemia usually appear postoperatively in the postanesthesia care unit (PACU). They include fever, chills, low

blood pressure, and tachycardia. Symptoms may be related to bacterial endotoxins, in which case they are self-limited, or direct bloodstream seeding with bacteria.

Antibiotics administered prophylactically before TURP do not sterilize the urine because they do not easily penetrate the prostatic gland. Nevertheless, the preoperative administration of antibiotics is strongly recommended.

If sepsis is suspected postoperatively in a patient who has undergone TURP, broad-spectrum antibiotics should be started immediately without waiting for blood culture results.

Malhotra V. Transurethral resection of prostate. *Anesthesiol Clin North Am*. 2000;18:883–897.

D.3. Is postoperative hypothermia a risk factor for myocardial ischemia?

Yes. Unexpected hypothermia and shivering is associated with a significantly higher incidence of postoperative demand myocardial ischemia. Therefore, it is important to maintain normothermia during the perioperative period, particularly in an elderly population at higher risk for hypothermia due to decreased subcutaneous fat. Also see Chapter 14, section D.4.

Frank SM, Beattie C, Christopherson R, et al. Unintentional hypothermia is associated with postoperative myocardial ischemia. The Perioperative Ischemia Randomized Anesthesia Trial Study Group. *Anesthesiology*. 1993;78:468–476.

D.4. What is postoperative cognitive dysfunction (POCD)? How does this differ from delirium, and what is the time course to resolution?

POCD is a syndrome defined by worsening cognitive performance postoperatively compared to perioperative baseline. The deficit is present in multiple domains and presents days to

weeks after surgery, highly correlated with age. POCD usually resolves within months; however, time course varies and sustained deficits have been reported.

Postoperative delirium, by contrast, manifests as acute fluctuation in orientation shortly following emergence.

However, for clinical purposes, a multispecialty working group recommends that "perioperative neurocognitive disorders" (PND) be used as an overarching term for cognitive impairment identified in the preoperative or postoperative period. This includes cognitive decline diagnosed before operation (described as neurocognitive disorder); any form of acute event (postoperative delirium) and cognitive decline diagnosed up to 30 days after the procedure (delayed neurocognitive recovery) and up to 12 months (postoperative neurocognitive disorder).

Evered L, Silbert B, Knopman DS, et al. Recommendations for the nomenclature of cognitive change associated with anaesthesia and surgery—2018. *Br J Anaesth*. 2018;121:1005–1012.

D.5. What are the mechanisms and risk factors for POCD? How would you mitigate the risk of POCD? Does anesthesia type influence development of POCD?

The proposed mechanisms include a preexisting neuroinflammation or neurodegeneration, which primes the brain to react more strongly to the systemic inflammatory response to the surgical procedure itself, resulting in accelerated progression of neuroinflammation and neurodegeneration with delay in neurocognitive recovery. Progression or eventual resolution of POCD may be impacted by several intraoperative and postoperative factors.

Preoperative risk factors include preexisting cognitive impairment, older age, and lower educational achievement. Intraoperative risk factors include major, prolonged, or emergency surgical procedures, as well as selection and dosing of certain anesthetic and adjunct agents, and possibly depth of general anesthesia.

The recommended strategies to mitigate the risk of POCD include the following:

- Avoid use of benzodiazepines, opioids (particularly meperidine), anticholinergics (particularly scopolamine), diphenhydramine, metoclopramide, and agents that may cause serotonin syndrome.
- Use raw or processed electroencephalography (EEG) or other neuromonitoring techniques, when available as a supplemental guide to manage intraoperative dosing of anesthetic agents.
- Avoid hypotension and hypoxemia.
- Avoid hyperventilation because cerebral blood flow decreases by 2% to 4% for each mmHg decrease in $PaCO_2$. Prolonged $PaCO_2$ below 30 mmHg may result in cerebral ischemia and possibly POCD.
- Evidence suggests that postoperative administration of dexmedetomidine may decrease the incidence of delirium, although results are inconsistent for intraoperative administration, and there is scant evidence for other types of POCD.
- Inadequate postoperative pain control is associated with increased incidence of delirium. A multimodal approach could be employed to reduce the risk of opioid-related side effects.
- In a severely agitated PACU patient, after treatment of reversible causes and redirection and reorientation have failed, administration of a small dose of haloperidol (e.g., 0.5

to 2 mg) is reasonable; this dose may be repeated (up to approximately 5 mg total dose). However, prophylactic haloperidol is not recommended to prevent delirium.

Neuraxial or regional anesthesia with either light or deep sedation does not consistently decrease the incidence of postoperative neurocognitive disorders compared with general anesthesia. When general anesthesia is selected, neither a total intravenous anesthesia (TIVA) technique nor an inhalation-based anesthetic technique affects the incidence of postoperative delirium in adult patient.

Small prospective studies have compared spinal anesthesia with intravenous sedation to general anesthesia in elderly TURP patients, showing no difference in perioperative mental function between the groups at 30 days.

E. Comparing M-TURP, B-TURP, and L-TURP

E.1. What differentiates M-TURP from B-TURP?

M-TURP uses high-energy cautery, which allows a fast cutting technique of prostatic tissue with minimal coagulation in the process. The body is the conduit of the energy dispersed from the monopolar electrode to complete the electrical circuit to a large-surface skin grounding pad placed on the patient. It also requires the use of an electrolyte-free bladder irrigating fluid. In B-TURP, the electrical circuit is completely contained within the resectoscope. This prevents energy from traveling through the body. Instead, the energy remains confined to the site of prostatic resection and is returned via the second limb of the bipolar resectoscope. With the bipolar electrode, less bleeding occurs at the prostatic tissue site and normal saline can be used as the bladder irrigating fluid.

E.2. Are decreased morbidity and mortality associated more closely with M-TURP or with B-TURP?

In a meta-analysis that reviewed the safety of M-TURP versus B-TURP in a small number of TURP patients (1,802), a significant benefit was reported in the bipolar group in overall complication rate, need for transfusion, and the absence of TURP syndrome. Subsequent randomized controlled trials have confirmed this morbidity benefit.

outcome of transurethral resection of the prostrate: a prospective multicenter evaluation of 10,654 patients. *J Urol*. 2008;180:246–249.

E.3. What differentiates the technologies for L-TURP?

L-TURP delivers light energy to coagulate or vaporize prostatic tissue. Holmium laser enucleation of the prostate (HoLEP), in particular, has been suggested as the new gold standard for surgical treatment of benign prostate hypertrophy (BPH). Prostatic tissue is vaporized, and the resulting heat dissipation coagulates small to medium blood vessels. HoLEP can be used safely on patients with larger prostatic glands with similar outcomes as patients undergoing open prostatectomy, and compared to traditional M-TURP, HoLEP demonstrates lower transfusion rates, catheterization time, and shorter hospital stays. Photoselective vaporization and bipolar plasma vaporization have shown similar benefits.

There are five advantages of L-TURP: (1) It uses normal saline as the irrigating bladder solution; (2) it minimizes the absorption of irrigating fluid; (3) it minimizes or altogether eliminates TURP syndrome; (4) it produces significantly less bleeding, which allows the procedure to be performed on an anticoagulated patient if needed; and (5) it de-emphasizes regional anesthesia as the preferred anesthetic technique.

25 Kidney Transplant

Christine Lennon and Fun-Sun F. Yao

A 50-year-old man with rapid onset of end-stage renal disease (ESRD) prefers not to start hemodialysis. He would like to receive an organ transplant from a living related donor, but other options include a deceased donor or a paired donor exchange program.

A. Medical Disease and Differential Diagnosis

1. What are the causes of chronic renal disease that can progress to renal failure?
2. How is chronic kidney disease (CKD) diagnosed?
3. What are the indications for dialysis?
4. What are the common clinical manifestations of ESRD?
5. What electrolyte imbalances occur in patients with impaired renal function, and how are they treated?
6. How is metabolic acidosis managed in chronic renal failure?
7. Are patients with renal disease at increased risk of cardiovascular disease?
8. When is the best time to receive a kidney transplant?
9. How are immunosuppressive drugs managed in kidney transplant recipients?
10. How are kidneys allocated to recipients on the waiting list in the United States?

11. What is donation after cardiac death (DCD)?
12. What is a living donor transplant program?
13. What is a paired donor exchange transplant program?
14. What are some barriers to receiving a kidney transplant?
15. What surgical techniques are available for donor nephrectomy (DN)?
16. How is a donor kidney preserved?
17. Describe the operative procedure of kidney transplantation.

B. Preoperative Evaluation and Preparation

1. What preoperative workup would you order for a recipient?
2. How does the presence of obesity affect the outcome of a transplanted kidney?
3. How are routine medications and immunosuppressive medications managed in the perioperative period?

C. Intraoperative Management

1. Are a central venous pressure (CVP) monitoring line, an arterial line, and a pulmonary artery catheter required for the transplant procedure?
2. What type of intravenous fluid should be used during surgery?
3. How would you conduct the anesthesia induction?
4. Is succinylcholine contraindicated in renal failure patients?
5. How are the nondepolarizing muscle relaxants affected by renal failure?
6. How would you maintain anesthesia during the case?
7. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration (GFR), and urine output?
8. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?
9. How does renal failure affect the pharmacology of opioids?

D. Postoperative Management

1. How is the diagnosis of transplant rejection made?
2. What are immunosuppressive agents, and how do they affect anesthetic care?

A. Medical Disease and Differential Diagnosis

A.1. What are the causes of chronic renal disease that can progress to renal failure?

The most common etiologies of renal disease leading to kidney transplant are the following:

- Diabetes
- Hypertension
- Glomerular diseases
- Polycystic kidney disease
- Vascular diseases (e.g., systemic lupus erythematosus)
- Congenital and metabolic diseases
- Tubular and interstitial diseases
- Neoplasms
- Retransplant and graft failure

CKD has many potential causes that differ among the world's populations. In developed countries, age, hypertension, cardiovascular disease, diabetes, increased body mass index (BMI), and smoking are predominantly associated with CKD. In the developing world, unique causes of kidney failure include infections due to bacteria, viruses, and parasites.

The global increase in CKD parallels the obesity epidemic. Obesity has been associated with a secondary focal segmental glomerulosclerosis, which is referred to as obesity-related glomerulopathy (ORG). The accumulation of lipid in the cellular structure of the kidney is associated with structural and functional changes.

de Vries AP, Ruggenenti P, Ruan XZ, et al. Fatty kidney: emerging role of

ectopic lipid in obesity-related renal disease. *Lancet Diabetes Endocrinol*. 2014;2(5):417–426.

Hart A, Smith JM, Skeans MA, et al. OPTN/SRTR 2017 annual data report: kidney. *Am J Transplant*. 2019;19(suppl 2):19–123.

A.2. How is chronic kidney disease (CKD) diagnosed?

CKD is defined as an abnormality of kidney structure or function that is present for more than 3 months, with implications for health. It is not dependent on the etiology leading to deteriorated kidney function.

The criteria for CKD include any of the following present for more than 3 months:

- Albuminuria
- Urine sediment abnormalities
- Electrolyte and other abnormalities due to tubular disorders
- Abnormalities detected by histology
- Structural abnormalities detected by imaging
- History of kidney transplantation
- GFR less than 60 mL/min/1.73 m^2

GFR and the progression of CKD may be estimated using several formulas, one of the most common in the United States being the Modification of Diet in Renal Disease (MDRD) formula. ESRD is established when GFR is less than 15 mL/min/1.73 m^2.

GFR, in mL/min/1.73 m^2 = 175 × $(SCr)^{-1.154}$ × $(age)^{-0.203}$ × (0.742 if female) × (1.21 if black)

SCr is the serum creatinine (milligrams per deciliter). Among individuals with established CKD, progression is based on estimation of GFR and level of albuminuria.

Kidney Disease: Improving Global Outcomes. KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl*. 2013;3(1):1–150.

National Kidney Foundation. KDOQI clinical practice guideline for hemodialysis adequacy: 2015 update. *Am J Kidney Dis*. 2015;66(5):884–930.

A.3. What are the indications for dialysis?

The decision about when to start dialysis is complex and patient specific and generally depends on the estimated GFR, the rate of decline of the GFR, and the presence of ESRD-related signs and symptoms. Recent data indicate that mortality may be higher when dialysis is initiated early, with no significant benefit in terms of quality of life. It is generally recommended that dialysis be initiated in patients with GFR between 5 and 15 mL/min/1.73 m^2 and concomitant signs and symptoms that could be due to ESRD, and in all patients with GFR <5 mL/min/1.73 m^2 regardless of the presence of additional signs or symptoms.

Patients with uremic symptoms (e.g., encephalopathy, pericarditis, and pleuritis) should be started on dialysis even if GFR is not at critically low levels. Other indications for dialysis in CKD include refractory volume overload; refractory acidosis, hyperkalemia, or hyperphosphatemia; declining nutritional status; fatigue and malaise; and mild cognitive impairment.

Cooper BA, Branley P, Bulfone L, et al. A randomized, controlled trial of early versus late initiation of dialysis. *N Engl J Med*. 2010;363(7):609–619.

National Kidney Foundation. KDOQI clinical practice guideline for hemodialysis adequacy: 2015 update. *Am J Kidney Dis*. 2015;66(5):884–930.

A.4. What are the common clinical manifestations of ESRD?

The common problems related to ESRD are the following:

- Electrolytes: volume expansion, hyponatremia, hyperkalemia, metabolic acidosis, hyperuricemia, hyperphosphatemia, hypocalcemia
- Gastrointestinal: gastroparesis, nausea, vomiting, pancreatitis, anorexia, uremic gastroenteritis, peptic ulcer disease, gastrointestinal bleeding
- Cardiovascular: accelerated atherosclerosis, systemic hypertension, left ventricular hypertrophy, congestive heart

failure, pulmonary edema, cardiomyopathy, pericarditis, hyperdynamic circulation

- Hematologic: anemia, B- and T-cell dysfunction, qualitative platelet dysfunction, bleeding diathesis
- Musculoskeletal: muscle weakness, uremic osteodystrophy (osteomalacia, osteosclerosis, osteitis fibrosa cystica)
- Neurologic: encephalopathy, loss of memory, seizures, peripheral neuropathy, autonomic dysfunction (postural hypotension), myoclonus, asterixis, dialysis disequilibrium (dehydration, weakness, nausea and vomiting, hypotension, and occasionally convulsion and coma)
- Endocrine: vitamin D deficiency, secondary hyperparathyroidism, carbohydrate intolerance, hypertriglyceridemia

Pain is extremely common in ESRD and can result from renal and nonrenal etiologies. In a prospective study of 205 hemodialysis patients, musculoskeletal pain was most common (63.1%), followed by dialysis-associated pain (13.6%), peripheral neuropathy (12.6%), and peripheral vascular disease claudication pain (9.7%). Polycystic kidney disease can cause chronic abdominal pain. Fentanyl and methadone are considered the safest opioids for use in patients with ESRD. Secondary hyperparathyroidism often results in bone pain.

O'Connor NR, Corcoran AM. End-stage renal disease: symptom management and advance care planning. *Am Fam Physician*. 2012;85(7):705–710.

A.5. What electrolyte imbalances occur in patients with impaired renal function, and how are they treated?

Chronic renal insufficiency and ESRD are associated with abnormalities in sodium (Na), potassium, calcium, and magnesium balance as well as metabolic acidosis.

Na and water (H_2O) balance are closely related. The kidney has its own inherent circadian rhythm involved in the

transcription genes for renal Na excretion and blood pressure control. This function is impaired in renal disease. In patients with chronic renal failure, the total body content of Na and H_2O may be increased. This can be due to glomerular disease promoting Na retention or excessive ingestion of Na leading to extracellular fluid (ECF) expansion. The ECF expansion and hyperosmolarity contributes to hypertension. Nonanuric patients may be treated with loop diuretics and salt restriction.

The renal mechanisms for conserving Na and H_2O are impaired in ESRD. Urine in nonoliguric patients is isosthenuric. This means the usual indices of detecting prerenal azotemia (high urine osmolality, low urine Na, and low fractional excretion of sodium [FE_{Na}]) are not applicable in such patients. If additional fluid loss (vomiting, fever) is imposed, they may become severely hypovolemic, necessitating careful rehydration with normal saline.

Hyperkalemia rarely occurs in patients with a GFR greater than 25 mL/min/1.73 m^2 in the absence of an endogenous or exogenous potassium load. Patients with GFR less than 25 mL/min/1.73 m^2 may be chronically hyperkalemic. Severe hyperkalemia increases cardiac and skeletal muscle excitability. The earliest changes begin with levels above 6.5 mEq per L. The electrocardiogram (ECG) shows peaked T waves, flattened P waves, lengthened PR interval, disappearance of P waves, and a widened QRS complex that can progress to a “sine wave,” ventricular asystole, or ventricular fibrillation. Muscle weakness can cause respiratory failure. Membrane excitability is more dependent on the rate of increase in potassium than on potassium concentration per se. The treatment of hyperkalemia includes a combination of insulin, glucose, loop diuretics (nonanuric), sodium bicarbonate, calcium, and magnesium (**Table 25.1**). The anesthesiologist may also institute

hyperventilation in mechanically ventilated patients. Hemodialysis or peritoneal dialysis is the definitive treatment for severe hyperkalemia.

TABLE 25.1 Drug Treatment for Hyperkalemia

Drug	Dose
Calcium chloride	5 mL of 10% solution IV over 2 min (monitor for bradycardia)
Calcium gluconate	10 mL of 10% solution IV over 2 min (monitor for bradycardia)
Insulin	5–10 units regular insulin with 1–2 amps $D_{50}W$ IV bolus
Sodium bicarbonate	1 mEq/kg slow IV push or continuous drip; not to exceed 50–100 mEq
β-Agonists (albuterol)	2.5 mg mixed with 3 mL isotonic saline through nebulizer every 20 min as tolerated
Diuretic (furosemide)	20–40 mg IV push
Magnesium	1–2 g IV over 30–60 sec; repeat every 5–15 min as required or 3–10 mg/min IV infusion

$D_{50}W$, 50% dextrose in water; IV, intravenous.

Magnesium imbalance can accompany chronic renal failure. High blood magnesium levels cause dose-dependent neuromuscular toxicity and increased sensitivity to depolarizing and nondepolarizing neuromuscular blockers. Bradycardia, hypotension, and heart block are due to the calcium channel blocking effects of magnesium. The acute toxicity can be antagonized by intravenous infusion of calcium. Conversely, decreased dietary intake and impaired intestinal absorption can lead to hypomagnesemia. Magnesium deficiency has been related to progression of atherosclerosis and low parathyroid hormone (PTH) levels.

Phosphate retention occurs when GFR begins to decline. Retained phosphate promotes secondary hyperparathyroidism by lowering ionized plasma calcium levels, decreasing renal formation of calcitriol (1,25-dihydroxyvitamin D), and stimulating PTH gene expression.

Ionized and protein-bound calcium levels are lower in uremic

patients. This is the result of hyperphosphatemia and reduced gastrointestinal absorption secondary to the decreased production of vitamin D.

A.6. How is metabolic acidosis managed in chronic renal failure?

A mild-to-moderate acidosis is commonly noted when the GFR decreases to less than 20% to 25% of normal. The decreased renal mass results in decreased production and excretion of proton load. The plasma bicarbonate concentration ranges between 12 and 22 mEq per L, and blood pH remains greater than 7.20. This does not routinely require correction. It may gradually evolve into a high anion gap acidosis when the GFR is below 20 mL/min/1.73 m^2. Some patients with ESRD maintain close to normal acid–base parameters even when renal function is severely compromised. However, when exposed to an increased dietary acid load, these patients may have decreased ability to increase bicarbonate generation.

The correction of acidosis by oral sodium bicarbonate or a diet rich in fruits and vegetables can attenuate rate of decline of renal function.

Loniewski I. Combining a fruit and vegetable diet with sodium bicarbonate supplementation seems the best dietary option for chronic kidney disease

patients. *Kidney Int*. 2012;82(8):937.

A.7. Are patients with renal disease at increased risk of cardiovascular disease?

ESRD is associated with an increased incidence and prevalence of a wide range of cardiovascular morbidities including hypertension, coronary artery disease, stroke, congestive heart failure, atrial fibrillation, sudden cardiac death, pulmonary hypertension, and valvular heart disease.

Extensive vascular calcification contributes to early-onset cardiovascular disease and cardiovascular mortality. In addition to traditional cardiovascular risks, risk factors specific to CKD such as phosphate retention, hypercalcemia, history of dialysis, high-dose vitamin D therapy, and deficiency of calcification inhibitors promote arterial calcification. There is no specific therapy to reverse vascular calcification, but statin therapy is associated with decreased cardiovascular death. Additional measures such as reduction of calcium phosphate load, using non–calcium-containing phosphate binders, and moderate doses of active vitamin D may attenuate arterial hardening.

The rate of sudden cardiac death increases as the stage of CKD increases and could be responsible for 60% of cardiac deaths in patients undergoing dialysis. The uremic load results in cardiac fibrosis and in left ventricular systolic and diastolic dysfunction. The occurrence of conduction abnormalities and arrhythmias is exacerbated by electrolyte shifts, diabetes, and autonomic neuropathy. Cardioverter-defibrillator implantation decreases the risk of sudden death in patients with CKD.

Hypertension has been reported to occur in 85% to 95% of patients with CKD (stages 3 to 5). The relationship between hypertension and CKD is cyclic in nature. Uncontrolled hypertension is a risk factor for developing CKD and leads to a more rapid progression of CKD. In turn, renal disease

exacerbates uncontrolled hypertension due to volume expansion and increased systemic vascular resistance. An imbalanced autonomic system results in an exaggerated sympathetic drive with a loss of vagal tone. Autonomic neuropathy creates a setting for silent myocardial ischemia.

Correction of the uremic state and improved GFR after kidney transplant may decrease the incidence and severity of cardiovascular complications.

A.8. When is the best time to receive a kidney transplant?

In general, a patient is a candidate for a kidney transplant if the estimated GFR (eGFR) is 20 mL/min/1.73 m^2 or less, and renal function has irreversibly deteriorated to the point that a transplant or dialysis will be inevitable. Studies show that survival of a transplanted kidney is incrementally worse if the recipient has been on long-term dialysis. The best outcomes are seen for patients who are preemptively transplanted before dialysis is initiated. Therefore, if it is obvious the patient will eventually require dialysis and a living donor is available now, transplant is practical and cost-effective option.

Patients who are potentially interested in a transplant and with no known contraindications should be referred to a transplantation program early, when the eGFR is around 30 mL/min/1.73 m^2. Preparation for a transplant candidate can take several months, involving thorough medical evaluation and optimization of cardiac and pulmonary status.

A.9. How are immunosuppressive drugs managed in kidney transplant recipients?

In order to decrease the incidence of graft rejection, several regimens of immunosuppressive agents have been devised. Centers throughout the world may use different combinations of these drugs, but the central purpose is to prevent acute and chronic T-cell alloimmune rejection. The regimens are separated into an induction phase and a long-term maintenance phase. Four classes of immunosuppressive medications are used: corticosteroids, calcineurin inhibitors (CNIs) (cyclosporine and tacrolimus), antimetabolites (mycophenolate mofetil, mycophenolate sodium, and azathioprine), and the target-of-rapamycin (TOR) inhibitor (sirolimus). The maintenance phase involves a combination of two or three of these drugs, each from a separate class.

Immunosuppressant therapy is started in the immediate preoperative period. In the intraoperative period, induction therapy is targeted to eliminate lymphoid cells that may cause acute rejection of the graft. An induction agent may be withheld if immediate graft function occurs from a living donor kidney. After surgery, maintenance therapy is initiated and continued for the lifetime of the recipient. Although lifelong immunosuppression helps prevent rejection of the allograft, it also increases the risk of malignancy and infectious diseases. The regimens may not prevent the slow deterioration associated with chronic graft rejection.

In an effort to reduce the long-term toxicities of immunosuppressant drugs, corticosteroid- and CNI-sparing protocols have become popular in managing kidney transplant

patients. This is because the long-term use of steroids contributes to cardiovascular disease and/or infectious disease complications.

CNIs prevent acute rejection but are associated with reduced long-term allograft function. Protocols with agents such as mycophenolate mofetil, mycophenolate sodium, sirolimus, everolimus, and belatacept allow discontinuation of CNI within 6 months or avoid the CNIs.

Helal I, Chan L. Steroid and calcineurin inhibitor-sparing protocols in kidney transplantation. *Transplant Proc*. 2011;43(2):472–477.

A.10. How are kidneys allocated to recipients on the waiting list in the United States?

A national allocation policy for deceased-donor kidneys was established in 1987 by the United Network for Organ Sharing (UNOS) and the Organ Procurement and Transplant Network (OPTN). In 2014, the kidney allocation system (KAS) was extensively revised in order to increase utilization of available kidneys, reduce regional variability in access to transplantation, and improve outcomes for individual kidneys that are transplanted.

Adult patients may be registered on the waiting list after the diagnosis of irreversible kidney disease is made and GFR ≤20 mL/min/1.73 m^2. The estimated posttransplant survival (EPTS) is a measure used to estimate the number of years of potential benefit from a kidney transplant and is calculated for all candidates on the waiting list using candidate age, time on dialysis, presence or absence of diabetes, and prior history of solid organ transplant. A combination of a candidate's EPTS score and the time spent on the waiting list is used to determine their ranked priority on the waiting list. Additional priority is given to candidates with rare blood types and high immune system sensitivity because these patients have fewer

opportunities for a transplant.

The kidney donor risk index (KDRI) is a measure that provides information about the quality of a donor kidney graft based on how long it is estimated to function after transplant. The KDRI is calculated using donor age, ethnicity, creatinine, history of hypertension or diabetes, cause of death, height, weight, hepatitis C virus (HCV) status, and whether the kidney was donated after circulatory death. Kidneys with the highest KDRI score (i.e., the shortest predicted lifespan) must be offered over a wider geographic area in order to increase the utilization of donated kidneys. Transplant programs must have informed consent from potential recipients to receive a kidney with a KDRI score >85%.

A.11. What is donation after cardiac death (DCD)?

DCD has opened new perspectives in the donor pool. It refers to kidney donation from patients with brain injuries who do not meet the criteria for brain death and who experience cardiopulmonary arrest after withdrawal of ventilatory support. This criterion does increase the number of organs available, but DCD kidneys do have a greater than fivefold increase in the incidence of delayed graft function and a higher primary nonfunction rate compared to donation after brain death. DCD kidneys also have a higher rate of discard and retrieval-associated injury. Long-term graft function is equivalent between brain death and cardiac death donors. Renal preservation fluid is delivered either with rapid laparotomy and direct aortic cannulation or using an intra-aortic catheter placed via the femoral artery. Rapid laparotomy is associated with lower kidney discard rate, shorter warm ischemia times, and higher graft survival rates. Newer preservation strategies using

extracorporeal membrane oxygenation (ECMO) are under study to develop uniform guidelines for procurement.

A.12. What is a living donor transplant program?

A living donor transplant program allows recipient and donor surgery to be scheduled simultaneously. It offers the advantage of minimal organ preservation time. The total ischemia time from removal of the kidney from the donor to the restoration of blood flow in the recipient can be less than 1 hour. A short preservation time allows immediate graft function, high-volume urine output, and initiation of creatinine clearance.

A large number of recipients have preformed antibodies to potential living donors. These antibodies are the result of exposure to foreign antigens by blood transfusions, prior transplantation, or pregnancy. As a result, the recipients have positive crossmatches against living donor tissue antigens. There are preoperative measures that can facilitate the transplant to occur. One such regimen involves the combination of plasmapheresis and low-dose intravenous immunoglobulin with or without rituximab (a B-cell depleter) administered to a positive crossmatch and/or highly sensitized recipient. The living donor transplant is conducted when the crossmatch converts to negative. The recipient usually has to undergo additional plasmapheresis treatments and immunoglobulin infusions postoperatively.

A.13. What is a paired donor exchange transplant program?

This program is sometimes referred to as a "kidney swap." For example, one incompatible donor–candidate pair is matched to another pair with a complementary incompatibility, such that the donor from one pair gives an organ to a compatible candidate in the other pair and vice versa. Each kidney paired donation (KPD) has developed its own features to accommodate local needs. Reasons for participating in KPD include blood group incompatibility, sensitization of the recipient against the donor, the potential for improvement in transplant quality (e.g., age difference or graft size), and tissue compatibility. Sophisticated algorithms allow simultaneous two-way, three-way, or four-way exchanges or nonsimultaneous chains of transplants over the course of months.

There are many benefits to a paired donor exchange program:

- It expands the pool of donors.
- By using ABO-compatible but nonidentical donors, transplants can be performed at individual centers without requiring large sharing networks.
- Type O recipients with incompatible donors are likely to be the primary beneficiary of exchange programs.
- These programs reflect a paradigm shift for live donation, converting a private resource (the donor) to a shared one.
- Both donors and recipients are more willing to participate if their intended recipient, or donor is enthusiastic about participating.

A.14. What are some barriers to receiving a kidney transplant?

Absolute contraindications to kidney transplant include active infections, active malignancy, active substance abuse, reversible renal failure, uncontrolled psychiatric disease, documented active and ongoing treatment nonadherence, and a significantly shortened life expectancy. Recipient age alone is not a contraindication to transplant. However, in order to be an acceptable candidate to receive a transplant, patients should have an estimated life expectancy longer than the anticipated waiting time for a kidney. A living donor transplant is often the best option for an older patient.

Recipient with HIV infection is not a contraindication to acquiring a kidney. The U.S. Congress passed a law called the HIV Organ Policy Equity (HOPE) Act. This law ended a federal ban on transplantation of organs from deceased HIV-infected donors to HIV-infected recipients. The new policy will expand the number of donor organs available for transplantation into HIV-positive patients. The potential recipient should be clinically stable on highly active antiretroviral therapy (HAART), with an undetectable viral load, and a CD4 count ≥200 cells per μL.

Because the incidence of obesity has increased in the general population, more obese patients are referred for kidney transplantation. Obese patients have increased risk for delayed graft failure. Diet and/or bariatric surgery are beneficial for patients with a BMI of 40 kg per m^2 or more prior to transplant. Improvements in postoperative management have resulted in similar graft survival and mortality in obese patients compared

to nonobese patients.

Many patients on dialysis are infected with hepatitis B and/or hepatitis C. Currently, chronic hepatitis B is treated with interferon α-2a or interferon α-2b and lamivudine. Antiviral treatment with interferon is contraindicated after transplantation due to the risk of rejection, so treatment is recommended before transplant. Unlike interferon, lamivudine is a safe and effective antiviral hepatitis B virus (HBV) treatment both before and after renal transplantation. New treatment strategies with oral nucleotide NS5B polymerase inhibitors (sofosbuvir) are revolutionizing therapy for HCV. A recipient infected with HCV may accept an organ from an HCV-positive donor. Established HBV or HCV with cirrhosis and active viral infection is a relative contraindication to renal transplant.

A.15. What surgical techniques are available for donor nephrectomy (DN)?

The standard techniques for DN are open surgery, laparoscopic, and hand-assisted laparoscopic DN. Laparoscopic living-DN (LLDN) has increased in popularity. In some centers, it has replaced open DN as the standard technique. Laparoscopic DN results in less blood loss, reduced operative time, and shorter hospital stay than open DN. Hand-assisted laparoscopic DN has

the potential to decrease warm ischemia time for renal allografts. Donors managed laparoscopically have fewer complications, significantly less wound-related morbidity, and less delayed graft function than patients who undergo open DN.

Robotic nephrectomy offers several advantages compared to standard laparoscopic approaches. In particular, a robotic system restores the three-dimensional vision lost in the laparoscopic approach and enhances the ability of the surgeon to perform complex tasks.

Laparoendoscopic single-site surgery (LESS) uses one extraction site to place all ports to minimize the invasiveness of the planned procedure. A hybrid technique uses one periumbilical access and extraction site and an additional 2-mm needlescopic port. A robot can be used to aid in the surgery.

A.16. How is a donor kidney preserved?

Currently, static cold storage and hypothermic pulsatile machine perfusion are the two methods used to preserve donor kidneys. The benefit of one method over the other remains debated.

In static cold storage, the kidney is flushed, cooled with one of several cold preservation solutions, and transported on ice. In hypothermic machine perfusion, after an initial washout of blood, the kidney is connected to a perfusion device, and a solution is pumped continuously through the organ at temperatures between 1°C and 10°C until the moment of graft placement.

Preservation solutions are agents that do not readily permeate the cell membrane and have an electrolyte composition similar

to the intracellular environment (low sodium, high potassium), thus preventing loss of cellular potassium. The organ-preserving cold storage interval is called cold ischemia time (CIT). It extends from the initiation of cold preservation of donor organs to restoration of warm circulation in the organ recipient. In general, kidneys with a CIT over 24 hours or more are susceptible to delayed graft function. Delayed graft function means a requirement for dialysis in the first week after receiving a transplant.

As more suboptimal donor kidneys are used, machine perfusion has regained clinical interest. Hypothermic machine perfusion reduces delayed graft function compared with static cold. There is no difference in primary nonfunction, acute rejection, long-term renal function, or patient survival between the two methods.

Kidneys from living donors are easier to handle. The organ is flushed with preservation solution or iced Ringer's lactate solution containing heparin and mannitol. The ischemic time during implantation is usually 20 to 30 minutes because the transplant operation takes place immediately. Some practices place the living donor kidney in a pulsatile preservation machine that maintains organ viability for longer periods of time. The influence of improved immunosuppression, lower CIT have contributed to the recent improvements in graft function and survival.

A.17. Describe the operative procedure of kidney transplantation.

Prior to the induction of anesthesia, a large-bore peripheral intravenous line (18- or 16-gauge) is required. Following induction of anesthesia, a triple-lumen central line may be placed either via the internal jugular or subclavian route. A Foley catheter is placed in the bladder, and the bladder is irrigated with an antibiotic solution. Fluids are infused liberally through the central line and intravenous line. An arterial line may also be placed depending on the patient's underlying clinical status.

A kidney is harvested from a living donor using a left-flank laparoscopic approach. Harvesting of the left kidney is favored because the left renal vein is longer. New surgical techniques allow preservation of longer arterial length on the harvested kidney. Longer vessel preservation facilitates a right kidney donation.

The donor kidney is placed in either the right or left iliac fossa. The right kidney is usually placed in the left groin and vice versa. The renal artery of the donor kidney is connected to the external or internal iliac artery in the recipient. The renal vein of the donor kidney is connected to the external iliac vein in the recipient. Occasionally, a donor kidney has multiple renal arteries. This is addressed using primary or secondary anastomosis. A multiple-artery donor kidney has a longer operative and ischemic time than a kidney with a single artery. In the event that the recipient weighs less than 20 kg, the kidney is placed intra-abdominally posterior to the right colon. Urinary continuity is restored by placing the distal ureter into the bladder through a tunnel without opening the bladder.

In deceased donor kidney transplant, prior to the release of the arterial clamp and following completion of the anastomosis, an intra-arterial injection of verapamil or papaverine may be given by direct push into the renal artery to prevent arterial vasospasm.

In dual kidney transplantation, two kidneys from a donor are placed into one recipient. It is a reflection of donor shortage and reluctance to discard potentially functional organs. Such kidneys have usually been refused for single kidney transplantation. The criteria extends to very old (>60 years) or very young (<3 years) donors. The kidneys are transplanted en bloc. The donor aorta and vena cava are anastomosed to the external iliac artery and vein of the recipient. A dual kidney transplant procedure is of longer duration and involves more third spacing, greater volume requirements, and blood loss.

B. Preoperative Evaluation and Preparation

B.1. What preoperative workup would you order for a recipient?

The transplant recipient should receive a thorough, multidisciplinary workup prior to being listed as a candidate on the wait-list. This workup should include routine tests such as ECG, chest radiograph, complete blood counts, serum electrolytes and glucose, blood urea nitrogen and creatinine concentration, coagulation tests, and liver function tests.

Because cardiac disease is prevalent in this patient population and cardiac events are the leading cause of posttransplant mortality, a thorough cardiac evaluation is recommended. In addition to adhering to the established 2014 American College of Cardiology/American Heart Association (ACC/AHA) guidelines on perioperative cardiovascular evaluation of patients

undergoing noncardiac surgery, additional testing may be considered in pretransplant patients. Specifically, noninvasive stress testing may be considered in kidney transplantation candidates with no active cardiac conditions based on the presence of multiple coronary artery disease risk factors regardless of functional status. Relevant risk factors among transplantation candidates include diabetes mellitus, prior cardiovascular disease, more than 1 year on dialysis, left ventricular hypertrophy, age greater than 60 years, smoking, hypertension, and dyslipidemia. Additionally, there is some recent evidence that the coronary artery calcium score (CACS), which is a noninvasive diagnostic test for advanced coronary artery disease performed by nonenhanced computed tomography with minimal radiation, may be useful as a primary risk stratification tool in this patient population. Medical treatment or intervention for coronary artery disease is recommended when indicated by the cardiologist.

Routine dialysis should be avoided in the 24 hours prior to transplantation because it may increase the risk of delayed graft function. (This recommendation is different than for dialysis-dependent patients undergoing nontransplant surgery, for whom dialysis in the 24 hours prior to surgery is generally recommended.) If dialysis needs to be done within 24 hours of the operation, it is best to avoid overzealous ultrafiltration as expanded filling pressures are desired, and intravascular volume depletion may result in severe hypotension during or after anesthetic induction.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64(22):e77–e137.

statement from the American Heart Association and the American College of Cardiology Foundation. *J Am Coll Cardiol*. 2012;60:434–480.

Winther S, Bøttcher M, Jørgensen HS, et al. Coronary calcium score may replace cardiovascular risk factors as primary risk stratification tool before kidney transplantation. *Transplantation*. 2016;100(10):2177–2187.

B.2. How does the presence of obesity affect the outcome of a transplanted kidney?

The benefit of renal transplantation in obese patients is controversial, with many centers setting upper limits on BMI in consideration for listing patients for transplant. High BMI at transplant is associated with increased risk of wound and surgical site infections, delayed graft function, acute rejection episodes, and graft loss. Prospective evaluations of the impact of targeted risk modification such as dietary changes and monitored exercise programs are being investigated at this time. Bariatric surgery is both safe and effective in patients with CKD and ESRD. A sleeve gastrectomy improves eligibility for transplant based on BMI and does not affect postoperative immunosuppressant dosing regimens. All patients presenting for kidney transplant should be considered to have full stomachs regardless of the period of preoperative fasting.

Lentine KL, Delos Santos R, Axelrod D, et al. Obesity and kidney transplant candidates: how big is too big for transplantation? *Am J Nephrol*. 2012;36(6):575–586.

Pham PT, Danovitch GM, Pham PC. Kidney transplantation in the obese transplant candidates: to transplant or not to transplant? *Semin Dial*. 2013;26(5):568–577.

B.3. How are routine medications and immunosuppressive medications managed in the perioperative period?

Patients awaiting transplant often have comorbidities such as hypertension and diabetes. Antihypertensive drugs should be continued until the time of surgery. There are no rigorous

studies in the transplant population regarding the protective value of β-blockers. It is recommended that β-blockade be continued to reduce the risk of myocardial infarction. Medications such as angiotensin-converting enzyme inhibitor (ACE-I) and angiotensin II receptor blocker (ARB) should be omitted because of the risk of severe and refractory intraoperative hypotension. In spite of careful antihypertensive therapy, patient hemodynamics may still remain labile during induction, laryngoscopy, intubation, and extubation.

Oral hypoglycemic agents should be held on the morning of surgery. An insulin sliding scale can be used to manage patients on insulin. The sliding scale may be used intraoperatively if high blood glucose levels are measured. Antibiotic prophylaxis for infectious complications includes a first-generation cephalosporin (cefazolin 2 g intravenously), or if penicillin-allergic, an alternative such as vancomycin (1 g intravenously).

Anxiolytics should be titrated carefully because these patients may have increased sensitivity to premedication drugs. For example, diazepam is highly bound to albumin, but with decreased albumin levels, the effect of the drug is increased. Midazolam is water soluble, less affected by albumin levels, and useful prior to induction.

Prior to entering the operating room, patients are given intravenous corticosteroids and an immunosuppressive agent. Diphenhydramine and acetaminophen should be given before the rabbit antithymocyte globulin (Thymoglobulin) is infused intraoperatively. Under specific circumstances, basiliximab (Simulect) is substituted for Thymoglobulin. This is typically done if the patient has history of reaction to Thymoglobulin, has significantly decreased cardiac function, or is a perfect match to the donor kidney. No prophylactic premedication is required with basiliximab. Rituximab and plasmapheresis followed by intravenous immunoglobulin are incorporated into the regimens

of those patients with a positive crossmatch. A steroid-sparing regimen includes intraoperative methylprednisolone, which is tapered over 4 days. Patients go home taking only tacrolimus (Prograf) and mycophenolate mofetil (CellCept). In the steroid protocol, patients are continued on prednisone.

Spiro MD, Eilers H. Intraoperative care of the transplant patient. *Anesthesiol Clin*. 2013;31(4):705–721.

C. Intraoperative Management

C.1. Are a central venous pressure (CVP) monitoring line, an arterial line, and a pulmonary artery catheter required for the transplant procedure?

Measuring the CVP is not an absolute requirement; however, ensuring adequate hydration is an important part of the anesthetic management in renal transplant. Most patients will have undergone hemodialysis within 48 hours of surgery and may have intravascular volume depletion as a result. To decrease the incidence of postoperative acute tubular necrosis (ATN), a liberal hydration policy is employed intraoperatively. Although the utility of the CVP to guide fluid resuscitation is the subject of some debate, studies have shown that hydration guided by CVP monitoring can maintain stable hemodynamics and promote diuresis in kidney transplant recipients. The systolic blood pressure is maintained between 130 and 160 mmHg (or close to the individual patient's baseline blood pressure), and the CVP is maintained between 12 and 14 mmHg. Maintaining adequate CVP is especially important in pediatric recipients because reperfusion of an adult-size kidney graft may divert a significant amount of their own blood volume. CVP may decline 1 to 2 hours after revascularization despite aggressive fluid management in the operating room. The decline

in CVP is similar in recipients of both cadaveric and living related donor kidneys. It may decline 25% to 50% below the CVP measured in the operating room at reperfusion of the transplanted kidney. The reason for the decline is not clear but may be multifactorial such as redistribution of fluids, changes in vascular permeability, or increased nitric oxide levels. Increased hydration likely works to counteract this mechanism by atrial distension and the subsequent release of atrial natriuretic peptide and increased renal perfusion. Postoperatively, the patient should receive an equal amount of fluid to replace their urine output. If a central venous line is not placed, large-bore peripheral IV access or a large-bore central access via a midline catheter should be established.

An arterial line is not absolutely required for the transplant procedure. It should be placed if a patient has an advanced comorbid condition that requires close monitoring of blood pressure or acid–base status. Oftentimes, placement of an intra-arterial line is difficult because many recipients have poor arterial access secondary to diabetes, peripheral vascular disease, arteriovenous fistulas, and shunts. Major swings in blood pressure may occur, with hypotension (49.6%) being more likely than hypertension (26.8%). Administration of induction drugs and maintenance agents should be titrated carefully. The main utility of instantaneous blood pressure reading is toward the end of the procedure. Hypotension may occur after unclamping of the iliac vessels and/or from partial systemic absorption of the vasodilator (verapamil or papaverine) injected by the surgeon into the graft vessels. Hypotension must be avoided during this period because it can lead to delayed graft function and/or renal vein thrombosis.

A pulmonary artery catheter is not routinely placed for kidney transplantation. Patients with severe comorbid conditions, such as symptomatic coronary artery disease, left ventricular

dysfunction, congestive heart failure, valvular heart disease, or severe chronic obstructive pulmonary disease, can be monitored precisely with a pulmonary artery catheter. A transesophageal echocardiography can help determine if hypotension is caused by hypovolemia or myocardial dysfunction.

Trzebicki J, Flakiewicz E, Nowakowski P, et al. Is external jugular venous pressure a good predictor of volume status in kidney graft recipients? *Transplant Proc*. 2009;41(8):3033–3035.

C.2. What type of intravenous fluid should be used during surgery?

Traditionally, the administration of normal saline and normal saline–based fluids (5% albumin) has been the standard of care for fluid management in patients undergoing renal transplant surgery. This practice is primarily based on avoidance of potassium-containing fluids, which could theoretically contribute to intraoperative hyperkalemia. However, several recent studies suggest a higher risk of acidosis and hyperkalemia when using normal saline solutions versus balanced saline solutions such as lactated Ringer's or Plasma-Lyte, and no difference in clinical outcomes. Therefore, many transplant centers have made the switch to administering balanced, potassium-containing solutions. The typical fluid requirement for a 70-kg adult is about 3,000 to 4,000 mL. In addition, 500 mL of 5% albumin is given.

The recipient's blood is usually typed and screened, but blood loss is minimal, so transfusion is unlikely. The anesthesiologist should attempt to maintain a systolic blood pressure in the normal-to-high range of 130 to 160 mmHg, and CVP between 10 and 14 cm H_2O.

The intravenous administration of adequate volumes of fluid is associated with earlier onset of graft function, lower postoperative serum creatinine, higher postoperative creatinine clearance, reduced incidence of delayed graft function, and improved graft survival.

C.3. How would you conduct the anesthesia induction?

The circumstances for renal transplant can vary between a scheduled or emergent procedure. Living donor transplants are scheduled surgical cases. Patients receiving cadaver kidneys may learn of the surgical procedure under short notice. Standard anesthesia monitors are required prior to induction. A central venous line and/or arterial line are usually placed after induction.

The induction of general anesthesia and intubation of the trachea can be safely accomplished with several of the commonly used drugs. The induction drugs should be given slowly to minimize the chance of drug-induced hypotension. Regardless of blood volume status, these patients often respond to induction of anesthesia as if they were hypovolemic. The sympathetic nervous system response may be attenuated by antihypertensive therapy or diabetic autonomic neuropathy. A blunted sympathetic response impairs compensatory peripheral vasoconstriction. In addition, the central nervous system (CNS)

may exhibit an increased sensitivity to the induction drugs. Low serum protein and albumin levels can increase the level of unbound drug crossing the blood–brain barrier into CNS receptors. Uremia can also disrupt the blood–brain barrier. The dose of induction agent may need to be adjusted based on volume status, acidic pH, and comorbidities. Propofol or etomidate can be used in routine circumstances. A reduced induction dose of propofol may be considered because lower plasma protein levels and postdialysis hypovolemia can exaggerate its cardiac depressant effects. Ketamine pharmacokinetics are not significantly altered by renal disease, but its hypertensive effects make it undesirable in patients with underlying hypertension. Etomidate is well tolerated and preserves hemodynamic stability.

Large fluctuations in blood pressure and heart rate may occur in patients with preexisting hypertension during intubation. Underlying coronary artery disease should be carefully considered. Opioids can blunt the response to laryngoscopy. Fentanyl can be used in moderate doses, but there is a small risk of hypotension after induction and lack of stimulation. Remifentanil is also effective for heart rate control. A short-acting β-blocker such as esmolol (0.5 to 1.0 mg per kg) can blunt the response to intubation.

A number of neuromuscular blocking agents can be used to facilitate tracheal intubation. Patients with uremia and diabetes may have gastroparesis. Pretreatment with a clear, nonparticulate antacid such as 30 mL of sodium citrate raises gastric pH. A rapid sequence induction with cricoid pressure using either succinylcholine or rocuronium may be required to prevent reflux and aspiration. Succinylcholine can be used safely because potassium release is not exaggerated in patients with chronic renal failure. If the preoperative potassium is in the high normal range or if there is underlying metabolic acidosis,

the additional increase of 0.5 to 1.0 mEq per L should be considered. When choosing a nondepolarizing agent for maintenance, it is better to use ones that are independent of renal clearance mechanisms (cisatracurium, atracurium).

Schmid S, Jungwirth B. Anaesthesia for renal transplant surgery: an update. *Eur J Anaesthesiol*. 2012;29(12)552–558.

C.4. Is succinylcholine contraindicated in renal failure patients?

Normally, succinylcholine causes an increase in serum potassium of 0.5 to 1.0 mEq per L within 3 to 5 minutes after intravenous administration and lasts less than 10 to 15 minutes. Succinylcholine can be used safely in patients with chronic renal failure if the potassium concentration is less than 5.5 mEq per L and repeated doses are avoided. Potassium flux after administration of succinylcholine in patients with renal failure does not differ from normal patients. Plasma cholinesterase activity has been reported to be below normal in more than 20% of ESRD patients whether they are receiving any form of dialysis. Values are rarely so low that they cause a prolonged block.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1956.

C.5. How are the nondepolarizing muscle relaxants affected by renal failure?

Table 25.2 notes the commonly used nondepolarizing agents and how they are affected by renal failure. The prolonged duration of action to nondepolarizing agents is primarily due to slow renal clearance. Cisatracurium mainly undergo Hofmann elimination that is not altered in patients with CKD. Renal failure may delay clearance of laudanosine, the principal metabolite of cisatracurium. Laudanosine does not have effect at

the neuromuscular junction but at high plasma levels may act as a CNS stimulant. The long-acting muscle relaxant such as pancuronium is not suitable for use because the kidneys excrete most of the drug and its metabolite. The prolonged effect of a nondepolarizing agent may not be apparent after a single small dose. After a small dose, the termination of action is by redistribution rather than elimination. It is only after a single large dose, repeated dosing, or prolonged infusion that the increased elimination half-life becomes clinically apparent. It has also been shown that there are large differences in pharmacokinetics with renal failure patients receiving rocuronium. Maintenance doses for patients with decreased renal function should be smaller, and the interval between doses should be increased. Monitoring of neuromuscular blockade with a nerve stimulator is recommended.

TABLE 25.2 Pharmacokinetics of Neuromuscular Blocking Agents in Normal versus Anephric Patients

Drug	Renal Excretion (%)	Normal $T_{1/2}$ (min)	Anephric $T_{1/2}$ (min)
Pancuronium	85	132	258
Rocuronium	10	42	58
Vecuronium	40–50	54	84
Atracurium	10–40	18	24
Cisatracurium	16	34	No effect
Mivacurium	<5	1.8	3.6
Succinylcholine	<25	1	1

$T_{1/2}$, half life.

and sugammadex in patients with severe to end-stage renal failure: a pharmacokinetic study. *Br J Anaesth*. 2010;104(1):31–39.

C.6. How would you maintain anesthesia during the case?

General anesthesia is the preferred technique for kidney transplantation. Volatile agents, opioids, and a muscle relaxant are required to provide optimal operating conditions.

The choice of inhaled anesthetic includes desflurane and isoflurane. Sevoflurane may be avoided because the metabolism of sevoflurane has been implicated in renal toxicity due to production of fluoride and compound A. Desflurane and isoflurane do not have any nephrotoxic potential secondary to fluoride accumulation.

Opioids such as fentanyl, sufentanil, alfentanil, and remifentanil can be used during the procedure. Morphine and meperidine have metabolites that depend on renal clearance and can accumulate. A muscle relaxant that is not dependent on renal clearance such as cisatracurium should be used.

Hypotension may occur after unclamping the iliac vessels and reperfusion of the graft. It is important to maintain the blood pressure because renal function is critically dependent on adequate perfusion. It is critical that the patient is adequately hydrated throughout surgery in preparation for reperfusion of the graft. Close monitoring of the CVP and lightening the level of anesthesia during hemodynamic instability can prevent hypotension. Vasopressors with α-agonist action should be avoided because they can comprise blood flow to the transplanted organ. Additional fluid may be required to maintain blood pressure and replace urine output. Furosemide or mannitol can enhance urine output. Loop diuretics block the Na/K channels in the thin ascending loop of Henle. This prevents reabsorption of electrolytes in this part of the nephron. The high-osmolar fluid then prevents reabsorption of water in the distal tubule. A large volume of fluid with high electrolyte content is

excreted. Mannitol is freely filtered in the glomerulus but not reabsorbed. It causes osmotic expansion of urine volume.

The estimated blood loss during the case ranges between 200 and 500 mL. In some cases, greater blood loss may require transfusion of packed red blood cells. Packed red blood cells should be cytomegalovirus negative. At the end of surgery, patients can be given reversal agents and extubated promptly. Patients are then transferred to the postanesthesia care unit (PACU) for continued monitoring of urine output and electrolytes.

Spiro MD, Eilers H. Intraoperative care of the transplant patient. *Anesthesiol Clin*. 2013;31(4):705–721.

C.7. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration (GFR), and urine output?

All volatile anesthetics produce a dose-related transient and reversible decrease in RBF, GFR, urine output, and the urinary excretion of sodium. This is primarily in response to a decline in systemic blood pressure and cardiac output. Reduced RBF, loss of renal autoregulation, and neurohumoral and neuroendocrine factors also contribute. Specific differences among the agents on renal function are to be noted. Desflurane and sevoflurane are two most frequently used inhalational anesthetics. Desflurane has demonstrated better hepatic and renal function tests after surgery when compared to sevoflurane.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1929–1956.

Ko JS, Gwak MS, Choi SJ, et al. The effects of desflurane and sevoflurane on hepatic and renal functions after right hepatectomy in living donors. *Transpl Int*. 2010;23(7):736–744.

C.8. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?

Fluoride-induced nephrotoxicity is a potential hazard following metabolism of volatile anesthetics. Desflurane (0.02%), isoflurane (0.2%), enflurane (2%), sevoflurane (2% to 3%), and halothane (12% to 20%) are metabolized in the body (rule of 2). When serum inorganic fluoride reaches 50 to 80 mmol per L, subclinical renal toxicity (laboratory abnormalities) occurs. Clinical nephrotoxicity usually becomes apparent when the serum fluoride level is more than 80 mmol per L. The high-output renal failure is dose related and characterized by vasopressin-resistant polyuria, hypernatremia, serum hyperosmolarity, increased serum urea nitrogen, and inorganic fluoride concentration. Despite the potential for relatively high plasma levels of fluoride after long exposure to newer anesthetics, the minimal amount of sevoflurane and enflurane renal defluorination may explain the relative absence of serious renal concentrating defects with these anesthetics. Although the conventional measurements of renal function (blood urea nitrogen, creatinine) are not altered, evidence shows transient impairment of renal concentrating ability and renal tubular injury in patients receiving sevoflurane or enflurane. Nevertheless, it has not been confirmed whether administration of sevoflurane in patients with preexisting renal disease could further deteriorate renal function. Fluoride levels after isoflurane and halothane increase by 3 to 5 μM per L and 1 to 2 μM per L, respectively. These agents do not pose a risk for nephrotoxicity. Desflurane is resistant to biodegradation because fluorine is the only halogen in the desflurane molecule. Mean inorganic fluoride concentration after 1 minimum alveolar concentration (MAC) hour exposure to desflurane is less than 1 μmol per L.

Prolonged exposure to desflurane (7.0 MAC hours) has been associated with normal renal function in patients without renal disease. Neither desflurane nor isoflurane lead to a deterioration of creatinine clearance in patients with preexisting renal impairment.

Sodium or barium hydroxide lime absorbents react with sevoflurane, resulting in a by-product called *compound A*. The nephrotoxic potential of compound A has been noted in animals and is inconclusive in human studies. The concentrations that occur in humans are far below the nephrotoxic levels in animals. A fresh gas flow of 1 L per minute or higher is recommended to minimize the accumulation of compound A in the breathing circuit. Low-flow sevoflurane (1 L per minute) has been used on many occasions with no effect on renal function. Carbon dioxide absorbents that contain calcium hydroxide and calcium chloride do not result in compound A formation when exposed to sevoflurane. The U.S. Food and Drug Administration (FDA) recommends the use of sevoflurane with fresh gas flow rates at least 1 L per minute for exposures up to 1 hour and at least 2 L per minute for exposures greater than 1 hour. Nevertheless, it is important to note that other countries have not recommended such limitations on the clinical use of sevoflurane and problems have not been noted.

1136.

C.9. How does renal failure affect the pharmacology of opioids?

The effect of renal failure on individual opioids varies, so one must consider the effect of renal failure on drug metabolites as well as the parent compound.

Morphine is metabolized in the liver to morphine-6-glucuronide (M6G) (10%), morphine-3-glucuronide (M3G) (55%), and normorphine (4%), all of which are excreted by the kidneys, along with about 10% of the parent compound, in subjects with normal renal function. M6G has been reported to mediate CNS and respiratory depression when it accumulates in renal failure.

Meperidine is metabolized in the liver to normeperidine, also excreted by the kidneys. Accumulation of this metabolite may lead to excitatory CNS effects such as convulsions.

Fentanyl is metabolized by the liver, with only 7% excreted unchanged in the urine. Fentanyl is suitable for use during surgery and is safe in the short term. There are reports of the parent compound accumulating during renal failure, but clinical experience is that there are no adverse effects. However, if being used long term in renal failure patients, the pharmacodynamic effects should be monitored carefully.

Alfentanil metabolism occurs by inducible cytochrome c enzymes in the liver, making it suitable for renal failure patients. The clearance and half-life of sufentanil and alfentanil are not significantly different in patients with reduced renal function.

Remifentanil is metabolized by blood and tissue esterases. The principle metabolite of remifentanil (GR90291) is eliminated by the kidney. The reduced renal elimination of this metabolite is not of clinical significance because the potency is 1 in 4,000 of the parent compound.

D. Postoperative Management

D.1. How is the diagnosis of transplant rejection made?

There are various forms of rejection such as hyperacute, accelerated acute, acute, and chronic. Acute rejection is the most common, but less common with immunosuppressive agents. It is usually seen within days to a few months posttransplant. The diagnosis is made with a renal biopsy. In patients with prolonged delayed graft function, surveillance biopsies can detect or exclude acute rejection episodes. The process is associated with systemic symptoms such as fever, chills, malaise, and arthralgias. However, with current immunosuppressive drugs, most acute rejection episodes are generally asymptomatic. Laboratory data note a rapid increase in creatinine of 10% to 25% over baseline with or without a decrease in urine output.

Nankivell BJ, Alexander SI. Rejection of the kidney allograft. *N Engl J Med*. 2010;363:1451–1462.

D.2. What are immunosuppressive agents, and how do they affect anesthetic care?

Induction drugs are antirejection medicines used at the time of transplant. The patient is then placed on maintenance drugs for the long term.

There are generally four classes of maintenance drugs:

- Calcineurin inhibitors: tacrolimus, belatacept, cyclosporine
- Antiproliferative agents: mycophenolate mofetil, mycophenolate sodium, azathioprine
- TOR inhibitors: sirolimus, everolimus

- Steroids: prednisone

Some of the side effects of immunosuppressive agents may be encountered if a posttransplant patient presents for other surgeries and are pertinent to anesthetic care:

- Calcineurin inhibitors: nephrotoxicity, hypertension, hyperchloremic acidosis, hyperkalemia, hypomagnesemia, hypocalcemia, glucose intolerance, coarse tremor, dysesthesia, headache, seizure, prolonged QT interval, hypercoagulability, acute microvascular disease (similar to thrombotic thrombocytopenic purpura)
- Mycophenolate mofetil: nausea, vomiting, cytopenia (leukopenia, anemia, thrombocytopenia), leukocytosis
- TOR inhibitors: mucocutaneous ulceration, hypokalemia, hypomagnesemia, impaired wound healing, interstitial pneumonia, cytopenia
- Azathioprine: cytopenia, hepatitis

26 Robotic-Assisted Laparoscopic Surgery

Judith Weingram

A 72-year-old man with biopsy-proven carcinoma of the prostate had a prostate-specific antigen (PSA) of 22 ng per mL but negative pelvic computed tomography (CT) and bone scans. He weighed 120 kg. Despite hypertension, a 50 pack-year smoking history, and recent surgery for retinal detachments, he was vigorous and active. He chose to be treated surgically.

A. Medical Disease and Differential Diagnosis

1. What is the incidence of carcinoma of the prostate?
2. How is prostate cancer diagnosed?
3. How is prostate cancer treated?
4. Define laparoscopy.
5. Describe the development of robotic-assisted laparoscopy.
6. What are the advantages and disadvantages of minimally invasive surgery over open surgery?
7. What are the contraindications to laparoscopic or robotic-assisted laparoscopic surgery? Is pregnancy a contraindication to robotic surgery?
8. What other specialties commonly perform robotic surgery?
9. Why is carbon dioxide (CO_2) the gas of choice for robotic

laparoscopy? What are its disadvantages?

10. How much endogenous CO_2 is produced at basal level and at maximal exercise?
11. How much CO_2 is stored in the body? Where is it stored? Of what significance is this to laparoscopy?
12. Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.
13. Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?

B. Preoperative Evaluation and Preparation

1. What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for robotic surgery?
2. What factors increase this patient's risk of pulmonary complications?
3. What laboratory tests should be performed preoperatively?
4. What specific information should the patient be given about robotic surgery before obtaining informed consent?
5. What additional procedures should be done before surgery?
6. What are the three major forces that uniquely alter the patient's physiology during robotic laparoscopy?

C. Intraoperative Management

1. What is the anesthetic technique of choice for robotic-assisted laparoscopy? Why?
2. Can a laryngeal mask airway (LMA) be used?
3. What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic agents contraindicated?
4. Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?

5. Can laparoscopy be performed under local or regional anesthesia?
6. What monitors and devices would you apply to the patient? Why?
7. How is the patient to be positioned? What special precautions are required for robotic laparoscopy?
8. How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?
9. What techniques are available for initial access to the peritoneal cavity? What anesthetic problems can arise during insufflation?
10. What intravenous (IV) solution and how much fluid volume do you plan to infuse?
11. Under what circumstances should laparoscopy be converted to laparotomy?
12. What is the arterial to end-tidal CO_2 gradient ($PaCO_2$–$EtCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?
13. Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $EtCO_2$ exceed the $PaCO_2$? Why?
14. What are the possible causes of hypercarbia?
15. What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?
16. How rapidly does the $PaCO_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $PaCO_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?
17. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the cardiovascular system?
18. What is the net effect of pneumoperitoneum, hypercarbia, and

steep Trendelenburg on the respiratory system?

19. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the central nervous system?
20. What are the neuroendocrine changes that occur during laparoscopy?
21. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the renal system?
22. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the bowel and gastrointestinal system?
23. How would you recognize a CO_2 embolism during laparoscopy? How does this differ from an air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of CO_2 emboli?
24. What is the mechanism of increase in shunting resulting from embolization?
25. How is a gas embolism (CO_2 or air) treated?
26. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?
27. How would you decide when to extubate?

D. Postoperative Management

1. What are some of the unique complications of laparoscopy?
2. In the postanesthesia care unit (PACU), our patient complains of numbness and weakness of the lower extremities after 6 hours of anesthesia for robotic prostatectomy. What tests will you order? When would you remove the Foley catheter and arterial line? Under what circumstances would you order a chest x-ray film?
3. What is the incidence of postoperative nausea and vomiting?

A. Medical Disease and Differential Diagnosis

A.1. What is the incidence of carcinoma of the prostate?

Carcinoma of the prostate is the most frequently diagnosed nonskin cancer in American men. The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute estimated that in 2018, there were 165,000 new cases of prostate cancer (or 9.5% of all new cancer cases) and more than 29,000 deaths from prostate cancer (or 4.8% of all cancer deaths). Based on their data from 2013 to 2015, approximately 11.2% of men will be diagnosed with prostate cancer at some point in their lifetime.

Undetected microscopic prostate cancer cells are believed to be present in 30% to 40% of men older than the age of 50 years and in 75% of men older than the age of 75 years, but it is estimated that only approximately 8% of these men will develop clinically significant disease. It has been stated that more men die *with* prostate cancer than *from* it. Therefore, it is not yet known whether early detection of subclinical disease, much of which may have remained clinically insignificant, will improve survival.

Carcinoma of the prostate is rare in Asian men, whereas African-American men have about twice the incidence as white American men.

Siegel RL, Miller KD, Jemal A. Cancer statistics, 2018. *CA Cancer J Clin*. 2018;68(1):7–30.

A.2. How is prostate cancer diagnosed?

The most reliable methods for diagnosis include a digital rectal examination plus the serum PSA level. Palpation of a tumor or indurated area and finding an elevated PSA should be followed by prostatic needle biopsies under transrectal ultrasound guidance and/or magnetic resonance imaging (MRI) and new

genetic biomarkers.

Qaseem A, Barry MJ, Denberg TD, et al. Screening for prostate cancer: a guidance statement from the Clinical Guidelines Committee of the American College of Physicians. *Ann Intern Med*. 2013;158:761–769.

A.3. How is prostate cancer treated?

Treatment choices vary not only with the stage of the disease but also with the patient's age and life expectancy, associated medical conditions, and lifestyle. In patients with localized disease, treatment choices include "watchful waiting," brachytherapy (in which radioactive seeds are implanted in the prostate gland), radiation (including external beam, intensity-modulated radiation therapy, stereotactic therapy, proton beam therapy, etc.), cryosurgery, vaccine therapy, and other nonsurgical treatments. Surgical options include the traditional open radical prostatectomy performed through either a retropubic (lower abdominal) or perineal incision or laparoscopic radical prostatectomy, which can be hand-assisted or robot-assisted.

A patient with nonlocalized disease may choose to be treated with radiation, hormones, chemotherapy, other nonsurgical options, or even to have no treatment.

Coelho RF, Rocco B, Patel MB, et al. Retropubic, laparoscopic, and robot-assisted radical prostatectomy: a critical review of outcomes reported by high-volume centers. *J Endourol*. 2010;24:2003–2015.

Lim SK, Kim KH, Shin TY, et al. Current status of robot-assisted laparoscopic radical prostatectomy: how does it compare with other surgical approaches? *Int J Urol*. 2013;20:271–284.

A.4. Define laparoscopy.

Laparoscopy (or peritoneoscopy) is a “minimally invasive” procedure allowing endoscopic access to the peritoneal cavity after insufflation of a gas (CO_2) to create space between the anterior abdominal wall and the viscera. The space is necessary for the safe manipulation of instruments and organs. Laparoscopic surgery can also be extraperitoneal. It can also be gasless with abdominal wall retraction, and more recently, it may be hand-assisted or robotically assisted.

A.5. Describe the development of robotic-assisted laparoscopy.

The era of open incisions in which surgeons could directly see, touch, and manipulate organs was superseded by minimally invasive surgery in which tiny cameras and laparoscopes could be inserted through small ports in the patient’s body. However, conventional laparoscopy is limited by poor depth perception (visualization on a two-dimensional monitor) and the use of long, straight instruments that limit mobility and dexterity.

Robotic devices were initially designed by National Aeronautics and Space Administration (NASA) for the purpose of performing tasks outside the space shuttle while being controlled remotely from inside the spacecraft or from earth. This technology was adapted for surgery as the da Vinci computer-assisted robotic system.

The surgeon sits at a remote control console near the patient and operating room table and views the operative field as a high-resolution magnified three-dimensional image transmitted from a video camera. By using hand-and-finger control devices, the surgeon can precisely manipulate the mechanical arms of the robot to achieve wrist-like motion. Foot pedals also allow the surgeon to more precisely control the robot, camera, and cautery.

Awad H, Walker CM, Shaikh M, et al. Anesthetic considerations for robotic prostatectomy: a review of the literature. *J Clin Anesth*. 2012;24:494–504.

A.6. What are the advantages and disadvantages of minimally invasive surgery over open surgery?

The advantages include the cosmetic results of small non–muscle-splitting incisions, decreased blood loss, less postoperative pain and ileus, shorter hospitalization and convalescence, and ultimately lower cost. Postoperative respiratory muscle function returns to normal more quickly than in open surgery, especially in laparoscopic cholecystectomy and other upper abdominal procedures. Wound complications such as infection and dehiscence are less frequent, and host defense mechanisms may be greater in laparoscopic than in open surgery.

The disadvantages include the long learning curve for the surgeon (most complications occur during the first 10 laparoscopies), the narrowed two-dimensional visual field on video in conventional laparoscopy, the need for general anesthesia with muscle paralysis, and the potentially longer operative duration.

Robotic-assisted laparoscopy, by virtue of its high-resolution three-dimensional visualization and greater precision, offers a greater likelihood of nerve sparing in prostatectomy and, therefore, retention of continence and potency. The disadvantages of the robot include added operative time, the high cost (in millions of dollars) of equipment purchase and maintenance, and the need for a permanently dedicated operating room location for this heavy and bulky equipment.

Soto E, Lo Y, Friedman K, et al. Total laparoscopic hysterectomy versus da Vinci robotic hysterectomy: is using the robot beneficial? *J Gynecol Oncol*. 2011;22:253–259.

Wilson T, Torrey R. Open versus robotic-assisted radical prostatectomy: which is better? *Curr Opin Urol*. 2011;21(3):200–205.

A.7. What are the contraindications to laparoscopic or robotic-assisted laparoscopic surgery? Is pregnancy a contraindication to robotic surgery?

Increasing experience with the laparoscopic technique has made most contraindications relative rather than absolute. However, it is probably best to avoid or to use extreme caution in patients with a coagulopathy, a diaphragmatic hernia, severe cardiovascular or pulmonary disease (including bullae), morbid obesity, increased intracranial pressure or space-occupying masses, a retinal detachment, acute glaucoma, impending renal shutdown, a history of extensive surgery or adhesions, sickle cell disease (because sickle crisis may be precipitated by acidosis), peritonitis, a large intra-abdominal mass, a tumor of the abdominal wall, or hypovolemic shock. Patients with shunts (e.g., ventriculoperitoneal) are at risk for gas emboli, shunt obstruction, and intracranial hypertension, all of which may occur during laparoscopy and may require intracranial pressure monitoring and ventricular drainage if laparoscopic surgery is necessary. In summary, most of the contraindications concern patients who are unable to tolerate extremes of position, pneumoperitoneum, and/or hypercarbia.

Pregnancy is no longer considered a contraindication to robotic surgery. In order to preserve fetal and maternal well-being and to prevent premature labor, the anesthesiologist must weigh the effects of hypercarbia, pneumoperitoneum and extreme positions on the parturient who may present with increased blood volume, increased cardiac output, decreased systemic vascular resistance (SVR), hypercoagulability, the supine hypotensive syndrome, increased respiratory minute volume, decreased residual volume, decreased functional residual capacity (FRC), increased oxygen consumption, mild hypocapnia, increased risk of aspiration, and decreased

anesthetic requirement. This combination of factors tends to promote hypercarbia and hypoxemia. However, extreme hyperventilation may result in decreased uteroplacental perfusion. Arterial blood gas monitoring has been suggested to detect fetal acidosis because capnography may not reveal a large arterial to end-tidal difference in CO_2. In all cases, preoperative and postoperative fetal and uterine monitoring is essential.

A.8. What other specialties commonly perform robotic surgery?

Robotic procedures in urology have become standard, especially for prostatectomy, uncomplicated adrenalectomy, and nephrectomy including live donor nephrectomy. Robotic gynecologic surgery includes tubal surgery (sterilization, treatment of ectopic pregnancy, etc.), cystectomies, hysterectomies, various ablations (endometriosis), and so on. Robotic surgery is performed in pregnancy and also in pediatrics.

Robotic general surgery includes cholecystectomy, hernia repair, antireflux procedures, splenectomy, appendectomy, bowel surgery including bariatric procedures, and various other upper and lower abdominal procedures.

Thoracoscopic, cardiovascular, and neurosurgical intracranial surgery, using modified laparoscopic instruments without the need for gas insufflation, are some of the more recent areas of endoscopic surgery. Lumbar discectomies and other types of

spinal surgery also have been done laparoscopically through an anterior approach. Even autopsies have been attempted laparoscopically. The list continues to grow.

A.9. Why is carbon dioxide (CO_2) the gas of choice for robotic laparoscopy? What are its disadvantages?

CO_2 is the insufflating gas of choice because it is nonflammable, does not support combustion, readily diffuses across membranes, is rapidly removed in the lungs, and is highly soluble because of rapid buffering in whole blood. The risk of CO_2 embolization is small. As much as 200 mL of CO_2 injected directly into a peripheral vein may not be lethal, whereas only 20 mL of air may prove to be so. In addition, CO_2 levels in blood and expired air can easily be measured, and its elimination can be facilitated by increasing ventilation. As long as oxygen requirements are met, a high concentration of blood CO_2 can be tolerated. Also, medical grade CO_2 is readily available and inexpensive.

It is for these reasons that the following gases are unsatisfactory for pneumoperitoneum: N_2O (does not cause pain intra-abdominally but does not suppress combustion); oxygen (flammable); helium, air, and nitrogen (each has no hemodynamic or acid–base sequelae but can cause gas emboli); and argon (adverse effect on hepatic blood flow, emboli).

It should be emphasized, however, that CO_2 plays a dual role in the body, and it is not inert. Under normal circumstances, it is an intrinsic waste product of metabolism. During laparoscopic

surgery, it acts as an extrinsic drug often present in quantities far larger than the body is physiologically capable of generating even with the most extreme exercise or hypermetabolic state.

The disadvantages mainly stem from the fact that CO_2 is not inert, and it has contradictory roles as an endogenous chemical and as an exogenous foreign substance. Changes in its concentration and tensions have enormous biochemical and physiologic consequences. Changes at the local tissue level are often at odds with the overall systemic effect. It causes direct peritoneal irritation and pain during laparoscopy under local anesthesia because it transiently forms carbonic acid when in contact with the moist peritoneum. In addition, CO_2 is not very soluble in the absence of red blood cells, and therefore, it can remain in gaseous form intraperitoneally (subhepatic) after laparoscopy, causing referred shoulder pain. Hypercarbia and respiratory acidosis occur when the buffering capacity of blood is temporarily exceeded. In addition, CO_2 exerts widespread local and systemic effects that may manifest overall as hypertension, tachycardia, cerebral vasodilation, hypercarbia, and respiratory acidosis.

A.10. How much endogenous CO_2 is produced at basal level and at maximal exercise?

CO_2 and water are the major end products of aerobic metabolism in the mitochondria of the cells. Carbonic acid, the major acid produced in the body, is uniquely volatile, and

therefore, it must be eliminated mainly by the lungs. (Other acids are eliminated by the kidney.)

At basal rate, an average adult manufactures approximately 200 mL of CO_2 per minute (while consuming 250 mL of oxygen) or 12 L of CO_2 (35 g) per hour. At maximal metabolic rate, it is estimated that the body can produce, transport, and excrete 90 to 100 L per hour, an 800% increase over the basal rate.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–169.

A.11. How much CO_2 is stored in the body? Where is it stored? Of what significance is this to laparoscopy?

The body contains approximately 120 L of stored CO_2, most of it in the form of carbonate ion in bone. (This is approximately 100 times the amount of stored oxygen.) CO_2 in the blood is in equilibrium with CO_2 in different tissues. The rate of uptake and distribution of CO_2 from the blood (where it exists as bicarbonate ion) depends on the perfusion and storage capacity of those different tissues. The well-perfused tissues, including brain, kidneys, and blood, come to rapid equilibrium. The medium-perfused compartment consists mainly of resting skeletal muscle. The slowly perfused compartment, mainly fat and bone (where it exists as the carbonate ion), has the largest CO_2 storage capacity. In contrast to rapidly changing oxygen levels, CO_2 levels reach equilibrium more slowly.

These storage sites serve to buffer and stabilize blood CO_2 levels because they provide a place for excess CO_2 to "park" until ventilation can catch up and restore equilibrium. The increase in CO_2 storage during laparoscopy is illustrated clinically by the decelerating rate of rise in Et_{CO_2} despite

continuing insufflation. Blood or end-tidal CO_2 levels increase rapidly at first and plateau between 15 and 35 minutes despite continuing low flow insufflation. At constant ventilation, CO_2 levels increase but not as much as if no simultaneous storage processes were occurring. But if ventilation is increased to keep CO_2 constant, then the increase needed is only approximately 40% of the predicted volume of ventilation because of the drain off of CO_2 into the storage sites.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–169.

Seed RF, Shakespeare TF, Muldoon MJ. Carbon dioxide homeostasis during anaesthesia for laparoscopy. *Anaesthesia*. 1970;25:223–231.

A.12. Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.

Diffusion describes the process by which gases travel from an area of higher partial pressure to one of lower partial pressure. For a gaseous environment, Graham law states that the rate of diffusion of a gas is inversely proportional to the square root of its density (i.e., the smaller the molecule, the more easily it will diffuse).

When that same gas molecule arrives at an aqueous membrane (e.g., a gas–liquid interface), the solubility of that gas in water now becomes the major factor in determining its diffusing capacity (as shown in **Table 26.1**). The water solubility of CO_2 is 24 times that of oxygen, whereas the diffusion capacity of CO_2 is 20.5 times that of oxygen. The capacity of a gas to diffuse across an aqueous membrane is directly proportional to its solubility in water and inversely proportional to its molecular weight. However, the actual movement of that gas across the aqueous membrane depends not only on its diffusing capacity but also more importantly on the

pressure gradient across that membrane (**Table 26.1**).

TABLE 26.1 Influence of Physical Properties on the Diffusion of Gas through a Gas–Liquid Interface

Gas	Molecular Weight	Density Relative to O_2	Solubility Relative to O_2	Water Diffusion Capacity Relative to O_2
O_2	32	1.0	1.0	1.0
N_2	28	0.88	0.515	0.55
CO_2	44	1.37	24.0	20.5
N_2O	44	1.37	16.3	14.0
He	4	0.125	0.37	1.05

CO_2, carbon dioxide; He, helium; N_2, dinitrogen; N_2O; nitrous oxide; O_2, oxygen.

The fate of CO_2 gas insufflated into the peritoneal cavity is the same that would occur in any other closed but distensible cavity. The pressure obtained within the cavity varies directly with the volume of gas insufflated and indirectly with the compliance of the closed cavity.

Therefore, the ability of CO_2 to move from the closed peritoneal cavity to the lungs for excretion is dependent on its intrinsic diffusion and solubility properties, the rate of continuing CO_2 insufflation, the surface area of the cavity, and the partial pressure difference across membranes.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–169.

McHoney M, Corizia L, Eaton S, et al. Carbon dioxide elimination during laparoscopy in children is age dependent. *J Pediatr Surg*. 2003;38:105–110.

A.13. Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?

CO_2 is relatively insoluble in plasma, interstitial fluid, and water. (Think of the rapid escape of gas from a freshly opened

carbonated soft drink.) The solubility of CO_2 in water at 37°C (98.6°F) is only 0.03 mmol/L/mmHg. This must be contrasted to the very high solubility of CO_2 in whole blood. This extremely important distinction exists because of a zinc-containing enzyme, carbonic anhydrase, that exists within the erythrocyte but not at all in plasma.

$$H_2O + CO_2 \xrightarrow{\text{carbonic anhydrase}} H_2CO_3 \rightarrow H^+ + HCO_3^-$$

In the equation shown, carbonic anhydrase catalyzes the left side of the equation (i.e., the hydration of CO_2 to $H_2CO_3^-$). Once formed, carbonic acid is unstable and immediately dissociates into H^+ and HCO_3^-. It is estimated that without carbonic anhydrase, it would take 200 seconds at 38°C (100.4°F) for the previous reaction to come to 10% equilibrium. Because blood travels through the pulmonary capillaries in less than 1 second, carbonic anhydrase speeds up the reaction by a factor of 7,500 times.

Carbonic anhydrase, therefore, allows the insufflated CO_2 gas to be dissolved and carried as bicarbonate in the blood. The process is reversed in the lungs, and the reconstituted CO_2 gas is removed by respiration.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:151–169.

B. Preoperative Evaluation and Preparation

B.1. What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for robotic surgery?

All patient comorbidities must be evaluated to ensure optimal pharmacologic management preoperatively. Because of this patient's advanced age, it is best to form one's own observations of his mental and physical condition. Is he confused, short of breath, kyphoscoliotic, and so forth? A glimpse at where and how this patient's body weight is distributed means more than just knowing that he weighs 120 kg. Ask about smoking, wheezing, any change in exercise tolerance, cough, recent upper respiratory infection, or change in medications. Perform your usual preoperative evaluation and obtain any consultations that may be informative. Consult with the surgeon regarding the need for appropriate preoperative antibiotics. Does he need pulmonary function tests or an echocardiogram or cardiac stress test? Is he as "well-tuned" as he can be? Find out when his retinal detachments were repaired and if intraocular gas was used.

Efron DT, Bender JS. Laparoscopic surgery in older adults. *J Am Geriatr Soc*. 2001;49:658–663.

B.2. What factors increase this patient's risk of pulmonary complications?

- *The robotic procedure itself*. The steep Trendelenburg position and the increased intraperitoneal volumes and pressures in a paralyzed, mechanically ventilated patient cause respiratory dysfunction. Insufflation pressures should not exceed 12 to 15 mmHg. Lower pressures are especially advantageous in American Society of Anesthesiologists (ASA) class III and IV patients with diminished cardiopulmonary reserve. In addition, an increased CO_2 load might call for respiratory minute volumes that are so large that further cardiopulmonary compromise occurs. In addition, the robotic procedure itself, including docking and undocking, adds additional immobile time under anesthesia.

- *Age.* Pulmonary function declines with age, especially in a patient older than age 70 years.
- *Smoking/chronic obstructive pulmonary disease (COPD).* Smokers have increased tracheobronchial secretions with decreased ciliary transport function. They may already have significant pulmonary dysfunction, which may be manifested by diminished exercise tolerance. The forced vital capacity may be diminished in restrictive pulmonary disease, whereas the forced expired volume in 1 second is likely to be decreased in obstructive pulmonary disease.
- *Obesity.* Obesity compounds the problems of immobility and increased intra-abdominal pressure in the Trendelenburg position, possibly for many hours. Excessive weight and pressure on the diaphragm and lung bases can lead to marked ventilation and perfusion abnormalities, difficulty in inserting trocars, upward displacement of the carina (leading to possible endobronchial intubation), barotrauma, and so forth.
- *Overhydration*. Patients often experience oliguria during laparoscopy. This may be interpreted as insufficient hydration, and a relative overhydration with IV fluids may ensue. Unless frank pulmonary edema occurs, this cause of mild or moderate respiratory distress in the PACU may not be recognized without a chest x-ray film.

Kendall AP, Bhatt S, Oh TE. Pulmonary consequences of carbon dioxide insufflation for laparoscopic cholecystectomies. *Anaesthesia*. 1995;50:286–289.

B.3. What laboratory tests should be performed preoperatively?

Basic tests should include complete blood count, urinalysis, clotting functions, electrocardiogram (ECG), and blood typing and screening. In addition, baseline electrolytes, chemistries, and renal function tests (blood urea nitrogen, creatinine) should

be obtained because of the possibility of oliguria during a long laparoscopy. Baseline pulmonary function tests, arterial blood gas measurement, and oxygen saturation values while breathing room air would be helpful in this patient. Markedly abnormal values might suggest the need for bronchodilators, antibiotics, postural drainage, and a delay in surgery until pulmonary function is optimal for this particular patient. Baseline chest films are necessary not only to rule out active disease but also for postoperative comparison of acute changes such as subcutaneous or mediastinal emphysema, pneumothorax, or interstitial or pulmonary edema. The presence of bullae on preoperative chest x-ray films may represent a contraindication to laparoscopic surgery because of the accompanying large tidal volumes and high intrathoracic pressures.

In patients with cardiac issues, echocardiogram, stress test, and cardiology clearance may be advisable.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2236–2250.

B.4. What specific information should the patient be given about robotic surgery before obtaining informed consent?

In addition to the usual general complications of the planned surgery and anesthesia, the patient must also be told of the complications unique to robotic laparoscopy, and consent for possible open laparotomy must be obtained. Emergency laparotomy may be required in the event of complications such as hemorrhage, organ perforation, or anatomic or technical difficulties.

B.5. What additional procedures should be done before surgery?

Although the surgery is described as minimally invasive, the

patient must be ready for maximally invasive surgery if necessary. Therefore, the patient must comply with preoperative orders regarding the following:

- Diet—clear liquids may be ingested up to 2 hours before procedures requiring general anesthesia, regional anesthesia, or procedural sedation and anesthesia. A light meal may be ingested for up to 6 hours before elective procedures requiring anesthesia. Additional fasting time, up to 8 hours or more, may be needed in cases of patient intake of fried foods, fatty foods, or meat.
- A complete bowel preparation is necessary.
- Preoperative antibiotics, as per surgeon

American Society of Anesthesiologists. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Task Force on preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration. *Anesthesiology*. 2017;126:376–393.

B.6. What are the three major forces that uniquely alter the patient's physiology during robotic laparoscopy?

- *Pneumoperitoneum* and problems related to the creation, maintenance, and consequences of the increase in intra-abdominal pressure and volume
- CO_2, including its chemical and physical properties and its local and systemic effects
- Extremes of patient *positioning* on the operating table, which in this case will be steep Trendelenburg with total immobility and inaccessibility to the patient's limbs.

It is vital that the anesthesiologist have a thorough understanding of the physiologic consequences of changes in these three forces. Separately or in combination, they have profound effects on the patient's hemodynamic, respiratory, and metabolic functions. The early gynecologic laparoscopies were

usually brief, and they were performed on young, healthy women who tolerated these physiologic trespasses with nearly insignificant changes. These same three forces, however, may produce significant physiologic changes in long, complex procedures in older, sicker patients who may be less able to compensate.

C. Intraoperative Management

C.1. What is the anesthetic technique of choice for robotic-assisted laparoscopy? Why?

The technique of choice for robotic-assisted laparoscopy is general anesthesia with a cuffed endotracheal tube and controlled positive pressure ventilation because of the following reasons:

- The duration of the procedure may be long.
- The Trendelenburg position may cause respiratory compromise and dyspnea in the awake or in the spontaneously breathing patient with abdominal contents under pressure. The obese patient may be especially uncomfortable in this position.
- A nasogastric or orogastric tube, which may be difficult to insert in a conscious patient, is necessary to decompress the stomach and minimize the risk of aspiration or perforation by

trocars. CO_2, as well as N_2O, diffuses into the stomach.

- However, perhaps the most important reason relates to muscle relaxation. Muscle relaxation and paralysis are absolutely necessary because the increase in intra-abdominal pressure and splinting of the diaphragm make spontaneous breathing difficult. It provides a quieter surgical field and better surgical exposure. "Bucking" increases negative pressure in the chest, which increases the risk of pneumothorax or gas dissection. Coughing can further increase pressure in the abdomen and cause movement of, and perforation by, intra-abdominal instruments. Any movement of the patient while robotic instruments are docked may lead to devastating injuries. Moreover, muscle relaxation is necessary to control and augment ventilation to compensate for the hypercarbia and respiratory acidosis that result from absorption of CO_2.

Whalley DG, Berrigan MJ. Anesthesia for radical prostatectomy, cystectomy, nephrectomy, pheochromocytoma, and laparoscopic procedures. *Anesthesiol Clin North Am*. 2000;18(4):899–917.

C.2. Can a laryngeal mask airway (LMA) be used?

Although successful use of the LMA has been reported by several British groups for very brief laparoscopic procedures in healthy patients, its use is contraindicated in robotic procedures. The LMA does not provide stable airway control or protect against aspiration. It also limits the ability to apply positive pressure ventilation and interferes with the use of an orogastric tube.

Bapat PP, Verghese C. Laryngeal mask airway and the incidence of regurgitation during gynecological laparoscopies. *Anesth Analg*. 1997;85:139–143.

C.3. What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic

agents contraindicated?

Almost any combination that provides amnesia, analgesia, and paralysis is suitable.

Use of an antiemetic is recommended to counteract the nausea that results from peritoneal stimulation and bowel distention (secondary to diffusion of CO_2 into the bowel). Small doses of the antiemetic droperidol had been used effectively because it potentiated sedation; was long acting; could be given early in the procedure; and as an α-blocker, helped counteract the hypertensive effects of systemic CO_2. Other antiemetics include the serotonin ($5\text{-}HT_3$) receptor antagonists, ondansetron, and dolasetron. These may be combined with dexamethasone.

Propofol also has an HT_3 antiemetic effect. However, a propofol-based maintenance anesthetic, when combined with neuromuscular block, may not adequately prevent patient awareness. A bispectral index (BIS) monitor may be helpful in that situation.

A vagolytic drug should be at hand because acute stretching of the peritoneum may cause reflex bradycardia. This is more likely to occur in young women than in older adults.

Halothane, although no longer current, was known to cause arrhythmias in the presence of hypercarbia. Hypnotics and sedatives should be used cautiously in older adults because their duration may be prolonged.

Scuderi PE, D'Angelo R, Harris L, et al. Small-dose propofol by continuous infusion does not prevent postoperative vomiting in females undergoing outpatient laparoscopy. *Anesth Analg*. 1997;84:71–75.

Seed RF, Shakespeare TF, Muldoon MJ. Carbon dioxide homeostasis during anaesthesia for laparoscopy. *Anaesthesia*. 1970;25:223–231.

C.4. Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O

cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?

The use of N_2O in laparoscopy has been considered controversial because of its effects on bowel distention during surgery and nausea and vomiting postoperatively.

In examining the issue of bowel distention with N_2O, note that the diffusion capacity of N_2O is approximately 14 times that of oxygen and 28 times that of nitrogen (see **Table 26.1**). Therefore, in a closed space that contains air, N_2O enters faster than N_2 can leave, thereby increasing the size of the closed space. If the walls of that space cannot expand, then the pressure within that space will rise. It has been shown that the volume of an enclosed intestinal air pocket can be doubled by the inhalation of 70% N_2O for 2 hours and tripled in 4 hours. When N_2O is limited to 50%, pocket volume increases no more than 50%. A much more rapid increase in gas volume occurs in the pleural space, where volume was shown to double in 10 minutes, triple in 45 minutes, and quadruple in 2 hours. The faster rate of pleural gas expansion as compared to bowel gas expansion may in part be due to the greater blood flow to the pleura and possibly due to direct diffusion of N_2O from the alveoli adjacent to the pleura.

However, during laparoscopy, we are concerned about CO_2 pockets and not air pockets. N_2O, which has a diffusion capacity almost as great as CO_2, will diffuse from the bloodstream into the intraperitoneal pocket of 100% CO_2 at a rate determined by its solubility in water, its diffusing capacity through an aqueous membrane, and its pressure gradients (as discussed in section A.12). Similarly, CO_2 will leave the peritoneal cavity according to its pressure gradients and solubility and diffusion characteristics. Eventually, the amount of N_2O found in the

peritoneal cavity can be significant, and theoretically, it can form an ignition hazard. However, Hunter et al. state that it is necessary for methane or hydrogen to occupy at least 5.5% of the gas volume for N_2O to support combustion, a condition that does not naturally occur.

In the situation of an air pocket in the bowel, it is well known that N_2O will diffuse in according to its gradients, thereby enlarging the pocket. However, even in the absence of N_2O, CO_2 also will diffuse into this pocket and expand it in a manner that is clinically indistinguishable from N_2O.

N_2O is often blamed for a distended bowel during laparoscopy; however, CO_2 is equally capable of diffusing into and distending the bowel. In a double-blinded study of bowel distention in patients undergoing laparoscopic cholecystectomy with either isoflurane 70%-N_2O-oxygen or isoflurane-air-oxygen, the surgeon was able to identify the use of N_2O correctly only 44% of the time. In addition, postoperative nausea and vomiting was independent of the use of N_2O because the incidence was similar in both groups. Another study found no difference in the incidence of postoperative nausea and vomiting between groups receiving propofol-air-oxygen or propofol-N_2O-oxygen in gynecologic laparoscopy. In fact, the propofol-N_2O-oxygen group had the advantages of significantly more rapid emergence, using 30% less propofol, additional analgesia, and less risk of awareness.

Because of these issues, it is recommended that N_2O, if used at all, be limited to not more than 50% of the inspired mixture. Alternatively, a mixture of 75% air and 25% oxygen (fraction of inspired oxygen [F_{IO_2}] = 40%) may be a wiser choice.

C.5. Can laparoscopy be performed under local or regional anesthesia?

Yes. Although unsuitable for robotic procedures, the use of local or regional anesthesia for very brief diagnostic laparoscopic procedures has been reported. However, under local anesthesia, CO_2 may cause pain intraperitoneally, which is referred to the shoulder. It is for this reason that N_2O, which is nonirritating to the peritoneum, had been used as the insufflating gas without cautery. However, rapid peritoneal distention causes nausea that may be exacerbated without a nasogastric tube. Because of patient discomfort, the surgeon may obtain suboptimal visualization of the surgical field. Also, the possibility of having to open the abdomen, although unlikely, speaks against local anesthesia.

Regional anesthesia can be used for laparoscopy. However, it too has serious drawbacks. It requires a high level of sensory block, possibly causing dyspnea in the Trendelenburg position. A nasogastric tube may not be tolerated. Hyperventilation in

response to hypercarbia may cause too much movement in the surgical field, and spontaneous ventilation may be inadequate to compensate for hypercarbia in the Trendelenburg position.

Regional anesthesia may also be combined with general anesthesia. Because the systemic response to hypercarbia is mediated primarily through sympathetic stimulation, the sympathetic denervation resulting from high regional anesthesia will result in hypotension and decreased cardiac output rather than the hypertension and increased cardiac output usually seen with general anesthesia.

Use of IV analgesics or propofol during regional anesthesia may result in respiratory depression or obstruction, especially in steep Trendelenburg position. Hypoxia in the presence of hypercarbia may have serious cardiovascular consequences.

C.6. What monitors and devices would you apply to the patient? Why?

The usual intraoperative monitors, including standard five-lead ECG with ST trending; systemic blood pressure (BP) using automated oscillometry; pulse oximetry; capnography; a nerve stimulator; and indicators of inspired oxygen fraction, minute ventilation, and peak airway pressures are necessary. An esophageal probe may be used for both temperature monitoring (optimal at the distal esophagus) and for breath, heart, and murmur sound monitoring (at heart level). Body temperature should be maintained with a forced warm air heating blanket, warmed IV fluids, or other means. (For robotic procedures, the warming blanket may be placed under the patient.) Rarely,

central venous pressure (CVP), pulmonary artery pressure, pulmonary artery occlusion pressure (PAOP), and cardiac output may be measured in patients with severe cardiac or pulmonary abnormalities. A BIS monitor may be used. Other possibilities include Doppler, transesophageal echocardiography, and noninvasive assessment of cardiac output by thoracic bioimpedance or thoracic ultrasound. An arterial line is suggested for longer, more complex procedures in sicker (ASA classes III and IV) patients. All monitors must be placed and checked before the patient becomes secured to the table and inaccessible as the robot is docked.

Intermittent sequential compression antiembolic stockings should be applied. Shoulder braces or adhesive taping are used for support in the Trendelenburg position. After induction, a nasogastric or orogastric tube and a Foley catheter are inserted for decompression of stomach and bladder. Use of an orogastric tube is not optional. In addition to the danger of regurgitation from the increased abdominal pressure, there are reports of stomach perforation by trocars. The orogastric tube should not be clamped after initial placement, and intermittent suctioning should continue because CO_2 gas continues to diffuse into the stomach and distend it.

In addition to mechanical monitoring, visual and tactile monitoring should be attempted if the position of the robotic arms allow it. Skin color, skin turgor, and capillary refill should be monitored because they can change abruptly. The head, neck, and upper chest may assume a purplish color in the dependent position, especially during hypercarbia. The upper chest wall may not be accessible to check for subcutaneous emphysema. The cornea and conjunctiva should be checked periodically for edema, especially in the Trendelenburg position, and also whenever oliguria occurs because the extent of the edema may influence your decision on when to extubate.

It is important to maintain accurate data on the volume of fluids infused, and the patient's hourly or half-hourly urine output, along with observations on its color and concentration. Despite adequate hydration, oliguria frequently occurs during pneumoperitoneum, especially at intra-abdominal pressures approaching or exceeding 15 mmHg. The acute increase in intra-abdominal pressure is transmitted to the kidneys and is believed to cause shunting from the cortex to the medulla of the kidney, resulting in a decreased urine output. Diuresis usually occurs rapidly on release of intra-abdominal pressure.

C.7. How is the patient to be positioned? What special precautions are required for robotic laparoscopy?

In pyeloplasties, the side to be worked on is usually elevated, enabling gravity to assist in separating the organs and allowing blood to pool away from the operative field. For other laparoscopies, the patient may be supine; in the Trendelenburg position for urology; in dorsal lithotomy for gynecology; in the head-up position for upper gastrointestinal and biliary tract surgery; and in the lateral decubitus position for thoracoscopy, nephrectomy, and adrenalectomy. For standard conventional laparoscopy, you may or may not be able to keep one or both arms out on boards.

Robotically assisted laparoscopies require careful attention to detail before the robot is docked because no movement of any kind should be possible afterward. Thus, it is especially

important to check that any IV or arterial lines as well as BP cuff, ECG leads, and pulse oximeter are functioning properly after the arms have been carefully padded and tucked at the patient's sides. This must be done before the patient is lowered into Trendelenburg position. Once the robot is locked into position, you will no longer have access to check the arms or look under the drapes. It is a good idea to cut off the clamps on the IV tubing that may press into the patient's skin while the arms are tightly tucked.

Next, after satisfactory general endotracheal anesthesia has been obtained, the surgeons must secure the patient's position on the table so that he does not slide when placed in extreme Trendelenburg position. One technique is to place towels or sponges across the patient's chest, followed by crisscrossing of wide adhesive tape reaching from one side of the table and patient's chest to the opposite shoulder and opposite side of the table. This X formation is designed to secure the patient to the table. While the surgeons are applying the tape, it is recommended that you put your hand under the chest sponge to ensure that the tape is not tight enough to restrict chest expansion. Other techniques such as padded shoulder braces may be used instead of tape, but the incidence of brachial plexus injury is higher with these.

With the knees flexed in padded leg holders, the patient is now carefully lowered into steep Trendelenburg position. Robotic laparoscopy frequently requires steeper Trendelenburg positioning than conventional laparoscopy, resulting in a greater number of positioning injuries. Care must also be taken to ensure that movements of the large bulky robotic arms do not come in contact with the patient.

C.8. How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?

Respiratory

Vital capacity and FRC are reduced. The abdominal contents restrict movement of the diaphragm, especially in the obese and in older adults. Decreased compliance, increased ventilation-perfusion abnormalities, and cephalad displacement of the mediastinum commonly occur. Upper airway edema and displacement of the endotracheal tube may occur.

Circulatory

In healthy patients, the Trendelenburg position results in minimal circulatory changes. Venous return and cardiac output are increased, whereas CVP, PAOP, SVR, and heart rate are essentially unchanged. In patients with cardiovascular disease, the Trendelenburg position may result in increased CVP, PAOP, and decreased cardiac output. The increase in venous return and myocardial oxygen demand that occurs in severe cardiovascular disease can precipitate acute heart failure.

These respiratory and circulatory changes caused by the Trendelenburg position are further amplified by the CO_2 insufflation. Ventilation may become difficult, especially in obese patients. Use of positive end-expiratory pressure (PEEP) is advised to prevent atelectasis. To prevent peak inspiratory pressures from becoming excessive, switching from volume-

controlled to pressure-controlled ventilation may be warranted. In addition, a prolonged inspiratory duration, such as an inspiratory-to-expiratory (I:E) ratio of 1:1 or 2:1 rather than the conventional 1:2, may provide better gas exchange.

C.9. What techniques are available for initial access to the peritoneal cavity? What anesthetic problems can arise during insufflation?

Pneumoperitoneum can be achieved by a “blind” or closed technique of percutaneous insertion of the 2-mm diameter

hollow Veress needle, which after verification of correct positioning, is connected to the CO_2 insufflator.

Alternatively, if previous surgery or adhesions are to be avoided, an "open" approach or periumbilical mini-incision is created, and the blunt-tipped Hasson cannula is inserted without prior pneumoperitoneum. The laparoscope is then inserted through the trocar to verify the intra-abdominal position before insufflation begins.

Before either technique is attempted, the stomach must be decompressed with an orogastric tube and the bladder with a Foley catheter. During insufflation, abdominal distention should be evenly distributed in all four quadrants. CO_2 is insufflated slowly until a pressure of 10 to 15 cm is reached. Respiratory variations of intraperitoneal pressure should be visible, and peak inspiratory pressures will gradually increase as the abdomen distends. It is at this time that the anesthesiologist should be alert to the possibility of vagally mediated reflexes. Bronchospasm, bradycardia, and even sinus arrest have been reported, especially in young women. Visceral and vascular perforations are also well-reported complications, especially with the blind technique. Cardiovascular collapse and gas emboli have been reported when CO_2 has been inadvertently insufflated directly into a blood vessel.

C.10. What intravenous (IV) solution and how much fluid

volume do you plan to infuse?

Large-bore IV catheters should be placed because of the possibility of major hemorrhage. The amount of IV fluid infused is of vital importance, especially in older adults. Transient oliguria during laparoscopy is common. In calculating fluid requirements during laparoscopy, it is important to remember that much less "third spacing" occurs than in open surgery, no fluid loss is caused by evaporation, and the volume of retained (after suctioning) intraperitoneal saline used for irrigation by the surgeon should be added to the final total volume of infused IV fluids. In addition, the intra-abdominal humidification of the insufflated dry CO_2 gas results in only a negligible insensible water loss. Unlike open intraperitoneal cases, our starting fluid replacement is approximately 4 mL/kg/hr of Ringer's lactate solution; as needed, additional fluid is given based on the patient's preoperative hemodynamic status, intraoperative blood loss, and the volume of residual intraperitoneal irrigation fluid used by the surgeon.

After the pneumoperitoneum is released, diuresis occurs promptly and renal function quickly returns to normal (see section C.22).

For robotic laparoscopies, surgeons prefer that IV fluids are minimized until the anastomoses are completed. This keeps excessive fluids out of the surgical field and also helps prevent edema of the face, eyes, and larynx while in the steep Trendelenburg position. At our institution, after the anastomoses are complete, we infuse the majority of the IV hydration, the average blood loss is less than 250 mL, and the usual total fluid replacement is 3 to 3.5 L of lactated Ringer's solution.

C.11. Under what circumstances should laparoscopy be converted to laparotomy?

Laparotomy should be performed immediately in cases of major bleeding or organ damage. Other circumstances include persistent problems with inadequate exposure, a procedure beyond the surgeon's capability, a procedure taking too long, the inability to create or maintain pneumoperitoneum, patient deterioration, equipment failure, and discovery of other unsuspected disease.

Tabboush ZS. When hypotension during laparoscopic cholecystectomy indicates termination of the laparoscopy. *Anesth Analg*. 1994;79:195–196.

C.12. What is the arterial to end-tidal CO_2 gradient ($PaCO_2$–$EtCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?

In the awake person at rest, the normal arterial to end-tidal co_2 gradient is small, ranging from 2 to 6 mmHg. The gradient and its variations are measures of the alveolar dead space. The gradient is the sum of the difference between the arterial CO_2 ($Paco_2$) and alveolar CO_2 ($PAco_2$) plus the difference between the alveolar CO_2 ($PAco_2$) and end-tidal CO2 ($Etco_2$). It is commonly increased in emphysema. The difference is increased when underperfused alveoli are ventilated, as often occurs during hyperventilation in laparoscopy.

The total physiologic dead space consists of the anatomic

dead space (passageways that do not participate in gas exchange, approximately 150 mL) and the alveolar dead space (i.e., underperfused alveoli). The alveolar dead space gas is expired at the same time as the alveolar ideal gas from well-perfused alveoli in equilibrium with pulmonary capillary blood. The dilution of the ideal alveolar gas by the alveolar dead space gas is represented by the end-tidal CO_2.

Some of the factors resulting in a relative increase in ventilation:perfusion ratio include mechanical ventilation, hyperventilation, rapid or shallow ventilation, and the Trendelenburg or lateral decubitus position.

Some of the factors resulting in a relative decrease in ventilation:perfusion ratio include hypotension, decreased cardiac output, myocardial depression from inhalational anesthetics, pulmonary emboli, high positive airway pressure, and ablation of the hypoxic pulmonary vasoconstriction reflex.

C.13. Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $Et CO_2$ exceed the $Pa CO_2$? Why?

An arterial line is recommended whenever the laparoscopic procedure is unusually complex or long or when the patient has significant cardiopulmonary disease. In such cases, ventilation-perfusion abnormalities, intraoperative hypoxemia, marked hypercarbia, or high airway pressures may be expected. During these situations, and possibly in all laparoscopies, an unsteady state exists with respect to CO_2, and the assumption that $Et CO_2$

may accurately reflect a predictable relationship to $PaCO_2$ is not valid.

End-tidal CO_2 tension can either estimate $PaCO_2$, frequently underestimate $PaCO_2$, or infrequently overestimate $PaCO_2$. Furthermore, the values for these two measurements do not always change proportionally or do they always change in the same direction. The relationship between $EtCO_2$ and $PaCO_2$ varies during the course of the procedure. At the beginning of insufflation, $EtCO_2$ can be used as a rough estimate of $PaCO_2$. However, when redistribution of the excess CO_2 from the well-perfused tissues to the less well-perfused tissues begins, $EtCO_2$ begins to underestimate the $PaCO_2$. Characteristically, the arterial to end-tidal CO_2 difference progressively increases as hyperventilation (and dead space) increases.

Especially during strenuous exercise when metabolic CO_2 production is increased and during laparoscopy when excess exogenous CO_2 must be excreted, the $EtCO_2$ may be found to exceed the $PaCO_2$. This condition has also been reported in a hyperventilating patient during cesarean section. This occurs because the $PaCO_2$ fluctuates during each deep breath and may not represent the highest value at that instant, whereas the $EtCO_2$ shows the maximal value (i.e., because of tidal ventilation and pulsatile blood flow in exercise, $EtCO_2$ may exceed mean alveolar and arterial CO_2).

C.14. What are the possible causes of hypercarbia?

- Hypoventilation
- CO_2 in the inspired gas—rebreathing endogenous CO_2 will increase $PaCO_2$ by 3 to 6 mmHg per minute.
- Increased endogenous CO_2 production or exogenous CO_2 supply—occurring in the hypermetabolic states of malignant hyperpyrexia, fever, and hyperthyroidism or occurring during laparoscopy and following the administration of bicarbonate or lactate (One ampule of 50 mEq of bicarbonate liberates more than 1 L of CO_2.)
- Increased dead space (rare) as in pulmonary embolism, ventilation of a lung cyst, or advanced COPD

C.15. What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?

- Patients with significant cardiopulmonary disease
- Intra-abdominal pressure greater than 15 mmHg
- Presence of subcutaneous emphysema
- Retroperitoneal rather than intraperitoneal approach
- Long duration of laparoscopy

C.16. How rapidly does the $PaCO_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $PaCO_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?

In the apneic patient, $Paco_2$ rises at the rate of 3 to 6 mmHg per minute. Rebreathing, or inhalation of 5% CO_2 in oxygen, causes a much more rapid rise in $Paco_2$ up to 8 to 10 mmHg per minute. The difference in rate of rise between endogenous and exogenous CO_2 is explained by the presence of large body stores of CO_2. Approximately 120 L of CO_2 exist in the body (100 times the amount for oxygen) distributed among well-perfused tissue (e.g., blood, brain), moderately perfused tissue (e.g., muscle), and poorly perfused tissue (e.g., fat, bone). These storage places adjust slowly to acute CO_2 changes. In the steady state, the amount of CO_2 produced metabolically in the body is equal to the amount expired through the lungs, and there is no change in the body stores of CO_2. During laparoscopy, an unsteady state exists, with the rate of rise of Pco_2 being greatest during the first 20 to 30 minutes. After that time, new equilibrium levels are reached between the different compartments, and the Pco_2 rate of rise is slower.

Frumin et al. studied the hypercarbic state during their classic study of apneic oxygenation. In paralyzed apneic intubated denitrogenated oxygenated patients receiving only thiopental for amnesia, Frumin et al. demonstrated at least a 3 mmHg average

rise in $Paco_2$ per minute and an ultimate $Paco_2$ as high as 250 mmHg (pH 6.72) while maintaining 98% to 100% oxygen saturation after 53 minutes of apnea. They also found that the hypercarbia was accompanied by hypertension; mean arterial pressure rose 26% and then fell 14% after the return of respirations and normocarbia. Other features accompanying apneic hypercarbic hypertension included normal sinus rhythm with an essentially unchanged rate, rising arterial epinephrine and norepinephrine concentrations, and rising arterial potassium levels (which rose still further after ventilation and normocarbia resumed) with unchanged sodium levels.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:319–326.

C.17. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the cardiovascular system?

The effects of hypercarbia on the circulatory system are complex and often contradictory. At the cellular level, hypercarbia is a direct depressor of myocardial contractility and rate of contraction; it is also a direct stimulant of myocardial irritability and arrhythmicity. These effects may be enhanced by acidosis.

The direct effect of hypercarbia on isolated or denervated blood vessels is a diminished responsiveness to catecholamines and vasodilation especially on the venous side, leading to peripheral pooling, decreased venous return, and decreased cardiac output. The exception to the dilatory effect of hypercarbia and acidosis on blood vessels exists in the pulmonary vessels, which vasoconstrict. It appears, however, that the effects on the pulmonary vessels are actually due to

acidosis rather than hypercarbia because if the pH is kept constant while the P_{CO_2} rises, pulmonary vascular resistance (PVR) does not change.

In the patient, however, the direct or local effects of CO_2 can be overshadowed by a variety of systemic effects. Simultaneous with these local or direct effects, hypercarbia causes profound systemic changes secondary to stimulation of the central nervous system and sympathoadrenal system. The net effect usually includes an increase in cardiac output, heart rate, force of myocardial contraction, BP, and CVP, vasoconstriction in the pulmonary (capacitance) vessels, and a decrease peripheral resistance. The rise in cardiac output of up to 50% exceeds the rise in BP because of the drop in peripheral resistance and increase in blood flow primarily in the cerebral and coronary circulations. This net stimulatory effect accompanies the elevation of Pa_{CO_2} up to approximately 90 mmHg. Above this level, further increases in CO_2 cause a marked drop in response.

In a normal anesthetized human breathing 7% to 15% inspired CO_2, these stimulatory changes were shown to correspond primarily to rising plasma concentrations of epinephrine and norepinephrine. When the sympathoadrenal response was prevented by subarachnoid block, ganglioplegics, or α-adrenergic blockers, the cardiovascular response to inhaled CO_2 were hypotension and decreased cardiac output. The stimulatory response also is diminished by general anesthesia.

Hypercarbia can cause arrhythmias during epinephrine infiltrations or in the presence of halothane but not other anesthetics. Other than in these two circumstances, hypercarbia is not arrhythmogenic unless hypoxia also is present.

The full range of possible effects of hypercarbia on the cardiovascular system are subject to many influences. Healthy (ASA class I) patients are less likely than ASA class III patients

to undergo extreme changes. Similarly, a brief surgical duration, head-up positioning, low intra-abdominal pressures, and intraperitoneal (rather than extraperitoneal) surgery can limit the range of physiologic and metabolic responses to near normal.

In the patient with marginal cardiovascular function, however, peritoneal insufflation can result in a significant increase in cardiac workload. In this situation, transesophageal echocardiography can be a useful noninvasive method to assess left ventricular function.

Arrhythmias such as bradycardia, nodal rhythm, or even asystole can follow rapid peritoneal distention and vagal stimulation. In general, BP, pulse, cardiac output, and CVP will increase up to an intra-abdominal pressure of 15 mmHg. At insufflation pressures of 20 to 30 mmHg, a decrease in BP, cardiac output, and CVP will occur because pressure on the inferior vena cava decreases venous return. Pneumoperitoneum also may induce changes in the cardiac electrical axis, which may affect interpretation of the ECG seen on the monitor during the operation.

C.18. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the respiratory system?

Hypercarbia and acidosis stimulate the respiratory center both directly and indirectly through chemoreceptors, hormones, and autonomic nerves. In the conscious patient breathing oxygen, the maximal stimulating effect occurs at 100 to 150 mmHg, producing minute volumes of up to 75 L. Above these levels, CO_2 becomes a respiratory depressant. Current anesthetics blunt the stimulatory respiratory response to CO_2. Diethyl ether, however, the only volatile anesthetic known to stimulate respiration, reportedly allowed a patient to continue to breathe spontaneously with an inadvertent P_{CO_2} of 234 mmHg.

In the awake patient, each millimeter of mercury increase in $Paco_2$ increases ventilation by 2 to 3 L per minute (if Pa_{O_2}, is constant). This response is diminished by anesthesia. Hypercarbia also produces bronchodilatation; acidosis, rather than hypercarbia per se, causes pulmonary vascular constriction.

General anesthesia with intubation and mechanical ventilation results in a decrease in FRC, which is caused by loss of muscle tone, diaphragmatic displacement, and loss of thoracic volume. Lung compliance drops, airway pressures increase, and ventilation/perfusion mismatch occurs. However, most patients have no difficulty tolerating these changes. These changes are exaggerated in the Trendelenburg position, especially in older adults, the obese, and those with preexisting cardiopulmonary disease. Intrathoracic, peak inspiratory, and plateau pressures increase and then increase even further when

pneumoperitoneum creates an increase in pressure and volume by pushing abdominal contents cephalad. Endobronchial intubation can occur as a result of cephalad movement of the carina, and it should be ruled out if hypoxemia occurs.

C.19. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the central nervous system?

The brain is particularly sensitive to changes in Pa_{CO_2}. Slight elevations of CO_2 cause direct cortical depression and increase the threshold for seizures. Higher levels of CO_2 (25% to 30%) stimulate subcortical hypothalamic centers, resulting in increased cortical excitability and seizures. This hyperexcitability level is enhanced by adrenal cortical and medullary hormones released secondary to hypercarbia-induced

stimulation of the hypothalamus. Further elevations of CO_2 cause an anesthetic-like state of cortical and subcortical depression.

CO_2 was first used as an anesthetic by Hickman in 1824 and reintroduced by Leake and Waters in 1928. CO_2 caused an N_2O-like narcosis at approximately 90 to 120 mmHg. However, hypercarbia also causes increased excitability of neurons so that seizures occurred shortly afterward.

CO_2, not H^+, crosses the blood–brain barrier and the brain cell membrane and affects the cell's metabolism. Therefore, a change in $Paco_2$ also causes a rapid change in cerebrospinal fluid (CSF) pH. CO_2 is the most important factor in regulating cerebral blood flow (CBF). The relation between CBF and $Paco_2$ is essentially linear from 20 to 100 mmHg, with maximal vasodilatation occurring at approximately 120 mmHg. Normal CBF is approximately 12% to 15% of cardiac output or 50 mL/100 g/min. For each 1 mmHg increase in $Paco_2$ between 20 and 80 mmHg, CBF increases by 2% to 4%. Hypercarbia decreases cerebral vascular resistance, causing CBF to increase.

Hypercarbia causes an increase in intracranial pressure, probably secondary to vasodilation. When the patient is placed in the Trendelenburg position, venous congestion of the head and neck occurs. Additional increases in intra-abdominal and intrathoracic pressures contribute to further increase intracranial and CSF pressures.

Therefore, an acute rise in intra-abdominal pressure (pneumoperitoneum) causes an immediate rise in intracranial pressure. This occurs through intermediary steps that include compression of the inferior vena cava (resulting in decreased drainage in the lumbar plexus), increased CVP, increased mean arterial pressure, increased intrathoracic pressure, increased venous stasis, increased pressure in the sagittal sinus, and

decreased resorption of CSF. Hypercarbia contributes to the increased intracranial pressure, but hyperventilation will not decrease the elevated intracranial pressure until the elevated intra-abdominal pressure is released.

Intraocular pressure is also increased during Trendelenburg position with pneumoperitoneum but apparently is well tolerated by most patients.

C.20. What are the neuroendocrine changes that occur during laparoscopy?

Excessive intra-abdominal pressure and hypercarbia may activate the sympathoadrenal axis, resulting in increased plasma levels of epinephrine and norepinephrine. Renin, cortisol,

aldosterone, antidiuretic hormone, and atrial natriuretic peptide levels are also increased. In awake patients in the Trendelenburg position, increased secretion of atrial natriuretic peptide occurs, probably in response to increased venous return and atrial stretching. During pneumoperitoneum, however, secretion of atrial natriuretic peptide diminishes, suggesting interference with venous return.

C.21. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the renal system?

Oliguria has been observed frequently during laparoscopy despite adequate hydration. Although prerenal causes such as hypovolemia, positive pressure ventilation, and PEEP can contribute to oliguria, it is believed that neurohumoral changes (e.g., antidiuretic hormone secretion) secondary to hypercarbia and increased intra-abdominal pressure secondary to insufflation may be responsible for the oliguria that occurs during laparoscopy. Sympathetic stimulation causes a release of catecholamines, resulting in decreased renal cortical blood flow with shunting of blood to the adrenal medulla, constriction of glomerular afferent arterioles, and decreased glomerular filtration rate. It has been shown that when intraperitoneal insufflation reaches a pressure of 15 mmHg, renal cortical blood flow decreases approximately 60% and a reversible 50% drop in

urine volume occurs. In contrast, no decrease in urine output occurred when the abdominal wall was lifted with a force of 15 mmHg during "gasless laparoscopy." It has also been shown that pneumoretroperitoneum, which causes a more gradual increase in intra-abdominal pressure, also caused a more gradual decrease in renal perfusion. Finally, it has been shown that unilateral retroperitoneal insufflation causes decreased renal cortical perfusion of only the ipsilateral kidney if the intra-abdominal pressure is not elevated.

C.22. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the bowel and gastrointestinal system?

Although CO_2 directly causes vasodilatation of the splanchnic capillary beds, the increased intra-abdominal pressure of laparoscopy decreases perfusion, increases SVR, impairs gastric submucosal perfusion and metabolism, and may cause bowel hypoxia at high pressures. On release of the intra-abdominal

pressure, residual CO_2 again causes vascular dilation, allowing additional CO_2 to enter the bloodstream. Myoelectric activity and recovery from ileus is faster after laparoscopic than after open surgery. The combined effect of the increase in abdominal pressure, stretching of the peritoneum by insufflation, and diffusion of CO_2 into bowel is probably responsible for any postoperative nausea.

C.23. How would you recognize a CO_2 embolism during laparoscopy? How does this differ from an air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of CO_2 emboli?

The incidence of venous gas embolism is less in robotic-assisted laparoscopic radical prostatectomies than in radical retropubic prostatectomies. It is more likely to occur during the transection of the deep dorsal venous plexus than during the initial insufflation.

Gas embolism can occur whenever the internal pressure of an open vessel is less than the external pressure. Gas embolism may cause increased ventilatory dead space, increased PVR, increased pulmonary artery pressure, and decreased cardiac output. Early signs include a rapid drop in end-tidal CO_2 and Pa_{O_2} and an increased Pa_{CO_2}. During laparoscopy, insufflation of a large amount of CO_2 directly into a blood vessel can occur initially after blind Veress needle insertion, especially at high pressures. Hypotension, hypoxia, cyanosis, and/or cardiac arrest can occur. If the gas volume is large enough, a "mill-wheel" murmur may be heard through a precordial or esophageal stethoscope. If ventilation is kept constant, a sudden decrease in end-tidal CO_2 may be noted. The most sensitive means to detect gas emboli are the precordial and transesophageal Doppler and transesophageal echocardiography. Aspiration of foamy blood from a central venous catheter is diagnostic.

CO_2 embolism, however, must be distinguished from air embolism, which is a far more ominous event, as shown in **Table 26.2**. CO_2, being extremely soluble in the presence of red blood cells, is much less life-threatening than an identically sized intravascular bolus of air. It has been reported that the lethal volume of intravascular CO_2 gas in cats is 30 times greater than the lethal volume of intravascular air.

TABLE 26.2 Differences between Air and Carbon Dioxide Emboli

Embolism	Air	CO_2
Composition	79% N_2, 21% O_2	100% CO_2
Origin	Vein open to air	No contact with air
Pressure source	Hydrostatic	Insufflator
Solubility	Negligible	Large
Effect of N_2O	Enlarged	Not enlarged

CO_2, carbon dioxide; N_2, dinitrogen; N_2O; nitrous oxide; O_2, oxygen.

Air emboli can be entrained into open veins above the level of the heart (e.g., head and neck surgery, neurosurgery, cesarean section). Other gases that are present, N_2O, for example, will diffuse into that air space according to their diffusion capacities and pressure gradients. Therefore, N_2O will diffuse in, oxygen will be consumed and/or diffuse out, and the size or pressure of the bubble will increase in proportion to the concentration and duration of N_2O being administered until equilibrium is reached. It has been demonstrated that inhalation of 70% N_2O increased the volume of intestinal gas pockets in dogs by twofold in 2 hours and up to threefold in 4 hours. They calculated that at equilibrium, bowel volume could increase up to a maximum of 400%. When N_2O is limited to 50%, however, the size of the gas pocket will not be more than doubled at equilibrium. It has also been demonstrated that inhalation of 68% to 78% N_2O would cause 300 mL of air in the pleural space to double in volume in 10 minutes and to triple in 45 minutes.

A gas bubble composed of 100% CO_2, however, will not enlarge in a patient inhaling 50% or even 75% N_2O because more CO_2 will diffuse out, be absorbed, or be buffered (also more quickly) than N_2O will move in. CO_2 gas has caused fatal embolisms, and N_2O should be discontinued if embolism is suspected. A study using transesophageal echocardiography in 16 patients undergoing laparoscopic cholecystectomy reported that 11 of the 16 patients (5 during peritoneal insufflation and 6 during gallbladder dissection) had a gas embolism, but all were subclinical with no signs of cardiorespiratory instability. In addition, conditions for creating a CO_2 embolism differ from the conditions required for an air embolism. Other than during direct insufflation of CO_2 into a vein, as during Veress needle insufflation, the capillaries and veins within the abdomen are

collapsed by the positive pressure within the abdomen, thereby minimizing the chance for CO_2 to enter open vessels.

Kim CS, Kim JY, Kwon JY, et al. Venous air embolism during total laparoscopic hysterectomy: comparison to total abdominal hysterectomy. *Anesthesiology*. 2009;111(1):50–54.

C.24. What is the mechanism of increase in shunting resulting from embolization?

Emboli in the pulmonary capillaries cause an increase in PVR (i.e., vasoconstriction), which leads to increased pulmonary artery, right ventricle, and right atrium pressures and an opening of pulmonary precapillary arteriovenous anastomoses, resulting in shunt and hypoxemia.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:109–136.

C.25. How is a gas embolism (CO_2 or air) treated?

- N_2O should be discontinued, and the F_{IO_2} should be increased to 100%.
- Identify and occlude the air entrainment site. Insufflation (in the case of CO_2) should be halted, and the pneumoperitoneum should be released immediately.
- An increase in the rate and volume of controlled ventilation with PEEP has been suggested as a method of minimizing air

entrainment. However, this may decrease the cardiac output and excessively increase the airway pressure and PVR and can lead to paradoxical air embolization.

- If possible, the patient should be placed in steep left lateral decubitus Trendelenburg position to prevent obstruction of the pulmonary outflow tract and right ventricular failure. However, during robotic surgery, movement of the patient is prevented until the robot is undocked.
- A CVP catheter can be useful for diagnosis and for therapeutic aspiration of air. Radial artery cannulation can be useful to track improvement or deterioration.
- Therapy is essentially supportive and may include fluids, vasopressors, and pulmonary arterial catheterization. A large bolus of gas may form a gas lock in the right atrium, decreasing the cardiac output. Smaller bubbles can lodge in the lungs, causing pulmonary hypertension, right ventricular failure, and pulmonary edema. Venous gas emboli may also enter the arterial circulation through an atrial septal defect or patent foramen ovale, a condition that may exist in 20% of patients.

C.26. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?

A pneumothorax can result from the migration of the laparoscopic gas under pressure or from direct pulmonary barotrauma. CO_2 gas insufflated retroperitoneally gains rapid direct access to a vast space and may result in widespread

subcutaneous emphysema and a pneumomediastinum.

During laparoscopy, CO_2 under pressure can pass from the abdominal cavity into the pleural and pericardial spaces through anatomic or congenital paths (e.g., the hiatus around the esophagus) or through acquired defects in the diaphragm. (Embryologically, before the formation of the diaphragm, the peritoneal and pleural cavities are derived from one sac.)

A pneumothorax can be diagnosed by a sudden decrease in pulmonary compliance, an increase in airway pressure, an increase in Et_{CO_2} and Pa_{CO_2}, an unchanged or decreased Pa_{O_2}, an unchanged or decreased BP, abnormal motion of the involved side hemidiaphragm, and the absence of breath sounds without wheezing on the affected side. The shape of the capnogram usually is unchanged. Fiberoptic bronchoscopy will rule out endobronchial intubation, and an intraoperative chest fluoroscopy or x-ray film will confirm the diagnosis.

A pneumothorax caused by laparoscopic gas is easily treated, or it can resolve spontaneously. One study reports an incidence of pneumothorax in 7 of 46 patients undergoing laparoscopic fundoplication for repair of hiatus hernia. In these cases, intraoperative treatment consisted of PEEP and increased minute ventilation to reinflate the lung and increased pressure to decrease the gradient from abdomen to pleural cavity and possibly to seal the tear.

Alternatively, a pneumothorax may be undetected until the patient wakes up and exhibits respiratory distress and restlessness, which can be misinterpreted as pain or inadequate reversal of the muscle relaxant. Treatment consists of 100% oxygen by mask. CO_2 will quickly diffuse out, as can be easily seen by serial blood gases and x-ray films; invasive treatment is unnecessary.

Subcutaneous emphysema is usually identified by finding

crepitus on physical examination; it can also be seen on a radiograph. A pneumomediastinum is diagnosed with a portable chest radiograph. The treatment usually only consists of oxygen and supportive measures. However, tension pneumomediastinum and a compartment syndrome due to severe subcutaneous emphysema will require surgical intervention.

Because of the increased volumes and pressures in the lung during laparoscopy, pneumothorax, pneumomediastinum, and subcutaneous emphysema can also result from barotrauma. This cause of pneumothorax is far more serious and may require tube thoracostomy. Attempts at hyperventilating to decrease the Et_{CO_2} can result in overdistention and rupture of alveoli, with subsequent dissection of the anesthetic gases into the perivascular sheaths, mediastinum, pleura, and fascial planes of the head and neck. Large tidal volumes and rapid ventilator rates can be especially dangerous in patients with COPD or bullae because insufficient emptying time may increase air trapping.

Joris JL, Chiche JD, Lamy ML. Pneumothorax during laparoscopic fundoplication: diagnosis and treatment with positive end-expiratory pressure. *Anesth Analg*. 1995;81:993–1000.

C.27. How would you decide when to extubate?

In addition to the usual criteria for extubation, prolonged laparoscopy in the Trendelenburg position requires that the following problems are resolved before the patient is extubated.

If significant subcutaneous emphysema has occurred (diagnosed by crepitus and persistent hypercarbia), continue mechanical ventilation with oxygen. A significant amount of CO_2 may be held in the vast retroperitoneal space.

Delay extubation if the patient has edema, venous congestion, and duskiness of the head and neck. Check the tongue for edema and the eyes for periorbital, conjunctival, or lid edema. The cuff of the endotracheal tube should be deflated to make sure that a gas leak exists. If it does not, the patient should remain intubated. Keep the patient in head-up position until the conjunctivae no longer seem raised or watery. Potential laryngeal edema will also be diminished by the head-up position.

Causes of edema include dependent stasis from the Trendelenburg position, resistance from elevated abdominal and thoracic pressures, and temporary fluid overload after intraoperative oliguria or anuria. In some cases, it is best to leave the patient intubated with a Foley catheter in place until diuresis has begun.

D. Postoperative Management

D.1. What are some of the unique complications of laparoscopy?

Injuries from Instruments

Improper placement of Veress needle or trocars can cause abdominal wall bleeding, blood vessel or visceral puncture, subcutaneous emphysema, peritonitis, wound infections, hernia at the trocar site, and hemorrhage. Thermal injuries may occur from cautery or laser use. Staples and clips can cause nerve entrapment.

Complications of Pneumoperitoneum

Increased intra-abdominal pressure can result in bowel ischemia, omental or bowel herniation, gastric regurgitation, excessive compression of vena cava, decreased venous return, venous

stasis in legs, hypotension, increased intrathoracic pressure, mediastinal and subcutaneous emphysema, pneumothorax, barotrauma, CO_2 gas embolism, atelectasis, bradyarrhythmias from vagal stimulation of trocar insertion and peritoneal distention, dysfunction of ventriculoperitoneal shunts, referred shoulder pain from CO_2 gas retained under the diaphragm, and nausea and vomiting.

Systemic Effects of CO_2 Absorption

Among the systemic effects of CO_2 absorptions are hypercarbia, acidosis, increased sympathoadrenal stimulation, hypertension, tachycardia, increased intracranial pressure, subcutaneous emphysema, embolization, and sickle cell crisis. Arrhythmias can occur from hypercarbia, hypoxia, and catecholamines.

Trendelenburg Position

Venous congestion of head and neck; increased venous pressure; increased intracranial pressure; retinal hemorrhage; retinal detachment; increased intraocular pressure and glaucoma attack; corneal and conjunctival edema; endobronchial intubation and hypoxemia; ventilation/perfusion mismatch and hypoxia; edema of airway including larynx; airway obstruction and closure; brachial plexus injury from shoulder braces, femoral nerve, peroneal, and other neuropathies; and an assortment of respiratory complications have been reported with use of the Trendelenburg position.

Late Complications

Among the late complications are bowel obstruction from injury, cautery burn, intestine or omentum herniation through the trocar site, adhesions, deep vein thrombosis, and nerve injury resulting from improper padding. Fever may indicate infection from bowel necrosis. Cutaneous metastasis can occur at the port site.

D.2. In the postanesthesia care unit (PACU), our patient complains of numbness and weakness of the lower extremities after 6 hours of anesthesia for robotic prostatectomy. What tests will you order? When would you remove the Foley catheter and arterial line? Under what circumstances would you order a chest x-ray film?

Rhabdomyolysis and compartment syndrome must be ruled out because both occur more frequently in obese patients undergoing long immobilizing procedures. Serial monitoring should be begun for creatine phosphokinase (CPK), lactate dehydrogenase (LDH), creatinine, electrolytes including potassium and calcium, and urinalysis for presence of myoglobin and presence of casts. Treatment should include diuretics and alkalinization of the urine with the aim of high urine output.

Immediate chest x-ray film is ordered if respiratory distress, subcutaneous emphysema, and actual or suspected pneumothorax occurred.

Do not remove the arterial line until the patient is stable and blood gas values are normal. For those patients who have an uneventful recovery, expect an immediate diuresis. Do not remove the Foley catheter until the patient is stable with fluid intake and volume output stable. Order IV fluids. Check voiding after the catheter is removed. Appropriate medications for nausea and pain control must be written. Ketorolac may be given if the surgeon agrees and there is no contraindication. Prophylactic antimuscarinic belladonna and opium (B&O) suppositories may be given to reduce the pain from bladder spasms. Patient-controlled analgesia usually is not necessary. For ambulatory patients, an adult escort must be available to take them home. Most patients, however, stay overnight.

D.3. What is the incidence of postoperative nausea and vomiting?

The incidence of nausea and vomiting after laparoscopy has been reported to be as high as 42%. It is the most important factor in causing an overnight admission after ambulatory surgery. IV antiemetics such as ondansetron, often with dexamethasone, may be given, preferably during surgery. The cause of nausea and vomiting is believed to be rapid peritoneal distention. Neurogenic pathways are activated by traction reflexes and by splanchnic pressure and manipulation.

SECTION 7 The Reproductive System

27 Placenta Previa/Placenta Accreta Spectrum

Jill Fong

A 40-year-old woman, gravida 6 para 5, is electively scheduled for her fourth cesarean section at 36 weeks of gestation. She has placenta previa that was diagnosed by sonography after a single episode of painless vaginal bleeding at 27 weeks of gestation, which resolved spontaneously. Her vital signs are as follows: blood pressure, 110/56 mmHg; heart rate, 85 beats per minute; respiratory rate, 18 breaths per minute; and oxygen saturation (SpO_2), 98% on room air. Her hematocrit (Hct) is 35%.

A. Medical Disease and Differential Diagnosis

1. What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?
2. What is the differential diagnosis for an antepartum

hemorrhage?

3. How would you diagnose the etiology of antepartum bleeding after midpregnancy?
4. What is the incidence of placenta previa, and what are the associated conditions?
5. What are the different types of placenta previa?
6. What is the usual obstetric management for placenta previa?
7. What is vasa previa? How is it diagnosed and managed?
8. What are the risk factors for the development of a placental abruption?
9. How is placental abruption diagnosed and managed?
10. What complications are associated with placental abruption?
11. Who is at risk for uterine rupture, and how is uterine rupture diagnosed?
12. What is the treatment for uterine rupture?
13. Is this patient at risk for postpartum bleeding?
14. What is the placenta accreta spectrum (PAS)?
15. How is the PAS diagnosed?
16. How is the PAS managed obstetrically?
17. What tests and/or interventions can improve neonatal outcome of a preterm birth?

B. Preoperative Evaluation and Preparation

1. How does pregnancy change respiratory function, and what impact does this have on anesthetic care?
2. What are the maternal cardiovascular changes of pregnancy?
3. What are the maternal gastrointestinal changes of pregnancy?
4. What hematologic changes occur during pregnancy?
5. What laboratory data do you need before taking this patient to the operating room?
6. What preoperative medications would you administer to this patient?

C. Intraoperative Management

1. What monitors would you use for this patient?
2. What anesthetic could be used in this patient?
3. What are the absolute and relative contraindications for neuraxial anesthesia?
4. How is postpartum hemorrhage (PPH) defined, and what are the etiologies of this bleeding?
5. After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this patient's bleeding?
6. After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial contractility and therefore decrease blood loss?
7. When should this patient receive tranexamic acid (TXA)?
8. If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?
9. What laboratory tests should be ordered during the resuscitation of this patient?
10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?
11. What is the role of recombinant activated factor VII (rFVIIa) in the hemorrhaging obstetric patient?
12. What is the role of type O Rh-negative (universal donor) uncrossmatched blood in emergency transfusions, and how does this change your future management?
13. What complications can occur from the transfusion of blood products?
14. What is the role of autologous transfusion in obstetric patients?
15. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?

16. What is disseminated intravascular coagulation (DIC)?
17. Define amniotic fluid embolism (AFE) syndrome and discuss treatment.

D. Postoperative Management

1. If the patient received epidural anesthesia and subsequently developed DIC, when should the epidural catheter be removed?
2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?

A. Medical Disease and Differential Diagnosis

A.1. What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?

According to 2018 World Health Organization (WHO) reporting, 99% of maternal deaths occur in developing countries. The WHO defines the maternal mortality ratio (MMR) as the number of direct and indirect maternal deaths per 100,000 live births; it does not include late maternal deaths occurring more than 42 days but less than 1 year after pregnancy termination. The 2015 MMR in developing versus developed countries was approximately 239 versus 12 maternal deaths per 100,000 live births, respectively. Between 1990 and 2015, the worldwide maternal mortality rate dropped by about 44%. Nearly 75% of all maternal deaths are due to severe bleeding, infections, hypertensive disorders of pregnancy, delivery complications, and unsafe abortions. The remainder of deaths are caused by or associated with diseases such as malaria and AIDS during pregnancy. The highest risk of maternal mortality is for

adolescent girls younger than 15 years old, and complications in pregnancy and childbirth are a leading cause of death for adolescent girls in developing countries.

In the United States, based on data from the Pregnancy Mortality Surveillance System of the Centers for Disease Control and Prevention, the pregnancy-related mortality ratio (PRMR) fell significantly during the 20th century. The PRMR tallies the pregnancy-related deaths per 100,000 live births; it includes maternal deaths while pregnant and within 1 year of the termination of pregnancy that occur from any cause related to or aggravated by the pregnancy regardless of the duration or site of that pregnancy but excludes accidental or incidental causes. Because this Pregnancy Mortality Surveillance System was implemented, the number of pregnancy-related deaths has steadily increased from 7.2 deaths per 100,000 live births in 1987 to 18.0 deaths per 100,000 live births in 2014. The reason for this increase is unclear. It may be that more actual deaths are occurring, that reporting has improved, that there is an artificial increase due to code changes with the new International Statistical Classification of Diseases, 10th Revision (ICD-10), that the number of pregnant women with severe chronic health conditions is greater, or that there is an increased proportion of births to women older than 40 years of age. From 2011 to 2014, hemorrhage accounted for 11.5% of these pregnancy-related maternal deaths, cardiovascular disease for 15.2%, other noncardiovascular medical disorders for 14.7%, sepsis 12.8%, cardiomyopathy for 10.3%, thrombotic pulmonary embolism 9.1%, cerebrovascular accidents for 7.4%, hypertensive disorders of pregnancy for 6.8%, AFE for 5.5%, and anesthesia complications for 0.3% of the pregnancy-related deaths. The risk of maternal death is increased in non-Hispanic Black women compared to non-Hispanic White women and in women of advanced maternal age.

In the United Kingdom, the Confidential Enquiry into Maternal Deaths found that from 2014 to 2016, 9.8 women per 100,000 died during pregnancy or up to 6 weeks after childbirth. Most of the women had multiple health problems or other vulnerabilities. The Enquiry includes surveillance data on women who died during or up to a year after pregnancy in the United Kingdom, on women who have died in the United Kingdom and Ireland from mental health conditions, thrombosis/thromboembolism, malignancy and homicide, and on the morbidity associated with the care of women having a major obstetrical hemorrhage. The rate of maternal deaths from direct causes did not change significantly from 2011 to 2013 to 2014 to 2016. Thrombosis/thromboembolism were the leading cause of direct maternal death during or up to 6 weeks after pregnancy. Suicide was the third largest cause of direct maternal deaths occurring during or within 42 days of the end of pregnancy, but it was the leading cause within a year after the end of pregnancy with a mortality rate of 2.8 per 100,000 maternities. The maternal mortality from hemorrhage in the United Kingdom was 0.78 per 100,000 maternities. Of the women who died with obstetrical hemorrhage, they found that 28% of the women had good care, whereas improvements in care may have made a difference for 38% of the women.

In developed regions, the estimated anesthesia-related MMR ranges between 1 and 3 deaths per 1,000,000 live births. If a maternal death can be attributed to an anesthetic complication and if an ideal anesthetic would have likely avoided this death, the death is considered anesthetic related. Based on data from the United States, historically, cesarean sections under general anesthesia were more hazardous than those under neuraxial anesthesia, but case fatality rates for general anesthesia have decreased considerably, whereas those for neuraxial anesthesia have risen slightly leading to no significant difference between

the two in the 1997 to 2002 time period. Looking at 257,000 parturients receiving neuraxial or general anesthesia between 2004 and 2009, the Serious Complication Repository Project of the Society for Obstetric Anesthesiology and Perinatology found that approximately 1 of 3,000 patients had serious anesthesia-related complications with high neuraxial block; respiratory arrest in the labor suite and unrecognized spinal catheters were the most common of these complications. In low- and middle-income countries, however, about 1 in 7 maternal deaths during or after cesarean section were due to anesthesia, which is a very high mortality rate compared with that in developed countries.

A.2. What is the differential diagnosis for an antepartum hemorrhage?

Up to one-fourth of pregnant women may have antepartum vaginal bleeding, but only a small fraction experience an antepartum hemorrhage. Most of this bleeding occurs in the first

trimester, and bleeding in the first 20 weeks is presumed to be a threatened abortion or an ectopic pregnancy. Even if pregnancy loss does not occur, the risk for adverse outcomes later in pregnancy is increased. The rest of this discussion will be confined to pregnancies with a viable living fetus.

Antepartum bleeding generally poses a greater threat to the fetus than the mother. The most common causes of antepartum hemorrhage are placenta previa and placental abruption. From the Canadian Perinatal Network, Sabourin et al. looked at 806 women with an antepartum hemorrhage between 22 and 28 weeks of gestation. The most common causes were placental abruption (31.7%), placenta previa (21.2%), and cervical bleeding (6.6%), whereas no cause for hemorrhage was found in a third of the cases. Placenta previa is the abnormal implantation of the placenta over or adjacent to the cervical os and in front of the fetal presenting part. Placental abruption, or abruptio placentae, refers to the premature separation of a normally implanted placenta from the uterus' decidua basalis before delivery of the fetus.

Rare causes of antepartum bleeding include velamentous insertion of the umbilical cord with the involved placental vessels overlying the cervix, which is known as vasa previa, uterine rupture, cervicitis, and local genital tract lesions.

In the remaining cases, it is not always possible to identify the source of antepartum bleeding. Usually, this type of bleeding begins with minimal symptoms, if any, and stops; no anatomic cause is identified at delivery, and it is likely attributable to marginal placenta separation. However, these pregnancies have a higher risk of poor neonatal outcome and preterm delivery.

A.3. How would you diagnose the etiology of antepartum bleeding after midpregnancy?

With antepartum uterine bleeding after midpregnancy, placenta previa and placenta abruption should always be considered in the differential diagnosis. Digital examination of the cervix *should be avoided* until the diagnosis of placenta previa has been excluded because it can cause immediate, severe hemorrhaging. Classically, it has been taught clinically that painless uterine bleeding is indicative of placenta previa, whereas painful uterine bleeding signifies placental abruption. The differential diagnosis, however, is not actually that straightforward; for instance, labor or placental separation accompanying a previa may cause pain, whereas pain from an abruption may mimic normal labor. Transabdominal sonography is a simple and safe method of locating the placenta in a suspected placenta previa. Transvaginal sonography has been shown to be superior to transabdominal sonography and is currently the imaging modality of choice. Recently, transperineal sonography has been shown to have a 98% positive-predictive value and 100% negative-predictive value of placenta previa. On the other hand, sonography infrequently aids in the diagnosis of an acute placental abruption because fresh clot and placenta appear sonographically similar. Negative findings on sonographic examination do not rule out a placental abruption. Magnetic resonance imaging (MRI) has been used by numerous investigators to visualize placental abnormalities, including placenta previa and placental abruption, and should be considered if the diagnostic information would change patient

management.

A.4. What is the incidence of placenta previa, and what are the associated conditions?

The incidence of placenta previa in the United States is about 1 in 300 to 400 deliveries. The risk of having placenta previa increases with advancing maternal age, multiparity, multifetal gestations, previous cesarean delivery, prior uterine surgery, cigarette smoking, cocaine use, infertility treatments, and unexplained increases in maternal serum α-fetoprotein levels. In approximately 90% of the patients with sonographic evidence of placenta previa at 20 weeks, the placenta moved away from the cervix and out of the lower uterine segment by term.

Placenta previa is associated with an increased risk of antepartum bleeding, intrapartum and PPH, abnormalities of placental adherence, peripartum hysterectomy, blood transfusions, preterm birth with perinatal morbidity and mortality, congenital malformations, and septicemia. In the presence of a prior cesarean section, the patient with placenta previa is at greater risk for having a PAS; this risk increased, as the number of cesarean sections increased. Silver et al. found that in women with placenta previa, the risk of placenta accreta was 3%, 11%, 40%, 61%, and 67% for the first, second, third, fourth, and fifth or greater repeat cesarean deliveries, respectively.

A.5. What are the different types of placenta previa?

Classifications and terminology for placenta previa based on the degree to which the internal cervical os is covered have been confusing; they have been simplified to two terms. Normally, the placenta implants in the upper uterine segment. Currently, *placenta previa* is a term used to describe a placenta that partially or totally covers the internal cervical os, whereas the term *low-lying placenta* refers to a placenta implanted in the lower uterine segment but does not cover and is less than 2 cm away from the os. Clearly, the classification in some cases of placenta previa depends on the degree of cervical dilation at the time of cervical assessment. In vasa previa, the fetal vessels course through the membranes and cover the internal cervical os.

A.6. What is the usual obstetric management for placenta previa?

Obstetric management of placenta previa patients depends on three things: fetal age and therefore maturity, presence or absence of labor, and severity of bleeding. The goal of management is to maximize fetal growth and minimize the possibility of antepartum hemorrhage. With many previa patients, the first episode of bleeding usually begins without warning or pain, stops spontaneously, and rarely causes maternal or fetal compromise, but bleeding often recurs. A mature fetus with or without labor should be delivered; if bleeding occur at or beyond 36 weeks, immediate delivery is indicated. If hemorrhaging is severe or there is concern about the fetal condition, delivery should take place regardless of gestational age. Otherwise, conservative management may safely prolong the pregnancy by an average of 4 weeks after the initial bleed. Between 24 and 34 weeks of gestation, betamethasone, a corticosteroid, often is given to the patient with placenta previa to accelerate fetal lung maturity (FLM), and the Society for Maternal-Fetal Medicine (SMFM) recommends that antenatal steroids be given to women being managed expectantly if delivery is likely within 7 days, the gestational age is between 34 0/7 and 36 6/7 weeks of gestation, and antenatal corticosteroids have not been given previously.

With a preterm fetus and no persistent active uterine bleeding, management consists of close observation for bleeding and activity restriction in an inpatient setting or, in certain selected patients, an outpatient setting. For stable patients with no bleeding in the previous 48 hours who have ready access to hospital care, maternal and fetal outcome did not differ between outpatient and inpatient management. Maternal vital signs and hemoglobin (Hgb) are checked at regular intervals depending on when the bleeding, if it exists, subsides. The American Association of Blood Banks recommends that a blood type and screen be done every 3 days in actively bleeding pregnant

women because of the risk for developing new alloantibodies. Fetal well-being also is assessed regularly. The use of tocolytic therapy in placenta previa patients with preterm labor and bleeding is controversial; it has been used to prolong gestation if both the mother and fetus are stable.

The SMFM recommends that delivery for stable women with placenta previa without bleeding should take place at 36 to 37 6/7 weeks, and if a placenta accreta is suspected, it has been recommended that delivery take place between 34 to 37 weeks. As gestational age increases, there is an increased risk of significant bleeding that would necessitate delivery: 4.7% at 35 weeks, 15% at 36 weeks, 30% at 37 weeks, and 59% at 38 weeks. If an indication for delivery is present, FLM testing does not aid in guiding management in the late preterm period when an indication for delivery is present.

Patients with placenta previa almost always are delivered by cesarean section, and some contend that all women whose placentas lie within 2 cm of the cervical os should be delivered by cesarean section. When the placenta is greater than 1 cm away from the cervical os, however, Vergani et al. and Bronsteen et al. suggest that vaginal delivery may be safe.

Normally, with placenta removal, the myometrium of the uterus contracts and reestablishes vascular integrity by constricting the open vessels in the placental bed. In patients with placenta previa, bleeding after placenta removal can be brisk because the lower uterine segment contracts poorly and therefore does not constrict the avulsed vessels. There is a known association between placenta previa and placenta accreta syndrome that may further exacerbate uterine bleeding and require additional surgical and/or radiologic interventions to staunch the bleeding.

As needed, adequate intravenous access and laboratory studies, including a complete blood count, coagulation profile,

and a type and screen/crossmatch, should be obtained as circumstances dictate. In United States, Rh (anti-D) immunoglobulin (IG) is offered to unsensitized Rh-negative women at 28 weeks of gestation when the fetal blood type is unknown or known to be Rh-positive and again after delivery if the neonate is Rh-positive. Anti-D IG should be administered to Rh-negative women who have an antenatal hemorrhage after 20 weeks. Management of the patient who has intermittent antenatal bleeding is complex. With an acute bleeding episode in an Rh-negative parturient, the most conservative approach is to do a quantitative Kleihauer-Betke test to determine if a fetal–maternal transfusion has occurred and if additional IG is required. It has been proposed that cell-free DNA testing to determine the fetal Rh D status be done to avoid repeated administration of anti-D IG if the fetus is Rh-D negative.

A.7. What is vasa previa? How is it diagnosed and managed?

Vasa previa refers to intramembranous fetal vessels, unprotected by placenta or umbilical cord, coursing through the membranes over the cervical os and under the fetal presenting part. The incidence is approximately 1 in 2,500 deliveries and associated risk factors include a second trimester low-lying placenta/placenta previa, a placenta with accessory lobes, velamentous umbilical cord insertions, multiple pregnancies, and pregnancies from in vitro fertilization. An undiagnosed vasa previa is associated with a high fetal mortality (about 60%). Because fetal blood volume is small, any bleeding puts the fetus in jeopardy. When membranes rupture, either spontaneously or artificially, the fetal vessels running through these membranes often rupture. Vaginal bleeding with fetal distress or death when the membranes rupture is seen in an undiagnosed vasa previa and necessitate an emergency cesarean section based on fetal distress. If vaginal blood is present, the presence of fetal (RBCs) can be determined using a Kleihauer-Betke test or flow cytometry, although there is rarely time for this. Fortunately, the majority of cases of vasa previa can be diagnosed prenatally by routinely evaluating placental cord insertion by ultrasound examination and transvaginal sonographic color Doppler if the insertion site cannot be delineated clearly. Good outcomes in patients with vasa previa require a prenatal diagnosis and delivery by cesarean section before the membranes rupture. If stable, the SMFM recommends that women with vasa previa be delivered between 34 and 37 weeks of gestation.

A.8. What are the risk factors for the development of a placental abruption?

The frequency of placental abruption is about 1 in 200 deliveries. The premature separation of the normally implanted placenta can be total or partial and can lead to external or concealed bleeding. Concealed hemorrhage is associated with greater maternal and fetal risks. The most common condition associated with placental abruption is some type of hypertension, either gestational hypertension, preeclampsia, chronic hypertension, or some combination thereof. The incidence of placental abruption is increased with increased maternal age, body mass index, use of assisted fertility methods, African-American or Caucasian race, prematurely ruptured membranes, a history of previous abruption, cigarette smoking, cocaine use, leiomyomas, an isolated uterine artery, and external trauma. The bleeding in the nontraumatic placental abruption almost always is maternal because the placental separation is within the maternal decidua.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill Education; 2018:767–773.

Downes KL, Grantz KL, Shenassa ED. Maternal, labor, delivery, and perinatal outcomes associated with placental abruption: a systematic review. *Am J Perinatol*. 2017;34(10):935–957.

A.9. How is placental abruption diagnosed and managed?

The signs and symptoms of placental abruption vary considerably. Ultrasonography often does not confirm the diagnosis as the placenta and fresh clots have similar appearances. In severe placental abruptions, the diagnosis often is obvious with fetal distress and demise common. With a live

fetus and vaginal bleeding, milder abruptions may be difficult to diagnose. If knowing would change the patient's management, MRI is a highly sensitive test for detecting placental abruption and should be considered.

Treatment depends on fetal gestational age and fetal and maternal condition. If the diagnosis is uncertain and the fetus is uncompromised, inpatient expectant management with close observation can be practiced. However, further placental separation can occur at any time and lead to serious fetal compromise or death. The use of tocolytics to prolong pregnancy is controversial. Rapid delivery of the compromised, but alive, fetus is by cesarean delivery. Kayani et al. looked at 33 pregnancies with a clinically overt placental abruption and fetal bradycardia. Of the 22 neurologically intact neonates, 15 were delivered within a 20-minute decision to delivery time, whereas 8 of the 11 neonates who died or had cerebral palsy on 1 year follow-up had a >20-minute interval.

If placental separation has led to fetal death, a vaginal delivery usually is preferred; there are two exceptions: a massive hemorrhage that cannot be managed with vigorous blood replacement and obstetric complications that prevent vaginal delivery will necessitate an operative delivery.

Kayani SI, Walkinshaw SA, Preston C. Pregnancy outcome in severe placental abruption. *BJOG*. 2003;110(7):679–683.

Masselli G, Brunelli R, Di Tola M, et al. MR imaging in the evaluation of placental abruption: correlation with sonographic findings. *Radiology*. 2011;259(1):222–230.

A.10. What complications are associated with placental abruption?

Maternal complications with severe abruption can include PPH, hemorrhagic shock, a consumptive coagulopathy, acute renal

injury, and Sheehan syndrome (pituitary failure). Placental abruption can lead to fetal compromise or fetal demise.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill Education; 2018:772.

A.11. Who is at risk for uterine rupture, and how is uterine rupture diagnosed?

Women who have had a uterine rupture in a prior pregnancy have a higher risk of having another one. Women with a previous cesarean delivery have an increased risk of uterine rupture with a classical, T-shaped, or low vertical uterine incision increasing the incidence when compared to a low transverse incision. Other risk factors associated with uterine rupture include previous uterine surgery involving the myometrium; a tumultuous labor; difficult forceps delivery; uterine trauma; breech extraction; external and internal version; labor stimulation with oxytocin or prostaglandins; inappropriate uterotonic medication use; uterine anomalies; placenta increta/percreta; connective tissue defects such as Marfan or Ehlers-Danlos syndrome; and uterine overdistention by fetal macrosomia, hydramnios, or multifetal pregnancy. Primary uterine rupture is defined as a rupture occurring in a previously intact unscarred uterus, whereas a secondary rupture is associated with a preexisting myometrial incision, injury, or anomaly. Uterine rupture is typically classified as either complete, with all of the uterine wall layers separated, or incomplete (uterine dehiscence), with the uterine muscle separated but the visceral peritoneum intact. Uterine dehiscence is more common; it is less likely to cause adverse maternal and fetal derangements or necessitate cesarean delivery. The morbidity and mortality rates are higher when the rupture is complete. Fortunately, uterine ruptures are rare. In developed countries, Getahun et al. report the uterine rupture incidence to

be 1 in 4,800, whereas in developing countries, the incidence is higher. Al-Zirqi et al. found that the incidence of uterine rupture in Norway over a 40-year period increased significantly to about 1 in 1,560 deliveries with obstetric interventions contributing to this increase but not entirely explaining it. The frequency of primary rupture is about 1 in 10,000 to 15,000 births, whereas the incidence in women attempting a trail of labor after previous cesarean delivery varies between about 0.5% and 4%.

Uterine rupture can be difficult to diagnose because of the varied symptoms and physical findings that can occur. The most consistent sign of uterine rupture is a nonreassuring fetal heart rate pattern. In some patients, the symptoms of uterine rupture will be indistinguishable from those of placental abruption. Other signs that may be present include maternal hypotension, tachycardia, vaginal bleeding, abdominal pain, change in the uterine contour, changes in the uterine contraction pattern, and cessation of labor. There may be little pain, and because most of these ruptures occur during labor, any pain may be masked by the analgesics given to treat the discomfort of labor.

Porreco RP, Clark SL, Belfort MA, et al. The changing specter of uterine rupture. *Am J Obstet Gynecol*. 2009;200(3):269.e1–269.e4.

A.12. What is the treatment for uterine rupture?

With a complete uterine rupture, fetal distress and maternal bleeding occur; an emergent cesarean delivery is imperative to deliver the fetus and stabilize the mother. After delivery of the fetus, the uterus can be repaired, the uterine arteries can be ligated, or a hysterectomy can be performed, depending on the size of the rupture and the patient's condition. Fetal distress and/or death are common, whereas maternal death in the developed world is not.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill Education; 2018:598–600, 767.

A.13. Is this patient at risk for postpartum bleeding?

Yes, this patient has a higher chance of postpartum bleeding because of her known placenta previa and the increased risk of having an associated PAS. There is a strong association between placenta previa, prior uterine surgery, and the PAS. In the absence of placenta previa, the frequency of PAS in women having cesarean sections was much lower. The rate of PAS increased from 0.3% in women with one prior cesarean section to 6.74% for women with five or more cesarean deliveries.

Silver RM. Abnormal placentation: placenta previa, vasa previa, and placenta accreta. *Obstet Gynecol*. 2015;126(3):654–668.

A.14. What is the placenta accreta spectrum (PAS)?

PAS, which includes placenta accreta, increta, and percreta, refers to a placenta that adheres abnormally to the myometrium of the uterus due to a partial or total absence of the decidual basalis and an incomplete development of the fibrinoid layer. It was formerly referred to as morbidly adherent placenta. The normal placenta has three general layers: the decidua, which is maternal in origin and adherent to the uterus; the chorion, including the chorionic villi; and the amnion. Both the chorion

and amnion are of fetal origin. Normally, in the first few minutes after delivery of the neonate, the placenta separates from its implantation site at a physiologic cleavage line through the spongy layer of the decidua basalis. In PAS, evidence suggests that not only is the decidua basalis scanty or absent but also that the cytotrophoblasts may exert some control of over decidua invasion via angiogenesis and growth expression allowing chorionic villi to attach to and invade uterine myometrium. Placenta accreta occurs when the placental chorionic villi are attached directly to the uterine myometrium without a decidual layer. With placenta increta, the villi invade into the myometrium, and with placenta percreta, the villi penetrate through the myometrium and serosa of the uterus and, sometimes, into adjacent organs. The abnormal adherence may involve the entire placenta (total placenta accreta), several placental lobules (partial accreta), or part or all of a single lobule (focal placenta accreta).

The incidence of PAS is increasing due mainly to rising cesarean section rates. The incidence was approximately 1 in 2,510 deliveries in the 1980s versus 1 in 533 deliveries for the period from 1982 to 2002. Other more recent reports cite a rate as high as 1 in 300 pregnancies. Increasing cesarean section rates and placenta previa are by far the two most important risk factors. Decidual formation is commonly defective over a previous cesarean section scar, in the lower uterine segment, and/or after uterine surgery. Maternal age greater than 35 years, multiparity, Asherman syndrome, and otherwise unexplained elevations in maternal serum α-fetoprotein concentration and β-human chorionic gonadotropin (β-hCG) are other risk factors associated with placenta accreta.

A.15. How is the PAS diagnosed?

In patients with conditions such as placenta previa and previous uterine surgery that are highly associated with the PAS, it is important to have a high index of suspicion and to look carefully for signs of PAS. Prenatal diagnosis of PAS allows for effective planning that helps minimize maternal morbidity.

Transabdominal and transvaginal ultrasonography are useful modalities for evaluating placental position and implantation; perhaps the most important ultrasonographic association in the second and third trimesters is the presence of placenta previa, which is present in more than 80% of accreta in most large series. Intraplacental vascular lacunae, the loss of the hypoechoic (i.e., clear space) boundary between the placenta and myometrium and/or bladder, decreased retroplacental myometrial thickness, and increased vascularity of the uterine serosa-bladder interface are strongly suggestive of PAS. The sensitivity and specificity of grayscale ultrasonography in detecting PAS are approximately 77% to 87% and 96% to 98%, respectively. Although ultrasound evaluation is important, the lack of ultrasound findings does not rule out a diagnosis of PAS. Clinical factors remain equally important predictors of PAS; there is no single diagnostic modality that determines the diagnosis of PAS with absolute accuracy. Color flow Doppler and MRI can be used as adjunctive diagnostic tools. Placental biomarkers, such as α-fetoprotein, are too nonspecific for clinical use.

A.16. How is the PAS managed obstetrically?

Optimal management of PAS has yet to be defined. Care should be individualized for each patient, and a multidisciplinary approach to delivery planning should be taken. Prenatal diagnosis and management is important because it provides the opportunity to optimize outcome. The problems associated with PAS depend on the site of implantation, depth of myometrial penetration, and the number of placental lobules involved. Only a focal placenta accreta may not require aggressive surgical intervention. Otherwise, surgical management can be difficult and requires a multidisciplinary approach in order to minimize maternal complications. If PAS is known to exist antenatally, it is generally accepted that it is treated with an elective cesarean section and hysterectomy; the placenta should be left in place during surgery. The optimal timing for the delivery of the patient with PAS remains controversial and should be individualized. In a retrospective series, Warshak et al. found that patients with a predelivery diagnosis of accreta, who had a planned en bloc hysterectomy without the removal of the placenta at 34 to 35 weeks of gestation after betamethasone administration, had decreased maternal hemorrhagic morbidity and no significant increase in neonatal morbidity. Optimal maternal and neonatal outcome in a stable patient seems to occur with a planned delivery at 34 weeks, with a window of 34 0/7 to

35 6/7 weeks, of gestation without amniocentesis. For women with suspected PAS, some suggest preoperative placement of balloon catheters into the internal iliac arteries. After delivery of the fetus, the catheters may be inflated intermittently during hysterectomy, which may potentially decrease blood loss and provide optimum exposure of the operative field. They also may be used for intraoperative or postoperative embolization of persistent bleeders. The placement of these catheters is not risk-free; thrombosis and thromboemboli have been reported. The American College of Obstetricians and Gynecologists (ACOG) found that data on the efficacy of this intervention is unclear. Some investigators suggest that the placement of preoperative ureteral stents reduced morbidity in cesarean hysterectomies; others use stents intraoperatively as needed.

Because a hysterectomy renders the patient infertile, there has been some interest in attempting to leave the uterus intact in those patients with a strong desire to maintain their fertility. The success of "conservative" expectant management, which is defined as leaving part or all of the placenta in situ without removing the uterus seems to correlate to the degree of the placental attachment abnormality. Timmermans et al. reviewed publications using "conservative" management. They found that in some reports, the placenta was partially removed, whereas in others, it was left intact; some reported the use of methotrexate and/or uterine artery embolization. Overall, 15% of this whole patient population required hysterectomy for hemorrhaging and 3% for infection; approximately 13% of the patients had subsequent pregnancies. They concluded that only in highly select cases when blood loss is minimal and maintenance of fertility is desired should "conservative" management be considered. In one of the largest retrospective reviews, Sentilhes et al. reported that 22% of the patients required a hysterectomy after an attempt at expectant management with the failure rate of

44% in percreta patients compared with 7% in those with less extensive defects. In addition to leaving the placenta in situ in conservative management, adjunct techniques to diminish blood loss and/or speed placental resorption have been tried. Uterine devascularization using uterine artery balloon placement, embolization, or ligation has been used with varying results, and ACOG states that "there is no convincing data for the use of methotrexate for postpartum management of placenta accreta." This method of management is rarely indicated, but if the placenta is left in situ, these women should have serial ultrasounds or MRIs because serum β-hCG test are not helpful.

Although antepartum diagnosis of PAS would be ideal, currently, there is no single diagnostic modality that determines the diagnosis of PAS with absolute accuracy. Unfortunately, the diagnosis is occasionally made postpartum during the third stage of labor when separation of the placenta does not occur with the first clinical manifestation of PAS being profuse, potentially life-threatening bleeding at the time of attempted manual placental separation. During vaginal delivery, uterine inversion can occur. Studies have shown that these PAS patients have a higher blood loss and transfusion requirement when compared to patients with a known antenatal diagnosis of PAS.

A.17. What tests and/or interventions can improve neonatal outcome of a preterm birth?

Because significant neonatal morbidity has been reported with elective delivery before 39 weeks of gestation, elective planned repeat cesarean deliveries are to be done after 39 weeks of gestation. Neonatal survival increases as birth weight and/or gestational age increases. The pivotal complication of preterm delivery is respiratory distress syndrome (RDS). ACOG considers first-trimester ultrasonography the most accurate method for establishing or confirming gestational age. Pregnancies without an ultrasound confirming or revising the estimated due date before 22 0/7 weeks of gestation should be considered suboptimally dated. Amniocentesis for FLM is not recommended as a routine component when considering delivery in this patient population; ACOG recommends a late-term delivery at "41 weeks' gestation" using the best clinical estimate of gestational age instead. If an indication for delivery is present, the use of amniocentesis to assess FLM does not aid in guiding management. In our case of preterm vaginal bleeding from a sonographically documented placenta previa, the patient should be electively delivered before 39 weeks because the risk of bleeding increases, as gestation progresses. If there is maternal hemorrhaging, fetal maturity would not impact the decision to perform an immediate cesarean delivery.

RDS is the leading cause of morbidity and mortality in preterm infants. Sixty percent of infants born below 28 weeks of gestation will develop RDS, whereas the incidence of RDS is 30% and <5% in infants born between 28 and 34 weeks and after 34 weeks, respectively. The use of maternal antenatal

corticosteroids, neonatal nasal continuous positive airway pressure (nCPAP) and neonatal exogenous surfactant, if needed, have helped decrease neonatal morbidity and mortality.

According to ACOG, antenatal corticosteroids should be administered when a woman is at risk of preterm delivery within 7 days to decrease the rate of neonatal respiratory complications. Between 24 and 34 weeks of gestation, a single-dose course of corticosteroid, such as betamethasone (two doses of 12 mg intramuscularly, 24 hours apart) or dexamethasone (four doses of 6 mg intramuscularly, 12 hours apart), should be given to accelerate FLM in a parturient who is at risk for imminent preterm delivery. A single repeat course of antenatal steroids should be considered if the first course was greater than 14 days, the fetus is <34 0/7 weeks of gestation, and the delivery is likely within the next 7 days. At 23 0/7 weeks of gestation, corticosteroids may be considered based on a family's decision about resuscitation, irrespective of membrane rupture status and fetal number. A single course of betamethasone is recommended for pregnant women at risk for late-preterm delivery, 34 0/7 to 36 6/7 weeks of gestation, who have not had a previous course of antenatal corticosteroids.

Early CPAP with subsequent selective surfactant administration in extremely preterm infants, defined as <32 weeks of gestation or weighing <1,500 g, results in lower rates of mechanical ventilation, surfactant administration, and bronchopulmonary dysplasia (BPD)/death when compared to treatment with prophylactic or early surfactant treatment. In neonates who receive the combination of maternal antenatal steroids and early nCPAP in the delivery room, prophylactic surfactant therapy is no longer recommended. Infants with RDS on CPAP who fail to maintain an SpO_2 above 90% on a fraction of inspired oxygen (FIO_2) of 0.40 or higher, have a respiratory acidosis (arterial pH <7.2 and partial pressure of arterial carbon

dioxide ($PaCO_2$) >60 to 65 mmHg), or are apneic, require intubation and surfactant administration. Surfactant is most effective when given within the first 30 to 60 minutes of life.

Caffeine is used to treat apnea of prematurity, lower BPD rates, and improve neurodevelopment during early childhood; it is widely used for newborns weighing ≤1,250 g. Vitamin A administration has been shown to decrease BPD rates in neonates weighing <1500 g.

The use of magnesium sulfate for fetal neuroprotection in threatened preterm delivery is recommended; recommendations about dose, duration, upper gestational age, and repeating treatment vary and differ. Of those physicians using magnesium sulfate, patients at risk for preterm delivery have received a range of 4 to 6 g loading bolus over 20 to 30 minutes followed by a 1 to 2 g per hour infusion until birth or for up to 12 to 24 hours. Some use it in patients at risk for a preterm delivery from 24 0/7 to 27 6/7 weeks of gestation, whereas others use 31 6/7, not 27 6/7, weeks as the cut-off time. ACOG recommends that women at risk for imminent delivery before 32 0/7 weeks of gestation be considered candidates for fetal neuroprotection treatment with magnesium sulfate.

The use of amniocentesis for FLM tests is rarely done in the United States. ACOG does not recommend it for assessment to guide the timing of delivery. Some may still use it in patients with poorly dated gestations when FLM may influence plans for delivery (e.g., repeat cesarean delivery in a woman with a prior classical cesarean delivery and unconfirmed gestational age). FLM is not generally assessed before 32 weeks of gestation because pulmonary maturity is unlikely before this time and is not assessed after 39 weeks. There are two types of tests used to determine pulmonary maturity. One type measures the concentration of particular components of pulmonary surfactant and includes lamellar body counts, phosphatidylglycerol

analysis, lecithin-sphingomyelin (L/S) ratio, and surfactant-to-albumin ratio (TDx-FLM II). The other, the foam stability test, evaluates the surfactant function of these phospholipids. Other tests exist, and the choice of test should be based on availability, presence or absence of contaminants, and physician preference.

B. Preoperative Evaluation and Preparation

B.1. How does pregnancy change respiratory function, and what impact does this have on anesthetic care?

A number of maternal respiratory changes are seen:

- Capillary engorgement of the mucosa is found throughout the respiratory tract, causing swelling of the nasal and oral pharynx, larynx, and trachea; this begins in the first trimester and increases progressively throughout pregnancy.
- By term, there are increases in minute ventilation (45%), tidal volume (45%), and oxygen consumption (30% to 40%); respiratory rate does not change. These changes do not return to their prepregnancy state for at least 6 to 8 weeks after delivery.
- Arterial $Paco_2$ decreases to about 30 mmHg by 12 weeks of gestation and remains there until it slowly increases after delivery over about 6 to 8 weeks postpartum.
- Arterial pH increases to about 7.44, and there is a partial metabolic compensation for the respiratory alkalosis (20 mEq per L).
- Functional residual capacity (FRC) begins to decrease by the fifth month and by term is 20% below prepregnancy values. After delivery, FRC increases and by 1 to 2 weeks postpartum returns to its prepregnant level. Additionally, the

supine position will further decrease the FRC to approximately 70% of prepregnant volume.

Capillary engorgement of the airway mucosa necessitates the use of a smaller, internal diameter (I.D.) 6.0, 6.5, or 7.0 mm, cuffed endotracheal tube in pregnant women. This vascular engorgement results in airway edema and increased airway friability, which may potentially make tracheal intubation more difficult. Because epistaxis is more likely to occur, nasal intubation is relatively contraindicated. Pilkington et al. showed that the number of pregnant women with a Mallampati class IV airway increased 34% between 12 and 38 weeks of gestation. Boutonnet et al. found that the incidence of Mallampati classes III and IV increased during labor when compared to the prelabor period; these changes are not fully reversed by 48 hours after delivery. No predictive factors for the increase in airway class were found; these changes occurred irrespective of any increase in body weight, the duration of first and second stages of labor, or the volume of intravenous fluid received. Regardless of the cause, difficult and failed intubations are more common in the pregnant than in the nonpregnant population.

The combination of a decreased FRC and increased oxygen consumption make the pregnant patient more susceptible to the rapid onset of hypoxemia in the apneic state. Therefore, before the induction of general anesthesia, the parturient should be “preoxygenated” with 100% oxygen for 3 to 5 minutes while taking normal tidal breaths or, if time is limited, for four vital capacity breaths. This effectively washes nitrogen out of FRC and provides maximal maternal oxygen reserves to allow longer apneic time during tracheal intubation. The reduced FRC combined with the increased minute ventilation increase the rapidity of changes in the depth of anesthesia while employing an inhaled anesthetic technique. In addition, the minimum alveolar concentration (MAC) of inhaled anesthetic agents has

been found to be decreased by about 40% in pregnancy. In a small prospective electroencephalographic study, Ueyama et al. found that pregnancy did not enhance the hypnotic effect of sevoflurane, and they suggest that the decreased MAC during pregnancy is not indicative of an enhanced volatile anesthetic effect on the brain but reflects the anesthetic effect on the spinal cord.

B.2. What are the maternal cardiovascular changes of pregnancy?

Most cardiovascular changes of pregnancy begin early in the first trimester and peak by 30 to 34 weeks of gestation. At term, the cardiovascular changes include the following:

- Cardiac output increases 40% to 50%. During the first trimester of pregnancy, the cardiac output increases to 40% or 50% above normal and plateaus at approximately 28 weeks of gestation. It remains fairly stable until the stresses imposed by labor increase it further. During labor, cardiac output increases approximately 15% with uterine contractions during the latent phase, 30% in the active phase, and 45% in the expulsive phase when compared to prelabor values. The greatest increase in cardiac output occurs immediately

postpartum when it increases an average of 80% above prelabor values. Cardiac output and heart rate decline to prelabor values within 1 hour of delivery. Postpartum, over the next 2 to 4 weeks, cardiac hemodynamic parameters return toward pregravid levels. It can take a year, however, for the residual effects of cardiovascular remodeling to subside.

- Stroke volume increases approximately 30%.
- Heart rate increases to about 15%.
- Systolic blood pressure is minimally affected by pregnancy.
- Diastolic blood pressure decreases up to 20% by midpregnancy but returns to its prepregnant level at term.
- Systemic vascular resistance decreases 20%.
- Central venous pressure (CVP) remains unchanged.
- *Aortocaval compression* refers to the gravid uterus compressing the inferior vena cava (IVC) and/or the abdominal aorta. The extent of the compression depends on the patient's position and weeks of gestation. In the supine position, compression of the IVC begins by 20 weeks of gestation. At term in the supine position, the IVC is occluded almost completely with venous return from the lower extremities occurring through the dilated azygos system of veins as the dominant pathway of collateral circulation. On MRI, this IVC occlusion was significantly reduced with a 30-degree, but not the standard 15-degree, left uterine tilt position. At term, compression of the aorta did not occur on MRI in the supine position at the level of the renal veins but was reduced at the level of the aortic bifurcation. Despite this impaired blood flow and concomitant decrease in cardiac output, the majority of supine women are not hypotensive or symptomatic because of the compensatory rise in systemic vascular resistance and venous return via collateral circulation. However, up to 11% of supine women at term

develop supine hypotension syndrome with hypotension, bradycardia, and symptoms of dizziness, light-headedness, nausea, and even syncope. Studies of the impact of aortocaval compression on uteroplacental perfusion provide inconsistent results; aortocaval compression, however, can decrease uteroplacental perfusion and have a negative impact on the fetus. For these reasons, it has been customary for all patients after 20 weeks of gestation to be positioned with left lateral uterine displacement. Recently, this practice has been questioned, Lee and Landau have suggested that maternal tilt during elective cesarean delivery of healthy women with uncomplicated pregnancies may not be necessary because they found that after spinal anesthesia, the maternal supine position when compared to 15 degrees left tilt was not detrimental to neonates if the maternal blood pressure was supported with a phenylephrine infusion and a fluid coload.

B.3. What are the maternal gastrointestinal changes of pregnancy?

Parturients are considered to be at an increased risk for aspiration of gastric contents. Pregnancy itself does not alter gastric emptying of liquid or solid materials, but during labor, gastric motility does decrease. Gastric acid secretion appears to be unchanged. Because of the upward displacement of the stomach by the gravid uterus, tone in lower esophageal high-pressure zone, however, is decreased. This zone normally prevents the reflux of gastric contents. In the first trimester, the tone in this zone may be unchanged, but in the second and third trimesters, lower esophageal high-pressure zone tone falls gradually to about 50% of its preconceptual level. By 36 weeks of gestation, it reaches its lowest point and does not return to prepregnancy levels until 1 to 4 weeks postpartum. As a result, 30% to 50% of women experience heartburn during pregnancy. The increased aspiration risk is thought to be due to the parturient's decrease lower esophageal high-pressure zone tone and the increased risk of having difficulty with intubation.

Ramu B, Mohan P, Rajasekaran MS, et al. Prevalence and risk factors for gastroesophageal reflux in pregnancy. *Indian J Gastroenterol*. 2011;30:144–147.

B.4. What hematologic changes occur during pregnancy?

The hematologic changes seen by term are as follows:

- Intravascular fluid volume increases 45%.
- Plasma volume increases 55%.
- RBC volume increases 30%.

The disproportionate increase in plasma volume compared to RBC volume results in the relative, or physiologic, anemia of pregnancy. By midgestation, Hct has typically fallen approximately 15% below prepregnant levels; the Hgb and Hct are approximately 11.2 g per dL and 34%, respectively. In late gestation, RBC volume increases, and at term, maternal Hgb and Hct are approximately 11.6 g per dL and 35.5%, respectively. This decreased viscosity may aid in maintaining the patency of the uteroplacental vascular bed.

In addition, the following coagulation factors are increased at term: factors I (fibrinogen), VII, VIII, IX, X, and XII. Plasminogen, fibrin degradation products, and fibrinopeptide A are also increased. Factors II and V are unchanged. Factors XI and XIII are decreased as is antithrombin III. Overall, pregnancy is associated with an accelerated, but compensated, rate of intravascular coagulation. Both, the prothrombin time (PT) and activated partial thromboplastin time (aPTT) are shortened 20%, and thromboelastography (TEG) suggests a hypercoagulable state. The platelet count is typically unchanged at term. However, 0.9% of otherwise normal women will have a platelet count less than 100,000 per μL; gestational thrombocytopenia refers to maternal platelet counts of less than 150,000 μL in otherwise normal women.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:22–25.

B.5. What laboratory data do you need before taking this patient to the operating room?

The laboratory values needed in this healthy parturient having an elective scheduled cesarean section are minimal. A complete blood count with platelets and a type and crossmatch should be sent because this patient is at an increased risk for bleeding due not only to her placenta previa but also to the increased

likelihood of an associated placenta accreta because it is her third cesarean delivery. There is no consensus on the type or amount of blood products that should be available. However, many obstetricians and anesthesiologists suggest that at least 4 units of pRBCs be immediately available with other blood products readily available. Unless the patient has a coagulation disorder or is actively bleeding, a PT, an aPTT, and a fibrinogen level are not needed because the values should be within normal limits.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:571–572, 917–918.

B.6. What preoperative medications would you administer to this patient?

Patients at increased risk for aspiration should receive a nonparticulate oral antacid such as sodium citrate 30 minutes prior to the induction of anesthesia. Intravenous H_2-receptor antagonists, such as ranitidine, and/or metoclopramide may also be given preoperatively for aspiration prophylaxis. This patient is having an elective cesarean delivery and should have a 6- to 8-hour fasting period for solids depending on the fatty content of the consumed food; if the fatty content is high, wait 8 hours.

This patient should receive antimicrobial prophylaxis within the 60-minute period before skin incision for the cesarean delivery. As per the 2018 ACOG guidelines, a single dose of the first-generation cephalosporin, cefazolin, is the first-line antibiotic of choice unless a patient is allergic to this medication. Weight-based dosing can be done with patients weighing ≤80 kg receiving 1 g intravenously and those over 80 kg receiving 2 g; for ease of administration, some institutions, including ours, uniformly give 2 g of cefazolin to all adult patients undergoing cesarean delivery. If an allergy exists, then a single intravenous

dose of clindamycin (900 mg) and an aminoglycoside (e.g., gentamicin 5 mg per kg infused over 30 to 120 minutes. The dose is based on the patient's actual body weight unless the patient's actual weight is 20% above ideal body weight [IBW] and then the dose can be determined by the formula: dose = IBW + 0.4[actual weight − IBW]). In addition, azithromycin 500 mg infused over 1 hour may be added to the standard antibiotic regimen if a patient is undergoing a nonelective cesarean delivery.

C. Intraoperative Management

C.1. What monitors would you use for this patient?

Standard monitors should be used and include the following: electrocardiogram (ECG), blood pressure cuff, pulse oximeter, end-tidal carbon dioxide monitor, and Foley catheter. In addition, two large-bore intravenous lines, a forced air body warming blanket, intravenous fluid warmers, and intermittent pneumatic compression stockings should be used. A radial arterial line should also be considered if multiple blood samples will be needed and/or hemodynamic instability occurs. Central venous access, placed above the diaphragm, should be considered if vasoactive drugs and additional volume are required for hemodynamic resuscitation. Equipment for the rapid infusion of intravenous fluids and blood products should be readily available.

C.2. What anesthetic could be used in this patient?

In the patient with placenta previa, a regional or general anesthetic technique could be used. Many anesthesiologists would choose to perform a continuous neuraxial anesthetic in this patient. The choice of anesthetic depends on the cesarean section indication and urgency and the maternal volume status. All patients with placenta previa are at risk for increased intraoperative blood loss due to the poor contractility of the lower uterine segment, the increased risk of an associated placenta accreta, and the possibility of an anterior placenta being cut during uterine incision. Markley et al. retrospectively reviewed the anesthetics of 129 patients having nonemergent cesarean deliveries for placenta previa with suspected PAS and found that 95% of these parturients had neuraxial anesthesia as their primary anesthetic; the type of neuraxial anesthesia was not reported. Twenty-one percent of the 72 neuraxial anesthesia patients who needed a hysterectomy had their anesthetic converted to a general anesthesia intraoperatively. Options for neuraxial anesthesia include continuous spinal, combined spinal epidural, and continuous epidural anesthesia. Single-injection spinal anesthesia can be used, but the unpredictable length of the surgery may make this a poor choice. All patients having neuraxial anesthesia should be informed that if the need arises, general anesthesia may be induced. If the patient has a suspected placenta percreta, a general anesthetic is the usual choice for the operative cesarean section and hysterectomy because of the

extensive surgery that may be required.

If postpartum hemorrhaging occurs, a coordinated multidisciplinary team approach aimed at early recognition and treatment is essential.

American College of Obstetricians and Gynecologists Committee on Practice Bulletins—Obstetrics. Practice Bulletin No. 183: postpartum hemorrhage. *Obstet Gynecol*. 2017;130(4):e168–e186.

C.3. What are the absolute and relative contraindications for neuraxial anesthesia?

Absolute contraindications

- Patient inability to cooperate or patient refusal
- Uncorrected maternal hypovolemia or hypovolemic shock
- Infection at the site of needle insertion
- Frank coagulopathies
- Recent pharmacologic anticoagulation
- Mass lesions causing increased intracranial pressure
- Providers' lack of experience in techniques
- Lack of appropriate monitoring and/or resuscitative equipment

Relative contraindications have included maternal systemic infection, neurologic disease, severe stenotic heart lesions, and some isolated blood coagulation test abnormalities. Most cases of properly treated systemic infection or neurologic disease, however, do not currently contraindicate the use of neuraxial anesthesia. Each patient should be treated individually with careful consideration of the benefits and risks of neuraxial anesthesia.

C.4. How is postpartum hemorrhage (PPH) defined, and what are the etiologies of this bleeding?

The ACOG reVITALize program currently defines PPH as a cumulative blood loss equal to or greater than 1,000 mL or blood loss accompanied by signs and symptoms of hypovolemia within 24 hours of delivery regardless of the delivery route. This differs from the more traditionally accepted definition that an estimated blood loss greater than 500 mL for vaginal deliveries and 1,000 mL in cesarean sections constitutes PPH. Despite this new definition, ACOG suggests that a blood loss greater than 500 mL after a vaginal delivery should be considered abnormal and be investigated.

Depending on a woman's nonpregnant blood volume and the corresponding magnitude of pregnancy-induced hypervolemia, a dangerous feature of postpartum bleeding is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood, usually about 25% of the woman's blood volume, which is approximately ≥1,500 mL, have been lost. Recognition of PPH before vital sign deterioration should be the goal to improve outcomes. Risk assessment tools are available to help. Sixty percent to 85% of patients who will experience a significant obstetrical bleed may be identified, but diligent surveillance of all patients including those initially thought to be low risk is prudent.

Recognizing the severity of an obstetrical hemorrhage is crucial to management. Visual estimations of blood loss are inaccurate and usually underestimate the true blood loss. Quantification of blood loss by measuring the amount of blood in the suction canister and drapes and weighing surgical lap pads is significantly more accurate than estimated blood loss.

The etiologies of PPH generally can be categorized as those occurring early within 24 hours of delivery and those occurring late, 24 hours after delivery. Because the obstetrician typically is

faced with early PPH, the remainder of this discussion focuses on its causes. The two broad etiologies of early PH are based on bleeding from the placental implantation site and genital tract trauma. Within the category of placental site bleeding, bleeding is usually due to either myometrial hypotonia, such as that seen with uterine atony and placenta previa, or retained placental tissue as can be seen with invasive placentation, such as that seen with placenta accreta syndrome and uterine inversion. Genital tract traumas that lead to postpartum bleeding include genital tract lacerations and uterine rupture. Coagulation defects intensify the bleeding that occurs with any of the earlier abnormalities.

C.5. After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this

patient's bleeding?

The most likely causes of bleeding in this patient are myometrial hypotonia due to the poor contraction of the lower uterine segment and a focal placenta accreta syndrome. Near term, at least 600 mL per minute of blood flows through the intervillous space carried by about 120 spiral arteries and their accompanying veins. Due to endotrophoblastic remodeling to create a low-pressure system, these arteries have no muscular layer. With placental separation, these vessels are avulsed; hemostasis at the placental implantation site is first achieved by contraction of the myometrium that compresses these relatively large vessels and reestablishes vascular integrity. Subsequently, clotting occurs and the vessel lumens are obliterated. Ineffective myometrial contractions, such as occur with retained placenta or massive blood clots, can impair hemostasis at the implantation site. In this patient, the lower uterine segment, which contains less myometrial tissue, contracts poorly, and hemorrhaging can result despite normal coagulation. Bleeding that occurs after placenta delivery is usually a steady, not a sudden massive, hemorrhage. The constant seepage, however, can lead to an enormous blood loss. Severe PPH, therefore, can result from uterine atony despite normal coagulation. Conversely, even if coagulation is impaired, vigorous myometrial contraction within and adjacent to the denuded placental implantation site makes severe hemorrhage from this implantation site unlikely. During rapid bleeding, the Hct may not accurately reflect the amount of blood lost due to the lack of equilibration with other fluid compartments.

C.6. After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial

contractility and therefore decrease blood loss?

Regarding guidelines for PPH management, national and professional guidelines are based on the same literature, but differences in definition and treatment exist between different guidelines on this subject.

Uterotonic medications, such as oxytocin, cause myometrial contractions and decrease postpartum bleeding. They should be the first-line treatment for PPH caused by uterine atony, which accounts for 70% to 80% of the PPH cases. Synthetic oxytocin (Pitocin, Syntocinon) is usually recommended as the drug of choice and is given once the fetus is born and the placenta is delivered. Given prophylactically, the uterotonics prevent most cases of uterine atony. Oxytocin increases the frequency and duration of uterine contractions; these contractions are most likely mediated through an increase in intracellular calcium levels. The number of oxytocin receptors in the uterus increases from about 20 weeks of gestation to 34 weeks of gestation, and receptor sensitivity increases during labor. Although oxytocin is routinely given, there is no standard prophylactic dose for either vaginal or cesarean delivery. Intravenous therapy is often the preferred route of administration, but intramuscular (IM) dosing is possible. Intravenous oxytocin has a rapid onset of about 1 minute and a fast mean elimination half-life of 3 to 5 minutes. ACOG recommends 10 to 40 units per 500 to 1,000 mL as a continuous infusion or 10 units intramuscularly. At our institution, 30 units of Pitocin per 500 mL of normal saline (NS) is run intravenously over 2 hours after vaginal or cesarean delivery; the infusion rate may be adjusted to sustain uterine contraction and control uterine atony. Different countries do have different guidelines on oxytocin dosing. Lavoie et al. found that women having cesarean deliveries after exposure to exogenous oxytocin during labor required higher infusion rates of oxytocin to prevent uterine atony than women without prior

exposure. The posterior pituitary produces the polypeptide hormones, oxytocin and antidiuretic hormone. Because they differ from one another by only two amino acids, oxytocin exhibits a small antidiuretic effect that is clinically insignificant unless very large doses are given; in this situation, water intoxication might occur. A bolus of oxytocin can decrease peripheral vascular resistance due to a direct relaxing effect on vascular smooth muscle leading to hypotension that on occasion requires treatment with appropriate vasopressors (ephedrine or phenylephrine). Patients may also exhibit tachycardia and arrhythmias. In some countries other than the United States, carbetocin (Duratocin), a long-acting oxytocin analogue, is available.

When oxytocin fails to produce adequate uterine tone and uterine atony is present, other uterotonic medications are often used in prompt succession. The second-line agent chosen depends on its side effect profile and contraindications. Ergot alkaloids, methylergonovine (Methergine) and ergonovine (ergometrine), are effective uterotonic agents; they are usually given intramuscularly and produce tetanic contractions of the uterus that may be mediated through α-adrenergic receptors. Their usefulness is limited because the induced hypertension, due to vasoconstriction, can be prominent. These agents should be avoided in patients with preexisting hypertensive disease. Other cardiovascular affects include coronary artery spasm leading to myocardial infarction, arrhythmias, or cerebrovascular accidents. Pulmonary complications have been reported including pulmonary artery vasoconstriction and pulmonary hypertension. Associated side effects include headache, dizziness, nausea, and vomiting.

Prostaglandins are uterotonic agents. The prostaglandins cause an increase in myometrial intracellular calcium levels leading to an increase in myosin light-chain kinase activity and

uterine contraction. IM and intrauterine administration of 15-methyl prostaglandin $F_{2\alpha}$ (carboprost tromethamine [Hemabate]) can be used to control uterine atony. Due to its bronchoconstrictive properties, its use is strongly contraindicated in asthma patients. Rectally administered prostaglandin E_2 (Prostin E_2) is a naturally occurring uterotonic agent that has not been tested in clinical trials for postpartum bleeding, and its unfavorable side effects include fever/chills, nausea/vomiting, diarrhea, and headaches. In Europe, there is an intravenous prostaglandin E_2 available (Sulprostone), which can be used as a second-line drug in PPH. Finally, Mousa et al. reported that rectally administered misoprostol (Cytotec), a synthetic prostaglandin E_1 analogue, provided no added benefit when compared to standard therapy with oxytocin and ergometrine (ergonovine) in primary PPH patients.

Manual uterine massage is often done and is thought to stimulate the myometrium to contract. The evidence for this common practice, however, is not strong.

If pharmacologic methods fail to control atony-related hemorrhage, prompt alternative measures, including uterine tamponade, selective arterial embolization, and surgical intervention must be undertaken.

C.7. When should this patient receive tranexamic acid (TXA)?

Once this patient has an estimated blood loss of more than 1,000 mL after cesarean delivery or any blood loss sufficient to compromise her hemodynamic stability, she should receive intravenous TXA. The WHO now considers TXA a standard part of the treatment regimen for PPH following vaginal or cesarean delivery. The WHO recommends that it be given in all cases of PPH, regardless of whether the bleeding is due to genital tract trauma or other causes, unless there is a clear contraindication to antifibrinolytic therapy. It should be given as soon as possible after the onset of bleeding and within 3 hours of birth. TXA is a competitive inhibitor of plasminogen activation and can reduce bleeding by inhibiting fibrinolysis. TXA should be administered intravenously over 10 minutes in a fixed dose of 1 g in 10 mL; if bleeding continues after 30 minutes or restarts

within 24 hours of completing the first dose, a second dose of 1 g should be given. The WHO recommends against giving a first dose of TXA more than 3 hours after birth. The WOMAN Trial found that TXA reduced death due to bleeding in women with PPH with no adverse effects. It should be noted that ACOG is less definitive about TXA administration and recommends that it be considered in the setting of obstetric hemorrhage when initial medical therapy fails.

C.8. If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?

Treatment of serious bleeding demands prompt and adequate refilling of the intravascular compartment. Normovolemia should be maintained, and usually non–dextrose-containing crystalloid solutions are used for the initial volume resuscitation. These solutions rapidly equilibrate into the extravascular space, and therefore, the volume of crystalloid given should be 3 times as much as the blood loss. Colloid solutions can also be used to

maintain normovolemia but confer no greater benefit than crystalloid solutions. Depending on colloid solution (e.g., 5% albumin), the volume that should be administered is the same as that of the blood loss; this may be helpful in facilitating a more rapid repletion of a preexisting volume deficit.

After the hypervolemia of pregnancy is lost at delivery, blood loss can be estimated by every 3 vol% drop in Hct representing a 500-mL loss of blood. With acute blood loss, the real-time Hct measured in the delivery or operating room is often at a maximum. In the PPH patient, the reason for their hypoperfusion is blood loss. If she is not receiving diuretics, urine output reflects renal perfusion, which in turn reflects perfusion of other vital organs, and should be maintained at ≥ 0.3 mL/kg/hr or at least 30 mL per hour but preferably >50 mL per hour. Although physiologic parameters, such as blood pressure, heart rate, urine output, and perhaps CVP, are monitored during surgery, use of these static parameters to guide fluid therapy may result in either hypovolemia or hypervolemia, and may not recognize significant intraoperative reductions in tissue perfusion. Dynamic hemodynamic parameters, such as pulse pressure variation, however, are often not practical in the hemorrhaging obstetrical patient if they are awake and breathing spontaneously with a neuraxial anesthetic.

Defining a universal Hct or Hgb value below or above, which transfusion is either mandatory or contraindicated is difficult. RBCs carry oxygen to the tissues, and the goal of RBC transfusions is to maintain adequate tissue oxygenation. The 2015 American Society of Anesthesiologists Practice Guidelines state that determining whether patients with an Hgb concentrations between 6 and 10 g per dL require RBC transfusion should be based on potential or actual ongoing bleeding, intravascular volume status, signs of organ ischemia, and adequacy of cardiorespiratory reserve. RBC transfusions

should be considered in all patients with clinical evidence of inadequate oxygen carrying capacity. In most bleeding obstetric patients, maintaining an Hgb level above 7 g per dL is suggested unless evidence of impaired pulmonary or cardiac function indicates a need for a higher Hgb level.

C.9. What laboratory tests should be ordered during the resuscitation of this patient?

Once the patient loses 1,000 mL of blood with ongoing bleeding occurring, blood specimens for Hct, Hgb level, platelet count, coagulation tests (aPTT, PT, and fibrinogen levels) should be sent. An arterial blood gas and lactate level can be done to establish an early baseline. *Blood products should be administered without waiting for results if needed based on clinical assessment.* During the resuscitation, the aforementioned blood tests should be sent periodically to help guide treatment including blood component therapy. If the volume of blood lost requires treatment with a massive transfusion, then electrolyte levels, including potassium and calcium, also will need to be followed. Patients can develop hyperkalemia due to the elevated potassium levels in transfused blood and the cellular shifts caused by acidosis. Patients can develop hypocalcemia from citrate toxicity; citrate is the anticoagulant found in transfused pRBCs. Arterial blood gases

and serum lactate levels also should be monitored to evaluate the acidosis that may develop due to poor tissue perfusion and the development of shock. Changes in lactate levels have been used to follow the response to treatment. If DIC is a concern, the level of fibrin degradation products also should be checked.

Time is important in postpartum hemorrhaging patients. Results from the central laboratory take more time to receive than results from point-of-care devices. Devices for point-of-care measurements of blood gases, electrolytes, lactate, Hct, Hgb, and viscoelastic assays of coagulation, such as TEG or rotational thromboelastometry (ROTEM), should be used if available (also see Chapter 12, sections B.8, B.9, and B.10; Chapter 31, section A.1; and Chapter 57, section C.25).

C.10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?

When blood replacement therapy is indicated, compatible whole blood is ideal for maintaining intravascular volume in the treatment of hypovolemia from catastrophic acute hemorrhage. One unit of whole blood raises the Hct by 3 to 4 vol% and replaces many coagulation factors, especially fibrinogen. Importantly, using whole blood versus pRBCs and components decreases the exposure of women with severe hemorrhage to blood donors. When whole blood transfusions were compared

with pRBCs transfusions or blood product combinations, Alexander et al. reported that the incidence of renal failure, adult RDS, pulmonary edema, hypofibrinogenemia, admission to an intensive care unit, and maternal death decreased significantly in women delivered at Parkland Hospital. However, availability of whole blood is limited. Few units of whole blood are kept in the modern blood bank because over 85% of globally collected donor blood is fractionated into blood components; in high-income countries compared to low-income countries, 97% versus 50% of whole blood is fractionated into components. For women who do not have massive blood loss, pRBC transfusions are suitable, and component therapy provides better treatment because only the specific component needed is given.

Blood component therapy provides the patient with only the components that they require. The products available are pRBCs, fresh frozen plasma (FFP), cryoprecipitate, and platelets. A unit of pRBC is prepared from 1 unit of whole blood; its plasma is removed and replaced with additives such as citrate, phosphate, dextrose, and adenine. Its volume is about 250 to 325 mL with an Hct of 55 to 80 vol% depending on the method used for preparation and storage. A unit of pRBCs increases the patient's Hct approximately 3 vol% and Hgb by about 1 g per dL. Crystalloid infusion and pRBC transfusion are the mainstays of therapy in the bleeding obstetric patient.

FFP contains all the necessary coagulation factors including 660 to 700 mg of fibrinogen per unit; each unit has a volume of approximately 250 mL and takes about 30 minutes to thaw. Fibrinogen falls earlier than other coagulation factors during postpartum hemorrhaging and can be low despite a normal PT and aPTT. Charbit et al. found that a fibrinogen level less than 200 mg per dL was associated with a high risk of severe bleeding as defined by either a ≥4 g per dL decrease in Hgb, ≥4 RBC unit transfusion, invasive hemostatic intervention, or death.

When replacement of coagulation factors is needed for hemostasis during massive transfusion, FFP transfusion is indicated. In a parturient with surgical bleeding, a fibrinogen level of less than 150 mg per dL, a prolonged PT, and/or a prolonged aPTT are indications for FFP administration in initial doses of 10 to 15 mL per kg. FFP administration is not indicated for hypovolemia. During active hemorrhaging, attempts should be made to maintain the fibrinogen level higher than 150 to 200 mg per dL. Cryoprecipitate is prepared from FFP and 15 mL contains 200 mg fibrinogen, factor VIII:C, factor VIII:von Willebrand, factor XIII, and fibronectin. Ten pooled bags (10 to 15 mL per bag) of cryoprecipitate will increase the fibrinogen level by 65 to 70 mg per dL. A critically low fibrinogen level should be anticipated in PPH due to placental abruption or AFE, and early use of cryoprecipitate is commonly used as part of the resuscitation.

With obstetric hemorrhage, the platelet count should be maintained above 50,000 per μL with the infusion of platelet concentrates. One unit of platelets increases the platelet count from 5,000 to 10,000 per μL in an adult woman. A single-donor platelet apheresis unit provides the equivalent amount of platelets as six random-donor platelet units and should be used if available. Platelets are difficult to store and have a short shelf life (5 days). Typically, the blood bank provides platelets from ABO- and Rh-compatible donors. Platelet unit donor plasma must be compatible with, not identical to, recipient erythrocytes, but only units from D-negative donors should go to D-negative recipients.

Massive transfusion protocols (MTP) function to speed blood product delivery to the operating room and permit product infusion early in the resuscitation process to prevent the adverse effects of aggressive resuscitation with only crystalloid and pRBC transfusions. Massive transfusion is often defined as

transfusing 10 or more pRBC units in a 24 hour period, 4 units of pRBCs within 1 hour with an anticipated ongoing need for more blood, or replacement of a complete blood volume. At our institution, once a hemorrhaging obstetrical patient has lost >1,500 mL of blood, has abnormal vital signs, and/or has received >2 units of pRBC with rapid ongoing losses expected, we notify the blood bank to activate the MTP. At other institutions, their MTP is not activated until >4 to 5 units of pRBCs have been given in a 2-hour period. When an MTP is needed, fixed ratios of pRBCs, FFP, and platelets should be used. Some protocols include TXA and rFVIIa.

Recommendations for the rapid transfusion protocols have been adapted from trauma literature and a few clinical reports. Although replacement therapy with plasma, platelets, and RBCs generally should not be based on any set formula, the results from these studies suggest that patients with severe trauma, massive blood replacement, and coagulopathy have improved survival when the ratio of transfused pRBCs (units) to FFP (units) to platelet (units) approaches 1:1:1. Most of these studies found that patients receiving between 5 and 10 units of pRBCs rarely needed component replacement. Pasquier et al. retrospectively found that PPH patients transfused a higher ratio of FFP:pRBC (1:1.2 vs. 1:1.6) had more successful bleeding control with the uterotonic therapy, sulprostone alone, and less need for advanced interventional procedures. In a recent survey, more than 80% of academic institutions in the United States reported using the 1:1 pRBC:FFP ratio. Previous MTP protocols have suggested different ratios, such as 4:4:1 or 6:4:1, and are related to how a unit of platelets is defined. Because there are only a limited number of studies in parturients requiring massive transfusion, what is more important than the actual ratio of blood products is that each institution has a specific protocol for multicomponent transfusions in place.

Data concerning the use of prothrombin concentrates (PCCs) and virus-inactivated fibrinogen concentrate in the PPH patient are limited. The ACOG recommends that their use should only be considered after multiple rounds of standard massive transfusion agents and in consultation with an expert in massive transfusion. Different preparations of PCCs, the human plasma–derived concentrates of vitamin K–dependent clotting factors, are available containing either three factors (factors II, IX, and X) or four factors (factors II, VII, IX, and X). Each gram of fibrinogen concentrate increases the fibrinogen level approximately 40 mg per dL.

C.11. What is the role of recombinant activated factor VII (rFVIIa) in the hemorrhaging obstetric patient?

rFVIIa (NovoSeven), a synthetic vitamin K–dependent glycoprotein, has been used to facilitate hemostasis in patients bleeding from coagulopathies, surgery, trauma, and severe obstetric hemorrhage. Use of rFVIIa in obstetrics has been reported in case series and international registries; no randomized controlled trials have been published. The ACOG recommends that its use be reserved for extenuating circumstances after multiple rounds of standard transfusion agents and in consultation with an expert in massive hemorrhage.

At pharmacologic doses, rFVIIa promotes hemostasis by activating the extrinsic pathway of the coagulation cascade; it replaces deficient activated factor VII. It complexes with tissue factor and may activate the conversion of factor X to Xa and factor IX to IXa; when complexed with other factors, factor Xa converts prothrombin to thrombin, which is a key step in the formation of a fibrin-platelet plug that may control bleeding. Franchini et al. reviewed the literature and found that a median dose of 81.5 μg per kg of rFVIIa has been effective in stopping or decreasing bleeding in 85% of obstetric cases where it has been utilized. They outlined a treatment scheme for the off-label use of rFVIIa in the treatment of PPH. They suggest that rFVIIa be considered only after the failure of medical treatment, blood component therapy, and conservative surgical/invasive treatment. Before administering rFVIIa, acidosis, thrombocytopenia, hypofibrinogenemia, hypocalcemia, and hypothermia should be corrected. Although the optimal dose of rFVIIa for PPH has not been determined, 90 μg per kg can be given intravenously over 3 to 5 minutes. If no response has

occurred 20 minutes later, a second dose of 90 μg per kg may be given. If there is no response after two doses, hysterectomy should be considered. Because to date all of the information about rFVIIa in obstetrics is anecdotal, the use of rFVIIa should be determined on an individual case basis. There are unanswered concerns about the increased likelihood of thrombotic events, and the role of rFVIIa remains undefined.

C.12. What is the role of type O Rh-negative (universal donor) uncrossmatched blood in emergency transfusions, and how does this change your future management?

When typed and screened/crossed blood is unavailable and the hemodynamically unstable, hemorrhaging obstetric patient requires an RBC transfusion in addition to crystalloid and/or colloid solutions, uncrossmatched type O Rh-negative blood can be given. People with type O blood are considered universal donors because they lack A and B antigens, and therefore, their erythrocytes are not hemolyzed by a recipient's anti-A or anti-B antibodies if present. Some type O donors, however, produce high titers of hemolytic anti-A and anti-B antibodies. pRBCs, therefore, are preferable to whole blood because packed erythrocytes have a smaller volume of plasma and therefore a

minimal amount of anti-A and anti-B antibodies if present. If whole blood is to be used, the blood bank should supply type O blood that is free of anti-A and anti-B antibodies. Some confusion exists as to when it is safe to switch back to the patient's native blood type. After a patient has received 2 units of type O Rh-negative uncrossmatched whole blood, the patient should not be switched to their type-specific (A, B, AB) blood; additional transfusions should be continued with type O blood. The patient must not receive a transfusion of her correct blood type until the blood bank determines that switching back to the patient's native blood type is safe. Patients who have received uncrossmatched type O Rh-negative pRBCs can receive many more units without concern for antibody reactions. Individual centers have different policies governing the maximum number of uncrossmatched type O Rh-negative blood units that can be given before switching back to the patient's specific blood type. Most centers do recommend switching to the patient's native blood type as soon as safely possible in order to conserve the emergency supply of type O Rh-negative blood. Recommendations should be received from your local blood bank representative.

C.13. What complications can occur from the transfusion of blood products?

Allogenic blood transfusion safety has improved over the past several decades. Deaths from allogenic transfusions are rare. When they occur, they are primarily due to transfusion-related acute lung injury (TRALI), ABO- and non-ABO hemolytic transfusion reactions (HTRs), and transfusion-related sepsis. Other transfusion-related adverse reactions include transfusion-associated circulatory overload, delayed HTRs, febrile and

allergic non-HTRs, infection due to bacterial and/or viral contamination of blood products, transfusion-associated graft-versus-host disease, transfusion-related immunomodulation, and posttransfusion purpura.

TRALI is the most common cause of transfusion-related mortality. TRALI is a noncardiogenic pulmonary edema that occurs within 6 hours after transfusion; this life-threatening complication is characterized by severe dyspnea and hypoxia. A delayed form of TRALI has been reported to occur 6 to 72 hours after transfusion. All blood products can cause TRALI, but plasma-containing products account for 50% to 63% of the fatalities. Its pathogenesis is incompletely understood, but the lung injury appears to involve the activation of recipient white blood cells by human leukocyte antigen antibodies and/or human neutrophil antigen antibodies in the donor plasma. Because the risk of multiparous female donors having these offending antibodies is increased, male-only plasma donation policies have decreased the TRALI rate. Currently, the American Red Cross plasma distribution from male donors exceed 99% for blood groups A, B, and O but is only 60% for group AB. The risk of TRALI after plasma transfusion has been markedly reduced for groups A, B, and O (1.8 per million distributed products) but not for AB (26.3 per million distributed products) due to the continuing use of AB plasma from female donors to meet demand.

HTRs can be acute or delayed. Fatalities from HTRs are rare but do continue to occur in about 1 in 1.5 million to 1.8 million transfusions. The severity of an HTR depends on the incompatible recipient antibody, which is most severe in an ABO mismatch, and the volume of blood transfused, with more than 200 mL transfused usually needed to cause a fatality. The accidental transfusion of ABO-incompatible blood can result in acute intravascular hemolysis. This is typically characterized by

the symptoms of fever, chills, nausea, flushing, chest and flank pain, tachycardia, hypotension, DIC, hemoglobinuria, acute renal failure, and potentially death. Immediate supportive care includes the discontinuation of the transfusion, treatment of the hypotension and hyperkalemia, administration of a diuretic, and urine alkalinization. The unused blood product should be sent back to the blood bank along with a new patient specimen for a second crossmatch. Assays for urine and plasma Hgb concentration and a direct antiglobulin antibody screen confirm the diagnosis. Reported fatalities due to acute HTRs secondary to non-ABO antibody incompatibilities have increased in the United States and were implicated in 69.2% of all fatal HTRs. Although acute HTRs occur within 24 hours of the transfusion, delayed reactions occur approximately 7 to 10 days after the transfusion of seemingly compatible blood. Death from delayed HTRs occurs much more infrequently than those from an acute reaction.

Because they are stored at room temperature, platelets present the greatest risk of bacterial contamination that can lead to transfusion-related sepsis. The introduction of culture-negative platelets has decreased the risk of receiving an infected platelet transfusion.

The risk of viral infection transmission is low. The risk of contracting human immunodeficiency virus (HIV) or hepatitis C is approximately 1 in 2 million units transfused. The risk of *hepatitis B* transmission is estimated to be less than 1 per 200,000 to 500,000 units transfused. The risk of transfusion-transmitted cytomegalovirus (CMV) can lead to serious morbidity in the immunocompromised patient and/or the fetus or neonate; therefore, pregnant women should receive blood that is seronegative and leukocyte-depleted to decrease the risk of CMV infection. There have been rare reports of West Nile virus infection, variant Creutzfeldt-Jakob disease, human T-

lymphocyte virus type 1, toxoplasmosis, and parvovirus B19 acquired via transfusion. In the United States, blood products are screened for the following infectious agents: HIV-1, HIV-2, human T-lymphocyte virus type I and II, Hepatitis B and C, West Nile virus, Zika virus, Treponema pallidum (syphilis), Trypanosoma cruzi, CMV (only on enough units to have a sufficient inventory for at-risk recipients), and Babesia microti (in high-risk regions only).

The biochemical changes that occur with the storage of blood can lead to problems in the recipient especially when large amounts are rapidly infused. Hypocalcemia, hyperkalemia, and hypothermia can occur and should be promptly corrected.

C.14. What is the role of autologous transfusion in obstetric patients?

Autologous blood transfusion may avoid the risks of alloimmunization, hemolytic reactions, and viral infections; may potentially decrease the demands on the allogenic blood supply; and may provide a psychological benefit to the patient. There are three methods of autologous transfusion: preoperative (antepartum) donation, normovolemic hemodilution, and

intraoperative blood salvage.

Due to the inability to correctly anticipate which patients will require transfusions and the limited amount of transfusable blood obtained, preoperative donation and normovolemic hemodilution are ineffective strategies for avoiding allogenic transfusions in the obstetric patient. Women with rare blood types or unusual antibodies, however, may benefit from preoperative donation.

Intraoperative blood salvage has been used in obstetric patients and is considered to be safe. The limitations are primarily due to the availability of equipment and the appropriate staff, and it only provides RBCs. During cesarean section after placenta delivery, blood is suctioned from the surgical site, collected, and processed through a cell salvage machine that yields a washed, pRBC product for transfusion. Earlier concerns about the safety of blood salvage during cesarean section related to contamination with amniotic fluid have been dispelled with higher quality filtering. Leukocyte depletion filters may improve the margin of safety of the salvaged pRBC product. Because washed pRBCs may contain fetal RBCs, isoimmunization of the mother is possible; anti-D IG should be given when appropriate.

Jehovah's Witness patients have an increased risk of maternal death due to maternal hemorrhage because their religious beliefs prevent them from receiving blood transfusions. The use of intraoperative blood salvage during surgery sometimes is accepted because continuity of the salvaged blood with the patient's circulatory system can be maintained. The exact possibilities for acceptable treatment options should be discussed with each individual patient early in pregnancy.

C.15. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?

The obstetric patient can rapidly develop a coagulopathy. It may be a dilutional coagulopathy or DIC. A dilutional coagulopathy can occur when massive blood loss is replaced with crystalloid solutions and pRBCs leading to a relative depletion of platelets and soluble clotting factors. Thrombocytopenia, hypofibrinogenemia, and factor depletion occur. Pregnancy-related causes of DIC include hemorrhagic shock, AFE, placental abruption, intrauterine fetal demise, preeclampsia/hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome, sepsis, and acute fatty liver of pregnancy. Additionally, HTRs with acute intravascular hemolysis can cause DIC. Acidosis and hypothermia both interfere with the normal functioning of the coagulation system and worsen any coagulopathy.

Erez O. Disseminated intravascular coagulation in pregnancy—clinical phenotypes and diagnostic scores. *Thromb Res*. 2017;151(suppl 1):S56–S60.

C.16. What is disseminated intravascular coagulation (DIC)?

DIC, a consumptive coagulopathy, is a pathologic activation of the coagulation system that occurs in response to a variety of diseases. The process of coagulation is dysregulated and widespread intravascular clotting and resultant bleeding due to the inappropriate consumption of factors and platelets occurs. Thrombi are deposited in the microcirculation and can diminish blood flow to the organs and lead to multisystem organ failure. Simultaneously, increased fibrinolysis occurs with the formation of fibrin degradation products (also called fibrin split products). Once DIC begins, the pathophysiology is the same regardless of the inciting cause. Resolution of DIC requires treatment of the underlying cause. Supportive treatment is aimed at replacing the consumed blood products-"feeding the fire." Laboratory values are indicative of this consumption of clotting products and the increased fibrinolysis that this excess clotting activates and can help guide management. Thrombocytopenia, decreased levels of fibrinogen and coagulation factors, increased levels of fibrin degradation products (D-dimers), increased PT, and increased aPTT are seen.

Erez O. Disseminated intravascular coagulation in pregnancy—clinical phenotypes and diagnostic scores. *Thromb Res*. 2017;151(suppl 1):S56–S60.

C.17. Define amniotic fluid embolism (AFE) syndrome and discuss treatment.

The typical presentation of AFE includes a triad of sudden cardiac and respiratory compromise with DIC occurring in relation to labor and delivery. Classically, it is characterized by the abrupt onset of maternal hypotension, dyspnea, hypoxemia, cyanosis, loss of consciousness, seizures, cardiopulmonary arrest, and hemorrhaging due to DIC. AFE is a complex disorder that is poorly understood.

The cause of AFE syndrome is unknown. The diagnosis of AFE is a clinical one of exclusion; no diagnostic tests exist. The pathophysiology seems to involve an abnormal activation of maternal proinflammatory mediators in response to fetal tissue exposure during breaks in the maternal–fetal barrier during parturition. Multiple possible mechanisms have been proposed, but none adequately explains this complex syndrome. The abnormal endogenous mediator release has clinical similarities to the systemic inflammatory response syndrome seen with severe sepsis and anaphylaxis. Laboratory findings are nonspecific. The detection of squamous cells, trophoblasts, and other debris of fetal origin is neither sensitive nor specific for AFE.

The estimated AFE incidence is approximately 1 in 40,000 deliveries. Cesarean or instrumented vaginal delivery, precipitous labor, advanced maternal age, placenta abruption, placenta previa, PAS, grand multiparity, cervical lacerations, uterine rupture, uterine or pelvic vein tears, eclampsia, pharmacologic labor induction, and polyhydramnios are risk factors.

The overall maternal mortality was reported to be between 11% and 90% but is currently reported to range from 20% to 60%. The reported incidence and outcome vary in part because AFE is a diagnosis of exclusion, and perhaps the changing mortality rates reflect improved intensive care. In survivors, the neurologic outcome is often poor with as many as 85% suffering significant neurologic dysfunction. The neonatal mortality rate is estimated to be between 20% and 60%, and up to 50% of the survivors are neurologically intact. Overall, neonatal outcomes have improved with prompt delivery.

Maternal treatment is primarily prompt supportive resuscitation. The need for delivery is made on a case-by-case basis, but prompt delivery of the fetus in the mother who has

sustained a cardiopulmonary arrest is critical. There is no data that any type of intervention improves maternal prognosis with AFE, although case reports using hemofiltration, exchange transfusion, cardiopulmonary bypass, or extracorporeal membrane oxygenation exist.

D. Postoperative Management

D.1. If the patient received epidural anesthesia and subsequently developed DIC, when should the epidural catheter be removed?

There is little information available concerning this topic. Sprung et al. made recommendations about the removal of an epidural catheter after DIC. First, they suggest that the patient's neurologic status be evaluated frequently and that the coagulopathy be treated; if there is no indication of intraspinal bleeding, they recommend removing the catheter as early as possible. If, however, bleeding is occurring around the catheter insertion site, the catheter may be left in place to tamponade this bleeding. Any neurologic deficits should be evaluated immediately; prompt surgical decompression may be needed. However, if a patient's neurologic status cannot be evaluated (e.g., postoperative intubation and sedation), an argument can be

made for the removal of an indwelling catheter as soon as possible after the replacement of coagulation factors has created a state of normal coagulation even if it is temporary. The recommendations for the best hemostatic conditions for epidural catheter removal should reflect those used for placement of a neuraxial block.

Sprung J, Cheng EY, Patel S. When to remove an epidural catheter in a parturient with disseminated intravascular coagulation? *Reg Anesth*. 1992;17(6):351–354.

D.2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?

She may have developed Sheehan syndrome. Sheehan syndrome refers to the development of a postpartum pituitary infarction with necrosis that is typically precipitated by an obstetric hemorrhage with severe hypotension. Sheehan syndrome is a rare complication. The damage to the pituitary may affect the secretion of one, several, or all of its hormones. Any of the manifestations of hypopituitarism (e.g., failure to lactate, amenorrhea/oligomenorrhea, hypotension, hyponatremia, hypothyroidism) can occur at any time from the immediate postpartum period to years after delivery. If the patient remains hypotensive after control of hemorrhage and adequate volume replacement, she should be evaluated and treated for adrenal insufficiency immediately; treatment of possible adrenal crisis

should not be delayed while diagnostic tests are performed. Glucocorticoids have a role in maintaining peripheral vascular adrenergic tone, and the sudden loss of corticotropin (adrenocorticotropic hormone) secretion, particularly in conjunction with other serious physical stress, can lead to hypotension and shock. Prompt treatment with stress doses of glucocorticoids (e.g., 4-mg dexamethasone by intravenous bolus) is necessary for survival. The workup includes measuring adrenocorticotropic hormone, cortisol, thyroxine, prolactin, and growth hormone levels. The evaluation of other hormonal deficiencies is not urgent and can be deferred until 4 to 6 weeks postpartum.

28 Hypertensive Disorders of Pregnancy

Sharon Abramovitz and
Jennifer Wagner

A 39-year-old woman gravida 1 para 0 at 29 weeks' gestation was admitted to the hospital because of an elevated blood pressure (BP) (182/111 mmHg), headache, and proteinuria.

A. Medical Disease and Differential Diagnosis

1. What is the classification of hypertension disorders in pregnancy as defined by the American College of Obstetricians and Gynecologists?
2. What is preeclampsia?
3. What is preeclampsia with severe features?
4. What is eclampsia?
5. What is HELLP syndrome?
6. What are the risk factors for developing preeclampsia?
7. What is the mortality associated with preeclampsia?
8. Discuss the pathogenesis of preeclampsia.
9. Discuss the pathologic alterations of preeclampsia.
10. What are some of the complications associated with preeclampsia?

B. Preoperative Evaluation and Preparation

1. What initial laboratory studies are recommended for patients with preeclampsia?
2. Discuss bleeding time and platelet count evaluation during preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.
3. What types of monitoring are important for patients with preeclampsia? When is a central venous pressure (CVP) monitor indicated?
4. Discuss the obstetric management of preeclampsia with severe features.
5. What are the antihypertensive agents of choice for preeclampsia?
6. What drug therapy is the treatment of choice for seizure prophylaxis?
7. Discuss the mechanism of action of magnesium sulfate.
8. What are the fetal effects of magnesium sulfate therapy?
9. Discuss the treatment of magnesium sulfate toxicity.
10. What conditions mandate immediate delivery, regardless of the gestational age?
11. Discuss the management of eclampsia.

C. Intraoperative Management

1. What is your choice of labor analgesia for patients with preeclampsia?
2. What is the advantage of prehydration prior to initiation of neuraxial analgesia?
3. What sensory level of analgesia is required for labor and delivery?
4. Discuss the commonly used local anesthetics for labor analgesia.
5. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?

6. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after neuraxial analgesia is instituted?
7. What would you do after an accidental dural puncture? How do you treat postdural puncture headache?
8. How would you manage total spinal anesthesia?
9. Should methylergonovine be given to preeclamptic patients?
10. When and how would you give spinal anesthesia?
11. Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.
12. What agents can you use to prevent hypertension during the induction of general anesthesia for cesarean delivery?

D. Postoperative Management

1. Discuss the postpartum management of preeclamptic patients.
2. Can nonsteroidal anti-inflammatory drugs (NSAIDs) be used to treat postpartum pain in preeclamptic patients?

A. Medical Disease and Differential Diagnosis

A.1. What is the classification of hypertension disorders in pregnancy as defined by the American College of Obstetricians and Gynecologists?

Hypertensive disorders of pregnancy are classified as follows:

- Gestational hypertension
- Preeclampsia
- Preeclampsia without severe features
- Preeclampsia with severe features
- Chronic hypertension preceding pregnancy
- Chronic hypertension with superimposed preeclampsia

American College of Obstetricians and Gynecologists Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on

Hypertension in Pregnancy. *Obstet Gynecol*. 2013;122:1122–1131.

A.2. What is preeclampsia?

Preeclampsia is a multiorgan disease characterized by the development of hypertension, along with proteinuria or end-organ dysfunction, after the 20th week of gestation. It is a disorder affecting approximately 2% to 8% of all pregnancies worldwide, with most cases occurring during the first pregnancy, and is unique to humans. Preeclampsia is a leading cause of maternal and perinatal morbidity and mortality worldwide, particularly in developing countries. Hypertension is defined as a systolic BP of at least 140 mmHg or a diastolic BP of at least 90 mmHg on two occasions at least 4 hours apart in a previously normotensive patient. A single reading of a systolic BP of 160 mmHg or more or diastolic BP of 110 mg Hg or more also defines hypertension. Proteinuria is defined as 300 mg or more of protein in a 24-hour urine collection, a protein–creatinine ratio of 0.3 or greater, or 1+ protein on a urine dipstick. (Dipstick results may be variable and should only be used if other tests are not readily available.) Signs of end-organ dysfunction may include thrombocytopenia (platelet count less than 100,000 per μL), elevated liver transaminases (twice the normal concentration), elevated serum creatinine (greater than 1.1 mg per dL or a doubling of the serum creatinine in the absence of other renal disease), pulmonary edema, or new-onset cerebral or visual disturbances. Peripheral edema is no longer part of the diagnostic criteria because it lacks specificity and is found in many healthy pregnant women.

Sibai BM, Stella CL. Diagnosis and management of atypical preeclampsia-eclampsia. *Am J Obstet Gynecol*. 2009;200(5):481.e1–481.e7.

A.3. What is preeclampsia with severe features?

Preeclampsia with severe features includes at least one of the following features:

- BP: systolic BP ≥160 mmHg or diastolic BP ≥110 mmHg on two occasions at least 4 hours apart while the patient is on bedrest
- Thrombocytopenia (platelet count less than 100,000 per μL)
- Serum creatinine concentration greater than 1.1 mg per dL or greater than two times the baseline serum creatinine concentration
- Pulmonary edema
- New-onset cerebral or visual disturbances
- Impaired liver function, indicated by elevated blood concentrations of liver enzymes (twice baseline values) or severe, persistent right upper quadrant or epigastric pain
- Fetal growth restriction and severe proteinuria (<5 g in 24 hours) are *no* longer considered features of severe preeclampsia.

American College of Obstetricians and Gynecologists Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol*. 2013;122:1122–1131.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:840–842.

A.4. What is eclampsia?

Eclampsia is defined as convulsions and/or coma not caused by coincidental neurologic disease (e.g., epilepsy), which occurs during pregnancy or the puerperium in a woman whose

condition also meets the criteria for preeclampsia.

Broughton Pipkin F. The hypertensive disorders of pregnancy. *BMJ*. 1995;311:609–613.

Sibai BM. Diagnosis, prevention, and management of eclampsia. *Obstet Gynecol*. 2005;105(2):402–410.

A.5. What is HELLP syndrome?

HELLP syndrome is a severe form of preeclampsia characterized by hemolysis (*H*), elevated liver enzymes (*EL*), and low platelets (*LP*). It can occur antepartum or postpartum. Delivery represents the only definitive treatment of HELLP syndrome. HELLP syndrome is associated with maternal and neonatal morbidity and mortality. Hemolysis is defined by an abnormal peripheral blood smear and an increased bilirubin level (1.2 mg per dL or greater). Elevated liver enzymes are defined as an increased serum glutamic-oxaloacetic transaminase (aspartate aminotransferase) of at least 70 U per L and a lactate dehydrogenase level of more than 600 U per L. A low platelet count is generally defined as a count of less than 100,000 per μL. Patients with HELLP syndrome have a high incidence of serious maternal complications including disseminated intravascular coagulation, placental abruption, need for blood transfusion, pleural effusion, acute renal failure, and wound infection.

Audibert F, Friedman SA, Frangieh AY, et al. Clinical utility of strict diagnostic criteria for the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome. *Am J Obstet Gynecol*. 1996;175:460–464.

A.6. What are the risk factors for developing preeclampsia?

The risk factors for developing preeclampsia are as follows:

Hypertensive disease

- Preeclampsia in prior pregnancy
- History of chronic hypertension
- Family history of hypertension during pregnancy
- Systolic hypertension during early pregnancy

Coexisting vascular and endothelial disease

- Diabetes mellitus (pregestational or gestational)
- Chronic renal disease
- Systemic lupus erythematosus
- Protein S deficiency
- Activated protein C resistance
- Antiphospholipid antibody syndrome
- Angiotensinogen gene *T235*
- Thrombophilia

Obstetric factors

- Nulliparity
- Increased trophoblastic mass (e.g., multiple gestation, molar pregnancy)
- Large-for-gestational-age fetus
- Polyhydramnios, particularly in young primigravidas
- Use of assisted reproductive technology
- Erythroblastosis fetalis

Other

- African-American race
- Obesity
- Obstructive sleep apnea
- Advanced maternal age (greater than 35 years)

A.7. What is the mortality associated with preeclampsia?

From 2011 to 2016, hypertensive disorders of pregnancy accounted for 6.9% of pregnancy-related deaths in the United States.

A.8. Discuss the pathogenesis of preeclampsia.

Preeclampsia is most likely a disease of heterogeneous causes of both maternal and placental origin.

Immunologic Factors

Immunologic disorders may arise from an abnormal maternal–fetal antigen–antibody response or from the contents of seminal fluids; spermatozoa may cause antibody formation or prostaglandins may initiate uterine vasoconstriction. The fetus acquires 50% of its genes from the father, which represents in part a paternal allograft that interacts with maternal tissue as the fetal trophoblast migrates into the maternal decidua after implantation. Migration normally occurs in two phases.

Trophoblasts displace the muscular structure of the maternal spiral arteries before 20 weeks of gestation, causing their adrenergic denervation and converting them from high-resistance to low-resistance vessels. At the same time, biochemical adaptations occur in the maternal vasculature, with an increased dominance of endothelium-dependent vasodilators, prostacyclin (prostaglandin I [PGI]), and nitric oxide (NO). In preeclampsia, the second wave of trophoblastic migration fails. This failure can result in a high-resistance, low-flow uteroplacental circulation and consequent placental ischemia and hypoxia. These changes may represent an aberrant immunologic mechanism.

Genetic Factors

A familial tendency toward preeclampsia exists in some populations, and it may result from a recessive genetic inheritance.

Endothelial Factors

Vascular endothelial damage or dysfunction is the common pathologic feature of preeclampsia and occurs in the placental decidual vessels and renal microvasculature. Endothelial cell dysfunction in response to unknown factors may cause a hormonal imbalance in women with preeclampsia (**Fig. 28.1**).

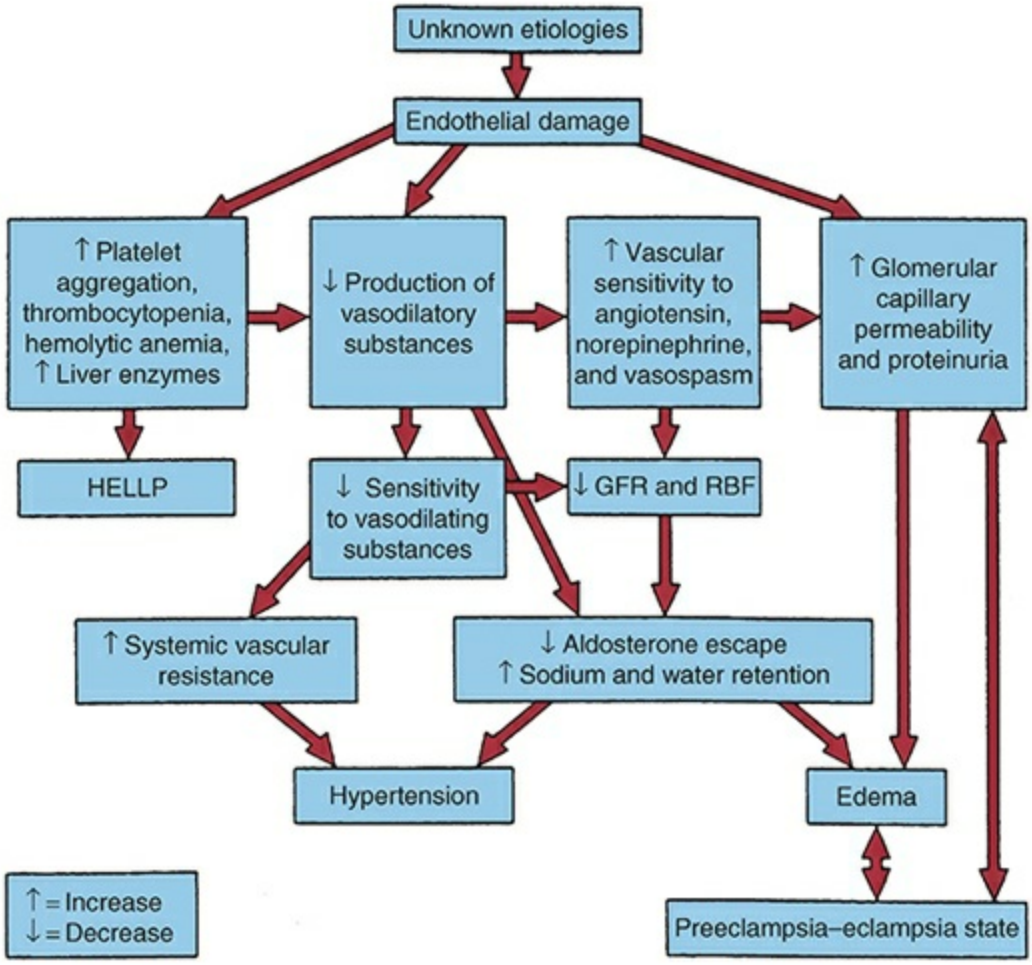

FIGURE 28.1. Endothelial cell dysfunction in response to unknown factors may cause a hormonal imbalance in women with pregnancy-induced hypertension. GFR, glomerular filtration rate; HELLP, hemolysis, elevated liver enzymes, and low platelets; RBF, renal blood flow. (*Reprinted from Chestnut DH, Wong CA, Tsen LC, et al, eds*. Chestnut's Obstetric Anesthesia: Principles and Practice. *6th ed. Philadelphia, PA: Elsevier; 2019. Copyright © 2019 Elsevier. With permission.*)

The metabolic end products of normal vascular endothelium include PGI_2 and endothelium-derived relaxing factor (EDRF), which is either NO or a related nitrosyl substance. Both PGI_2 and EDRF are potent vasodilators. In patients with preeclampsia, the failure of the trophoblast to invade the uteroplacental vascular bed may encourage an increased production of free radicals and lipid peroxides by the decidual lymphoid tissue. As a result, an imbalance occurs between the production of the vasoconstrictor thromboxane A_2 (TXA_2),

which is derived from platelets, and the production of endothelium-derived PGI_2. This imbalance results in a reduced perfusion of the intervillous space. Some investigators have concluded that hypoxia-induced impairment of NO production by the syncytiotrophoblast results in uteroplacental insufficiency and production of a toxin responsible for the clinical manifestations of preeclampsia.

It has been shown that production of endothelin-1 (ET-1), which is the most potent endogenous vasoconstrictor and produced mainly by vascular smooth muscle cells as well as by the vascular endothelium, is markedly increased in preeclampsia and correlates inversely with NO production. Therefore, the imbalance between NO and ET-1 may play a significant role in the pathophysiology of preeclampsia.

Fetoplacental blood vessels or, more specifically, the human placental chorionic plate arteries constrict in response to ET-1. There is now some evidence that amniotic concentration of ET-1 is elevated in pregnancies associated with preeclampsia. Margarit et al. found a statistically significant increase in ET-1 concentration in the amniotic fluid of women at 17 weeks' gestation who developed preeclampsia, as compared to those who did not develop preeclampsia. By the second trimester, higher levels of ET-1 have also been shown in the amniotic fluid of women with preterm premature rupture of the membranes.

Platelet Factors

In mild preeclampsia, serotonin (5-HT) released from aggregating platelets interacts with endothelial $5\text{-}HT_1$ receptors, resulting in the release of prostacyclin and NO (EDRF). The released prostacyclin induces angiotensin II release, improving uteroplacental perfusion. In early-onset severe preeclampsia, damaged uteroplacental vessels cannot respond to $5\text{-}HT_1$ effects. Instead, serotonin interacts with $5\text{-}HT_2$ receptors on vascular

smooth muscle cells, inducing vasoconstriction. Platelet-derived serotonin also activates 5-HT_2 platelet receptors, establishing a positive feedback loop and intensifying platelet aggregation. The loss of 5-HT_1 receptors prevents stimulation of angiotensin II release (**Fig. 28.2**).

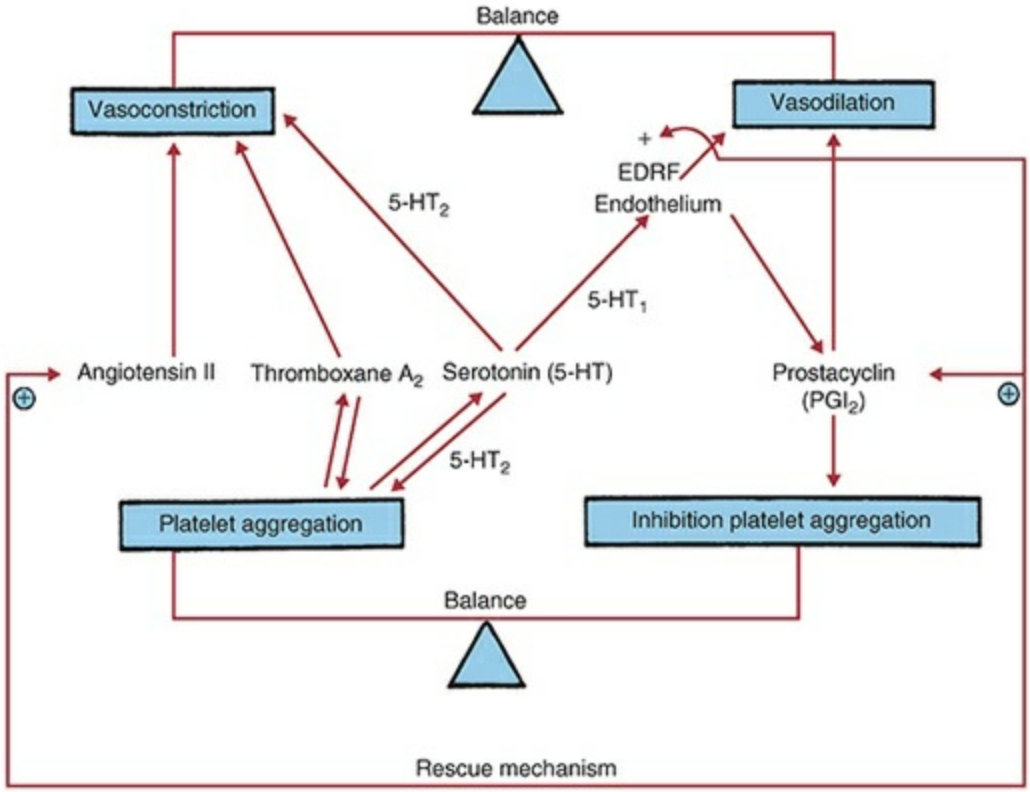

FIGURE 28.2. The loss of 5-HT_1 receptors prevents stimulation of angiotensin II release. EDRF, endothelium-derived relaxing factor. (*Reprinted from Chestnut DH, Wong CA, Tsen LC, et al, eds.* Chestnut's Obstetric Anesthesia: Principles and Practice. *6th ed. Philadelphia, PA: Elsevier; 2019. Copyright © 2019 Elsevier. With permission.*)

Calcium

In normal pregnancy, the intracellular free calcium concentration increases slowly, but this increase is significantly greater in the third trimester in women with preeclampsia. The increase in cytoplasmic calcium levels is enhanced by angiotensin II, and the enhancement is greater in women with preeclampsia compared with normotensive women. This

response to angiotensin II occurs long before signs of preeclampsia become evident and is a sensitive indicator of its subsequent development.

Coagulation Factors

Platelet activation in preeclampsia is surface mediated. Women with preeclampsia have an increased tendency toward thromboembolism, which may result in part from an alteration in the plasma ratio between von Willebrand factor and factor VIII coagulant activity.

Fatty Acid Metabolism

Altered handling of fatty acids by the liver is a key factor in the pathogenesis of preeclampsia. Both increased hepatic uptake of free fatty acids and hypertriglyceridemia are seen more frequently in women who develop preeclampsia.

Markers of Angiogenesis

Preeclamptic patients have elevated plasma levels of endoglin and soluble FLT-1, the receptor for vascular endothelial growth factor, throughout gestation. Recent research suggests that these molecules are not just disease markers but are involved in the pathogenesis of preeclampsia.

A.9. Discuss the pathologic alterations of preeclampsia.

Cardiovascular Changes

- *Blood pressure*. The increase in BP results from an increase in peripheral vascular resistance secondary to a state of sympathetic overactivity.
- *Blood volume*. Reduction in intravascular volume leads to hemoconcentration.

Hemodynamic Changes

- Three hemodynamic subsets exist:
  - Hyperdynamic with increased cardiac output, normal or slightly increased systemic vascular resistance (SVR), and normal or slightly decreased blood volume and filling pressures
  - High SVR with normal cardiac output and lower filling pressures
  - Markedly increased SVR with decreased blood volume and depressed left ventricular function
- Poor correlation between CVP and pulmonary artery (PA) occlusion pressure exist.
  - Decreased colloid oncotic pressure occurs in pregnancy with further reduction in preeclampsia. The low colloid oncotic pressure, coupled with increased vascular permeability and the loss of intravascular fluid and protein into interstitial tissues, increases the risk of pulmonary edema.

Hematologic Changes

- Hypercoagulable state (**Table 28.1**)

TABLE 28.1 Changes that Imply Hypercoagulation in Preeclampsia

↑ Common pathway activity
↓ Fibrinogen
↑ Fibrin-degradation products
D-Dimer positive
↑ Fibrinopeptide A

↑ Factor VIII antigen; factor VIII activity
↓ Antithrombin-III
↑ Antithrombin-III/antithrombin complex
↓ Platelets
↑ β-Thromboglobulin
↑ Platelet aggregability
↓ Sensitivity to prostacyclin

↓, decreased; ↑, increased.

Reprinted from Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019. Copyright © 2019 Elsevier. With permission.

- Platelet activation: Thrombocytopenia occurs in 15% to 30% of women with preeclampsia or eclampsia. Preeclampsia may be associated with a significant defect in *both* platelet function and platelet number. Thrombocytopenia without other coagulation abnormalities but with evidence of hemolysis and increased liver enzymes characterizes HELLP syndrome.

Renal Changes

- Glomerular enlargement results in ischemia, leading to decreased glomerular filtration rate.
- Proteinuria occurs as a result of an increased permeability to most large molecular weight proteins.
- Urate clearance decreases and serum uric acid concentrations increase. Hyperuricemia may provide an early indication of preeclampsia.
- Oliguria parallels the severity of preeclampsia.

Endocrine Changes

In women with preeclampsia, a breakdown of the normal balance between vasodilators (PGI_2, NO) and vasoconstrictors (angiotensin II, TXA_2, serotonin, ET-1) occurs. There is also a decrease in plasma renin concentration and suppression of the renin–angiotensin–aldosterone system.

Respiratory Changes

- Pharyngeal and laryngeal edema may make airway management difficult, necessitating the use of smaller endotracheal tubes.
- Pulmonary edema occurs in 3% of cases, with some cases occurring postpartum.

Hepatic Changes

- Serum transaminase levels frequently increase in patients with mild preeclampsia.
- Epigastric or subcostal pain is an ominous symptom that is typically caused by distension of the liver capsule by edema or subcapsular or parenchymal bleeding. Hepatic swelling produces epigastric pain.
- Liver rupture is a rare complication but is associated with more than 80% mortality.

Neurologic Changes

- The classic manifestations of preeclampsia include severe headache, visual disturbances, central nervous system hyperexcitability, and hyperreflexia.
- The occurrence of seizures indicates eclampsia until proven otherwise. Etiologies of seizures include hypertonic encephalopathy, vasospasm, microinfarctions and punctate hemorrhages, thrombosis, and cerebral edema.
- Postpartum eclampsia may occur up to 4 weeks after delivery.

Uteroplacental Perfusion

- Uteroplacental perfusion is decreased in preeclampsia with the potential for intrauterine growth retardation.

A.10. What are some of the complications associated with preeclampsia?

Maternal complications include disseminated intravascular coagulation, congestive heart failure with pulmonary edema, placental abruption, postpartum hemorrhage, acute kidney injury, rupture of the liver, cerebrovascular accident, and septic shock. The leading cause of maternal death is intracranial hemorrhage.

Fetal complications include prematurity with respiratory distress, intrauterine growth retardation, oligohydramnios, intracranial hemorrhage, small for gestational age, and aspiration of meconium. The leading cause of intrauterine morbidity and mortality is uteroplacental insufficiency caused by placental infarcts, followed by placental abruption, and chorioamnionitis.

B. Preoperative Evaluation and Preparation

B.1. What initial laboratory studies are recommended for patients with preeclampsia?

- Hemoglobin and hematocrit

- Platelet count
- Coagulation assay including activated partial thromboplastin time, prothrombin time, fibrinogen, D-dimer
- Serum electrolytes
- Blood urea nitrogen, creatinine, and uric acid concentration
- Liver function tests
- Urinalysis, microscopy, 24-hour specimen for protein and creatinine clearance
- Type and screen (crossmatch if antibodies present)

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:856–859.

B.2. Discuss bleeding time and platelet count evaluation during preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.

The bleeding time does not specifically measure platelet function, and it can be abnormal in a number of coagulation disorders, such as factor deficiencies. No evidence suggests that the skin bleeding time predicts the potential for bleeding from a traumatized epidural vein in a woman with severe preeclampsia. Therefore, the bleeding time should not be used to measure platelet function. A specific platelet count that predicts the risk of complications from regional anesthesia has not been determined. The *trend* in platelet count is important to note because preeclampsia is a dynamic disorder, and a rapid decrease in platelet count in a short interval may warrant concern.

Many anesthesiologists will place an epidural anesthetic at a platelet count of 80,000 per μL and some at lower platelet counts, especially in otherwise healthy parturients. The preeclamptic patient must be individualized and a thorough

bleeding history, along with the trend in platelet count, should always be considered. If the platelet count is below 100,000 per μL, serial platelet counts as well as the prothrombin time, partial thromboplastin time, and fibrinogen levels should be measured.

B.3. What types of monitoring are important for patients with preeclampsia? When is a central venous pressure (CVP) monitor indicated?

- BP monitoring with noninvasive cuff
- Maternal respiratory function assessment with oxygen saturation
- Foley catheter for assessing urine output
- Monitor deep tendon reflexes and serial magnesium levels
- Tocodynamometer and continuous fetal heart rate monitoring
- Consider invasive BP monitoring with an arterial line when severe refractory hypertension is present; when rapid-acting vasodilators, such as sodium nitroprusside (SNP) or nicardipine, are used; or when noninvasive BP measurement proves difficult (e.g., obesity).
- A CVP monitor or a PA catheter may be indicated for the following conditions:
  - Persistent oliguria
  - Difficulty in fluid management therapy in antepartum and/or postpartum period
  - Presence of pulmonary edema

A survey on the use of invasive hemodynamic monitoring among anesthesiologists who care for patients with preeclampsia indicates that central monitoring is used in 7.5% of patients. When invasive hemodynamic monitoring is used, 56% of anesthesiologists use an arterial line, 26% use an arterial line and central monitoring, and 20% use central monitoring only. Also, 92% of respondents use a CVP monitor, whereas only 8% use a PA catheter. The etiology of pulmonary edema, however, may be due to an increase in capillary permeability as well as from diastolic dysfunction, complicating assessment of cardiac function and volume status. Only in severe forms of preeclampsia is left ventricular systolic function markedly reduced. Furthermore, there may be technical difficulties with placing the PA catheter that are both patient related (awake, anxious, short neck with poorly visible landmarks, coagulopathy) and physician related (inexperience with central venous catheterization), which may alter the balance between benefit and risk of invasive monitoring. Whenever possible, a bedside transthoracic echocardiogram may be obtained; however, there may be limited windows for imaging due to the gravid uterus causing distention of the abdomen.

B.4. Discuss the obstetric management of preeclampsia with severe features.

The goal of therapy is to stabilize the mother and to safely deliver the fetus and placenta.

- Administer antihypertensive agents to prevent stroke, myocardial ischemia, or heart failure.

- Administer seizure prophylaxis.
- Determine timing of delivery.

B.5. What are the antihypertensive agents of choice for preeclampsia?

Labetalol is a commonly used antihypertensive agent that decreases maternal SVR without increasing maternal heart rate or decreasing cardiac index, uterine blood flow, or fetal heart rate when it is given in a total dose of less than 1 mg per kg. When given in an initial intravenous bolus dose of 10 to 20 mg, it has a faster onset of action than hydralazine, and, if necessary, the dose may be doubled every 10 minutes. It is useful in the management of refractory hypertension. If a second agent must be administered (e.g., hydralazine, SNP, or nicardipine), labetalol helps to prevent reflex tachycardia. It is important to note that the mechanism of hypertension is mediated greatly by circulating catecholamines, making labetalol a preferred antihypertensive agent that will antagonize the vasoconstrictive effects of norepinephrine, in particular. Other agents may reduce the BP as reflected by a peripheral BP monitor; however, unopposed vasoconstriction at the central and at the microcirculatory levels may cause end-organ injury. Labetalol should be avoided in women with asthma due to risk of bronchospasm.

Hydralazine is another antihypertensive agent that can be used because of its direct vasodilating effect. The full extent of its effect is evident in 20 minutes; therefore, if sufficient time is not allowed between injections, severe hypotension will be seen. It is used in 5- to 10-mg increments intravenously every 20 to 30 minutes until the diastolic BP is decreased, with a cumulative dose of 20 mg. Hydralazine directly decreases peripheral vascular resistance. Reflex sympathetic activity can result in tachycardia and increased stroke volume and cardiac output.

Tachycardia can be treated with labetalol, 10 to 20 mg intravenously. The patient may complain of headache and flushing of the face during therapy.

Nitroglycerin (NTG) causes vascular smooth muscle relaxation by means of its intracellular degradation to NO. The primary effect of NTG is venodilation, but it is less effective in prehydrated patients. NTG readily crosses the placenta. The drug is most useful for short-term treatment (e.g., to control the response to tracheal intubation). Small doses, 50 to 100 μg, may be given intravenously, or NTG may be given sublingually in a 400 μg metered spray.

SNP relaxes the arterial vessels, thereby reducing afterload. However, SNP also reduces venous return. The drug is most useful for short-term treatment, similar to NTG. Cyanide toxicity is proposed to be more likely with prolonged infusion rates that exceed 4 μg/kg/min over several hours to days. However, Naulty et al. demonstrated that intravenous infusion of nitroprusside solution in pregnant ewes, maintained at a rate sufficient to decrease mean maternal arterial pressure by 20% for 1 hour, resulted in equilibration of maternal and fetal levels of nitroprusside at the 20-minute sample. Five of the eight animals exhibited tachyphylaxis to nitroprusside, and their fetuses died in utero with lethal levels of cyanide. No significant changes were observed in uterine blood flow. There have been attempts to counteract the cyanide toxicity of nitroprusside by coadministration of sodium thiosulfate. Curry et al. administered sodium thiosulfate and nitroprusside to pregnant ewes and only nitroprusside to a control group. Although control ewes and fetuses suffered progressive increases in red cell cyanide concentrations into the toxic range, experimental ewes and fetuses never developed toxic red cell cyanide levels. These results suggest that coadministration of sodium thiosulfate with SNP to pregnant women at doses currently in use for

nonpregnant patients will prevent fetal, as well as maternal, cyanide toxicity. Unfortunately, it is not known whether these findings are transferable to humans, raising major concern over ongoing clinical use of nitroprusside in obstetrics when safer drugs such as nicardipine and labetalol are available.

Nifedipine is a calcium entry blocker that affects predominantly arterial and arteriolar smooth muscle. Common maternal side effects include facial flushing, headache, and tachycardia. Nifedipine rapidly lowers BP after oral or sublingual administration. After an initial dose of 10 mg sublingually, it may be repeated in 30 minutes and subsequently given in a maintenance dose of 10 to 20 mg every 3 to 6 hours. Caution must be exercised in the patient receiving both magnesium sulfate and calcium entry blockers because of the risk of myocardial depression and resultant pulmonary edema.

B.6. What drug therapy is the treatment of choice for seizure prophylaxis?

Magnesium sulfate is the initial therapy for seizure prophylaxis. The Eclampsia Trial Collaborative Group compared magnesium sulfate, phenytoin, and diazepam administration for the prevention of recurrent seizures in women with preeclampsia.

They found that magnesium sulfate was more effective in preventing recurring seizures than either phenytoin or diazepam.

An initial bolus of 4 to 6 g of magnesium sulfate is administered over 20 minutes and followed with an intravenous infusion of 1 to 2 g per hour. Urine output, respiratory rate, and patellar reflexes are monitored during magnesium therapy. The serum magnesium sulfate concentration should be measured at least 4 hours after initiation of therapy. The therapeutic range for serum magnesium sulfate concentrations is between 4 and 6 mEq per L. Loss of deep tendon reflexes occurs at 7 mEq per L with evidence of prolonged PQ intervals and widening QRS complexes. Respiratory depression occurs at 10 mEq per L, and asystole or cardiac arrest occurs at 25 mEq per L.

The Eclampsia Trial Collaborative Group. Which anticonvulsant for women with eclampsia? Evidence from the collaborative eclampsia trial. *Lancet*. 1995;345(8963):1455–1463.

B.7. Discuss the mechanism of action of magnesium sulfate.

Magnesium has the following effects:

- It is a central nervous system depressant and anticonvulsant.
- It may protect the blood–brain barrier, decrease cerebral edema, or act centrally at *N*-methyl-D-aspartate receptors to raise the seizure threshold.
- It inhibits the release of acetylcholine at the neuromuscular junction, decreases the sensitivity of the motor end plate to acetylcholine, and decreases muscle membrane excitability, thereby potentiating the effects of nondepolarizing and depolarizing muscle relaxants.

- It decreases uterine hyperactivity by its mild relaxant effect on vascular and uterine smooth muscle; it may improve uterine blood flow. Postpartum, it may lead to uterine atony and increased hemorrhage risk.
- It is a mild vasodilator in vascular beds (including small-diameter cerebral vessels) by a direct or indirect (calcium-competing) effect, and it has a mild antihypertensive effect.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:854–855.

Euser AG, Cipolla MJ. Magnesium sulfate treatment for the prevention of eclampsia: a brief review. *Stroke*. 2009;40(4):1169–1175.

B.8. What are the fetal effects of magnesium sulfate therapy?

Magnesium sulfate crosses the placenta. There can be evidence of decreased beat-to-beat variability in the fetal heart rate. Neonatal depression (e.g., respiratory depression and hyporeflexia) also can occur.

Pauli JM, Repke JT. Preeclampsia: short-term and long-term implications. *Obstet Gynecol Clin North Am*. 2015;42(2):299–313.

B.9. Discuss the treatment of magnesium sulfate toxicity.

Magnesium sulfate is excreted by the kidneys. Therefore, urine output must be followed closely and serial serum concentrations of magnesium sulfate must be checked, especially in women with renal dysfunction. If magnesium sulfate toxicity is suspected, the magnesium sulfate infusion should be immediately discontinued. Intravenous calcium gluconate, 1 g, or calcium chloride, 300 mg, should be administered if needed to antagonize the effects of magnesium sulfate along with intravenous furosemide to accelerate urinary excretion. If respiratory distress occurs, the patient may require endotracheal intubation and mechanical ventilation.

Naulty J, Cefalo RC, Lewis PE. Fetal toxicity of nitroprusside in the pregnant ewe. *Am J Obstet Gynecol*. 1981;139(6):708–711.

B.10. What conditions mandate immediate delivery, regardless of the gestational age?

- Severe hypertension that is unresponsive to antihypertensive medications
- HELLP syndrome
- Epigastric or right upper quadrant (RUQ) pain that is unresponsive to analgesics
- Persistent headache or other neurologic sequela of preeclampsia (including seizure or stroke)
- New or worsening renal dysfunction (including severe oliguria)
- Pulmonary edema
- Evidence of deteriorating fetal status

B.11. Discuss the management of eclampsia.

- Turn patient to the left side; apply jaw thrust.

- Administer oxygen.
- Apply pulse oximeter and monitor.
- Secure intravenous access.
- Check BP at frequent intervals.
- Monitor electrocardiogram (ECG) recordings.
- Secure airway with aspiration precautions if necessary.
- Administer magnesium sulfate to prevent recurrent seizures.
- Deliver the baby expeditiously after maternal stabilization.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 202: gestational hypertension and preeclampsia. *Obstet Gynecol*. 2019;133(1):e1–e25.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:866–868.

C. Intraoperative Management

C.1. What is your choice of labor analgesia for patients with preeclampsia?

Most anesthesiologists and obstetricians consider epidural analgesia the safe and preferred form of pain relief for labor and delivery in preeclamptic women. Epidural analgesia provides the following advantages:

- Pain relief that is superior to other analgesic methods
- Attenuation of the exaggerated hypertensive response to pain in preeclamptic women
- Decrease in circulating levels of catecholamines and stress-related hormones, which facilitate BP control
- Improvement of intervillous blood flow in preeclamptic women
- Stable cardiac output
- Preeclamptic women are at increased risk for cesarean delivery compared with other parturients, and early administration of epidural analgesia for labor facilitates the

subsequent administration of epidural anesthesia for emergent cesarean delivery while avoiding the risks of general anesthesia.

Abboud T, Artal R, Sarkis F, et al. Sympathoadrenal activity, maternal, fetal, and neonatal responses after epidural anesthesia in the preeclamptic patient. *Am J Obstet Gynecol*. 1982;144(8):915–918.

Pauli JM, Repke JT. Preeclampsia: short-term and long-term implications. *Obstet Gynecol Clin North Am*. 2015;42(2):299–313.

C.2. What is the advantage of prehydration prior to initiation of neuraxial analgesia?

Prehydration helps compensate for reductions in preload and afterload during the administration of neuraxial analgesia. Two studies have investigated the effects of intravenous volume loading with crystalloid on atrial natriuretic peptide (ANP) secretion in preeclamptic women. ANP is a vasodilator secreted from the cardiac atria in response to an acute volume load, and this response is more pronounced in preeclamptic women. ANP has properties that counteract vasospasm and improve renal elimination of excess extracellular fluid. These studies support the use of volume expansion before administration of neuraxial analgesia in preeclamptic women.

However, in current practice, lower concentrations of local anesthetics combined with an opioid are used for labor analgesia, and fluid preloading is of less clinical relevance. One still needs to be vigilant to the risk of pulmonary edema in the severely preeclamptic patient because the incidence of global diastolic dysfunction, although usually mild, is about 40%.

Melchiorre K, Sutherland GR, Baltabaeva A, et al. Maternal cardiac dysfunction and remodeling in women with preeclampsia at term. *Hypertension*. 2011;57(1):85–93.

C.3. What sensory level of analgesia is required for labor and delivery?

- First stage of labor: T10–L1
- Second stage of labor: S2–S4

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:241.

C.4. Discuss the commonly used local anesthetics for labor analgesia.

Bupivacaine, ropivacaine, and levobupivacaine (amide local anesthetics) are commonly used because they provide potent analgesia with a longer duration but less motor block compared to lidocaine.

Bupivacaine is four times more potent than lidocaine. However, it is also known to be more cardiotoxic. The mechanism relates to its action on cardiac sodium channels. Bupivacaine is a "fast-in, slow-out" agent. While bupivacaine and lidocaine both rapidly block sodium channels to the nerves and to the heart, bupivacaine takes five times longer. This delayed recovery may precipitate arrhythmias.

Ropivacaine is a homolog of mepivacaine and bupivacaine, but it is formulated as a single levorotatory isomer rather than as a racemic mixture. It appears to be less cardiotoxic than bupivacaine.

Levobupivacaine is also a single levorotatory isomer formulation of a local anesthetic. Levobupivacaine appears to be less cardiotoxic than bupivacaine.

2-Chloroprocaine is an ester type of local anesthetic. It is hydrolyzed by plasma cholinesterase, and it has a rapid metabolism, allowing for a very quick onset of action.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:271–274.

C.5. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?

Clinical evidence supports the safety of epidural administration of an epinephrine-containing local anesthetic in preeclamptic women. However, care must be taken when using epinephrine-containing local anesthetic solutions in severe preeclamptic women because inadvertent intravascular injection may result in acute severe hypertension.

Dror A, Abboud TK, Moore J, et al. Maternal hemodynamic responses to epinephrine-containing local anesthetics in mild pre-eclampsia. *Reg Anesth*. 1988;13:107–111.

Heller PJ, Goodman C. Use of local anesthetics with epinephrine for epidural anesthesia in preeclampsia. *Anesthesiology*. 1986;65(2):224–226.

C.6. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after neuraxial analgesia is instituted?

- Administration of oxygen with face mask
- Left uterine displacement
- Administration of intravenous fluids
- Elevation of lower extremities to facilitate venous return
- Administration of small increments of phenylephrine, 50 to 100 μg, or ephedrine, 5 to 10 mg, intravenously, if the BP falls more than 20% of baseline

Vercauteren M. Obstetric spinal analgesia and anesthesia. *Curr Opin Anesthesiol*. 2003;16(5):503–507.

C.7. What would you do after an accidental dural puncture? How do you treat postdural puncture headache?

Accidental dural puncture can be managed with one of two options. First, the epidural needle can be removed and the placement of the epidural catheter may be reattempted in another interspace. Local anesthetic must be administered slowly because now, there is a direct communication with the

intrathecal space through the dural hole, and thereby, a more profound analgesic/anesthetic block may occur. Alternatively, a catheter can be threaded into the intrathecal space and maintained for continuous spinal labor analgesia. This approach may be prudent when the initial placement of the epidural catheter was difficult, allowing for faster pain relief and eliminating the risk of a second dural puncture.

The incidence of a postdural puncture headache after an accidental wet tap with an epidural needle is more than 50%. The headache occurs within 5 days of dural puncture and symptoms may include nausea or vomiting, tinnitus, blurry vision, and neck pain. The only effective treatment is epidural blood patch. Immediate relief occurs in almost 90% of patients on first attempt. Transient side effects include backache and neck pain.

Gaiser R. Postdural puncture headache: an evidence-based approach. *Anesthesiol Clin*. 2017;35(1):157–167.

C.8. How would you manage total spinal anesthesia?

- High spinal anesthesia may occur several minutes after an epidural injection of local anesthetic, especially if the injection is into the subarachnoid or subdural space. It is vitally important to communicate with the patient. Agitation, dyspnea, and difficulty speaking may indicate the onset of total spinal anesthesia.
- Avoid aortocaval compression.
- Administer 100% oxygen.
- Provide positive pressure ventilation if necessary, preferably through an endotracheal tube.
- Monitor maternal BP, ECG recordings, and fetal heart rate.
- Support maternal circulation with intravenous fluids and vasopressors as needed. Give epinephrine if needed.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:263–264.

C.9. Should methylergonovine be given to preeclamptic patients?

Preeclampsia is a relative contraindication to the use of ergot alkaloids because of the risk of inducing a hypertensive crisis. In preeclamptic patients, uterine atony unresponsive to oxytocin may be treated with 15-methylprostaglandin $F_{2\alpha}$.

Suresh M, Segal BS, Preston RL, et al, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2013:159–163.

C.10. When and how would you give spinal anesthesia?

Spinal anesthesia may be used for cesarean delivery in patients with preeclampsia. Hyperbaric bupivacaine 0.75% in a dose of 11.25 to 12 mg with or without fentanyl, 15 to 20 μg, and morphine, 100 to 200 μg, may be given.

Advantages of spinal anesthesia in patients with preeclampsia with severe features include the following:

- Avoidance of general anesthesia and risks of difficulty with an edematous airway
- Elimination of risk of severe hypertensive response to laryngoscopy and endotracheal intubation, which can result in intracranial hemorrhage
- More reliable anesthesia than with an epidural anesthetic technique
- Smaller needle size than an epidural and therefore possibly less risk of trauma to epidural veins

One study by Aya et al. noted that the risk of hypotension was almost six times less in severely preeclamptic women than in healthy pregnant women receiving spinal anesthesia for elective cesarean section. In these preeclamptic patients, spinal anesthesia may cause a higher incidence than epidural

anesthesia; however, this hypotension is typically easily treatable and short-lived and has not been linked to clinically significant differences in maternal or neonatal outcomes.

Aya AG, Mangin R, Vialles N, et al. Patients with severe preeclampsia experience less hypotension during spinal anesthesia for elective cesarean delivery than healthy parturients: a prospective cohort comparison. *Anesth Analg*. 2003;97(3):867–872.

Henke VG, Bateman BT, Leffert LR. Focused review: spinal anesthesia in severe preeclampsia. *Anesth Analg*. 2013;117(3):686–693.

C.11. Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.

- Aspiration prophylaxis. Acceptable methods include 30 mL of an oral nonparticulate antacid, and/or an H_2-blocker intravenously, and possibly metoclopramide, 10 mg intravenously.
- Consider arterial line placement before induction in patients with preeclampsia with severe features for continuous BP measurement. The transient but severe hypertension that accompanies tracheal intubation in preeclamptic women can significantly increase maternal intracranial pressure, with the attendant risks of cerebrovascular accident.
- Prepare for possible difficult airway, with available equipment such as a video laryngoscope.
- Preoxygenation and denitrogenation with 100% oxygen through face mask
- Induction of anesthesia with cricoid pressure and either propofol and/or etomidate
- Succinylcholine, 1.5 mg per kg, for rapid sequence intubation
- Use a smaller endotracheal tube (6.0 or 6.5 mm internal diameter) because of airway edema.
- Continue magnesium sulfate administration during the intraoperative and postoperative periods; magnesium sulfate

potentiates the effects of both depolarizing and nondepolarizing muscle relaxants.

- Administer volatile anesthetics until delivery to prevent awareness under anesthesia.
- Consider adding nitrous oxide (N_2O) and reducing volatile anesthetic to 0.5 to 0.75 minimum alveolar concentration (MAC) after delivery to minimize uterine atony and bleeding.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:862–864.

C.12. What agents can you use to prevent hypertension during the induction of general anesthesia for cesarean delivery?

Before induction, labetalol, 5- to 10-mg increments; NTG, 50- to 100-μg increments; or SNP, 50-μg increments, can be used to attenuate the pressor response to laryngoscopy and intubation. The short-acting opioid remifentanil or lidocaine 1.5 mg per kg can also be used.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:862–864.

Pant M, Fong R, Scavone B. Prevention of peri-induction hypertension in preeclamptic patients: a focused review. *Anesth Analg*. 2014;119(6):1350–1356.

D. Postoperative Management

D.1. Discuss the postpartum management of preeclamptic patients.

- Provide adequate analgesia.
- Continue magnesium sulfate for at least 24 hours after delivery, regardless of mode of delivery.
- Maintain strict intake/output during magnesium infusion.
- Maintain hemodynamic control with antihypertensives if

necessary.

- Continue to monitor for symptoms of eclampsia, stroke, and pulmonary edema in the postpartum period.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 202: gestational hypertension and preeclampsia. *Obstet Gynecol*. 2019;133(1):e1–e25.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:865.

D.2. Can nonsteroidal anti-inflammatory drugs (NSAIDs) be used to treat postpartum pain in preeclamptic patients?

Increasing concerns surrounding the opioid epidemic as well as narcotic use in breastfeeding women have led to a preference for administration of NSAIDs over opioids for postpartum pain. NSAIDs do not cause a significant elevation of BP in nonpregnant, normotensive individuals but can lead to increased BP in patients with chronic hypertension. However, data suggest NSAID use in hypertensive postpartum patients is safe. For example, one retrospective study by Viteri et al. including 399 patients with preeclampsia found that NSAID use was not associated with persistent postpartum hypertension or adverse outcomes. Also, a randomized controlled trial found that administration of ibuprofen, compared to acetaminophen, did not prolong the duration of severe BP elevations in patients with preeclampsia. In light of this research, the American College of Obstetricians and Gynecologists recommends use of NSAIDs over opioid analgesics in this patient population.

29 Breech Presentation, Fetal Distress, and Mitral Stenosis

Jill Fong and Jaime Aaronson

A 24-year-old primigravida at 37 weeks of gestation with fetal breech position presents to the labor and delivery unit for external cephalic version (ECV). The patient has a history of rheumatic fever with no subsequent medical follow-up. On physical examination, she has an opening snap and a diastolic murmur. She reports having shortness of breath when climbing two flights of stairs. Prior to attempting ECV, an epidural catheter is placed without event. After adequate analgesia is achieved, the obstetrician begins to rotate the fetus. Several minutes into the attempted ECV, the fetal heart rate (FHR) decreases to 60 beats per minute. Despite intrauterine resuscitative efforts, the FHR remains at 60 beats per minute. The patient is rushed to the operating room for an emergency cesarean section. Her blood pressure is 100/60 mmHg; pulse rate, 100 beats per minute; and respiratory rate, 18 breaths per minute.

A. Medical Disease and Differential Diagnosis

1. How are fetal lie, presentation, and position defined and determined?
2. What is the approximate frequency of the various lies and

presentations at or near term?

3. What are the different types of breech presentation, and what is their incidence?
4. What is the cause of breech presentation?
5. What are the delivery problems associated with breech presentation?
6. What is the usual obstetrical management for patients with breech presentation?
7. What is the incidence of heart disease in pregnancy and the mortality rate associated with maternal cardiac disease?
8. How is peripartum cardiomyopathy defined?
9. What classifications help predict an individual pregnant woman's cardiac risk?
10. What are the cardiovascular changes of pregnancy?
11. What changes normally occur in heart sounds during pregnancy?
12. What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?
13. What causes rheumatic heart disease?
14. What are the physiologic consequences of mitral stenosis?
15. What are the auscultatory findings associated with mitral stenosis?
16. What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?
17. What are the echocardiographic findings associated with mitral stenosis?
18. What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?
19. If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?
20. What are the determinants of fetal oxygenation?
21. What are the determinants of uterine blood flow?

B. Preoperative Evaluation and Preparation

1. How is fetal well-being assessed during labor?
2. How are FHR and maternal contractions monitored?
3. What is the normal FHR with beat-to-beat variability?
4. What are FHR decelerations?
5. How accurate is FHR monitoring in predicting fetal well-being?
6. In a fetus with minimal FHR variability, what other modalities can be used to assess fetal well-being?
7. What is the significance of meconium-stained amniotic fluid?
8. What is meconium aspiration syndrome?
9. What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?
10. What preoperative medications, if any, would you give this patient?

C. Intraoperative Management

1. What monitors would you use in this functional New York Heart Association (NYHA) class II patient during her cesarean section?
2. When would you use invasive monitoring in a pregnant patient with cardiac disease?
3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?
4. What anesthetic technique would you use for this emergency cesarean section?
5. How would you manage local anesthetic systemic toxicity (LAST) in this patient?
6. If cardiac arrest were to occur prior to delivery, how would you proceed?
7. What technique could you use for general anesthesia in this patient?
8. If you are unexpectedly unable to intubate this patient, how

would you manage the airway?
9. Would this patient benefit from the use of β-blockers?
10. What is the effect of the inhalation agents on uterine contractility?
11. What is the Apgar scoring system?
12. What is the significance of Apgar scores?
13. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?
14. If the Apgar score of the newborn is 3 at 1 minute, how would you treat the newborn?
15. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?

D. Postoperative Management

1. Immediately after the baby is delivered, the mother's oxygen saturation decreases. What is the differential diagnosis?
2. Additional bleeding occurs in the postanesthesia care unit, and the obstetrician diagnoses retained placenta. What, if any, antibiotics are indicated to prevent endometritis after manual extraction of retained placenta?

A. Medical Disease and Differential Diagnosis

A.1. How are fetal lie, presentation, and position defined and determined?

- Fetal lie—longitudinal, transverse, or oblique—describes the position of the long axis of the fetus relative to the long axis of the mother. Longitudinal lies are either cephalic or pelvic (breech) depending on which fetal structure enters the maternal pelvis. Transverse lies are either back up or back down with the long axis of the fetus perpendicular to the mother's long axis. An oblique lie results when the long axis of the fetus is at an acute angle to that of the mother; it is

usually transitory and converts to transverse or longitudinal when labor begins.

- Presentation describes the part of the fetus that is lowermost in the pelvis: cephalic or breech if the lie is longitudinal, or shoulder if the lie is transverse. Cephalic presentations are further subdivided into vertex, sinciput (anterior fontanel), brow, and face.
- Position describes the relationship of the presenting part to either side (right or left) of the birth canal. For vertex, face, and breech presentations, the determining points are the fetal occiput, chin (mentum), and sacrum, respectively.
- Fetal lie, presentation, and position are determined by manual pelvic and abdominal examination. Ultrasonography is also useful, particularly, when palpation is inconclusive, as can occur with maternal obesity, multiple gestations, placenta previa, and/or polyhydramnios.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:422.

A.2. What is the approximate frequency of the various lies and presentations at or near term?

Longitudinal lie, >99%, which includes cephalic (97%) and breech (3% to 4%); transverse lie, 0.3%. Frequencies of the various presentations are as follows: compound (an extremity prolapses alongside the presenting part), 0.1%; face, 0.05%; and brow, 0.01%.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:422.

A.3. What are the different types of breech presentation, and what is their incidence?

- *Frank breech*: Both fetal lower extremities are flexed at the hips and extended at the knees; the incidence is

approximately 60% (48% to 73%).

- *Complete breech*: One or both knees are flexed; the incidence is approximately 10% (4.6% to 11.5%).
- *Incomplete or footling breech*: One or both hips are extended and one or both feet or knees hangs below the breech; the incidence is approximately 30% (12% to 38%).

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:539.

A.4. What is the cause of breech presentation?

Although the etiology of breech presentation is unknown, certain factors are associated with it; these include prematurity, polyhydramnios, uterine relaxation secondary to high parity, multiple fetuses, oligohydramnios, hydrocephaly, anencephaly, uterine anomalies (e.g., uterine septum), pelvic tumors, placenta previa, cornual–fundal placenta implantation, and previous breech delivery. Ford et al. found the rate of breech recurrence after a previous breech pregnancy to be 9.9% and after two prior breech pregnancies to be 27.5%. After a prior cesarean delivery, a twofold increase in the incidence of breech presentation has been reported.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:422.

Ford JB, Roberts CL, Nassar N, et al. Recurrence of breech presentation in consecutive pregnancies. *BJOG*. 2010;117(7):830–836.

A.5. What are the delivery problems associated with breech presentation?

There is an increased incidence of both maternal and fetal morbidity with breech presentation. For the mother, the mode of delivery—vaginal versus cesarean—correlates with the nature of the morbidity. With vaginal delivery, for example, genital tract laceration is a concern, whereas with cesarean delivery,

extraction of the head may require extension of the hysterotomy. Fetal morbidity occurs in the way of birth trauma, prolapsed umbilical cord, preterm delivery, and fetal anomalies.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:542–550.

A.6. What is the usual obstetrical management for patients with breech presentation?

ECV is a procedure whereby a breech fetus is rotated to vertex position before the onset of labor. The American College of Obstetricians and Gynecologists (ACOG) recommends that ECV be offered to patients with a term singleton breech fetus who desire a planned vaginal delivery (of a vertex-presenting fetus) and have no contraindications. The reported success rate of ECV varies from 35% to 86% and is associated with multiparity, abundant amniotic fluid, a nonengaged presenting part, fetal size ranging from 2,500 to 3,000 g, a posterior placenta, and non-obesity. Tocolysis is variably effective in improving version success rates, and there is more evidence to support betamimetic tocolysis versus, for example, oral nifedipine (10 to 20 mg) or IV nitroglycerin (50 to 100 μg). The use of neuraxial techniques increases the success rate of ECV and reduces cesarean delivery rates for fetal malpresentation. There is no consensus, however, regarding the optimal dose of local anesthetic to facilitate ECV. According to available data, anesthetic doses of neuraxial blockade are better than analgesic doses.

According to ACOG, the decision regarding mode of delivery depends on the experience of the health care provider. To this end, planned vaginal delivery of a term singleton breech fetus may be reasonable under hospital-specific protocol guidelines. Cesarean delivery is commonly performed in the following circumstances: lack of operator experience, incomplete or

footling breech, hyperextended fetal head, fetal macrosomia, unfavorable pelvic shape, severe fetal growth restriction, fetal anomaly incompatible with vaginal delivery, healthy preterm fetus with maternal labor or indicated delivery, previous perinatal death/trauma, maternal cesarean section request, and possibly previous cesarean delivery. The availability of skilled operators to perform safe vaginal delivery of breech fetuses seems to be declining. This trend is likely related to publication of the Term Breech Trial in 2000—a large, international, multicenter, randomized clinical trial that compared planned, breech vaginal delivery to planned cesarean delivery and found perinatal mortality, neonatal mortality, and serious neonatal morbidity to be significantly lower in the planned cesarean group.

A.7. What is the incidence of heart disease in pregnancy and the mortality rate associated with maternal

cardiac disease?

Cardiac disease occurs in 1% to 4% of pregnancies and is the leading cause of indirect (i.e., non-obstetric) maternal deaths (15% to 20%). In developing nations, rheumatic fever remains the main cause of valvular disease in pregnancy, and it also continues to be a problem in immigrants to developed countries. In developed countries, congenital, not rheumatic, heart disease is the major cause of heart disease in pregnancy. Other cardiac conditions encountered in pregnancy include cardiomyopathy (peripartum and non-peripartum), pulmonary hypertension, and even ischemic heart disease.

Centers for Disease Control and Prevention. Pregnancy Mortality Surveillance System. https://www.cdc.gov/reproductivehealth/maternalinfanthealth/pregnancy-mortality-surveillance-system.htm. Accessed February 7, 2019.

A.8. How is peripartum cardiomyopathy defined?

Peripartum cardiomyopathy is an idiopathic cardiomyopathy that presents toward the end of pregnancy or in the months following delivery with heart failure due to left ventricular systolic dysfunction. Unlike valvular heart disease in pregnancy, peripartum cardiomyopathy is a diagnosis of exclusion, and although the left ventricle may not be dilated, the ejection fraction is almost always less than 45%. Because early symptoms may mimic those of normal pregnancy, the index of suspicion for peripartum cardiomyopathy must be high. The incidence worldwide is thought to be 1 per 1,000 pregnancies.

A.9. What classifications help predict an individual pregnant woman's cardiac risk?

There are three models for maternal cardiac risk stratification—Cardiac Disease in Pregnancy (CARPREG), Zwangerschap bij Aangeboren Hartafwijkingen I (ZAHARA), and World Health Organization (WHO) (**Table 29.1**). The NYHA classification, although not widely used to determine overall risk, is included in each of the models:

TABLE 29.1 World Health Organization (WHO) Risk Classification for Cardiovascular Disease in Pregnancy

WHO class I: no increase mortality risk; no/mild increase morbidity	• Uncomplicated, small or mild – Pulmonary stenosis – Patent ductus arteriosus – Mitral valve prolapse • Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage). • Atrial or ventricular ectopic beats, isolated
WHO class II: small increase mortality risk; moderate increase morbidity	• Unoperated atrial or ventricular septal defect • Repaired tetralogy of Fallot • Most arrhythmias
WHO classes II to III (depends on individual)	• Mild left ventricular impairment • Hypertrophic cardiomyopathy • Native or tissue valvular heart disease not considered WHO class I or IV • Marfan syndrome without aortic dilation • Aorta <45 mm in aortic disease associated with bicuspid aortic valve • Repaired coarctation

WHO class III: significant increase mortality risk; severe increase morbidity	• Mechanical valve • Systemic right ventricle • Fontan circulation • Cyanotic heart disease (unrepaired) • Other complex congenital heart disease • Aortic dilation 40–45 mm in Marfan syndrome • Aortic dilation 45–50 mm in aortic disease associated with bicuspid aortic valve
WHO class IV: extremely high-risk mortality/morbidity; pregnancy contraindicated; discuss termination	• Pulmonary arterial hypertension of any cause • Severe systemic ventricular dysfunction (LVEF <30%, NYHA III–IV) • Severe mitral stenosis, severe symptomatic aortic stenosis • Marfan syndrome with aorta dilated >45 mm • Aortic dilation >50 mm in aortic disease associated with bicuspid aortic valve • Native severe coarctation

LVEF, left ventricular ejection fraction; NYHA, New York Heart Association.
Modified from Thorne S, MacGregor A, Nelson-Piercy C. Risks of contraception and pregnancy in heart disease. *Heart*. 2006;92(10):1520–1525; with permission from BMJ Publishing Group Ltd.; Regitz-Zagrosek V, Blomstrom Lundqvist C, Borghi C, et al. ESC guidelines on the management of cardiovascular diseases during pregnancy: the Task Force on the Management of Cardiovascular Diseases during Pregnancy of the European Society of Cardiology (ESC). *Eur Heart J*. 2011;32(24):3147–3197.

- *Class I*: no limitation of physical activity
- *Class II*: slight limitation of physical activity; symptoms with ordinary activity
- *Class III*: marked limitation of physical activity; symptoms with less than ordinary activity
- *Class IV*: unable to carry out any physical activity without discomfort; symptoms may be present at rest

According to the American College of Cardiology, the WHO model best predicts cardiovascular risk in pregnant patients with congenital heart disease. The Task Force for the Management of Cardiovascular Diseases during Pregnancy of the European Society of Cardiology recommends disease-specific risk be assessed using the modified WHO classification and that risk estimation should be further refined by CARPREG, ZAHARA, and Registry of Pregnancy and Cardiac Disease (ROPAC).

Neonatal and maternal adverse events are highly correlated; specifically, maternal cardiac disease is associated with neonatal complications, which include small for gestational age, prematurity, and death. In women with cardiac disease, maternal predictors of increased neonatal adverse events include baseline NYHA class >II, cyanosis, smoking during pregnancy, left-sided heart obstruction, multiple gestations, oral anticoagulation during pregnancy, and presence of a mechanical valve prosthesis.

A.10. What are the cardiovascular changes of pregnancy?

During the first trimester of pregnancy, cardiac output increases 40% to 50% above the normal nonpregnant level and plateaus at approximately 28 weeks of gestation. It remains fairly stable until the stresses imposed by labor increase it further. The increase in cardiac output is due to a 30% increase in stroke volume and a 15% increase in heart rate. Blood pressure, however, is not elevated because peripheral vascular resistance decreases. Central venous pressure, pulmonary capillary wedge

pressure, pulmonary artery diastolic pressure, and left ventricular stroke work index are unchanged when compared to nonpregnant values.

During labor, cardiac output increases approximately 15% with uterine contractions during the latent phase, 30% in the active phase, and 45% in the expulsive phase when compared to prelabor values. The greatest increase in cardiac output occurs immediately postpartum when it increases an average of 80% above prelabor values. Cardiac output and heart rate decline to prelabor values within 1 hour of delivery, and by approximately 24 hours, mean blood pressure and stroke volume return to prelabor baseline. The cardiovascular changes of pregnancy resolve in the first 3 to 6 months after delivery. It can take up to a year, however, for the residual effects of cardiovascular remodeling to subside.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:13–20.

A.11. What changes normally occur in heart sounds during pregnancy?

It is normal for changes in heart sounds to occur in pregnancy. There may be, for example, an exaggerated splitting of the first heart sound and increased loudness of both components. There may also be a loud third heart sound. Soft diastolic murmurs occur, as do continuous murmurs arising from the breast vasculature.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:61.

A.12. What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?

It is also normal for changes in the ECG and echocardiogram to occur in pregnancy. Commonly seen electrocardiographic

changes include slight left axis deviation as well as Q waves in leads II, III, and avF. Flat or inverted T waves may also occur. ST elevations, however, do not occur normally and should be considered pathologic. Normal echocardiographic findings include an increase in both left ventricular wall mass and the atrial diameters bilaterally, whereas left ventricular function may be unchanged or slightly improved. The annuli of the pulmonary, tricuspid, and mitral valves dilate progressively, and term pregnant women may have mild tricuspid, pulmonic, and/or (but much more infrequently) mitral regurgitation. A small pericardial effusion may develop as well.

Cunningham FG, Leveno KJ, Bloom SL, et al, eds. *Williams Obstetrics*. 25th ed. New York: McGraw-Hill; 2018:61.

A.13. What causes rheumatic heart disease?

Rheumatic heart disease occurs in patients who have had acute rheumatic fever (ARF)—an immune-mediated illness that develops after an untreated group A streptococcal infection. It predominantly affects the heart and joints and may lead to chronic heart disease. ARF occurs most commonly in the winter and spring in children between the ages of 5 and 15 years old. In developed countries, ARF is much less common than it was a few decades ago.

The pathogenetic mechanism of ARF is unknown. The manifestations are extremely variable, and specific laboratory tests to confirm the diagnosis do not exist. The diagnosis is clinical and made using the Jones criteria, revised by the American Heart Association in 1992, and again in 2000. Diagnosis of ARF requires evidence of a preceding group A streptococcal infection in conjunction with two major or one major plus two minor manifestations (**Table 29.2**).

TABLE 29.2 Revised Jones Criteria

For all patients with a preceding GAS infection	
• Diagnosis: initial ARF	Two major or one major plus two minor manifestations
• Diagnosis: recurrent ARF	Two major or one major and two or three minor manifestations
Major criteria—low-risk populations	Major criteria—moderate-/high-risk populations
• Carditis (clinical and/or subclinical)	• Carditis (clinical and/or subclinical)
• Arthritis (polyarthritis only)	• Arthritis (mono- or polyarthritis; polyarthralgia)
• Chorea	• Chorea
• Erythema marginatum	• Erythema marginatum
• Subcutaneous nodules	• Subcutaneous nodules
Minor criteria—low risk populations	Minor criteria—moderate/high risk populations
• Polyarthralgia	• Monoarthralgia
• Fever (≥38.5°C)	• Fever (≥38°C)
• ESR ≥60 mm in first hr and/or CRP ≥3.0 mg/dL (or upper limit of normal for laboratory; use peak value)	• ESR ≥30 mm/hr and/or CRP ≥3.0 mg/dL (or upper limit of normal for laboratory; use peak value)
• Prolonged PR interval (after accounting for age (unless carditis is a major criterion)	• Prolonged PR interval (after accounting for age (unless carditis is a major criterion)

ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A streptococcus.

Reprinted with permission from Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones Criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: a scientific statement from the American Heart Association. *Circulation*. 2015;131(20):1806–1818. Copyright © 2018 American Heart Association, Inc.

Of note, rheumatic heart disease is the only long-term sequelae of ARF. With improved ability to prevent recurrent attacks, prognosis has improved and is related directly to the severity of cardiac involvement during the acute phase. More widespread use of echocardiography has revealed the prevalence of rheumatic heart disease in developing countries to be about 10-fold greater than that recognized by conventional screening.

In almost all adults, mitral stenosis is caused by previous rheumatic carditis, although approximately 60% of patients with rheumatic mitral valve disease do not report a history of rheumatic fever or chorea. In about 40% of all patients with

rheumatic heart disease, isolated mitral stenosis occurs. Mitral valve insufficiency and aortic valve stenosis and insufficiency can also occur in these patients.

A.14. What are the physiologic consequences of mitral stenosis?

The normal mitral valve orifice area is 4 to 6 cm^2, but with mitral stenosis, the valve area is reduced to varying degrees. When it reaches 2 cm^2, cardiovascular hemodynamics are impaired. A valve area of ≤1.5 cm^2 is considered moderate mitral stenosis, and as the cross-sectional area decreases further to 1 cm^2 and mean left atrial pressure increases to at least 25 mmHg to maintain an adequate cardiac output, it is considered severe. The pathophysiology of mitral stenosis results from obstruction of blood flow from the left atrium into the left ventricle.

The increase in heart rate, cardiac output, red blood cell mass, and plasma volume that occurs with pregnancy can lead to increased atrial pressure and cardiac decompensation in patients with mitral stenosis. Specifically, cardiac consequences include a decline in functional capacity, atrial arrhythmias, and pulmonary edema. Pulmonary hypertension can also result due to elevated left atrial pressure and pulmonary arteriolar constriction. If severe pulmonary hypertension develops, right-

sided heart failure can ensue.

A.15. What are the auscultatory findings associated with mitral stenosis?

The first heart sound is accentuated, whereas the second heart sound is normal or accentuated. There may be an opening snap, which is usually loudest at the apex. A diastolic rumbling murmur is best heard at the apex with the patient in left lateral decubitus position and usually starts with or shortly after the opening snap and may continue through the entire diastolic phase. The presence of pulmonary hypertension may, however, alter the auscultatory findings associated with mitral stenosis; the first heart sound may be normal or only slightly accentuated, and the opening snap and diastolic murmur may be absent.

Dack S, Bleifer S, Grishman A, et al. Mitral stenosis: auscultatory and phonocardiographic findings. *Am J Cardiol*. 1960;5:815–835.

A.16. What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?

Broadened, diphasic P waves in lead V_1 are a common finding. There may be signs of right ventricular hypertrophy if pulmonary hypertension is marked. Atrial fibrillation may be present.

Walsh RA, Fang JC, Fuster V, eds. *Hurst's The Heart: Manual of Cardiology*. 13th ed. New York: McGraw-Hill; 2013:383.

A.17. What are the echocardiographic findings associated with mitral stenosis?

Mitral stenosis is characterized by both thickening and shortening of the leaflets and chordae and fusion of the commissures, which results in doming of the leaflets in diastole. Together, these changes restrict valve opening, leading to varying degrees of mitral stenosis. On echocardiogram, the anterior leaflet is commonly described as having a "hockey stick" appearance (**Fig. 29.1**).

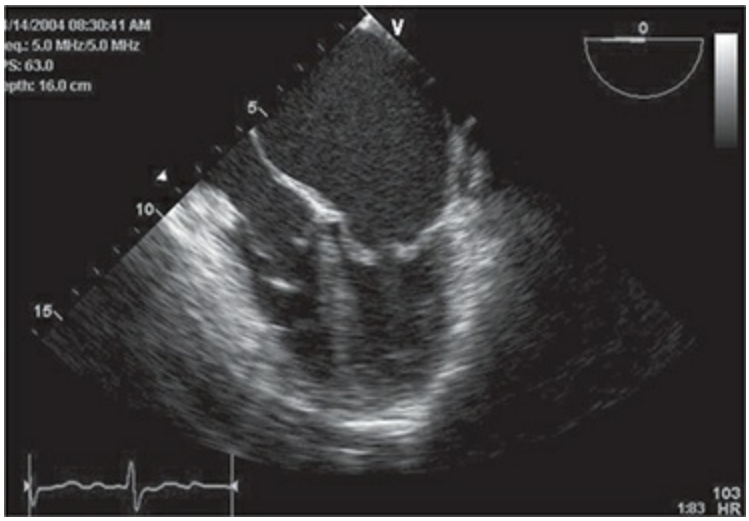

FIGURE 29.1. Two-dimensional echocardiography of the mitral valve showing severe mitral stenosis with the typical "hockey-stick" appearance.

With mitral stenosis, diastolic filling of the left ventricle is compromised, and in turn, left atrial pressure increases and the left atrium may become dilated. Long-standing mitral stenosis leads to pulmonary hypertension by way of increased pulmonary vascular resistance. Two-dimensional echocardiography is used to evaluate mitral valve area and morphology. Three-dimensional echocardiography, however, enhances the ability to examine mitral valve morphology and allows for complete assessment in a single-imaging plane. Continuous Doppler across the mitral valve best measures the severity of the lesion.

Wunderlich NC, Beigel R, Siegel RJ. Management of mitral stenosis using 2D and 3D echo-Doppler imaging. *JACC Cardiovasc Imaging*. 2013;6(11):1191–1205.

A.18. What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?

The increased cardiovascular load of pregnancy can cause patients to deteriorate and even advance from one NYHA classification to another. Increased cardiac output, tachycardia, and fluid retention increase the pressure gradient across the stenotic valve, which explains why more than half of NYHA class I and II patients with mitral stenosis, therefore, have worsening clinical symptomatology during pregnancy. A decline in functional capacity, atrial fibrillation, and/or pulmonary edema, for example, may occur. The incidence of maternal and fetal complications is related to the severity of stenosis, and maternal and perinatal outcomes depend largely on maternal functional status during pregnancy. Maternal mortality and morbidity is, not surprisingly, increased in parturients with NYHA III and IV disease.

Hameed A, Karaalp IS, Tummala PP, et al. The effect of valvular heart disease on maternal and fetal outcome of pregnancy. *J Am Coll Cardiol*. 2001;37(3):893–899.

A.19. If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?

Heart rate reduction and decreased left atrial pressure are the standard therapeutic goals for women with moderate to severe mitral stenosis. Therefore, β-adrenergic receptor blockade is the cornerstone of medical therapy in the symptomatic patient. It is useful in preventing tachycardia and prolonging diastolic filling time, which can result in marked improvement of symptoms.

Atrial fibrillation or flutter should be treated aggressively; a rapid ventricular response compromises diastolic flow time and can lead to pulmonary edema. For rate control, digoxin or a β-adrenergic receptor blocker should be given. Calcium channel blockers are also thought to be safe in pregnancy, although there is less data to support their use. If, on the other hand, the patient is unstable, synchronized cardioversion should be used. Atrial fibrillation not only increases the risk of pulmonary edema but also increases the likelihood of a thromboembolic event, which is why patients with persistent atrial fibrillation should be anticoagulated. There is some data to suggest that patients with severe mitral stenosis should receive antithrombotic therapy even if they are in sinus rhythm because of the potential for thrombotic events.

If symptoms of pulmonary congestion develop, salt restriction and cautious use of diuretics decrease left atrial pressure by decreasing blood volume. Avoidance of both hypovolemia and decreased uteroplacental perfusion are essential. If symptoms are uncontrolled by medical therapy, the mitral valve should be repaired or replaced. Percutaneous balloon valvuloplasty can be done using echocardiography or, if radiographic imaging is required, with appropriate shielding of the fetus. It has a low morbidity rate for both the mother and fetus and has favorable long-term results when performed in NYHA functional class III and IV patients. If a contraindication to balloon valvuloplasty exists, surgical commissurotomy or valve replacement should be done, although it is usually well tolerated by the mother (i.e., comparable to nonpregnant women), fetal loss of over 20% has been reported.

A.20. What are the determinants of fetal oxygenation?

Oxygen delivery to the fetal circulation occurs via the placenta. The factors that affect oxygen exchange across the placenta include blood flow (maternal placental and fetal placental), maternal blood oxygen capacity, maternal and fetal blood oxygen affinity, and both placental oxygen diffusion capacity and oxygen consumption.

Carter AM. Evolution of factors affecting placental oxygen transfer. *Placenta*. 2009;30(suppl A):S19–S25.

A.21. What are the determinants of uterine blood flow?

Uterine blood flow is derived from Ohm's law, which states that pressure equals flow multiplied by resistance. It is shown as follows:

$$\text{Uterine blood flow} = \frac{\text{uterine artery pressure} - \text{uterine venous pressure}}{\text{uterine artery resistance}}$$

At term, 10% to 15% of maternal cardiac output goes to the uterus (i.e., approximately 750 mL per minute). Uterine blood flow is directly related to maternal blood pressure because the uterine vessels do not autoregulate.

B. Preoperative Evaluation and Preparation

B.1. How is fetal well-being assessed during labor?

Fetal well-being is dependent on an intact uteroplacental unit. Simultaneous monitoring of FHR and uterine contractions aids in the detection of fetal distress.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 106: intrapartum fetal heart rate monitoring: nomenclature, interpretation, and general management principles. *Obstet Gynecol*. 2009;114(1):192–202.

B.2. How are FHR and maternal contractions monitored?

FHR can be monitored noninvasively using the Doppler technique or invasively using a fetal scalp electrode. Uterine contractions may be monitored noninvasively by a tocodynamometer, which measures the tightening of maternal abdominal muscles, or invasively by a transcervical pressure catheter connected to a strain gauge.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 106: intrapartum fetal heart rate monitoring: nomenclature, interpretation, and general management principles. *Obstet Gynecol*. 2009;114(1):192–202.

Bakker JJ, Janssen PF, van Halem K, et al. Internal versus external tocodynamometry during induced or augmented labor. *Cochrane Database Syst Rev*. 2013;(8):CD006947.

B.3. What is the normal FHR with beat-to-beat variability?

In the third trimester, the normal baseline FHR is between 110 and 160 beats per minute with beat-to-beat variability (6 to 25 beats per minute). A baseline FHR <110 beats per minute is termed *bradycardia* and >160 beats per minute is *tachycardia*.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 116: management of intrapartum fetal heart rate tracings. *Obstet Gynecol*.

2010;116(5):1232–1240.

B.4. What are FHR decelerations?

A deceleration is a decrease in FHR from baseline. Decelerations fall into three categories—early, late, or variable—depending on their shape and timing with respect to maternal contractions (Fig. 29.2).

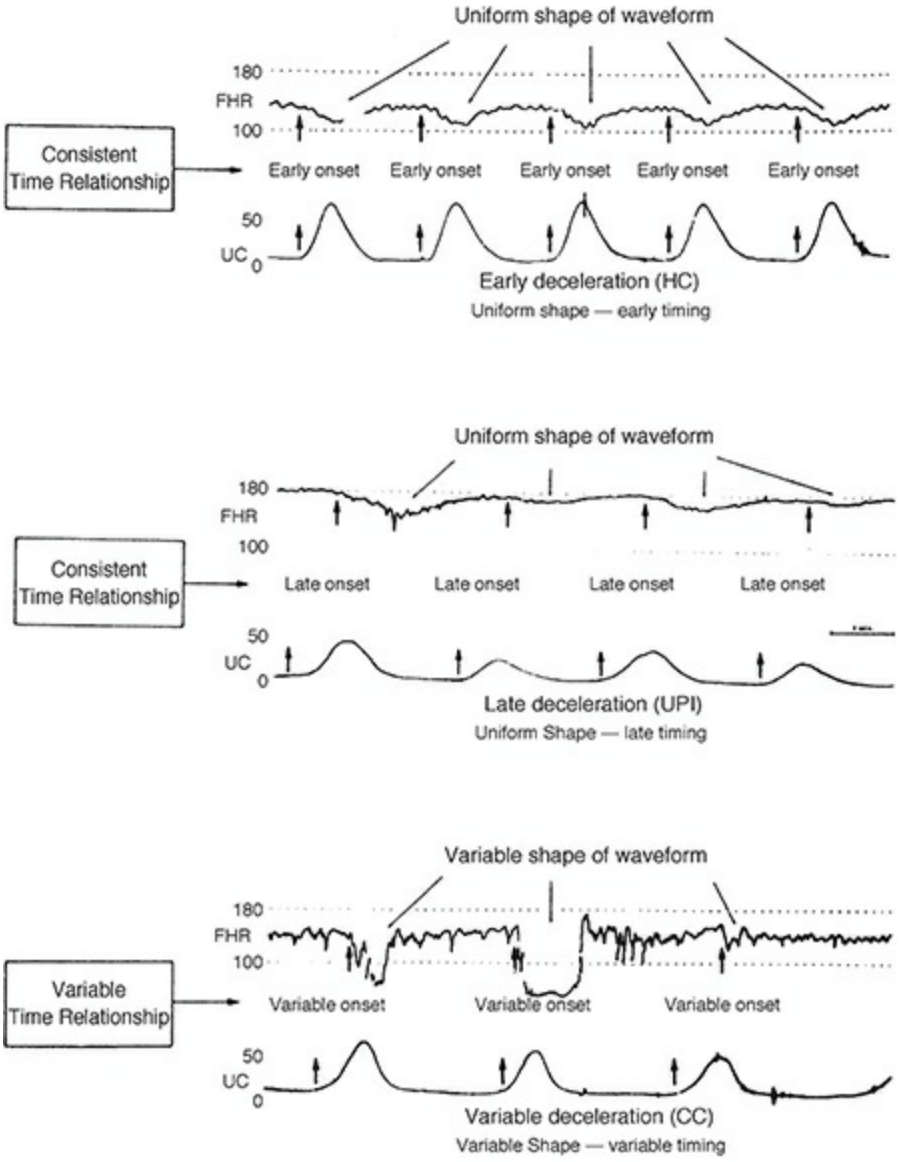

FIGURE 29.2. Fetal heart rate (FHR) decelerations in relation to the time of onset of uterine contractions (UCs). CC, cord compression; HC, head compression; UPI, uteroplacental insufficiency. (*From Hon EH.* An Atlas of Fetal Heart Rate Patterns. *New Haven, CT: Harty Press; 1968, with permission.*)

- Early deceleration—symmetrical, gradual decrease and return of FHR that coincides with the onset, peak, and end of a uterine contraction. They are thought to be a vagal response caused by fetal head compression and are not associated with fetal hypoxia, acidemia, or low Apgar scores.
- Late deceleration—symmetrical, gradual decrease and return of FHR that begins after the onset of a contraction and lasts beyond the end. They indicate uteroplacental insufficiency and require prompt evaluation and treatment.
- Variable deceleration—abrupt decrease in FHR with an onset, depth, and duration that varies with successive uterine contractions. The decrease in FHR is 15 beats per minute or greater, and lasts between 15 seconds and 2 minutes. They are FHR reflexes that reflect fetal blood pressure changes due to umbilical cord compression or changes in fetal oxygenation.

A prolonged deceleration is a decrease from baseline that is 15 beats per minute or more and lasts 2 or more minutes but less than 10 minutes.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 116: management of intrapartum fetal heart rate tracings. *Obstet Gynecol*. 2010;116(5):1232–1240.

B.5. How accurate is FHR monitoring in predicting fetal well-being?

FHR monitoring is used to determine fetal oxygenation (i.e., fetal well-being). This is because the fetal brain, via a combination of sympathetic and parasympathetic pathways, modulates the FHR. The accuracy of FHR monitoring is thought to be limited, however, by various factors, which include questions about its overall efficacy as well as clinician reliability.

At the present time, a three-tiered system is used to evaluate

and manage intrapartum electronic FHR patterns. Category I FHR tracings are normal and include a baseline heart rate of 110 to 160 beats per minute, moderate beat-to-beat variability, and no late or variable decelerations; early decelerations and accelerations may or may not be present. Category I tracings are not associated with fetal acidemia. Category III FHR tracings are abnormal and are characterized by the absence of variability and either recurrent late decelerations, recurrent variable decelerations, bradycardia, or a sinusoidal pattern. Unlike category I FHR tracings, category III tracings are associated with an increased risk for fetal acidemia (at the time of interpretation). Category II FHR tracings are considered to be indeterminate and include all those not categorized as either category I or III. They are not predictive of abnormal fetal acid–base status but require evaluation, intervention when applicable, and continuous surveillance. Of interest, Cahill et al. conducted a retrospective cohort study of more than 5,000 term births and found that none of the three categories had a significant association with neonatal blood acidemia (pH ≤7.10) when considered in the last 10 or 30 minutes prior to delivery. *Minimal variability without an identifiable cause or that does not resolve with appropriate resuscitative measures may indicate fetal acidemia.*

American College of Obstetricians and Gynecologists. Practice Bulletin No. 106: intrapartum fetal heart rate monitoring: nomenclature, interpretation, and general management principles. *Obstet Gynecol*. 2009;114(1):192–202.

Obstet Gynecol. 2008;112(3):661–666.

B.6. In a fetus with minimal FHR variability, what other modalities can be used to assess fetal well-being?

There are four techniques that can be used to elicit or improve FHR variability—fetal scalp sampling, Allis clamp scalp stimulation, vibroacoustic stimulation, and digital scalp stimulation. The latter two options are preferred given the invasiveness of the former. In a parturient with a breech fetus, any technique that requires access to the fetal head would, of course, not be applicable.

American College of Obstetricians and Gynecologists. Practice Bulletin No. 106: intrapartum fetal heart rate monitoring: nomenclature, interpretation, and general management principles. *Obstet Gynecol*. 2009;114(1):192–202.

Skupski DW, Rosenberg CR, Eglinton GS. Intrapartum fetal stimulation tests: a meta-analysis. *Obstet Gynecol*. 2002;99(1):129–134.

B.7. What is the significance of meconium-stained amniotic fluid?

Meconium-stained amniotic fluid occurs in 4% to 22% of births. In and of itself, it does not indicate an adverse outcome. In fact, it has been suggested that meconium becomes an environmental hazard when fetal acidemia occurs rather than meconium release being a marker of preexisting fetal compromise.

American College of Obstetricians and Gynecologists Committee on Obstetric Practice. ACOG Committee Opinion Number 346, October 2006: amnioinfusion does not prevent meconium aspiration syndrome. *Obstet Gynecol*. 2006;108(4):1053.

environmental hazard. *Obstet Gynecol*. 1996;87(2):181–184.

B.8. What is meconium aspiration syndrome?

Meconium aspiration syndrome is a respiratory condition that occurs in neonates born through meconium-stained amniotic fluid. The degree of respiratory distress is variable, but severe cases are associated with perinatal mortality. The pathophysiology of meconium aspiration is incompletely understood and complex, with a number of contributing factors —airway obstruction, surfactant dysfunction, chemical pneumonitis, and persistent pulmonary hypertension of the newborn. Treatment is mainly supportive in nature, although infants who fail conventional ventilation strategies appear to benefit from extracorporeal membrane oxygenation.

B.9. What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?

Physical examination, exercise tolerance, ECG, pulse oximetry, Holter monitoring, and echocardiography with Doppler flow studies may all be useful to evaluate these patients. Cardiac magnetic resonance imaging is safe in pregnant women, but the use of contrast dye should be limited to those situations in which its use will improve diagnostic performance. Tests using radiation should be avoided unless absolutely necessary, and it is best to delay radiologic exams until as late as possible in the pregnancy and to use protective fetal radiation shielding. The risk of fetal anomalies is low, however, with less than 50 mGy

of radiation exposure. Radiation exposure with a chest radiograph is, for example, less than 0.1 mGy, whereas the fetal exposure is between 0.0005 and 0.01 mGy.

Jain C. ACOG Committee Opinion No. 723: guidelines for diagnostic imaging during pregnancy and lactation. *Obstet Gynecol*. 2019;133(1):186.

B.10. What preoperative medications, if any, would you give this patient?

Prophylactic antibiotics to prevent endocarditis are not recommended for women with acquired (or congenital) heart disease for either vaginal or cesarean delivery in the absence of infection. According to the American Heart Association, it is reasonable to consider antibiotic prophylaxis only for those women at highest risk of an adverse outcome from infective endocarditis (e.g., prosthetic cardiac valve or material, previous endocarditis, unrepaired cyanotic heart disease, during the first 6 months after complete repair of congenital heart disease, presence of residual defects after repair of congenital heart disease, and valvulopathy after heart transplant). When prophylactic antibiotics are indicated, the regimens are as follows: amoxicillin (2 g orally), or in patients unable to take anything by mouth, ampicillin (2 g intravascular [IV]), or cefazolin (1 g IV), or ceftriaxone (1 g IV) should be given 30 to 60 minutes before the procedure. If the patient is allergic to ampicillin or penicillin, cefazolin (1 g IV), or ceftriaxone (1 g IV), or clindamycin (600 mg IV) should be given.

Prophylactic antibiotics are indicated for patients undergoing cesarean section to prevent endometritis, febrile morbidity, and wound infections. ACOG recommends that a prophylactic antibiotic, namely a first-generation cephalosporin (i.e.,

cefazolin) be given within 1 hour of surgical incision. This time frame is known to decrease postcesarean section maternal infections without adverse neonatal effects.

Pregnant patients are considered to be at increased risk for aspiration of gastric contents. Gastric fluid volume, though, is not different in pregnant patients versus their nonpregnant counterparts, and pregnancy itself does not decrease gastric emptying (except during labor). The increased risk for aspiration is thought to be due to a decrease in lower esophageal sphincter tone as well as an increased risk of difficult intubation. Although the exact time at which the risk increases is unclear, it is prudent to consider pregnant patients to be at increased risk for aspiration of gastric contents after 16 to 20 weeks of gestation.

In this patient for emergency cesarean delivery, an oral nonparticulate antacid, such as 15 to 30 mL of 0.3 M sodium citrate, given immediately before induction reduces the risk of developing aspiration pneumonitis. H_2-receptor antagonists (ranitidine and famotidine), as well as metoclopramide may also decrease the risk, but require more time (at least 30 to 40 minutes) to be effective. These drugs may be given after the anesthetic induction if time does not allow for dosing before. Avoiding general anesthesia is the most effective way to prevent the risk of aspiration.

C. Intraoperative Management

C.1. What monitors would you use in this functional New York Heart Association (NYHA) class II patient during her cesarean section?

Heart rate (via ECG), blood pressure, oxygen saturation, and temperature need to be monitored throughout the anesthetic. A urinary catheter should also be used. For patients undergoing general anesthesia, continuous end-tidal carbon dioxide monitoring is needed. Assessment of neuromuscular function using a peripheral nerve stimulator, although not mandated by the American Society of Anesthesiologists, is critical. In addition, electroencephalogram-processing monitors may be used, although they probably do not reduce the incidence of intraoperative awareness during general anesthesia for cesarean section when end-tidal gas monitoring is used.

Standards for Basic Anesthetic Monitoring. Committee of Origin: standards and practice parameters (approved by the ASA House of Delegates on October 21, 1986, last amended on October 20, 2010, and last affirmed on October 28, 2016). https://www.asahq.org/~/media/Sites/ASAHQ/Files/Public/Resources/standardguidelines/standards-for-basic-anesthetic-monitoring.pdf. Accessed May 6, 2016.

C.2. When would you use invasive monitoring in a pregnant patient with cardiac disease?

NYHA class I and II patients do not routinely require invasive hemodynamic monitoring. In the past, parturients in class III or IV were often monitored with a pulmonary artery catheter; routine use of this modality, however, has fallen out of favor given the invasiveness required for its use. Echocardiography, on the other hand, is far less invasive, yet both safe and effective—a combination that has led to its increasing popularity in the perioperative period. An arterial line is warranted if serial blood gas determinations and/or continuous blood pressure monitoring are needed. Hemodynamic monitoring should be continued for at least 24 hours postdelivery because the sudden increase in preload can precipitate pulmonary edema.

Canobbio MM, Warnes CA, Aboulhosn J, et al. Management of pregnancy in patients with complex congenital heart disease: a scientific statement for healthcare professionals from the American Heart Association. *Circulation*. 2017;135(8):e50–e87.

C.3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?

- Avoid tachycardia.
- Maintain sinus rhythm.
- Avoid marked decreases in systemic vascular resistance.
- Avoid marked increases in blood volume.
- Avoid increases in pulmonary vascular resistance.

Increased heart rates should be avoided because decreasing the amount of diastolic time for blood to flow across the stenotic mitral valve can lead to pulmonary edema and decreased cardiac output. Atrial fibrillation with a rapid ventricular response, similarly, can result in cardiac decompensation, and the loss of atrial contraction is detrimental. Marked decreases in systemic

vascular resistance should be avoided because a compensatory increase in heart rate can result. Elevation of pulmonary vascular resistance, which can occur with hypercarbia, hypoxia, and acidosis, is poorly tolerated by these patients.

Kannan M, Vijayanand G. Mitral stenosis and pregnancy: current concepts in anaesthetic practice. *Indian J Anaesth*. 2010;54(5):439–444.

C.4. What anesthetic technique would you use for this emergency cesarean section?

The choices of anesthetic techniques for cesarean section are neuraxial (spinal, epidural, combined spinal epidural) or general anesthesia. In this case, the patient's epidural catheter should be dosed with additional local anesthetic to provide surgical anesthesia to a T4 level. If an adequate level of anesthesia cannot be achieved via an existing epidural catheter, conversion to general anesthesia is needed, especially in the setting of an abnormal FHR tracing.

In the non-emergent setting, patients with mitral stenosis are good candidates for epidural anesthesia for cesarean (or vaginal) delivery. Combined spinal–epidural analgesia, particularly when an opioid only spinal dose is used, is also a reasonable option. Spinal anesthesia, on the other hand, may lead to a sudden and profound decrease in systemic vascular resistance with hypotension and reflex tachycardia, which can exacerbate fetal distress and lead to maternal decompensation in patients with mitral stenosis.

Cohen K, Minehart R, Leffert L. Anesthetic treatment of cardiac disease during pregnancy. *Curr Treat Options Cardiovasc Med*. 2018;20(8):66.

C.5. How would you manage local anesthetic systemic toxicity (LAST) in this patient?

LAST is a serious and potentially fatal complication of regional/neuraxial anesthesia. It is caused by a high plasma

concentration of local anesthetic, either as a result of direct IV injection or from delayed absorption at the injection site. Pregnancy increases the risk for LAST, and it appears that epidural conversion from labor analgesia to surgical anesthesia puts patients at particular risk. Management of LAST includes the use of lipid emulsion according to the most current practice advisory by the American Society of Regional Anesthesia and Pain Medicine in conjunction with advanced cardiovascular life support (ACLS) guidelines, although there have been no randomized controlled trials to determine differences in either timing or dosing in pregnancy (**Fig. 29.3**).

AMERICAN SOCIETY OF REGIONAL ANESTHESIA AND PAIN MEDICINE

CHECKLIST FOR TREATMENT OF LOCAL ANESTHETIC SYSTEMIC TOXICITY (LAST)

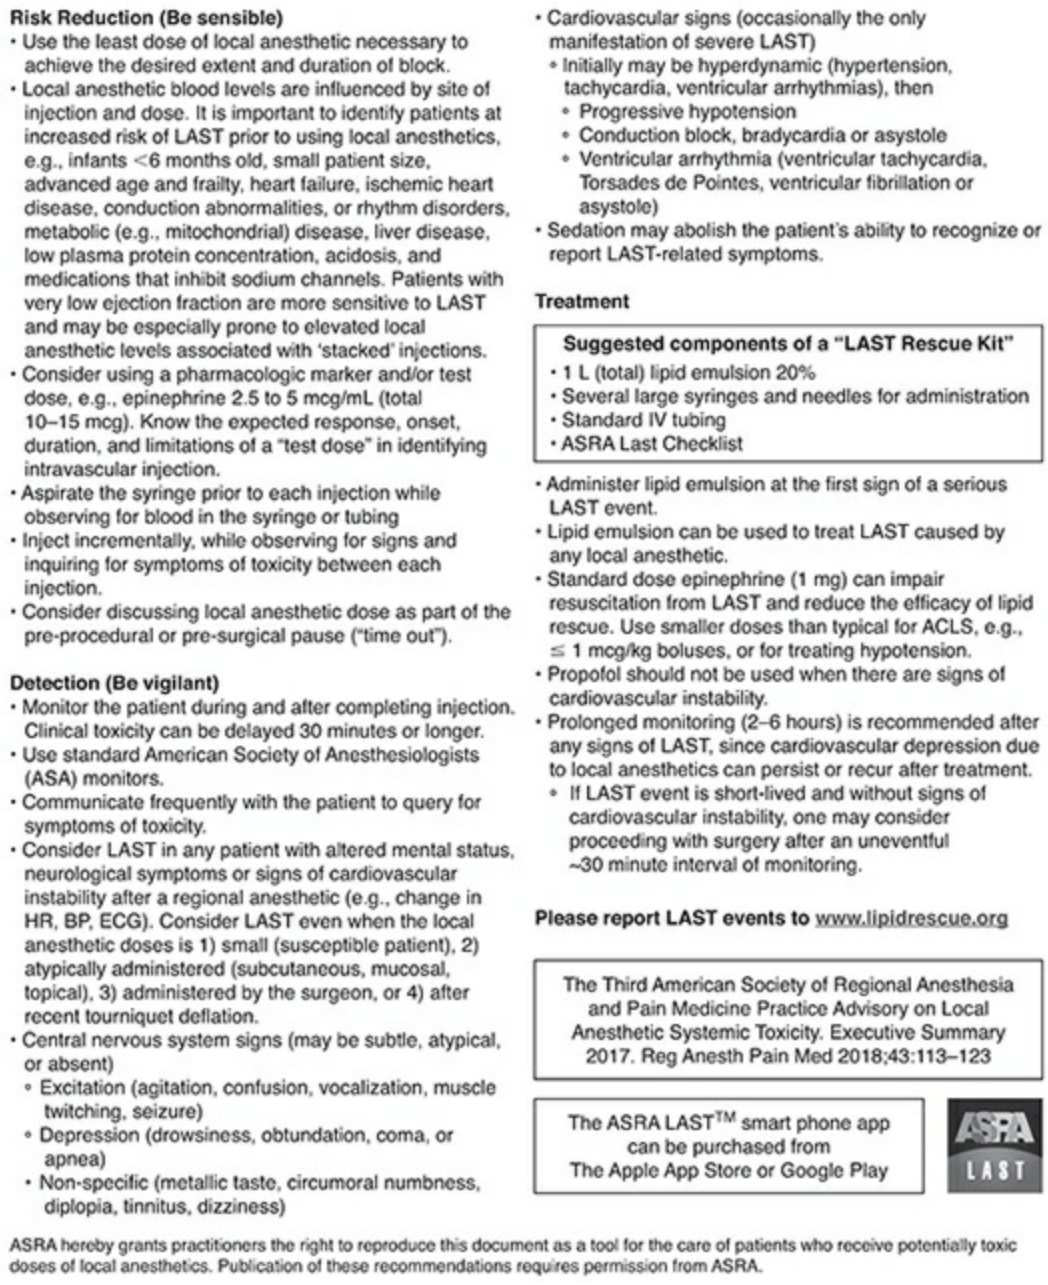
The Pharmacologic Treatment of LAST is Different from Other Cardiac Arrest Scenarios

- **Reduce** individual **epinephrine** boluses to ≤ 1 mcg/kg
- **Avoid** vasopressin, calcium channel blockers, beta blockers, or other local anesthetics

- Stop injecting local anesthetic
- Get help
  - Consider lipid emulsion therapy at the first sign of a serious LAST event
  - Call for the LAST Rescue Kit
  - Alert the nearest cardiopulmonary bypass team – resuscitation may be prolonged
- Airway management
  - Ventilate with 100% oxygen / avoid hyperventilation / advanced airway device if necessary
- Control seizures
  - Benzodiazepines preferred
  - **Avoid** large doses of **propofol**, especially in hemodynamically unstable patients
- Treat hypotension and bradycardia – **If pulseless, start CPR**

Lipid Emulsion 20% (Precise volume and flow rate are not crucial)	
Greater than 70 kg patient	Less than 70 kg patient
Bolus 100 mL Lipid Emulsion 20% Rapidly over 2–3 minutes • Lipid emulsion infusion 200–250 mL over 15–20 minutes	**Bolus 1.5 mL/kg Lipid Emulsion 20%** Rapidly over 2–3 minutes • Lipid emulsion infusion ~0.25 mL/kg/min (ideal body weight)
If patient remains unstable: • Re-bolus once or twice at the same dose and double infusion rate; be aware of dosing limit (12 mL/kg) • Total volume of lipid emulsion can approach 1 L in a prolonged resuscitation (e.g., > 30 minutes)	

- Continue monitoring
  - At least 4–6 hours after a cardiovascular event
  - Or, at least 2 hours after a limited CNS event
- Do not exceed 12 mL/kg lipid emulsion (particularly important in the small adult or child)
  - Much smaller doses are typically needed for LAST treatment
- See reverse side of this checklist for further details



Risk Reduction (Be sensible)

- Use the least dose of local anesthetic necessary to achieve the desired extent and duration of block.
- Local anesthetic blood levels are influenced by site of injection and dose. It is important to identify patients at increased risk of LAST prior to using local anesthetics, e.g., infants <6 months old, small patient size, advanced age and frailty, heart failure, ischemic heart disease, conduction abnormalities, or rhythm disorders, metabolic (e.g., mitochondrial) disease, liver disease, low plasma protein concentration, acidosis, and medications that inhibit sodium channels. Patients with very low ejection fraction are more sensitive to LAST and may be especially prone to elevated local anesthetic levels associated with 'stacked' injections.
- Consider using a pharmacologic marker and/or test dose, e.g., epinephrine 2.5 to 5 mcg/mL (total 10–15 mcg). Know the expected response, onset, duration, and limitations of a "test dose" in identifying intravascular injection.
- Aspirate the syringe prior to each injection while observing for blood in the syringe or tubing
- Inject incrementally, while observing for signs and inquiring for symptoms of toxicity between each injection.
- Consider discussing local anesthetic dose as part of the pre-procedural or pre-surgical pause ("time out").

Detection (Be vigilant)

- Monitor the patient during and after completing injection. Clinical toxicity can be delayed 30 minutes or longer.
- Use standard American Society of Anesthesiologists (ASA) monitors.
- Communicate frequently with the patient to query for symptoms of toxicity.
- Consider LAST in any patient with altered mental status, neurological symptoms or signs of cardiovascular instability after a regional anesthetic (e.g., change in HR, BP, ECG). Consider LAST even when the local anesthetic doses is 1) small (susceptible patient), 2) atypically administered (subcutaneous, mucosal, topical), 3) administered by the surgeon, or 4) after recent tourniquet deflation.
- Central nervous system signs (may be subtle, atypical, or absent)
  - Excitation (agitation, confusion, vocalization, muscle twitching, seizure)
  - Depression (drowsiness, obtundation, coma, or apnea)
  - Non-specific (metallic taste, circumoral numbness, diplopia, tinnitus, dizziness)
- Cardiovascular signs (occasionally the only manifestation of severe LAST)
  - Initially may be hyperdynamic (hypertension, tachycardia, ventricular arrhythmias), then
    - Progressive hypotension
    - Conduction block, bradycardia or asystole
    - Ventricular arrhythmia (ventricular tachycardia, Torsades de Pointes, ventricular fibrillation or asystole)
- Sedation may abolish the patient's ability to recognize or report LAST-related symptoms.

Treatment

Suggested components of a "LAST Rescue Kit"

- 1 L (total) lipid emulsion 20%
- Several large syringes and needles for administration
- Standard IV tubing
- ASRA Last Checklist

- Administer lipid emulsion at the first sign of a serious LAST event.
- Lipid emulsion can be used to treat LAST caused by any local anesthetic.
- Standard dose epinephrine (1 mg) can impair resuscitation from LAST and reduce the efficacy of lipid rescue. Use smaller doses than typical for ACLS, e.g., ≤ 1 mcg/kg boluses, or for treating hypotension.
- Propofol should not be used when there are signs of cardiovascular instability.
- Prolonged monitoring (2–6 hours) is recommended after any signs of LAST, since cardiovascular depression due to local anesthetics can persist or recur after treatment.
  - If LAST event is short-lived and without signs of cardiovascular instability, one may consider proceeding with surgery after an uneventful ~30 minute interval of monitoring.

Please report LAST events to www.lipidrescue.org

C.6. If cardiac arrest were to occur prior to delivery, how would you proceed?

High-quality chest compressions and oxygenation must be performed along with manual left lateral uterine displacement; this is true for all pregnant patients when the uterine size is ≥20 weeks. When the rhythm is shockable, defibrillation is appropriate (without risk to the fetus) in pregnancy. If return of spontaneous circulation fails to occur within 4 minutes of resuscitation efforts, perimortem cesarean delivery is advised. Of note, IV access should be obtained above the diaphragm because compression of the inferior vena cava by the gravid uterus prevents both fluids and medications from reaching the heart.

C.7. What technique could you use for general anesthesia in this patient?

- Induction
  - Crystalloid hydration through a large-bore, peripheral cannula
  - Supine position with left lateral tilt to avoid aortocaval compression
  - Preoxygenation with 100% inspired concentration of oxygen (F_{IO_2}) by face mask for 3 to 5 minutes if time permits, or four maximally deep inspirations (vital capacity breaths) if time is limited
  - Rapid sequence induction (after a team "time-out" and abdominal preparation and draping) with thiopental sodium (4 mg per kg; not available in the United States)

or etomidate (0.2 to 0.3 mg per kg) and succinylcholine (1 mg per kg)

- Although propofol (2 mg per kg) is most often used for induction of general anesthesia for cesarean delivery, it may cause hypotension, making it a less ideal choice in this patient.
- Ketamine should also be avoided because it increases heart rate.
- Because pregnant women tend not to experience severe fasciculations, a defasciculating dose of nondepolarizing muscle relaxant is not recommended.
- Depending on the severity of the lesion, patients with mitral stenosis may benefit from use of a β-adrenergic receptor antagonist, such as esmolol, or a modest dose of opioid (e.g., remifentanil) during induction of general anesthesia.
- If hypotension occurs, phenylephrine, not ephedrine, is the vasopressor of choice because it does not cause tachycardia in the mother (and is less likely than ephedrine to cross the placenta and increase concentrations of lactate, glucose, and catecholamines in fetal circulation).

– It is important to inform the neonatologist in the delivery room about medications given to the mother.
– Mucosal swelling and capillary engorgement in pregnancy may make intubation more difficult. Using a smaller endotracheal tube, such as one with a 7-mm internal diameter, may increase the likelihood of successful endotracheal intubation on the first attempt. The value of cricoid pressure—traditionally maintained until the endotracheal tube cuff is inflated and the position of the tube verified—is unknown. In human cadavers, it seems to effectively prevent regurgitation with gastric pressures

as high as 50 to 94 cm H_2O. Rice et al. showed that cricoid pressure compresses the hypopharynx leading to effective compression of the conduit between the stomach and the pharynx. Smith et al. found, however, that cricoid pressure in awake volunteers leads to airway displacement and does not reliably produce midline esophageal compression. In practice, its protective effect against passive reflux may actually be limited and even make intubation more difficult.

- Maintenance—prior to delivery of the neonate
  - N_2O with 50% oxygen and volatile anesthetic (e.g., 1% sevoflurane)
    - If pulmonary hypertension is present, N_2O should, however, be avoided because it increases pulmonary vascular resistance.
    - No more than 0.5 minimum alveolar concentration (MAC) should be used because halogenated anesthetic agents promote uterine atony. In this patient, both isoflurane and desflurane are best avoided because they cause tachycardia.
  - Muscle relaxant (vecuronium, cisatracurium, or rocuronium), as needed
  - Attention to maintenance of eucapnia is also important.
  - As always, the anesthetic technique should be tailored to the severity of the patient's underlying condition.
- Maintenance—after delivery of the neonate
  - Use of midazolam, fentanyl (or other opioid), muscle relaxant, and oxygen (usually with N_2O and 0.5 MAC of volatile agent, as earlier)
  - It is important to remember that the MAC of volatile agents is decreased by up to 40% in pregnant patients. MAC is a spinal nociceptive reflex involving both sensory

and motor components; the decrease in MAC has been interpreted to mean that pregnant patients have a decreased inhalational anesthetic requirement. In a small study of 30 patients, however, there was no difference in bispectral index (BIS) values between cesarean section patients and nonpregnant gynecologic patients undergoing general anesthesia with sevoflurane. According to Zand et al., BIS is not reliable for monitoring depth of anesthesia during cesarean section. Regardless of the anesthetic agents chosen, the aim is to achieve a satisfactory balance between hemodynamic stability, maternal amnesia, adequate uterine tone, and minimal neonatal depression.

- IV oxytocin infusion—begin immediately after delivery of the neonate
  - Bolus administration of oxytocin, methylergonovine, or 15-methyl prostaglandin $F_{2\alpha}$ should be avoided.
- Tracheal extubation—after protective laryngeal reflexes have returned and the patient has regained consciousness

C.8. If you are unexpectedly unable to intubate this patient, how would you manage the airway?

Figure 29.4 illustrates management of failed intubation in the obstetric patient with an unrecognized difficult airway. In the case of failed intubation when delivery of the neonate must occur, it is of utmost importance to maintain maternal oxygenation either via facemask or supraglottic airway device. The mother's life should not be endangered to deliver a distressed fetus. Calling for help promptly when difficulties arise is essential.

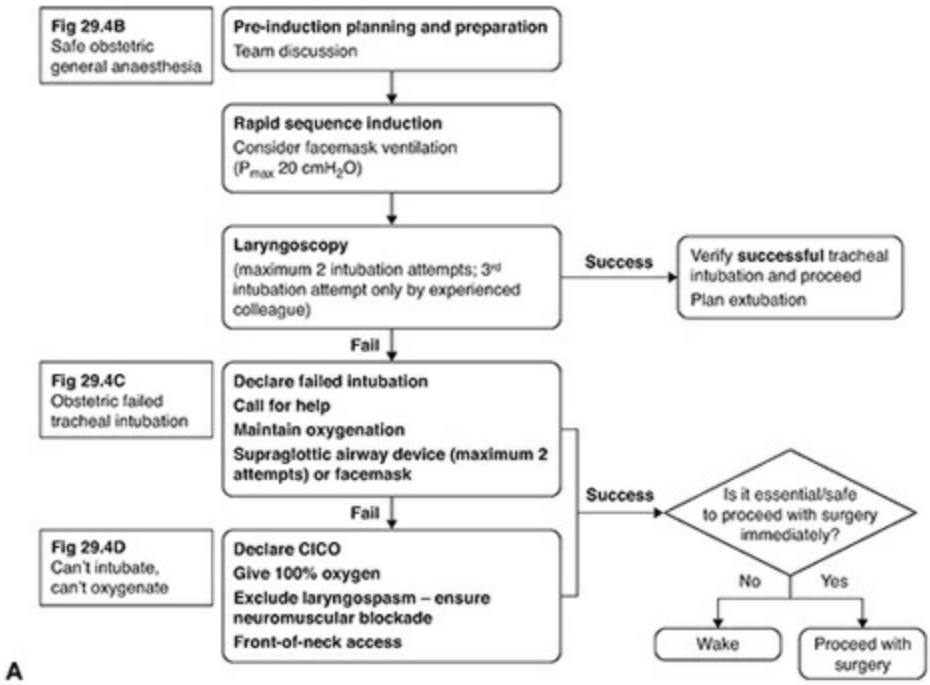

Fig 29.4B
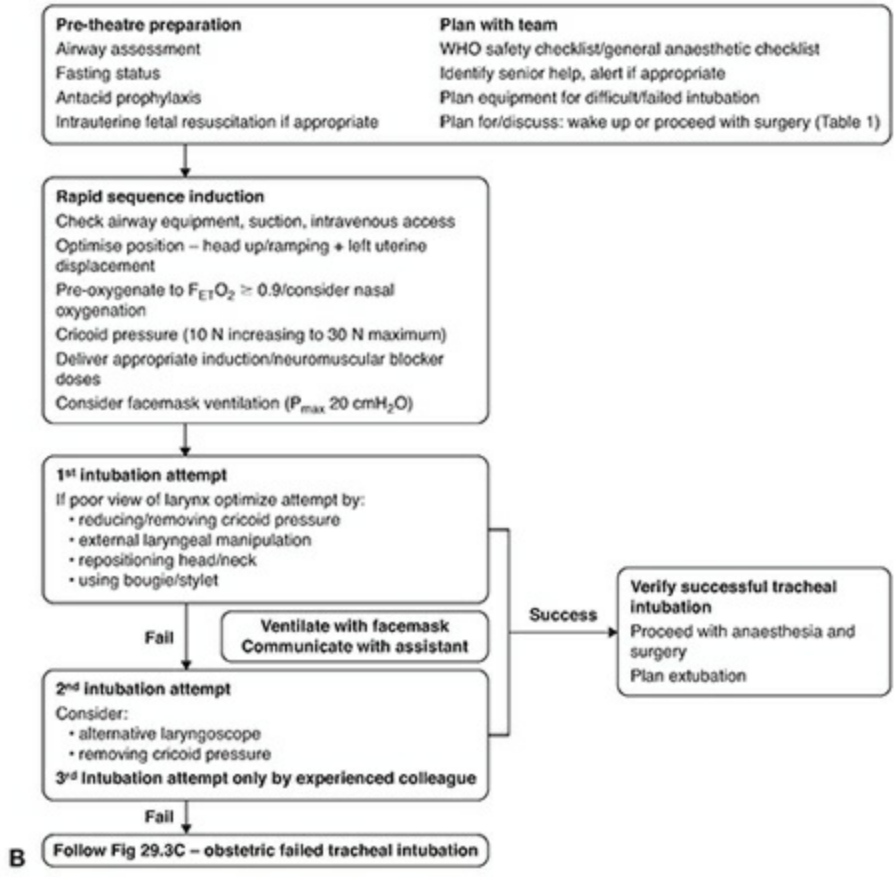
Safe obstetric general anaesthesia
Pre-induction planning and preparation
Team discussion
Rapid sequence induction
Consider facemask ventilation
(P_{max} 20 cmH_2O)
Laryngoscopy
(maximum 2 intubation attempts; 3rd intubation attempt only by experienced colleague)
Success
Verify successful tracheal intubation and proceed
Plan extubation
Fail
Fig 29.4C
Obstetric failed tracheal intubation
Declare failed intubation
Call for help
Maintain oxygenation
Supraglottic airway device (maximum 2 attempts) or facemask
Success
Fail
Fig 29.4D
Can't intubate, can't oxygenate
Declare CICO
Give 100% oxygen
Exclude laryngospasm – ensure neuromuscular blockade
Front-of-neck access
Is it essential/safe to proceed with surgery immediately?
No
Yes
Wake
Proceed with surgery
A



Pre-theatre preparation
Airway assessment
Fasting status
Antacid prophylaxis
Intrauterine fetal resuscitation if appropriate
Plan with team
WHO safety checklist/general anaesthetic checklist
Identify senior help, alert if appropriate
Plan equipment for difficult/failed intubation
Plan for/discuss: wake up or proceed with surgery (Table 1)
Rapid sequence induction
Check airway equipment, suction, intravenous access
Optimise position – head up/ramping + left uterine displacement
Pre-oxygenate to $F_{ET}O_2 \geq 0.9$/consider nasal oxygenation
Cricoid pressure (10 N increasing to 30 N maximum)
Deliver appropriate induction/neuromuscular blocker doses
Consider facemask ventilation (P_{max} 20 cmH_2O)
1st intubation attempt
If poor view of larynx optimize attempt by:
• reducing/removing cricoid pressure
• external laryngeal manipulation
• repositioning head/neck
• using bougie/stylet
Fail
Ventilate with facemask
Communicate with assistant
Success
Verify successful tracheal intubation
Proceed with anaesthesia and surgery
Plan extubation
2nd intubation attempt
Consider:
• alternative laryngoscope
• removing cricoid pressure
3rd intubation attempt only by experienced colleague
Fail
Follow Fig 29.3C – obstetric failed tracheal intubation
B

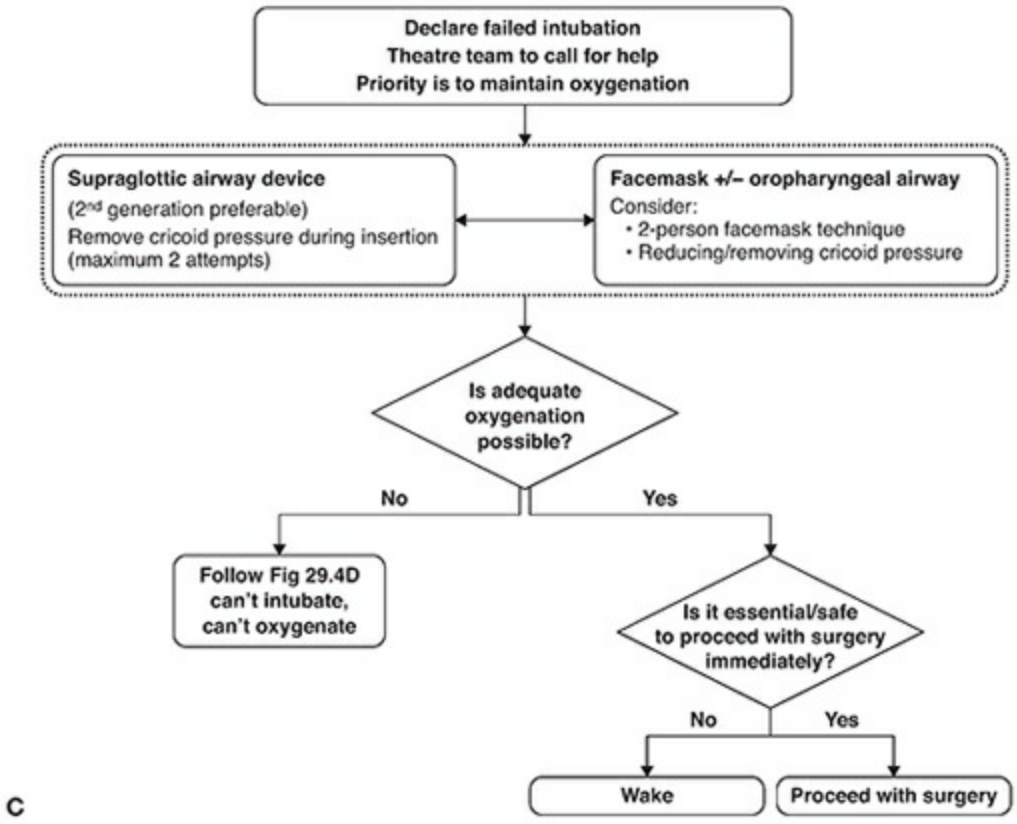


FIGURE 29.4. Algorithms for management of failed tracheal intubation in obstetric patients. A. C.9. Would this patient benefit from the use of *β*-blockers?

Because this patient is asymptomatic, *β*-blockade is unnecessary. Should tachycardia occur, *β*-blockade with drugs such as propranolol, atenolol, or esmolol may be useful, as may digoxin, and/or cardioversion depending on the dysrhythmia. Al Kasab et al. have shown that pregnant patients with symptomatic mitral stenosis who receive *β*-blockade with propranolol or atenolol to attenuate tachycardia have a significant decrease in the incidence of pulmonary edema with no adverse neonatal side effects.

al Kasab SM, Sabag T, al Zaibag M, et al. Beta-adrenergic receptor blockage in the management of pregnant women with mitral stenosis. *Am J Obstet Gynecol*. 1990;163:37–40.

C.10. What is the effect of the inhalation agents on uterine contractility?

At less than one MAC, there is no decrease in uterine contractility (or increase in blood loss) because the uterus still responds to oxytocin. At higher concentrations, uterine contractility is decreased, and as a result, blood loss is increased.

Tjeuw MT, Yao FS, van Poznak A. Depressant effects of anesthetics on isolated human gravid and non-gravid uterine muscle. *Chinese Med J (Engl)*. 1986;99(3):235–242.

C.11. What is the Apgar scoring system?

The Apgar scoring system is used to assess the neonate's condition at 1 minute and 5 minutes of life. Each of five categories is given a rating of 0 to 2, and the final score at each time is the sum of the individual category scores. Ten points is the best possible score (**Table 29.3**).

TABLE 29.3 Apgar Scoring System

		Score		
Mnemonic	**Sign**	**0**	**1**	**2**
A	Appearance (color)	Blue, pale	Body pink, extremities blue	Pink
P	Pulse	Absent	<100/min	>100/min
G	Grimace (reflex irritability; response to catheter in the nose)	Absent	Grimace	Cough, sneeze
A	Activity (muscle tone)	Limp	Some extremity flexion	Active motion
R	Respiratory effect	Absent	Slow, irregular	Good cry

Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg*. 1953;32:260–267.

C.12. What is the significance of Apgar scores?

The Apgar score is a standardized assessment of neonates at the time of delivery. It is measured at 1 and 5 minutes of life for all infants and then every 5 minutes up to 20 minutes for those with a score less than 7. The Apgar score provides information about the response to resuscitation but does not predict mortality or neurologic outcome.

American Academy of Pediatrics Committee on Fetus and Newborn, American College of Obstetricians and Gynecologists Committee on Obstetric Practice. The Apgar score. *Pediatrics*. 2015;136(4):819–822.

Silverman F, Suidan J, Wasserman J, et al. The Apgar score: is it enough? *Obstet Gynecol*. 1985;66(3):331–336.

C.13. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?

For many years, obstetricians suctioned the mouth and nose of the newborn before its first breath and delivery of the shoulders. At the present time, neither routine suctioning (oropharyngeal/nasopharyngeal), nor tracheal intubation, even in the presence of meconium-stained fluid is recommended. In the case of neonatal depression, it is recommended that emphasis be placed on initiating positive pressure ventilation; routine intubation, even in this situation, is not supported.

American College of Obstetricians and Gynecologists Committee on Obstetric Practice. ACOG Committee Opinion No. 379: management of delivery of a newborn with meconium-stained amniotic fluid. *Obstet Gynecol*. 2007;110(3):739.

Wyckoff MH, Aziz K, Escobedo MB, Kapadia VS, et al. Part 13: neonatal resuscitation: 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation*. 2015;132:S543–S560.

C.14. If the Apgar score of the newborn is 3 at 1 minute, how would you treat the newborn?

Positive pressure ventilation and preductal pulse oximetry (right upper extremity) should be initiated at 1 minute of life when the heart rate is <100 beats per minute or the infant is gasping or apneic. If the heart rate remains below 100 beats per minute, an attempt to correct ventilation should occur; but if it is below 60, chest compressions are indicated. The F_{IO_2} used during the initial resuscitation should be low (21% in term infants and 21% to 30% in infants ≤35 weeks) because hyperoxia may lead to tissue and organ injury. If, however, chest compressions are needed, then the F_{IO_2} can be increased. For term infants born at sea level, target preductal SpO_2 levels based on the time after delivery are as follows:

- 1 minute, 60% to 65%
- 2 minutes, 65% to 70%
- 3 minutes, 70% to 75%
- 4 minutes, 75% to 80%
- 5 minutes, 80% to 85%
- 10 minutes, 85% to 95%

Target data on SpO_2 levels does not exist for preterm or term infants born at different altitudes, but the above levels are thought to be reasonably usable in both of these patient populations.

Medications are rarely needed during neonatal resuscitation. However, if the heart rate remains below 60 beats per minute

despite adequate ventilation and chest compressions, IV epinephrine (0.01 to 0.03 mg per kg) should be given. Umbilical vein catheterization is the quickest way to gain IV access.

Rook D, Schierbeek H, Vento M, et al. Resuscitation of preterm infants with different inspired oxygen fractions. *J Pediatr*. 2014;164(6):1322.e3–1326.e3.

C.15. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?

In term infants, normal blood gases are as follows:

Umbilical artery

- pH, 7.27 ± 0.069
- P_{CO_2}, 50.3 ± 11.1 mmHg
- P_{O_2}, 22.0 ± 3.6 mmHg
- Bicarbonate, 22.3 ± 2.5 mEq per L

Umbilical vein

- pH, 7.35 ± 0.05
- P_{CO_2}, 38.2 ± 5.6 mmHg
- P_{O_2}, 29.2 ± 5.9 mmHg
- Bicarbonate, 20.4 ± 2.1 mEq per L

Umbilical artery blood gas values reflect fetal conditions, whereas umbilical vein blood gas values represent those of the uteroplacental unit and mother. ACOG recommends that cord blood gas measurements be obtained in the following circumstances: cesarean section for fetal compromise, low 5-minute Apgar score, severe fetal growth restriction, abnormalities in the FHR tracing, maternal thyroid disease,

intrapartum maternal fever, and/or multiple gestation. In 2003, the American Academy of Pediatrics and ACOG defined metabolic acidosis as umbilical arterial pH <7.0 and a base deficit of at least 12 mmol per L. Umbilical cord blood gas and pH measurements alone, however, are poorly predictive of immediate or long-term adverse neurologic outcome, but they do provide objective evidence of the fetal metabolic state at birth.

American College of Obstetricians and Gynecologists Committee on Obstetric Practice. ACOG Committee Opinion No. 348, November 2006: umbilical cord blood gas and acid-base analysis. *Obstet Gynecol*. 2006;108(5):1319–1322.

D. Postoperative Management

D.1. Immediately after the baby is delivered, the mother's oxygen saturation decreases. What is the differential diagnosis?

The following are possible causes of hypoxemia in this patient:

- Mechanical problems with the endotracheal tube (e.g., kinking)
- Cardiac decompensation with pulmonary edema
- Pulmonary venous embolism: air, amniotic, or thrombotic

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2019:937–955.

Fong J, Gadalla F, Pierri MK, et al. Are Doppler-detected venous emboli during cesarean section air emboli? *Anesth Analg*. 1990;71(3):254–257.

D.2. Additional bleeding occurs in the postanesthesia care unit, and the obstetrician diagnoses retained placenta. What, if any, antibiotics are indicated to prevent endometritis after manual extraction of retained placenta?

Manual extraction of the placenta is indicated when excessive bleeding occurs and/or when part of the placenta is retained after delivery. There is conflicting data regarding the risk for endometritis after manual extraction of the placenta, and the need for antibiotic prophylaxis, therefore, remains in question. Despite a lack of consensus regarding the need for routine antibiotics, the WHO recommends one IV dose of ampicillin or a first-generation cephalosporin. In a retrospective cohort study of more than 400 women who delivered vaginally, there was not a statistically significant difference in the rate of postpartum endometritis after manual extraction of the placenta between those who had or had not received prophylactic antibiotics.

30 Appendectomy for a Pregnant Patient

Robert S. White and Farida Gadalla

A 25-year-old woman at 32 weeks' gestation presented to the emergency room with vague right-sided abdominal pain. She had lost her appetite and experienced two episodes of emesis. Her temperature was 37.5°C (99.5°F); pulse rate, 100 beats per minute; hematocrit, 34%; and white blood cell (WBC) count, 15,000 per μL.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis for acute abdomen in the pregnant patient?
2. How would you make the clinical diagnosis of acute appendicitis?
3. What is the incidence of surgery during pregnancy? What is the incidence of appendicitis during pregnancy?
4. What is the incidence of gangrenous appendix/peritonitis during pregnancy, and is this incidence higher in pregnant than in nonpregnant women?
5. What are the main concerns associated with nonobstetric surgery in the pregnant patient?
6. What are the factors influencing teratogenicity from anesthetic

agents in humans?

7. Are there any specific concerns regarding neurotoxicity and cognitive development in the developing fetus?
8. What factors influence fetal oxygenation, and how would you prevent intrauterine fetal asphyxia?
9. What is the incidence of trauma during pregnancy, and what are the risks to the mother and the fetus secondary to trauma?
10. What are other common surgeries performed during pregnancy?

B. Preoperative Evaluation and Preparation

1. Preoperatively, what would you discuss with this patient? Are any additional medical consultations warranted?
2. Is there a difference in the goal of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?
3. How would you premedicate this patient?

C. Intraoperative Management

1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?
2. If you choose epidural anesthesia, describe your technique and dosage.
3. If the patient needs supplemental analgesia, what would be your choice?
4. What vasopressor would you choose to improve uteroplacental perfusion?
5. When this patient arrived in the operating room, she desired a general anesthetic. Describe your technique.
6. Does any controversy exist surrounding the use of nitrous oxide?
7. Does any controversy exist surrounding operating room personnel, anesthetic exposure, and pregnancy outcomes?
8. What is the impact of nonobstetric surgery on maternal mortality, birth defects, and fetal loss? What factors influence

it?

9. Should intraoperative fetal heart rate (FHR) monitoring be used? What would you expect to see on the electronic fetal monitor during anesthesia?
10. How would your anesthetic management differ if the patient were having upper extremity surgery?
11. The surgeon schedules the procedure to be performed laparoscopically. Does this pose any additional problems?

D. Postoperative Management

1. When would you extubate this patient?
2. Postoperatively, what monitors would you use?
3. What other postoperative precautions would you take? What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?
4. The next day, the patient went into premature labor and now needs a cesarean section for prematurity and breech presentation. She requires another general anesthetic. In what way would your technique differ from your previous anesthetic technique?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis for acute abdomen in the pregnant patient?

The differential diagnosis for acute abdomen in the pregnant patient includes appendicitis, cholecystitis, and intestinal obstruction as the most common nonobstetric surgical emergencies.

Medical Conditions

- Sickle cell disease
- Porphyria

- Glomerulonephritis
- Inflammatory bowel disease
- Pyelonephritis
- Pneumonia
- Splenic disorders
- Withdrawal from drug addiction

Obstetric Conditions

- Ectopic pregnancy
- Hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome
- Labor
- Abruptio placentae
- Chorioamnionitis

Gynecologic Conditions

- Fibroid degeneration
- Salpingitis
- Degenerating myoma
- Ovarian cyst or tumor, either torted or ruptured
- Tubo-ovarian abscess

Surgical Conditions

- Appendicitis
- Cholecystitis
- Pancreatitis
- Mesenteric adenitis
- Intestinal obstruction
- Maternal trauma

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Tase A, Kamarizan MF, Swarnkar K. Appendicitis in pregnancy: difficulties in diagnosis and management. Guidance for the emergency general surgeon: a systematic review. *Int J Surg Open*. 2017;6:5–11.

A.2. How would you make the clinical diagnosis of acute appendicitis?

The diagnosis is based on a detailed history, physical exam, imaging, and the following symptoms:

- Vague abdominal pain (right flank or upper quadrant): The position is variable because of the cephalad displacement of appendix due to the growing uterus, but the most common presenting symptom is right lower quadrant pain.
- Gastrointestinal distress: anorexia, nausea, vomiting
- Abdominal tenderness, guarding, rebound pain, rectal tenderness
- Mildly elevated temperature, 37°C to 38°C (98.6°F to 100.4°F)
- Mildly elevated pulse rate
- An increase in WBC count: Because pregnant patients normally have a higher WBC count, a physiologic leukocytosis, than nonpregnant patients, an increased WBC count may not be a reliable marker.

Ultrasonography is the most frequently used imaging modality, is not associated with risk, and allows for the exclusion of other causes of acute abdominal pain and for the assessment of the fetal condition. Use is operator dependent, and acute appendicitis may have normal abdominal findings. When the ultrasound is equivocal, magnetic resonance imaging (MRI) has lower rates of nonvisualization. Gadolinium-based contrast during pregnancy is controversial with restricted use. Computed tomography (CT) scan has limited role in pregnancy because of radiation and contrast risks; however, radiation exposure is at dose much lower than the exposure associated with fetal harm and clinically necessary imaging should not be withheld.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Committee on Obstetric Practice. Committee Opinion No. 723: guidelines for diagnostic imaging during pregnancy and lactation. *Obstet Gynecol*. 2017;130(4):e210–e216.

Walker HG, Al Samaraee A, Mills SJ, et al. Laparoscopic appendicectomy in pregnancy: a systematic review of the published evidence. *Int J Surg*. 2014;12:1235–1241.

A.3. What is the incidence of surgery during pregnancy? What is the incidence of appendicitis during pregnancy?

Between 0.75% and 2% or approximately 75,000 pregnant women will yearly require emergency nonobstetric surgery—mostly for acute appendicitis, cholecystitis (6:1,000 pregnancies), maternal trauma, and cancer. Gastrointestinal surgery accounts for 45% of the nonobstetric surgery in the pregnant patient and orthopedic procedures account for 24%. Appendicitis is the most common surgical emergency with varying incidence between 1:500 and 1:635 and has been reported as low as 1:2,000. It occurs more frequently in the second (45%) than in the first (30%) or third trimesters (25%). In epidemiologic studies, the reduced incidence of appendicitis in pregnant women compared to matched controls suggests a protective effect of pregnancy.

Prodromidou A, Machairas N, Kostakis ID, et al. Outcomes after open and laparoscopic appendectomy during pregnancy: a meta-analysis. *Eur J Obstet Gynecol Reprod Biol*. 2018;225:40–50.

Walker HG, Al Samaraee A, Mills SJ, et al. Laparoscopic appendicectomy in pregnancy: a systematic review of the published evidence. *Int J Surg*. 2014;12:1235–1241.

A.4. What is the incidence of gangrenous appendix/peritonitis during pregnancy, and is this incidence higher in pregnant than in nonpregnant

women?

During pregnancy, the gravid uterus pushes the appendix cephalically away from the omentum (**Fig. 30.1**), thereby causing the diseased appendix to produce little pain typically in the right lower quadrant and obfuscating the classic symptoms with flank pain. MRI studies have confirmed that the appendix is displaced upward to a mean distance of 45 mm above the iliac crest at term. This delays diagnosis and surgical intervention, allowing the appendix to become gangrenous. Also, contributing to diagnostic delay is postponement in diagnostic procedures such as radiography and laparoscopy for fetal concern. A 24-hour surgical delay can cause a 66% increase in perforation rate. The incidence of perforation of the appendix is approximately 15%. The perforation rates for first, second, and third trimesters tend to be 8.7%, 12.1%, and 26.1%, respectively. Epidemiologic data, however, show no higher incidence of perforated appendix in pregnant women compared to matched controls.

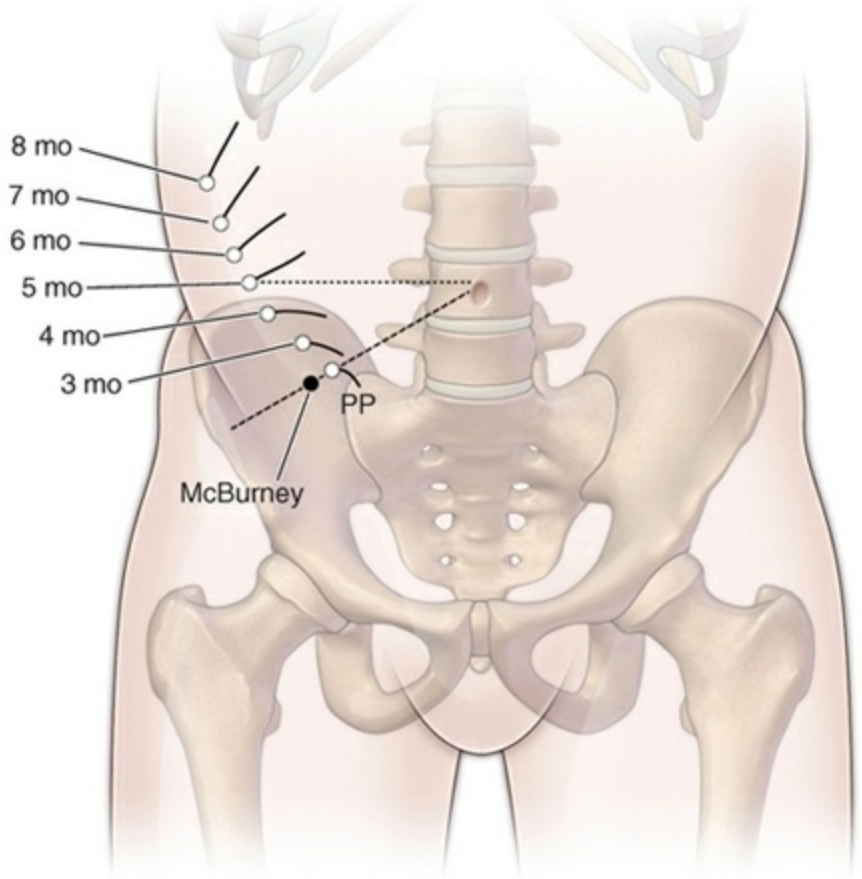

FIGURE 30.1. Changes in position and direction of the appendix during pregnancy. McBurney, McBurney's point; PP, prepregnancy. (*Adapted from Baer JL, Reis RA, Arens RA. Appendicitis in pregnancy with changes in position and axis of the normal appendix in pregnancy*. JAMA. *1932;98:1359*.)

A.5. What are the main concerns associated with nonobstetric surgery in the pregnant patient?

Abdominal surgeries during pregnancy have an increased risk of poor pregnancy outcomes—premature delivery, spontaneous

abortion, premature labor, and perinatal morbidity and mortality. Maternal mortality rate is very low, and to ensure maternal safety, awareness of the physiologic changes of the parturient is of great importance. Special care should be taken to prevent aspiration pneumonitis especially after midgestation. Failed intubation is increased. Faster uptake of anesthetics and a decrease in minimum alveolar concentration (MAC) for volatile anesthetics may rapidly render patients unconscious at lower doses.

As early as 8 weeks of gestation, most of the increases in cardiac output and stroke volume and decreases in vascular resistance are apparent. There is the risk of supine hypotensive syndrome (aortocaval compression). For fetal safety, it is essential to avoid teratogenic anesthetic agents and intrauterine fetal asphyxia. Maintenance of adequate maternal oxygenation, oxygen-carrying capacity, and uteroplacental perfusion are critical to fetal well-being.

American College of Obstetricians and Gynecologists (ACOG)/American Society of Anesthesiologists (ASA) have recommended that indicated surgery should never be denied to a pregnant woman, regardless of trimester; elective surgery should be postponed until after delivery; and, if possible, nonurgent surgery should be performed in the second trimester when preterm contractions and spontaneous abortion are least likely.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Reitman E, Flood P. Anaesthetic considerations for non-obstetric surgery during pregnancy. *Br J Anaesth*. 2011;107(suppl 1):i72–i78.

A.6. What are the factors influencing teratogenicity from anesthetic agents in humans?

An ACOG/ASA committee opinion states the following generalization: “No currently used anesthetic agents have been shown to have any teratogenic effects in humans when using standard concentrations at any gestational age.” Nevertheless, most anesthesiologists adhere to the use of only time-tested anesthetics with the goal of minimizing anesthetic exposures and exposure time. The factors influencing teratogenicity are genetic predisposition, inherent toxicity of the administered drug, drug dosage used and duration, placental transfer to the fetus, and fetal developmental stage at time of exposure.

Almost all anesthetics are teratogenic in some animals, but no animal model is perfectly applicable to humans. The most susceptible time for human teratogenicity is during organogenesis between days 31 and 71 after the last menstrual period. Before implantation of the ovum, teratogenicity leads to abortion. Later, malformation, functional deficiencies, and even death can occur. There are no documented reports of teratogenicity, congenital anomalies, or increase in birth defects in humans ascribed to any anesthetic agent used during pregnancy. Associations between the use of benzodiazepines and cleft palate and cardiac anomalies have been refuted; no evidence exists that a single dose of a benzodiazepine is harmful.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut’s Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Tolcher MC, Fisher WE, Clark SL. Nonobstetric surgery during pregnancy. *Obstet Gynecol*. 2018;132(2):395–403.

A.7. Are there any specific concerns regarding

neurotoxicity and cognitive development in the developing fetus?

Concern exists regarding exposure to anesthesia and potential neurotoxicity impacting neurodevelopment. A single and relatively brief exposure to general anesthesia is not associated with detectable deficits in most cognitive domains or academic achievement. In December 2016, the U.S. Food and Drug Administration (FDA) released a Drug Safety Communications warning and medication labelling changes that stated "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains." The response to this FDA rule change from concerned medical societies has been critical for the poor quality of scientific evidence used, lack of involvement of stakeholder medical societies, and its untoward impact on appropriate medical care with possible patient reluctance to undergo medically necessary procedures.

A.8. What factors influence fetal oxygenation, and how would you prevent intrauterine fetal asphyxia?

Maintaining maternal homeostasis (i.e., prevention of hypoxemia, hypotension, acidosis, and hyperventilation) is essential to fetal well-being. Fetal oxygenation is directly

dependent on maternal oxygen tension, oxygen saturation, hemoglobin content, oxygen affinity, and uteroplacental perfusion. Maternal hypoxia will result in fetal hypoxia; if uncorrected, fetal abnormalities or death can occur. Uterine blood flow is determined by uterine vascular resistance and uterine perfusion pressure (relative passive perfusion); factors that decrease uterine blood flow must be avoided. Uterine blood flow may be decreased by the following: maternal hypotension; stress, pain, or anxiety (due to the release of maternal catecholamines); hypoxia; hypercarbia, which also directly results in fetal respiratory acidosis; hyperventilation (hypocapnia); positive pressure ventilation; and pressor agents. Overall, one should attach greater importance to anesthetic management than to the agents used, and fluid administration should be appropriate for estimated or anticipated blood loss.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Reitman E, Flood P. Anaesthetic considerations for non-obstetric surgery during pregnancy. *Br J Anaesth*. 2011;107(suppl 1):i72–i78.

A.9. What is the incidence of trauma during pregnancy, and what are the risks to the mother and the fetus secondary to trauma?

Trauma occurs in 6% to 8% of all pregnancies and is the leading cause of nonobstetric maternal death. Most common causes of trauma during pregnancy are motor vehicle accidents (207:100,000 live births), falls and slips (48.9:100,000), and domestic violence (8,307:100,000). Maternal mortality and fetal mortality due to trauma are 1.4 per 100,000 and 3.7 per 100,000 pregnancies, respectively. Death rates and complications are higher in mothers at term compared to nonpregnant women.

Maternal complications are due to uterine rupture, placental abruption, and premature rupture of membranes. Fetal complications are due to these factors as well as to premature and stillbirths. Fetal viability should be assessed.

The primary goal of treatment is to stabilize the mother with an aggressive resuscitation. Uterine displacement is used and initial evaluation should be based on standard trauma guidelines. Emergent delivery may be necessary. Radiographic studies, if indicated, should be done. CT imaging is at a radiation exposure dose lower than that associated with fetal harm.

Mendez-Figueroa H, Dahlke JD, Vrees RA, et al. Trauma in pregnancy: an updated systematic review. *Am J Obstet Gynecol*. 2013;209(1):1–10.

A.10. What are other common surgeries performed during pregnancy?

Cardiac surgery: The physiologic changes of pregnancy (i.e., the increases in blood volume, cardiac output, and the decrease in systemic vascular resistance) can exacerbate preexisting heart disease, leading to congestive heart failure, particularly in patients with stenotic mitral or aortic valvular disease and pulmonary hypertension. Two periods are especially associated with cardiac decompensation—at 24 to 28 weeks when cardiac output reaches a maximum and immediately after delivery when uterine auto transfusion increases venous return causing volume overload. Procedures consist of surgical repair and percutaneous balloon valvuloplasty. Considerations include the use and type of cardiopulmonary bypass.

Neurosurgical procedures: The physiologic changes of pregnancy resulting in cardiac and hormonal (i.e., softening of

vascular connective tissue) system changes can theoretically increase the risk of hemorrhaging from intracranial saccular aneurysms or arteriovenous malformations. Other common conditions encountered include brain tumors, traumatic brain injury, and spinal surgery. Specific considerations include the use of "controlled hypotension," prone positioning, and intraoperative maternal hypothermia.

In these unique surgical situations, the importance of a multidisciplinary approach involving the anesthesia, obstetric, and surgical services cannot be overstated.

Cheek TG, Baird E. Anesthesia for nonobstetric surgery: maternal and fetal considerations. *Clin Obstet Gynecol*. 2009;52:535–545.

Tolcher MC, Fisher WE, Clark SL. Nonobstetric surgery during pregnancy. *Obstet Gynecol*. 2018;132(2):395–403.

B. Preoperative Evaluation and Preparation

B.1. Preoperatively, what would you discuss with this patient? Are any additional medical consultations warranted?

The pregnant patient undergoing nonobstetric surgery requires a standard anesthesia preoperative assessment and reevaluation with a frank discussion regarding anesthetic and surgical risks to the pregnancy and fetus. Obstetric consultation before surgery is essential as is utilization of a multidisciplinary team approach to provide for optimal safety of the woman and the fetus. The primary obstetric care provider should be notified and an obstetrician with hospital privileges should be involved. Use of fetal monitoring should also be discussed, again emphasizing communication, coordination, and planning between the different physician services. Decisions regarding preterm labor

and tocolysis should be delineated.

It is important to discuss her options concerning regional versus general anesthesia, emphasizing that the fetal outcome is statistically similar, but regional anesthesia is the technique of choice for the mother whenever possible (avoid fetal exposure to drugs and need for airway protection). In this specific case, if the appendectomy is planned laparoscopically, general anesthesia with airway control is preferred. Outcome studies show that woman who undergo surgery during pregnancy deliver earlier and have smaller babies than those who do not. Any increase in miscarriage or preterm birth are mostly attributable to surgical concerns.

Cheek TG, Baird E. Anesthesia for nonobstetric surgery: maternal and fetal considerations. *Clin Obstet Gynecol*. 2009;52:535–545.

B.2. Is there a difference in the goal of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?

The aim of obstetric anesthesia is to permit pain-free labor and delivery without interfering with the progress of child birth. Obstetric anesthesia should provide maternal analgesia without fetal neurologic depression and delayed neonatal breathing. Conversely, the aim of surgical anesthesia is to provide maternal anesthesia without stimulating uterine activity and precipitating premature labor. Surgical anesthesia is designed to maintain uteroplacental perfusion without consideration for fetal neurologic or respiratory depression.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia:*

Principles and Practice. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391, 568–626.

B.3. How would you premedicate this patient?

Premedication has traditionally been avoided in favor of verbal anxiolysis, reassurance, and support. If necessary, benzodiazepines can be given for sedation. Glycopyrrolate, which does not cross the placental barrier, can be used as a vagolytic and antisialagogue. For general anesthesia, a nonparticulate antacid, such as 30 mL of 0.3 M sodium citrate, is given about 30 minutes before surgery to prevent aspiration pneumonitis; an H_2-receptor antagonist may also be given.

C. Intraoperative Management

C.1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?

The maternal anatomic and physiologic changes of pregnancy have anesthetic implications.

Cardiovascular System

- Increased blood volume by 40% to 50% (20% reduction in hematocrit due to physiologic anemia of pregnancy with more increase in plasma volume than in red blood cell count)
- Increased cardiac output (stroke volume and heart rate) by 40% to 50%
- Decreased peripheral resistance
- Decreased mean arterial blood pressure
- Aortocaval compression in the supine position secondary to

growing uterus as shown in **Figure 30.2**. This can reduce venous return and cardiac output by 30%. Left uterine displacement (supine patient tilted by wedge under her right hip) should be used.

- Lower extremity venous stasis can lead to pedal edema and deep venous thrombosis (also caused by hypercoagulable state of pregnancy).

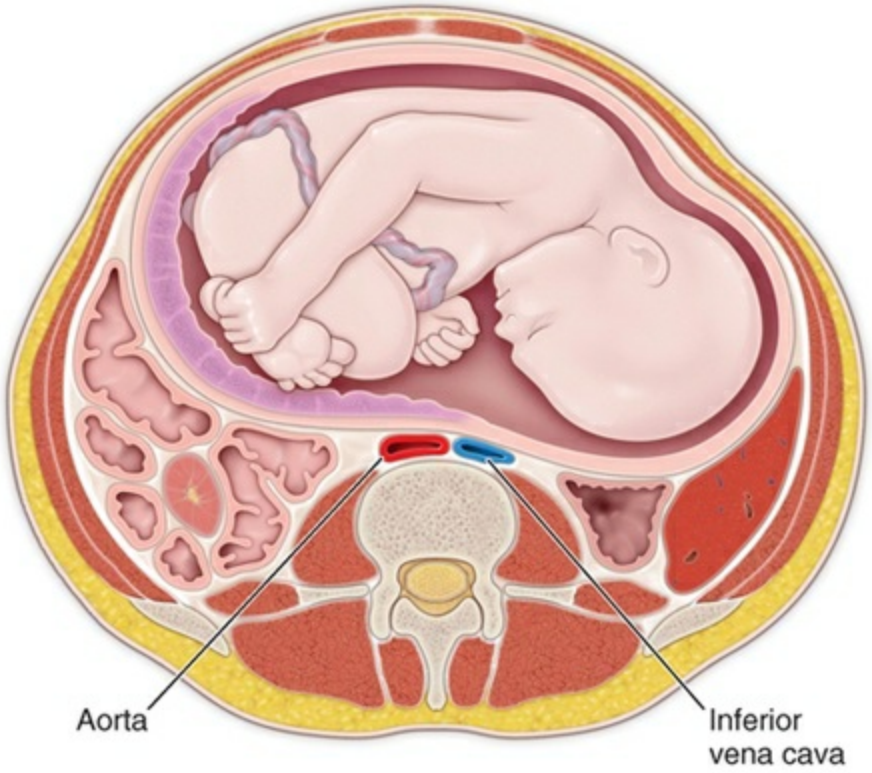

FIGURE 30.2. The pregnant uterus compressing the aorta and the inferior vena cava (aortocaval compression) in supine position. (*Adapted from Ostheimer GW*. Regional Anesthesia Techniques in Obstetrics. *New York: Breon Laboratories; 1980*.)

Respiratory System

- Increased minute ventilation (hyperventilation from progesterone shifting $Paco_2$ curve); chronic respiratory alkalosis with subsequent decrease in bicarbonate buffering capacity
- Increased oxygen consumption by 20%
- Decreased functional residual capacity (FRC) by 20% as

shown in **Figure 30.3**

- Both factors contribute to a rapid decrease in Pa_{O_2} during apneic periods.
- Inhalational induction occurs more rapidly secondary to alveolar hyperventilation and decreased FRC.

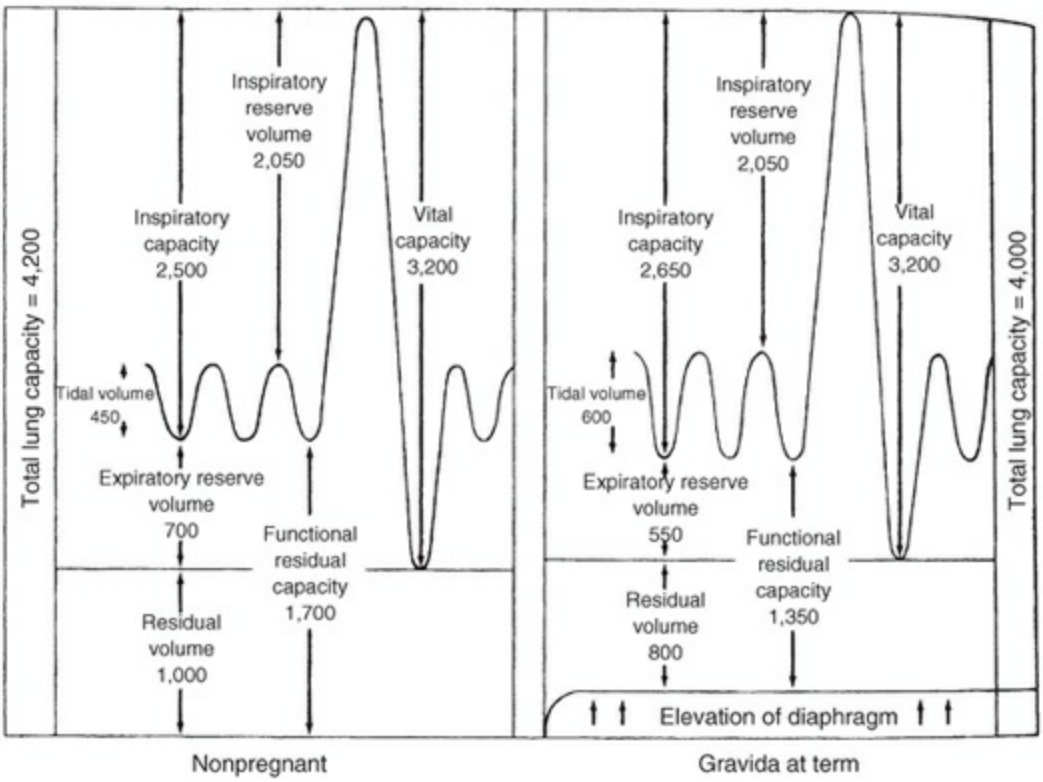

FIGURE 30.3. Pulmonary volumes and capacities during pregnancy. (*From Bonica JJ*. Principles and Practice of Obstetric Analgesia and Anesthesia. *1st ed. Philadelphia, PA: FA Davis; 1967, with permission*.)

Gastrointestinal System

- Decreased esophageal and intestinal motility
- Gastric emptying time is normal except in laboring patient.
- Decreased volume of gastrointestinal secretions
- Distortion of gastric anatomy secondary to growing uterus
- Increased gastric acidity
- Decreased lower esophageal (gastroesophageal) sphincter tone secondary to increased progesterone level. Increased incidence of heartburn/reflux. A pregnant patient beyond the

first trimester should always be considered as having a full stomach and must be considered at risk for regurgitation and aspiration (cautious use of mask ventilation or laryngeal mask airway [LMA]).

Central Nervous System

- Decreased MAC of inhaled anesthetics (30% to 40%)
- Increased sensitivity to local anesthesia
- Decreased volume of epidural anesthetic required because of engorgement of epidural veins and consequent decrease in size of epidural space; also increases risk of intravascular injection

Airway, Skin, and Mucous Membranes

- Swelling of oropharyngeal tissues with decreased caliber of glottis opening (difficulty performing mask ventilation and intubation; increased risk of failed intubation)
- More friable mucous membranes and engorged mucosal capillaries (Avoid nasal manipulation—insertion of nasal airways, nasotracheal, and nasogastric tubes.)
- Mallampati classification maybe more predictive of difficult intubation

Reitman E, Flood P. Anaesthetic considerations for non-obstetric surgery during pregnancy. *Br J Anaesth*. 2011;107(suppl 1):i72–i78.

C.2. If you choose epidural anesthesia, describe your technique and dosage.

The patient is placed either in the sitting position or on her side for epidural placement at L2–L3 or L3–L4. Adequate hydration is achieved with intravenous fluids. After testing for inadvertent

spinal or intravascular placement, the local anesthetic is given in divided doses to attain a T4 level. An inadvertent spinal injection is detected by the rapid onset of a solid motor block; an intravascular injection is evidenced by signs of systemic toxicity (dizziness, tinnitus, circumoral numbness, metallic taste). Local anesthetics used are 2% lidocaine, 0.5% bupivacaine, or 0.5% or 0.75% ropivacaine. These agents provide good analgesia with a degree of motor blockade for muscular relaxation. Epidural fentanyl promotes quicker onset and more solid block. The patient is once again placed with left uterine wedge, oxygen is delivered by nasal cannula, and her blood pressure is monitored closely.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:238–270.

C.3. If the patient needs supplemental analgesia, what would be your choice?

Morphine and fentanyl are narcotics that have been time tested. Small doses of ketamine (0.25 mg per kg intravenously) may also be given.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

C.4. What vasopressor would you choose to improve uteroplacental perfusion?

ASA practice guidelines state that "either IV ephedrine or phenylephrine may be used for treating hypotension during neuraxial anesthesia" and that "in the absence of maternal

bradycardia, consider selecting phenylephrine because of improved fetal acid–base status in uncomplicated pregnancies." Ephedrine was traditionally considered the safest vasopressor because its β-adrenergic effects increase cardiac output, mean arterial pressure, and uterine artery blood flow without a concomitant decrease in uteroplacental perfusion. However, use of ephedrine has been associated with adverse effects on fetal acid–base status (lower neonatal pH and fetal acidosis). Phenylephrine (pure α-agonist) use is now preferred because phenylephrine does not adversely affect neonatal outcome and decreases the incidence of fetal acidosis. This evidence is based on studies conducted in elective cesarean sections, and there is a paucity of evidence on the vasopressor of choice for nonelective cesarean deliveries or other surgical procedures.

Ngan Kee WD, Khaw KS, Tan PE, et al. Placental transfer and fetal metabolic effects of phenylephrine and ephedrine during spinal anesthesia for cesarean delivery. *Anesthesiology*. 2009;111(3):506–512.

Practice guidelines for obstetric anesthesia: an updated report by the American Society of Anesthesiologists Task Force on Obstetric Anesthesia and the Society for Obstetric Anesthesia and Perinatology. *Anesthesiology*. 2016;124(2):270–300.

C.5. When this patient arrived in the operating room, she desired a general anesthetic. Describe your technique.

- Apply standard ASA monitors, ensure free flowing intravenous cannula, use of left uterine displacement, and consider blood glucose monitoring for long procedures.
- Preoxygenate for at least 3 minutes to ensure denitrogenation.
- Induction via a rapid sequence induction intubation technique (intubation using a cuffed endotracheal tube with a 7-mm internal diameter or less) with cricoid pressure

- Anesthesia maintenance using time-tested agents: morphine, fentanyl, nondepolarizing muscle relaxants, sevoflurane, and/or desflurane. Inhalation anesthetics additionally relax the uterus and may aid in preventing premature labor.
- Maintain an appropriate maternal oxygenation and a normotensive blood pressure to ensure uteroplacental perfusion and avoid hyper-/hypoventilation.
- Extubate the trachea when the patient is awake and has regained her laryngeal reflexes.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:56–76, 368–391.

C.6. Does any controversy exist surrounding the use of nitrous oxide?

Nitrous oxide inhibits methionine synthase, potentially affecting DNA synthesis and myelin deposition, and has been shown to be teratogenic in animals. The neuronal apoptosis and learning impairment observed in animals after exposure to nitrous oxide remain to be determined in humans. As of this writing, no detrimental effects of nitrous oxide on the development of the human fetus have been demonstrated. Nitrous oxide also increases adrenergic tone and decreases uterine blood flow. This can be prevented by the addition of a volatile agent. Nitrous oxide may be used as a component of the inhalational anesthetic.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

C.7. Does any controversy exist surrounding operating

room personnel, anesthetic exposure, and pregnancy outcomes?

Case reports and epidemiologic studies from the 1960s and 1970s showed associations between increased spontaneous abortions (increased miscarriage rates) and operating room and dental surgical personnel. Subsequent independent repeat analysis of this work identified methodologic flaws and bias in data collection, causing spurious findings. Prospective studies have found no causal relationships. Additionally, modern volatile anesthetic exposure can be reduced by more than 90% with the use of modern scavenging systems.

C.8. What is the impact of nonobstetric surgery on maternal mortality, birth defects, and fetal loss? What factors influence it?

Meta-analysis including 12,452 pregnant women having surgery estimated maternal death at 0.006% (<1/10,000). Surgery and anesthesia did not increase the risk of major birth defects and were not major risk factors for spontaneous abortion. However, acute appendicitis with peritonitis poses a significant risk for fetal loss. Fetal loss was estimated at less than 5% in cases of uncomplicated acute appendicitis; the rate of fetal loss increased to 20% with perforated appendicitis and 35.7% with generalized peritonitis. In summary, the literature suggests that miscarriage and preterm birth are slightly increased after surgery with the severity of the disease process requiring surgery or the site of surgery having the strongest influence.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

C.9. Should intraoperative fetal heart rate (FHR) monitoring be used? What would you expect to see on the electronic fetal monitor during anesthesia?

The use of intraoperative FHR monitoring is recommended only if it will alter case management. This decision is individualized and dependent on gestational age, type of surgery, and facilities available. FHR monitoring is practical from 18 to 22 weeks, and heart rate variability can be observed from 25 weeks on. ACOG/ASA guidelines for fetal monitoring state that for a previable fetus, it is generally sufficient to ascertain the FHR by Doppler before and after the procedure. For a viable fetus, simultaneous electronic FHR and contraction monitoring should be performed before and after the procedure to assess fetal well-being and the absence of contractions.

One would expect to see a decrease in beat-to-beat FHR variability during general anesthesia using inhalational agents. FHR slowing (bradycardia) can also be observed, but this could also be secondary to nonbenign situations such as fetal hypoxemia and acidosis. FHR variability is also decreased by the use of opioids and induction agents.

Reitman E, Flood P. Anaesthetic considerations for non-obstetric surgery during pregnancy. *Br J Anaesth*. 2011;107(suppl 1):i72–i78.

C.10. How would your anesthetic management differ if the patient were having upper extremity surgery?

A brachial plexus block regional technique could be used. Additionally, it is possible to monitor the fetal heart during surgery and to monitor for uterine contractions using a tocodynamometer.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

Committee on Obstetric Practice, American Society of Anesthesiologists. Committee Opinion No. 696: nonobstetric surgery during pregnancy. *Obstet Gynecol*. 2017;129(4):777–778.

C.11. The surgeon schedules the procedure to be performed laparoscopically. Does this pose any additional problems?

Laparoscopy has been performed during pregnancy both for diagnostic and procedural surgery. Benefits appear similar to those in nonpregnant patients—reduced postoperative pain, postoperative ileus, and other complications and decreased length of hospital stay with faster return to work. Traditionally, there has been concern for direct fetal and uterine trauma and increased intra-abdominal pressure, causing a decrease in maternal cardiac output and uteroplacental perfusion. Carbon dioxide (CO_2) pneumoperitoneum can cause fetal respiratory acidosis. General guidelines are to maintain a low intra-abdominal insufflation pressure of 10 to 15 mmHg, limiting extremes in positioning (Trendelenburg or reverse Trendelenburg), and limiting surgery duration. Intraoperative CO_2 monitoring via capnography is adequate to guide ventilation, and end-tidal CO_2 should be maintained at approximately 32 mmHg. Laparoscopic appendectomy has been shown to be associated with a low rate of intraoperative complications in all three trimesters. Results of multiple meta-analyses, however, have found that fetal loss was statistically significantly higher in those who underwent laparoscopic

compared to open appendectomy. It should be noted that the findings concerning fetal loss were largely dominated by one large study and with study exclusion from pooled meta-analysis, there was no effect of laparoscopy on fetal loss. In summary, the current literature is inconclusive and further larger volume studies are needed to better elucidate the association between fetal loss and laparoscopic appendectomy. The Society of American Gastrointestinal Endoscopic Surgeons states that "laparoscopic appendectomy is the treatment of choice for pregnant patients with acute appendicitis." Furthermore, "Laparoscopy can be safely performed during any trimester of pregnancy when operation is indicated" and "postponing necessary operations until after parturition has been shown in some cases, to increase the rates of complications for both mother and fetus."

D. Postoperative Management

D.1. When would you extubate this patient?

The patient can be extubated when she is fully awake, in control of her airway reflexes, and able to avoid pulmonary aspiration.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

D.2. Postoperatively, what monitors would you use?

Postoperative monitors should include electrocardiogram, pulse

oximeter, intermittent blood pressure and temperature monitoring, urinary catheter (to be discontinued within 24 hours, unless specifically indicated), FHR monitor to ensure fetal well-being, and tocodynamometer to detect premature labor.

Chestnut DH, Wong CA, Tsen LC, et al, eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2020:368–391.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2036–2041.

D.3. What other postoperative precautions would you take? What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?

Postoperative precautions include adequate hydration, supplemental oxygen as needed, continued left uterine displacement, early mobilization, and use of antiembolic massage devices and/or anticoagulation to prevent deep venous thrombosis.

Many obstetricians use intravenous fluids and β-agonist drugs to prevent premature labor. It is recommended that pregnant patients be observed postoperatively on the obstetric floor for a minimum of 12 hours. Magnesium sulfate is given intravenously if preterm labor occurs.

In a study of 778 women who underwent appendectomy while pregnant, 22% delivered during the following week if surgery occurred between 24 and 36 weeks' gestation. There is an increased risk of low birth weight infants (less than 2,500 g) and premature labor before 37 weeks.

Augustin G. *Acute Abdomen during Pregnancy*. New York: Springer; 2014:3–34.

Principles and Practice. 6th ed. Philadelphia, PA: Elsevier; 2020:368–391.

D.4. The next day, the patient went into premature labor and now needs a cesarean section for prematurity and breech presentation. She requires another general anesthetic. In what way would your technique differ from your previous anesthetic technique?

Magnesium sulfate will both prevent the muscle fasciculations that normally occur following the administration of succinylcholine and will potentiate the effects of nondepolarizing muscle relaxants (use smaller doses). Avoid the use of narcotics until after delivery and then after delivery stop the inhalation agent and begin using a narcotic technique.

SECTION 8 The Hematologic System

31 Hemophilia and Disorders of Coagulation

Elizabeth M. Staley

A 46-year-old, HIV-positive man with congenital hemophilia A is scheduled for elective elbow synovectomy with resection of the radial head because of pain with movement and limited range of motion.

A. Medical Disease and Differential Diagnosis

1. Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.
2. What is the difference between platelet adhesion, activation, and aggregation at sites of vascular injury?
3. Describe the physiologic events that occur following endothelial interruption in the blood vessel.
4. What factors prevent the extension of a clot beyond the site of

injury?

5. Describe the factors involved in the extrinsic, intrinsic, and common coagulation cascade.
6. Describe the typical presentation history and pathophysiology associated with von Willebrand disease (vWD).
7. Explain the pathophysiology, frequency, and treatment of significant rare disorders of coagulation (factor VII [FVII], factor XII [FXII], and fibrinogen).
8. Differentiate between hemophilia A, B, and C.
9. What are the differences in factor replacement therapy between patients with hemophilia A and hemophilia B?
10. What is acquired hemophilia?
11. Which plasma protein is important in maintaining normal levels of factor VIII (FVIII)?
12. How are patients with severe hemophilia managed in the outpatient setting?
13. Describe the levels of FVIII necessary to maintain hemostasis in patients with spontaneous or surgical bleeding.

B. Preoperative Evaluation and Preparation

1. What steps would you take to normalize this patient's coagulation status before surgery?
2. What is meant by 1 unit of FVIII clotting activity, and how much does 1 unit of FVIII clotting activity per kilogram of body weight increase FVIII concentrations?
3. Would you administer FVIII using a bolus or infusion technique?
4. Can hemophiliac patients fail to mount an appropriate coagulation response following FVIII infusion?
5. If a patient with hemophilia does not respond to a bolus injection of FVIII, can an infusion technique be effective?
6. How much FVIII activity is present in plasma? What are the risks associated with plasma administration?

7. What are the indications for the administration of plasma?
8. What is cryoprecipitate, and how is it prepared? How much FVIII activity is present in cryoprecipitate? When is cryoprecipitate indicated?
9. Describe the advantages and disadvantages of the products that are available for repletion of FVIII activity.
10. What is the role of desmopressin (D-amino D-arginine vasopressin [DDAVP]) for hemostatic management in this patient?
11. What is the role of antifibrinolytic therapy in the perioperative period for the patient with hemophilia? What are examples of antifibrinolytics used in the treatment of hemophilia?
12. What are the options for operative treatment of patients with acquired hemophilia? Describe the mechanism of action and dosing considerations for each of these therapies.

C. Intraoperative Management

1. Is it safe to administer an intramuscular injection to this patient before surgery?
2. Would an axillary block be appropriate for this patient?
3. If general anesthesia is used, would it be safe to intubate the patient's trachea?
4. Would you use any special precautions for this patient who is positive for HIV?
5. What special considerations should be taken in choosing anesthetic drugs for this patient?
6. During an operative procedure, if the surgeon indicates that significant blood loss is occurring, would you transfuse this patient with packed red blood cells (RBCs) or whole blood?
7. During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8°C to 37.9°C (98.2°F to 100.2°F). What immediate steps should be taken by the anesthesiologist at this time?

8. Does giving blood intraoperatively increase the potential for the development of FVIII inhibitors?
9. Can FVIII be safely administered to patients who have developed circulating inhibitors?
10. The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?
11. Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?

D. Postoperative Management

1. What special consideration should be given to postoperative pain management for this patient?
2. What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?
3. Can this patient be treated with FVIII supplements using home infusion?

A. Medical Disease and Differential Diagnosis

A.1. Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.

Numerous laboratory tests evaluate specific components of the coagulation cascade.

Routine assessment or monitoring (i.e., pharmacologic anticoagulation) of the coagulation cascade is usually performed with both prothrombin time (PT) and activated partial thromboplastin time (aPTT). Specific factors assessed by different coagulation tests are shown in **Table 31.1**. The PT is measured after recalcification by combining tissue factor (TF) with a plasma specimen and measuring the time to clot formation. This test will detect abnormalities in factor II (FII),

factor V (FV), FVII, and factor X (FX) or the presence of an inhibitor (such as a lupus anticoagulant, or a true antibody-mediate, acquired coagulation factor inhibitor). Clot formation can be measured either mechanically or optically depending on the laboratory method used, the various methods having differential susceptibility to interference from lipemia or icterus and the reagents used have varying sensitivities to factor level depletion (i.e., therefore, cut-offs for abnormal results are set with each reagent). The PT maybe also be prolonged in the setting of hypofibrinogenemia. Typically, fibrinogen (factor I) must be less than 100 mg per dL to affect the PT. The PT is frequently used to monitor warfarin. Results are standardized to accommodate the use of different formulations of thromboplastin activating agents; the international sensitivity index (ISI) rates the sensitivity of a given reagent with respect to a standard with an assigned ISI value of 1. The international normalized ratio (INR) is calculated by determining the ratio of the patient PT to that of the normal/reference population and raising it to the power of the ISI as follows: INR = (patient test result/mean of normal reference population)^{ISI}. The PT is not useful for measuring the effects of other forms of anticoagulant therapy, particularly direct oral anticoagulants (DOACs).

TABLE 31.1 Specific Factors Assessed by Different Coagulation Tests

Laboratory Tests	Components Measured
Prothrombin time	I, II, V, VII, and X
Activated partial thromboplastin time	I, II, V, VII, IX, X, XI, and XII
Thrombin time	I, II
Platelet function analyzer 100 (PFA-100)	vWF, platelet count/function, vascular integrity

vWF, von Willebrand factor.

The aPTT result is determined as the time to clot when partial thromboplastin (no TF) and a negatively charged activating

substance (e.g., celite or kaolin) are added to a test tube of recalcified citrated plasma. Prolongations in the aPTT can be associated with deficiencies in factor I (FI), FII, FV, FVIII, factor IX (FIX), FX, factor XI (FXI), and FXII or the presence of an inhibitor (such as a lupus anticoagulant, or a true antibody-mediated, acquired coagulation factor inhibitor). The aPTT has been used as means of monitoring heparin therapy, with a goal of targeting 1.5 to 2.5 times the mean normal value. However, this practice has fallen in to disuse because the reagents have varying sensitivity to the anti-FXa/anti-FIIa effects of unfractionated heparin. Anti-FXa activity level can be used to monitor heparin anticoagulation when patients have deficiencies of the contact factors, with lupus anticoagulants, or in the setting of DOAC use if the assay is calibrated using the specific DOAC to be monitored. The aPTT is also not useful for measuring the effects of DOACs.

The activated clotting time (ACT) measures the time to clot formation when whole blood is activated by diatomaceous earth (kaolin) or other activators (e.g., celite). This test is used most often to measure the response to large heparin doses (concentrations greater than 1 U per mL and up to 10 U per mL) during percutaneous cardiology interventions, renal dialysis, or cardiopulmonary bypass (CPB). Although the relationship between ACT and heparin level is fairly linear within a given patient, there are substantial differences between patients with regard to the heparin dose-response relationship. The ACT has several limitations: It may be insensitive to specific factor deficiencies; it lacks specificity, and similar to aPTT values, ACT values can be prolonged as related to lupus anticoagulant antibodies or other clinically significant or insignificant inhibitors. Additionally, ACT can be prolonged independent of heparin levels by either hypothermia or hemodilution that are commonly observed with extracorporeal circulation, as during

cardiac surgery.

Thrombin time is an assay that bypasses most of the coagulation cascade and simply measures the conversion of fibrinogen to fibrin. This test can be especially useful to evaluate fibrinogen levels (hypofibrinogenemia) as well as abnormal fibrinogen function (dysfibrinogenemia). The thrombin time is also sensitive to very low concentrations of heparin. The thrombin time can be used to exclude the presence of direct thrombin inhibitors (DTIs) such as bivalirudin or small amounts of residual circulating heparin. A modified (i.e., patient plasma diluted eightfold) version of the thrombin time may be helpful to assess the effects of some of the new oral anti-FIIa inhibitors (e.g., dabigatran).

The thromboelastography (TEG) or rotational thromboelastometry (ROTEM) (**Fig. 31.1**) assesses the viscoelastic properties of blood by measuring the speed of clot formation and clot firmness (i.e., maximum amplitude vs. maximal clot firmness). These tests allow evaluation of a clot from early formation of fibrin strands to clot dissolution through fibrinolysis. The TEG tracings consist of several parameters: reaction time (R value), coagulation time (K value), maximum amplitude (MA value), α angle, and the amplitude 60 degrees after the MA or maximum clot firmness (MCF) (A60) or fibrinolysis indices (MA/A60 ratio). A deviation from a prototypical tracing represents one or more abnormalities in the patient's coagulation profile, and these abnormalities have been shown to be associated with either bleeding (i.e., low MA value) or thrombotic (i.e., with high MA value) complications. Although abnormal TEG or ROTEM tracings can provide useful information, many of the parameters are not necessarily specific for any defined hemostatic abnormality. The MA or MCF can be affected by thrombocytopenia or qualitative platelet abnormalities, fibrinogen deficiencies, or even anemia. More

recent modifications of the TEG and ROTEM devices incorporate the use of various agonists (e.g., kaolin vs. TF) or inhibitors (i.e., of platelets with cytochalasin D or fibrinolysis with aprotinin) that enhance the systematic analysis of intraoperative coagulation defects by increasing specificity with respect to detection of specific defects and can facilitate a more directed approach to therapy. An example of TEG/ROTEM interpretative guidelines is shown in **Table 31.2**.

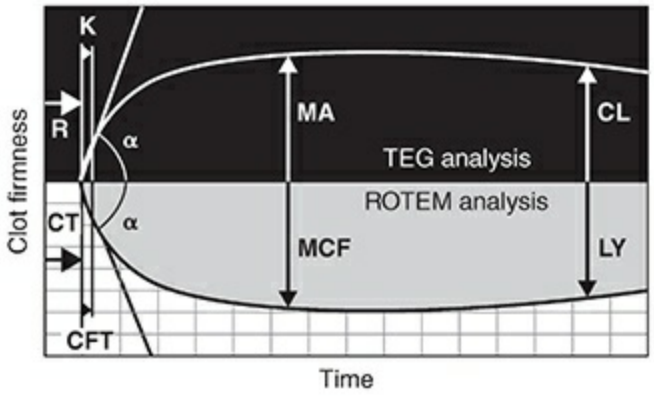

FIGURE 31.1. Tracings of thromboelastography (TEG) and rotational thromboelastometry (ROTEM). Upper side: TEG tracing: *α*, slope between R and K; CL, clot lysis; K, kinetics; MA, maximum amplitude; R, reaction time. Lower side: ROTEM tracing: *α*, slope of tangent at 2-mm amplitude; CFT, clot formation time; CT, clotting time; LY, lysis; MCF, maximal clot firmness.

TABLE 31.2 Interpretation of Thromboelastography (TEG)/Rotational Thromboelastometry (ROTEM) Parameters

TEG	ROTEM	Definition	Etiology	Management
R	CT	Time from the start of test until clot initiation	Prolonged: factor deficiency or anticoagulant	Prolonged: plasma
K	CFT	Time from clot initiation to when curve achieves an amplitude of 20 mm	Prolonged: factor deficiency, hypo-/dysfibrinogenemia, thrombocytopenia, platelet dysfunction	Cryoprecipitate
α	*α*	Angle between the baseline and the tangent to the curve through the starting point of coagulation	Prolonged: factor deficiency, hypo-/dysfibrinogenemia, thrombocytopenia, platelet dysfunction	Cryoprecipitate
MA	MCF	Amplitude measured at the maximum curve width	Prolonged: factor XIII deficiency, hypo-/dysfibrinogenemia,	Platelets. Consider plasma or cryoprecipitate.

			thrombocytopenia, platelet dysfunction	
LY	CL	Reduction in area under the curve (LY) or in amplitude (CL) from the time MA/MCF is achieved until 30–60 min later	Increased: hyperfibrinolysis	Antifibrinolytics

α, alpha angle; CL, clot lysis; CT/R, clotting time/reaction time; K/CFT, kinetics/clot formation time; LY, lysis; MA, maximum amplitude; MCF, maximum clot firmness.

Additionally, there are tests available for specifically assessing platelet function; these assays typically use optical density or impedance methods to assess inducible platelet aggregation. The more recently available assays are the VerifyNow and PFA-100. VerifyNow (Accumetrics, San Diego, CA) is a point-of-care instrument that uses light transmission to assess platelet activity and/or inhibition. The test is performed using whole blood and evaluates platelet aggregation of fibrinogen-coated beads in response to stimulation with a potent thrombin receptor agonist. As platelets aggregate/coalesce, there is an increase in light transmittance. Platelets from patients taking antiplatelet therapy will demonstrate impaired aggregation, as demonstrated by reduced light transmission. Much of the data using VerifyNow has focused on assessing the effects of adenosine diphosphate (ADP) $P2Y_{12}$ receptor antagonists such as clopidogrel and prasugrel. However, it may also be used to assess inhibition of platelet aggregation in the setting of glycoprotein (GP) IIb/IIIa receptor antagonists (e.g., abciximab and eptifibatide).

The PFA-100 (Dade Behring, Miami, FL) assesses platelet adhesion and aggregation/activation in response to ADP or epinephrine. This assay draws whole blood through a capillary tube into a chamber through a 150-μm aperture within a collagen membrane coated with one of the two previously mentioned

agonists. Platelet adhesion and aggregation seals the aperture, and the time required for closure or the "closure time" is evaluated. The test is typically used to assess antiplatelet therapy. However, due to the shear forces involved in pulling blood through the aperture, the test is also sensitive to defects in von Willebrand factor (vWF)-mediated platelet adhesion. The test may also be useful in assessing Bernard-Soulier syndrome and/or other congenital and acquired platelet defects. Koscielny et al. studied over 5,500 patients using a standard bleeding history in addition to laboratory screening tests, including PFA-100. The PFA-100 was able to identify patients with impaired clinical hemostasis (history of abnormal bleeding and a defined hemostatic defect with laboratory testing); in a follow-up study, reduced bleeding complications were observed when the PFA-100 was used to direct therapy.

A.2. What is the difference between platelet adhesion, activation, and aggregation at sites of vascular

injury?

Platelets are recruited to sites of vascular injury via binding with vWF bound to collagen fibers in the vessel wall and the platelet GP Ib-IX-V receptor. vWF deposits on exposed collagen fibers present at sites of vascular injury and rapidly unfolds in response to vascular shear forces. Conformational changes in the vWF molecule lead to increased exposure of platelet binding sites and adhesion as mediated by platelet surface receptor GP Ib. Platelet activation is mediated via multiple platelet signaling pathways, including initial release of ATP and ADP, and thrombin present as a result of vascular damage, signaling downstream of the GP Ib-IX-V complex and binding of the GP VI collagen receptor. Platelet activation induces conformational changes leading to subsequent interactions between platelet integrin molecules and collagen ($\alpha_2\beta_1$ integrin) and vWF ($\alpha_{IIb}\beta_3$) enhancing adhesion. Activated platelets release alpha and dense granule contents (i.e., thromboxane A2 and ADP), which are agonists for expression of additional surface receptors for further platelet activation and ultimately induce aggregation. Platelet aggregation is the result of platelet cross-linking (clumping) via GP IIb/IIIa receptors that are bound by either vWF or fibrinogen. The degree of platelet aggregation is influenced by varying shear rates in vascular beds and local concentrations of thrombin and other platelet activating agents (e.g., ADP, PAF, epinephrine).

A.3. Describe the physiologic events that occur following endothelial interruption in the blood vessel.

The small size of platelets relative to other blood components, such as red or white blood cells, results in slower transit in the blood vessel with resultant margination. Platelet diffusivity or margination is the process in which the faster moving, larger cellular components within blood push the platelets toward the walls of the blood vessel; accordingly, in the setting of anemia, reduced margination of platelets can result in fewer platelets in close proximity to the vessel wall. Marginated platelets in circulation are in close contact with vascular surfaces and can immediately respond to endothelial defects. Endothelial breaks expose platelets to subendothelial structures, including collagen and other proteins that activate the hemostatic system (e.g., TF). This promotes adhesion of platelets to the subendothelium via platelet GP Ib receptors and induces generation of thrombin. Platelet adhesion promotes platelet activation, resulting in conformational changes to the platelet structure and release of the contents of the cytoplasmic granules. Platelet α and dense granules contain factors such as ADP and serotonin and FVa, which further promote platelet activation and aggregation. The platelet plug formed through this process provides initial hemostasis. The degree of platelet activation, release, and ultimate aggregation is in large part predicated by the concentration of thrombin (FIIa) in the local milieu. The final stage of platelet plug formation is driven by FIIa-mediated expression of platelet IIb/IIIa receptors. Platelet receptor IIb/IIIa facilitates cross-linking of platelets (aggregation) by fibrinogen (fibrin) and vWF. Thrombin converts fibrinogen to fibrin as a means of strengthening the platelet matrix. Finally, activation of factor XIII (FXIII) via thrombin cross-polymerizes the loose

fibrin to produce a firm and stable platelet—coagulation factor cross-linked matrix resulting in a stable clot.

A.4. What factors prevent the extension of a clot beyond the site of injury?

The localization of coagulation and control of primary/secondary hemostasis results from the interplay/coordination of multiple factors. Circulating heparin (i.e., endogenous or via administration of unfractionated heparin) or endothelial glycosaminoglycans and/or reduced levels of thrombin result in release of tissue factor pathway inhibitor (TFPI). TFPI inhibits TF-mediated activation of FX. Additionally, increased levels of activated thrombin and increased expression of thrombomodulin on the intact endothelial glycocalyx propagate activation of the anticoagulant protein C (along with its cofactor protein S), which subsequently inactivates activated FVa and FVIIIa. The heparin–antithrombin (AT) complex binds and inhibits activated clotting factors, including FXIIa, FXIa, FIXa, FXa, and FIIa. Finally, the intact endothelial surface secretes many mediators that have platelet-inhibiting (e.g., triphosphate dephosphorylases, prostacyclin or prostaglandin I_2 [PGI_2], nitric oxide) or clot-lysing effects. One such mediator, tissue plasminogen activator (tPA), catalyzes conversion of plasminogen to plasmin. Plasmin initiates the physiologic process of fibrinolysis resulting in proteolysis of FV/FVIII, fibrin, and fibrinogen. Fibrin degradation (split) products (fibrin split products [FSPs]) and D-dimers (cross-linked fibrin), respectively, are removed from circulation by the liver via mononuclear phagocyte system. Accumulation of these

by-products (FSPs and D-dimer) in the setting of substantial liver dysfunction can contribute to abnormal hemostasis secondary to platelet dysfunction (perhaps via binding to GP IIb/IIIa receptors).

A.5. Describe the factors involved in the extrinsic, intrinsic, and common coagulation cascade.

When normal blood is placed in an empty test tube in the absence of any additional agents, a clot will form. The clotting factors involved in this process were originally classified as "intrinsic" factors because everything necessary for blood to clot was "intrinsic" to the test tube. It has also been referred to as the "contact activation pathway" because clotting is initiated via contact with negatively charged surfaces (i.e., glass or subendothelial collagen). In the classical description of this pathway, FXII is converted to FXIIa. FXIIa subsequently converts FXI into FXIa. FXIa activates FIX, which with its cofactor FVIIIa forms the tenase complex that activates FX to FXa. Subsequently, the Va/Xa complex activates thrombin and the common pathway. The laboratory test focusing on assessment of factors characteristic of the intrinsic/common pathways is the aPTT.

The "extrinsic" pathway is so named as the stimulus for thrombin generation involves the binding of tissue thromboplastin or TF to FVIIa. TF and FVIIa form a complex that functions to convert FIX to FIXa, FX to FXa, and, ultimately, FII to FIIa, also resulting in stimulation of the

common pathway. The laboratory test believed to assess the extrinsic/common pathways is the PT.

The extrinsic and intrinsic pathways converge with activation of FX, hence the term “common pathway.” The common pathway proceeds when FXa acting with FVa converts FII (prothrombin) into FIIa (thrombin). Thrombin subsequently cleaves fibrinogen into fibrin, in addition to mediating activation of FV, FVIII, and FXIII.

This classic separation of procoagulant factors into extrinsic, intrinsic, and common coagulation cascades is a convenient framework/reference standard. However, it is now considered by many to be an incredibly limited model of the hemostatic system. This classic paradigm fails to incorporate the cross talk of the multiple factors that play an integral role in coagulation (e.g., endothelium, platelets, and leukocytes). The more current coagulation paradigm uses a cell-based model and emphasizes the contribution of the many localized factors in vivo, perhaps most important the endothelium itself, that are critical for induction of coagulation and the formation of the platelet-rich hemostatic plug. Although the factors represented in the classic intrinsic and extrinsic coagulation pathways propagate the formation and activation of thrombin (and hence the amplification of coagulation), considering their actions in a vacuum can be misleading with respect to an accurate understanding of in vivo mechanisms.

The cell-based theory describes three distinct phases of coagulation: initiation, amplification, and propagation. Each stage represents a different aspect of hemostasis at a cellular level, with pivotal points predicated on a spike or “burst” in the concentration of thrombin that ultimately results in the formation of a stable clot. Thrombin generation is crucial to coagulation, as demonstrated by the fact that the vast majority of anticoagulation strategies involve inhibition of Xa and/or

thrombin. The initiation phase of the cell-based model is notable not only for thrombin generation (secondary to platelet adhesion) but also through exposure of TF to circulating FVIIa, which again leads to generation of thrombin as the essential step. Thrombin generation is amplified by FXIa, ultimately resulting in generation of more thrombin through the amplification and propagation phases. As such, thrombin is crucial for the final two phases of coagulation and serves as a potent catalyst for hemostasis.

The importance of these mechanisms is illustrated by the effectiveness of the hemostatic agent known as recombinant activated FVII or rFVIIa (NovoSeven, Novo Nordisk, Plainsboro, NJ). The effectiveness of rFVIIa is predominately related to its ability to propagate thrombin generation. It has been proposed that rFVIIa is ideally suited for bleeding involving localized sites of injury that express TF (e.g., localized, not traumatic central nervous system [CNS] bleeds). In the setting of high systemic levels of TF (e.g., disseminated intravascular coagulation [DIC], use of extracorporeal devices), administration of rFVIIa can lead to systemic activation of thrombin and intravascular thrombosis. The classic coagulation cascade is depicted in **Figure 31.2**.

A.6. Describe the typical presentation history and pathophysiology associated with von Willebrand disease (vWD).

vWD is the most common inherited bleeding disorder (approximately 0.1% to 1% of the general population); it is characterized by the absence or functional deficiency of vWF. vWF plays a critical role in primary hemostasis, by stimulating

platelet activation via platelet adhesion mediated through binding both platelets (i.e., via GP Ib receptors) and subendothelial matrix components (collagens 1 to 6). vWF can also promote platelet aggregation as a ligand for GP IIb/IIIa receptors. vWF plays an additional role in secondary hemostasis by serving as a carrier/stabilizer for FVIII. vWF is synthesized by endothelial cells, and substantial posttranslational protein modification within the Golgi apparatus leads to high molecular weight (HMW) and very high molecular weight (VHMW) forms of this multimeric protein. These larger forms have the greatest hemostatic functional activity.

vWD manifests clinically as bruising, epistaxis, mucocutaneous bleeding, and menorrhagia in women but can also lead to serious and even life-threatening bleeding with trauma or with high-risk surgical operations. Because vWD is caused by a variety of mutations/types, it manifests along a spectrum of symptoms (see **Table 31.3**) and, as such, there is heterogeneity in its clinical manifestations and relative risk of bleeding. The diagnosis is often suggested by the patient's history of a bleeding diathesis and/or the presence of a prolonged bleeding time (BT) (not often performed), prolonged aPTT (in 50% of patients), or abnormal PFA-100 result despite a normal platelet count and no drug effect. Laboratory analysis is useful for classifying the types and subtypes of vWD and to guide therapy. Interestingly, acquired forms of vWD have been rarely described associated with lymphoproliferative disease, tumors, cardiac valvular lesions, as well as others.

TABLE 31.3 von Willebrand Disease: Diagnosis, Classification, and Response to Desmopressin D-Arginine Vasopressin (DDAVP)

Type	RCoA	vWFAg	Platelet Count	RIPA	FVIII	DDAVP Effective	Multimer Pattern
1	↓	↓	NL	NL or ↓	NL or ↓	Yes	Uniform decrease with all

							multimers present
2A (15%)	↓	NL or ↓	NL	NL or ↓	NL	+/−	Decreased large multimers
2B (5%)	↓	NL or ↓	NL or ↓	↑	NL	No	Decreased large multimers
2M (<1%)	↓	NL or ↓	NL	NL or ↓	NL	No	Uniform decrease with all multimers present
2N (3%)	NL	NL	NL	NL	↓	No	Normal
3 (1%)	↓↓	↓↓	NL	↓↓	↓↓	No	Undetectable

Adapted from Sadler JE, Budde U, Eikenboom JC, et al. Update on the pathophysiology and classification of von Willebrand disease: a report of the subcommittee on von Willebrand factor. *J Thromb Haemost*. 2006;4(10):2103–2114. Copyright © 2006 John Wiley & Sons, Inc.

Six different vWD types/subtypes exist (type 1, type 2A, type 2B, type 2N, type 2M, and type 3). Type 1 and type 3 represent quantitative deficiency of vWF related to either modest (type 1) or severe (type 3) reductions in vWF expression. Patients with type 2 disease have qualitative defects in vWF and are subdivided based not only on the expression levels of HMW forms of vWF but also on the corresponding mechanistic defects in platelet adhesion, platelet activation/aggregation, or FVIII binding.

vWF type 1 is the most common (85%) and mildest form of the disease. It is inherited as an autosomal dominant trait and has a reported incidence as high as 2% to 3% of northern European populations (approximately 0.1% total population). However, it is believed to be frequently misdiagnosed as a result its mild clinical symptoms (epistaxis, menorrhagia, increased postoperative bleeding) in combination with the variant expression of vWF associated with other factors (i.e., blood type, menstrual cycle, etc.). It is currently recommended that the diagnosis of type 1 vWF be made only when vWF levels are below 30 U per dL, which may require repetitive testing. First-line treatment for type 1 disease is with desmopressin (DDAVP). DDAVP can normalize vWF and FVIII by inducing

release of vWF from the endothelium, with hemostatic regulation being restored in the setting of normal expression of other hemostatic factors (i.e., tPA, prostacyclin, etc.).

Type 3 vWD is both the rarest and the most severe form of the disease. It is inherited in an autosomal recessive fashion and is characterized by a near-complete absence of vWF expression (<2 U per dL). Unfortunately, many cases present as uterine fetal demise or death in the immediate postnatal period. DDAVP is not beneficial in type 3 because patients have little to no endogenous production of vWF. Treatment for vWF type 3 and all forms of type 2 relies on repletion of vWF using factor concentrates.

Type 2A vWD is an autosomal dominant qualitative defect, characterized by normal total expression of vWF in the setting of reduced vWF-mediated platelet adhesion. Decreased activity is the result of reduced expression of the optimally biologically active HMW and VHMW multimers. The deficiency of large multimers is believed to result from defects in multimer assembly or enhanced vWF cleavage by ADAMTS13. Laboratory testing shows normal vWF protein levels in the setting of reduced functional activity. DDAVP has been shown to be beneficial in some patients.

Type 2B vWD is inherited in an autosomal dominant fashion and is characterized by a structural abnormality in the HMW form of vWF resulting in enhanced affinity for platelet GP Ib. This induces heightened platelet activation and spontaneous platelet aggregation. Patients with type 2B can have reduced HMW forms of vWF (selective removal) in the setting of thrombocytopenia. Subtype 2B is diagnosed when patients have an exaggerated response to the ristocetin, an antibiotic that stimulates binding of vWF to platelet GP Ib and induces platelet aggregation and thrombocytopenia. In the absence of HMW forms of vWF, no agglutination will occur during ristocetin

cofactor activity assay. A similar disease entity known as pseudo- or platelet-type von Willebrand disease (pt-vWD) has been described. pt-vWD is also inherited in an autosomal dominant fashion and results from enhanced functionality of the platelet receptor GP Ib. pt-vWD is virtually indistinguishable from vWF type 2B; however, it is believed to be exceedingly rare and is described only in case reports. DDAVP is contraindicated in the setting of both vWF type 2B and pt-vWD because it can aggravate platelet activation/binding and results in clinically significant thrombocytopenia. Repletion of vWF is effective in treating vWF type 2B; however, it would not be effective in the setting of pt-vWD.

Type 2N (Normandy) vWD is an autosomal recessive bleeding disorder that results from a decreased affinity of vWF for FVIII. Patients with type 2 vWD have reduced expression of FVIII binding receptors on vWF. These patients typically have normal levels of vWF and reduced expression of FVIII and thus are often misdiagnosed with hemophilia A. Repletion of vWF is considered optimal therapy.

Type 2M vWD is sometimes described as a diagnosis of exclusion. The condition is inherited in an autosomal dominant fashion and is characterized by reduced vWF-dependent platelet adhesion despite normal expression of vWF and its HMW multimers; however, these HMW multimers may have reduced binding affinity. DDAVP has been shown to be beneficial in some patients; however, treatment usually consists of vWF repletion. The diagnosis and classification of different types of vWD and their response to DDAVP are shown in **Table 31.3**.

A.7. Explain the pathophysiology, frequency, and treatment of significant rare disorders of coagulation (factor VII [FVII], factor XII [FXII], and fibrinogen).

Hemostasis is maintained as a balance between hemostatic and anticoagulant forces, and, as such, the absence of any one of the forces that play a role in maintaining that balance can predispose an individual to bleeding or thrombosis in the various clinical settings. Hemophilia A and B are the most commonly occurring congenital factor deficiencies; however, deficiencies of other key components of the coagulation cascade have been reported, albeit much less commonly. The frequency of hereditary hemostatic disorders is shown in **Table 31.4**. Plasma-derived concentrates are available for fibrinogen, FVII, FVIII, FIX, FX, FXI, and FXIII; additionally, there are recombinant factor replacement products for FVII, FVIII, and FIX. Deficiencies in other coagulation factor products can be accomplished using plasma or cryoprecipitate. Rare coagulation deficiencies (RCDs) typically manifest as mucosal bleeding, excessive bleeding during, and/or following surgical procedures, although severe bleeding and death can occur. The most common RCD is FVII deficiency, reportedly occurring at a frequency of 1:500,000 patients. FVII deficiency may be initially detected due to isolated PT prolongation. Clinical manifestations are heterogeneous, from asymptomatic to severe/fatal bleeding that appears to be unrelated FVII plasma levels. FVII is relatively easily monitored and repleted; the manufacture recommends doses 15–30 μg/kg in the setting of congenital factor deficiency.

Increased dosing maybe recommended in the setting of an acquired factor inhibitor.

TABLE 31.4 The Prevalence of Hereditary Defects of the Hemostatic System

Hemostatic Deficit	Prevalence/Incidence
Platelet disorders (i.e., GP/granule deficits)	8%; 1:250
Coagulation factor deficiencies	
FVIII	1:5,000–1:10,000
FIX	1:30,000
FXI	1:1,000,000 or 1:50 Ashkenazi Jewish births
FVII	1:500,000
FV, FX	1:1,000,000
Afibrinogenemia/dysfibrinogenemia	1:1,000,000
FII, FXIII	1:2,000,000
von Willebrand disease	1.5%; 1:10,000

FII, factor II; FV, factor V; FVII, factor VII; FVIII, factor VIII; FIX, factor IX; FX, factor X; FXI, factor XI; FXIII, factor XIII; GP, glycoprotein.

From Despotis G, Eby C, Lublin DM. A review of transfusion risks and optimal management of perioperative bleeding with cardiac surgery. *Transfusion*. 2008;48(suppl 1):2S–30S. Copyright © 2008 American Association of Blood Banks. Adapted by permission of John Wiley & Sons, Inc.

FXIII deficiency is also very rare, reportedly occurring in 1 in every 2 to 3 million people. FXIII functions to cross-link fibrin monomers and fibronectin, stabilizing fibrin clots rendering them more resistant to mechanical stress and proteolytic degradation. Deficiency is associated with abnormal wound healing, recurrent miscarriages, and excessive bleeding in the postoperative period after operative procedures, with the majority of patients presenting in childhood with umbilical cord bleeding. Patients with FXIII deficiency have an increased incidence of spontaneous intracranial hemorrhage. A FXIII level of <1% is associated with the severe bleeding phenotype, whereas levels between 1% and 4% typically show a moderate bleeding pattern. In the absence of factor concentrates, cryoprecipitate should be used for FXIII repletion.

Congenital fibrinogen disorders can be quantitative (hypo- or afibrinogenemia) or qualitative (dysfibrinogenemia). Afibrinogenemia occurs in 1 in a million people. Hypo- and dysfibrinogenemia are likely more common, but they typically only experience severe bleeding in the setting of trauma or operative interventions and may therefore remain undiagnosed. Congenital afibrinogenemia is typically diagnosed in the setting of prolonged bleeding from an umbilical stump. Afibrinogenemia is associated with spontaneous splenic rupture, poor wound healing, and painful bone cysts. Cryoprecipitate is often used for fibrinogen repletion, although there is now an approved fibrinogen concentrate as well.

A.8. Differentiate between hemophilia A, B, and C.

Hemophilia, one of the oldest known genetic disorders, can be classified into types A, B, or C. Hemophilia A is the most common form of the disease, accounting for 85% of all patients with hemophilia. Hemophilia A typically presents as a congenitally inherited X-linked recessive bleeding disorder (approximately 1:5,000 male births and rare homozygous females), resulting from absent or decreased activity of coagulation FVIII. It is typically classified as mild (endogenous FVIII levels are >5%), moderate (FVIII between 1% and 5%), and severe (FVIII <1%). However, clinical disease severity (i.e.,

bleeding diathesis) correlates both with the FVIII activity level as well as the presence and efficacy of a neutralizing inhibitor. Severe disease manifests as spontaneous bleeding into joints, muscles, and vital organs and can involve life-threatening bleeding events (e.g., CNS, retroperitoneum). Patients with mild disease may remain undiagnosed until such time as they face a hemostatic stress (i.e., surgery, trauma). The aPTT has been used as a screening test for moderate to severe hemophilia A. The aPTT will be prolonged in hemophilia A with moderate to severe disease, with variable detection of patients with milder forms depending on the sensitivity of the coagulation methods/reagents used. Directly assessing FVIII activity can provide a diagnosis; however, it is important to note that reproducibly normal levels do not exclude carrier status. FVIII is an acute phase reactant and, as such, concentrations can become elevated in times of stress especially when vWF (FVIII carrier protein) is released from endothelium. Genetic testing provides a definitive diagnosis in the setting of an inherited disorder of protein synthesis.

Hemophilia B is the second most common form of disease, representing approximately 14% of known hemophiliacs. Similar to hemophilia A, hemophilia B is a congenital bleeding disorder resulting from impaired functional activity of coagulation FIX. This X-linked genetic disorder has an inheritance pattern and clinical features that are similar to those of hemophilia A. Hemophilia B may be diagnosed by measuring both the concentration and function of FIX. However, it is important to note that FIX is a vitamin K–dependent coagulation factor and is likely to be reduced in the setting of Coumadin or vitamin deficiency.

The remaining 1% of patients with hemophilia are deficient in FXI, classified as hemophilia C. Hemophilia C, or Rosenthal syndrome, is an extremely rare autosomal recessive disorder,

occurring almost solely in people of Ashkenazi Jewish descent. Hemophilia C is clinically distinguishable from A and B due to the absence of spontaneous bleeding into joints and muscles. In fact, bleeding in patients with hemophilia C is typically mild; however, it has been associated with trauma involving the oral and nasal cavities or the urinary tract. Perplexingly, there is a discrepancy in the literature suggesting that FXI activity levels and/or aPTT results are not predictive of bleeding in hemophilia C patients.

Deficiencies of other coagulation factors may occur, albeit, at a much lower frequency with an incidence in the general population of (1:20,000 to 1:1,000,000) as seen in **Table 31.4**.

A.9. What are the differences in factor replacement therapy between patients with hemophilia A and hemophilia B?

Patients with hemophilia A typically require repletion of FVIII prior to major surgery to normalize FVIII levels to approximately 100% of normal. The half-life of administered pooled or recombinant FVIII is about 12 hours but can vary based on the recombinant formulation. Further supplementation or redosing is typically performed every 12 hours for days to weeks depending on the severity of the bleeding episode and

baseline factor levels. Patients with hemophilia B typically require higher initial doses of FIX due to extensive redistribution of FIX to the extravascular compartment. However, FIX has a much longer half-life (18 to 30 hours), and thus, redosing is typically only preformed every 24 hours.

A.10. What is acquired hemophilia?

Acquired hemophilia is caused by the formation of antibody targeting and neutralizing FVIII, or less commonly FIX. Antibody formation may be de novo (approximately 1:100,000 to 1:1,000,000), or it can be associated with hemophilia presumably as a result of therapeutic exposure animal sources of FVIII. Patients with de novo acquired hemophilia are typically >65 years of age (approximately 80%) and approximately 50% of cases are associated with an underlying medical condition (i.e., an autoimmune disorder, malignancy, or a drug/allergic reaction). Acquired hemophilia should be suspected when a prolonged aPTT fails to correct following a mixing study in a patient with previously normal results or when a patient with known hemophilia fails to adequately respond to appropriate doses of clotting factors. The recommend test for the detection/measurement of inhibitors is the Bethesda assay. The test measures the amount of factor that is inactivated by patient plasma. A Bethesda unit (BU) is the amount of inhibitor necessary to inactivate half of the factor present in normal human plasma. Patients with low titer inhibitors (<5%) may achieve hemostasis following treatment with slightly increased

doses of factor concentrates.

Interestingly, the formation of antibodies directed at FIX is far less common in patients with hemophilia B (1% to 5%) than the formation of anti-FVIII antibodies in hemophilia A (25% to 30%). It has been theorized that the genetic mutations most common in hemophilia B (point mutations) are more likely to result in non- or hypofunctional FIX, whereas the mutations more commonly associated hemophilia A (inversions) are more likely to result in absent protein expression.

A.11. Which plasma protein is important in maintaining normal levels of factor VIII (FVIII)?

FVIII is an X-linked gene product that functions to accelerate FIXa-mediated activation of FX by four orders of magnitude. However, FVIII is one of the largest and least stable coagulation factors with a half-life of about 2 hours when unbound. FVIII circulates in the plasma covalently bound to vWF, which serves to stabilize the protein by protecting it from inactivation by activated protein C and preventing its binding to phospholipids and activated platelets. vWF also facilitates optimal delivery of FVIII localizing it to sites of endothelial injury and enabling approximation with FIX (i.e., the FVIII and FIX complex leads to activation of FX on the platelet surface). Although vWF is important in maintaining adequate levels of FVIII, less than 10% of vWF multimers bind FVIII.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders; 2017:477–506.

A.12. How are patients with severe hemophilia managed in

the outpatient setting?

Episodic or as needed clotting factor replacement at the time of clinically significant bleeding was the standard of care for patients with hemophilia for many years. However, in the past 15 to 20 years, it has been conclusively shown that morbidity and mortality can be significantly reduced for patients with severe disease through the implementation prophylactic clotting factor therapy. Prophylactic treatment is initiated as early as 1 to 2 years of age with the goal of reducing chronic progressive joint disease or in older children/adults to prevent rebleeding into a target joint. There are now a variety of options available for factor replenishment for patients with severe hemophilia. Historically, factor repletion was performed using pooled plasma concentrates derived from thousands of volunteer donors. The use pooled concentrates was the source of transfusion-related transmission of human immunodeficiency virus (HIV) and hepatitis C virus (HCV) to hemophiliacs in the 1980s. Plasma-derived concentrates are still available, and donors are subjected to rigorous screening along with repetitive retesting to overcome with silent or window phase of testing insensitivity (e.g., 12 months after initial donation), and products additionally undergo viral inactivation processes. However, pooled concentrates may still carry a risk for transfusion-related transmission of infection, particularly from nonenveloped viruses. There is a lack of trust in the safety of plasma-derived products inherent in the hemophilia community.

The cloning of the FVIII gene in 1984 opened the door for the production of the recombinant factor products. Recombinant products are now in their third generation of production, with each successive generation being designed with the goal of reducing immunogenicity and increasing product half-life. The half-life of plasma-derived FVIII is 8 to 12 hours; thus, it is dosed frequently, typically 2 to 3 times weekly. FVIII undergoes

extensive posttranslational modification in the form of glycosylation and sulfonylation and is stabilized by its chaperone protein vWF. Strategies to prolong FVIII half-life in recombinant products involve conjugating with larger molecules such as polyethylene glycol (PEG), albumin, or human immunoglobulin Fc, and/or generating single chain or domain deleted products (**Table 31.5**). The products also differ with respect to the type of stabilizer used (albumin/sucrose) and viral inactivation method applied. Currently, products are available with reported half-lives of 14 to 19 hours. Interestingly, none of these products have yet conclusively demonstrated superiority with respect to reducing immunogenicity or rates of inhibitor formation. Similarly, there are recombinant forms of FIX available and considerable progress has been made in developing extended half-life forms of FIX allowing for less frequent dosing (7 to 14 days).

TABLE 31.5 Factor VIII Replacement Products

Product	FVIII	Technology	Half-life
Antihemophilic factor (Koate-DVI, Hemo ÀI M, Monarc-M, Monoclate-P)	Full length	Pooled human plasma	14.8–17.5
Antihemophilic factor/vWF complex (Alphantate, Humate-P, Wilate)	Full length	Pooled human plasma	12.2–17.9
Recombinant antihemophilic factor—first generation (Recombinate)	Full length	Culture—BSA/albumin stabilizer	14.6 (±4.9)
Recombinant antihemophilic factor—second generation (Helixate, Kogenate)	Full length	Culture—human plasma proteins	13.7
Recombinant antihemophilic factor—third generation (Advate, Kovaltry)	Full length	No human/animal protein	12–14.2
Recombinant—second generation (ReFacto)	BDD	Culture—human plasma proteins	14.5 (±5.3)
Recombinant—third generation (Xyntha, Novoeight)	BDD	No human/animal protein	10.8–12
Recombinant—fourth generation (Nuwiq)	BDD	Glycosylated in HEK cells	17.1 (±11.2)

Recombinant—third generation EHL (Adynovate)	BDD-Pegylated	Pegylated Advate (no human/animal protein)	14.7 (±3.7)
Recombinant—fourth generation EHL (Eloctate)	BDD-rFVIII-Fc	Glycosylated in HEK cells	19.7 (±2.3)
Recombinant—third generation EHL (Afstyla)	Single chain	No human/animal protein	14.2

BDD, B domain deleted; BSA, bovine serum albumin; EHL, extended half-life; HEK, human embryonic kidney; rFVIII, recombinant factor VIII; vWF, von Willebrand factor.
Adapted from Lieuw K. Many factor VIII products available in the treatment of hemophilia A: an embarrassment of riches? *J Blood Med*. 2017;8:67–73.

Recently, a novel bispecific antibody, emicizumab (ACE910; Hoffman-La Roche Pharmaceutical, Basel, Switzerland), which mimics the in vivo function of FVIII (by simultaneously binding activated FIX and FX, allowing for proteolysis and activation of FX) has been U.S. Food and Drug Administration (FDA) approved. Emicizumab has efficacy in preventing bleeding events in patients with both congenital and acquired hemophilia. However, many patients still require coagulation factor bypass agents in the setting of acute/active bleeding. Based primarily on results from preliminary ex vivo studies, it has been suggested that bypass agents containing FIX (i.e., prothrombin complex concentrates [PCC] or activated prothrombin complex concentrates [aPCC] or factor eight inhibitor bypassing activity [FEIBA]; Baxter Healthcare Corp, Deerfield, IL) may have an enhanced coagulant effect on patients receiving emicizumab potentially predisposing them to the formation of thrombus.

Additionally, early clinical trials are currently being conducted focusing on inhibitors of the anticoagulant cascade. Two such drugs, fitusiran (Alnylam Pharmaceuticals, Cambridge, MA) and concizumab (Novo Nordisk, Bagsværd, Denmark), targeting AT and TFPI, respectively, are in clinical trials.

Finally, there is ongoing work developing gene therapy for patients with hemophilia. Studies have used adeno-associated

viral vectors (AAVs), lentiviral vectors, and, more recently, gene-editing approaches based on designer nucleases or clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) technologies. Early gene therapy trials have had variable success showing clinically transient or subtherapeutic clotting factor expression levels. Recently, therapeutic FVIII and FIX expression levels (e.g., mean of 30% to 40% activity) have been described after gene therapy in patients with severe hemophilia. However, complications related to transient liver toxicity and the use of immunosuppression have been reported. Patients who have undergone gene therapy will likely still benefit from preoperative FVIII assessment and may yet require additional repletion in the setting of bleeding events.

A.13. Describe the levels of FVIII necessary to maintain hemostasis in patients with spontaneous or surgical bleeding.

The levels of FVIII necessary for hemostasis vary given patient clinical condition/presentation (**Table 31.6**). When life-

threatening airway, neurologic bleeding, or major surgery is anticipated, correction to 100% FVIII levels is desired. In the setting of operative need, correction should be performed preoperatively and maintained for some interval postoperatively as defined by the bleeding risk and clinical circumstances. Patients receiving outpatient/home therapy using factor-derived, recombinant, and/or even porcine factor products can have testing performed with minimal difficulty to assess FVIII functional activity for repletion in the setting of a bleed or impending operative intervention. The new FVIII monoclonal reagent is more complicated from a monitoring standpoint. Emicizumab cofactor restores activity of missing activated FVIII and will overcorrect any laboratory tests that use total intrinsic clotting time, including the one-stage FVIII activity assay, which is based on the aPTT. However, assays utilizing chromogenic or immuno-based methods are unaffected. Of note, chromogenic assays containing human coagulation factors may overestimate hemostasis. Hemostatic assays utilizing bovine coagulation factors are insensitive and are optimal for monitoring endogenous or infused FVIII activity or to measure anti-FVIII inhibitors. Similarly, emicizumab remains active in the presence of inhibitors and can cause false-negative results in clot-based Bethesda assays; a bovine-based FVIII chromogenic assay should be used instead.

TABLE 31.6 Levels of Factor VIII Necessary for Hemostasis

Type of Bleeding	Desired Factor Level	Suggested Duration of Treatment
Dental procedures (including extractions)	30%–60%	1 hr prior to the procedure
Intramuscular hemorrhage	30%–50%	2–5 d
Iliopsoas or other retroperitoneal bleeding	30%–50%	3–10 d
Retropharyngeal bleeding	40%–50%	3–4 d

Gastrointestinal bleeding	30%–50%	2–3 d
Intracranial hemorrhage	80%–100%	10–14[a] d
Surgery	80%–100%	10–14[a] d

[a]Continuous infusion may be preferable in order to avoid dangerously low trough levels.

B. Preoperative Evaluation and Preparation

B.1. What steps would you take to normalize this patient's coagulation status before surgery?

Orthopedic surgical procedures in particular require maintenance of normal levels of FVIII in order to minimize bleeding into and/or around a prosthetic joint, which can lead to infection risk or destruction of the surrounding tissue or hematoma formation. FVIII levels of 30% of normal are usually considered adequate for baseline hemostasis; nevertheless, most clinicians will target normal FVIII levels prior to most surgical procedures (approximately 100%). These levels are necessary because factor levels typically decrease due to redistribution in addition to normal consumption and decay.

For major orthopedic procedures, FVIII levels should be corrected to 100% of normal 1 hour before the procedure. A repeat dose may be needed based on the duration of the procedure, amount of blood loss, and dose initially used. Repletion strategies are typically based on quantification of

peaks and troughs or factor levels.

Rodriguez-Merchan EC. Aspects of current management: orthopaedic surgery in haemophilia. *Haemophilia*. 2012;18(1):8–16.

B.2. What is meant by 1 unit of FVIII clotting activity, and how much does 1 unit of FVIII clotting activity per kilogram of body weight increase FVIII concentrations?

One unit of FVIII clotting activity is defined as the amount of factor present in 1 mL of fresh, normal plasma; however, normal factor levels typically range between 0.8 and 1.2 U per mL because there is substantial variability in factor levels in normal patients. On average, an individual with a plasma volume of 3,000 mL would have 3,000 IU of each clotting factor in their circulation (i.e., intravascular compartment). If an individual has less than 1% of normal FVIII activity, it would take 3,000 IU of FVIII to raise the plasma levels to normal (assuming the absence of an inhibitor), which is around 100%, assuming the source of the FVIII does not result in expansion of the patient plasma volume compartment beyond 3,000 mL (e.g., 3,000 U administered via a factor concentrate requiring reconstitution using only 50 to 100 mL) and the patient does not have a neutralizing antibody. In other words, 100% factor activity is equivalent to a concentration of 1 IU per mL of the factor of interest. Dosing a single unit of FVIII clotting activity per kilogram of body weight will increase plasma FVIII levels approximately 1 U per mL or 100% activity. Therefore, to prescribe the FVIII activity necessary to correct a 70-kg hemophilia patient with 5% FVIII activity to 95% of normal, one can calculate using 0.90 U per mL × plasma volume [blood volume × (1 − Hct)] or either of the following approaches:

Approach 1

Weight (kg) × (desired percent increase) × 0.5 = Dose of FVIII (IU)

70 kg × (95% – 5%) × 0.5 = 3,150 IU of FVIII

Approach 2

(Plasma volume [PV]) × (desired increase in factor level [U per mL]) = Dose of FVIII (IU)

Plasma Volume Calculation

PV = kg weight × (65 [female] or 75 [male] mL per kg) × (1 – Hematocrit [Hct])

For example, PV = 70 kg × 75 mL per kg × (1 – 0.4) = 3,150 mL

3,150 mL × (0.95 – 0.5 U per mL) = 2,835 U

Henrard S, Speybroeck N, Hermans C. Body weight and fat mass index as strong predictors of factor VIII in vivo recovery in adults with hemophilia A. *J Thromb Haemost*. 2011;9(9):1784–1790.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:830–839.

B.3. Would you administer FVIII using a bolus or infusion technique?

Based on the relative stability of FVIII concentrates at room temperature after reconstitution, infusions can be used. By titrating the infusion, the desired FVIII level can be maintained, eliminating both the overshoot and the subtherapeutic levels seen with the bolus technique. A continuous infusion is typically initiated to maintain factor levels following administration of an initial loading dose of FVIII.

Batorova A, Martinowitz U. Intermittent injections vs. continuous infusion of factor VIII in haemophilia patients undergoing major surgery. *Br J Haematol*. 2000;110(3):715–720.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:830–839.

B.4. Can hemophiliac patients fail to mount an appropriate coagulation response following FVIII infusion?

As described earlier, a substantial percentage of hemophiliacs (approximately 30% of patients with hemophilia A) develop a neutralizing antibody (inhibitor) against FVIII and thus the anticipated response following FVIII infusion will not be achieved. Inhibitor titers can vary between patients. The development of neutralizing inhibitors is important to recognize because it causes patients to be refractory to FVIII concentrates, which if undiagnosed can lead to excessive and perhaps life-threatening bleeding. Patients with high-titer inhibitors may require alternative acute management interventions (e.g., rFVIIa, PCC, or even recombinant porcine FVIII or intravenous immunoglobulin [IVIg]) or when time permits, more sustainable effects with other interventions (e.g., plasma exchange or rituximab).

Individuals with congenital factor deficiencies may develop alloantibody inhibitors targeting specific epitopes of the hemostatic factor. The mechanisms leading to functional factor inhibition by these inhibitors include steric hindrance of appropriate functional binding sites, hydrolysis of the factor, and more rapid clearance by the reticuloendothelial system. The antibodies may be directed against one of many different domains, some of which are pathologic and others are not. Pathogenicity is generally determined by which of the domains is targeted by the antibody.

B.5. If a patient with hemophilia does not respond to a bolus injection of FVIII, can an infusion technique be effective?

Some patients who do not respond well to bolus injections may in fact have low-titer FVIII inhibitors. A continuous infusion may prove effective in this situation to stop hemorrhage because appropriate levels of the missing factor can be achieved relatively easily by infusion. In fact, some patients with high antibody/inhibitor titers and no measurable factor level during the infusion may respond to an infusion technique. This is believed to be due to the kinetics of inhibitors; that is, complete inhibition of the factor may require 1 to 2 hours. In the setting of continuous FVIII infusion, there will always be some factor that is circulating in an unneutralized and hemostatically active state. Depending on the degree of the inhibitor, efforts at immune tolerance may be effective. An immune tolerance regimen consists of continuous infusions in conjunction with immunosuppression over an extended period of time to promote development of immune tolerance to the factor and thereby eradicate the inhibitor.

Schulman S, Martinowitz U. Continuous infusion instead of bolus injections of factor concentrate? *Haemophilia*. 1996;2:189–191.

B.6. How much FVIII activity is present in plasma? What are the risks associated with plasma administration?

Following whole blood donation and separation of RBCs and plasma by centrifugation, approximately 200 mL of plasma is

prepared from one unit of whole blood. Thus, plasma is prepared from a single donor and contains all coagulation factors and plasma proteins, including FVIII. When people refer to plasma in the United States, they typically mean fresh frozen plasma (FFP). However, the vast majority of what is dispensed from the blood bank is actually thawed plasma (TP) or plasma frozen within 24 hours of collection (FP24). FFP specifically refers to products that are processed and frozen within 8 hour of phlebotomy. FP24 is frozen within 24 hours of collection. When either of these products is thawed, but not transfused within 24 hours, it is relabeled as TP, which may be dispensed/transfused for up to 5 days if stored at 4°F. These products are considered hemostatically equivalent. The typical FVIII activity of plasma is 0.5 to 0.9 units of clotting activity per milliliter because the activity of FVIII and FV decays during storage.

The risks associated with transfusion of FFP are similar to those associated with any single-donor product. The most feared risk is potential exposure to infectious agents, particularly lipid-enveloped viruses that cause hepatitis B and C as well as HIV. The incidence of transfusion-related infections has decreased over the last several decades largely due to the implementation of rigorous screening and testing procedures (e.g., donor history questionnaires, serologic and nucleic acid amplification technology [NAT]/polymerase chain reaction [PCR]-based testing). Currently, the risk of transmitting hepatitis B infection following transfusion of FFP slightly exceeds that of HIV and hepatitis C. The decrease in transfusion-related hepatitis C is in part related to the implementation of NAT to reduce or minimize the window period. Hepatitis B occurs at approximately 1:300,000 (this may be an overestimate with the implementation of PCR testing for hepatitis B), and hepatitis C occurs at approximately 1:1,500,000. HIV infection currently occurs at approximately 1:2,000,000 donor exposures, although these

numbers can vary because they are mathematical estimates.

In contrast to plasma, nonrecombinant factor concentrates undergo several interventions to reduce infectious risk of pooled products. Techniques commonly used for factor concentrate preparation include donor retesting after 12 months, heat (pasteurization), nanofiltration, and solvent detergent treatments, which can minimize the risk of viral pathogen transmission.

There are additional risks associated with transfusion that are not associated with transmission of infectious organisms. These include allergic reactions, transfusion-associated circulatory overload (TACO), transfusion-related acute lung injury (TRALI), in addition to the common cytokine mediated occurrence of febrile nonhemolytic reactions. TRALI is the leading case of transfusion related mortality in the United States. It is more common following transfusion of plasma as opposed to other blood products. However, the incidence of TRALI following plasma transfusion has decreased since the early 2000s following the practice of limiting plasma collection to male donors. Female donors have been excluded from the donor pool because of the higher likelihood of antibodies associated with TRALI (i.e., antibodies targeting either human leukocyte antigens [HLA] and/or human neutrophil antigens [HNA]) acquired during/through pregnancy. It has been proposed these antibodies activate recipient neutrophils along the pulmonary endothelium resulting in degranulation and development of noncardiogenic pulmonary edema. TACO is a serious and underrecognized transfusion complication of plasma transfusion. The typically used doses of 2 or 4 units of plasma represent a volume of 400 to 800 mL. This volume, in addition to potentiating fluid overload, often represents an inadequate therapeutic dose of plasma (recommended dosing is 10 to 15 mL per kg body weight). Plasma exposure additionally carries the risk for allergic reactions to blood proteins in up to 1% to 2% of

recipients. Anaphylactic reactions are unusual and are sometimes associated with patients with immunoglobulin A (IgA) deficiency who through exposure have developed antibodies to IgA. Patients with this condition should only receive plasma from IgA-deficient donors and must only receive RBCs and/or platelets that have been washed to remove a high percentage of plasma proteins.

B.7. What are the indications for the administration of plasma?

The National Institutes of Health multidisciplinary consensus development panel determined that plasma was the most overused blood product for transfusion. Although there are few if any large-scale randomized clinical trials regarding the optimal/appropriate use of plasma, there are consensus guidelines providing recommendations for plasma use. It is generally deemed appropriate to transfuse plasma to patients who are massively bleeding (as part of a massive transfusion protocol) or have deficits/consumption of multiple coagulation factors (DIC) or as replacement fluid for patients with thrombotic thrombocytopenic purpura. In all other scenarios,

plasma transfusion is sometimes recommended when better products are unavailable, that is, for the reversal of vitamin K antagonist (if factor concentrates are unavailable) or for the treatment of bleeding patients with an isolated congenital factor deficiency (when no factor concentrate is available), hereditary angioedema (if C1 esterase inhibitor is unavailable), or treatment of AT deficiency (if AT concentrate is unavailable). Despite this, plasma is often inappropriately used as a volume expander or as prophylaxis in stable, nonbleeding with mild elevation of their coagulation factor tests prior to minor procedures.

B.8. What is cryoprecipitate, and how is it prepared? How much FVIII activity is present in cryoprecipitate? When is cryoprecipitate indicated?

Cryoprecipitate is the fraction of plasma that precipitates when FFP is thawed at 1°F to 6°F. After centrifugation, the precipitate is extracted and refrozen for use as cryoprecipitate. Each unit of cryoprecipitate consists of 10 to 15 mL and thaws rapidly. Cryoprecipitate must be used within 4 to 6 hours of thawing. In addition to FVIII, it contains significant levels of vWF, FXIII, fibronectin, and fibrinogen. The American Association of Blood Banks (AABB) Standards require that 1 unit of cryoprecipitate must contain a minimum 80 IU of FVIII as well at least 150 mg of fibrinogen.

Cryoprecipitate can be used to manage patients with

hemophilia A, vWD, hereditary or acquired hypofibrinogenemia (especially when concentrates are unavailable), hereditary FXIII deficiency (if concentrates are unavailable), uremia-induced platelet dysfunction along with DDAVP as well as thrombolysis-related bleeding with low fibrinogen levels. However, cryoprecipitate is most frequently used to replete fibrinogen in bleeding patients. Fibrinogen plays a critical role in hemostasis; it functions both as the precursor to fibrin and as a mediator of platelet aggregation. In bleeding patients, fibrinogen is sometimes the first coagulation factor to be depleted. It is recommended that fibrinogen levels be maintained at >100 mg per dL for bleeding patients or those undergoing surgery; however, more recent evidence indicates that even higher levels should be maintained during cardiac surgery. Fibrinogen factor concentrate is now available in the United States. Fibrinogen concentrate is only approved for use in the United States for patients with congenital fibrinogen deficiency, including afibrinogenemia and hypofibrinogenemia. Fibrinogen concentrate may represent an improvement over cryoprecipitate in that it undergoes a viral inactive step during manufacture, it can be rapidly reconstituted and can be infused immediately (no need to thaw), is stable at room temperature, and the dose can be easily titrated to clinical response; these advantages may offset its high cost in certain circumstances.

Of note, small amounts of red cell fragments may be present in cryoprecipitate; therefore, use of cryoprecipitate constitutes a potential sensitization risk for Rhesus (Rh)-negative individuals.

B.9. Describe the advantages and disadvantages of the products that are available for repletion of FVIII activity.

When cost is not an issue, recombinant or monoclonal purified FVIII is generally preferred. Alternatively, plasma-derived FVIII concentrates may be the optimal choice. Hospitals that stock both plasma-derived and recombinant FVIII may have a policy such that patients who have already been diagnosed with hepatitis C or HIV be supplied with plasma-derived factor concentrates. If FVIII concentrates are unavailable, cryoprecipitate, plasma, or PCC may be used to replete FVIII activity.

B.10. What is the role of desmopressin (D-amino D-arginine vasopressin [DDAVP]) for hemostatic management in this patient?

This synthetic analog of the antidiuretic hormone is FDA approved for use in patients with mild and moderate hemophilia for minor surgery to attenuate the incidence and severity of bleeding complications especially with high-risk operative procedures. Intravenous DDAVP induces rapid release of FVIII and vWF from storage sites, resulting in a twofold to threefold increase in circulating FVIII within 30 to 60 minutes of

administration. The recommended intravenous dose is 0.3 μg per kg body weight (max dose 20 μg over 30 minutes to minimize the incidence of hypotension related to the concomitant release of endothelial prostacyclin) and with repeat dosing every 12 to 24 hours. However, patients can have tachyphylaxis if repeat dosing is used at frequent intervals, likely as a result of depleted endothelial storage reservoirs. Given the substantial variability in response to therapy, a preprocedural DDAVP trial is often performed to assess the response to therapy. Postinfusion levels of 30% are considered adequate for minor bleeding, whereas levels of 50% or greater are adequate for surgical interventions. Of note, desmopressin is a potent antidiuretic, and thus, there is a slight but realistic risk of hyponatremia/water intoxication following repetitive use. It is recommended that patients receiving desmopressin not receive hypotonic fluids postoperatively and that electrolytes be monitored closely. DDAVP also induces the release of plasminogen activator (which can cause fibrinolysis); however, it is usually unnecessary to inhibit fibrinolysis when DDAVP is used clinically in operative scenarios other than cardiac surgery or liver transplantation.

DDAVP is also approved to manage some patients with type 1 vWD. DDAVP may also be useful for patients with hereditary or acquired platelet abnormalities (e.g., uremia-induced or CBP-induced platelet dysfunction).

Despotis GJ, Levine V, Saleem R, et al. Use of point-of-care test in identification of patients who can benefit from desmopressin during cardiac surgery: a randomised controlled trial. *Lancet*. 1999;354(9173):106–110.

B.11. What is the role of antifibrinolytic therapy in the

perioperative period for the patient with hemophilia? What are examples of antifibrinolytics used in the treatment of hemophilia?

Antifibrinolytics have been used successfully in patients with hemophilia to prevent or manage bleeding, following minor bleeding (e.g., menorrhagia and epistaxis) and in preparation for minor surgical procedures (e.g., dental extractions). Their use in major surgical procedures for patients with hemophilia has not been well documented. Tranexamic acid (TXA) and ε-aminocaproic acid (EACA) are both lysine analogue antifibrinolytic agents that have been used for prevention and treatment of bleeding. Use of these agents to minimize bleeding and transfusion has been extensively studied; these agents have been shown to be effective to a variable degree in several surgical populations such as patients undergoing liver transplantation (i.e., during anhepatic stage), trauma, and high-risk cardiac and orthopedic procedures.

B.12. What are the options for operative treatment of patients with acquired hemophilia? Describe the mechanism of action and dosing considerations for each of these therapies.

Hemophilia A represents the majority of patients afflicted with hemophilia. Risk factors for the development of inhibitors include race, severity of the disease (<1% FVIII levels), having a hemophiliac brother with inhibitors, certain genetic mutations involving the FVIII gene, and/or exposure to FVIII derived from animal sources as opposed recombinant techniques. Acquired

hemophilia can also occur in patients without congenital hemophilia; these patients are typically >65 years old and have additional underlying medical conditions.

In patients with inhibitors, alternative treatment is occasionally necessary to address surgical and nonsurgical hemorrhagic crises. Frequently, the strategy employed is a FVIII bypass agent. These agents circumvent the need for FVIII activity in the coagulation cascade. The FDA has approved use of either rFVIIa or PCC for actively bleeding patients with FVIII inhibitors.

FVIIa binds to TF exposed at the site of injury and leads to generation of enough local thrombin to activate FV, FVIII, and FXI as well as platelets via an alternate mechanism other than the FVIIIa/FIXa complex. Moreover, in high doses, rFVIIa binds to activated platelets and activates FX. The prohemostatic effect of rFVIIa is generally limited when there are one or a few sites of local injury (e.g., spontaneous or traumatic CNS bleeding) because the expression of TF is limited to these localized sites. The risk of thrombosis is increased when there is a systemic state of TF activation as occurs in many clinical conditions that result in DIC. For on-label use, the typical doing schedule for hemostatic prophylaxis in patients undergoing elective surgery is 90 to 120 μg per kg, with repeated doses every 2 to 3 hours.

Prothombin complex concentrates (PCC or Profilnine SD, Grifols Biologicals, Los Angeles, CA; KCentra, CSL Behring, King of Prussia, PA) and aPCC (FEIBA, Baxter, Vienna, Austria) are commercially available plasma-derived products containing FII, FVII, FIX, and FX. Activated PCC contains activated FVII and small amounts of activated FII, FIX, and FX. PCCs have been shown to have a higher rate of adverse reactions and be less effective than aPCCs in treating patients with FVIII inhibitors. In the 1990s, rFVIIa concentrate was

available for use for patient with FVIII inhibitors. In clinical trials, both aPCCs and rFVIIa were shown to be efficacious for the management of bleeding in inhibitor patients with FVIII inhibitors.

aPCC is dosed at 50 U per kg and can be redosed if needed depending on the extent of the bleeding/clinical situation. However, there is no laboratory testing available for monitoring any of the bypass reagents. Moreover, there are multiple published cases associating repeated large doses of PCCs with myocardial infarctions in young patients with FVIII inhibitors. Additionally, it has been reported that coadministration of large doses of aPCC and emicizumab (the novel bispecific antibody therapy for hemophilia A patients with an inhibitor) is associated with venous thrombus and skin necrosis, leading to the recent guidance that first-line treatment of bleeding patients on emicizumab should be rFVIIa.

Recently, there has been increased focus on the use of porcine FVIII for the treatment of bleeding in hemophilia A patients with inhibitors. The original product derived from pig plasma (pd-FVIII; Hyate:C, Ipsen Biopharmaceuticals, Cambridge, MA) was withdrawn from use in 2004 out of concern for parvovirus contamination. However, recombinant porcine FVIII (rpFVIII; OBIZUR, Baxalta Inc, Deerfield, IL) was made available in 2014, and it has been shown be hemostatically effective in patients with FVIII inhibitors. The dose used in the initial studies (200 U per kg) frequently results in FVIII activity higher than is desirable in some patients. Dose adjustment should be considered to titrate to clinical response and inhibitor titers. Porcine FVIII may be preferable to bypass agents because its effects are quantifiable using the FVIII activity assay.

One additional approach to patients with inhibitors involves immune tolerance induction (ITI). ITI regimens typically involve administration of large doses of FVIII (50 or 200 U per

kg) daily or twice weekly until the inhibitor titer becomes negative, FVIII levels recover, and/or sustained half-lives are normal.

C. Intraoperative Management

C.1. Is it safe to administer an intramuscular injection to this patient before surgery?

Intramuscular injections can be safely administered to any patient with an FVIII activity greater than 30%. Therefore, if appropriate FVIII correction has occurred, an intramuscular injection would be safe. It is unlikely, though, that an intramuscular injection would be necessary for this patient. If a sedative hypnotic or anticholinergic drug is indicated before the induction of anesthesia, it may be more appropriate to use an

intravenous route, if available. Intravenous administration also enables immediate bioavailability with higher peak levels.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:419–458.

C.2. Would an axillary block be appropriate for this patient?

Regional anesthesia has been considered contraindicated in patients with hemophilia because the concern of hematoma formation at the injection site. However, with proper management of coagulation status, regional techniques have been successfully performed in patients with hemophilia. As with any patient, the benefit of the regional technique must be weighed against the potential risks. In a patient with a full stomach, a regional technique may be more appropriate to reduce the potential risk of aspiration. For a completely elective procedure in the patient with hemophilia, a more prudent course might be general anesthesia. If a regional anesthetic technique were being considered, it would be advisable to verify appropriate levels of factor activity at the time of the intervention as well as prior to removal of an epidural catheter, especially in the setting of the presence of neutralizing antibodies.

Sampson JF, Hamstra R, Aldrete JA. Management of hemophiliac patients undergoing surgical procedures. *Anesth Analg*. 1979;58:133–135.

C.3. If general anesthesia is used, would it be safe to intubate the patient's trachea?

Airway management of the patient with hemophilia presents a unique challenge for the anesthesiologist due to the potential for hemorrhage in the tongue or neck, which could compromise (i.e., complete or near complete occlusion) the upper airway. Therefore, manipulation of the airway during elective intubation

ideally should not be performed until appropriate replacement factors have been administered. Care should be used when applying pressure during mask ventilation to avoid trauma to the lips, tongue, or face; elective laryngoscopy should be attempted only following appropriate factor correction. Careful examination for swelling of the upper airway should be pursued prior to extubation; if substantial swelling or a hematoma is observed, extubation should be postponed until resolution. Depending on the procedure and operative needs, a smaller than predicted well-lubricated tracheal tube should be considered for intubation. Nasal intubation, with its propensity for epistaxis, should be avoided if possible.

Bogdan CJ, Strauss M, Ratnoff OD. Airway obstruction in hemophilia (factor VIII deficiency): a 28-year institutional review. *Laryngoscope*. 1994;104:789–794.

C.4. Would you use any special precautions for this patient who is positive for HIV?

Standard precautions should be used for all patients regardless of their HIV status. Strict attention to aseptic technique throughout the surgical procedure should be emphasized. Postoperative infections may be more common in HIV-positive patients undergoing orthopedic procedures such as these due to their potentially immunocompromised state.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders; 2017:477–506.

Thomason HC III, Wilson FC, Lachiewicz PF, et al. Knee arthroplasty in hemophiliac arthropathy. *Clin Ortho*. 1999;360:169–173.

C.5. What special considerations should be taken in choosing anesthetic drugs for this patient?

Historically, coexisting liver disease was a frequent complication in patients with hemophilia, likely resulting from

transfusion-transmitted hepatitis, an unfortunate consequence of a history of multiple previous blood or factor transfusions. This has been dramatically reduced due to improvements in donor screening and allogeneic blood testing. It is thus reasonable to use caution with drugs that are metabolized by the liver in the setting of substantial liver dysfunction (i.e., reduced protein synthetic function).

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier Saunders; 2017:477–506.

C.6. During an operative procedure, if the surgeon indicates that significant blood loss is occurring, would you transfuse this patient with packed red blood cells (RBCs) or whole blood?

As general transfusion practice, blood banks fractionate donated blood into component parts, resulting in the production of RBCs, platelets, plasma, and/or cryoprecipitate components. Following blood loss and subsequent to substantial volume replacement with crystalloids and/or colloids, RBCs may be required when oxygen-carrying capacity and oxygen delivery reach critically low levels. The trigger for RBC transfusion can be variable between patients with various clinical scenarios. Important factors to be considered include hematocrit, rate of blood loss, age, and comorbidities, in addition to monitoring other indices that allow assessment of a critical imbalance in oxygen delivery/consumption systemically, or in critical organ systems (i.e., CNS or myocardial ischemia). In a patient with hemophilia, transfusion of packed RBCs will further dilute already depressed circulating FVIII levels; therefore, transfusion of whole blood in such a patient would be appropriate, if it can be obtained. With administration of whole blood, both oxygen-carrying capacity and all components of coagulation would be replenished. Given the general unavailability of whole blood

other than for use as part of massive transfusion protocols within the trauma setting, additional factor repletion is typically required depending on the amount, rate, and expected course of the bleeding. Replenishment may take the form of whole blood fractions (cryoprecipitate or plasma), additional recombinant factor replacements, or pooled factor concentrates.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1579–1603.

C.7. During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8°C to 37.9°C (98.2°F to 100.2°F). What immediate steps should be taken by the anesthesiologist at this time?

Ruling out an acute hemolytic transfusion reaction should always be considered when a patient becomes febrile during a blood transfusion. The anesthesiologist should immediately discontinue the transfusion, drain any remaining allogeneic blood from the intravenous blood administration set, and blood should be drawn from the patient and sent to the blood bank with the unit of blood in question to allow for the performance of a transfusion reaction workup. Although blood banks may vary slightly with regard to the extent/manner of reaction testing performed, most blood banks will repeat product crossmatching and will use the sample to assess the plasma for visual evidence of free hemoglobin or icterus as well perform a direct antiglobulin test (DAT) to assess for antibody bound to transfused RBCs (mixed field pattern). If there is concern for hemolysis, haptoglobin, bilirubin, and lactate dehydrogenase (LDH) would be helpful for the assessment of intravascular hemolysis. Urine may also be assessed for hematuria and urine free hemoglobin. In the presence of an acute hemolytic blood transfusion reaction, profound hypotension requiring use of vasopressors is believed to be related to release of a number of

vasoactive mediators (e.g., serotonin, bradykinin, cytokines, histamine). Fluid and diuretic therapy as well as alkalization of the urine should be considered to reduce renal injury and maintain function. A febrile reaction that is not due to an acute hemolytic transfusion reaction frequently occurs with blood transfusion (e.g., 1% to 2%); these reactions are usually self-limited or easily managed. They are believed to be related to cytokines that are released by apoptotic leukocytes during red cell processing and storage. Simultaneous to the transfusion reaction evaluation, further investigations into the temperature increase is warranted because there are other potential causes of fever. Additionally, the transfusion reaction evaluation may take a few hours. Of note, a negative DAT makes transfusion-related immune-mediated intravascular hemolysis unlikely.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1579–1603.

C.8. Does giving blood intraoperatively increase the potential for the development of FVIII inhibitors?

Although approximately 30% of all patients with hemophilia A will develop a circulating inhibitor of FVIII, there is no evidence to suggest that development of an inhibitor is related to the number of transfusions a patient receives. As a result, administration of blood products in this setting should not be withheld for fear of inducing inhibitor development.

Rodriguez-Merchan EC, Lee CA. *Inhibitors in Patients with Haemophilia*. Oxford: Wiley-Blackwell; 2002:17–19.

C.9. Can FVIII be safely administered to patients who have developed circulating inhibitors?

Occasionally, patients with the most severe phenotype of hemophilia (factor levels <1%) develop immunoglobulin antibodies (IgG) to the deficient factor. The inhibitors may be of

low titer (generally thought of as less than 5 BU) or of extremely higher titer. The “Bethesda unit” of inhibition is defined as the amount of inhibitory activity present in 1 mL of plasma that decreases the FVIII level in 1 mL of normal plasma by 50% (i.e., from 1 to 0.5 units). The more dilutions needed to produce 50% activity, the higher the titer of antibody and the greater the number of BU. It is almost impossible to overpower a high-titer inhibitor with large doses of FVIII, but when life-threatening hemorrhage occurs, massive doses of FVIII concentrates or plasmapheresis with concomitant administration of FVIII may be of temporary benefit. However, this approach requires a substantial amount of time because four to five plasma exchange procedures are typically required to reduce IgG levels by 90%. Replacement with large amounts of FVIII concentrate may provide temporary hemostasis but may stimulate an increase in the antibody titer. Porcine FVIII, when available, may provide hemostasis because of its distinct antigenicity, even in the presence of a circulating inhibitor. Immunosuppressive therapy is of no value in the acute setting.

Alternative approaches to therapy of the hemophiliac patient with inhibitors involve the use of other agents, such as aPCCs such as FEIBA that contain activated vitamin K–dependent coagulation factors as well as use of recombinant FVIIa. These activated factors affect the coagulation cascade downstream of FVIII and therefore bypass the FVIII mechanism for hemostatic system activation and negate the effects of the inhibitor. FEIBA, a PCC that is used in the United States to treat hemophilia patients with inhibitors, has been associated with thrombosis in several case reports; the propensity for thrombosis with this agent may be related to the fact that it contains four activated factors as well as other by-products that promote hemostatic system activation. Therefore, thrombosis is a possible complication when using aPCC.

Porcine FVIII is sometimes effective in patients with hemophilia with inhibitors. Porcine FVIII provides adequate FVIII activity in patients with less than 50 BU of inhibitor. The usual starting dose is 100 to 150 porcine units per kg.

Hines RL, Marschall KE. *Stoelting's Anesthesia and Co-existing Disease*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2012:407–436.

C.10. The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?

Although the tourniquet may optimize surgical conditions, the physiologic and hemodynamic consequences can be significant. Anaerobic metabolism distal to the tourniquet begins approximately 8 minutes after inflation; a decrease in nicotinamide adenine dinucleotide (NAD) and creatine phosphate stores in muscle beds will occur over the next 30 to 60 minutes. As a result, the anaerobic conditions lead to cellular acidosis, which will in turn cause the release of myoglobin, intracellular enzymes, and potassium. In addition, the limb loses heat and may approach room temperature.

Hemodynamic disturbances are seen when the tourniquet is deflated. Exsanguination of the limb and tourniquet inflation acutely expands central venous blood volume, which can have significant hemodynamic consequences in a patient with limited cardiac reserve (i.e., reduced myocardial function). Tourniquet deflation and reperfusion of the limb can be associated with profound decreases in central venous and arterial blood pressure, as a result in a decrease in vascular resistance, which is related

to vasodilation that occurs with the circulation of metabolites produced during the ischemic period. Prolonged inflation (>45 to 60 minutes) can result in systemic hypertension likely due to the presence of a critical level of ischemia in the muscle or nerve or to pain.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1579–1603.

C.11. Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?

Removal of secretions that might be aspirated is essential before the extubation of any patient; nevertheless, suctioning of the oropharynx of hemophiliac patient can irritate mucosa by the suction catheter and result in the formation of an oral hematoma. In a patient with hemophilia, gentle oral suctioning with reduced suction pressures under direct vision is appropriate to eliminate secretions.

Hyderally H, Stark DC. Hemophilia: anesthetic implications. *Mt Sinai J Med*. 1977;44:397–399.

D. Postoperative Management

D.1. What special consideration should be given to postoperative pain management for this patient?

It is important to avoid any postoperative pain supplements that may predispose hemophiliac patients to a bleeding diathesis. Analgesics containing aspirin or nonsteroidal anti-inflammatory drugs should be avoided based on their antiplatelet effects. Antihistamines and antitussives may also inhibit platelet aggregation. Opioid analgesics or acetaminophen-based products should be appropriately titrated for postoperative pain management. If regional blockade with a catheter technique was

used for anesthesia, postoperative analgesics should be administered through this route; because the patient has undergone the risk of placement, they should also receive the benefit. Care must be taken to ensure appropriate timing for removal of the catheter, preferably after confirmation of normal FVIII levels.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1579–1603.

D.2. What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?

It is important that FVIII levels are supplemented following surgery. If FVIII levels are allowed to fall to the levels normally seen in these patients, it can result in postoperative hemorrhage. Postoperatively, many clinicians recommend maintaining levels at 80% of normal for the first 4 postoperative days, whereas others have opined that levels of at least 40% of normal are adequate. The consensus is that FVIII levels on postoperative days 5 to 8 should be maintained at least at 30% to 40% of normal, whereas levels of 10% to 20% of normal should be maintained for several weeks unless there is evidence of ongoing bleeding (see **Table 31.6**).

Mintz P, ed. *Transfusion Therapy: Clinical Principles and Practice*. 3rd ed. Bethesda, MD: AABB Press; 2011:167–195.

D.3. Can this patient be treated with FVIII supplements using home infusion?

Administration of FVIII concentrate by continuous infusion can be administered to patients with hemophilia at medical centers in the postoperative inpatient period. With transition of many

surgical procedures to the outpatient arena, home infusion of FVIII can provide the same level of hemostatic integrity. Home infusion of purified FVIII concentrate has been shown to be safe, efficacious, and convenient for postoperative patients and should be considered for patients with hemophilia.

32 Sickle Cell Disease

Chris R. Edmonds and Vinod Malhotra

A 30-year-old African-American woman with avascular necrosis of her right hip was admitted for a total hip arthroplasty. Her hematocrit was 22%, blood pressure was 130/90 mmHg, and pulse was 107 beats per minute. Her medications included hydroxyurea and oxycodone. She has a past medical history of recurrent joint pain, bone pain, acute chest syndrome, dyspnea, multiple transfusions, jaundice, and abdominal pain requiring multiple hospitalizations for analgesia. Her past surgical history was remarkable for a cholecystectomy, and her postoperative course was remarkable for a prolonged hospitalization for respiratory complications.

A. Medical Disease and Differential Diagnosis

1. What was the most likely underlying medical condition in this patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?
2. What is sickle cell disease (SCD)?
3. What is sickle cell trait (SCT)?
4. What are some of the other common hemoglobinopathies and what are their clinical features?
5. What are the clinical features of SCD?
6. Describe the different types of sickle cell crises.

7. Discuss the pathophysiologic effects of SCD.
8. What is acute chest syndrome?

B. Preoperative Evaluation and Preparation

1. What preoperative evaluation and testing would you perform on this patient prior to anesthesia? Would you ask for a hematology consult, and what question(s) would you ask?
2. What preoperative instructions would you give this patient prior to being admitted to the hospital? How would you prepare this patient for general anesthesia and regional anesthesia?
3. Discuss the indications for perioperative exchange transfusion in this patient.
4. What are the indications for blood transfusion in SCD?

C. Intraoperative Management

1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.
2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.
3. What precautions should one take to prevent sickling in this patient?
4. Discuss what issues or concerns should be brought up by the team during the debrief at the conclusion of the case. What would you sign-out to the postanesthesia care unit (PACU) staff?

D. Postoperative Management

1. Discuss the postoperative management of this patient. What opioid sparing techniques can you use and discuss a multimodal analgesic plan?
2. What complications might occur in this patient in the immediate postoperative period?
3. What is the treatment of sickle cell crisis?

4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?

A. Medical Disease and Differential Diagnosis

A.1. What was the most likely underlying medical condition in this patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?

For a young African-American patient presenting with a history of joint pain, bone pain, abdominal pain, and anemia, the most likely diagnosis is SCD. Other diagnoses to consider include other hemoglobinopathies, dermatomyositis, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and porphyria. Nevertheless, given the constellation of symptoms and the laboratory findings, SCD is the most likely diagnosis. A hemoglobin (Hgb) electrophoresis will confirm the diagnosis and provide the percentage of abnormal hemoglobin S (HgbS).

A.2. What is sickle cell disease (SCD)?

SCD is a hereditary hemoglobinopathy resulting from inheritance of a *β-globin* gene mutation located on chromosome 11. This mutation leads to a single-point mutation where adenine

is replaced with thymine. The mutant *β*-allele codes for production and assembly of a variant Hgb (*β*-S). The molecular basis of SCD has been demonstrated to be the substitution of valine for glutamic acid in the sixth position from the *N*-terminus of the *β*-chains of Hgb. This substitution replaces a hydrophilic negative-charged amino acid (glutamic acid) with a hydrophobic nonpolar amino acid (valine). This greatly destabilizes the structure of Hgb and exposes highly reactive hydroxyl groups on the protein surface. The mutation in *β*-S Hgb accelerates the denaturation of the Hgb molecule and significantly decreases its solubility. Decreased oxygen tension causes conformational changes in the Hgb molecule, allowing hydrophobic bonds to form between the BS-6 valine of one chain and the BS-85 phenylalanine and the BS-88 leucine of a second chain. This bond forms insoluble tetramers that bond with other tetramers to form long helical strands that subsequently polymerize, causing deformation of the red blood cell membrane into a sickle shape. The result is a red blood cell that is less able to transverse the capillaries of the microcirculation, disposing the end organ to hypoxia, and ischemic damage when sickle cells are present in sufficient quantity. In the United States, the estimated prevalence of Hgb SS disease is 1:625 (0.2%) in people of African descent. Patients with SCA have early mortality, with the median age of death in the late 40s to early 50s.

A.3. What is sickle cell trait (SCT)?

SCT is the heterozygous or carrier state of SCD. Large-scale screening for SCD in American military recruits revealed an incidence of SCT (HbAS) of 8% to 10% in African Americans and 0.05% to 0.08% in others. HbAS cells begin to sickle only when oxygen saturation of Hgb is less than 20%. No difference has been found between normal persons (HbAA) and those with HbAS regarding survival rates or incidence of severe disease, with one exception: patients with HbAS have a 50% increased risk for pulmonary infarctions. Studies have suggested that SCT provides a survival advantage over hematologic normal individuals when infected by the malarial parasite *Plasmodium falciparum*.

A.4. What are some of the other common hemoglobinopathies and what are their clinical features?

The most common hemoglobinopathies include the thalassemias, Hgb C disease, and SCA. Thalassemia arises from

alterations in one or more of the four genes that code for the α-chain. The mildest form of thalassemia (loss of one α-gene) presents as a mild form of anemia, whereas the most severe form (loss of all four genes) is incompatible with life. Hgb C results from a mutation in the *β-globin* gene. Hgb C disease is a relatively benign disease producing a mild hemolytic anemia and splenomegaly. However, when it is paired with a β-S mutation, the disease is more severe. Other rare hemoglobinopathies will not be discussed further.

Each Hgb gene mutation of the heterozygous form causes little or no clinical consequence, but when both genes of a heterozygote are abnormal, a disease state is evident. Heterozygous combinations such as HbS and HbC (HbSC disease), and β-thalassemia mutation (HbS-β-thalassemia) usually cause a milder clinical course than that of SCD.

A.5. What are the clinical features of SCD?

The clinical features of SCD are manifested through indolent end-organ damage with intermittent acute episodes of severe pain and pulmonary complications. Although SCD is a disease of Hgb, it ultimately affects all organ systems. It is usually the acute problems that bring these individuals to the attention of a physician. The clinical manifestations by organ systems are presented in **Table 32.1**.

TABLE 32.1 Clinical Manifestations of Sickle Cell Disease

System	Symptoms
Central nervous system/neurologic	• Stroke (cerebrovascular accident) in children as well

	as adults (50%−70% recurrence within 3 years) • Proliferative retinopathy/blindness • Painful crisis (>70%) • Chronic pain (not common) • Peripheral neuropathy (not common) • Poor school performance
Cardiovascular	• Conduction abnormalities secondary to iron overload • Hypertension • Cor pulmonale • Left and right ventricular dysfunction • Chronic ulcers
Pulmonary	• Infarction, pulmonary fibrosis • Infection • Restrictive/obstructive lung disease (10%−15%) • Acute chest syndrome (40%) • Pulmonary hypertension (30%−40%) • Airway hyperactivity
Genitourinary	• Hyposthenuria, hematuria, proteinuria • Chronic renal insufficiency (5%−20%) • Renal failure • Priapism (10%−40% of men) • Urinary tract infection
Gastrointestinal	• Cholelithiasis (70%) • Acute hepatic syndrome • Elevated liver function tests, hyperbilirubinemia • Hepatopathy • Cirrhosis (16%−29%) • Dyspepsia secondary to mucosal ischemia • Sickle girdle syndrome (mesenteric ischemia)
Musculoskeletal	• Osteomyelitis (*Staphylococcus/Salmonella*) • Dactylitis • Avascular necrosis (50%) • Infarction
Heme/immunologic	• Chronic anemia • Autosplenism • Susceptibility to infections with encapsulated organisms • Erythrocyte alloimmunization from blood transfusions • Sequestration crisis • Hemolytic crisis • Aplastic crisis • Immune dysfunction • Hypercoagulability

The progression and severity of SCD is variable. Many of the patients have an indolent course, whereas a smaller subset suffer from an early end-organ failure and an early death. Pulmonary, neurologic, and renal disease are the leading causes of morbidity and mortality. Hydroxyurea is a medication that increases the percentage of fetal Hgb, thereby decreasing the severity of the disease. However, it does not seem to decrease the perioperative complications of the disease.

A.6. Describe the different types of sickle cell crises.

Sickle cell crisis refers to the acute clinical picture generally caused by sickling of red blood cells in the *microcirculation*. Four main clinical types of crises have been described as follows in **Table 32.2**.

TABLE 32.2 Types of Sickle Cell Crises

Type	Pathophysiology	Treatment
Vaso-occlusive	Pain secondary to obstruction of flow in the microvascular beds leading to localized ischemia	• Hydration • Analgesia • Incentive spirometry
Splenic sequestration	Acute painful enlargement of the spleen Acute hypovolemia	• Restore circulatory volume, possible splenectomy
Aplastic	Sudden cessation of bone marrow activity Acute worsening of anemia usually associated with viral	• Supportive therapy • Blood transfusion

	infection (parvovirus B19) Recovery in 7–10 days	
Hemolytic crisis	Acute accentuated decrease in hemoglobin level Secondary to red cell destruction Usually associated with coexisting G6PD deficiency	• Supportive therapy • Blood transfusion

G6PD, glucose-6-phosphate dehydrogenase.

The most common crises in SCD is vaso-occlusive crisis, which is characterized with intermittent, recurrent acute episodes of severe pain. It is generally felt that the central cause of pain is ongoing acute ischemia, vaso-occlusion, and infarction. The precise pathophysiology and nociceptive pathways have not been elucidated. Patients in vaso-occlusive crisis present with fever, anemia, spine pain, limb pain, and abdominal pain. They are tachypneic and may have an enlarged liver and spleen in addition to abdominal tenderness. Serjeant et al. reported that in 118 patients having 183 painful crises, the location was noted to be in the lumbar spine (49%), abdomen (32%), femoral shaft (30%), and the knee (21%). There is usually no identifying triggering agent for most vaso-occlusive crises. The average rate of painful crises per patient year is 0.8%. There is a subset of patients (5.2%) who average 8 to 10 crises a year, which accounts for 33% of all hospitalizations. Mortality positively correlates with increased pain rate in adults.

A.7. Discuss the pathophysiologic effects of SCD.

The pathophysiologic effects of SCD is not limited to the structure or deformation of the erythrocyte. The interaction and

balance between the Hgb molecule, cytoplasm, and cell wall and the vascular endothelium is drastically altered to create chronic systemic biochemical alterations that produce the clinical features of SCD. As in vaso-occlusive crisis, there is a triggering insult, such as infection, surgical stress, or ischemia-reperfusion injury, that catalyzes a complex interaction among sickled cells, endothelial regulation of flow, inflammatory cytokines, platelet aggregation factors, and vasoconstriction, leading eventually to ischemia, infarction, and cell death. This cascade leads to a vicious cycle that eventually causes end-organ damage and dysfunction. End-organ damage that occurs in sickle cell states is attributable to three pathways. In the erythrocyte cytoplasm, the loss of Hgb structural stability leads to increased oxidation of heme with subsequent denaturation, deterioration, and polymerization. Iron oxidation produces superoxides (O_2^-) and hydrogen peroxides ($H_2O_2^-$), which increases the formation of highly reactive hydroxyl radicals (−OH). In the cell membrane, free iron and iron-containing compounds accumulate, leading to clustering of membrane surface membranes, abnormal cation permeability, and cellular dehydration. This complex series of events within the erythrocyte increases adherence to the vascular endothelium, exposing it to shear and oxidative stress. The interaction between the abnormal erythrocytes and the vascular endothelium produces chronic inflammation, upregulation of endothelial cell adhesion molecules, and altered expression of endothelial nitric oxide synthetase. Systemically, there is an increase in leukocyte counts, activation of the coagulation pathways, increase in inflammatory compounds, and increase in circulating endothelial cells in the plasma. The complex pathologic interaction between sickling of cells in blood vessels and the vascular endothelium leads to infarcts, tissue destruction, and consequent end-organ failure. The pathogenesis

is shown in **Figure 32.1**.

A.8. What is acute chest syndrome?

Acute chest syndrome is a term used to describe an acute pulmonary complication of SCD. It is defined by the finding of a new pulmonary infiltrate involving at least one complete lung segment on chest radiograph that is not due to atelectasis. It presents with a constellation of pulmonary symptoms and signs in a patient with SCD. These include fever (temperature 38.5°C [101.3°F]), wheezing, coughing, tachypnea, chest pain, and hypoxemia (less than 92% on room air). Pleural effusions (55%) are commonly seen on chest radiographs. Acute chest syndrome frequently follows vaso-occlusive crises; therefore, vaso-occlusive pulmonary infarction may be a precipitating factor. Other causes include infection (viral, chlamydia, mycoplasma, and bacterial) and pulmonary fat embolism resulting from bone marrow necrosis. Acute chest syndrome is a common postoperative complication in patients with SCD who have a history of pulmonary disease following general anesthesia. It is one of the most common causes of death in adults with SCD. Acute chest syndrome can be prevented by judicious hydration, incentive spirometry, effective analgesia, and avoidance of even mild hypothermia during the crises. Acute chest syndrome should be treated with bronchodilators, antibiotics, and exchange transfusion, when necessary. Exchange transfusion is recommended if the patient is clinically deteriorating.

B. Preoperative Evaluation and Preparation

B.1. What preoperative evaluation and testing would you perform on this patient prior to anesthesia? Would you ask for a hematology consult, and what question(s) would you ask?

The aim of the preoperative assessment in a patient with SCD is to determine the preoperative risk of this multisystemic disease and how the end-organ damage will affect the anesthetic management (see **Table 32.1**). A careful history should be obtained with a complete physical examination. The cardiopulmonary status should be thoroughly investigated, in view of the increased incidence of cardiac and pulmonary morbidity in these patients especially in a patient with a history of acute chest syndrome and dyspnea. A history of frequent hospitalizations in the year before surgery significantly increases the likelihood of a vaso-occlusive crisis in the perioperative period. Immunization status for Pneumovax and *Haemophilus influenzae* vaccine should be checked. Other characteristics that increase the perioperative risk are age, pregnancy, smoking, and infection. If possible, cessation of smoking prior to elective surgery should be strongly encouraged because smoking

increases the risk of acute chest syndrome and pain in the preoperative period. One should correct hypovolemia and treat infection appropriately preoperatively. Laboratory investigation should include a complete blood count, blood urea nitrogen, serum creatinine, urinalysis, electrocardiogram, chest radiograph, pulse oximetry, and liver function tests. In addition, the following tests may be helpful:

- Arterial blood gas, if indicated
- Sickle cell preparation (if diagnosis is unclear)
- Hgb electrophoresis to determine HbS, quantitatively
- Reticulocyte count
- Type and cross (Alloimmunization may make this difficult.)
- Pulmonary function test (if severe pathology, paroxysmal dyspnea, or history of acute chest syndrome)
- Echocardiogram in patients with history of pulmonary hypertension or cardiomegaly
- Neurologic imaging (if there are psychological or behavioral changes)

A hematology consult should be asked for if the diagnosis of SCD is unclear and/or to obtain an Hgb electrophoresis to determine the percentage of sickle Hgb. They can also help in patients that are difficult to crossmatch.

Knight-Madden JM, Barton-Gooden A, Weaver SR, et al. Mortality, asthma,

smoking and acute chest syndrome in young adults with sickle cell disease. *Lung*. 2013;191(1):95–100.

B.2. What preoperative instructions would you give this patient prior to being admitted to the hospital? How would you prepare this patient for general anesthesia and regional anesthesia?

Prior to being admitted to the hospital for elective surgery, this patient should be given nothing by mouth instructions, which include clear fluids up until 2 hours prior to surgery and carbohydrate loading to maintain a baseline metabolic state.

- Informed consent should be obtained to explain the options, risk, and benefits of the different types of anesthetics used.
- Preoperative hydration should be initiated to treat baseline volume deficit.
- Euvolemia should be maintained preoperatively (remembering that the patient is on nothing by mouth status and may have a urine concentration defect requiring volume replacement).
- Any infections should be treated preoperatively, if possible.
- End-organ dysfunction should be identified and treated appropriately.
- Type and crossmatching may be difficult in these patient's because of alloimmunization.
- Consider transfusion of red blood cells to maintain oxygen-carrying capacity. Transfusion guidelines should be based on comorbidities, surgical risk, and degree of anemia. Transfusions should be individualized and based on the patient's risk/benefit. Efforts should be made for leukocyte reduction techniques, as with buffy coat–poor red cells, to reduce the incidence of leukocyte antigen alloimmunization. The goals of transfusion are to achieve an Hgb concentration of greater than 8 g per dL and to ensure that Hgb A represents

more than 40% of the total Hgb present. Past practices of reducing HgbS levels to less than 30% do not seem to improve outcome and increase transfusion-related complications.

B.3. Discuss the indications for perioperative exchange transfusion in this patient.

Controversy exists as to whether these patients benefit from preoperative exchange transfusion. For high-risk surgical procedures such as cardiopulmonary bypass an exchange transfusion may be recommended. Nevertheless, a series of reports of cardiopulmonary bypass cases in which exchange transfusions were not performed or only a partial exchange was performed. If an exchange transfusion is required, the exchange transfusion should be performed with buffy coat–free packed red blood cells to reduce the HbS fraction to less than 40%. Nevertheless, growing evidence indicates that most surgical procedures can be safely performed in patients with SCD without aggressively transfusing. For example, for certain surgical procedures, it has been shown that a packed red blood cell transfusion done simply to increase the Hgb level to 10 g per dL is as effective in decreasing perioperative morbidity, as is

exchange transfusions to reduce the HbS(S) levels to less than 40%. Exchange transfusion is a therapy often used in patients with SCD complicated by acute chest syndrome. It is beneficial to keep the hematocrit lower than 35% with an exchange transfusion because an increased hematocrit will increase blood viscosity and stasis in the circulation.

B.4. What are the indications for blood transfusion in SCD?

Blood transfusions should be guided by the clinical picture and the potential for blood loss. Prophylactic transfusion remains controversial and is of questionable benefit in mild-to-moderate risk cases. Some of the clinical indications for blood transfusion in SCD include the following:

Acute conditions

- Vaso-occlusive crises with organ infarction and dysfunction
- Sequestration syndrome
- Acute hemolysis with exacerbation of anemia
- Aplastic crisis
- Acute chest syndrome
- Acute multiorgan failure
- Severe unresponsive priapism
- Protracted painful crisis

- High-risk surgery (e.g., cardiovascular, thoracic)

Chronic conditions

- Intractable leg ulcers
- Complicated pregnancy
- Stroke
- Recurrent painful syndrome
- Recurrent acute chest syndrome

C. Intraoperative Management

C.1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.

The definitive anesthetic technique has not been established secondary to the wide clinical spectrum of SCD and the different severities in the surgical procedures. Koshy et al. retrospectively reviewed 1,079 anesthetics and noted an apparent association between postoperative complications and the use of regional anesthesia. Nevertheless, this study did not control for obstetric procedures and the tendency that clinicians often use regional anesthesia for sicker patients. Other studies did not find an adverse effect of regional anesthesia. Theoretically, regional anesthesia, especially when used with epinephrine, may produce a compensatory vasoconstriction in the nonblocked area, but this has not been supported in the literature. Yaster et al. found that epidural analgesia markedly improved oxygenation in children in vaso-occlusive crises, either through superior pain control or

opioid sparing effects. Therefore, almost any anesthetic technique can be used, provided the following principles are considered:

- Good intravenous access for maintenance of intravascular volume
- Adequate oxygenation
- Denitrogenation before induction of general anesthesia
- Endotracheal intubation for general anesthesia to ensure a controlled airway and adequate ventilation
- Maintenance of adequate oxygen-carrying capacity through judicious use of red cell transfusions
- Maintenance of normothermia
- Opioids for analgesia carefully titrated for perioperative and postoperative analgesia
- Avoidance of tourniquet use
- Considering regional analgesia for both intraoperative and postoperative courses
- Avoidance of hypotension and venous stasis to prevent sickling of red blood cells
- Considering invasive monitoring (arterial line, central venous pressure line) for beat-to-beat blood pressure monitoring, volume monitoring, and frequent laboratory test
- Avoidance of hypoventilation of lungs to prevent acidosis
- Possible increased inspired oxygen concentration to ensure maintenance of normal to increased Pa_{O_2}

C.2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.

SCA is a disease that can affect every end organ. Therefore, evaluating the patient for end-organ dysfunction is paramount. This patient is anemic, tachycardic, and hypertensive. She may have dyspepsia, a hyperreactive airway, chronic renal insufficiency, and liver disease and might be debilitated with cardiopulmonary complications. Patients with SCD often present with cardiomegaly, pulmonary hypertension, and heart failure. For this surgery, she will probably require transfusions and may be difficult to crossmatch. In the postoperative period, pulmonary infarcts and infection are common, which can lead to acute chest syndrome. These problems, in addition to the potential for sickling crisis or sequestration syndrome, pose a greater risk than normal for perioperative morbidity and mortality. The patients at greater risk include those with a homozygous state SCD, sickle C disease (HbSC), and sickle thalassemia. In contrast, patients with SCT do not present an increased risk for intraoperative morbidity. As a perioperative specialist, one can have a profound effect on outcome in these patients by attention to detail, with a multisystem approach to address all end-organ dysfunction to reduce morbidity by maintaining oxygen delivery and preventing ongoing sickling.

Firth PG. Anesthesia and hemoglobinopathies. *Anesthesiol Clin*. 2009;27:321–336.

Khurmi N, Gorlin A, Misra L. Perioperative considerations for patients with sickle cell disease: a narrative review. *Can J Anaesth*. 2017;64:860–869.

C.3. What precautions should one take to prevent sickling

in this patient?

Sickling of red blood cells is triggered by a variety of factors. One should avoid or correct factors that can precipitate sickling. Special precautions include the following:

- Avoid hypoxia by preoxygenating the patient and employing higher than usual concentrations of inspired oxygen.
- Prevent acidosis by maintaining adequate oxygenation, normovolemia, and cardiac output.
- Prevent respiratory acidosis by avoiding hypoventilation.
- Prevent stasis. This requires proper hydration and good regional blood flow. Blood viscosity should be maintained at a low level by limiting a rise in hematocrit to 35% and avoiding over transfusion.
- Avoid hypovolemia.
- Avoid hypothermia by using body warming and intravenous fluid warming devices perioperatively.
- Replace blood loss to prevent anemia.
- The use of tourniquets is controversial. Some advise against the use of tourniquets, although they have been used without ill effects by others. If a tourniquet is to be used, it should only be used when absolutely necessary and for a short period as possible. Special attention should be paid to maintain adequate oxygenation and to prevent respiratory or metabolic acidosis at the time of tourniquet release.

C.4. Discuss what issues or concerns should be brought up by the team during the debrief at the conclusion of

the case. What would you sign-out to the postanesthesia care unit (PACU) staff?

Checklist, surgical time outs, and a postoperative debrief are all ways to improve patient safety by creating an environment where there is team involvement and communication is enhanced not diminished. They promote collaborative information sharing by pausing to allow the team as a whole to address both positive aspects of the case and to address deficiencies and areas for improvement in a nonpunitive way. Operating room efficiency, patient safety, and the opportunity to learn from each case is improved. For a patient with SCD who underwent a total hip arthroplasty (THA), the postoperative concerns include pain control, adequate hydration, cardiopulmonary monitoring, and hematologic monitoring. Early ambulation, incentive spirometry, supplemental oxygen, multimodal analgesia, and laboratory evaluation of hematocrit and renal function is paramount until the patient is stable from a multiorgan stand point. The sign-out to the PACU should include all of these concerns and any issues that have happened preoperatively, intraoperatively, or may occur postoperatively.

D. Postoperative Management

D.1. Discuss the postoperative management of this patient. What opioid sparing techniques can you use

and discuss a multimodal analgesic plan?

The postoperative period is a crucial time with SCD. Surgical pain, hypoventilation, a high incidence of pulmonary infarction, and an expected decrease in Pa_{O_2} will predispose these patients to the formation of sickle cells, leading to the possibility of developing vaso-occlusive crisis or acute chest syndrome. The mainstay of postoperative management is supportive and preventive care. Supplemental oxygen, maintenance of intravascular fluid volume, maintenance of normothermia, glycemic control, blood transfusion management, and adequate analgesia are important considerations. There is evidence suggesting that patients with SCD have an altered pain response and both intravenous patient-controlled analgesia and epidural patient-controlled analgesia has been shown to improve postoperative pain control. However, regional analgesia has been shown to decrease pain scores while improving oxygenation. A multimodal analgesia approach to pain control is paramount, which improves patient recovery and reduces reliance on opioids. Supportive and preventive care should be continued in the extended postoperative period. The basic outline of routine postoperative care includes the following:

- Early mobilization
- Maintenance of normothermia
- Supplemental oxygenation
- Early effective multimodal analgesia or adjunctive analgesic should be continued in the extended postoperative period, pregabalin.
- Maintain euvolemia.
- Conservative transfusion therapy and Hgb management
- Incentive spirometry
- Pulse oximetry
- Pulmonary monitoring
- Psychological support

- Considering extended postoperative cardiovascular monitoring
- Considering regional analgesia for postoperative pain management

D.2. What complications might occur in this patient in the immediate postoperative period?

The postoperative complications most likely to occur in the patient with SCD include deep vein thrombosis, vaso-occlusive crisis, pulmonary infarction, acute chest syndrome, and infection. Hypoxemic episodes are always a threat in the postoperative period secondary to pain, splinting, or oversedation and can precipitate a sickling crisis. The incidence of postoperative respiratory infection is high and is a leading cause of morbidity and mortality. Acute chest syndrome is one of the most common causes of death in adult patients and is a potentially lethal postoperative complication in patients with SCD who undergo major or high-risk surgery. Sequestration syndrome with shock is another potentially lethal complication, especially in the obstetric patient immediately postpartum. Patients with cardiomegaly and pulmonary hypertension are susceptible to heart failure. Renal and hepatic dysfunction may result in prolongation of the effects of certain medications. Orthopedic patients with SCD are at risk for deep vein thrombosis, acute thrombosis, and pulmonary embolism. Antithrombotic therapy has to be geared toward decreasing this

common complication.

D.3. What is the treatment of sickle cell crisis?

The treatment of sickle cell crisis is to break the vicious cycle of sickling, ischemia, infarction, pain, and end-organ failure. An aggressive multimodal approach can reduce the clinical symptoms of the crises. The principles of treatment of painful sickle cell crisis include the following:

- Rest
- Hydration
- Oxygen therapy
- Treatment of infection
- Analgesics (consider patient-controlled analgesia)
- Considering regional analgesia
- Transfusion to reduce the Hgb SS disease concentration
- Incentive spirometry
- Maintenance of normothermia

D.4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?

Hyperbaric oxygen has been used empirically in some institutions for treatment of acute sickle cell crisis, although it is

not widely available. Although some published reports claim instant improvement of symptoms, others have failed to show beneficial effects. There is better evidence that therapy is useful in management of ischemic disorders of the anterior segment of the eye or in chronic leg ulcers. Studies have shown no apparent effects of hyperbaric oxygen on sickle cell morphology in vitro. It appears, then, that its reported benefit in vivo may be due to a decrease in the rate of sickling or improved tissue oxygenation by direct diffusion. Although case series have supported its use, there is not enough evidence to recommend its routine use over conventional therapy.

SECTION 9 Eye, Ear, Nose, and Throat

33 Airway Trauma

Richard P. Dutton and LaRita Yvette Fouchè-Weber

A 46-year-old man was thrown from his motorcycle at a high rate of speed and impaled in the base of the neck by a tree branch. At presentation to the trauma center, he is awake and alert with a heart rate (HR) of 122 beats per minute, blood pressure of 143/85 mmHg, respiratory rate of 20 breaths per minute, and oxygen saturation of 98% on 100% nonrebreathing mask. There is a 5-cm-wide piece of wood protruding from his anterior lower neck at the sternal notch, without visible bleeding. The patient is neurologically intact but admits to consuming six beers in the hours before injury. His medical history is unremarkable.

A. Medical Disease and Differential Diagnosis

1. What variables mitigate injury from motorcycle collisions?
2. What other significant trauma may be present?
3. How is the initial assessment of a trauma patient organized?

4. How would you evaluate airway and breathing?
5. How would you evaluate the circulation?
6. How would you evaluate mental status and neurologic condition?
7. What diagnostic tests are indicated for this patient based on the mechanism of injury?
8. What are the zones of the neck, and what is their clinical significance?
9. What immediate treatment is necessary before diagnostic studies?
10. When and where should the impaling object be removed?

B. Preoperative Evaluation and Preparation

1. What laboratory tests would you want?
2. What x-ray studies are most important to the anesthesiologist?
3. Is an electrocardiogram (ECG) necessary?
4. Should this patient be intubated before going for computed tomography (CT) scanning?
5. When and where should this patient's airway be managed?
6. Are any prophylactic medications indicated?

C. Intraoperative Management

1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?
2. What is the surgical approach to a zone I neck injury?
3. Is the patient likely to require tube thoracostomy? Should this be placed before managing the airway?
4. What are the options for managing this patient's airway?
5. What are the risks of rapid sequence induction in this patient?
6. What anesthetic agents would you use for a rapid sequence induction?
7. How can you minimize the risk of exacerbating cervical spine trauma?
8. How can you minimize the risks of aspiration?

9. How would you anesthetize the airway for an awake intubation?
10. What are the risks of awake fiberoptic intubation?
11. If the patient cannot be ventilated, what options are available?
12. Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?
13. What surgical airway options are available in this case?
14. What maintenance anesthetics are indicated or contraindicated in this patient?
15. What complications will the surgical plan introduce?

D. Postoperative Management

1. What are the criteria for extubation?
2. What techniques may be used during extubation?
3. How does alcohol abuse affect postoperative management?
4. What pain medication should be used?

A. Medical Disease and Differential Diagnosis

A.1. What variables mitigate injury from motorcycle collisions?

Trauma involving motorcycles accounts for 2% to 5% of all motor vehicle trauma, but there is a higher proportion of death and serious injury because of the relative exposure of the motorcycle rider to the environment. Factors such as youth, high speed, and intoxication contribute to motorcycle collisions just as they do for automobiles. Motorcycle riders also are much more susceptible to factors beyond their own control, such as lack of vigilance on the part of automobile and truck drivers, road conditions (oil or debris), and the weather.

Factors that can reduce the seriousness of motorcycle collisions when they do occur include helmets and protective clothing. Reenactment of a mandatory helmet law in the state of

Washington in 1990 resulted in a decline in serious brain injury in motorcycle trauma victims from 20% to 9% and a reduction in mortality from 10% to 6%. Full leather or synthetic "armor" reduces the risk of massive skin and soft-tissue injuries in the event of a high-speed collision.

Liu BC, Ivers R, Norton R, et al. Helmets for preventing injury in motorcycle riders. *Cochrane Database Syst Rev*. 2008;(1):CD004333.

Meredith L, Brown J, Ivers R, et al. Distribution and type of crash damage to motorcyclists' clothing: validation of the zone approach in the European Standard for motorcycle protective clothing, EN13595. *Traffic Inj Prev*. 2014;15(5):501–507.

A.2. What other significant trauma may be present?

Motorcycle collisions are high-energy trauma that can result in injury to any organ system or region of the body. This patient will need a complete head-to-toe assessment and a number of diagnostic studies to establish the full extent of injury. Common injuries in motorcyclists include brain trauma from direct impact with the road and with other vehicles, pelvic fractures from impact with the frame of the motorcycle, abdominal trauma from impact with the handlebars, and lower extremity orthopedic and soft tissue trauma from impact with the road.

A.3. How is the initial assessment of a trauma patient organized?

The initial management of trauma patients is best described by the tenets of the Advanced Trauma Life Support (ATLS) course, written by the American College of Surgeons Committee on Trauma. This course provides a unified philosophy and common language to organize practitioners from different specialties in the care of complex patients with the potential for multiple injuries. Assessment of the seriously injured patient begins with the ABCs: *A*irway, *B*reathing, and *C*irculation; followed by a brief neurologic examination and a catalogue of visible injuries.

This "primary survey" is followed by diagnostic testing and a more detailed secondary survey to discover all of the patient's injuries. Despite the revision of this assessment in the combat and disaster setting, ATLS continues to support prioritizing the rapid assessment and treatment of life-threatening airway and breathing problems ahead of circulation problems. No evidence-based data were identified that justified a modification to this approach in the care of civilian patients. One important principle of ATLS is interruption of the diagnostic sequence as necessary to provide lifesaving resuscitative care, up to and including surgery for airway management or hemorrhage control prior to completion of diagnostic studies.

American College of Surgeons. *Advanced Trauma Life Support*. 10th ed. Chicago: American College of Surgeons; 2018:2–21.

A.4. How would you evaluate airway and breathing?

On first contact with the patient, the provider should attempt verbal communication: "How are you?" A patient who answers coherently in a normal voice has no immediate airway issue, adequate circulatory function, and minimal traumatic brain injury. In an unconscious patient, initial assessment is by looking, listening, and feeling for airflow. If airflow is absent, the airway should be opened by jaw thrust (*not* head tilt because this may exacerbate a cervical spinal column injury), cleared of any visible foreign bodies or secretions, and should have the placement of an oral or nasopharyngeal airway.

Breathing is assessed by observation of the chest wall and diaphragm once the airway is open and by immediate placement of a pulse oximeter probe. Patients who are not breathing adequately should be assisted with bag-valve-mask ventilation while preparations are made for securing a definitive airway and instituting mechanical ventilation.

A.5. How would you evaluate the circulation?

Initial assessment for shock is by vital signs (HR, blood pressure, pulse oximetry) and physical examination (pallor, diaphoresis, peripheral circulation, visible or suspected hemorrhage). Mental status is also a useful sign; the patient in hemorrhagic shock will be first agitated and then lethargic. Young patients have significant compensatory reserves and will maintain a normal systolic blood pressure even in the face of hemorrhage as great as 40% of their blood volume. This state of compensated shock can be diagnosed by a narrowed pulse pressure (especially on automated sphygmomanometers), elevated HR, pallor, abnormal lactate, and a base deficit. Shock in this patient could be the result of hemorrhage from chest or abdominal trauma (including a great vessel injury associated with the impalement) or tension pneumothorax in either side of the chest.

American College of Surgeons. *Advanced Trauma Life Support*. 10th ed. Chicago: American College of Surgeons; 2018:2–21.

Dutton RP. Initial resuscitation of the hemorrhaging patient. In: Spiess B, Spence R, Shander A, eds. *Perioperative Transfusion Medicine*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:289–300.

Glorsky SL, Wonderlich DA, Goei AD. Evaluation and management of the trauma patient for the interventional radiologist. *Semin Intervent Radiol*. 2010;27(1):29–37.

A.6. How would you evaluate mental status and neurologic condition?

The quick neurologic examination consists of questions to determine alertness and orientation (assuming the patient is responsive) followed by gross assessment of voluntary motion in all extremities. In the less responsive patient, the Glasgow Coma Score (GCS) (**Table 33.1**) is used to stratify the degree of

impairment: GCS 3 to 8 is a severe injury, GCS 9 to 13 is moderate traumatic brain injury, and GCS 14 to 15 is mild injury. Cranial nerve, spinal cord, and peripheral nervous system function is assessed by specific motor and sensory testing of each extremity during the secondary survey.

TABLE 33.1 Glasgow Coma Scores[a]

Eye-Opening Response	Verbal Response	Motor Response
4 = Spontaneous	5 = Oriented to name	6 = Follows commands
3 = To speech	4 = Confused	5 = Localizes to painful stimuli
2 = To pain	3 = Inappropriate speech	4 = Withdraws from painful stimuli
1 = None	2 = Incomprehensible sounds	3 = Abnormal flexion (decorticate posturing)
	1 = None	2 = Abnormal extension (decerebrate posturing)
		1 = None

[a]The Glasgow Coma Score is the sum of the best scores in each of three categories.

Teasdale G, Jennett B. Assessment of coma and impaired consciousness. A practical scale. *Lancet*. 1974;2:81–84.

A.7. What diagnostic tests are indicated for this patient based on the mechanism of injury?

Because of the high-energy mechanism of injury, this patient must be assessed from head to toe. Ultrasonography examination of the abdomen and chest is used to diagnose free peritoneal fluid, pneumothorax (in the hands of a skilled operator), and pericardial tamponade. Chest and pelvis plain-film radiography will reveal fractures, pneumothoraces, and hemothorax. CT scanning should include the head, neck, chest, abdomen, and pelvis; newer technology will allow for three-dimensional (3D) reconstructions of organs and vasculature with sensitivity and specificity equivalent to more traditional angiographic imaging.

This patient's obvious injury—to zone I of the neck—will

necessitate a focused assessment of the trachea, great vessels, esophagus, and bilateral pleural cavities. Traditionally, this has been accomplished by a combination of plain-film radiography, angiography, bronchoscopy, and esophagoscopy. Increasing CT speed and resolution as well as point-of-care ultrasonography is leading to the increased use of these tests at centers with experienced radiographers and traumatologists. The sequencing of diagnostic studies will depend on the patient's stability. In this case, he is likely to require intubation and perhaps exploratory surgery first. A noninvasive study such as contrast-enhanced CT (with angiographic reconstructions) may help to guide the surgical approach to removal of the impaling object if the patient is calm and stable enough to tolerate the test.

Wilson CT, Clebone A. Initial assessment and management of the trauma patient. In: Scher CS, ed. *Anesthesia for Trauma: New Evidence and New Challenges*. New York: Springer; 2014:1–15.

A.8. What are the zones of the neck, and what is their clinical significance?

Zone I of the neck includes the area from the inferior aspect of the cricoid cartilage down to the thoracic outlet. Zone I injuries require the complex diagnostic workup described in the previous section, followed by a surgical approach that allows access to both the neck and chest. Partial or complete median sternotomy is often necessary to access an injured great vessel or to repair the trachea or esophagus.

Zone II of the neck includes the area from the angle of the mandible down to the cricoid cartilage. Injuries in zone II are addressed through a lateral or transverse cervical incision, with the surgeon able to achieve both proximal and distal control of the carotid or jugular vessels before exploring the wound itself.

Zone III of the neck includes the area from the angle of the mandible upward to the base of the skull. Zone III vascular

injuries pose a significant operative risk because distal control of an injured vessel cannot be achieved. Injuries in zone III are therefore approached angiographically or as part of a more complex neurosurgical operation.

Britt LD, Weireter LJ, Cole FJ. Management of acute neck injuries. In: Feliciano DV, Mattox KL, Moore EE, eds. *Trauma*. 6th ed. New York: McGraw-Hill; 2008:467–478.

A.9. What immediate treatment is necessary before diagnostic studies?

The key to this case will be control of the patient's airway. Once hemodynamic stability is confirmed, the timing and sequence of diagnostic studies will be determined by the patient's degree of cooperation and ability to spontaneously ventilate. Although a CT scan before a controlled intubation in the operating room (OR) would be ideal, it is possible that the patient will decompensate before this can be accomplished. Preemptive airway control will allow for a more secure and safer diagnostic workup before the operation.

A.10. When and where should the impaling object be removed?

All things being equal, the impaling tree branch is best removed in the OR in an anesthetized patient. All of the personnel and equipment should be present to perform an emergent median sternotomy and major vascular and/or tracheal surgery if necessary.

B. Preoperative Evaluation and Preparation

B.1. What laboratory tests would you want?

The patient should have a full set of laboratory studies, both to identify abnormalities and to establish a baseline for future

changes. Hemoglobin and hematocrit will not indicate hemorrhage on the initial draw—the bleeding trauma patient is losing whole blood—but will drop with subsequent fluid resuscitation. Arterial blood gas and arterial or venous lactate measurement will be the most sensitive indicators of hypoperfusion and shock. Serum electrolytes will reveal baseline abnormalities, if any, and the effects of alcohol consumption and dehydration. Clotting studies are important to rule out congenital abnormalities or the effects of liver disease before what could be a major surgical procedure; coagulopathy at the time of trauma center admission is an indicator of substantial blood loss and severe hemorrhagic shock. Toxicology screening is indicated in every trauma patient and is important to rule out the use of drugs of abuse, such as heroin or cocaine, that have implications for the anesthesiologist.

Initial laboratory studies also should include a sample for the blood bank with the request for an urgent crossmatch of red blood cells and plasma. If there has been a major vascular injury, substantial blood loss is a possibility and should be treated with immediate transfusion of blood and coagulation factors.

American College of Surgeons. *Advanced Trauma Life Support*. 10th ed. Chicago: American College of Surgeons; 2018:2–21.

Hess JR, Lindell AL, Stansbury LG, et al. The prevalence of abnormal results of conventional coagulation tests on admission to a trauma center. *Transfusion*. 2009;49(1):34–39.

B.2. What x-ray studies are most important to the anesthesiologist?

Although all of the studies described in the preceding text will have some relevance, there are a few that have particular implications for the anesthesiologist. The chest radiograph and/or CT scan will suggest the degree of tracheal involvement

of the impaling object, the risk that there is of a major vascular injury, or the presence of a pneumothorax. Plain radiographs or a CT scan of the cervical spine will be useful in ruling out bony or ligamentous injury that might be exacerbated by manipulation of the neck during airway management.

B.3. Is an electrocardiogram (ECG) necessary?

In the absence of dysrhythmias on the cardiac monitor, the criteria for ordering a preoperative ECG are the same as in any other surgical candidate, that is, patients presenting with symptoms or with a history suggestive of coronary artery disease. Dysrhythmias or visible injury to the precordium would be an indication for a baseline ECG and cardiac enzyme assay.

B.4. Should this patient be intubated before going for computed tomography (CT) scanning?

The answer to this question involves an assessment of risks and benefits. If the patient is cooperative, vital signs are stable, CT scanner is close at hand, and anesthesia personnel are available to accompany the patient, then an immediate CT scan would be indicated. If the patient is deteriorating in any way, his degree of cooperation is in doubt, or a CT scan would place the patient far from expert resources for an extended period, then it would be wise to secure the airway first. In this case, there is a possibility that successful airway management will precipitate patient deterioration (e.g., hemorrhage, conversion from simple to tension pneumothorax), which suggests that if airway management is attempted before CT, it should probably be done in the OR with the surgical team on hand.

One approach to this kind of complex decision is to define an ideal course of care that provides the best information for each of the experts involved while minimizing risk to the patient and maximizing flexibility in dealing with changing circumstances. In this case, the surgeon and anesthesiologist might define a plan

that includes transport to the OR; induction, intubation, and mechanical ventilation in this (safest possible) environment; transport to CT or angiography with the anesthesiologist in attendance for diagnostic studies; and then return to the OR for definitive surgery.

B.5. When and where should this patient's airway be managed?

Because of the potential for rapid deterioration and the desire to examine the airway closely before and during the intubation process, the patient should be moved as rapidly as possible to the OR before airway management is attempted. The surgical team should be on hand from the start, and instruments should be available for video laryngoscopy and bronchoscopy, emergent tracheostomy, control of large vessel bleeding, and median sternotomy.

B.6. Are any prophylactic medications indicated?

Tetanus toxoid treatment is indicated for any trauma patient with an open wound who is more than 5 years removed from his or her last booster. Any patient with a significant open wound should receive prophylactic antibiotic therapy that covers gram-positive organisms for at least the first 24 hours following injury.

Prophylactic treatment to reduce the consequences of aspiration would be considered but probably rejected in this case. Promotility agents such as metoclopramide and histamine H_2-receptor antagonists such as ranitidine will not have time to work before definitive airway control is achieved and the more immediate approach of administering oral sodium citrate/citric acid (e.g. Bicitra) would be contraindicated because of the possibility of esophageal injury.

Because of the patient's history of intoxication, prophylactic

intravenous administration of vitamins and thiamine is indicated. Prophylaxis against alcohol withdrawal and deep venous thrombosis are indicated in the immediate postoperative period.

C. Intraoperative Management

C.1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?

Blood pressure, electrocardiography, capnography, and pulse oximetry should be employed as with any patient. A Foley catheter should be inserted once the patient is anesthetized, although urine output is not an accurate measure of intravascular volume status in a recently intoxicated patient. An arterial line is useful for moment-to-moment measurement of blood pressure and for easy access to blood for laboratory assay including arterial blood gases. A central venous catheter should be placed if there is need to monitor central venous intravascular volume, in anticipation of the need for rapid intravascular expansion (using a large-bore catheter such as a pulmonary artery introducer), and for the administration of vasoactive drugs. A pulmonary artery catheter is rarely indicated and seldom used acutely for resuscitation, although it *may* be helpful in selected patients with known coronary artery or valvular disease. Because of the potential for great vessel injury in this case, initial central access should be through the femoral vein.

Invasive monitoring lines usually are best placed after induction and intubation, when the patient is anesthetized and both surgeons and anesthesiologists can be working at the same time. Delaying surgical hemostasis in an unstable patient is unwise. In the case under discussion, it would be appropriate to place an arterial line in the OR before airway management, as

long as the patient remains cooperative and stable, and in this case to place a femoral central line thereafter. Placing the arterial line on the right side also will allow for assessment of blood flow in the innominate artery during surgical exploration.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2115–2155.

C.2. What is the surgical approach to a zone I neck injury?

In the present case, the surgery is likely to start with a collar incision through the impalement wound to allow for better visualization of the path of injury. If injury to the trachea or a great vessel is discovered, a partial or complete median sternotomy would be the next step. It is the uncertain nature of this patient's injuries that makes preoperative diagnostic information so valuable, which is why a CT scan before definitive surgery (but after airway management) is a strong consideration.

C.3. Is the patient likely to require tube thoracostomy? Should this be placed before managing the airway?

Pneumothorax and hemothorax are common in trauma patients and should be suspected and definitively ruled out following any high-energy blunt trauma (e.g., motor vehicle collision, pedestrian struck, fall from a height) or any penetrating trauma to the neck, thorax, or upper abdomen. Immediate temporizing needle decompression and/or tube thoracostomy are indicated in any hemodynamically unstable patient with a suspicious injury, even before chest radiograph. Intubation and the change to positive pressure ventilation may precipitate decompensation in a patient with chest injury, due to either decreased preload in the setting of hemorrhage or increased intrathoracic pressure caused by conversion from a simple to tension pneumothorax.

In this case, there is the possibility of pathology in either or both hemithoraces. A portable anterior-posterior chest radiograph should be obtained at the earliest moment, followed by CT of the chest as outlined previously. If a simple pneumothorax is present, it is most prudent to prepare for chest tube placement (personnel, equipment) before airway management but to wait until the airway is secure before actually placing the chest tube.

C.4. What are the options for managing this patient's airway?

Choices for induction of anesthesia should be considered in concert with choices for securing the airway and transitioning to positive pressure ventilation. Airway management can occur with the patient awake under topical anesthesia or asleep, with either a continued spontaneous ventilation (a "breathe down" induction with a volatile anesthetic) or an immediate transition to positive pressure, as in a rapid sequence induction.

C.5. What are the risks of rapid sequence induction in this patient?

Although most trauma patients are best managed with rapid sequence induction and intubation, this case may represent an exception. Swelling or bleeding in the airway may make intubation physically difficult and the impaling object itself may prevent distal passage of an endotracheal tube. Furthermore, dislodgment due to patient agitation or intubation attempts could precipitate hemorrhage or airway disruption. Finally, the transition from spontaneous to positive pressure ventilation could precipitate a tension pneumothorax.

Stephens CT, Kahntroff S, Dutton RP. The success of emergency endotracheal intubation in trauma patients: a 10-year experience at a major adult trauma referral center. *Anesth Analg*. 2009;109:866–872.

C.6. What anesthetic agents would you use for a rapid sequence induction?

Succinylcholine is the key component of a rapid sequence intubation (RSI). No other relaxant provides as consistently good intubating conditions as quickly and as reversibly as succinylcholine. The usual dose for a trauma patient is 1.5 mg per kg—somewhat greater than normal to compensate for a potentially lower cardiac output due to hemorrhage.

Because succinylcholine has no amnestic or analgesic properties, an induction sedative is also indicated in most patients. Any induction agent, including ketamine or etomidate, will precipitate hypotension in the hypovolemic patient with a high endogenous catecholamine level; so care with dosing is required. In young and previously healthy patients, sodium thiopental in a titrated dose from 1 to 5 mg per kg or propofol 0.5 to 2 mg per kg is effective and inexpensive. Etomidate (0.1 to 0.4 mg per kg) is a reasonable choice in elderly patients or in those with known cardiovascular disease.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2115–2155.

C.7. How can you minimize the risk of exacerbating cervical spine trauma?

Appropriate precautions must be taken to avoid worsening an occult spinal cord injury. In the worst case, fractures or ligamentous injury can leave the cervical spine so unstable that the normal manipulation of a direct laryngoscopy will injure the spinal cord. This is a low probability event but is of concern to the health care team because quadriplegia is a catastrophic complication.

Manual in-line cervical stabilization has been shown to be safe and effective in protecting the cervical spine over tens of thousands of direct laryngoscopies and is the common approach

to urgent intubations in the trauma population. Another option commonly used only in patients with known cervical instability is an awake intubation over a fiberoptic bronchoscope. This approach allows for the least manipulation of the neck but requires a cooperative patient who can tolerate the time required for topical anesthesia of the airway and a slower intubation. Awake fiberoptic intubation also may increase the risk of aspiration in patients with a full stomach, especially if topical anesthesia of the pharynx and vocal cords is provided.

Other intubation devices may also decrease the need for manipulation of the neck. Good results have been achieved with the newer generation of video laryngoscopes, lighted stylet intubations, and use of an intubating stylet with a less forceful laryngoscopy. Manual cervical stabilization is recommended with each of these approaches. In a difficult case such as the present one, the intubation technique chosen should be one that the anesthesiologist is experienced and comfortable with; this factor may be more relevant than the specific technology used.

Pierre EJ, McNeer RR, Shamir MY. Early management of the traumatized airway. *Anesthesiol Clin*. 2007;25(1):1–11.

C.8. How can you minimize the risks of aspiration?

Because any significant injury is associated with decreased gastrointestinal motility, all trauma patients are considered to have full stomachs. The risk of aspiration is further increased by intoxication with drugs or alcohol; obesity; the use of analgesics; and injuries to the face, neck, or abdomen that may lead to bleeding within the gastrointestinal tract.

Minimization of risk is a function of how quickly the

intubation must be accomplished. One component of prophylaxis is the normal use of rapid sequence induction to minimize the time during which the airway is at risk. Another is the use of cricoid pressure (the Sellick maneuver) to obstruct the upper esophagus against passive reflux, although recent magnetic resonance imaging research has shown significant variability in the relative anatomy of the cricoid ring and the esophagus, casting doubt on the efficacy of cricoid pressure. Application of cricoid pressure for patients undergoing RSI is controversial. Not only might cricoid pressure not be effective in preventing aspiration but also it may worsen laryngoscopic view and impair bag-valve-mask ventilation. Some experts think that cricoid pressure should be applied in trauma patients and patients at risk for aspiration; however, cricoid pressure, if necessary, should be altered or removed to facilitate intubation. In the case under consideration, there would be a risk of dislodging the impaling object, making cricoid pressure inadvisable. It would be reasonable to administer an H_2 antagonist such as cimetidine and a promotility agent such as metoclopramide if time allowed, but these agents would require 1 to 2 hours to have any substantial effect. An oral antacid is contraindicated because of the potential injury to the esophagus.

Stewart JC, Bhananker S, Ramaiah R. Rapid-sequence intubation and cricoid pressure. *Int J Crit Illn Inj Sci*. 2014;4(1):42–49.

C.9. How would you anesthetize the airway for an awake intubation?

Innervation of the airway can be separated into three neural pathways. If nasal intubation is planned, some method of anesthetizing maxillary branches from the trigeminal nerve is

required. Involvement of the posterior tongue will require blockade of the glossopharyngeal nerve. Structures more distal in the airway to the epiglottis will require blockade of vagal branches, with the superior laryngeal nerve supplying the pharyngeal apparatus and the recurrent laryngeal nerve supplying the vocal cord and the tracheal mucosa.

The trigeminal nerve, which supplies sensory innervation to the nasal mucosa, can be anesthetized by inserting a nasal airway lubricated with lidocaine jelly into the patent naris. Mixing the lidocaine jelly with oxymetazoline 0.05%, phenylephrine 10 mg, or 4% cocaine may help vasoconstrict the nasal blood vessels and diminish bleeding from the nasal mucosa. The liquid local anesthetic and vasoconstrictor may also be applied in droplet form from a syringe.

The glossopharyngeal nerves of interest are the tonsillar nerves, which provide sensation to the mucosa overlying the palatine tonsil and continuous parts of the soft palate, and the sensory branches to the posterior one-third of the tongue. First, one must provide topical intraoral anesthesia with local anesthetic spray or nebulized lidocaine. Following topical anesthesia of the tongue, the mouth is opened wide and the posterior tonsillar pillar (palatopharyngeal fold) is identified. Then, a 22-gauge needle can be inserted at the caudad portion of the tonsillar pillar. The needle tip is inserted submucosally and following careful aspiration for blood, 5 mL of 0.5% lidocaine is injected. The block is then repeated on the contralateral side. A similar block can be performed with direct application of anesthetic soaked cotton to the bilateral tonsillar fossae.

The vagus nerve supplies innervation to the mucosa of the airway from the level of the epiglottis to the distal airways through both the superior and recurrent laryngeal nerves. A superior laryngeal nerve block and a translaryngeal block can be useful in anesthetizing these pathways. With the patient lying

supine, the superior laryngeal block is done with a 22-gauge needle attached to a syringe, which is directed at the most posterior palpable part of the hyoid bone, near the greater cornu, and anterior to the carotid sheath. The needle must be parallel to the table and never directed posteriorly for fear of penetrating the carotid sheath. When the needle strikes the hyoid, it is carefully walked caudad until it just slips off the hyoid and then advanced a short distance through the hyothyroid membrane. Aspiration should produce nothing. Then, 2 mL of 2% lidocaine is injected and the block repeated on the opposite side.

The translaryngeal block is performed with a 20- or 22-gauge needle attached to a syringe. The needle is inserted through the cricothyroid membrane in the midline and air is aspirated. The patient is asked to inhale deeply and then to exhale fully. At the end of expiration, 4 mL of 2% to 4% lidocaine is injected rapidly and the needle is quickly removed. The resultant coughing will ensure a wide distribution of local anesthetic droplets throughout the airway. If stability of the cervical spine is in doubt, then in-line stabilization should be held while the block is performed and coughing occurs. In the present case, both superior laryngeal and transtracheal blocks would be difficult to perform, and induced coughing might exacerbate the injury. Administration of nebulized lidocaine might be a safer choice.

Gotta AW, Sullivan CA. Anaesthesia of the upper airway using topical anaesthetic and superior laryngeal nerve block. *Br J Anaesth*. 1981;53:1055–1058.

C.10. What are the risks of awake fiberoptic intubation?

The greatest risk of awake fiberoptic intubation is deterioration of the patient's airway and/or mental status during the

procedure. Ineffective topical anesthesia can lead to agitation and combativeness, which in turn leads to increased use of intravenous sedatives. Blood and secretions in the airway can cause coughing, laryngospasm, or aspiration. Oversedation causes respiratory depression and desaturation, which can pressure the anesthesia providers and lead to hasty decisions. More uncommon complications include injury to nerves or vessels during local nerve blocks, toxicity from local anesthesia ingestion, and direct injury to the laryngeal or pharyngeal mucosa.

This particular case also includes the possibility of inadvertent dislodgment of the impaling tree branch during sedation and topicalization or during the intubation effort itself. Bleeding from a loss of tamponade or open disruption of the airway could necessitate a sudden change in anesthetic and surgical plans. Although awake fiberoptic intubation in the OR is a reasonable starting point for this case, the anesthesiologists and surgeons involved must be prepared for other eventualities. These would include both RSI and emergency surgical airway access.

C.11. If the patient cannot be ventilated, what options are available?

Failure of awake fiberoptic intubation in this case should be followed by an immediate attempt at RSI. If RSI is not possible and the patient cannot be ventilated by mask or LMA, then a surgical airway may be required. An alternate technique involves placing a 14-gauge catheter over a needle through the cricothyroid membrane, removing the needle and using the catheter for jet ventilation. This technique provides a temporary route for oxygenation, as a bridge to a surgical airway, but is highly tenuous. Kinking or dislodgment of the jet catheter is common complications, with tension pneumothorax a possibility

if the catheter tip is displaced into the paratracheal tissues. In this case, accessibility to the trachea or cricoid cartilage may be difficult or impossible due to the impaling object.

Benumof JL, Scheller MS. The importance of transtracheal jet ventilation in the management of the difficult airway. *Anesthesiology*. 1989;71:769–778.

C.12. Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?

Although an LMA or other supraglottic airway support device is often a great help in the difficult airway algorithm, this case may represent an exception. Establishing an efficient mask airway is beneficial if the cause of patient distress is neurologic (diminished respiratory drive due to anesthesia or traumatic brain injury) or related to pharyngeal anatomy (obstruction after muscle relaxation). Supraglottic ventilation will not help with more distal causes of airway obstruction, such as laryngospasm, tracheal disruption, or massive aspiration. Although an LMA or equivalent device should be on hand when this patient is brought to the OR, it is less likely to be of use.

C.13. What surgical airway options are available in this case?

As with the LMA, surgical airway access is beneficial when the cause of airway obstruction is proximal to the intervention. Cricothyroidotomy—the fastest and most readily performed surgical airway procedure—is therefore of benefit in patients who cannot be intubated and have airway obstruction involving the pharynx or larynx. This procedure may be accomplished by surgical opening of the cricothyroid membrane and placing an endotracheal tube into the trachea. Operative cricothyrotomy can be performed more rapidly than conventional tracheostomy; however, it is more traumatic to the larynx, and the cricothyrotomy tube should be removed after 24 hours. If the

patient cannot be decannulated at this time, a conventional tracheostomy should replace the cricothyrotomy.

Tracheostomy, performed lower in the airway, requires more extensive surgical dissection, takes longer, and carries a greater risk of hemorrhage secondary to thyroid tissue trauma. Surgical access to the lower trachea might be necessary in the present case if the impaling object has transected or significantly disrupted the airway. This would be accomplished essentially through the wound itself but would require a partial or complete median sternotomy and the full resources of the OR.

Britt LD, Weireter LJ, Cole FJ. Management of acute neck injuries. In: Feliciano DV, Mattox KL, Moore EE, eds. *Trauma*. 6th ed. New York: McGraw-Hill; 2008:467–478.

C.14. What maintenance anesthetics are indicated or contraindicated in this patient?

If the initial awake fiberoptic examination of the trachea (at the time of intubation) rules out an airway injury, then muscle relaxation to facilitate surgical exploration would be appropriate for the duration of the case. Any of the commonly used intermediate-acting nondepolarizing relaxants could be used. If an airway injury is present, then management of the patient using inhalational anesthesia alone, with continued spontaneous ventilation, offers additional security in the event of airway discontinuity during the course of surgical repair. Sevoflurane, because of its greater palatability, is the easiest volatile anesthetic to administer without interrupting the patient's ventilation. Care must be taken to ensure adequate fluid volume replacement during a pure inhalational anesthetic because hemodynamic instability is possible. Nitrous oxide is contraindicated when the potential for pneumothorax exists or when airway continuity is in doubt.

Narcotics certainly will be required for postoperative

analgesia and may offer some intraoperative advantages as well. Once airway patency is assured, a narcotic-based anesthetic provides for the lowest level of circulating catecholamines, making it easier to assess and manage fluid resuscitation. The usual concern with delayed emergence in a patient receiving a large dose of narcotics is not relevant in this case because the patient will most likely require postoperative mechanical ventilation. The only caveat to intraoperative narcotics is the potential need to sustain spontaneous ventilation while the airway is assessed; narcotic administration should, therefore, be delayed until the anesthetic and surgical plans have become clear.

C.15. What complications will the surgical plan introduce?

Maintenance of homeostasis in the face of surgical provocations is the theme of many anesthetics, and the present case is no exception. At some point—ideally after anesthetic induction, successful airway management, and placement of lines and monitors—the impaling object is going to be removed from the patient's neck. Blunt object impalements in patients seen alive in the trauma center may produce less organ-specific damage than predicted from the location and course of the injury due to the ability of mobile anatomic structures to deform away from low-speed penetrations. Even so, it is entirely possible that this object has injured one of the great vessels or the trachea and that removing it might lead to torrential bleeding or significant disruption of the airway. The anesthesia team must be prepared to change course rapidly from a spontaneous breathing inhalational approach (assuming that airway continuity is the initial concern) to a hemodynamically friendly narcotic-based approach if blood loss and hemorrhagic shock become the major issue. An open team discussion of both surgical and anesthetic plans, including likely contingencies, is highly recommended

before beginning definitive treatment.

Dutton RP. Shock management. In: Smith CE, ed. *Trauma Anesthesia*. 2nd ed. Cambridge, United Kingdom: Cambridge University Press; 2015:65–78.

D. Postoperative Management

D.1. What are the criteria for extubation?

Assuming that the case goes well and the patient's anatomic injuries are successfully repaired, it is appropriate to consider emergence and extubation when the following criteria are satisfied:

- Hemodynamic stability with complete cessation of bleeding and normal systemic coagulation
- Adequate respiratory drive and reserve including complete return of neuromuscular function and minimal requirement for ventilator support
- Acceptable mental status. The patient should be calm, cooperative, comfortable, not overly sedated, and recovered from acute intoxication. The patient should be able to follow commands.
- Evidence of airway patency. Edema at the site of injury will not be an issue with an endotracheal tube in place but might obstruct the airway quickly following extubation. Although not 100% predictive, the presence of an air leak around the endotracheal tube when the cuff is deflated is very reassuring.
- Completion of the diagnostic workup for high-energy trauma, including indicated CT scans, laboratory studies, and completion of all procedures that are likely to require general anesthesia. It would be poor judgment to extubate the patient after tracheal repair only to have the orthopedic surgeons schedule him for urgent pelvic surgery.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed.

Philadelphia, PA: Elsevier; 2020:2115–2155.

D.2. What techniques may be used during extubation?

The best results from extubation will be achieved when the patient is most calm and comfortable and when the extubation itself is as nonstimulating as possible. The appropriate level of sedation and analgesia is a complicated, controversial, and very important question. Sedative agents, such as benzodiazepines and propofol, will diminish the patient's respiratory drive, cooperation, and ability to protect the airway and should be minimized. The right level of narcotics, on the other hand, will allow for a comfortable patient with diminished airway reactivity who can open his or her eyes and follow commands but is not otherwise distressed by the endotracheal tube or ventilator. The endotracheal tube should be suctioned ahead of time, and extubation deferred if there are copious secretions. Enough time should be allowed after suctioning for the stimulation to pass and the patient to relax. The posterior pharynx is then suctioned, the patient is asked to inhale deeply, the cuff is deflated, and the endotracheal tube is removed in one swift motion as the patient exhales.

The airway is in jeopardy immediately after extubation because edema and secretions may compromise respiratory function. Continuous pulse oximetry in a monitored setting is required, and humidified oxygen should be administered for 24 hours postextubation.

D.3. How does alcohol abuse affect postoperative management?

Symptomatic withdrawal from alcohol usually occurs within 24 hours and manifests as agitation, tachycardia, and hypertension. Delirium tremens can occur thereafter if prophylactic therapy is not initiated. Prophylaxis should consist of a small basal dose of benzodiazepines or a low-dose intravenous alcohol infusion,

with frequent assessment of mental status and the willingness to provide supplemental short-acting benzodiazepines if symptoms develop. The plan for delirium tremens prophylaxis should be coordinated with the pain management plan, ideally under the direction of a single individual, to provide for overall consistency and to avoid oversedation and respiratory arrest secondary to polypharmaceutical administration.

D.4. What pain medication should be used?

Postoperative analgesia in this case will depend on the extent of the surgical procedure and on the individual tolerance of the patient. Soft-tissue exploration of the neck, including surgery on the trachea or major vessels, requires relatively little postoperative analgesia. Titrated intravenous narcotics can be used in the first 24 hours with a rapid transition to an oral narcotic/acetaminophen preparation thereafter. Median sternotomy or other significant extension of the surgery into the chest will necessitate more intensive postoperative analgesia, including a continuous narcotic infusion while the patient remains intubated, followed by intravenous patient-controlled analgesia after emergence and extubation. Nonsteroidal anti-inflammatory drugs are an appropriate adjuvant therapy once the risk of traumatic hemorrhage is past.

34 Open-Eye Injury and Cataract Surgery

Alaeldin A. Darwich

A 28-year-old, otherwise, healthy man presented to the emergency room with a fishhook embedded in his eye. He ate a full meal just before the fishing accident.

A. Medical Disease and Differential Diagnosis

1. Why is this patient a particular challenge to the anesthesiologist?
2. What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?
3. How is aqueous humor formed and eliminated?
4. How is IOP affected by arterial P_{CO_2}, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?
5. What is the role of the central nervous system (CNS) on IOP?
6. What is glaucoma?
7. Is atropine contraindicated in patients with glaucoma?
8. How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic agents decrease IOP?
9. Are carbonic anhydrase inhibitors or osmotic diuretics indicated in open-globe injuries?

10. Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?

B. Preoperative Evaluation and Preparation

1. Is an open-globe injury always a surgical emergency?
2. What preoperative evaluation would you require?
3. The patient ate shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics to empty the stomach?
4. Could this case be done with topical anesthesia or a retrobulbar block?
5. How would you premedicate this patient?

C. Intraoperative Management

1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?
2. Will you intubate this patient? Would you consider a laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?
3. Would you consider an awake intubation?
4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?
5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?
6. How do nondepolarizing muscle relaxants affect IOP?
7. How will you perform a rapid sequence induction and intubation without using succinylcholine?
8. What are the effects of ketamine on the eye?
9. Would you consider the use of etomidate as an induction agent? What about propofol?
10. How do inhalation agents affect IOP and by what mechanism?
11. During the procedure, the patient's pulse suddenly dropped to

40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?

12. What are the afferent and efferent pathways of the OCR?
13. What factors contribute to the incidence of the OCR?
14. How do you diagnose and treat the OCR?
15. Is atropine useful for the OCR?
16. Can a retrobulbar block prevent the OCR? Is it appropriate in this patient?

D. Postoperative Management

1. Would you reverse the neuromuscular blockade in this patient?
2. Do reversal doses of atropine affect IOP?
3. What would you do before extubating this patient?
4. When would you extubate this patient?
5. The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?
6. Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?
7. What should you do when you suspect your patient might have a corneal abrasion?
8. A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?

A 77-year-old male is scheduled for cataract surgery. His medical history is significant for hypertension, diabetes mellitus type 2, chronic atrial fibrillation, coronary artery disease, and three coronary drug-eluding stents placed 5 years ago. He is on multiple medications related to his conditions.

E. Anesthesia for Cataract Surgery

1. What is a cataract?
2. What are the causes and risk factors of cataract formation?
3. How would you conduct the preoperative medical evaluation for a patient having cataract surgery?
4. What is the cardiac risk for this patient? If this patient is on anticoagulation and/or antiplatelet medications, should he stop or continue these medications?
5. What are the anesthetic options for cataract surgery?
6. What is the postoperative course after cataract surgery?

A. Medical Disease and Differential Diagnosis

A.1. Why is this patient a particular challenge to the anesthesiologist?

The combination of a full stomach and an open-globe injury presents a unique challenge to the anesthesiologist. In addition to the increased risk of aspiration of gastric contents, any drug or maneuver that raises IOP in the injured, open eye may cause extrusion of the vitreous humor and loss of vision when the globe is opened.

Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

A.2. What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?

IOP is determined by the balance between production and

drainage of aqueous humor, by changes in choroidal blood volume, and by vitreous volume and extraocular muscle tone. Resistance to outflow of aqueous humor in the trabecular tissue is probably the factor that maintains IOP within physiologic range, but the mechanism of homeostasis is unknown.

Normal IOP is 12 to 16 torr in the upright posture and increases by 2 to 4 torr in the supine position. IOP has been observed to nearly double in steep head-down position in the operating room.

When the globe is open, the IOP is lowered and may be as low as ambient pressure. The concern in this case is for the relative volume of choroid and vitreous humor within the eye. If this volume increases while the eye is open, the vitreous humor may be lost. Any deformation of the eye by external pressure in the globe may cause an increase in IOP.

A.3. How is aqueous humor formed and eliminated?

Aqueous humor is a clear fluid that occupies the anterior and posterior chambers of the eye. Its total volume is 0.3 mL. Aqueous humor is produced primarily by an active secretory process from the ciliary body in the posterior chambers at an equilibrium rate of 2 μL per minute. The aqueous humor then circulates through the pupil to the anterior chamber, passes through the trabeculated Fontana spaces, and enters the Schlemm canal. From here, the fluid drains into the episcleral veins and finally into the cavernous sinus or jugular venous systems (**Fig. 34.1**).

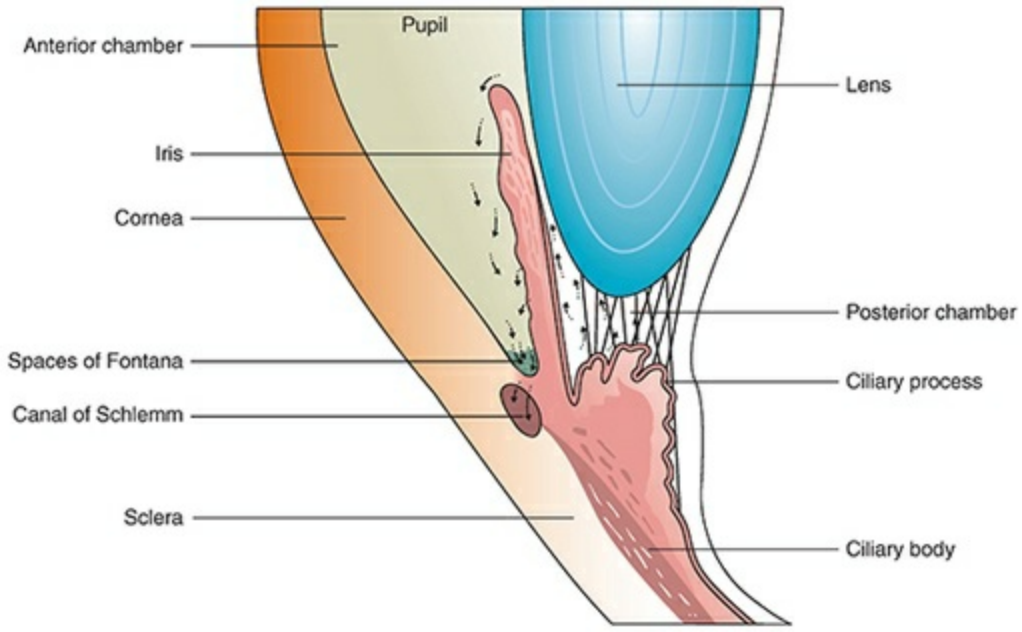

FIGURE 34.1. Sites of formation, circulation, and drainage of aqueous humor. (*Modified by permission from Springer: Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management*. Can Anaesth Soc J. *1986;33[2]:195–208. Copyright © 1986 Canadian Anesthesiologists.*)

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

A.4. How is IOP affected by arterial P_{CO_2}, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?

The choroidal arterioles vasodilate in response to hypercapnia and constrict during hypocapnia, thereby changing intraocular volume and pressure. However, the effect is minimal within the normal physiologic range of P_{CO_2}.

Minor fluctuations in arterial blood pressure also have minimal effects on IOP, although IOP may be seen to increase when hypertension is sustained and can fall significantly with induced hypotension. Changes in venous pressure, on the other hand, have a major impact on IOP. Vomiting, coughing, and bucking on the endotracheal tube cause a dramatic increase in IOP of 30 to 40 torr. These actions, and also a Valsalva

maneuver, cause congestion in the venous system, which impedes the outflow of aqueous humor and increases the volume of choroidal blood. A deep inspiration may reduce IOP by 5 torr. Hypoxemia may increase IOP through choroidal vasodilatation.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

A.5. What is the role of the central nervous system (CNS) on IOP?

The CNS influences IOP through alterations in extraocular muscle tone or, indirectly, by hormonal or hemodynamic changes.

Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

A.6. What is glaucoma?

Glaucoma is a pathologic elevation of IOP caused by an increased resistance to outflow of aqueous humor from the anterior chamber of the eye. It is classified as either open- or closed-angle glaucoma, depending on the anatomy and pathophysiology. Chronic elevation of IOP interferes with the intraocular blood supply and normal metabolism of the cornea. It can result in corneal opacities or decreased retinal blood flow.

The pathophysiology in open-angle glaucoma involves increased resistance to the flow of aqueous humor through the

Fontana spaces as a result of scarring of the trabecular network or thickening of the endothelial covering of these channels. In closed-angle glaucoma, the iris bulges forward blocking the access of aqueous humor to the trabecular network. This may occur with pupillary dilation or an acutely swollen lens.

LeMay M. Aspects of measurement in ophthalmology. *Br J Anaesth*. 1980;52:655–662.

A.7. Is atropine contraindicated in patients with glaucoma?

Topical atropine in the eye is generally contraindicated in patients with glaucoma, especially in those with closed-angle glaucoma. Atropine, studied in a single dose of 0.01 mg per kg intramuscularly (IM) or given orally as 0.6 mg in two doses 4 hours apart, caused no increase in IOP in either open- or closed-angle glaucoma because by calculation, only approximately 0.0001 mg reaches the eye, which is far less than a topical dose. Intravenous (IV) atropine is associated with mydriasis and might be contraindicated in patients with glaucoma; however, preemptive topical use of pupillary constrictors such as pilocarpine and timolol avoid this problem.

Schwartz B. Current concepts in ophthalmology: the glaucomas. *N Engl J Med*. 1978;299:182–184.

A.8. How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic

agents decrease IOP?

Carbonic anhydrase inhibitors, such as acetazolamide, interfere with the sodium-pump mechanism necessary for secretion of aqueous humor. An IV dose acts in 5 minutes, with maximal effect in 20 to 30 minutes. Chronic acetazolamide therapy may result in potassium depletion.

Osmotic agents, such as mannitol, increase plasma oncotic pressure relative to that of aqueous humor and produce an acute, transient drop in IOP. The maximum reduction in IOP occurs after 30 to 45 minutes, and the effect lasts 5 to 6 hours.

McGoldrick KE. Ocular drugs and anesthesia. *Int Anesthesiol Clin*. 1990;28(2):72–77.

A.9. Are carbonic anhydrase inhibitors or osmotic diuretics indicated in open-globe injuries?

No. If the globe is open, the IOP is low, and these agents are not useful. In addition, they may cause transient choroidal congestion, which could lead to loss of ocular contents.

Smith GB. *Ophthalmic Anaesthesia*. Baltimore: University Park Press; 1983.

A.10. Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?

Topical ophthalmic drugs may be absorbed through the conjunctiva or may drain through the nasolacrimal duct and be absorbed through the nasal mucosa. Absorption is increased when the eye is instrumented, diseased, or traumatized. Finger pressure on the inner canthus for a few minutes after instillation of eyedrops will impede absorption by occluding the nasolacrimal duct.

Usage of the following topical medications may have implications for the anesthesiologist:

Atropine

Atropine is used to produce mydriasis and cycloplegia. The 1% solution contains 0.2 to 0.5 mg of atropine per drop. Systemic reactions, seen primarily in children and older adults, include tachycardia, flushing, thirst, dry skin, and agitation. Atropine is contraindicated in closed-angle glaucoma.

Scopolamine

One drop of the 0.5% solution has 0.2 mg of scopolamine. CNS excitement can be treated with physostigmine, 0.015 mg per kg IV, repeated one or two times in a 15-minute period. Scopolamine is contraindicated in closed-angle glaucoma.

Cyclopentolate (Cyclogyl)

Cyclopentolate, a short-acting mydriatic and cycloplegic, may cause transient neurotoxic effects such as incoherence, visual hallucinations, slurred speech, ataxia, and seizures. It is contraindicated in closed-angle glaucoma.

Tropicamide (Mydriacyl)

Tropicamide is used to produce mydriasis for refraction or funduscopic examination. It may have CNS effects and can elevate IOP in closed-angle glaucoma.

Phenylephrine Hydrochloride (Neo-Synephrine)

Phenylephrine hydrochloride is used to produce capillary decongestion and pupillary dilatation. Applied to the cornea, phenylephrine hydrochloride can cause palpitations, nervousness, tachycardia, headache, nausea and vomiting, severe hypertension, reflex bradycardia, and subarachnoid hemorrhage. Solutions of 2.5%, 5%, and 10% (25 mg per mL, 50 mg per mL, and 100 mg per mL, respectively) are available.

There are 20 drops per mL. The dose is 1 drop per eye per hour of the 2.5% solution (children) or the 5% solution (adults).

Epinephrine

Topical 2% epinephrine will decrease aqueous secretion, improve outflow, and lower IOP in open-angle glaucoma. Side effects include hypertension, palpitations, fainting, pallor, and tachycardia. The effects last approximately 15 minutes. One drop of 2% solution contains 0.5 to 1 mg of epinephrine. Epinephrine 1:200,000 in a balanced salt solution is sometimes continuously infused into the anterior chamber during cataract surgery. Systemic effects may occur.

Timolol Maleate (Timoptic)

Timolol maleate is a β-blocker used in the treatment of chronic glaucoma. Side effects include light-headedness, fatigue, disorientation, depressed CNS function, and exacerbation of asthma. Bradycardia and bronchospasm may occur as well as potentiation of systemic β-blockers.

Betaxolol Hydrochloride (Betoptic)

Betaxolol HCl is a cardioselective (β_1) blocking agent used to treat glaucoma. It may be hazardous in patients with sinus bradycardia, heart block, or heart failure.

Acetylcholine

Acetylcholine may be injected intraoperatively into the anterior chamber to produce miosis. Side effects are due to its parasympathetic action and include hypotension, bradycardia, and bronchospasm. IV atropine is an effective treatment.

Echothiophate Iodide (Phospholine Iodide)

Echothiophate iodide, a cholinesterase inhibitor, is used as a miotic agent. It may prolong the effect of both succinylcholine and ester-type local anesthetics. Levels of pseudocholinesterase

decrease by 80% after 2 weeks on the drug. It takes 3 to 6 weeks to return to normal pseudocholinesterase activity after stopping the drug (4 weeks for return to 75% activity). Succinylcholine and ester-type local anesthetics should be avoided. Demecarium is another such cholinesterase inhibitor.

Cocaine

Cocaine is used to produce vasoconstriction and to shrink mucous membranes during dacryocystorhinostomy. One drop of 4% solution contains approximately 1.5 mg of cocaine, and the maximum dose is approximately 3 mg per kg. Systemic effects may be seen with a dose as low as 20 mg and involve the CNS, respiratory system, and cardiovascular system.

McGoldrick KE. Ocular drugs and anesthesia. *Int Anesthesiol Clin*. 1990;28(2):72–77.

B. Preoperative Evaluation and Preparation

B.1. Is an open-globe injury always a surgical emergency?

No. In most cases, surgery is not required immediately and some time may be spent in adequately preparing the patient for anesthesia and surgery. However, the surgery should probably be performed within 12 hours to minimize the possibility of infection and other complications. Delaying surgery for gastric emptying to occur is not reliable because gastric emptying may

be prolonged in this stressful situation.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2206.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin*. 2007;45:83–98.

B.2. What preoperative evaluation would you require?

An accurate, thorough history and physical examination are the best means of evaluating this patient preoperatively and should reveal any existing medical problems that will guide your selection of preoperative laboratory tests.

In this otherwise healthy young patient, no routine laboratory tests are indicated, unless required by the institution in which you are practicing. In cases where more extensive trauma is suspected, other injuries must also be addressed such as fractures to the skull and orbit, intracranial hemorrhage, and any other injuries suggested by the history and physical examination.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1381–1383.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2199.

B.3. The patient ate shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics to empty the stomach?

Absolutely not. These procedures are contraindicated when there has been a perforation of the eye. Gagging, vomiting, and straining could cause a potentially disastrous increase in IOP and extrusion of intraocular contents. A cough can increase central venous pressure and choroidal blood volume and may raise IOP by 34 to 40 torr.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin*. 2007;45:83–98.

B.4. Could this case be done with topical anesthesia or a retrobulbar block?

General anesthesia is the preferred technique for open-globe injuries. The patient is completely immobilized, and there is no time limit for the procedure. In this case, because the patient is not fasting, an endotracheal tube will guard against aspiration.

A retrobulbar or peribulbar injection has the potential to increase IOP because of the volume of local anesthetic used and the likelihood of the patient squeezing his eyes during the injection. However, there have been reports of blocks being used successfully for the repair of open-globe injuries. Topical anesthesia with IV sedation also has been used to repair the globe in select patients with limited injury when general anesthesia is contraindicated.

Boscia F, La Tegola MG, Columbo G, et al. Combined topical anesthesia and sedation for open-globe injuries in selected patients. *Ophthalmology*. 2003;110:1555–1559.

Lo MW, Chalfin S. Retrobulbar anesthesia for repair of ruptured globes. *Am J Ophthalmol*. 1997;123:833–835.

Scott IU, Mccabe CM, Flynn HW, et al. Local anesthesia with intravenous sedation for surgical repair of selected open globe injuries. *Am J Ophthalmol*. 2002;134:707–711.

B.5. How would you premedicate this patient?

Premedications should be given parenterally because gastrointestinal absorption is unreliable. Sedatives and anxiolytics may be given as necessary. Metoclopramide (0.15 mg per kg IM or IV) may be used to facilitate gastric emptying and to increase the tone of the cardiac, lower esophageal, sphincter. Narcotics should be used cautiously because they may

cause nausea and vomiting. Nonparticulate antacids and H_2 receptor antagonists (cimetidine 2 mg per kg IM) should be considered to reduce the risk of aspiration pneumonitis. IV ondansetron (0.1 mg per kg) can be given for antiemesis. Atropine or glycopyrrolate will be useful to reduce secretions and gastric acidity, and they may also inhibit the OCR.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1383.

Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

C. Intraoperative Management

C.1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?

Factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia include the following:

- Face mask pressing on the eyeball
- Increased pressure from coughing, straining, bucking, and head-down position
- Extraocular muscle spasm induced by depolarizing muscle relaxants or surgical stimulation during light anesthesia
- Poorly applied cricoid pressure that blocks venous drainage from the eye
- Choroidal congestion from hypercarbia, hypoxia, osmotic diuretics, intubation, or increases in blood pressure

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin*. 2007;45:83–98.

C.2. Will you intubate this patient? Would you consider a

laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?

It is imperative that this patient be intubated not only to maintain the airway, which is close to the surgical field, but also to avoid pressure by a face mask on the eyeball and to minimize the risk of aspiration. Although the laryngeal mask airway has been used successfully in ophthalmologic anesthesia, it is not appropriate in this case because it does not protect the airway from aspiration. Many studies have demonstrated a significant increase in IOP caused by laryngoscopy and intubation under varying states of anesthetic depth and muscle relaxation. IOP may be increased even when there is no visible reaction to intubation. This increase in IOP can be attenuated by topical laryngeal anesthesia and by increased depth of anesthesia to reduce coughing, straining, and increases in blood pressure. The cardiovascular response to intubation can also be reduced by IV lidocaine (1.5 mg per kg), β-blockers, α_2-agonists, or calcium channel blockers. Topical anesthesia of the larynx is not recommended in a full-stomach situation because of the increased risk of aspiration.

Akhtar TM, McMurray P, Kerr WJ, et al. A comparison of laryngeal mask airway with tracheal tube for intra-ocular ophthalmic surgery. *Anaesthesia*. 1992;47:668–671.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1383–1387.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

C.3. Would you consider an awake intubation?

Awake intubation is frequently accompanied by coughing and bucking and is risky in an open-globe injury when other safe methods of intubation are available. However, when dealing with a possible compromised airway or difficult intubation, an

awake fiberoptic intubation expertly done under careful sedation may be indicated to safely secure the airway.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin*. 2007;45:83–98.

C.4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?

The use of succinylcholine in open-globe injuries is controversial. In the intact eye, following thiopental induction, succinylcholine has been shown to increase IOP by 6 to 8 torr between 1 and 4 minutes after administration. Tracheal intubation further increases IOP. IOP returns to baseline in 5 to 7 minutes. In open-globe injuries, succinylcholine use has been associated with loss of ocular contents. The increase in IOP may be mediated by prolonged tonic contraction of the extraocular muscles, although IOP has been shown to rise after succinylcholine even when the extraocular muscles have been severed. Other factors that may be contributory include choroidal blood flow, increased central venous pressure, and increased resistance to outflow of aqueous humor resulting from the cycloplegic effects of succinylcholine.

The hemodynamic response to laryngoscopy or intubation may have a much more significant effect on IOP than succinylcholine alone. Simply blinking will raise the IOP in a normal eye by 10 to 15 torr, similar to the effect of succinylcholine. Pretreatment with nifedipine or lidocaine may attenuate the increase in IOP following succinylcholine and intubation.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in

contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

C.5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?

Available data are contradictory on this question, probably reflecting different methods of IOP measurement under varying depths of anesthesia with a variety of anesthetic adjuvant agents. Many techniques have been tried to prevent succinylcholine-induced elevation of IOP, and none has been consistently effective. However, there are no published reports of the loss of ocular contents when succinylcholine use has been preceded by pretreatment with a nondepolarizing relaxant and barbiturate for induction, and many anesthesiologists feel this is a safe combination for rapid sequence induction in the open-eye, full-stomach situation.

Bourke DL. Open eye injuries. *Anesthesiology*. 1985;63:727.

Calobrisi BL, Lebowitz P. Muscle relaxants and the open globe. *Int Anesthesiol Clin*. 1990;28(2):83–88.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

C.6. How do nondepolarizing muscle relaxants affect IOP?

Nondepolarizing muscle relaxants either decrease or have no effect on IOP.

Calobrisi BL, Lebowitz P. Muscle relaxants and the open globe. *Int Anesthesiol Clin*. 1990;28(2):83–88.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

C.7. How will you perform a rapid sequence induction and intubation without using succinylcholine?

The safety of the patient always must be the primary concern;

the preservation of the injured eye is secondary. Measures must be taken to guarantee adequate anesthetic depth and to blunt the hemodynamic responses to laryngoscopy and endotracheal intubation. Pretreatment measures such as narcotics, β-blockers, calcium channel blockers, lidocaine, or midazolam should be considered. Before induction, the patient should breathe 100% oxygen for several minutes, administered by a gently applied face mask. Anesthesia can then be induced using carefully applied cricoid pressure with IV methohexital (1 to 2 mg per kg) or propofol (2 to 3 mg per kg) and a nondepolarizing muscle relaxant. Several options exist:

- Atracurium (0.5 mg per kg) will allow safe intubation in 3 minutes. A larger bolus (1.5 mg per kg) will allow intubation in 60 to 90 seconds but may cause hypotension, tachycardia, and histamine release.
- Cisatracurium—because of its intermediate onset of action, cisatracurium (0.10 to 0.15 mg per kg) is not recommended for rapid sequence endotracheal intubations. Cisatracurium (0.4 mg per kg) 8 × effective dose (ED95) will allow intubation in 90 seconds without histamine release, but duration of action may exceed for 60 minutes. The ED95 is the amount of neuromuscular blocking agent (NMBA) required to reduce twitch height by 95%.
- Rocuronium in large dose (1.2 mg per kg) has been shown to create adequate intubating condition in 60 seconds. Sugammadex, in appropriate doses, can be used to effectively and quickly reverse the profound rocuronium blockade in case of difficult airway or short surgical time.
- Vecuronium (0.2 mg per kg) should provide adequate intubating conditions after 90 seconds.
- An alternative is to pretreat the patient with a small dose of the nondepolarizing relaxant several minutes before induction, which may shorten the onset of action and lessen

the dose required of subsequently administered relaxant. This has been referred to as a priming dose. Its use is controversial in that it may lead to diplopia, muscle weakness, respiratory distress, and aspiration while offering no definite advantage over the use of larger initial doses of nondepolarizing muscle relaxants. Whatever technique is selected, it is essential to monitor the degree of muscle relaxation with a neuromuscular blockade monitor. It is also possible to intubate the patient without any muscle relaxant at all after a deep level of anesthesia has been reached, but this is not a recommended technique. Not only is the airway unprotected for a long period but also prevention of bucking cannot be guaranteed, and positive pressure ventilation by face mask may exert pressure on the eye.

Disadvantages of use of a nondepolarizing NMBA include the risk of pulmonary aspiration of gastric contents during the longer period (compared to succinylcholine) when the airway is unprotected. Also, attempts to perform laryngoscopy and intubation prematurely, before full onset of neuromuscular blockade, may result in coughing and straining with a dramatic rise in IOP. For this reason, a peripheral nerve stimulator should be used to confirm muscle relaxation prior to laryngoscopy and endotracheal intubation when a nondepolarizing NMBA is used.

C.8. What are the effects of ketamine on the eye?

Ketamine may cause nystagmus and blepharospasm and is therefore not suitable for ophthalmic surgery. Studies with respect to the effect of ketamine on IOP have shown both increased and decreased IOP in children and no change in IOP in adults premedicated with diazepam and meperidine. This may depend on whether ketamine is administered through the IM or IV route.

Antal M, Mucsi G, Faludi A. Ketamine anesthesia and intraocular pressure. *Ann Ophthalmol*. 1978;10:1281–1289.

Peuler M, Glass DD, Arens JF. Ketamine and intraocular pressure. *Anesthesiology*. 1975;43(5):575–578.

C.9. Would you consider the use of etomidate as an induction agent? What about propofol?

Although etomidate has been associated with a decrease in IOP when used as an induction agent, the unpredictable incidence of generalized myoclonus seen with etomidate use and resultant elevation of IOP may preclude its use in open-globe injuries, unless rapid and complete prior muscle relaxation can be guaranteed. Propofol, with its antiemetic properties and ability to decrease IOP, would be an excellent choice for induction.

Kohli R, Ramsingh H, Makkad B. The anesthetic management of ocular trauma. *Int Anesthesiol Clin*. 2007;45:83–98.

C.10. How do inhalation agents affect IOP and by what mechanism?

Inhalation agents cause dose-related decreases in IOP as a consequence of the following:

- Reduced aqueous humor production
- Depression of the CNS control center
- Facilitation of aqueous humor outflow
- Decreased extraocular muscle tension
- Lowered arterial blood pressure

The degree of IOP reduction is proportional to the depth of anesthesia.

Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

Kelly DJ, Farrell SM. Physiology and role of intraocular pressure in contemporary anesthesia. *Anesth Analg*. 2018;126:1551–1562.

C.11. During the procedure, the patient's pulse suddenly dropped to 40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?

The OCR may be manifested by bradycardia, bigeminy, ectopy, nodal rhythms, atrioventricular block, and cardiac arrest. It is caused by traction on the extraocular muscles (especially medial

rectus), ocular manipulation, or manual pressure on the globe. The OCR is commonly seen during eye muscle surgery, detached retina repair, enucleation, or whenever there is extensive traction or rotation of the eyeball.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1379.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2196.

C.12. What are the afferent and efferent pathways of the OCR?

The OCR is trigeminovagal. The afferent pathway is by way of the ciliary ganglion to the ophthalmic division of the trigeminal nerve and through the gasserian ganglion to the main sensory nucleus in the fourth ventricle. The efferent pathway is the vagus nerve.

Adams AK, Jones RM. Anaesthesia for eye surgery: general considerations. *Br J Anaesth*. 1980;52:663–669.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1379.

C.13. What factors contribute to the incidence of the OCR?

Preoperative anxiety, light general anesthesia, hypoxia, hypercarbia, and increased vagal tone because of age or drugs are associated with an increased incidence of the OCR. The reported incidence of cardiac rhythm changes during eye muscle surgery is 32% to 82%. The incidence is higher in children.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2196.

C.14. How do you diagnose and treat the OCR?

- Monitor the electrocardiogram intraoperatively and during any eye manipulation.
- Stop the surgical stimulus immediately.

- Ensure that ventilation is adequate.
- Ensure sufficient anesthetic depth.

The OCR may fatigue with repeated stimulation.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2196.

C.15. Is atropine useful for the OCR?

Atropine use is controversial. Atropine, 0.4 mg IM, as a premedicant has no vagolytic effect after 60 minutes and is of no value in preventing or treating the OCR. Atropine, 0.4 mg IV, is effective for 30 minutes in preventing bradycardia associated with the OCR. Doses greater than 0.5 mg IV can cause tachycardia that may be detrimental in certain patients with heart disease. At least 2 to 3 mg is required to ensure a total vagal block.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2196.

C.16. Can a retrobulbar block prevent the OCR? Is it appropriate in this patient?

Retrobulbar block injection is not only unreliable in preventing the OCR but also may, during the injection, cause the OCR, a cardiac arrest, or a retrobulbar hemorrhage.

Local infiltration of the recti muscles and a delicate operating technique may decrease the incidence of the OCR. In this patient, a retrobulbar block is relatively contraindicated because it may increase IOP.

Allen ED, Elkington AR. Local anaesthesia and the eye. *Br J Anaesth*. 1980;52:689–694.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2196.

McGoldrick KE. Complications of regional anesthesia for ophthalmic surgery. *Yale J Biol Med*. 1993;66:443–445.

D. Postoperative Management

D.1. Would you reverse the neuromuscular blockade in this patient?

There is no contraindication to reversal provided that efforts are made to minimize coughing or bucking on the endotracheal tube.

D.2. Do reversal doses of atropine affect IOP?

Reversal doses of atropine, when given in conjunction with neostigmine, do not significantly alter IOP. This combination may be safely used even in patients with glaucoma.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1376–1377.

Cunningham AJ, Barry P. Intraocular pressure—physiology and implications for anaesthetic management. *Can Anaesth Soc J*. 1986;33:195–208.

D.3. What would you do before extubating this patient?

- Empty the stomach with an orogastric tube while the patient is still paralyzed.
- Suction the pharynx with the patient still paralyzed or deeply anesthetized.
- Give an antiemetic, such as ondansetron 0.1 mg per kg IV, 20 to 30 minutes before the end of surgery.
- Give lidocaine 1.5 mg per kg IV or remifentanil 0.5 to 0.8 μg per kg IV to prevent coughing during emergence.

Gefke K, Andersen LW, Friesel E. Lidocaine given intravenously as a suppressant of cough and laryngospasm in connection with extubation after tonsillectomy. *Acta Anaesthesiol Scand*. 1983;27:111–112.

D.4. When would you extubate this patient?

There may be a conflict between the desire to extubate awake because of the full stomach and the desire to extubate deep to prevent coughing and bucking. Because modern techniques of

eye repair involve minimal risk of suture disruption with coughing, one may extubate the patient awake, thereby protecting the airway.

D.5. The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?

General anesthesia decreases tear production and reduces normal mechanical eyelid closure. Corneal abrasions are the most common perioperative ocular injury, and this patient's complaints are consistent with that diagnosis.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1393.

Grixti A, Sadri M, Watts MT. Corneal protection during general anesthesia for nonocular surgery. *Ocul Surf*. 2013;11(2):109–118.

D.6. Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?

There is no guarantee that an eye that has been taped shut or lubricated will not sustain a corneal abrasion. Most anesthesiologists protect the eyes in some way; abrasions, however, still occur. Corneal abrasions represent the most common ophthalmic complication associated with general anesthesia. The incidence may be as high as 44% when no preventative measures have been taken and the cornea is exposed. The mechanism is thought to be drying of or direct trauma to exposed cornea. Possible contributing factors may be mask anesthesia; the prone, lateral, or Trendelenburg position; or having the patient's face in the surgical field.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1393.

Bronheim D, Abel M, Neustein S. Corneal abrasions following non-ophthalmic surgery: a retrospective view of 35,253 general anesthetics. *Anesthesiology*. 1995;83:A1071.

Nair PN, White E. Care of the eye during anaesthesia and intensive care. *Anaesth Intensive Care Med*. 2014;15(1):40–43.

D.7. What should you do when you suspect your patient might have a corneal abrasion?

Prompt consultation with an ophthalmologist should be solicited for precise diagnosis and treatment. The patient should be reassured that corneal abrasions usually heal and that relief of pain occurs within 24 to 48 hours. Possible treatments include eye patching and topical administration of antibiotics, short-acting cycloplegics, or anti-inflammatory agents. The use of eye patches is controversial.

A topical anesthetic for the cornea should never be given to a patient for self-administration. Misuse may cause delayed wound healing and keratopathy.

Hulbert MF. Efficacy of eyepad in corneal healing after corneal foreign body removal. *Lancet*. 1991;337:643.

Turner A, Rabiu M. Patching for corneal abrasion. *Cochrane Database Syst Rev*. 2006;(2):CD004764.

D.7. A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?

If a patient with intraocular gas needs to undergo general anesthesia before the gas bubble resorbs, nitrous oxide must be avoided because the gas will expand thereby increasing IOP. The effects on the eye may be disastrous. Various types of gases may be injected, with different durations. Patients are usually given bracelets to inform anesthesiologists that they have gas in their eye and nitrous oxide must be avoided.

E. Anesthesia for Cataract Surgery

E.1. What is a cataract?

A cataract is an opacity of the lens of the eye, which interferes with clear vision.

E.2. What are the causes and risk factors of cataract formation?

Aging is the most common cause of cataracts. Other risks factors that may be linked to cataract development are diabetes, hypertension, long-term steroid use (topical, systemic, oral, or inhaled), obesity, intraocular surgeries, smoking, exposure to ionizing radiation, and ultraviolet light.

Jacobs DS. Cataract in adults. https://www.uptodate.com/contents/cataract-in-adults. Accessed December 5, 2019.

E.3. How would you conduct the preoperative medical evaluation for a patient having cataract surgery?

The majority of cataract patients are elderly with chronic

multiple coexisting diseases. Cataract patients can proceed with their scheduled cataract surgery as long as their comorbidities are controlled. Routine preoperative testing before cataract surgery does not improve the outcome or patient safety and is not indicated. Medical history and physical examination should direct the need to order any test.

The evaluation should be focused on the patient's ability to understand and communicate because cataract surgery is done mostly under topical or regional anesthesia, and the patient needs to be still and cooperative. Any condition that interferes with maintaining supine position should be evaluated, for example, chronic obstructive pulmonary disease, congestive heart failure, or claustrophobia.

Mafi JN, Godoy-Travieso P, Wei E, et al. Evaluation of an intervention to reduce low-value preoperative care for patients undergoing cataract surgery at a safety-net health system. *JAMA Intern Med*. 2019;179:648–657.

E.4. What is the cardiac risk for this patient? If this patient is on anticoagulation and/or antiplatelet medications, should he stop or continue these medications?

Cataract surgery is a low-risk procedure. The risk of major adverse cardiac events or death is less than 1%.

Cataract surgery has a low risk of bleeding. Anticoagulants or aspirin may be continued in the perioperative period as their benefits outweigh the bleeding risks in most cases.

Chen CL, Lin GA, Bardach NS, et al. Preoperative medical testing in medicare patients undergoing cataract surgery. *N Engl J Med*. 2015;372:1530–1538.

Cheung JJC, Liu S, Li KKW. Phacoemulsification cataract surgery in patients receiving novel oral anticoagulant medications. *Int Ophthalmol*. 2019;39:623–630.

Kumar CM, Seet E. Stopping antithrombotics during regional anaesthesia and eye surgery: crying wolf? *Br J Anaesth*. 2017;118:154–158.

E.5. What are the anesthetic options for cataract surgery?

The majority of cataract surgery is performed with local anesthesia or topical anesthetics with or without sedation. Some patients require general anesthesia if they cannot maintain supine position or remain still and cooperative during surgery (e.g., children, severe dementia patients).

Topical anesthesia is the most common technique used in United States followed by peribulbar and retrobulbar blocks.

The goal of sedation is to minimize anxiety and maintain a cooperative patient during the procedure. Short-acting agents are used, for example, midazolam, remifentanil, or small dosed of propofol.

To prevent rebreathing of CO_2, medical air is flushed under the surgical drapes at 10 L per minute.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1373–1399.

E.6. What is the postoperative course after cataract surgery?

Hospitalization on the same day after cataract surgery is very rare (0.3%). The majority of patients are discharged from the recovery room once the discharge criteria are met. Complications require admission may include uncontrolled elevation in the intraocular pressure, retrobulbar hemorrhage, and suprachoroidal hemorrhage. Other indications for admission may be related to a patient's coexisting diseases (e.g., uncontrolled hypertension, diabetes mellitus, unstable respiratory, or cardiovascular conditions).

35 Laser Treatment for Laryngeal Lesions

Stephanie Marie Vecino and
Hugh C. Hemmings Jr.

A 7-year-old girl with a past history of recurrent respiratory papillomatosis (RRP) is scheduled for direct laryngoscopy and possible reexcision. The patient has had 10 papilloma reexcisions in the past 2 years. Currently, she is undergoing adjuvant treatment with α-interferon but now presents with slowly progressive hoarseness.

A. Medical Disease and Differential Diagnosis

1. What is the cause of RRP?
2. What is the usual presentation of RRP?
3. How do you diagnose RRP?
4. What are the available treatment options for RRP?
5. What are common adverse effects of α-interferon therapy?
6. What is the differential diagnosis of hoarseness in this child?

B. Preoperative Evaluation and Preparation

1. What are the key points of the preanesthetic history and physical examination in this patient?
2. What preoperative laboratory tests are necessary?
3. How should this child be premedicated before coming to the operating room?

4. What are the special anesthetic considerations prior to inducing anesthesia in this patient?

C. Intraoperative Management

1. What is a laser, and how does it work?
2. What are the characteristics of laser radiation?
3. Discuss some advantages associated with the use of lasers for laryngeal surgery.
4. What are some disadvantages of lasers compared with microdebriders?
5. How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?
6. What special ETTs are available for laser surgery?
7. How would you manage an airway fire?
8. What is the Venturi effect?
9. What is Venturi jet ventilation?
10. How would you institute and maintain manual jet ventilation?
11. How is anesthesia maintained during jet ventilation?
12. What are the complications of jet ventilation?
13. Are there contraindications for the use of jet ventilation?
14. Discuss airway management options during laryngeal papilloma resection.
15. How would you plan to monitor this patient?
16. How would you induce anesthesia for an intermittent apnea technique?

D. Postoperative Management

1. What are the common postoperative complications?

A. Medical Disease and Differential Diagnosis

A.1. What is the cause of RRP?

RRP is a disease of the respiratory mucosa characterized by

benign nonkeratinizing squamous papillomata caused by the human papilloma virus (HPV). Although there are approximately 100 genetically different HPV types identified to date, with respect to RRP, two types are important: HPV 6 and 11. They are not only the causative agents for RRP but are also responsible for 90% of genital warts (condylomata acuminata). Recently, there has been evidence implicating infections with non-HPV agents in the pathogenesis of RRP.

Donne AJ, Hampson L, Homer JJ, et al. The role of HPV type in recurrent respiratory papillomatosis. *Int J Pediatr Otorhinolaryngol*. 2010;74(1):7–14.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Venkatesan NN, Pine HS, Underbrink MP. Recurrent respiratory papillomatosis. *Otolaryngol Clin North Am*. 2012;45(3):671–694.

A.2. What is the usual presentation of RRP?

The most common presenting symptom of RRP is persistent hoarseness, usually seen in patients between 2 and 4 years of age. The other more frequent diagnosis for hoarseness at this age is laryngitis, secondary to vocal cord nodules from the overuse of voice.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Zacharisen MC, Conley SF. Recurrent respiratory papillomatosis in children: masquerader of common respiratory diseases. *Pediatrics*. 2006;118(5):1925–1931.

A.3. How do you diagnose RRP?

Any pediatric patient presenting with a change in voice, whether or not stridor is also present, should have a diagnostic flexible fiberoptic laryngoscopy. Definitive diagnosis usually involves a direct laryngoscopy and biopsy by a pediatric otolaryngologist for tissue diagnosis and viral typing. There are several types of

papilloma virus, with type 11 having a worse prognosis. If the diagnosis is delayed, it could potentially lead to respiratory distress due to upper airway obstruction (**Fig. 35.1**).

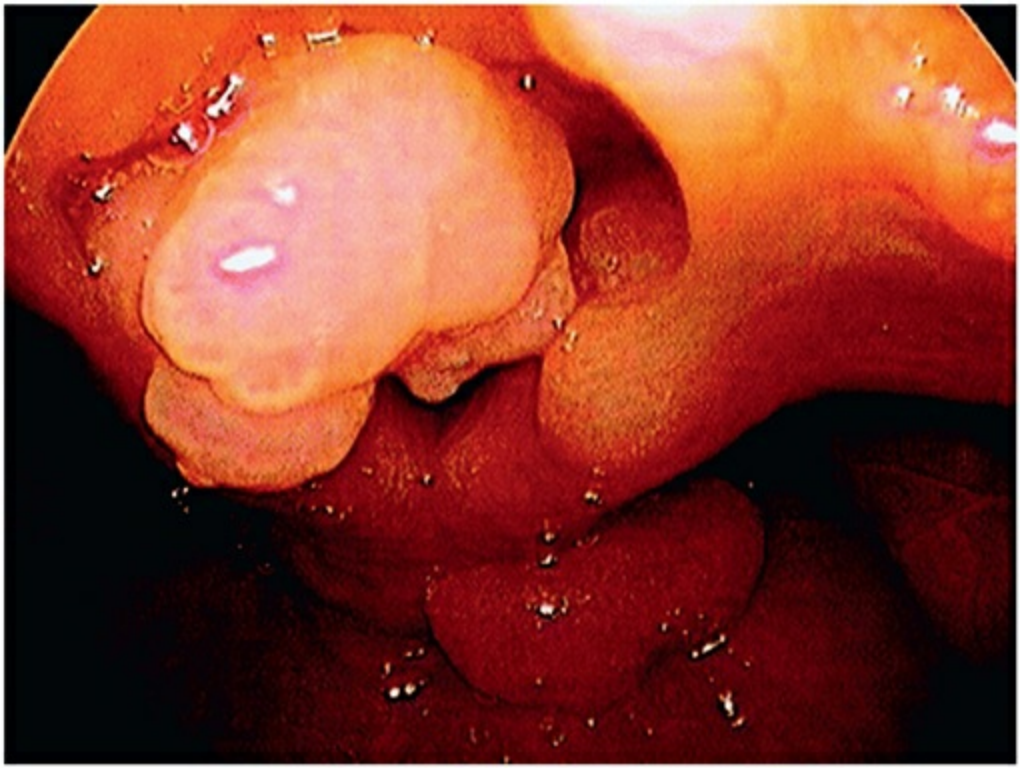

FIGURE 35.1. Laryngoscopic view of multiple papillomata surrounding the vocal cords and obstructing the airway. (*Reprinted with permission from Zacharisen MC, Conley SF. Recurrent respiratory papillomatosis in children: masquerader of common respiratory diseases.* Pediatrics. *2006;118[5]:1925–1931. Copyright © 2006 by the American Academy of Pediatrics*.)

A.4. What are the available treatment options for RRP?

There is no cure for RRP, but standard treatment involves carbon dioxide (CO_2) laser excision or microdebrider excision via direct laryngoscopy with adjuvant therapy as needed. The goal of treatment is to improve airway patency and also preserve voice quality. Because scarring from overaggressive laryngeal resections may lead to adverse clinical outcomes, most surgeons will accept incomplete papilloma resections, especially when near delicate structures such as the anterior laryngeal commissure. Even with removal of all clinically evident

papilloma, not all latent virus particles will have been eradicated.

Microdebriders have been used more frequently due to potential risks involved with the use of lasers. They are precise for surgical debulking and may also be used in combination with lasers. The advantage of using the microdebrider includes a shorter operating time and no risk of thermal injury to airway structures.

There continues to be an application for laser-based resections. Certain lesions, such as sessile lesions, those with ventricular involvement, or those in the area of significant scarring, are still best dealt with by CO_2, potassium titanyl phosphate (KTP), or pulsed-dye laser (PDL).

There is an increasing role for adjuvant medical therapy: α-interferon and various antiviral agents, of which the most commonly used is intralesional cidofovir.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Gallagher TQ, Derkay CS. Recurrent respiratory papillomatosis: update 2008. *Curr Opin Otolaryngol Head Neck Surg*. 2008;16:536–542.

Schraff S, Derkay CS, Burke B, et al. American Society of Pediatric Otolaryngology members' experience with recurrent respiratory papillomatosis and the use of adjuvant therapy. *Arch Otolaryngol Head Neck Surg*. 2004;130:1039–1042.

A.5. What are common adverse effects of α-interferon therapy?

Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulating, and antiproliferative activities. They are part of adjuvant therapy for the treatment of RRP; only α-interferon is clinically used in RRP. A common therapeutic

regimen entails daily subcutaneous applications for a month, followed by a 6-month period of injections three times a week, and then further slow weaning as tolerated. Known adverse effects associated with systemic application are an acute, relatively benign influenza-like syndrome, characterized by fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea as well as more serious dose-limiting comorbidities, including myelosuppression and neurotoxicity. Neurotoxicity is characterized by somnolence, confusion, behavioral disturbance, and, rarely, seizures, debilitating neurasthenia, and depression. Alopecia and personality change are common in IFN-treated children. Cardiovascular toxicity (hypotension and tachycardia) and hepatotoxicity are rare.

Brunton LL, Hilal-Dandan R, Knollmann BC, eds. *Goodman & Gilman's the Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:637–654.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

A.6. What is the differential diagnosis of hoarseness in this child?

Hoarseness always indicates an abnormality of laryngeal structure or function. Given the patient's previous history, local papilloma recurrence and/or postoperative scarring of laryngeal structures seems likely in this patient. A broader differential diagnosis for hoarseness in children would include:

- Anatomic and congenital causes
  - Cystic lesions (laryngocele, thyroglossal cyst)
  - Vocal fold nodules
  - Glottic webs
- Neoplastic causes
  - Squamous cell carcinoma
  - RRP

- Neurologic causes
  - Central (e.g., intracerebral hemorrhage, hydrocephalus)
  - Peripheral neuropathies
- Inflammatory
  - Gastroesophageal reflux
  - Rheumatoid arthritis
  - Angioneurotic edema
- Infectious
  - Croup syndrome
  - Laryngotracheobronchitis
  - Epiglottitis

McMurray JS. Disorders of phonation in children. *Pediatr Clin North Am*. 2003;50:363–380.

B. Preoperative Evaluation and Preparation

B.1. What are the key points of the preanesthetic history and physical examination in this patient?

It is important to detect and address quickly any serious respiratory compromise. In the absence of severe respiratory distress, a detailed history should be obtained. A review of previous anesthetic experiences with particular emphasis on problems pertaining to airway management is a good starting point. Are there signs of airway obstruction? Does the patient have stridor? Does the patient snore at baseline? What position does the child sleep in? Sleep position can assist the team in maintaining airway patency particularly for mask ventilation. Weight, general health, associated comorbidities, recent respiratory infections, allergies, medications, and nothing by mouth (NPO) status are also important. An inquiry about serious adverse effects from IFN therapy should be made.

With respect to voice changes, a more in-depth investigation

may offer some clues regarding the suspected location. A low-pitched, coarse, fluttering voice suggests a subglottic lesion, whereas a high-pitched, cracking voice, aphonia, or breathy voice suggests a glottic lesion. Associated high-pitched stridor also suggests a glottic or subglottic lesion. Because of the precision of laryngeal mechanics, hoarseness can result from a remarkably small lesion. On the other hand, if the origin of the lesion is remote from the vocal cords, hoarseness can result from a significantly larger lesion.

The goal is to recognize a lesion that may result in a partial or complete airway obstruction during anesthetic induction. A preoperative flexible nasopharyngoscopic examination is now routinely performed in most ear, nose, and throat (ENT) offices. If, however, it has not already been done before the patient's arrival to the operating room, an immediate preoperative flexible nasopharyngoscopic examination should be considered.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

B.2. What preoperative laboratory tests are necessary?

In recent years, the value of routine preoperative laboratory screening has been questioned. For a surgical procedure not associated with significant intraoperative blood loss in a child who is not at increased risk for severe anemia, no laboratory tests are required. This patient may however no longer fall into this latter category. Use of α-interferon is associated with serious side effects, such as neurotoxicity and myelosuppression. Because the effects of myelosuppression may not be diagnosed easily by history and physical examination, a preoperative complete blood count may be beneficial in this patient.

Coté CJ, Lerman J, Anderson MB, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2019:35–68.

B.3. How should this child be premedicated before coming to the operating room?

Children with RRP are often quite anxious and apprehensive coming back to the operating room for yet another reexcision. A reassuring preoperative visit by the anesthesiologist should help allay fears. Sedative premedication should be used very carefully, especially in the child with significant respiratory distress. It should not be administered without close monitoring and the immediate availability of oxygen, suction, and positive pressure ventilation. Dexmedetomidine, an α_2 adrenergic receptor agonist, given intranasally has minimal effect on respiration and has anxiolytic properties. Anticholinergic premedication can be used to reduce oral secretions.

Coté CJ, Lerman J, Anderson MB, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2019:35–68.

B.4. What are the special anesthetic considerations prior to inducing anesthesia in this patient?

Before the induction of anesthesia, the anesthesiologist should discuss the surgical plan with the surgeon. The anesthesiologist should have a thorough understanding of the surgical plan and closely communicate with the surgeon throughout the procedure. A strategy for maintaining oxygenation and ventilation during the case, while working around surgical needs, must be discussed. Special equipment (e.g., laser, jet ventilator, bronchoscopes) must be present and in working condition.

Equipment for securing a potentially difficult pediatric airway should be present in the operating room, which may include rigid bronchoscopes, a tracheostomy–cricothyrotomy set, as well as an experienced otolaryngologist.

The use of a laser greatly impacts airway management. The biggest concern here is prevention of an airway fire. The

anesthesiologist should also have an effective management plan should an airway fire occur. Operating room staff must wear protective eye gear when the laser is in use.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

C. Intraoperative Management

C.1. What is a laser, and how does it work?

Electromagnetic radiation consists of photons, which have properties consistent with both particles and waves. Like radio waves and Roentgen waves, visible light is another form of electromagnetic radiation. The characteristic features of these different forms of radiation are their respective wavelengths. Visual light is electromagnetic radiation with wavelengths from 385 to 760 nm, shorter wavelengths are ultraviolet, and longer wavelengths are infrared.

Laser is an acronym for light amplification by stimulated emission of radiation. What makes laser special is the high energy density that it provides and its ability to quickly transfer large quantities of energy to remote locations, either through fiberoptic channels (e.g., with the KTP laser) or through free air, as is usually the case with the CO_2 laser.

Several concepts are important for a basic understanding of lasers:

- *The photoelectric effect*. Light of a certain wavelength (e.g., blue) causes metal to eject electrons at a rate proportional to the brightness of this light. Intense light of different colors (e.g., red, orange, yellow) cannot do that.
- *The orbital model*. Electrons circling the nuclei of atoms are limited to a few specific orbital patterns and radii. Each orbital has a specific energy level. The energy differences

between electron orbitals are characteristic for specific atoms. The only way an electron can move from one orbital to another of higher or lower energy is to either absorb or emit energy equivalent to the difference in energy between the two orbitals.

- *Stimulated absorption*. The process by which a photon's energy is captured by an electron, thereby lifting the electron into a higher energy orbital (the electrons get "excited").
- *Spontaneous emission*. The opposite phenomenon in which an electron drops to a lower orbital by emitting a photon to remove the excess energy.
- *Population inversion*. Many (as opposed to one) electrons achieve a higher energy level (higher orbital). Once initiated by a single photon, a chain reaction of stimulated emission occurs (amplification).

The necessary components of a laser system consist of a laser medium (gaseous or solid) containing the atoms whose electrons create the laser light, resonating mirrors to enhance laser efficiency, and an energy source to excite the atoms of the laser medium into generating laser light. An energy source provides the means for obtaining a population inversion of orbital electrons of the laser medium. A pair of axial mirrors permits repeated passes of collimated photons through the medium, allowing maximum amplification by stimulated emission. One of the mirrors is partially transmitting, finally allowing the laser beam to emerge.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

C.2. What are the characteristics of laser radiation?

The high energy density of a laser is the result of three characteristics:

- Monochromaticity, which means that all of the photons in a

laser beam have the same wavelength.

- Electromagnetic fields of all photons in the laser beam oscillate in identical phase. Unlike ordinary light where the electromagnetic fields are randomly phased, this phenomenon of synchronous oscillation is called *coherence*.
- Whereas ordinary light beams spread out in all directions from a point source, laser light remains in a narrow collimated beam with the elements of the laser beam parallel.

These characteristics permit lasers to deliver intense energy via powerful light beams efficiently and accurately through lenses to small targets.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

C.3. Discuss some advantages associated with the use of lasers for laryngeal surgery.

With laser light, tissue penetration is mostly a function of wavelength. Long-wavelength infrared laser light, such as that from CO_2 (operating at 10,600 nm), is completely absorbed by water in the first few layers of cells. The thermal effect is therefore largely limited to the point of entry into the target tissue. This results in explosive vaporization of the surface tissue of the target with surprisingly little damage to underlying cells. When coupled to an operating microscope, the laser vaporizes lesions with precision, causing minimal bleeding and edema, an obvious advantage, especially in small pediatric airways.

In certain situations, a laser-based resection technique is the surgical method of choice: Sessile lesions, lesions in scarred areas, and those located near or in the laryngeal ventricle often are treated with PDL. This laser has a shorter wavelength that typically *spares* the epithelium but targets the microvascular supply of the overriding lesion. This has obvious advantages, where the epithelium of one wall is in proximity to epithelium of

an opposing wall, such as is the case in the anterior laryngeal commissure. An added benefit at least in the adult population is that the PDL can be used with topical anesthesia alone (delivery is typically via fiberoptic scope), thereby avoiding many of the complicating considerations for laser surgery under general anesthesia.

Derkay CS. Recurrent respiratory papillomatosis. *Laryngoscope*. 2001;111:57–69.

Gallagher TQ, Derkay CS. Recurrent respiratory papillomatosis: update 2008. *Curr Opin Otolaryngol Head Neck Surg*. 2008;16:536–542.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

C.4. What are some disadvantages of lasers compared with microdebriders?

There are significant risks associated with the use of laser for laryngeal surgery. Extra staff is typically required for the safe operation of the laser equipment, adding to the overall cost of the procedure. Special eye protection for both patient and staff is required because the laser beam can cause serious retinal injury. Other body parts may need to be carefully protected from inadvertent laser exposure in order to prevent tissue injury (burns).

The biggest concern with laser use, however, is the risk of an airway fire through ignition of the ETT by inadvertent laser strike. This is a potentially fatal complication if not managed quickly. To minimize the risk of an airway fire, the oxygen concentration should be minimized as clinically feasible, generally aiming to keep the fraction of inspired oxygen (F_{IO_2}) below 30%. Nitrous oxide is not a suitable diluting gas because it also supports combustion.

Inappropriate and aggressive use of the laser may cause injury to mucosa that is unaffected by disease and create an

environment suitable for implantation of viral particles which can actually promote spread of the disease. Laser-induced pneumothorax has been reported after a laryngeal procedure. Although the thermal effect is largely limited to the point of entry into the target tissue, if not used judiciously especially near delicate structures such as the anterior or posterior laryngeal commissure, the laser may cause unacceptable scarring and subsequent abnormal vocal fold function.

Laser smoke contains water vapor and destroyed tissue. It has been found to contain active viral DNA, a potential source of infection for operating room personnel. Smoke may also obstruct the surgeon's view during the resection. Staff should protect themselves by wearing N95 face masks.

When comparing the microdebrider to the CO_2 laser, there is evidence suggesting that removing papillomata using the microdebrider is associated with better short-term improvement in voice quality and a shorter procedure time, which may ultimately translate to reduced operative cost. Heat-induced scarring of nearby tissues is not a concern; there is no need for protection from an inadvertent laser strike, and the risk for an airway fire is no higher than in a standard case.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Gallagher TQ, Derkay CS. Recurrent respiratory papillomatosis: update 2008. *Curr Opin Otolaryngol Head Neck Surg*. 2008;16:536–542.

Werkhaven JA. Microlaryngoscopy-airway management with anaesthetic techniques for CO_2 laser. *Paediatr Anaesth*. 2004;14:90–94.

C.5. How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?

An inadvertent laser strike can ignite any hydrocarbon material in the airway, including an ETT. Because of their proximity to the operative field, ETTs pose a serious fire hazard during laser use, especially in the oxygen-enriched environment of a general anesthetic.

All commonly used ETTs are potentially flammable, but flammability is a function of the material used to manufacture the tube. Unfortunately, the common clear polyvinylchloride (PVC) plastic tubes are more flammable than older red rubber tubes. Also, red rubber tubes produce less toxic combustion products once ignited.

In addition to limiting F_{IO_2}, another strategy to make conventional PVC tubes safer is to wrap them with reflective tape. Conventional aluminum or copper tape is an inexpensive (although not U.S. Food and Drug Administration [FDA]-approved) way to offer some protection against a brief laser strike. FDA-approved tape is also available (Merocel Laser-Guard, Medtronic, Minneapolis, MN).

According to a recent practice advisory published by the American Society of Anesthesiologists (ASA) for laser surgery, the ETT should be laser resistant. They also advise that the cuff should be inflated with saline rather than air when possible. The ASA also agreed that the addition of methylene blue to the saline would be beneficial to detect cuff rupture by the laser. They also recommended that for surgery involving the airway, a cuffed ETT should be used rather than an uncuffed ETT whenever possible.

Apfelbaum JL, Caplan RA, Barker SJ. Practice advisory for the prevention and management of operating room fires: an updated report by the American

Society of Anesthesiologists Task Force on Operating Room Fires. *Anesthesiology*. 2013;118(2):271–290.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

Wöllmer W, Schade G, Kessler G. Endotracheal tube fires still happen—a short overview. *Med Laser Appl*. 2010;25(2):118–125.

C.6. What special ETTs are available for laser surgery?

FDA-approved specialized tubes for laser surgery are commercially available. Although these laser-resistant ETTs may withstand laser strikes longer than conventional tubes, they will ignite with longer exposure. Laser-resistant tubes are made of metal or have a metallic overlay on a nonmetal core (**Fig. 35.2**).

The Laser-Shield II (Medtronic, Minneapolis, MN) has a silicone-based core wrapped with laser-reflective aluminum topped with a smooth fluoroplastic overwrap on the outside. Other laser-resistant tubes with a metallic overlay on a nonmetal core are the Sheridan Laser-Trach and the Rüsch Lasertubus (Teleflex, Morrisville, NC).

The Covidien Mallinckrodt Laser Oral/Nasal Tracheal Tube (Covidien, Boulder, CO) is a metal tube model; it has an airtight stainless steel spiral tube with two independent distal PVC cuffs. If one ruptures, the second unruptured cuff will still limit egress of oxygen-rich gas. Currently, there are no available ETTs with cuffs that remain inflated after puncture. Not surprisingly, the rigidity and bulkiness of these tubes are practical disadvantages that discourage their routine use, especially in pediatric patients.

FIGURE 35.2. Example of laser-resistant endotracheal tubes (ETTs). (*From Botney R. Fire Safety. In: Woodworth G, Kirsch JR, Sayers-Rana S, eds.* Anesthesia Technician and Technologist's Manual. *Philadelphia, PA: Wolters Kluwer; 2012:506.*)

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

Wöllmer W, Schade G, Kessler G. Endotracheal tube fires still happen—a short overview. *Med Laser Appl*. 2010;25(2):118–125.

C.7. How would you manage an airway fire?

In case of an airway fire, rapid and effective action is required. When suddenly faced with this crisis situation, the "4 *E*s" mnemonic provides focus:

- *E*xtract
- *E*liminate
- *E*xtinguish
- *E*valuate

All combustible materials (ETT, pledgets) must be *e*xtracted from the airway at once. Oxygen supply through the tube must be quickly *e*liminated by disconnection from the circuit. Continued flow through a burning tube would lead to a

blowtorch effect. Any residual fire needs to be *e*xtinguished with normal saline. Ventilation with 100% oxygen should then be provided by mask, and anesthesia should be continued. *E*valuation of the injury is then in order and should be done with direct laryngoscopy and rigid bronchoscopy to assess the upper and lower airway. Any apparent airway damage makes reintubation the most prudent approach. For severe injury, a low tracheotomy may be indicated.

According the most recent practice advisory from the ASA for the prevention and treatment of operating room fires, when a suspected airway fire has occurred and the fire has not been extinguished with the use of saline, a CO_2 fire extinguisher should be used. The ETT should also be examined and assessed to exclude any fragments left behind in the airway.

Apfelbaum JL, Caplan RA, Barker SJ. Practice advisory for the prevention and management of operating room fires: an updated report by the American Society of Anesthesiologists Task Force on Operating Room Fires. *Anesthesiology*. 2013;118(2):271–290.

Werkhaven JA. Microlaryngoscopy-airway management with anaesthetic techniques for CO_2 laser. *Paediatr Anaesth*. 2004;14:90–94.

C.8. What is the Venturi effect?

The Venturi effect originally described the impact of constricted channels on fluid flow. As fluid passes through the constriction of a Venturi tube (a tube with two open ends and a narrowing in its midsection), it must speed up. At the same time, its hydrostatic pressure drops. This pressure drop is proportional to flow and can, for example, be used to measure flow in pipes without interfering with flow.

Ihra G, Aloy A. On the use of Venturi's principle to describe entrainment during jet ventilation. *J Clin Anesth*. 2000;12:417–419.

C.9. What is Venturi jet ventilation?

The jet injector technique of ventilation for upper airway surgery was introduced by Sanders in 1967. A high-pressure gas source is connected to a stiff, narrow cannula positioned at the inlet of the laryngoscope. With a manual switch, intermittent gas boluses are delivered. In the lumen of the laryngoscope, the high-velocity stream of gas encounters stationary gas, which it draws forward. Each jet bolus entrains ambient air through the open laryngoscope entrance, substantially augmenting the volume of the bolus and diluting the oxygen fraction of the jet.

Whether or not it is truly based on the phenomenon known as the *Venturi effect*, the jet injector provides a simple approach to delivering physiologic tidal volumes in a non–gas-tight delivery system. Venturi ventilation has become synonymous with jet ventilation.

Ihra G, Aloy A. On the use of Venturi's principle to describe entrainment during jet ventilation. *J Clin Anesth*. 2000;12:417–419.

McRae K. Anesthesia for airway surgery. *Anesthesiol Clin North Am*. 2001;19(3):497–541.

C.10. How would you institute and maintain manual jet ventilation?

Before effective jet ventilation can begin, the operating laryngoscope must be inserted, the larynx adequately exposed and evaluated for jet ventilation, the suspension system installed, and the jet injector needle attached to the laryngoscope in alignment with the axis of the trachea. This takes time in an anesthetized apneic patient. One option is to begin with laryngoscopy and intubation using a standard PVC ETT if the airway appears appropriate for jet ventilation. Uninterrupted ventilation can now be performed while the operating laryngoscope and jet injector are positioned. When ready, the ETT is removed, and jet ventilation begun. Alternatively,

following anesthesia induction and adequate mask airway ventilation, the patient is paralyzed and the operating laryngoscope and jet injector are inserted and positioned while the patient is apneic.

Ventilation begins with a jet pressure of 5 to 10 psi in infants and children and 15 to 20 psi in adults. The jet pressure is gradually increased until adequate chest excursions are evident. Jet ventilation should produce good clinical expansion of the chest at a rate appropriate for the patient's age. The inspiratory-to-expiratory (I:E) ratio should allow for complete passive exhalation in between jet applications. Monitoring of peripheral arterial saturation is mandatory as is monitoring ventilation both by auscultation and palpation.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

C.11. How is anesthesia maintained during jet ventilation?

The leak around the scope is smaller in children having jet ventilation, but the delivery of inhalational anesthetics is not optimal because of operating room pollution and the inability to precisely regulate gas concentrations. Most clinicians, therefore, favor a total intravenous anesthesia technique. By combining a hypnotic agent such as propofol with a short-acting opioid (such as remifentanil), hypnosis, amnesia, and analgesia can all be achieved, while allowing for a rapid recovery of the patient at the end of the procedure. Temporary muscle relaxation can be achieved with either a short-acting or an intermediate-duration neuromuscular blocker.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

C.12. What are the complications of jet ventilation?

Complications associated with jet ventilation include dehydration of the mucosa, inadequate oxygenation and ventilation, gastric distention, regurgitation, and barotrauma. Pneumomediastinum and pneumothorax have been reported and seem to occur most frequently when jet ventilation is used in a patient with a (partially) obstructed airway. This is best avoided by using muscle relaxation during jet ventilation. In addition, particulate matter and virus particles can be spread down the distal airway. End-tidal CO2 measurements are also inaccurate.

Borland LM. Airway management for CO_2 laser surgery on the larynx: Venturi jet ventilation and alternatives. *Int Anesthesiol Clin*. 1997;35(3):99–106.

Jaquet Y, Monnier P, Van Melle G, et al. Complications of different ventilation strategies in endoscopic laryngeal surgery: a 10-year review. *Anesthesiology*. 2006;104(1):52–59.

C.13. Are there contraindications for the use of jet ventilation?

Jet ventilation is most suited for patients with normal, unobstructed airways and normal lung and chest wall compliance.

The ability to fully exhale in between jet applications is crucial. If this is not possible (glottic lesion, significant interarytenoid scarring, laryngospasm), jet ventilation may not be appropriate. Decreased chest wall compliance, such as in obese patients, may lead to inadvertent gastric distension, further worsening respiratory compliance. Advanced chronic obstructive pulmonary disease with its inherent prolonged exhalation phase may again make jet ventilation impractical and, in the presence of pulmonary bullae, even hazardous. Significant overbite especially when combined with retrognathia makes orolaryngotracheal alignment challenging and accidental gastric

hyperinflation likely.

Jaquet Y, Monnier P, Van Melle G, et al. Complications of different ventilation strategies in endoscopic laryngeal surgery: a 10-year review. *Anesthesiology*. 2006;104(1):52–59.

C.14. Discuss airway management options during laryngeal papilloma resection.

In addition to (manual) Venturi jet ventilation, there are three different widely accepted methods for managing the airway during papilloma resection: controlled mechanical ventilation through a small ETT, spontaneous ventilation, and an apnea technique with intermittent ventilation.

Excluding the first option, all methods require an unsecured, unprotected airway during parts of the surgical resection. The use of an ETT during airway laser surgery, although reassuring, also presents the risk of an airway fire. In addition, surgical exposure to the larynx is often suboptimal in the presence of an ETT.

Access to all parts of the laryngeal mucosa using spontaneous ventilation without an additional airway device (e.g., tube, laryngeal mask airway) is naturally superior. Depending on the type of laser used, in the adult population, all that is sometimes required is *topical* anesthesia allowing for office-based treatments. In pediatric patients though, maintenance of spontaneous ventilation under general anesthesia is usually the most successful strategy. Since muscle relaxation is not an option, and the moving surgical field is somewhat of a challenge to using this technique.

Intermittent apnea offers a solution to this problem. During apnea with intermittent ventilation, the patient is repeatedly

hyperventilated, either by mask or after reintubation. Use of 100% oxygen will extend the tolerable apnea time. Inadvertent movement is best avoided using muscle relaxants. If an ETT is used, it is removed periodically, respirations are held while the surgeon operates for brief periods of time, and the peripheral oxygen saturation is closely monitored. Before desaturation occurs, the patient is then either reintubated or just masked and prepared for another period of apnea to allow for further resection as needed. Spreading the virus to more distal parts of the airway by repeated reintubations is a concern with this technique.

Spontaneous ventilation and intermittent apnea techniques seem to be favored by most members of the American Society of Pediatric Otolaryngology.

Flint PW, Haughey BH, Lund VJ, et al, eds. *Cummings Otolaryngology: Head and Neck Surgery*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2015:3142–3157.

Jaquet Y, Monnier P, Van Melle G, et al. Complications of different ventilation strategies in endoscopic laryngeal surgery: a 10-year review. *Anesthesiology*. 2006;104(1):52–59.

C.15. How would you plan to monitor this patient?

Routine monitors include a pulse oximeter, noninvasive blood pressure measurements, an electrocardiogram, a precordial stethoscope, a temperature probe, an oxygen analyzer, a CO_2 detector, and a neuromuscular blockade monitor. If using spontaneous ventilation, exposing the patient's chest can help the clinician assess adequate chest rise. In this otherwise healthy patient without the potential for significant blood loss or fluid shifts, no additional monitoring is necessary.

American Society of Anesthesiologists. Standards for basic anesthetic monitoring. Reaffirmed July 1, 2011. https://www.asahq.org/standards-and-

guidelines/standards-for-basic-anesthetic-monitoring. Accessed October 13, 2015.

C.16. How would you induce anesthesia for an intermittent apnea technique?

The choice of anesthetic induction is critically dependent on the presence of signs and symptoms suggesting possible airway compromise on induction. If present in an adult patient, an awake fiberoptic intubation can be performed, which not only secures the airway but also enables evaluation of the subglottic airway before ETT placement.

In children and uncooperative adults, an inhalational induction using sevoflurane is the next safest option. Maintenance of spontaneous ventilation is again critical. In this scenario, neuromuscular blockers are unsafe until it is clear that the patient can be ventilated and/or intubated.

Blind techniques (blind oral or nasal intubation) cannot be recommended in this setting because they carry the risk of bleeding and loss of the airway due to an obstructing lesion.

A word of caution: Papillomata are dynamic lesions in the sense that they can grow rapidly. The endoscopic airway examination should be current. Also, the absence of suggestive signs and symptoms does not truly guarantee a patent airway once anesthesia has been induced. Hence, extreme caution in managing these patients is essential.

If the patient truly has no airway compromise, any routine induction technique (intravenous or inhalational) can be used safely. An intermittent apnea technique will allow the surgeons to have a full view without an ETT in place.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2210–2235.

D. Postoperative Management

D.1. What are the common postoperative complications?

Laryngeal edema can occur early in the postoperative period and is usually manifested by chest retractions and inspiratory stridor. After microlaryngeal surgery, patients may benefit from humidified oxygen, intravenous steroids (e.g., dexamethasone), and inhalational racemic epinephrine. Laryngospasm can develop because of laryngeal hyperactivity. To reduce the incidence of laryngospasm, lidocaine can be sprayed on the vocal cords in the operating room. If laryngospasm develops postoperatively, it is treated with standard maneuvers, including a jaw thrust and positive pressure ventilation. Care must be taken not to insufflate the stomach with the use of greater than 20 cm H_2O airway pressure. Often, 5 to 10 cm H_2O airway pressure will suffice. More severe forms of laryngospasm may require the use of small doses of succinylcholine (one-tenth of a normal intubation dose, i.e., 0.2 mg per kg for pediatric patients and 0.1 mg per kg for adult patients intravenously). Pulmonary complications can result from retained secretions, atelectasis, or barotrauma (if jet ventilation was used).

SECTION 10 Pediatrics

36 Tracheoesophageal Fistula

Jacques H. Scharoun

A 12-hour-old full-term infant weighing 2.5 kg presents with choking and cyanosis during his first feed. Neonatal intensive care unit (NICU) staff is unable to pass a feeding tube into the stomach. The baby also has copious oral secretions. Before birth, polyhydramnios was noticed.

A. Pathophysiology and Differential Diagnosis

1. What is the diagnosis? What are the clinical features of this disease?
2. What is the pathophysiology of this disease?
3. Describe the normal development of the trachea and esophagus.
4. How are tracheoesophageal fistula (TEF) and esophageal atresia (EA) inherited?
5. How are the different types of TEF/EA classified?
6. What other problems may this child have, and when should

these be investigated?
7. What should the parents be told regarding perioperative risk? Risk of recurrence?

B. Preoperative Evaluation and Preparation

1. What laboratory workup should be obtained before surgery?
2. Describe management in the NICU before surgery.
3. How is severe lung disease managed before repair?
4. Should this patient be intubated preoperatively for airway protection?

C. Intraoperative Management

1. What invasive lines and monitoring are appropriate before induction? After induction?
2. Discuss fluid and temperature management for this baby.
3. What are the options regarding induction and intubation?
4. What is the role of rigid and fiberoptic bronchoscopy in this patient prior to incision?
5. Describe the steps of an open repair of EA/TEF.
6. What are common intraoperative problems, and how can they be managed?
7. If the surgeon decides to proceed thoracoscopically, how will you perform your anesthetic? Is one-lung ventilation required? What are some complications unique to thoracoscopy in the newborn?

D. Postoperative Management

1. When should the baby be extubated?
2. What options are available for postoperative analgesia?
3. What are early and late complications of TEF repair?

A. Pathophysiology and Differential Diagnosis

A.1. What is the diagnosis? What are the clinical features

of this disease?

This patient has EA with a TEF. This occurs in 1 per 3,000 live births. The diagnosis is suspected prenatally by the presence of polyhydramnios, which is caused by the failure of the fetus to swallow amniotic fluid (secondary to EA). Polyhydramnios is a nonspecific prenatal finding. The combination of polyhydramnios and absent stomach bubble on prenatal ultrasound gives a 44% to 56% likelihood of EA/TEF. After birth, the neonate will have copious drooling from inability to swallow secretions. Attempts to feed the baby will result in coughing and cyanosis. An orogastric tube (OGT) will coil up in the upper esophageal pouch rather than pass into the stomach.

Pinheiro P, Simões e Silva AC, Pereira RM. Current knowledge on esophageal atresia. *World J Gastroenterol*. 2012;18:3662–3672.

A.2. What is the pathophysiology of this disease?

In this abnormality, there are two distinct problems: TEF and EA. In TEF, the trachea is connected to the esophagus through a fistula. This causes two problems. First, inhaled air can bypass the lungs through the fistula into the stomach and cause hypoventilation and gastric distension. If the lungs are especially noncompliant or the fistula is large, attempts to institute positive pressure ventilation (PPV) can lead to severely compromised ventilation due to gastric expansion or even rupture. Second, there is the continual risk of acidic stomach contents refluxing via the fistula back into the trachea causing aspiration pneumonitis. With EA, the esophagus is divided into a proximal and distal portion. The proximal portion ends in a blind pouch. Secretions from the hypopharynx pool here and cause drooling,

coughing, and choking with feeds. The child is unable to feed orally.

A.3. Describe the normal development of the trachea and esophagus.

The foregut arises first from primitive endoderm. This structure will eventually differentiate into trachea and esophagus. Lung buds form anteriorly at pharyngeal arch 6. Differential expression of various growth factors results in the anterior foregut developing into trachea and lung tissue, whereas the posterior portion develops into esophagus. The actual septation process is believed to arise at the level of the lung bud and proceed toward the pharynx. This process requires *multiple* gene signals, including Sonic hedgehog, Sox2, and NKX2.1. Errors in this process of separation of the trachea from the foregut results in a residual fistula between the esophagus and trachea.

Stevenson RE, Hunter AGW. Considering the embryopathogenesis of VACTERL association. *Mol Syndromol*. 2013;4:7–15.

A.4. How are tracheoesophageal fistula (TEF) and esophageal atresia (EA) inherited?

TEF/EA is believed to be multifactorial in etiology and sporadic.

Rarely, it is associated with a specific genetic mutation or syndrome. These include trisomy 18, Hall-Hittner syndrome, anophthalmia-esophageal-genital (AEG) syndrome, Feingold syndrome, and 16q24.1 deletion syndrome. Most of the cases, however, are nonfamilial. There is a 1% chance of recurrence in each sibling of someone with EA. EA is twice as common in twins.

Brosens E, Ploeg M, van Bever Y, et al. Clinical and etiological heterogeneity in patients with tracheo-esophageal malformations and associated anomalies. *Eur J Med Genet*. 2014;57:440–452.

A.5. How are the different types of TEF/EA classified?

There are five types of TEF according to the classic Gross classification (**Fig. 36.1**). Type A is pure EA with no involvement of the respiratory tree; this occurs in 8% of cases. Gross type B has EA and a fistula connecting the proximal esophageal pouch to the trachea; this occurs in less than 1%. The most common is type C, with EA and fistula linking the distal esophagus to the trachea; this occurs in 75% to 80% of cases. Rarely, type D occurs with two fistula connecting both proximal and distal esophagus to the trachea (2%). Type E, known as an H-type fistula, has no atresia. Instead, an intact esophagus has a linkage with trachea through a fistula, and it occurs in 4%.

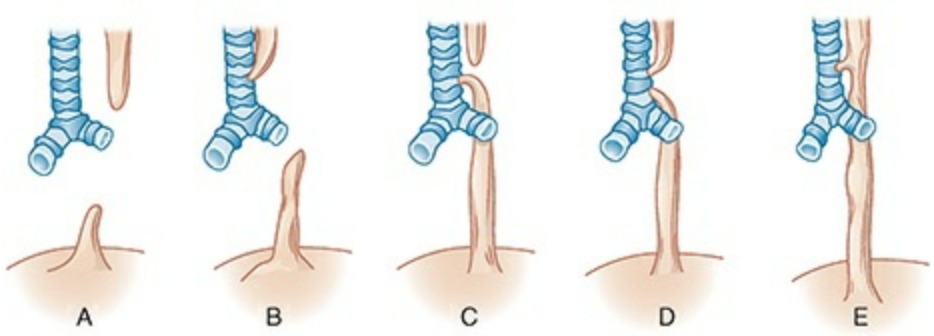

FIGURE 36.1. Gross classification of EA and TEF. (*Modified from Gregory GA, ed.* Pediatric Anesthesia. *2nd ed. New York: Churchill Livingstone; 1989:921, with permission.*)

Pinheiro P, Simões e Silva AC, Pereira RM. Current knowledge on esophageal atresia. *World J Gastroenterol*. 2012;18:3662–3672.

A.6. What other problems may this child have, and when should these be investigated?

Fifty percent of children with EA/TEF will have additional anomalies. Most often, they occur in the spectrum known as *VACTERL* (formerly known as *VATER*):

V = vertebral anomalies (10%)

A = anal canal defect (anal atresia) (14%)

C = cardiac malformations (29%), including ventricular septal defect, atrial septal defect, tetralogy of Fallot, right-sided arch, patent ductus arteriosus

TE = tracheoesophageal fistula

R = renal dysplasia

L = limb defect (radial aplasia)

A patient is considered to have VACTERL association with the presence of three or more of these lesions. Nearly one-third of TEF patients will have an additional VACTERL lesion, and an additional one-fifth will have two. Other possible gastrointestinal problems include malrotation of the midgut and duodenal atresia. Renal problems can include malposition, hydronephrosis, and ureteral abnormalities.

Because the existence of these associated defects may alter the surgical or anesthetic plan, and because the TEF is an urgent but not emergent procedure, these other possible defects should be assessed *prior* to TEF repair.

Husain M, Dutra-Clarke M, Lemieux B, et al. Phenotypic diversity of patients diagnosed with VACTERL association. *Am J Med Genetics*. 2018;176:1830–1837.

A.7. What should the parents be told regarding perioperative risk? Risk of recurrence?

The survival of TEF babies has improved over the years because of the improvements in intensive care unit care, anesthesia, and surgical technique. Risk of perioperative mortality remains well stratified by the Spitz Classification in a recent series of 248 neonates over a 20-year period.

- Spitz group I: birth weight more than 1.5 kg, no major cardiac disease, survival 96%
- Spitz group II: birth weight less than 1.5 kg, or major cardiac disease, survival 79%
- Spitz group III: birth weight less than 1.5 kg and major cardiac disease, survival 38%

Spitz L. Oesophageal atresia. *Orphanet J Rare Dis*. 2007;2:24.

B. Preoperative Evaluation and Preparation

B.1. What laboratory workup should be obtained before surgery?

- First, a plain chest x-ray is used to assess the presence and severity of pulmonary disease, especially looking for

aspiration pneumonia and respiratory distress associated with prematurity. It may also show the presence of congestive heart failure in the setting of associated cardiac disease, which may be optimized by administering a diuretic. A radiopaque OGT will be seen coiled in the proximal esophageal pouch, whereas an abdominal x-ray may show air in the bowels entering through the fistula. Because of the risk of aspiration, the use of contrast dye to delineate the fistula should be used only when there is diagnostic uncertainty. Of note, an OGT that appears to enter the stomach may in fact have passed through an esophageal perforation caused by repeated traumatic insertion attempts.

- Second, an echocardiogram is *mandatory* because major cardiac defects strongly influence survival and may have an impact on anesthetic management. If the child has severe tetralogy of Fallot, he may require placement of a temporary shunt between the systemic arterial and pulmonary circulation prior to repair of the TEF. In addition, one wants to look for presence of a right-sided aortic arch because this will require positioning the infant with the opposite side down from usual.
- Spinal plain films should be done to exclude vertebral anomalies, especially if epidural pain management is being considered. Renal ultrasound should be done to rule out abnormalities, especially hydronephrosis.
- In addition, complete blood count (CBC), arterial blood gas, and electrolytes should be drawn, and at least 1 unit of packed red blood cells should be type and crossed.

Broemling N, Campbell F. Anesthetic management of congenital tracheoesophageal fistula. *Paediatr Anaesth*. 2011;21:1092–1099.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:506–508.

Knottenbelt G, Skinner A, Seefelder C. Tracheo-oesophageal fistula (TOF)

and oesophageal atresia (OA). *Best Pract Res Clin Anaesthesiol*. 2010;24:387–401.

B.2. Describe management in the NICU before surgery.

After the diagnosis of TEF is established, the baby should not be fed, and intravenous (IV) replacement of fluid and glucose provided. A drainage tube should be placed in the proximal esophageal pouch and kept on intermittent suction to minimize aspiration of oral secretions. He should be positioned either prone or supine with the head up 30 degrees to minimize reflux of gastric fluids into the lungs via the fistula. Antibiotics to treat aspiration pneumonia should be given when appropriate. Ensure that blood is available from the blood bank. Because the patient will require a thoracotomy with lung retraction and intermittent compression of the trachea and great vessels, an arterial catheter is mandatory for the case. This should ideally be placed in the NICU. An umbilical artery catheter may be conveniently placed by a qualified neonatologist. Two additional IV catheters should also be placed. A central venous catheter is not necessary. Avoid placing IV access in the right arm because this arm will most likely be elevated during right thoracotomy and access to it may be limited.

Broemling N, Campbell F. Anesthetic management of congenital tracheoesophageal fistula. *Paediatr Anaesth*. 2011;21:1092–1099.

Knottenbelt G, Skinner A, Seefelder C. Tracheo-oesophageal fistula (TOF) and oesophageal atresia (OA). *Best Pract Res Clin Anaesthesiol*. 2010;24:387–401.

Pinheiro P, Simões e Silva AC, Pereira RM. Current knowledge on esophageal atresia. *World J Gastroenterol*. 2012;18:3662–3672.

B.3. How is severe lung disease managed before repair?

Very early primary repair is considered standard of care. However, there remains a subset of neonates with either severe pneumonia or respiratory distress syndrome (from prematurity), who are poor anesthetic and surgical risks (Waterston type C)

and who need to be intubated because of respiratory disease. The baby can be intubated conventionally while a simple gastrostomy is simultaneously placed to relieve gastric distension that can occur with PPV in the setting of a type C TEF. This procedure can be performed under local anesthesia. The problem with this approach is that by decompressing the stomach, gas from the trachea can now bypass the lungs and exit through the stomach. This is especially a concern if the baby's lungs are noncompliant from pneumonia or respiratory distress syndrome. This can make it difficult or impossible to ventilate the baby adequately. Alternately, the baby can be ventilated using a high-frequency oscillator, which has the advantage of providing oxygenation and carbon dioxide (CO_2) removal while minimizing the peak inspiratory pressure and therefore gastric distension.

Ho AM, Dion JM, Wong JC. Airway and ventilatory management options in congenital tracheoesophageal fistula repair. *J Cardiothorac Vasc Anesth*. 2016;30:515–520.

Holcomb GW III. Thoracoscopic surgery for esophageal atresia. *Pediatr Surg Int*. 2017;33:475–481.

B.4. Should this patient be intubated preoperatively for airway protection?

Unless mandated by severe pulmonary disease, the child is not intubated preoperatively to minimize the possibility of gastric distension from PPV through the fistula. Intubation does not protect the child from aspiration of gastric contents through the fistula.

Broemling N, Campbell F. Anesthetic management of congenital tracheoesophageal fistula. *Paediatr Anaesth*. 2011;21:1092–1099.

C. Intraoperative Management

C.1. What invasive lines and monitoring are appropriate before induction? After induction?

- At least one peripheral IV should be in place before induction. A second may be placed after the patient is anesthetized. If the surgeon intends to give the child total parenteral nutrition postoperatively, a central line may be placed. An arterial catheter for blood gas and hemodynamic monitoring should be in place before incision. It is especially useful if thoracoscopy is planned. If a peripheral arterial is not feasible, an umbilical arterial line may be placed by a skilled NICU practitioner.
- Electrocardiogram, oxygen saturation, end-tidal CO_2, and rectal temperature should also be monitored. A precordial stethoscope should be placed over the left axilla to assess breath sounds in case of inadvertent movement of the endotracheal tube (ETT) during surgical retraction or positioning. A second stethoscope placed over the stomach may be useful to assess if the fistula is being ventilated.

C.2. Discuss fluid and temperature management for this baby.

As with all neonates undergoing surgery, meticulous attention to fluid management and temperature is essential. Limited subcutaneous fat renders the neonate prone to hypothermia. Hypothermia is dangerous because it will increase pulmonary vascular resistance and may result in a reversion to transitional

circulation, greatly complicating intraoperative care. The child should be transported to the operating room (OR) in a warmed isolette, with a stocking cap on his head to minimize heat loss. The OR should be prewarmed to at least 30°C. Surgical irrigation and RBCs should be warmed. Using a forced-air convective warming system is strongly recommended.

The baby will require intraoperative glucose infusion. One must remember that once infused, the glucose will be rapidly metabolized, leaving behind a potentially hypotonic solution. In the past, free water was routinely infused in the form of a hypotonic glucose solution such as D10/0.2 normal saline (NS) administered at a rate of 4 mL/kg/hr. This was sufficient to prevent hypoglycemia. Recent studies have focused on the role of increased antidiuretic hormone (ADH) secretion, which occurs during surgery. This ADH secretion renders the infant at a fivefold increased risk of severe hyponatremia when given free water. Current recommendations including infusing *isotonic* glucose solution for maintenance. Insensible losses should be estimated at 3 to 4 mL/kg/hr and replaced with an isotonic (non–glucose-containing) solution. Urine output (ideally 1 mL/kg/hr) may be difficult to assess accurately in a low birth weight baby.

C.3. What are the options regarding induction and intubation?

The goal is to intubate the baby to allow adequate gas exchange with the lowest possible inspiratory pressure needed to inflate the lungs, avoid atelectasis, and minimize gas flow through the

fistula. One-lung ventilation is generally not required. The most important aspect of the intubation is the correct positioning of the ETT. The goal is to have the tip of the ETT distal to the fistula yet proximal to the carina. If the tube is deliberately placed deep (into the right mainstem) with the bevel facing forward, then slowly pulled back just until breath sounds occur on the left equal to the right, the tube is likely to be in good position. Keep in mind the following options:

1. Avoidance of PPV until the fistula is ligated will decrease the risk of gastric distension. One can intubate awake or after inhalation induction while maintaining spontaneous ventilation. Awake intubation can be associated with the risk of increased intracranial pressure or intraventricular hemorrhage in the premature infant and discomfort to the child. If one chooses to intubate after induction, this will require deep anesthesia with spontaneous ventilation using an inhalation anesthetic. The lowest inspiratory pressure assistance is used to prevent atelectasis while minimizing distension of the stomach. If the lungs are suspected of being poorly compliant due to pneumonia or prematurity, then mask ventilation should be avoided. Good intubating conditions can be achieved with a volatile agent, but maintaining adequate ventilation and surgical conditions during a thoracotomy without muscle relaxant may be challenging.
2. Rapid sequence IV induction and placement of the ETT below the fistula is another option. If the ETT is in good position, then muscle relaxants can be given and normal PPV maintained. The difficulty lies in maintaining good position of the ETT during surgical manipulation and turning the patient lateral. Alabbad et al. describe a disastrous scenario in which a neonate with TEF was intubated and ETT position confirmed by breath sounds; yet

after turning the patient, the ETT migrated *into* the fistula without being recognized. This resulted in failure to ventilate the baby and eventual cardiac arrest.

3. Another option, to avoid the risk of ETT malposition, is to deliberately keep the tip of the tube *above* the fistula (if it is shown by bronchoscopy to be small) and keep ventilation pressures low until the fistula is ligated. This comes with a high risk of gastric distension.
4. In cases where the lung compliance is poor, or the fistula is located near the carina, high-frequency oscillating ventilation (HFOV) can be used because it provides gas exchange with a much lower inspiratory pressure. This technique is technically cumbersome and requires utilization of a total IV anesthetic technique.

Alabbad SI, Shaw K, Puligandla PS, et al. The pitfalls of endotracheal intubation beyond the fistula in babies born with type C esophageal atresia. *Semin Pediatr Surg*. 2009;18(2):116–118.

Ho AM, Dion JM, Wong JC. Airway and ventilatory management options in congenital tracheoesophageal fistula repair. *J Cardiothorac Vasc Anesth*. 2016;30:515–520.

C.4. What is the role of rigid and fiberoptic bronchoscopy in this patient prior to incision?

Perioperative bronchoscopy before commencing TEF repair allows assessment of the size and location of the fistula. A cervical level fistula does not require a thoracotomy to repair. A low-lying or subcarinal fistula will predict difficult in placing an ETT that does not ventilate the fistula. The presence of a second fistula can be ruled out. If deemed appropriate, the fistula can be occluded using a no. 3 French Fogarty occlusion catheter, thereby allowing normal PPV without distending the abdomen. Following placement of the balloon, the rigid bronchoscope is

removed and the child intubated with a microcuff ETT *alongside* the catheter. There is a real possibility that during positioning or surgical manipulation, the Fogarty balloon may slide back into the trachea. This could precipitate immediate complete airway obstruction if not promptly recognized and treated.

C.5. Describe the steps of an open repair of EA/TEF.

First, the patient is positioned in the lateral position, left side down. If the patient has a right-sided aortic arch (rare), the surgeon will position the patient with right side down. A retropleural approach is used, which minimizes the danger from an anastomotic leak. The azygos vein is ligated to better visualize the fistula. The fistula is exposed and ligated, leaving a little stump; this usually occurs within 45 minutes. It is important to remember that a fistula stump remains after repair, at least initially. When the patient returns for follow-up surgery (e.g., esophageal dilations), during intubation, the ETT may be observed to pass through the vocal cords yet the tip end up in the stump, precluding effective ventilation. An anterior posterior chest x-ray (AP CXR) will not show this, but a lateral film will. This possibility should always be entertained if unable to ventilate one of these patients despite apparent successful

intubation. If the patient is stable, then normal PPV can commence while the repair of the esophagus begins. The upper esophagus is mobilized, then the distal esophagus. The esophagus is joined together. Following this, a feeding tube is placed across the anastomosis to allow feeding (if the patient does not have a gastrostomy). The lung should be carefully reexpanded to eliminate atelectasis before closure. Chest tubes are not routinely placed following repair.

Knottenbelt G, Skinner A, Seefelder C. Tracheo-oesophageal fistula (TOF) and oesophageal atresia (OA). *Best Pract Res Clin Anaesthesiol*. 2010;24:387–401.

Pinheiro P, Simões e Silva AC, Pereira RM. Current knowledge on esophageal atresia. *World J Gastroenterol*. 2012;18:3662–3672.

C.6. What are common intraoperative problems, and how can they be managed?

Interference with ventilation is the most common problem and can have many causes. Lung retraction with resulting atelectasis leads to frequent desaturation. It may be difficult if not impossible to maintain normocarbia. The partial pressure of arterial carbon dioxide ($PaCO_2$) may rise to 70 to 80 mmHg despite all attempts to optimize ventilation. If the patient has a Fogarty catheter in the fistula, it may be displaced into the trachea causing total airway obstruction. Surgical manipulation of the soft trachea makes the ETT vulnerable to kinking or displacement distally into right mainstem or proximally above the fistula. Frequent compression of vital structures in the mediastinum can lead to profound hemodynamic compromise. Blood and secretions are a constant problem, which risk obstructing the tube. The ETT should be suctioned frequently, more so if blood is seen. The retracted lung may need to be intermittently re-expanded to avoid severe hypoxia. Severe gastric distension before ligation of the TEF may require

emergent gastric needle decompression. It is crucial to maintain close communication with the surgeon. Avoid hypothermia.

C.7. If the surgeon decides to proceed thoracoscopically, how will you perform your anesthetic? Is one-lung ventilation required? What are some complications unique to thoracoscopy in the newborn?

Thoracoscopy to repair TEF/EA has gained increasing popularity over the past decade. Three major advantages are described. First, the approach provides excellent visualization of the fistula, which allows rapid ligation and stabilization of ventilation. Second, avoidance of thoracotomy results in less pain. Third, avoiding posterolateral thoracotomy results in better chest wall symmetry and less long-term scoliosis. A meta-analysis by Borruto et al. showed that the anastomosis leak rate was not increased in the thoracoscopic group.

To perform this anesthetic, an arterial line is mandatory due to the significant gradient between end-tidal and arterial CO_2. Concerns regarding intubation, PPV, paralysis, fluid, and temperature management are identical to that for an open repair. Opioid requirements may be reduced. Isolating the right lung is *not* required for a successful thoracoscopy. One lung ventilation is helpful but not necessary and may not be tolerated well in the neonate. Deliberate left mainstem ETT intubation to collapse the right lung may result in prolonged left upper lobe lung collapse.

Exposure of the fistula is attained by insufflation of the right chest cavity with CO_2 to a pressure of 5 mmHg. Hypercapnia and acidosis are expected with both open repair and thoracoscopic repair, but the degree of hypercapnia and acidosis is worse with thoracoscopy ($PaCO_2$ 59 mmHg vs. 51 mmHg in one study). The potentially impact of the raised intrathoracic pressure and hypercapnia associated with thoracoscopy on neonatal brain oxygenation has been explored. One single-center study found no significant effect on brain cerebral oximetry measurement in infants having repair thoracoscopically compared to open repair, provided mean arterial pressure was maintained with a combination of fluid and inotropic support.

D. Postoperative Management

D.1. When should the baby be extubated?

Although some surgeons prefer to have the baby extubated immediately in the OR to minimize tension on the suture line, this can be risky. Many infants with TEF have a deficiency of tracheal cartilage at the level of the fistula predisposing to

tracheomalacia. This can result in airway obstruction requiring immediate reintubation. Many of the children have significant lung disease from prematurity or aspiration pneumonia; they should stay intubated. If opioid-based postoperative analgesia is planned, mechanical ventilation is preferred due to the risk of hypoventilation. If early extubation is planned, an epidural technique might be helpful. However, if the child is to remain intubated, care should be made to limit inspiratory pressure to protect the repair from disruption.

Broemling N, Campbell F. Anesthetic management of congenital tracheoesophageal fistula. *Paediatr Anaesth*. 2011;21:1092–1099.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:510.

Knottenbelt G, Skinner A, Seefelder C. Tracheo-oesophageal fistula (TOF) and oesophageal atresia (OA). *Best Pract Res Clin Anaesthesiol*. 2010;24:387–401.

D.2. What options are available for postoperative analgesia?

For patients who are to remain intubated postoperatively, a narcotic anesthetic technique with fentanyl at 10 to 20 μg per kg with muscle relaxant will give hemodynamic stability and allow analgesia to be continued in the postoperative period. For experienced practitioners, an epidural catheter can also be placed. An epidural catheter threaded through the caudal space can be easily threaded up to the thoracic dermatomes. The position of the catheter placed in this way should be confirmed with fluoroscopy or ultrasound prior to use. This technique should only be undertaken by one who is experienced in regional anesthesia for children.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:510.

Knottenbelt G, Skinner A, Seefelder C. Tracheo-oesophageal fistula (TOF) and oesophageal atresia (OA). *Best Pract Res Clin Anaesthesiol*. 2010;24:387–401.

D.3. What are early and late complications of TEF repair?

Early anastomosis leakage occurs in up to 15% of patients. This may require immediate exploration or may be managed expectantly. Esophageal dysmotility and gastroesophageal reflux disease (GERD) are common. The dysmotility may be from abnormal innervation of the distal esophagus or may be related to vagal nerve injury during the repair. Stricture of the esophageal anastomosis may require repeated dilatations. Tracheomalacia may be evident postoperatively, and vocal cord paresis has been reported.

37 Congenital Diaphragmatic Hernia

Dana L. Gurvitch and Fun-Sun F. Yao

A full-term male baby was born with respiratory distress and cyanosis. Physical examination showed barrel chest and scaphoid abdomen. The breath sounds were absent in the left side of the chest; the heart sounds were best heard in the right side of the chest. Labored respiration, nasal flaring, and sternal retraction were found. The baby weighed 2,800 g. Blood pressure was 60/30 mmHg; heart rate, 160 beats per minute; respiration, 70 breaths per minute; and temperature, 36°C (96.8°F). Arterial blood gas analysis on room air showed the following: pH, 7.20; $Paco_2$, 55 mmHg; Pao_2, 35 mmHg; and CO_2 content, 19 mEq per L.

A. Medical Disease and Differential Diagnosis

1. What differential diagnoses are compatible with these signs and symptoms?
2. Describe the incidence and classification of congenital diaphragmatic hernia (CDH).
3. What are the causes of hypoxemia in patients with CDH?
4. How do you assess the severity of pulmonary hypoplasia?
5. How do you make a diagnosis of right-to-left shunting through

the patent ductus arteriosus?

6. What other congenital anomalies are usually associated with CDH?

B. Preoperative Evaluation and Preparation

1. How would you interpret the following arterial blood gas analyses: pH, 7.20; $Paco_2$, 55 mmHg; Pao_2, 35 mmHg; and CO_2 content, 19 mEq per L? How would you correct them?
2. What immediate treatment should be given to improve the newborn's respiratory status preoperatively?
3. Should CDH be repaired urgently once the diagnosis is made and confirmed?
4. What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?
5. What is the current role of extracorporeal membrane oxygenation (ECMO) in the management of CDH?

C. Intraoperative Management

1. What monitors would you use for this neonate during surgery?
2. How would you induce and maintain anesthesia?
3. Would you use nitrous oxide for anesthesia? Why?
4. How would you ventilate the patient?
5. Is the infant with CDH more at risk from hypothermia?
6. The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mmHg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you immediately do?
7. Discuss fluid therapy in this patient.

8. At the conclusion of surgery, would you extubate the patient in the operating room?

D. Postoperative Management

1. What is the mortality rate in patients with CDH? What postoperative problems would you expect in this patient?

A. Medical Disease and Differential Diagnosis

A.1. What differential diagnoses are compatible with these signs and symptoms?

The differential diagnosis of cyanosis and respiratory distress in the newborn is broad and includes respiratory distress syndrome, meconium aspiration, diaphragmatic hernia, persistent pulmonary hypertension (PPH) of the newborn, cyanotic congenital heart disease, choanal atresia, airway abnormalities, and bronchopulmonary sequestration. However, CDH should be suspected in any infant with respiratory distress, shift of cardiac sounds to the right, decreased breath sounds ipsilateral to the side of the hernia, bowel sounds heard in the chest and a concave/scaphoid abdomen. Confirmation of diagnosis includes a chest x-ray demonstrating herniation of abdominal contents into the hemithorax, little or no visible aerated lung on affected side and mediastinal shift (**Fig. 37.1**). If in doubt, a radiopaque dye may be injected through a nasogastric tube to delineate the stomach and intestine in the chest cavity. If the CDH is right sided, the liver may be the only herniated organ and appear as a thoracic soft tissue mass. The internal abdominal view of CDH is shown in **Figure 37.2**.

Kliegman RM, Stanton BF, St Geme JW, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:894.

A.2. Describe the incidence and classification of congenital diaphragmatic hernia (CDH).

The incidence of CDH is between 1 per 2,000 and 1 per 3,000 births. Eighty-five percent of defects are left sided and <5% are bilateral. Ninety percent of defects are posterolateral (Bochdalek hernia). Anteromedial and paraesophageal hernias and eventrations make up the remainders (**Fig. 37.3**). There is no difference in mortality between left- and right-sided herniations, although right sided may have a higher incidence of pulmonary complications. Associated anomalies can include central nervous system (CNS) lesions, esophageal atresia, omphalocele, and cardiovascular lesions. In addition, trisomy 21, trisomy 13, trisomy 18, and tetrasomy 12p are examples of syndromes associated with CDH.

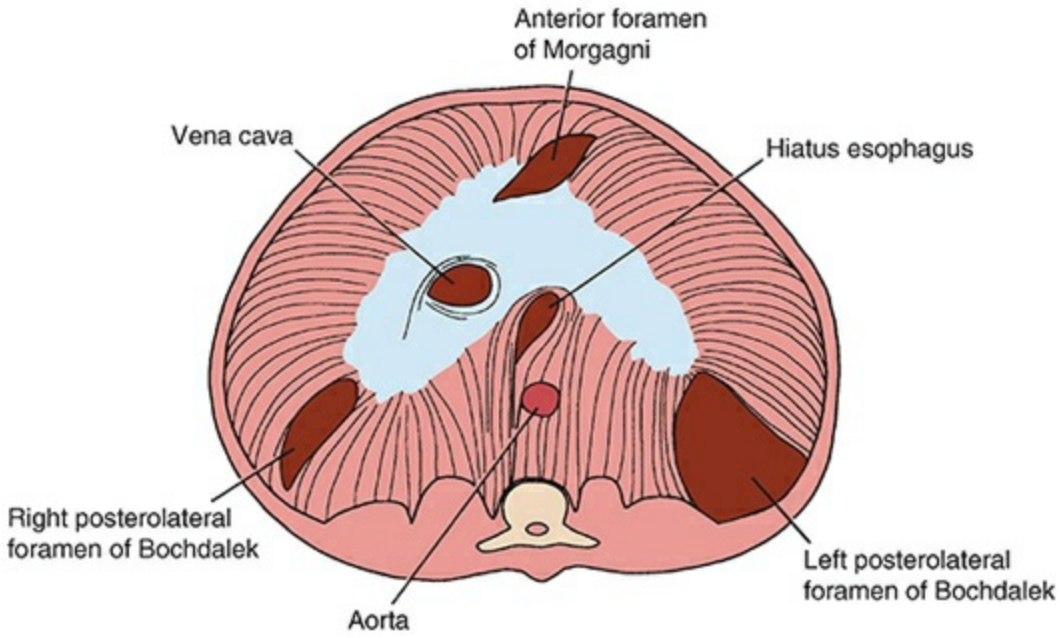

FIGURE 37.3. Potential sites of CDH.

A.3. What are the causes of hypoxemia in patients with CDH?

Infants with CDH have deficient bilateral major airway and vessel branching not explained by simple compression of the ipsilateral and contralateral lungs. The severity of pulmonary vascular hypoplasia correlates with mortality in CDH. Airway maldevelopment leads to reduced total number of bronchi and alveoli at birth with resulting decreased lung compliance and decreases in both ventilation and surface area for gas exchange.

Oxygenation is thus impaired. Pulmonary vascular hypoplasia results in pulmonary hypertension, causing right-to-left shunting through the patent ductus arteriosus, with resultant hypoxemia.

Bancalari E, ed. *The Newborn Lung: Neonatology Questions and Controversies*. 2nd ed. Philadelphia, PA: Elsevier; 2012:381–406.

A.4. How do you assess the severity of pulmonary hypoplasia?

The majority of infants with CDH are diagnosed prenatally by ultrasound, which demonstrates herniated viscera with or without liver in the fetal thorax. The degree of pulmonary hypoplasia is estimated by calculating the lung-to-head ratio where a high ratio (>1.4) indicates good lung size and predicts a good outcome compared to a low ratio (<1.0). In addition, color flow Doppler can be used to assess positioning of the umbilical and portal veins, which are indicative of liver herniation. Fetal magnetic resonance imaging (MRI) is increasingly being used for confirmation of CDH and for anatomy delineation as well as fast spin echo MRI for lung volume calculation and thus further assessment of pulmonary hypoplasia.

Postnatally, the degree of pulmonary hypoplasia can be assessed by the degree of respiratory distress, hypoxemia, acidosis, and ensuing PPH in the newborn. Severe hypoplasia necessitates immediate intubation and mechanical ventilation and ECMO for neonates with critical cardiopulmonary deterioration. Inability to resuscitate in the delivery room is a marker of lethal lung hypoplasia and most centers will not attempt emergency ECMO in this situation.

Hedrick HL, Crombleholme TM, Flake AW, et al. Right congenital diaphragmatic hernia: prenatal assessment and outcome. *J Pediatr Surg*. 2004;39:319–323.

A.5. How do you make a diagnosis of right-to-left shunting through the patent ductus arteriosus?

Clinical signs of ductal patency include murmur, tachycardia, bounding peripheral pulses with wide pulse pressure, congestive heart failure, and unexplained metabolic acidosis. Preductal (upper extremity) and postductal (lower/umbilical arteries) oxygen saturation measurements by pulse oximetry demonstrate a 10% or higher gradient difference (with preductal saturation being higher). The gold standard for diagnosis is with Doppler echocardiogram to demonstrate the size of the ductal opening and the shunt and allow estimation of mean pulmonary pressure.

A.6. What other congenital anomalies are usually associated with CDH?

About one-third of patients born with CDH have major congenital abnormalities.

- 10% having a chromosome abnormality, most commonly trisomy 18 and isochromosome 12p
- 25% having cardiovascular malformations including ventricular septal defect (VSD), autism spectrum disorder (ASD), tetralogy of Fallot (TOF), and hypoplastic left heart syndrome

- 28% having CNS abnormalities including neural tube defects, hydrocephalus, agenesis of corpus callous, and sensorineural hearing loss
- 15% having genitourinary abnormalities including undescended testis and hypospadias
- 20% having gastrointestinal malformations including malrotation, atresia, omphalocele, and gastroesophageal reflux

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. New York: Churchill Livingstone; 2012:510–512.

B. Preoperative Evaluation and Preparation

B.1. How would you interpret the following arterial blood gas analyses: pH, 7.20; $PaCO_2$, 55 mmHg; PaO_2, 35 mmHg; and CO_2 content, 19 mEq per L? How would you correct them?

The blood gas analyses demonstrate a mixed respiratory and metabolic acidosis with severe hypoxemia. In this patient, the severe hypoxemia is due to the pulmonary pathology and PPH. As alveolar P_{O_2} decreases below a threshold of 50 mmHg at normal P_{CO_2}, ventilation increases initially and respiratory alkalosis followers. However, if hypoxemia is not corrected, patient fatigue results in CO_2 retention and a respiratory acidosis. In addition, the hypoxemia results in anaerobic metabolism and a concomitant lactic acidosis.

Treatment includes mechanical ventilation with control of oxygenation and ventilation. Metabolic acidosis should be corrected by administration of sodium bicarbonate and improvement of circulation/perfusion with fluid therapy.

Kliegman RM, Stanton BF, St Geme JW, et al, eds. *Nelson Textbook of*

Pediatrics. 21st ed. Philadelphia, PA: Elsevier; 2019:410–421.

Pittman RN. *Regulation of Tissue Oxygenation*. San Rafael, CA: Morgan & Claypool Life Sciences; 2011:33–35.

B.2. What immediate treatment should be given to improve the newborn's respiratory status preoperatively?

Immediate treatment should include intubation and ventilation and decompression of the intrathoracic bowel with a nasogastric tube. Barotrauma and further pulmonary damage must be avoided by maintaining peak inspiratory pressures under 25 cm H_2O and fraction of inspired oxygen (FIO_2) adjusted to preductal arterial saturations >85%. Institution of pressure support ventilation, use of high-frequency oscillatory ventilation, permissive hypercarbia, and even ECMO are modes to optimize the oxygenation status.

B.3. Should CDH be repaired urgently once the diagnosis is made and confirmed?

Surgical repair of CDH was treated as a surgical emergency. However, improvement in gas exchange, thoracic compliance, or $PaCO_2$ was not proven from immediate surgery. This has resulted in delay for clinical stabilization of the neonate's respiratory and cardiovascular status and ensuring adequate end-organ perfusion, as evidenced by improved oxygenation, decreasing pulmonary vascular hypertension, and correction of metabolic acidosis.

B.4. What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?

In vivo, NO is an endothelium-derived relaxing factor, which causes smooth muscle relaxation and vasodilation. Inhaled NO (iNO) is unique in that it is a selective pulmonary vasodilator and has no effect on systemic circulation. In low concentrations, iNO diffuses into pulmonary smooth muscle, raises the concentration of current good manufacturing practice (cGMP), which induces selective vasodilation and decreased vascular tone. Unfortunately, most neonates with CDH with pulmonary hypertension plus lung hypoplasia do not have a dramatic response to iNO. A Cochrane review concluded that iNO does not improve outcomes in neonates with CDH and may, in fact, worsen outcomes.

B.5. What is the current role of extracorporeal membrane

oxygenation (ECMO) in the management of CDH?

Despite wide use over many decades, survival of patients with CDH treated with ECMO remains unchanged at 50%. A recent United Kingdom study showed infants who received ECMO for CDH had significant mortality in the first year of life and there was long-term physical and neurodevelopmental morbidity in the majority of survivors. Consensus of significant risks associated with ECMO, such as bleeding, intracranial hemorrhage, and sepsis, have shifted the implementation of ECMO, as a rescue therapy for infants with persistent preductal hypoxemia and acidosis despite inotropic and ventilator support.

C. Intraoperative Management

C.1. What monitors would you use for this neonate during surgery?

Respiratory

- Two pulse oximeters, for preductal and postductal oxygen saturation
- Capnometry
- Inspiratory pressure measurement
- Inspiratory oxygen concentration
- Intraoperative arterial blood gas analysis

Cardiovascular

- Five-lead electrocardiogram

- Blood pressure cuff
- Arterial line: right radial artery for preductal Pao_2
- Central venous pressure (CVP) line for evaluating volume status and right ventricular performance

Thermoregulatory

- Esophageal or rectal temperature probe

C.2. How would you induce and maintain anesthesia?

In general, the preoperative care of the neonate is continued into the operating room with the addition of high-dose opioids and nondepolarizing muscle relaxant. Ventilation strategies focus on permissive hypercarbia (60 to 65 mmHg), preductal oxygen saturation of 90% to 95%, and peak pressures <25 cm H_2O.

Volatile agents may be instituted with precaution because systemic vascular resistance may decrease more than pulmonary vascular resistance (PVR) resulting in worsening of right-to-left shunt. Frequent blood gas sampling will guide changes in respiratory management and assessment of acid–base status. Availability of agents to maintain blood pressure support should be readily available and include isotonic fluids and inotropes such as dopamine and/or dobutamine and hydrocortisone. Meticulous attention to temperature is essential because hypothermia can increase PVR and thus increase right-to-left shunting.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Saunders/Elsevier; 2018:860.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2016:595.

C.3. Would you use nitrous oxide for anesthesia? Why?

Nitrous oxide is avoided because it will expand air-filled cavities (such as bowel) and potentially further compress

functioning lung tissue and because it limits the inspired oxygen concentration, which can be provided to a compromised neonate.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Saunders/Elsevier; 2018:860.

C.4. How would you ventilate the patient?

The goals of ventilation and oxygenation in the operating room are the same as preoperative: Avoid volutrauma by using small tidal volumes and low-peak inspiratory pressures, adequate oxygenation with the goal of saturations in the low to mid 90s, and permissive hypercapnia with maintenance of pH >7.25.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Saunders/Elsevier; 2018:860.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2016:594–595.

C.5. Is the infant with CDH more at risk from hypothermia?

All neonates are susceptible to heat loss because of a high ratio of surface area to body weight, reduced subcutaneous fat, and an underdeveloped ability to shiver (thermogenesis) in response to cold. However, infants with CDH have increased morbidity and mortality secondary to hypothermia because the resulting increased PVR can cause decreased oxygen delivery, worsening acidosis, shunting, and continued increases in PVR. Concentrated efforts to maintain normothermia are mandatory and include maintaining ambient operating room temperature >23°C, use of warmed intravenous fluids, passive insulation with drapes and blankets, forced-air warming, and passive humidification of inspired anesthetic gases.

Bajwa SJS, Swati. Perioperative hypothermia in pediatric patients: diagnosis, prevention and management. *Anaesth Pain Intensive Care*. 2014;18(1):97–100.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2016:594–595.

C.6. The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mmHg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you immediately do?

Any sudden deterioration in blood pressure, heart rate, oxygen saturation, or pulmonary compliance is suggestive of tension pneumothorax. Auscultation of the chest, particularly the contralateral side, should be done immediately. If absent or diminished breath sounds confirm the diagnosis, a chest tube should be inserted immediately. A large-bore intravenous catheter with needle may be inserted to release the tension pneumothorax if a chest tube is not immediately available.

The tension pneumothorax is usually on the contralateral side because the high airway pressure required to inflate the hypoplastic lung may rupture the normal alveoli on the contralateral side, resulting in pneumothorax. Moreover, the ipsilateral chest usually already has a chest tube after surgery.

If there is no pneumothorax, or if deterioration is not improved after insertion of a chest tube, inferior vena cava compression (resulting in decreased venous return and decreased cardiac output) should be considered. The abdominal cavity is

often underdeveloped and unable to fully accommodate the returned abdominal organs, which increases the intra-abdominal pressure, displaces the diaphragm cephalad, and ultimately decreases pulmonary compliance (in the healthy lung). The net result clinically is desaturation, hypercarbia, and overall instability. In this circumstance, the abdominal wound should be reopened to relieve the compression on the great vessels and displacement of the diaphragm. A patch closure of the abdomen can be attempted or a Silo pouch is placed until growth allows safe return to the abdominal cavity.

Coté CJ, Lerman J, Anderson BJ, eds. *Coté and Lerman's A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Saunders/Elsevier; 2018:860.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2016:594–595.

C.7. Discuss fluid therapy in this patient.

Fluid and electrolyte management in newborns should be focused on maintaining homeostasis while recognizing the impact of gestational age, physiologic changes in renal function, redistribution of total body water, water loss secondary to environmental factors, underlying medical condition of neonate, and surgical stress on fluid requirements. Neonates are obligate sodium losers, and therefore, exogenous sodium should be supplied. In addition, urine concentrating ability is limited in the newborn and as a result, the risk of volume depletion is increased due to the inability to maximally concentrate urine, decreased response to antidiuretic hormone (ADH), limited sodium reabsorption due to tubular immaturity, and reduced responsiveness to aldosterone.

The preoperative fluid deficit may be evaluated by careful history taking, signs and symptoms of dehydration, urine output, and CVP monitoring. Maintenance fluids consisting of 5%

dextrose in one-fourth to one-half strength saline are given at 4 mL/kg/hr. Intraoperative evaporative and third-space losses are replaced with lactated Ringer's, Plasma-Lyte, or saline at approximately 6 to 8 mL/kg/hr. Each milliliter of blood loss is replaced with 3 mL of lactated Ringer's or 1 mL of 5% albumin. Blood pressure, heart rate, urine output, CVP, hematocrit, and electrolytes should guide fluid therapy.

Feld LG, Neuspiel DR, Foster BA, et al. Clinical practice guideline: maintenance intravenous fluids in children. *Pediatrics*. 2018;142:e20183083.

Kliegman RM, Stanton BF, St. Geme JW, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:425–428.

C.8. At the conclusion of surgery, would you extubate the patient in the operating room?

No, the patient should remain intubated at the conclusion of surgery. Varying degrees of pulmonary dysfunction, fluid shifts, and changes in abdominal compliance must be anticipated, and the need for postoperative mechanical ventilation and stabilization is mandatory.

D. Postoperative Management

D.1. What is the mortality rate in patients with CDH? What postoperative problems would you expect in this patient?

Despite advances in medical and surgical treatment, the mortality rate in patients with CDH has remained at approximately 20% to 30% over the past two decades. Pulmonary hypoplasia and PPH are the two main prognosticators. Survival is complicated by both restrictive and obstructive lung disease patterns and BPD is often documented radiographically. Curiously, by childhood or adolescence, survivors of CDH seem to recover and remodel achieving near-

normal lung volumes and mechanics. Gastroesophageal reflux disease, intestinal obstruction, delayed growth, neurocognitive defects, sensorineural hearing loss, and musculoskeletal abnormalities (mainly scoliosis and pectus excavatum) also complicate long term survival.

38 Tetralogy of Fallot

David Whiting and James A. DiNardo

A 5-month-old infant is being evaluated for stable persistent cyanosis with arterial oxygen saturation (Sa_{O_2}) of 70% to 80% since birth. She eats well and is in the 70th percentile for weight (6.5 kg). A transthoracic echocardiogram done before her arrival at your institution suggests that she has tetralogy of Fallot (TOF). Although she has never been noted to have a "Tet spell," her Sa_{O_2} was noted to decrease to 60% during a recent febrile illness. A repeat echocardiogram reveals TOF with severe valvar pulmonary stenosis (PS) and mild subvalvar PS secondary to anterior deviation of the conal septum into the right ventricle outflow tract (RVOT). There is a peak instantaneous pressure gradient of 70 mmHg across the RVOT, as determined by continuous wave Doppler.

A. Medical Disease and Differential Diagnosis

1. What is TOF?
2. What is the pathophysiology of TOF/PS?
3. What is shunting, and how is Q_P:Q_S calculated?
4. What is the pathophysiology of TOF with pulmonary atresia?
5. How is Sa_{O_2} determined in single ventricle physiology?
6. What is a "pink Tet"?

7. What are hypercyanotic spells? How are they treated?
8. What palliative surgical procedures are available for treating patients with TOF/PS?
9. What palliative catheter-based procedures are available for patients with TOF?
10. What definitive surgical procedures are available for treating patients with TOF/PS?
11. What palliative and definitive surgical procedures are available for patients with TOF with pulmonary atresia?
12. What are the long-term outcomes of patients with TOF?

B. Preoperative Evaluation and Preparation

1. What preoperative history and physical examination information do you want?
2. Which other abnormalities need to be considered in this patient?
3. What premedication will you give to a child with congenital heart disease?

C. Intraoperative Management

1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?
2. Why would end-tidal carbon dioxide (Et_{CO_2}) monitoring be of particular use in a patient with TOF/PS?
3. What is near-infrared spectroscopy (NIRS) and what does it measure?
4. What are the important management issues during creation of a palliative shunt?
5. What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?
6. What are the pre-cardiopulmonary bypass (pre-CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?

7. What interventions will reliably reduce PVR?
8. How does heparin administration and activated coagulation time (ACT) monitoring for CPB differ in children as compared with adults?
9. How is heparin reversed?
10. What is the incidence of protamine reactions in children?
11. What is the role of transesophageal echocardiography (TEE) in this patient?
12. What effect would a residual ventricular septal defect (VSD) have in this patient following separation from CPB?

D. Postoperative Management

1. How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?
2. Following complete repair of TOF/PS in an infant, what Sao_2 is acceptable?
3. Following placement of a modified Blalock-Taussig shunt (MBTS) for TOF/PS in an infant, what Sao_2 is acceptable?
4. What is junctional ectopic tachycardia (JET)?

A. Medical Disease and Differential Diagnosis

A.1. What is TOF?

In 1888, French physician Étienne-Louis Arthur Fallot described a congenital heart defect with four characteristics: (1) large VSD, (2) right ventricular (RV) outflow obstruction, (3) overriding aorta, and (4) right ventricle hypertrophy (RVH). Broadly defined, TOF is a complex of anatomic malformations consisting of a large malaligned conoventricular VSD; rightward and anterior displacement of the aorta such that it overrides the VSD; and a variable degree of subvalvar RVOT obstruction due to anterior, superior, and leftward deviation of the conal

(infundibular) ventricular septum. In addition, RV abnormalities in the septal and parietal bands of the crista supraventricularis exacerbate the infundibular RVOT obstruction. RVH is the result of chronic RVOT obstruction. The most common associated lesion is a right aortic arch with mirror image arch vessel branching that occurs in 25% of patients with TOF. In this lesion, the innominate artery gives rise to the left carotid and left subclavian arteries and the right carotid and subclavian arteries arise separately. TOF/PS and TOF with pulmonary atresia are two broad subsets of TOF. A third rare variant of TOF occurs when the pulmonary valve is absent.

Tetralogy of Fallot with Pulmonary Stenosis

TOF/PS has the four features of TOF in conjunction with varying degrees of valvar PS. At one end of the spectrum, the pulmonary valve annulus is mildly hypoplastic with minimal fusion of the pulmonary valve leaflets (**Fig. 38.1A**). At the other end of the spectrum, the pulmonary annulus is very small and the pulmonary valve leaflets are nearly fused. RVOT from valvar PS is fixed, whereas the subvalvar component of RVOT obstruction is dynamic. If left uncorrected, compensatory RVH from valvar or subvalvar components of the RVOT increases the mass of the RV and the infundibulum and worsens subvalvar obstruction. The anatomy of TOF/PS can usually be definitively delineated by two-dimensional transthoracic echocardiography, so further imaging with cardiac catheterization is rarely necessary or indicated.

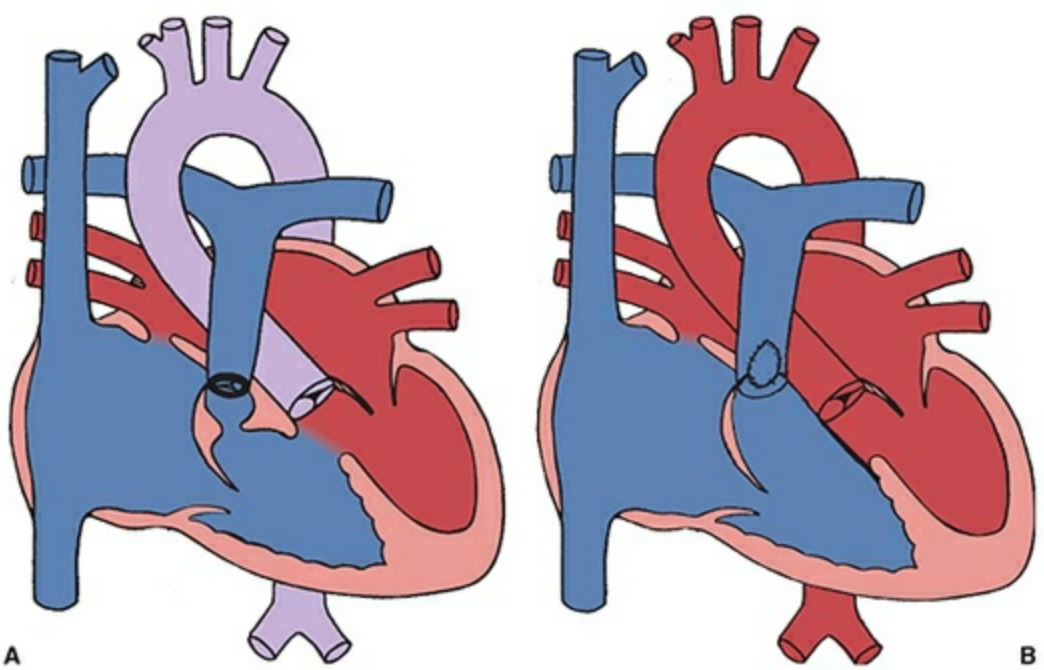

FIGURE 38.1. A. Uncorrected tetralogy of Fallot with pulmonary stenosis (TOF/PS) demonstrating malalignment ventricular septal defect (VSD) with aortic override, valvular and subvalvular (dynamic) PS. There is a left aortic arch. **B.** Definitively repaired TOF/PS with VSD closure creating left ventricle to aortic continuity, resection of subvalvular muscle bundles and deviated conal septum, and creation of a transannular patch (with pulmonary valvectomy) creating pulmonary insufficiency. A small atrial-level communication has been left.

Tetralogy of Fallot with Pulmonary Atresia

TOF with pulmonary atresia has the features of TOF with infundibular and pulmonary valvar atresia in conjunction with varying degrees of pulmonary artery (PA) atresia. TOF with pulmonary atresia patients are divided into four groups based on the degree of PA atresia. *Group 1* patients have isolated infundibular and pulmonary valve atresia with main PA and branch PAs of near-normal size and architecture. In some of these patients, the main PA may extend to the atretic infundibulum. In others, atresia involves a short segment of the main PA (**Fig. 38.2**). Patients in this group have pulmonary blood flow supplied from a patent ductus arteriosus (PDA). In *group 2* patients, the main PA is absent, but the left and right PAs are in continuity and supplied by a PDA. *Group 3* patients have severely hypoplastic native PAs, and the left and right PAs

may not be in continuity. Pulmonary blood flow is from collateral vessels from the aorta to the PAs, known as major aortopulmonary collateral arteries (MAPCAs). A PDA may be present as well. Some segments of lung may be perfused from MAPCAs, some only by the native PAs, and others by both sources (**Fig. 38.3**). *Group 4* patients have no native PAs, and all pulmonary blood flow is derived entirely from MAPCAs.

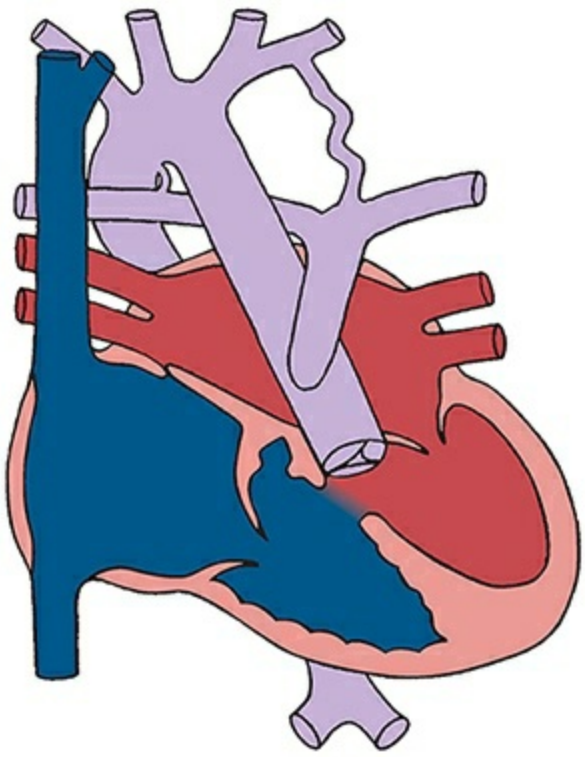

FIGURE 38.2. Illustration of TOF with pulmonary atresia group 1 with short segment pulmonary artery (PA), good-sized PAs in continuity supplied by a right-sided patent ductus arteriosus, and one major aortopulmonary collateral artery from the left subclavian artery. There is a right aortic arch with mirror image arch vessel branching.

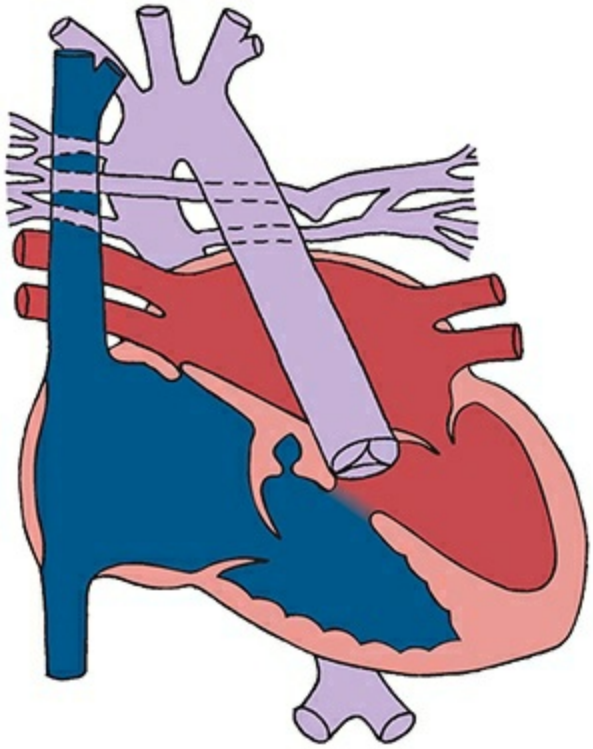

FIGURE 38.3. Illustration of TOF with pulmonary atresia group 3 with no main pulmonary artery (PA), small branch PAs in continuity supplied by major aortopulmonary collateral arteries (MAPCAs). Some lung segments are supplied by the native PAs, whereas others are supplied directly by MAPCAs. There is a right aortic arch with mirror image arch vessel branching.

The anatomy of MAPCAs in TOF with pulmonary atresia can almost never be clearly delineated by two-dimensional transthoracic echocardiography alone. Cardiac catheterization and/or magnetic resonance imaging or magnetic resonance angiography are usually necessary to delineate collateral anatomy and determine Q_P:Q_S.

Jonas RA, ed. Tetralogy of Fallot with pulmonary atresia. In: *Comprehensive Surgical Management of Congenital Heart Disease*. 2nd ed. Boca Raton, FL: CRC Press; 2014:585–602.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

Tetralogy of Fallot with Absent Pulmonary Valve

TOF with absent pulmonary valve is the least common variant of TOF and accounts for only 3% to 6% of cases of TOF. These

patients have a displaced infundibulum, VSD, and varying degrees of RVOT obstruction as well as aneurysmal dilation of the main and branch PAs from in utero pulmonary regurgitation. The pathophysiology of TOF is complicated by symptoms of tracheobronchial compression that are similar to those caused by an anterior mediastinal mass. These patients usually must be positioned on their sides even when mechanically ventilated.

A.2. What is the pathophysiology of TOF/PS?

The pathophysiology of TOF/PS is a right-to-left (R-L) shunt characterized by the presence of an interventricular communication (VSD) and partial obstruction to RV outflow caused by RV infundibular and valvar stenosis. This is a complex shunt because resistance to RV outflow is a combination of the resistance from the obstructive lesions and the PVR. If the resistance from the RV obstructive lesions is high, changes in PVR will have little effect on shunt magnitude and direction. In most patients with TOF/PS, there is a fixed (valvar) and dynamic (variations in caliber of the RV infundibulum) component to RVOT obstruction. In addition, because the aorta overrides the VSD and the RV, desaturated systemic venous blood tends to stream out of the RV directly to the aorta, even in the presence of mild RVOT obstruction resulting in further systemic desaturation.

The degree of cyanosis is related to the percentage of desaturated hemoglobin. A markedly hypoxemic child with baseline arterial saturations in the 70% range who is anemic may appear less cyanotic than another child with similar oxygen saturation and a hematocrit of 65%. The Sa_{O_2} is determined by the relative volumes and saturations of recirculated systemic venous blood and effective systemic blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } Sao_2 = \frac{[(\text{pulmonary venous } O_2 \text{ saturation} \times \text{effective systemic blood flow}) + (\text{systemic venous } O_2 \text{ saturation} \times \text{recirculated systemic venous blood flow})]}{(\text{total systemic blood flow})}$$

This is demonstrated in **Figure 38.4**. Notice that the patient has a Q_P:Q_S = 0.5:1.

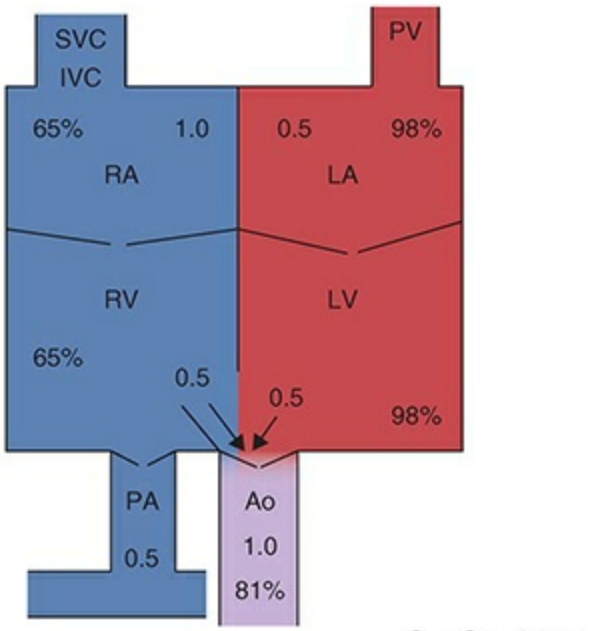

FIGURE 38.4. Chamber oxygen saturations and relative flows for a patient with uncorrected tetralogy of Fallot with pulmonary stenosis (TOF/PS). Arterial oxygen saturation (SaO_2) and Q_P:Q_S are illustrated. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

A.3. What is shunting, and how is Q_P:Q_S calculated?

Shunting is the process whereby venous return from one circulatory system is recirculated into the arterial outflow of the same circulatory system. Flow of blood from the systemic venous atrium (right atrium) to the aorta produces a physiologic R-L shunt with recirculation of systemic venous blood. Flow of blood from the pulmonary venous atrium (left atrium) to the PA produces a physiologic left-to-right (L-R) shunt with

recirculation of pulmonary venous blood. A physiologic R-L or L-R shunt is usually caused by a communication (orifice) at the level of the cardiac chambers or great vessels; however, physiologic shunts can exist in the absence of an anatomic shunt; transposition physiology is the best example.

Effective blood flow is the quantity of venous blood from one circulatory system reaching the arterial system of the other circulatory system. Effective pulmonary blood flow is the volume of systemic venous blood reaching the pulmonary circulation, whereas effective systemic blood flow is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary and effective systemic blood flows are always equal, no matter how complex the lesions. Effective blood flow usually is the result of a normal pathway through the heart, but it may occur as the result of an anatomic R-L or L-R shunt.

Total pulmonary blood flow (Q_P) is the sum of effective pulmonary blood flow and recirculated pulmonary blood flow. Total systemic blood flow (Q_S) is the sum of effective systemic blood flow and recirculated systemic blood flow. Total pulmonary blood flow and total systemic blood flow do not have to be equal because the amount of recirculated systemic or pulmonary venous blood do not have to equal. Q_S (systemic cardiac output) tends to remain constant to maintain end-organ blood supply, even in the presence of a physiologic R-L shunt (systemic venous recirculation), although the Sa_{O_2} will be lower. Conversely, a physiologic L-R shunt (pulmonary recirculation) causes pulmonary volume overload.

The calculation of Q_P:Q_S can be made by the Fick equation, where the pulmonary and systemic blood flows (Q_P and Q_S) are calculated individually by dividing the rate of oxygen extraction by the change in oxygen content in the arterial and venous side

of each circulation. The rate of oxygen extraction is the same as effective systemic or pulmonary blood flow and must be equal, so these numbers cancel out in the equation. The calculation of oxygen content is simplified when the determination is made using low inspired concentrations of oxygen (fraction of inspired oxygen [F_{IO_2}]), the contribution of oxygen carried in solution ($P_{O_2} \times 0.003$) can be ignored, so calculation of Q_P:Q_S can be simplified using oxygen saturations. Failure to account for the contribution of oxygen carried in solution, when calculation oxygen content of blood, will introduce substantial error.

$$(S_AO_2 - S_{SVC}O_2) / (S_{PV}O_2 - S_{PA}O_2)$$

where A = arterial, SVC = superior vena cava, PV = pulmonary vein that can be assumed to be 98% in the absence of significant pulmonary disease, and PA = pulmonary artery.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

38.

A.4. What is the pathophysiology of TOF with pulmonary atresia?

The pathophysiology of TOF with pulmonary atresia is characterized as single ventricle physiology because there is a VSD and little or no antegrade flow from the RV. In single ventricle physiology, there is complete mixing of pulmonary venous and systemic venous blood at the atrial or ventricular level and the ventricle(s) distributes output to both the systemic and pulmonary vascular beds. As a result of this physiology, the following are observed:

- Ventricular output is the sum of pulmonary blood flow (Q_P) and systemic blood flow (Q_S).
- Distribution of systemic and pulmonary blood flow is

dependent on the relative resistances to flow (both intracardiac and extracardiac) into the two parallel circuits.

- Oxygen saturations are the same in the aorta and the PA.

Single ventricle physiology can exist with one hypoplastic ventricle and one well-developed ventricle or with two well-formed anatomic ventricles when there is atresia or near atresia of outflow from one of the ventricles.

Examples include the following:

- TOF with pulmonary atresia where pulmonary blood flow is supplied through a large PDA or MAPCAs
- Truncus arteriosus
- Severe neonatal aortic stenosis and interrupted aortic arch; in both lesions, a substantial portion of systemic blood flow is supplied through a PDA.
- Heterotaxy syndrome

In cases where there is a single anatomic ventricle, there is complete or near-complete obstruction to inflow and/or outflow from the hypoplastic ventricle, so there must be an alternate source of either systemic or pulmonary blood flow to ensure postnatal survival. An example of alternate source of blood flow is in ductal-dependent circulation where a PDA forms a direct connection between the aorta and the PDA is the alternate (sole) source of systemic blood flow in hypoplastic left heart syndrome or of pulmonary blood flow in PA with intact ventricular septum. In other instances of a single anatomic ventricle, intracardiac pathways provide both systemic and pulmonary blood flow as in tricuspid atresia with normally related great vessels, a nonrestrictive VSD and minimal or absent PS.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.5. How is SaO_2 determined in single ventricle

physiology?

The Sa_{O_2} is determined by the relative volumes and saturations of pulmonary venous and systemic venous blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } O_2 \text{ saturation} = \frac{\begin{array}{c}[(\text{systemic venous saturation})(\text{total systemic venous blood flow}) \\ + (\text{pulmonary venous saturation})(\text{total pulmonary venous blood flow})]\end{array}}{(\text{total systemic blood flow} + \text{total pulmonary venous blood flow})}$$

The primary goal in the management of patients with single ventricle physiology is the optimization of systemic oxygen delivery and perfusion pressure to prevent end-organ (myocardial, renal, hepatic, splanchnic) dysfunction, so the systemic and pulmonary circulations must be balanced. The term balanced circulation is used because both laboratory and clinical evaluations have demonstrated that maximal systemic oxygen delivery (the product of systemic oxygen content and systemic blood flow) is achieved for single ventricle lesions when Q_P:Q_S is at or just below 1:1. Increases in Q_P:Q_S in excess of 1:1 are associated with a progressive decrease in systemic oxygen delivery because the subsequent increase in systemic oxygen content is more than offset by the progressive decrease in systemic blood flow and by diastolic hypotension due to runoff into the pulmonary circulation. Decreases in Q_P:Q_S below 0.7 to 0.8:1 are associated with a precipitous decrease in systemic oxygen delivery because the subsequent increase in systemic blood flow is more than offset by the dramatic decrease in systemic oxygen content.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.6. What is a "pink Tet"?

The term pink Tet refers to any patient with TOF/PS or TOF with pulmonary atresia who is not cyanotic. In these patients, Q_P:Q_S is sufficiently high (usually greater than 0.8:1 in the presence of a normal mixed venous saturation and pulmonary vein saturations) to maintain a deoxyhemoglobin concentration less than 5 g per dL with Sao_2 generally >80%. Examples are TOF/PS patients with minimal valvar and subvalvar PS and all patients with TOF with pulmonary atresia where pulmonary blood flow is supplied from a large PDA and/or MAPCAs.

DiNardo JA, Zvara DA. Congenital heart disease. In: DiNardo JA, Zvara DA, eds. *Anesthesia for Cardiac Surgery*. 3rd ed. Oxford: Blackwell; 2008:167–251.

A.7. What are hypercyanotic spells? How are they treated?

Hypercyanotic or "Tet" spells are sudden episodes of profound cyanosis in TOF patients that may be life-threatening. These spells occur more frequently in patients who are severely cyanotic at baseline but may occur in any patient with TOF. The peak frequency of spells is between 2 and 3 months of age. The onset of spells usually prompts urgent surgical intervention, so the anesthesiologist may care for an infant who is at great risk for spells during the perioperative period. The etiology of spells is not completely understood, but acute infundibular spasm that acutely decreases flow through the RV outflow tract and increased the magnitude of the R-L shunt through the VSD is thought to be causal. Crying, defecation, feeding, fever, and awakening from sleep all can be precipitating events. Paroxysmal hyperpnea is the initial finding with an increase in the rate and depth of respirations followed by increasing cyanosis and potential syncope, convulsions, or death. During a spell, the infant will appear pale and limp secondary to poor cardiac output. Hyperpnea maintains and worsens hypoxic spells

by increasing oxygen consumption and lowering the mean intrathoracic pressure, which increases systemic venous return. RV volume and pressure increase because there is an obstruction to RV outflow increasing the R-L shunt and the degree of cyanosis. During a spell, the infant will appear pale and limp secondary to poor cardiac output. Hyperpnea has several deleterious effects that can maintain and worsen a hypoxic spell. Hyperpnea increases oxygen consumption through the increased work of breathing. Hypoxia induces a decrease in SVR, which further increases the magnitude of the R-L shunt. Treatment of a "Tet spell" is focused on increasing pulmonary blood flow and decreasing the magnitude of the R-L shunt. It includes the following:

- Administration of 100% oxygen
- Compression of the femoral arteries or placing the patient in a knee-chest position to transiently increase SVR and reduce the magnitude of the R-L shunt
- Manual compression of the abdominal aorta to increase SVR and reduce the R-L shunt. This maneuver is particularly effective in the anesthetized patient. A cardiac surgeon can manually compress the ascending aorta to increase impedance to left ventricle (LV) ejection and reduce the R-L shunt.
- Administration of IV morphine sulfate (0.05 to 0.1 mg per kg) for sedation reduces oxygen demand and reduces hyperpnea by depressing the respiratory drive.
- Administration of 15 to 30 mL per kg of a crystalloid solution IV. Increasing preload to the heart increases the diameter of the RVOT and reduces dynamic RVOT obstruction.
- Administration of sodium bicarbonate to treat the severe metabolic acidosis that can be seen during a spell. Correction of the metabolic acidosis will help normalize SVR and reduce hyperpnea. Empiric administration of sodium bicarbonate (1

to 2 mEq per kg IV) in the absence of a blood gas determination should be considered during a spell.

- Phenylephrine (5 to 10 μg per kg IV or 2 to 5 μg/kg/min as an infusion) can be used to increase SVR and reduce R-L shunting. In the presence of severe RV outflow obstruction, phenylephrine-induced increases of PVR will have little or no effect on RV outflow resistance. Treatment with phenylephrine increases SVR and may decrease R-L shunting across the VSD and augment preload by decreasing unstressed venous volume, but the underlying cause of the spell is not treated.
- β-Adrenergic agonists are absolutely contraindicated. By increasing contractility, they will cause further narrowing of the stenotic infundibulum.
- Administration of β-adrenergic antagonists such as propranolol (0.1 mg per kg IV) or esmolol (0.5 mg per kg IV followed by an infusion of 50 to 300 μg/kg/min) may reduce infundibular spasm by depressing contractility. In addition, slowing of heart rate may increase preload by improving diastolic filling, increasing heart size, and the diameter RV outflow tract. Caution is warranted when administering β-adrenergic agonists after administering α-adrenergic agonists because the LV may not tolerate the increased SVR after β-mediated reduction in contractility.
- Extracorporeal membrane oxygenation resuscitation is another alternative in refractory episodes when immediate operative intervention is not possible.

A.8. What palliative surgical procedures are available for treating patients with TOF/PS?

Palliative shunt procedures to increase pulmonary blood flow

and relieve cyanosis are used when complicated surgical anatomy or institutional practice precludes definitive repair at the time of presentation. The palliative shunts are systemic-to-pulmonary artery (L-R) shunts that increase pulmonary blood flow. The volume load imposed on the LV by these shunts parallels the increases in pulmonary flow that they produce. The progressive hypertrophy of the body and infundibulum of the RV that is characteristic of TOF is unchanged, so RV outflow tract obstruction increases in the interval from shunt placement to definitive repair. The shunts can be summarized as follows:

Waterston shunt: a side-to-side anastomosis between the ascending aorta and the right PA. This procedure is performed through a right thoracotomy without CPB.

Potts shunt: a side-to-side anastomosis between the descending aorta and the left PA. This procedure is performed through a left thoracotomy without CPB.

Waterston and Potts shunts are of historic interest only. These shunts were difficult to size—too small of an orifice overly restricted pulmonary blood flow, whereas too large an orifice resulted in pulmonary overperfusion and congestion and predisposed the patient to development of unilateral pulmonary vascular obstructive disease. Furthermore, these shunts were difficult to take down at the time of the procedure and frequently distorted PA anatomy making definitive repair more difficult.

Central shunt: a synthetic tube graft between the ascending aorta and the main or branch PA. This shunt can be performed with or without CPB through a thoracotomy or median sternotomy. It is usually only used when prior shunt procedures have failed.

Blalock-Taussig shunt (BTS): an end-to-side anastomosis of the right or left subclavian artery to the ipsilateral branch PA. Currently, a modification of this procedure known as the MBTS is used. A Gore-Tex tube graft (usually 3.5 to 4.0 mm diameter

in infants) is interposed between the subclavian or innominate artery and the branch PA. These shunts usually are performed on the side opposite the aortic arch through a thoracotomy without CPB (**Fig. 38.5**).

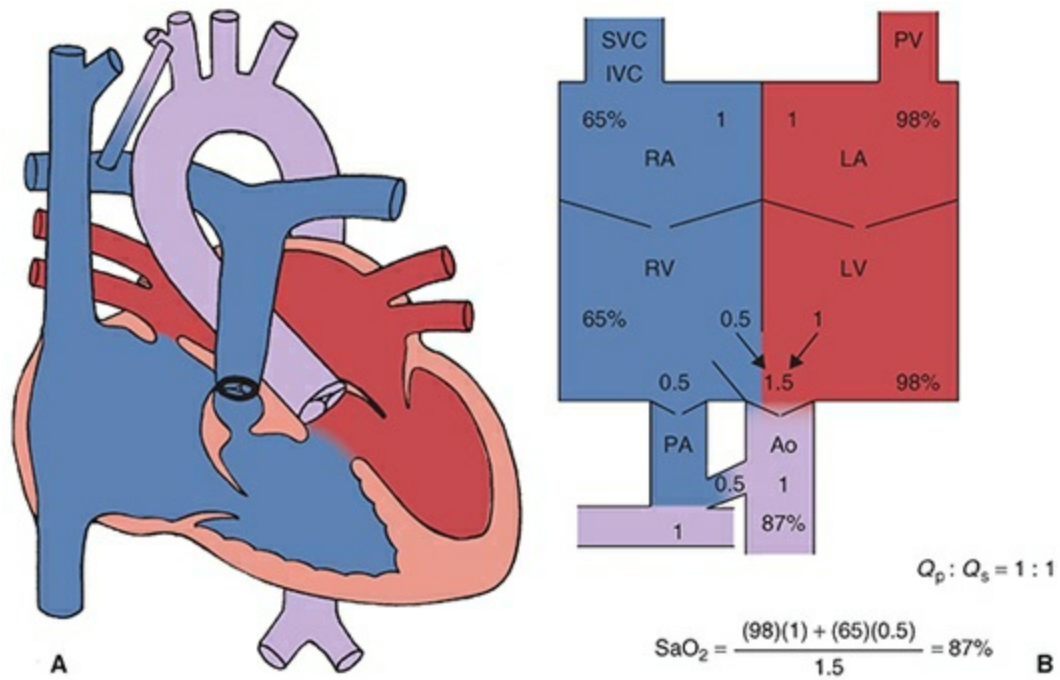

FIGURE 38.5. A. Palliative modified Blalock-Taussig shunt (MBTS) for tetralogy of Fallot with pulmonary stenosis (TOF/PS). Shunt is seen to connect the innominate artery to the right pulmonary artery (PA). This patient has a left aortic arch. **B.** Chamber oxygen saturations and relative flows for a patient with MBTS and TOF/PS. Arterial oxygen saturation (SaO_2) and Q_P:Q_S are illustrated. Ao, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

A.9. What palliative catheter-based procedures are available for patients with TOF?

A catheter-based palliative RVOT stent is an alternative to a systemic-to-pulmonary artery shunt in patients who are not candidates for a complete repair. These patients are usually symptomatic low birth weight infants with multiple comorbidities or infants with unfavorable anatomy (small PAs).

The procedure is performed in the cardiac catheterization lab or an operating room with biplane fluoroscopy. The stent is placed through a femoral vein or a hybrid perventricular approach where the apex of the RV is approached through a subxiphoid incision. The indications for the procedure are not clearly defined and vary from institution to institution. Results including early morbidity, time to complete repair, and rate of PA growth have been encouraging when compared to an MBTS.

Quandt D, Ramchandani B, Penford G, et al. Right ventricular outflow tract stent versus BT shunt palliation in tetralogy of Fallot. *Heart*. 2017;103(24):1985–1991.

A.10. What definitive surgical procedures are available for treating patients with TOF/PS?

Most patients with TOF/PS have an elective full correction between the ages of 2 and 10 months. Definitive repair for TOF/PS in the neonatal period is done in some centers if favorable anatomy is present, whereas other centers delay surgery as long as possible until cyanotic episodes require urgent repair. Surgery is aimed at relieving the RV outflow obstruction by resection of the hypertrophied muscles that obstruct the RV outflow tract and enlargement of the RV outflow tract with a pericardial patch. A transannular pericardial patch is placed across the pulmonary valve annulus and into the main PA unless the pulmonic annulus is near-normal size and the pulmonary valve is only mildly stenotic. A transannular patch is avoided if possible because the pulmonary valve is rendered insufficient and free pulmonary regurgitation is present until the valve is repaired or replaced at an older age. If stenosis of the PA extends to the bifurcation, the pericardial patch can be extended beyond the bifurcation of the PAs. In neonates, the VSD is closed through the right ventriculotomy that was created for resection of the RVOT obstruction and placement of the

transannular patch. In infants and older children, the VSD can be closed through the right atrium and the tricuspid valve.

An important surgical consideration for patients with TOF/PS is the presence of coronary artery abnormalities. Approximately 8% of patients have either the left main coronary artery or the left anterior descending artery as a branch of the right coronary artery. In these cases, a right ventriculotomy to enlarge the RVOT could endanger the left coronary artery. In such cases, an extracardiac conduit (RV to main PA) may be necessary to bypass the outflow tract obstruction and avoid injury to the coronary artery.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

A.11. What palliative and definitive surgical procedures are available for patients with TOF with pulmonary atresia?

Patients with TOF with pulmonary atresia in groups 1 and 2 are dependent on prostaglandin E_1 (PGE_1) to maintain pulmonary blood flow through a PDA so surgery to establish a reliable source of pulmonary blood flow must be performed in the neonatal period. These patients may undergo a palliative shunt procedure or a definitive procedure. A definitive procedure includes placement of an RV to PA and closure of VSD, usually through the ventriculotomy used for the proximal attachment of the RV to PA conduit.

Patients in groups 3 and 4 are more challenging to manage. These patients have single ventricle physiology with a tendency

toward excessive pulmonary blood flow (Q_P:Q_S >2 to 3:1) as the PVR drops in the neonatal period. In group 3 patients, neonatal repair with placement of an RV to PA conduit is undertaken to place the PAs in continuity with the RV in an effort to promote native PA growth. In this circumstance, the VSD is left open as a source of R-L shunting and delivery of desaturated blood to the systemic circulation because the RV cannot deliver an adequate cardiac output to the left atrium across the hypoplastic pulmonary vascular bed. These infants then undergo multiple cardiac catheterization procedures in order to dilate and stent the hypoplastic native PAs and to embolize MAPCAs, which provide pulmonary blood flow that is competitive to the blood flow supplied by native PAs. MAPCAs that provide pulmonary blood flow to segments of lung not supplied by native PAs must be unifocalized to the proximal pulmonary circulation. Unifocalization involves removal of the collateral vessel from the aorta with anastomosis to the RV to PA conduit or a proximal PA branch. This establishes antegrade blood flow from the RV to the pulmonary vascular bed. Usually, 80% to 90% of the pulmonary vascular bed (10 to 12 bronchopulmonary segments) must be in direct continuity with the RV to ensure that adequate cardiac output can cross the pulmonary bed and the VSD can be closed. In group 4 patients, the initial intervention may be to create an RV to PA conduit and unifocalize several large collaterals to the distal end of conduit from the RV. Alternatively, several large collaterals can be unifocalized to an MBTS or central shunt. These procedures serve to promote pulmonary vascular growth, prevent the development of pulmonary vascular obstructive disease, and control the Q_P:Q_S.

A.12. What are the long-term outcomes of patients with TOF?

Complete surgical repair of TOF has been performed for over 40 years with actuarial survival of 85% at 30 to 35 years. Most patients are largely asymptomatic and RV dysfunction may only be evident on echocardiography and exercise stress testing. Factors that adversely affect long-term survival include older age at initial repair, initial palliative procedures, and presence of residual PS and/or pulmonary regurgitation. RV dysfunction from chronic pressure and volume overload as well as the development of ventricular dysrhythmias may prompt pulmonary valve repair or replacement.

Geva T. Indications for pulmonary valve replacement in repaired tetralogy of Fallot: the quest continues. *Circulation*. 2013;128:1855–1857.

B. Preoperative Evaluation and Preparation

B.1. What preoperative history and physical examination information do you want?

The medical history and review of systems should include an assessment of ability to perform age-appropriate activities that will aid in the evaluation of cardiac function and reserve. The observation by a parent that the patient cannot keep the same pace as siblings is often a reliable clinical sign that cyanosis or congestive heart failure is worsening. Symptoms of low cardiac reserve include sweating, dyspnea, and circumoral cyanosis that may first occur during feeding, which is a strenuous activity for a newborn. Interpretation of vital signs must be age specific.

Growth curves also are useful because congestive heart failure will inhibit age-appropriate gains in weight, height, and head circumference. It is not unusual for patients with severe congestive heart failure to weigh less at 3 or 4 months of age than at birth. Interestingly, cyanotic children often do not manifest this failure to thrive.

It is often difficult to differentiate signs and symptoms of congestive heart failure from a mild upper respiratory tract infection in infants and children, so surgery may need to proceed even when the diagnosis is not clear. Children and infants with increased pulmonary blood flow are predisposed to multiple respiratory tract infections so surgery may need to proceed in these patients to reduce pulmonary blood flow and the propensity for chronic lung infections.

Physical examination might reveal cyanosis, clubbing, or signs of congestive heart failure similar to those seen in adults, such as hepatomegaly, ascites, edema, or tachypnea. Some manifestations of congestive heart failure such as rales may not be heard in infants and children, so the severity of heart failure may be more reliably assessed by the signs and symptoms outlined previously.

Physical examination should include an evaluation of the limitations to vascular access and monitoring sites imposed by previous surgeries. A child who has undergone a BT or MBT palliative shunt procedure may have a diminished pulse or unobtainable blood pressure in the ipsilateral arm, preventing accurate blood pressure and pulse oximetry measurement in that extremity. Venous access should also be assessed preoperatively because this may affect the mode of induction of anesthesia.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

B.2. Which other abnormalities need to be considered in

this patient?

Approximately 8% of children with congenital heart disease have other congenital abnormalities. Patients with TOF/PS or TOF with pulmonary atresia have a higher incidence of 22q11.2 deletion syndrome. Different phenotypes of this syndrome include DiGeorge syndrome, velocardiofacial syndrome, and conotruncal anomaly face syndrome. These syndromes are characterized by hypocalcemia; immunodeficiency; facial dysmorphia; palate anomalies; velopharyngeal dysfunction; renal anomalies; possible tracheoesophageal fistula; as well as speech, feeding, neurocognitive, behavioral, and psychiatric disorders. Many of these defects may complicate airway management.

McDonald-McGinn DM, Sullivan KE, Marino B, et al. 22q11.2 deletion syndrome. *Nat Rev Dis Primers*. 2015;1:15071.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

B.3. What premedication will you give to a child with congenital heart disease?

Premedication alleviates anxiety and eases separation of children from parents. In infants, premedication facilitates placement of an IV catheter for induction of anesthesia, alone or in combination with inhaled anesthetics. Midazolam (1 mg per kg PO) may be sufficient in infants and young children, but the addition of ketamine (3 to 5 mg per kg PO) is sometimes necessary in older children with heightened anxiety or in patients who are tolerant to benzodiazepines from previous procedures. Intramuscular (IM) ketamine (2 to 3 mg per kg) and glycopyrrolate (10 μg per kg) alone or in combination with midazolam (0.1 mg per kg) works well in children who will not take oral medications.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

C. Intraoperative Management

C.1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?

Induction of anesthesia with IM ketamine (3 to 5 mg per kg IM), succinylcholine (5 mg per kg IM), and glycopyrrolate (10 μg per kg IM) is an alternative to IV induction in infants and neonates with difficult peripheral IV access. Glycopyrrolate is an important adjunct to reduce airway secretions associated with ketamine administration and to prevent the bradycardia, which may be associated with succinylcholine. This technique provides prompt induction of anesthesia, allowing for immediate control of the airway with endotracheal intubation. This is useful in circumstances where it is anticipated that initial IV access will have to be obtained through the external jugular vein, femoral vein, or internal jugular vein. IM rocuronium (1 mg per kg IM) can be substituted for the succinylcholine, but the time to adequate intubating conditions and duration of action is variable.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017: 633–698.

C.2. Why would end-tidal carbon dioxide ($EtCO_2$) monitoring be of particular use in a patient with TOF/PS?

$EtCO_2$ monitoring is particularly helpful in patients with congenital heart disease because the difference between arterial CO_2 and alveolar CO_2 reflects physiologic dead space ventilation and is indicative of changes in lung perfusion. An

acute reduction in pulmonary blood flow (decreased cardiac output, pulmonary embolus, or increased intracardiac R-L shunting) will increase this gradient. In a patient with TOF/PS, a gradual reduction in Et_{CO_2} often precedes a decrease in Sa_{O_2} as the first manifestation of the increased R-L intracardiac shunting during a "Tet spell."

Levy RJ. Anesthesia for congenital heart surgery. In: Jonas RA, ed. *Comprehensive Surgical Management of Congenital Heart Disease*. 2nd ed. Boca Raton, FL: CRC Press; 2014:19–36.

C.3. What is near-infrared spectroscopy (NIRS) and what does it measure?

NIRS is a real-time, online monitor of cerebral tissue oxygenation. This technology is based on the physical principle that light of an appropriate wavelength passing through a solution of a colored compound (chromophore) will be absorbed by the compound. As a result of this absorption, the intensity of the light emerging from the solution will be lower than the intensity of the light projected into the solution. This principle through application of the Beer-Lambert equation "$\log [I_O / I] = c\, \alpha\, d$" allows quantification of the concentration (c) of a chromophore if the emergent light intensity (I) is measured and the following are known:

- Extinction coefficient (α), a constant that describes the absorption characteristics of a particular chromophore at a given wavelength of light
- Thickness of the solution (d)
- Incident light intensity (I_O)

NIRS technology is particularly suited to use in neonates and infants because the thin skull and small head allow light to be transmitted through one side of the head and detected on the other side, a technique known as *transmission spectrometry*.

Cerebral oxygen saturation (Sc_{O_2}) as measured by all NIRS

technology is the combined oxygen saturation of an uncertain mix of arterioles, capillaries, and venules. Traditional pulse oximetry differs in this respect from NIRS because it is capable of isolating and measuring the arteriole component by gating measurements to arterial pulsatility. It has been previously assumed that Sco_2 represented contributions of cerebral arterial and venous blood in a ratio of 25:75, with the contribution of capillary blood felt to be negligible. More recent data suggest that in children, the average ratio is 15:85. The issue is further complicated by the fact that there is significant variability in the ratio (from 0:100 to 40:60) between patients.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Ferradal SL, Yuki K, Vyas R, et al. Non-invasive assessment of cerebral blood flow and oxygen metabolism in neonates during hypothermic cardiopulmonary bypass: feasibility and clinical implications. *Sci Rep*. 2017;7:44117.

C.4. What are the important management issues during creation of a palliative shunt?

- Unilateral lung retraction will be required for surgical exposure if a thoracotomy approach is used. The resulting atelectasis may severely compromise ventilation and worsen oxygenation and CO_2 removal.
- The main or branch PAs will have to be partially occluded by a clamp to allow creation of the distal anastomosis of all palliative systemic to PA shunts. The resulting increase in physiologic dead space and $PaCO_2$ and $EtCO_2$ gradients may compromise oxygenation and CO_2 removal. Efforts to optimize ventilation, reduce PVR, and increase pulmonary blood flow should be initiated before PA occlusion.
- Partial occlusion of the aorta with a clamp will be necessary

during creation of Waterston, Potts, and central shunts. The resulting increase in LV afterload may compromise LV systolic function, and inotropic support may need to be initiated.

- All of the palliative shunts impose a volume load on the LV. Inotropic support may be necessary to ensure systemic and shunt perfusion after shunt creation.
- Palliative shunts are mildly restrictive simple shunts. It is important to maintain SVR and reduce PVR to maintain pulmonary blood flow in these patients.
- Be prepared to treat an episode of hypercyanosis.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

C.5. What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?

Sevoflurane, isoflurane, and desflurane induce a dose-dependent reduction in cardiac output and SVR with mild depression of contractility at 1 and 1.5 minimal alveolar concentration (MAC). At these concentrations, sevoflurane and isoflurane do not alter the ratio of PVR to SVR enough to induce any change in Q_P:Q_S.

Isoflurane and desflurane are not good choices for inhalational induction because their pungency is responsible for a high incidence of airway complications in children. Sevoflurane has cardiovascular effects similar to isoflurane and is a good agent for inhalational induction.

Laird TH, Stayer SA, Rivenes SM, et al. Pulmonary-to-systemic blood flow ratio effects of sevoflurane, isoflurane, halothane, and fentanyl/midazolam with 100% oxygen in children with congenital heart disease. *Anesth Analg*. 2002;95:1200–1206.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*.

Hoboken, NJ: Wiley; 2017.

C.6. What are the pre-cardiopulmonary bypass (pre-CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?

- Maintain heart rate, contractility, and preload to maintain cardiac output. Maintaining euvolemia is important to prevent exacerbation of dynamic RVOT obstruction from hypovolemia and reflex increases in heart rate and contractility.
- Avoid increases in the PVR:SVR ratio. Increases in PVR relative to SVR and decreases in SVR relative to PVR will increase R-L shunting, reduce pulmonary blood flow, and produce or worsen cyanosis. This effect is more pronounced when the RV outflow obstruction is not severe.
- Maintain or increase SVR. This is particularly important when RV outflow obstruction is severe, and changes in PVR will have little or no effect on shunt magnitude and direction.
- Treat episodes of hypercyanosis.
- Maintain contractility. Depression of contractility, particularly in the face of severe RV outflow obstruction, may produce RV afterload mismatch and drastically reduce pulmonary blood flow. The exception to this is a patient in whom the dynamic component of infundibular obstruction is active. Reducing contractility in these patients may reduce RV outflow obstruction through relaxation of the infundibulum.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

C.7. What interventions will reliably reduce PVR?

Increase P_{O_2}. High levels of inspired O_2 reduce elevated PVR, whereas alveolar hypoxia and arterial hypoxemia induce

pulmonary vasoconstriction. An arterial O_2 tension lower than 50 mmHg increases PVR over a wide range of arterial pH values. This effect is most pronounced when the pH is lower than 7.40.

Reduce P_{CO_2}. Consistent reductions in PVR and increases in pulmonary blood flow and P_{O_2} are seen in children with R-L shunts who are hyperventilated to a P_{CO_2} near 30 mmHg and a pH near 7.50. Hypocarbia reduces PVR through production of an alkalosis, but hypercarbia increases PVR independent of changes in arterial pH. Patient with preoperative pulmonary hypertension who are hyperventilated post-CPB to a P_{CO_2} of 30 to 35 mmHg and a pH of 7.50 to 7.56 have a reduction in PVR when compared with ventilation that produces normocarbia or hypercarbia.

Reduce *pH*. Both respiratory and metabolic alkalosis reduce PVR, whereas respiratory and metabolic acidosis increase PVR.

Variation in lung volumes. At small lung volumes, atelectasis compresses extra-alveolar vessels, whereas at high lung volumes, hyperinflation of alveoli compresses intra-alveolar vessels. Therefore, PVR is normally lowest at lung volumes at/or near the functional residual capacity. Positive end-expiratory pressure (PEEP) may cause an increase in PVR by increasing alveolar pressure through hyperinflation. However, a decrease in PVR generally is seen in situations in which PEEP works to recruit atelectatic alveoli and increase arterial P_{O_2}.

Vasodilator agents. PGE_1, prostaglandin I_2 (PGI_2), nitroglycerin, sodium nitroprusside, and tolazoline are IV drugs that induce pulmonary vasodilation as well as systemic vasodilation. There is no IV drug that selectively acts as a pulmonary vasodilator. Inhaled nitric oxide, PGE_1, and PGI_2 are the only specific pulmonary vasodilators available.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

C.8. How does heparin administration and activated coagulation time (ACT) monitoring for CPB differ in children as compared with adults?

Adequate anticoagulation, usually defined as an ACT greater than 400 seconds, is necessary before cannulation and the commencement of CPB. Most of the evidence for assessing the adequacy of anticoagulation in children during heart surgery has been extrapolated from the adult literature. The ACT will overestimate the antifactor IIa and Xa effects of heparin in children because the ACT is also prolonged by hypothermia, hemodilution, platelet dysfunction, and low coagulation factor levels. These factors are more significant in children than in adults during CPB because of their small size relative to the CPB circuits.

Most institutions use an age- or weight-based protocol to administer the initial pre-CPB dose of heparin. An example of a simple weight-based protocol is all patients weighing less than 30 kg receive 300 IU heparin per kg and patients greater than 30 kg receive 400 IU per kg. The large circuit prime volume to blood volume ratio in infants and children would be expected to decrease plasma heparin levels with initiation of CPB unless an appropriate quantity of heparin is added to the CPB prime. Most institutions add heparin to the CPB prime as follows: 3.0 IU heparin added per mL of CPB prime for patients less than 30 kg and 2.5 IU heparin added per mL of CPB prime in patients greater than 30 kg.

Heparin should always be given into a central line through which venous return can be demonstrated easily or directly into the heart by the surgeon. This is necessary to ensure that the heparin dose has reached the central circulation. An ACT can be

drawn within minutes of heparin administration as peak arterial ACT prolongation occurs within 30 seconds and peak venous ACT prolongation within 60 seconds.

Matte GS, DiNardo JA. Pediatric cardiopulmonary bypass. In: Gravlee GP, Davis RF, Hammon JW, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2015:655–682.

C.9. How is heparin reversed?

Systemic heparin is reversed with protamine, a polyvalent cation derived from salmon sperm. Protamine normally is given once the patient's hemodynamics have stabilized after termination of CPB and the team is satisfied with the repair. The cardiotomy suction should not be used and the arterial and venous cannulas should be removed before protamine neutralization of heparin begins. This prevents contamination of the heparinized CPB circuit with protamine so that prompt reinstitution of CPB is possible, if necessary.

There are several approaches to the neutralization of heparin with protamine, all with reportedly good clinical results. Some centers titrate the amount of protamine to the amount of heparin determined to exist at the termination of CPB using the in vitro protamine-heparin neutralization ratio of 1.3:1.0. This method had been criticized because the amount of heparin present post-CPB is calculated based on the ACT, and the ACT can be affected by factors other than the concentration of heparin, such as CPB-induced platelet dysfunction, hypothermia, and hemodilution. This may result in an overestimation of the heparin present at the termination of CPB and results in a larger than necessary calculated protamine dose. Other centers administer a fixed dose of protamine based on the patient's

weight (3 to 4 mg per kg IV) regardless of the ACT or heparin dose administered, whereas others administer 1.0 to 1.3 mg of protamine for each 100 units of heparin administered prior to and during CPB.

Matte GS. The bypass plan. In: Matte GS. *Perfusion for Congenital Heart Surgery: Notes on Cardiopulmonary Bypass for a Complex Patient Population*. Hoboken, NJ: Wiley; 2015:33–65.

Matte GS, DiNardo JA. Pediatric cardiopulmonary bypass. In: Gravlee GP, Davis RF, Hammon JW, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2015:655–682.

C.10. What is the incidence of protamine reactions in children?

The incidence of protamine reactions in children following cardiac surgery is substantially lower than in adults. Acute reactions to protamine may be mild with transient erythema and hypotension or severe with bronchoconstriction, PA hypertension, and cardiovascular collapse. The mechanism has not been fully characterized. A recent retrospective analysis of 1,249 children showed the incidence of hypotension (defined as a 25% decrease in mean arterial pressure) following protamine administration to be 1.76% to 2.88%, depending on the stringency of criteria linking the hypotensive episode to protamine administration. In this series, no episodes of pulmonary hypertension or RV dysfunction were noted. Clinical experience indicates that pulmonary hypertensive episodes in children following protamine administration are very rare.

Matte GS, DiNardo JA. Pediatric cardiopulmonary bypass. In: Gravlee GP, Davis RF, Hammon JW, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2015:655–682.

C.11. What is the role of transesophageal

echocardiography (TEE) in this patient?

TEE has a major impact on post-CPB decision making, such as return to CPB to repair residual lesions in approximately 15% of cases when it is used nonselectively in children. In the subset of patients undergoing valve repair and outflow tract reconstruction (such as this patient), the impact of TEE would be expected to be greater by providing immediate assessment of the adequacy of the operative procedure and directing the revision, if necessary. Although detection of retained intracardiac air is facilitated by the use of intraoperative TEE, it remains to be determined what role TEE will play in improving cardiac de-airing algorithms particularly in neonates/infants.

The role of TEE in the detection of residual VSDs following repair of both simple and complex defects deserves some discussion. Residual defects smaller than 3 mm are detectable by TEE but generally do not require immediate reoperation because they are hemodynamically insignificant. The majority (75%) of these small defects are not present at the time of hospital discharge as determined by transthoracic echocardiography. Residual defects greater than 3 mm detected by TEE require immediate reoperation only when intraoperative assessment suggests that the defect will be hemodynamically significant. Examples of concerning findings are elevated left atrial pressure and/or PA pressure in the presence of good ventricular function, right atrium to PA oxygen saturation step-up with $F_{IO_2} \leq 0.50$, and oximetric measurement of $Q_P:Q_S > 1.5$.

Yang SG, Novello R, Nicolson S, et al. Evaluation of ventricular septal defect repair using intraoperative transesophageal echocardiography: frequency and significance of residual defects in infants and children. *Echocardiography*. 2000;17:681–684.

C.12. What effect would a residual ventricular septal defect (VSD) have in this patient following separation

from CPB?

A residual VSD is likely to be poorly tolerated in patients with repaired TOF/PS. There is potential for a large L-R shunt through a residual VSD because RVOT obstruction will be completely or near completely eliminated postrepair and the PVR is likely to be low and the pulmonary vasculature very compliant. This will acutely place a large volume load on both the LV and RV. The RV is not likely to tolerate the volume load because the RV compliance is reduced from the preoperative concentric hypertrophy and the function may be impaired postbypass and from the ventriculotomy. The most likely manifestation will be low cardiac output associated with an elevated heart rate, elevated left atrial pressure, and elevated PA pressure (low cardiac output syndrome).

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

D. Postoperative Management

D.1. How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?

The inspiratory phase of mechanical positive pressure ventilation should be adjusted to minimize mean airway pressure. The inspiratory phase of mechanical positive pressure ventilation increases impedance to RV ejection and RV afterload by elevating alveolar pressure and creating more West zone I (alveolar pressure greater than arterial and venous pressure) and West zone II (alveolar pressure greater than venous pressure) lung segments. This is directly related to the duration of inspiration (respiratory rate and inspiratory-to-expiratory [I:E] ratio) and to mean airway pressure. Increasing RV afterload will

impede antegrade pulmonary blood flow and exacerbate the extent of pulmonary insufficiency induced by the transannular patch. RV afterload will also be increased by elevations in PVR.

As discussed in section C.7, ventilation and gas mixture should be adjusted to minimize PVR. This is usually accomplished with a tidal volume of 10 to 15 mL per kg, 3 to 5 mmHg of PEEP, and a respiratory rate and I:E ratio adjusted to minimize mean airway pressure.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

D.2. Following complete repair of TOF/PS in an infant, what SaO_2 is acceptable?

Following complete repair of TOF/PS with no residual lesions and minimal intrapulmonary shunt, the Sa_{O_2} should be 100%. The surgeon may choose to leave a small (3 to 4 mm) atrial level communication or patent foramen ovale in infants and small children, particularly in those patients with pulmonary insufficiency as the result of a transannular patch and those expected to have restrictive RV function as a result of a ventriculotomy and/or extensive RV hypertrophy. This will allow intracardiac R-L shunting, with the ability to augment systemic cardiac output at the expense of systemic oxygen saturation in the setting of RV dysfunction by allowing direct delivery of desaturated venous blood to the left atrium. In these patients, a Pa_{O_2} of 40 to 50 mmHg and a Sa_{O_2} of 70% to 80% are acceptable until RV function improves over the course of days.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

D.3. Following placement of a modified Blalock-Taussig

shunt (MBTS) for TOF/PS in an infant, what SaO_2 is acceptable?

As illustrated in **Figure 38.5B**, the expected Sao_2 would be 80% to 90% in the presence of some antegrade pulmonary blood flow. In the absence of any antegrade pulmonary blood flow, single ventricle physiology exists and a Sao_2 of 70% to 80% would be expected. Sao_2 is determined by the relative volumes and saturations of recirculated systemic venous blood and effective systemic blood flows that have mixed and reached the aorta. This is summarized in the following equation:

$$\text{Aortic } SaO_2 = \frac{[(\text{pulmonary venous saturation} \times \text{effective systemic blood flow}) + (\text{systemic venous saturation} \times \text{recirculated systemic venous blood flow})]}{(\text{total systemic blood flow})}$$

This is demonstrated in **Figure 38.5B**.

Three variables will ultimately affect Sao_2:

1. *The ratio of total pulmonary to total systemic blood flow* (Q_P:Q_S). A greater proportion of the arterial blood will consist of saturated blood (pulmonary venous blood) than of desaturated blood (systemic venous blood) when Q_P:$Q_S \geq$ 1:1. Q_P:Q_S will be increased when systemic arterial blood pressure is high and PVR is low.
2. *Systemic venous saturation*. For a given Q_P:Q_S and pulmonary venous saturation, a decrease in systemic venous saturation will result in a decreased arterial saturation. Decreases in systemic venous saturation occur as the result of decreases in systemic oxygen delivery or increases in systemic oxygen consumption. Recall that systemic oxygen delivery is the product of systemic blood flow and arterial oxygen content. Arterial oxygen content, in turn, is dependent on the hemoglobin concentration and the arterial saturation. Efforts should be made to increase hematocrit

into the range of 35% to 45%, increase cardiac output with inotropes, and reduce systemic O_2 consumption with appropriate levels of sedation/anesthesia and muscle relaxation if necessary.

3. *Pulmonary venous saturation.* For any given systemic venous saturation and Q_P:Q_S, a reduction in pulmonary venous saturation will result in a decreased arterial saturation. In the absence of large intrapulmonary shunts and/or ventilation/perfusion mismatch, pulmonary venous saturation should be close to 100% when breathing room air. In the presence of pulmonary parenchymal disease, pulmonary venous saturation may be reduced. The mismatched component of pulmonary venous desaturation will be largely eliminated with an F_{IO_2} of 1.0, whereas the intrapulmonary shunt contribution will not be eliminated.

Nasr VG, DiNardo JA, eds. *The Pediatric Cardiac Anesthesia Handbook*. Hoboken, NJ: Wiley; 2017.

D.4. What is junctional ectopic tachycardia (JET)?

Postoperative JET is a transient tachyarrhythmia that can occur immediately following congenital heart surgery. A rare form of congenital JET exists as well. JET is due to enhanced automaticity in the area of the atrioventricular (AV) node or proximal His bundle. Patients who develop JET have a higher than average incidence of postoperative AV block. The incidence of JET following TOF/PS repair may be as high as 20% and is felt to be secondary to trauma from surgical retraction near the AV node that is necessary to expose the VSD and RVOT from across the tricuspid valve.

JET typically manifests with a junctional rate only slightly faster than the sinus node rate. It is the only narrow complex tachycardia in which the atrial rate is less than the ventricular rate (A:V ratio <1:1). In fewer than 10% of cases of JET, there

may be retrograde activation of the atrium with inverted P waves and an A:V ratio of 1:1. Cardiac output is reduced because there is a loss of AV synchrony, which reduces the atrial transport factor (atrial kick). In many instances, this arrhythmia is well tolerated, but JET with heart rate greater than 170 beats per minute is associated with hemodynamic instability and increased postoperative mortality.

The most effective therapy for JET is atrial pacing at a rate slightly faster than the junctional rate such that AV synchrony is reinitiated. This therapy is effective unless the junctional rate is very high (>160 to 170 beats per minute), at which point atrial pacing at a faster rate is unlikely to improve hemodynamics because the reinitiation of AV synchrony is offset by the dramatic reduction in diastolic filling time present at these rates. In this circumstance, the most effective therapy is multimodal. The goal of multimodal therapy is to terminate JET or reduce the rate to the point where atrial pacing can be reinitiated. Note that cardioversion and adenosine are not effective.

The following modalities are applied in this order:

- Fever is aggressively treated with antipyretics.
- Sedation and hemodynamics are optimized.
- Doses of inotropic agents are reduced because most of these agents have positive chronotropic effects. This may be difficult in the setting of hemodynamic instability and low cardiac output syndrome.
- Mild systemic hypothermia is introduced. A cooling blanket and icepacks are used to reduce patient temperature to 32°C (89.6°F) to 35°C (95°F). This usually requires sedation and paralysis to prevent shivering.
- Procainamide or amiodarone therapy is initiated.

JET requiring aggressive treatment prolongs postoperative ventilation times and intensive care unit stay.

Walsh EP. Automatic atrial and junctional tachycardias. In: Walsh EP, Saul JP, Triedman JK, eds. *Cardiac Arrhythmias in Children and Young Adults with Congenital Heart Disease.* Philadelphia, PA: Lippincott Williams & Wilkins; 2001:115–135.

39 Transposition of the Great Arteries

David Whiting and James A. DiNardo

A 3-day-old, full-term, 3.4-kg male is scheduled for an arterial switch operation (ASO). Shortly after birth, he demonstrated reverse differential cyanosis with right arm arterial saturation of 40% and lower extremity saturation of 60%, despite prostaglandin E_1. A bedside balloon atrial septostomy was performed with resolution of reverse differential cyanosis and improvement of arterial saturation to 75%. Prostaglandin E_1 was discontinued 4 hours after the septostomy. He is breathing spontaneously with 0.5 L per minute supplemental oxygen through nasal cannula. His arterial oxygen saturation (Sao_2) is 75%; blood pressure, 63/37 mmHg; pulse, 145 beats per minute; and respiration, 46 breaths per minute.

2. What immediate postoperative problems would be anticipated following the Rastelli procedure?
3. What intermediate and long-term surgical problems are seen after ASO?
4. What are the long-term outcomes after ASO?
5. What are the long-term outcomes after Rastelli repair for patients with D-TGA with left ventricular outflow tract (LVOT) obstruction?
6. What is long-term neurologic outcome like after ASO?

A. Medical Disease and Differential Diagnosis

A.1. What defines the cardiac situs?

Cardiac situs refers to the orientation of the morphologic right atrium (RA). If the RA is to the right of midline, cardiac situs is "solitus"; otherwise, the cardiac situs is "inversus" (morphologic RA to the left atrium [LA]) or "ambiguous" when the situs is indeterminate. Cardiac structures may not be in the expected location, so echocardiography can help characterize the anatomy of the atria, atrioventricular (AV) valves, ventricles, ventriculoarterial (VA) valves, and great arteries. A few anatomic characteristics are consistent. The RA receives the vena cava and coronary sinus. There is always concordance (agreement) between the AV valves and the ventricle, so the tricuspid valve is always the inflow valve for the right ventricle (RV) and the mitral valve the inflow valve for the left ventricle (LV). A muscular conus (infundibulum) always separates the AV (tricuspid) and VA (pulmonary) valves of the RV and the inflow/AV (mitral) and VA (aortic) valves of the LV are always in fibrous continuity.

Williams GD, Feng A. Heterotaxy syndrome: implications for anesthesia management. *J Cardiothorac Vasc Anesth*. 2010;24:834–844.

A.2. What is transposition of the great arteries (D-TGA)?

D-TGA is a common congenital heart lesion accounting for 5% to 7% of all congenital cardiac defects, second in frequency only to isolated ventricular septal defects (VSDs). In D-TGA, there is concordance of the AV connections and discordance of the VA connections. The segmental anatomy is S, D, D, with atrial situs *S*olitus, *D*-loop ventricles, and *D*-loop great arteries. A right-sided RA connects through a right-sided tricuspid valve and RV to a right-sided and anterior aorta. A left-sided LA connects through a left-sided mitral valve and LV to a left-sided and posterior pulmonary artery (PA). As a result, there is fibrous continuity between the mitral and pulmonic valves with a lack of fibrous continuity (conus) between the tricuspid and aortic valves. The combination of AV concordance (RA to RV and LA to LV) and VA discordance (RV to aorta and LV to PA) produces a parallel rather than a normal series circulation.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.3. What additional cardiac lesions are associated with D-TGA?

The most commonly associated cardiac anomalies are a persistent patent foramen ovale (PFO), patent ductus arteriosus (PDA), VSD, and subpulmonic stenosis resulting in LVOT obstruction. Approximately 50% of patients with D-TGA will present with a PDA before prostaglandin E_1 administration and diagnosis of D-TGA. There is almost always a PFO, but a true

secundum atrial septal defect (ASD) exists in approximately 5% of patients. Although angiographically detectable, VSDs occur in 30% to 40% of patients, only approximately one-third of these defects are hemodynamically significant. Therefore, for practical purposes, 75% of patients have an intact ventricular septum (IVS). LVOT obstruction is present in approximately 30% of patients with VSD and is most often due to an extensive subpulmonic fibromuscular ring or posterior malposition of the outlet portion of the ventricular septum.

Allen HD, Shaddy RE, Penny DJ, et al, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents, Including the Fetus and Young Adult*. 9th ed. Philadelphia, PA: Wolters Kluwer; 2016:1163–1186.

A.4. What is the natural history of D-TGA?

Survival in the neonatal period is dependent on sufficient mixing of the parallel systemic and pulmonary circulations at the atrial, ventricular, or arterial level. Patency of the ductus arteriosus can be maintained with prostaglandin E_1, allowing for mixing at the arterial level. An emergent Rashkind-Miller balloon atrial septostomy can be performed to increase mixing at the atrial level in those infants who do not have adequate mixing through the PDA or VSD. Forty-five percent of patients with D-TGA will die within the first month, and 90% will die within the first year of life without intervention, despite being largely free from other extracardiac defects. Following stabilization, as a neonate, many of these infants can be offered the ASO, a definitive surgical procedure that will give them a quality of life similar to that of normal children. Infants with D-TGA who have anatomy that is not favorable for the ASO are offered palliative surgeries.

Hypoxia and intractable congestive heart failure (CHF) are the two primary causes of death in infants without intervention who survive the neonatal period. Infants with D-TGA are at particular risk for early-onset accelerated pulmonary artery

hypertension (PAH). The etiology is most likely related to systemic hypoxemia, the presence of bronchopulmonary collaterals (which deliver deoxygenated blood to the precapillary pulmonary arterioles), polycythemia, and platelet aggregation. Infants with D-TGA and a large VSD without LVOT obstruction are at highest risk for the early development of PAH due to exposure of the pulmonary vascular bed to systemic pressures with unrestricted flow. Advanced, nonreversible pulmonary hypertension reduces the corrective surgical options available to the patient.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.5. What is the pathophysiology of D-TGA?

Systemic and pulmonary circulations are in a parallel with varying degrees of intercirculatory mixing. Deoxygenated systemic venous blood recirculates through the systemic circulation (a physiologic right-to-left shunt) and oxygenated pulmonary venous blood recirculates through the pulmonary circulation (a physiologic left-to-right shunt). The physiologic shunt fraction or the percentage of venous blood from one system that recirculates in the arterial outflow of the same system is 100% for both circuits in parallel. This is why there must be a connection at the atrial, ventricular, or arterial level to allow for any survival, even in the neonatal period.

The sites available for intercirculatory mixing in D-TGA can be intracardiac (PFO, ASD, VSD) or extracardiac (PDA, bronchopulmonary collaterals). Several factors affect the amount of intercirculatory mixing. The number, size, and position of anatomic communications are important. One large nonrestrictive communication will provide better mixing than two or three restrictive communications. The position of the

communication is also important because poor mixing can occur with large anterior muscular VSDs if their orientation is not favorable. Reduced ventricular compliance and elevated systemic and pulmonary vascular resistance (SVR and PVR) tend to reduce intercirculatory mixing by impeding flow across the anatomic communications. In the presence of anatomically adequate intercirculatory mixing sites, mixing is directly related to the total pulmonary blood flow. Patients with reduced pulmonary blood flow secondary to subpulmonic stenosis or PAH will have reduced intercirculatory mixing.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.6. What determines the oxygen saturation in patients with D-TGA?

Arterial saturation (Sa_{O_2}) is determined by the relative volumes and saturations of the recirculated systemic and effective systemic blood flows reaching the aorta. This is summarized in the following equation:

$$\text{Arterial saturation} = \frac{\begin{array}{c}[(\text{systematic venous saturation})\ (\text{recirculated systemic blood flow})] \\ +\ [(\text{pulmonary venous saturation})\ (\text{effective systemic blood flow})]\end{array}}{(\text{total systemic blood flow})}$$

The anatomic left-to-right shunt produces effective systemic blood flow, which is the volume of pulmonary venous blood reaching the systemic circulation. The anatomic left-to-right shunt is the result of intercirculatory mixing at the atrial, ventricular, and arterial levels and must equal the amount of the right-to-left shunt at the same sites. The greater the effective systemic blood flow (intercirculatory mixing) relative to the recirculated systemic blood flow, the greater the Sa_{O_2}. For a given amount of intercirculatory mixing and total systemic

blood flow, a decrease in systemic venous or pulmonary venous saturation will result in a decrease in Sao_2.

Total systemic blood flow is the sum of recirculated systemic venous blood plus effective systemic blood flow. Likewise, total pulmonary blood flow is the sum of recirculated pulmonary venous blood plus effective pulmonary blood flow. Recirculated blood makes up the largest portion of total pulmonary and systemic blood flow, with effective blood flows contributing only a small portion of the total flows. This is particularly true in the pulmonary circuit where the total pulmonary blood flow and the volume of the pulmonary circuit (LA, LV, PA) is three to four times larger than the total systemic blood flow and the volume of the systemic circuit (RA, RV, aorta). The net result is transposition physiology, where the PA oxygen saturation is greater than the aortic oxygen saturation. **Figure 39.1** further elucidates these concepts.

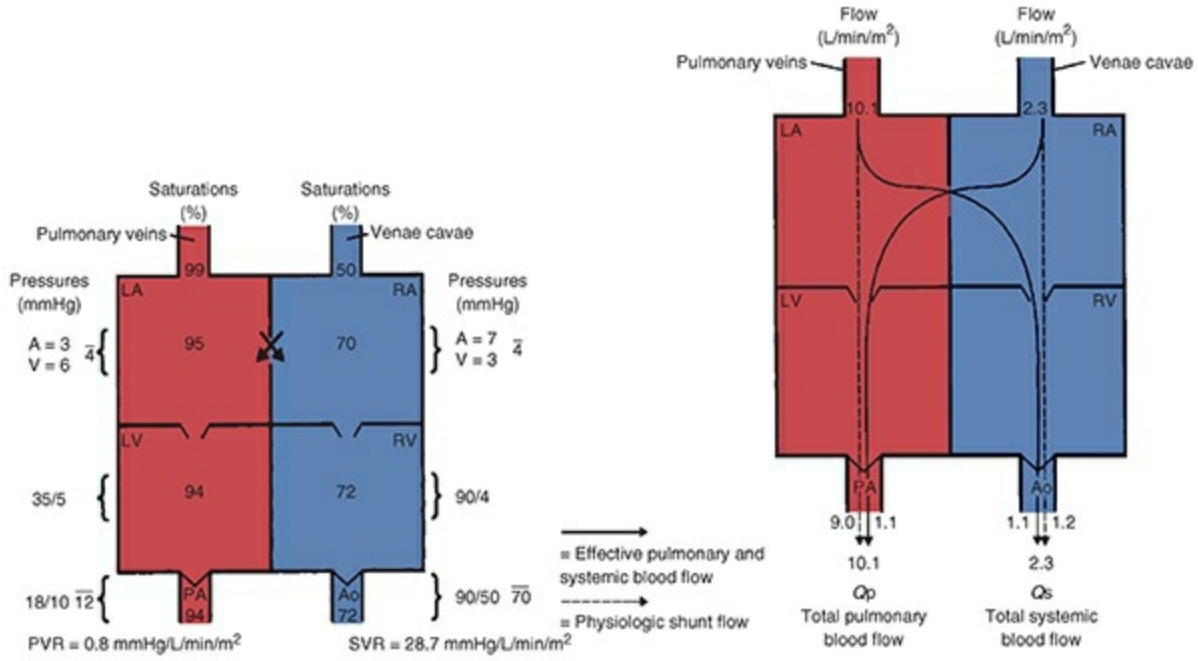

FIGURE 39.1. Depiction of saturations, pressures, and blood flows in complete transposition of the great vessels with intercirculatory mixing at the atrial level and a small LVOT gradient. It is apparent that total pulmonary blood flow (10.1 L/min/m^2) is almost five times the total systemic blood flow (2.3 L/min/m^2). Effective pulmonary and effective systemic blood flow are equal (1.1 L/min/m^2)

and are the result of an anatomic shunt at the atrial level. The physiologic left-to-right shunt is 9 L/min/m^2; this represents blood recirculated from the pulmonary veins to the pulmonary artery (PA). The physiologic right-to-left shunt is 1.2 L/min/m^2; this represents blood recirculated from the systemic veins to the aorta. In this depiction, pulmonary vascular resistance is low (approximately 1/35 of systemic vascular resistance), and there is a small (17 mm peak to peak) gradient from the left ventricle to the PA. These findings are compatible with the high pulmonary blood flow depicted. A, artery; Ao, aorta; LA, left atrium; LV, left ventricle; PVR, pulmonary vascular resistance; *Q*p, total pulmonary blood flow; *Q*s, total systemic blood flow; RA, right atrium; RV, right ventricle; SVR, systemic vascular resistance; V, vein. (*Modified with permission from Freed MO, Keane JF. Profiles in congenital heart disease. In: Grossman W, ed*. Cardiac Catheterization and Angiography. *Philadelphia, PA: Lea & Febiger; 1986:463*.)

$$SaO_2 = [(50)(1.2)] + [(99)(1.1)] / 2.3 = 73\%$$

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.7. Why did this infant have reverse differential cyanosis?

In D-TGA with IVS, the anatomic mixing sites are usually a PDA and a PFO. The dynamics of intercirculatory mixing in D-TGA with IVS are complex. Anatomic shunting at the atrial level is ultimately determined by the size of the atrial communication and the cyclic pressure variations between the left and right atria. The volume and compliance of the atria, ventricles, and vascular beds in each circuit as well as heart rate (HR) and phase of respiration influence this relationship. Shunting is from the RA to the LA during diastole as the result of the reduced ventricular and vascular compliance of the systemic circuit (RV and systemic arterial circuit). In systole, shunt is from the LA to the RA primarily because of the large volume of blood returning to the LA as a result of the high volume of recirculated pulmonary blood flow.

The direction of shunting across the PDA largely depends on the PVR and the size of the intra-atrial communication. When the PVR is low and the intra-atrial communication is

nonrestrictive, shunting is predominantly from the aorta to the PA through the PDA (effective pulmonary blood flow) and predominantly from the LA to RA across the atrial septum (effective systemic blood flow). When PVR is elevated, shunting across the PDA is likely to be bidirectional that in turn encourages bidirectional shunting across the atrial septum. When PVR is high and PA pressure exceeds aortic pressure, shunting at the PDA will be predominantly from the PA to the aorta. This will create reverse differential cyanosis—physiology wherein the preductal arterial saturation (right arm) is lower than the postductal arterial saturation (legs). This physiology is usually the result of a restrictive atrial communication producing left atrial hypertension and is associated with low effective blood flows (poor mixing) and hypoxemia. A balloon atrial septostomy can be lifesaving in this setting. Decompression of the LA promotes mixing at the atrial level and also reduces PVR and PA pressure promoting mixing at the PDA. Other causes of reverse differential cyanosis to be considered in D-TGA are the presence of an interrupted aortic arch or severe aortic coarctation.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.8. What are the preoperative issues pertaining to the coronary arteries in D-TGA?

As in normally related great vessels, the coronary arteries in D-TGA arise from the aortic sinuses that face the PA. In normally related vessels, these sinuses are located on the anterior portion of the aorta, whereas in D-TGA, they are located posteriorly. In most D-TGA patients (70%), the right sinus is the origin of the right coronary artery, whereas the left sinus is the origin of the left main coronary artery. In the remainder of cases, there is

considerable variability, with the most common variations being shown in **Figure 39.2**.

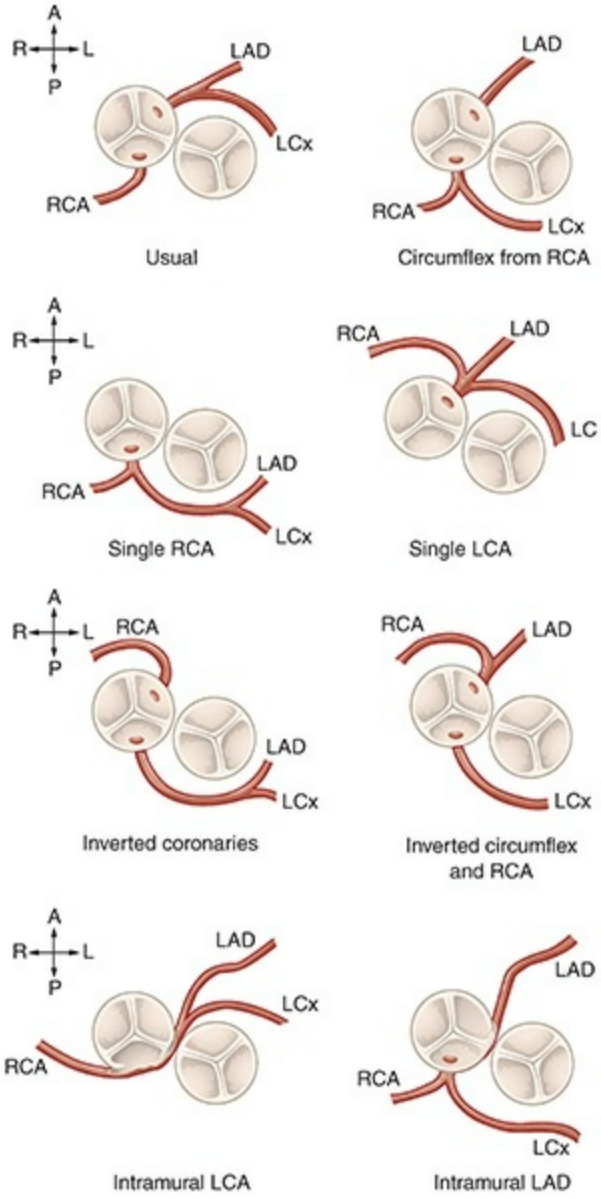

FIGURE 39.2. Depiction of the most common coronary artery patterns in transposition of the great vessels. The aorta is depicted anterior and to the right of the PA. LAD, left anterior descending coronary artery; LCA, left coronary artery; LCx, left circumflex coronary artery; RCA, right coronary artery. (*Adapted with permission from Mayer JE Jr, Sanders SP, Jonas RA, et al. Coronary artery pattern and outcome of arterial switch operation for transposition of the great arteries*. Circulation. *1990;82[5 suppl]:144*.)

Most patients with D-TGA have coronary anatomy that is suitable for the coronary reimplantation necessary in the ASO.

Patients with certain types of coronary anatomy (intramural coronaries, single coronary artery) are at risk for postoperative myocardial ischemia and early mortality because reimplantation can result in the distortion of the coronary ostia or the narrowing of the artery itself. Patients with intramural coronaries generally require resuspension of the posterior leaflet of neopulmonary valve once the coronaries and a surrounding tissue cuff are excised.

The presence of a single coronary artery or intramural coronary arteries is a risk factor for mortality, and this risk has persisted over the last two decades despite improvement in surgical technique.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Pasquali SK, Hasselblad V, Li JS, et al. Coronary artery pattern and outcome of the arterial switch operation for transposition of the great arteries: a meta-analysis. *Circulation*. 2002;106(20):2575–2580.

A.9. What are the clinical subsets of D-TGA?

The four clinical subsets of D-TGA are characterized by differences in anatomy, amount of pulmonary blood flow, and sites of intercirculatory mixing. These are summarized in **Table 39.1**.

TABLE 39.1 Clinical Subsets of Transposition of Great Arteries

Anatomy	Pulmonary Blood Flow	Intercirculatory Mixing
D-TGA with IVS	Increased	Small
D-TGA with IVS; nonrestrictive atrial septum or PDA	Increased	Large
D-TGA with VSD	Increased	Large
D-TGA with VSD and LVOT obstruction	Reduced	Small
D-TGA with PAH	Reduced	Small

D-TGA, transposition of great arteries; IVS, intact ventricular septum; LVOT, left ventricular outflow tract; PAH, pulmonary artery hypertension; PDA, patent ductus arteriosus; VSD, ventricular septal

defect.
Reprinted with permission from DiNardo JA. Transposition of the great vessels. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:357–380.

A.10. What is the differential diagnosis of D-TGA and how is the diagnosis made?

Figure 39.3 delineates the differential diagnosis for D-TGA in the cyanotic newborn.

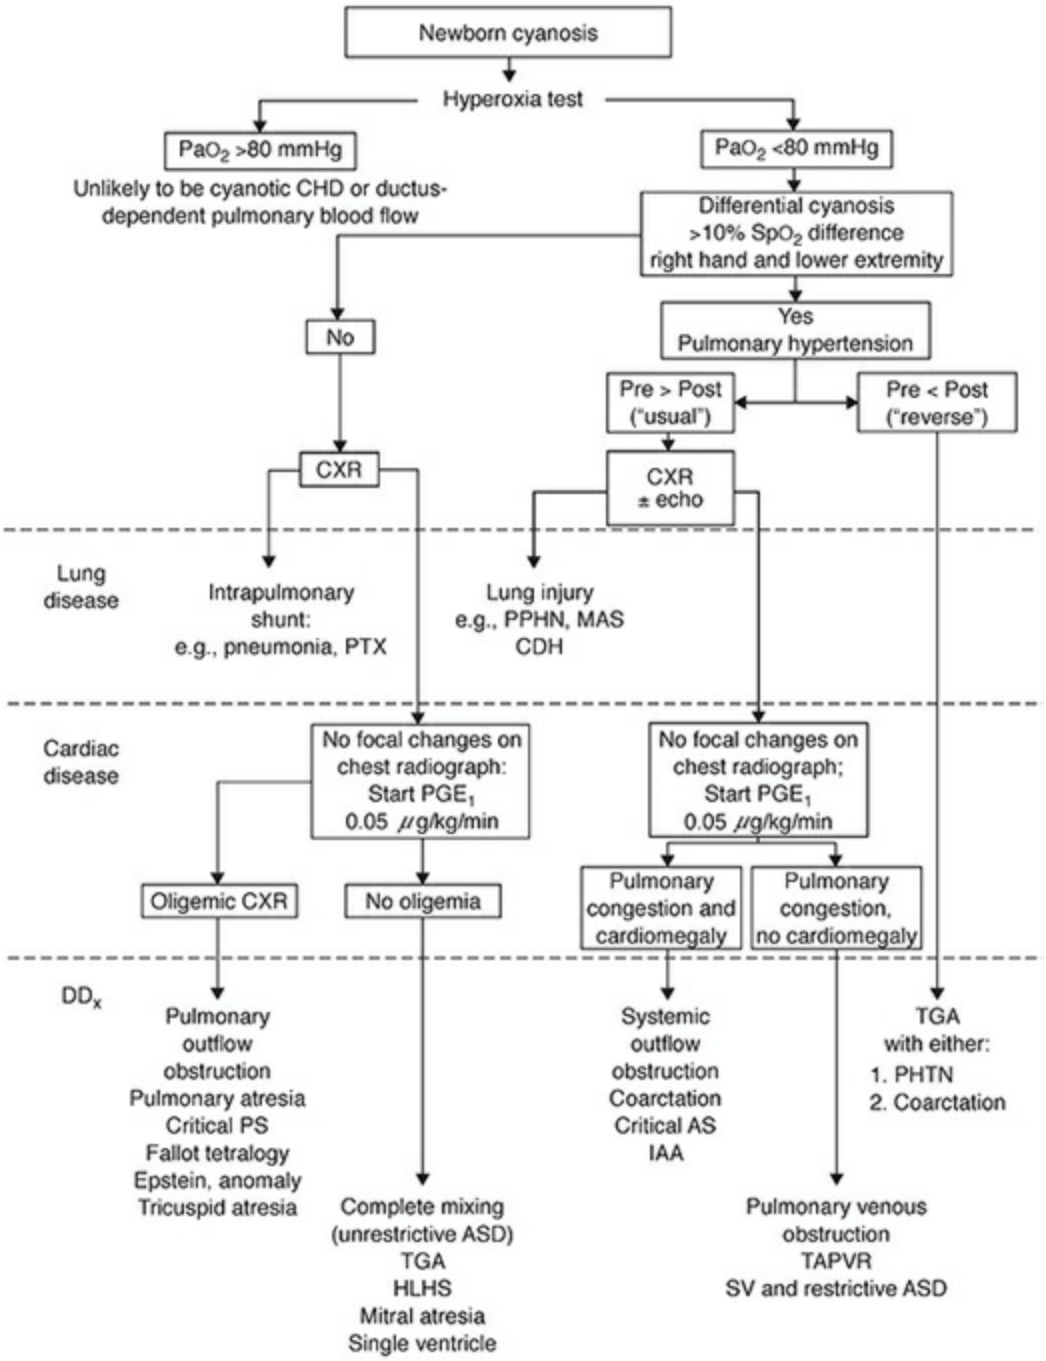

FIGURE 39.3. The differential diagnosis of transposition of the great arteries. AS, aortic stenosis; ASD, atrial septal defect; CDH, congenital diaphragmatic hernia; CHD, congenital heart disease; CXR, chest radiograph; DD_X, differential diagnosis; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; MAS, meconium aspiration syndrome; PGE_1, prostaglandin E_1; PHTN, pulmonary hypertension; PPHN, persistent pulmonary hypertension of the newborn; PS, pulmonary stenosis; PTX, pneumothorax; Spo_2, peripheral oxygen saturation; SV, single ventricle; TAPVR, total anomalous pulmonary venous return; TGA, transposition of great arteries.

D-TGA may be associated with either cyanosis or CHF. Cyanosis is severe in patients with limited intercirculatory mixing. Infants with a large quantity of intercirculatory mixing have increased pulmonary blood flow, mild cyanosis, and symptoms of CHF.

Chest radiographs may appear normal in the first few weeks of life in infants with D-TGA and IVS. Eventually, the triad of an enlarged egg-shaped heart (large RA and RV), narrow superior mediastinum, and increased pulmonary vascular markings evolve. In patients with D-TGA and VSD without LVOT obstruction, a large cardiac silhouette and prominent pulmonary vascular markings are seen at birth. Right axis deviation and right ventricular hypertrophy are the electrocardiographic (ECG) findings in D-TGA with IVS, whereas right axis deviation, LV hypertrophy, and RV hypertrophy are seen with D-TGA and VSD.

Two-dimensional echocardiography is the diagnostic modality of choice in the diagnosis and assessment of infants with D-TGA. It accurately establishes the diagnosis of D-TGA and reliably identifies associated abnormalities, such as VSD, mitral valve, and tricuspid valve abnormalities, and LVOT obstruction. It also reliably delineates coronary artery anatomy. Echocardiographic analysis of the IVS position or LV geometry is also used to noninvasively assess the LV to RV pressure ratio and IV mass in neonates with D-TGA and IVS who are being evaluated as candidates for an ASO.

In institutions with high-level echocardiography, a comprehensive cardiac catheterization is no longer routinely performed in neonates with D-TGA. A limited catheterization may be performed in conjunction with a balloon atrial septostomy. In the rare instance where coronary anatomy cannot be clearly delineated by echocardiography, coronary angiography may be indicated. During catheterization of infants

with PAH, a trial of ventilation at an fraction of inspired oxygen (FIO_2) of 1.0 may be used to determine whether PVR is fixed or remains responsive to oxygen-induced pulmonary vasodilation.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.11. What preoperative interventions can help stabilize a patient with D-TGA?

Intact Ventricular Septum

Most neonates with D-TGA and IVS will be hypoxemic (arterial saturation ≤60%) within the first day of life. A proportion of these patients will have severely reduced effective pulmonary and systemic blood flow resulting in a PaO_2 less than 20 mmHg, hypercarbia, and an evolving metabolic acidosis secondary to poor tissue oxygen delivery. Prostaglandin E_1 (0.01 to 0.05 μg/kg/min) is administered to dilate and maintain the patency of the ductus arteriosus. This will be effective in increasing effective pulmonary and systemic blood flow and in improving PaO_2 and tissue oxygen delivery *if* (1) PVR is less than SVR and (2) there is a nonrestrictive or minimally restrictive atrial septal communication. Prostaglandin E_1 infusion is associated with apnea, pyrexia, fluid retention, and platelet dysfunction.

An emergent balloon atrial septostomy is performed in the catheterization laboratory utilizing angiography or in the ICU utilizing echocardiography if prostaglandin E_1 does not improve tissue oxygen delivery. This increases the amount of intercirculatory mixing at the atrial level. Recall that for a given amount of intercirculatory mixing and total systemic blood flow, an increase in pulmonary venous or systemic venous saturation will result in an increase in arterial saturation. Pulmonary venous saturation will be increased by tracheal intubation and

mechanical ventilation with oxygen. This will also reduce ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and reduce PVR through induction of a respiratory alkalosis. Sedation and muscle relaxation reduce oxygen consumption, thereby increasing mixed venous oxygen saturation and arterial saturation.

In some centers, all neonates stabilized on prostaglandin E_1 have a balloon atrial septostomy to enlarge the atrial septal communication so that prostaglandin E_1 can be stopped and surgery scheduled on a semi-elective basis.

In rare instances, the combination of prostaglandin E_1, an atrial septostomy, and mechanical ventilation with sedation/muscle relaxation will be ineffective. In this circumstance, extracorporeal membrane oxygenation (either venoarterial or venovenous) support to improve tissue oxygenation and to reverse end-organ insult and lactic acidosis before surgery is an alternative approach to emergent surgery in a critically ill neonate.

Ventricular Septal Defect

Infants in this subset are mildly cyanotic with symptoms of CHF. Pulmonary blood flow is elevated, and there is extensive intercirculatory mixing. Reducing PVR to further augment pulmonary blood flow and intercirculatory mixing will not greatly influence the systemic oxygenation. Reducing PVR in these patients may increase the recirculated volume in the pulmonary circuit by increasing the compliance of the pulmonary circulation. Maintaining systemic blood flow will then necessitate an increase in cardiac output from a heart that is already volume overloaded. These patients are usually stable enough not to require immediate surgical or catheterization laboratory intervention. An ASO needs to be performed before intractable CHF or advanced PAH develops.

Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction

The degree of cyanosis in these infants will depend on the degree of LVOT obstruction. LVOT obstruction not only reduces pulmonary blood flow and intercirculatory mixing but also protects the pulmonary vasculature from increased pressures and volumes that accelerate the development of PAH. Efforts to increase pulmonary blood flow by decreasing PVR are less effective when LVOT obstruction is severe. These infants will be severely cyanotic and will develop erythrocytosis and may require a palliative aortopulmonary shunt to increase pulmonary blood flow prior to definitive repair. The Rastelli, LeCompte, and Nikaidoh procedures are performed for D-TGA with LVOT obstruction.

Pulmonary Artery Hypertension

The goal of diagnosis and treatment of infants with D-TGA is to intervene surgically before the development of PAH. As PAH progresses, the child becomes progressively cyanotic and polycythemic. Efforts to reduce PVR will increase pulmonary blood flow and intercirculatory mixing in infants where PVR is not fixed. Infants with advanced PAH (PVR >10 Wood units; histologic grade 4) are generally candidates only for palliative therapy. In particular, closure of a VSD in the presence of advanced pulmonary hypertension carries a high mortality rate owing to the afterload mismatch and the resultant pulmonary ventricular (LV) dysfunction. These patients are candidates for a palliative intra-atrial physiologic repair (Mustard or Senning procedure) without closure or with fenestrated closure (4- to 5-mm hole in the center of the VSD patch) of the VSD.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

A.12. What are the surgical options for repair? Why is one chosen over the others?

Arterial Anatomic Repair: Arterial Switch (Jatene) Operation

The ASO anatomically corrects the discordant VA connections and is the procedure of choice for patients with D-TGA. Following repair, the RV is connected to the PA and the LV to the aorta. Clinical success with the ASO, summarized in **Figure 39.4**, was achieved in 1975. In order for the ASO to be successful, the original pulmonary ventricle (LV) must have sufficient mass to be capable of functioning, as the systemic ventricle following the switch. Patient selection and the timing of the surgical procedure are important variables in determining the success of this procedure. The ASO was originally described in patients with D-TGA and a large VSD or a large PDA. In these patients, the pulmonary ventricle (LV) remains exposed to systemic pressures, and the LV mass remains sufficient to support the systemic circulation. For this subset of patients, the ASO is generally performed within the first 2 to 3 months of life before intractable CHF or irreversible PAH develops.

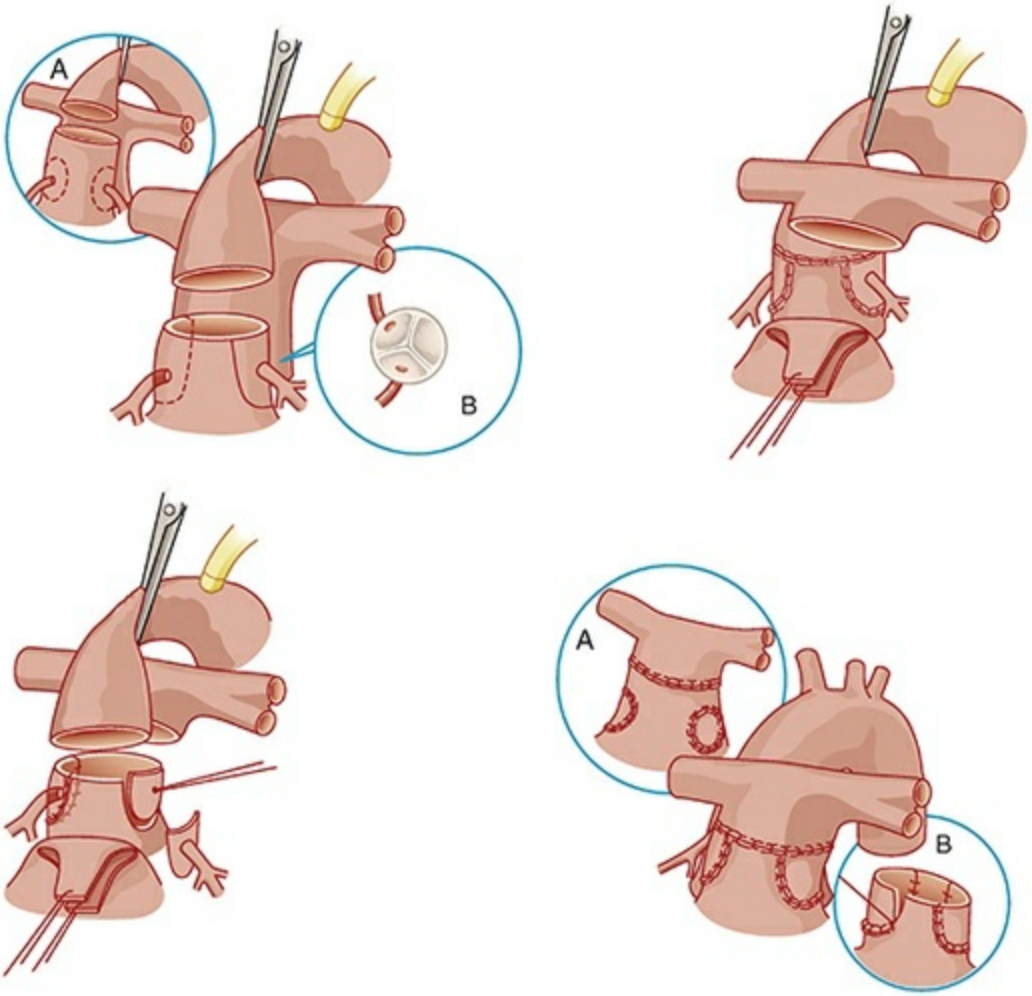

FIGURE 39.4. Details of the arterial switch procedure. Upper left. Aorta is transected and left and right main coronary arteries are excised using either button of aortic wall **(A)** or segment of aortic wall **(B)** extending from rim of aorta. **Lower left.** Equivalent segment of pulmonary arterial wall is excised, and coronary arteries are sutured to PA. **Upper right.** Distal PA is brought anterior to ascending aorta (LeCompte maneuver), and proximal PA is anastomosed to distal aorta. **Lower right.** Sites of coronary explantation are repaired using either patch of prosthetic material **(A)** or segment of pericardium **(B)**. Finally, proximal aorta is sutured to distal PA. (*Adapted from Castaneda AR, Norwood WI, Jonas RA, et al. Transposition of the great arteries and intact ventricular septum: anatomical repair in the neonate*. Ann Thorac Surg. *1984;38[5]:438–443. Copyright © 1984 The Society of Thoracic Surgeons. With permission.*)

Patients with D-TGA and IVS have a progressive reduction in LV mass over the first 3 or 4 weeks of life as the physiologic pulmonary hypertension present at birth resolves. Adequate mass to support the systemic circulation reliably exists in these patients only for the first 3 or 4 weeks of life, so a primary ASO

must be performed in this period. Most are performed in the first few days of life. Historically, favorable candidates for a primary ASO in the neonatal period were identified by cardiac catheterization with an LV to RV pressure ratio of at least 0.6. Currently, two-dimensional echocardiography is used to noninvasively assess the LV to RV pressure ratio. Three types of ventricular septal geometry have been described. Patients in whom the ventricular septum bulges to the left (type 3), indicating a low pressure in the pulmonary ventricle (LV), are not candidates for a neonatal ASO. Patients with septal bulging to the right (type 1), indicating a high pressure in the pulmonary ventricle (LV), and those patients with an intermediate septal position (type 2) are considered good candidates. Most neonates with D-TGA and IVS who are suitable candidates for an ASO have type 2 septal geometry.

The staged ASO for D-TGA with IVS is used for those neonates in whom surgery cannot be performed in the first month of life secondary to events such as prematurity, sepsis, low birth weight (<1.0 kg), or late referral. The first step of a staged procedure retrains the LV to accept the systemic workload and usually involves the creation of a nonrestrictive atrial septum (if it does not already exist), placement of a PA band, and creation of an aortopulmonary shunt with entry to the PA distal to the band. The PA band must be tight enough to increase pressure in the pulmonary ventricle (LV) to approximately one-half to two-thirds of that in the systemic ventricle (RV). This will increase the afterload sufficiently to stimulate an increase in LV mass. In the past, the PA band was left on for 3 to 6 months, after which the PA was debanded, the shunt taken down, and an ASO was performed. Currently, a rapid two-stage repair is favored where the ASO is performed as early as 1 week after preparatory PA banding, often during the same hospitalization. This approach is possible because the LV

mass usually doubles after 1 week of PA banding. Establishing the appropriate tightness of the band can be challenging, and the PA band as well as the systemic to PA shunt can distort the PA making the ASO difficult. Intraoperative echocardiography is useful in guiding placement of the PA band. The band is tightened enough to flatten the IVS by shifting it toward the RV.

Jonas RA, Giglia TM, Sanders SP, et al. Rapid, two-stage arterial switch for transposition of the great arteries and intact ventricular septum beyond the neonatal period. *Circulation*. 1989; 80 (3, pt 1):I203–I208.

Intra-atrial Physiologic Repairs: Mustard and Senning Procedures

The Mustard and the Senning procedures are atrial switch procedures that surgically create discordant AV connections so that there is a physiologic correction of the VA discordance. Systemic venous blood is routed to the anatomic LV and the PA, whereas pulmonary venous blood is routed to the anatomic RV and the aorta. This is not an anatomic correction because the RV becomes the systemic ventricle. These atrial switch procedures are primarily of historic interest, as the ASO is nearly universally performed for D-TGA.

Vejlstrup N, Sørensen K, Mattsson E, et al. Long-term outcome of Mustard/Senning correction for transposition of the great arteries in Sweden and Denmark. *Circulation*. 2015;132:633–638.

Rastelli, LeCompte, and Nikaidoh Procedures

These procedures are used to correct D-TGA with VSD and LVOT (subpulmonic and/or pulmonic) obstruction. Performance of an ASO under these circumstances would leave the infant with residual neoaortic or subneoaortic (LVOT) obstruction. In the Rastelli procedure, the subpulmonic LVOT obstruction is resected and the LVOT is baffled to the aorta with the patch used to close the VSD. An RV-PA conduit is created. The LeCompte procedure involves resecting the LV outlet septum,

closing the VSD to route the LV blood to the aorta, and bringing the PAs anteriorly to be reanastomosed to the RV. The Nikaidoh procedure is an aortic translocation procedure where the aortic root and coronary arteries are resected and reanastomosed to the RV after the outlet septum has been resected and the RVOT is reconstructed with a pericardial patch or homograft.

B. Preoperative Evaluation and Preparation

B.1. What information is important to prepare for this case?

The preoperative evaluation should begin with a careful history and physical examination. Gestational age, birth complications, family history, and any other medical problems should be noted. A comprehensive airway evaluation should be performed and any previously used endotracheal tube sizes and leak pressure should be noted. Arterial and intravenous access should be assessed. A type and cross must be sent to the blood bank to ensure adequate red blood cells and blood component therapies are available in the operating room.

The preoperative ECG, chest radiograph, and echocardiograms should be reviewed. Particular attention should be paid to septal geometry, biventricular function, coronary anatomy, and adequacy of mixing at the atrial septal and ductal

levels. The duct may remain patent even if prostaglandin E_1 has been discontinued.

Laboratory data should include a complete blood count, electrolytes, platelet count, arterial blood gas, calcium, blood urea nitrogen, creatinine, liver function tests, and blood glucose. Given that this infant presented with severe hypoxemia, end-organ dysfunction must be ruled out. The liver function tests and creatinine should be normal; if they are elevated, consideration should be given to further medical optimization. A head ultrasonographic examination should be performed to rule out intraventricular hemorrhage.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

B.2. What are the anesthetic goals before cardiopulmonary bypass (CPB)?

- Maintain HR, contractility, and preload to maintain cardiac output; decreases in cardiac output decrease systemic venous saturation with a resultant fall in arterial saturation.
- Maintain ductal patency with prostaglandin E_1 (0.01 to 0.05 μg/kg/min) in ductal-dependent patients.
- Avoid increases in PVR relative to SVR. Increases in PVR will decrease pulmonary blood flow and reduce intercirculatory mixing. In patients with PAH, ventilatory interventions should be used to reduce PVR. In patients with LVOT obstruction that is not severe, ventilatory interventions to reduce PVR will increase pulmonary blood flow and intercirculatory mixing.
- Reductions in SVR relative to PVR should be avoided. Reducing SVR increases recirculation of systemic venous blood and decreases arterial saturation.
- In patients with D-TGA and VSD with symptoms of CHF,

ventilatory interventions to reduce PVR are not warranted because they will produce small improvements in arterial saturation at the expense of a reduction in systemic perfusion.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

B.3. What is the plan for glucose management in this patient?

Maintenance for caloric requirements in the awake neonate/infant are 100 kcal/kg/day or 4 kcal/kg/hr. This caloric requirement can be met with glucose 25 g/kg/day or 1 g/kg/hr. From a practical point of view, this glucose requirement can be met with 10% dextrose (100 mg per mL) run at the maintenance volume replacement rate of 4 mL/kg/hr. Ten percent dextrose run at half this rate (2 mL/kg/hr) is usually sufficient to meet the caloric requirements of an anesthetized infant while avoiding both the hyperglycemia and hypoglycemia that can be detrimental to neurologic outcome particularly following DHCA. Dextrose infusions should be discontinued before commencement of CPB because the associated neuroendocrine response to CPB generally produces mild hyperglycemia. Some infants receive nutritional support as part of medical stabilization before surgery. High-calorie total parenteral nutrition and intralipid therapy should be discontinued and replaced with a 10% dextrose infusion several hours before transport to the operating room. Continued administration of these high-calorie infusions makes intraoperative serum glucose management problematic. In these patients, higher dextrose infusion rates may be necessary pre-CPB to avoid rebound hypoglycemia.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and*

Children. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

C. Intraoperative Management

C.1. How would you monitor this infant?

Preinduction monitoring should include noninvasive blood pressure, ECG, and pulse oximetry. Pulse oximeter probes should be placed on the right upper and left upper or lower extremities to measure preductal and postductal oxygen saturations, respectively. An intraarterial catheter is placed for invasive blood pressure monitoring and a double-lumen central venous line is usually placed for monitoring and drug administration. A nasopharyngeal temperature probe is important to estimate brain temperature, and a rectal or bladder temperature probe is important to measure core body temperature. Infants transferred from the ICU will have an umbilical artery or femoral artery catheter in place. A bladder catheter to measure urine output should be placed. A TEE probe can be inserted if the patient is large enough, otherwise a transthoracic echocardiogram is performed after endotracheal intubation and stabilization. In reality, a pulse oximeter and an ECG may be all that is practical in the early stages of induction. The other monitors are then quickly added as induction progresses. An epicardial echocardiogram is usually performed after the repair to assess the coronary artery anastomoses and intracardiac repairs if a TEE probe was not placed.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

C.2. What would be the best method of induction for this patient?

An IV induction is indicated for this patient. Infants born with

D-TGA are stabilized in an ICU so peripheral or central IV access and possibly invasive arterial monitoring would have been established. Anesthesia is generally induced and maintained with a synthetic opioid, such as fentanyl or sufentanil. In a high-dose opioid technique, the opioid is the primary anesthetic. Twenty-five to 100 μg per kg fentanyl or 2.5 to 10 μg per kg sufentanil is usually required for the entire case. Inhalational agents or benzodiazepines supplement opioids in a low or moderate opioid technique, so only 5 to 25 μg per kg fentanyl or 0.5 to 2.5 μg per kg sufentanil is usually required for the case. The high-dose opioid technique is particularly useful in neonates and infants, since opioids provide hemodynamic stability, do not depress the myocardium, and blunt reactive pulmonary hypertension.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

C.3. Is CPB in infants and children different from adults?

The major differences between adult and pediatric CPB are summarized in **Table 39.2**.

TABLE 39.2 Major Differences between Adult and Pediatric Cardiopulmonary Bypass

Parameter	Adult	Pediatrics
Hypothermic temperature	Rarely below 25°C–32°C	Commonly 15°C–20°C
Use of total circulatory arrest	Rare	Common
Pump prime		
Dilution effects on blood volume	25%–33%	200%–300%
Additional additives in pediatric primes		Blood, albumin
Perfusion pressures	50–80 mmHg (Some centers accept 30 mmHg.)	20–50 mmHg
Influence of pH management strategy	Minimal at moderate hypothermia	Marked at deep hypothermia
	30–45 mmHg	20–80 mmHg

Measured $PaCO_2$ differences		
Glucose regulation		
Hypoglycemia	Rare—requires significant hepatic injury	Common—reduced hepatic glycogen stores
Hyperglycemia	Frequent—generally easily controlled with insulin	Less common—rebound hypoglycemia may occur

Flows of 2.0 to 2.5 L/min/m^2 are commonly used for infants, children, and adults during mild to moderate systemic hypothermia. Flow rates (expressed in mL/kg/min) will be substantially higher in the neonate than in the adult because of age-related differences in surface area to weight ratios. The recommended full flow rates for pediatric CPB are summarized in **Table 39.3**.

TABLE 39.3 Recommended Full Flow Rates for Pediatric Cardiopulmonary Bypass

Patient Weight (kg)	Full CPB Flow Rates (mL/kg/min)
<3	150–200
3–10	125–175
10–15	120–150
15–30	100–120
30–50	75–100
>50	50–75

CPB, cardiopulmonary bypass.

The vast majority of operative procedures in children require the use of either total CPB or DHCA. Arterial and venous cannulation can be particularly challenging in neonates and infants. Venous cannulation for DHCA is usually accomplished with a single large venous cannula in the RA. Once cooling is complete, CPB flow rates are reduced to zero and the venous cannula is removed to allow for maximum surgical exposure. In cases requiring total CPB, the superior and inferior cavae and other sources of systemic venous return are cannulated and surgical tourniquets or tapes are passed around the external

circumference of the vessels. When these tapes are tightened around the cannulae, the right heart can be isolated completely and opened without entrainment of air into the venous circuit or obscuration of the surgical field by venous blood. At least one tape must be left untightened during delivery of antegrade cardioplegia to allow egress of cardioplegia solution from the coronary sinus without distention of the RA. The superior vena cava (SVC) is larger than the inferior vena cava (IVC) in neonates and infants, so the larger venous cannula is usually placed in the SVC. The opposite is true in older children where two-thirds of systemic venous return is from the IVC.

Aortic cannulation in children may be complicated by a hypoplastic ascending aorta or aortic arch, as in patients with hypoplastic left heart syndrome. In these cases, systemic circulation is ductal dependent, so it may be necessary to establish systemic perfusion through the ductus arteriosus by cannulating the PA. If the aortic arch is interrupted, cannulation of the aorta proximal and distal to the interruption is necessary. In infants and children, the arterial cannula is large relative to the size of the aorta, so constant vigilance is necessary to avoid complete or partial obstruction of the aorta by the cannula. Signs of this include dampening of the arterial pressure tracing, distension of the systemic ventricle, and an increase in the aortic line pressure during placement or manipulation of the aortic cannula. The surgeon must reposition the line to ensure adequate perfusion. Some centers utilize near-infrared spectroscopy and transcranial Doppler ultrasonographic technology as adjunctive methods to assess cerebral blood flow during CPB.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Wolters Kluwer; 2015:655–695.

C.4. What is modified ultrafiltration (MUF)?

Ultrafiltration removes excess fluid from blood by hydrostatic pressure across a semipermeable membrane. The devices are the same, as those used in hemodialysis, but no dialysate is used. When used in conjunction with CPB, they are commonly called hemoconcentrators because they produce an increase in hematocrit by removing excess fluid. These devices consist of a core of microporous hollow fibers made of polysulfone, polyamide, or polyacrylonitrile material arranged in a bundle. The pore size is generally 0.30 to 0.40 μm. Blood inflow must be from the arterial side of the CPB circuit because of the pressure drop across the device. Outflow is diverted to the cardiotomy reservoir or venous reservoir. The ultrafiltrate composition is similar to a glomerular filtrate. It is collected in a container connected to a vacuum source and discarded.

The rate at which ultrafiltrate is produced is dependent on the transmembrane pressure (TMP) gradient. TMP is determined by the arterial inlet pressure (P_a), the venous outlet pressure (P_v), the absolute value of applied suction at the outlet (P_n), the oncotic pressure at the inlet (P_i), and the oncotic pressure at the outlet (P_o):

$$\text{TMP} = \frac{P_a + P_v}{2} + P_n - \frac{P_i + P_o}{2}$$

P_n is increased by adjusting the regulated vacuum source connected to the outlet of the device. TMP should not exceed 500 mmHg.

MUF is a technique used to ultrafiltrate blood after weaning from CPB while maintaining the integrity of the bypass circuit. MUF may be performed using either an arteriovenous or venovenous system. In the arteriovenous system, blood flows

from the aortic cannula through a separate circuit and roller pump to the inflow of the hemoconcentrator before returning to the RA. Blood volume is kept constant as ultrafiltrate is lost by replacing the ultrafiltrate volume with blood from the venous reservoir of the CPB circuit, which also passes through the hemoconcentrator circuit before returning to the RA. In this way, the patient's blood as well as the CPB circuit blood is hemoconcentrated and the CPB circuit remains primed. In the venovenous system, blood passes from the IVC cannula through a separate circuit and roller pump to the inflow of the hemoconcentrator before returning to the patient through the SVC cannula. Blood volume is also kept constant in this system by replacing ultrafiltrate volume with blood from the CPB circuit, which also passes through the ultrafiltrator before returning to the patient. The end point for termination of MUF following CPB varies from institution to institution, with institutions terminating MUF after a set time interval (15 to 20 minutes), a set hematocrit (40%), or a set volume removed (750 mL per m^2). Heparin anticoagulation must be maintained during MUF, with protamine reversal of heparin initiated after termination of MUF.

Neonates and infants are the patients who most benefit from MUF because the volume of the CPB circuit is large relative to their blood volume. Hemoconcentration increases the hematocrit and concentration of coagulation factors and reduces total body water. MUF may be an effective method of attenuating the deleterious consequences of using large asanguinous primes, particularly in neonates and infants. In studies comparing MUF to no ultrafiltration, a large asanguinous pump prime was usually defined as a 400 to 900 mL prime with packed red blood cells added to reach a hematocrit of 15% to 20%.

Continuous ultrafiltration is a similar MUF except it can occur only during CPB and only when there is sufficient volume

in the CPB circuit. MUF and continuous ultrafiltration are indistinguishable in their effect on hematocrit, mean arterial pressure, HR, and LV shortening fraction when equal volumes of fluid are removed.

C.5. Briefly describe the surgical techniques of the Mustard/Senning, ASO, and Rastelli procedures.

Intra-atrial Physiologic Repairs: Mustard and Senning Procedures

The Mustard and Senning procedure are atrial switch procedures where the interatrial septum is excised and a baffle is used to redirect pulmonary and systemic venous blood. In the Mustard procedure, the baffle is made of native pericardium or synthetic material. The Senning procedure uses autologous tissue from the right atrial wall and interatrial septum. In both procedures, the pulmonary blood flows over the baffle and is directed across the tricuspid valve into the RV and aorta, and the systemic venous blood flows on the underside of the baffle and is directed across the mitral valve into the LV and out the PA. This results in a physiologic but not anatomic correction of D-TGA because the morphologic RV becomes the systemic ventricle. These procedures are performed with total hypothermic CPB, bicaval cannulation, aortic cross-clamping during cardioplegic arrest, and sometimes LFCPB.

Arterial Anatomic Repair: Arterial Switch (Jatene)

Operation

In the ASO, the great arteries are switched so that VA concordance is restored. First, the PA and the aorta are transected distal to their respective valve and then the coronary arteries are explanted from the ascending aorta with 3 to 4 mm of surrounding tissue and reimplanted into the proximal PA (neoaorta). The explant sites are repaired either with pericardium or synthetic material. The distal PA is brought anterior to the aorta (LeCompte maneuver) to be reanastomosed to the old proximal aorta (right ventricular outflow) and the distal aorta reanastomosed to the old proximal PA (left ventricular outflow). The ASO is a complete anatomic and physiologic repair of D-TGA. The ASO is done using total hypothermic CPB with aortic cross-clamping and cardioplegic arrest. Intervals of LFCPB are customarily used, and a short interval of DHCA may be employed to close the atrial septum or VSD if a single venous cannula rather than bicaval venous cannulation is used. Closure of a VSD is preferentially done with a transatrial approach through the tricuspid valve to avoid a ventriculotomy that could contribute to postoperative RV dysfunction.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Jatene AD, Fontes VF, Paulista PP, et al. Anatomic correction of transposition of the great vessels. *J Thorac Cardiovasc Surg*. 1976;72:364–370.

Rastelli Procedure

The Rastelli procedure is a physiologic repair for D-TGA with VSD and subpulmonic stenosis, where the LV and aorta are brought into continuity with a patch tunnel that also closes the VSD. The PA must be transected and ligated and the RV and proximal PA are brought into continuity with a valved conduit

or homograft. The VSD may have to be enlarged in some cases to prevent subaortic stenosis. The patch tunnel that connects the LV to the aorta bypasses subpulmonic and pulmonic stenosis. This procedure is performed under similar conditions as the ASO, with total hypothermic CPB, bicaval cannulation, aortic cross-clamping during cardioplegic arrest, and intervals of LFCPB.

Historically, most of these patients had a palliative systemic to PA shunt placed in the newborn period and then returned for the Rastelli procedure and takedown of the shunt at 2 to 3 years of age. The delay was felt necessary to avoid performing a right ventriculotomy in infants with immature myocardium and limited contractile elements and to allow adequate growth of the RV and PAs to permit placement of an RV to PA conduit. In the current era, with improvements in myocardial protection, CPB technology, and surgical technique, this procedure can be performed as a primary procedure in the neonatal period.

Jatene AD, Fontes VF, Paulista PP, et al. Anatomic correction of transposition of the great vessels. *J Thorac Cardiovasc Surg*. 1976;72:364–370.

C.6. What is hypothermia, and how is it classified? What is low-flow cardiopulmonary bypass (LFCPB)? What is deep hypothermic circulatory arrest (DHCA)?

The levels of systemic hypothermia employed during CPB are generally defined as follows: mild (35°C [95.0°F] to 32°C [89.6°F]), moderate (31°C [87.8°F] to 26°C [78.8°F]), deep (25°C [77°F] to 20°C [68°F]), and profound (<20°C [68°F]). It is not uncommon for temperatures less than 20°C (68°F) used in conjunction with pediatric cardiac surgery to be called deep hypothermia. LFCPB in neonates/infants conducted in

conjunction with temperatures of 18°C (64.4°F) to 25°C (77°F) is generally defined as flow rates 50 to 70 mL/kg/min or approximately 1.0 to 1.5 L/min/m^2.

Profound hypothermic circulatory arrest, commonly referred to as DHCA, is conducted at temperatures of 18°C (64.4°F) to 20°C (68°F) and allows cessation of CPB, venous and arterial cannula removal, and exsanguination of the patient into the venous reservoir of the CPB circuit. This technique used to improve exposure of intracardiac defects and to facilitate aortic arch reconstruction in infants and children. There has been substantial refinement of the technique of DHCA since its successful inception in the 1970s. In the current era, DHCA is used selectively and for short intervals. It is utilized primarily for the aortic arch reconstruction component of the Norwood procedure, repair of interrupted aortic arch, neonatal repair of total anomalous pulmonary venous connection, and complicated intracardiac repairs such as complete AV canal defects in small (<2.0 kg) neonates and infants.

C.7. Why is hypothermia beneficial to the brain during LFCPB and DHCA?

Hypothermia is arguably the most important component of LFCPB and DHCA. The hypothermia-induced reduction in cerebral metabolic rate for oxygen ($CMRO_2$) slows the rate of depletion of high-energy phosphates and the development of

intracellular acidosis and delays or prevents the neuronal energy failure that leads to terminal membrane depolarization and subsequent neuronal injury or death during an ischemic episode.

Q_{10} defines the ratio of organ oxygen consumption at a defined temperature to the oxygen consumption at a temperature 10°C (18°F) lower. The cerebral Q_{10} is approximately 3.65 in children and 2.3 in adults. The cerebral metabolic rate will still be approximately 10% to 15% of its normothermic baseline at 15°C (59°F). If it is assumed that 3 to 5 minutes of cerebral ischemia can be tolerated at 37°C (98.6°F) and the Q_{10} is 3.0, 9 to 15 minutes of ischemia can be tolerated at 27°C (80.6°F) and 27 to 45 minutes can be tolerated at 17°C (62.6°F).

In addition to reducing $CMRO_2$, hypothermia also serves to ameliorate some of the sequelae of neuronal ischemia when instituted before the ischemia insult. Specifically, hypothermia markedly reduces release of the excitatory neurotransmitters glutamate, aspartate, and glycine that accompany cerebral ischemia and subsequent reperfusion. In energy-deprived cells, glutamate in particular is neurotoxic in part due to the role it plays in inducing massive calcium influx through *N*-methyl-D-aspartic acid receptors. Hypothermia also blunts the inhibitory effect of hypoxia on nitroxidergic (postganglionic parasympathetic nerve where nitric oxide is the neurotransmitter)-induced cerebral vasodilation. In addition, there is evidence that hypothermia may attenuate neutrophil migration into ischemic tissue.

C.8. Explain the difference between *α*-stat and pH-stat blood gas management.

pH-stat and *α*-stat are acid–base management strategies that address the temperature-induced differences in blood pH, oxygen solubility, and CO_2 solubility. These management strategies directly influence blood flow to the brain and other organs during hypothermic CPB or DHCA. The difference between these two strategies becomes marked because patient temperature progressively decreases below 37°C (98.6°F) but is not clinically relevant until patient temperature is less than 30°C (86°F). At normothermia (37°C [98.6°F]), there is no difference between pH-stat and *α*-stat management.

Although pH-stat and *α*-stat acid–base management are commonly mentioned in association with temperature-corrected and temperature-uncorrected interpretation of blood gases, these are entirely different concepts. The method of blood gas interpretation (corrected or uncorrected) does not dictate the method of acid–base management (pH-stat or *α*-stat). *α*-Stat or pH-stat management is possible with use of both temperature-corrected and temperature-uncorrected blood gases.

When a blood gas sample is drawn from a hypothermic patient at 25°C (77°F) and sent to the blood gas laboratory, the sample is warmed to 37°C (98.6°F) before measurement. The values obtained at 37°C (98.6°F) are called the temperature-uncorrected values. These values are converted to temperature-corrected values using a nomogram. The nomogram accounts for temperature-induced changes in pH, oxygen solubility, and CO_2 solubility in a closed-blood system. When blood in a closed system is cooled to a lower temperature, the electrochemically neutral pH is higher and the associated P_{CO_2} is lower than in a closed blood system at 37°C (98.6°F). Therefore, electrochemical neutrality is maintained by keeping pH alkalotic

in temperature-corrected blood gases and normal in temperature-uncorrected gases. This is known as *α-stat regulation*. For practical purposes, it is easier to use uncorrected gases and keep pH and P_{CO_2} in the range considered normal at 37°C (98.6°F). It has been demonstrated clinically that cerebral blood flow and oxygen consumption are appropriately coupled when *α*-stat regulation is used. Deep hypothermia in the presence of *α*-stat regulation produces loss of cerebral autoregulation such that cerebral blood flow varies directly with arterial pressure.

pH-stat regulation refers to maintaining pH and P_{CO_2} at normal values for blood at 37°C (98.6°F) regardless of actual blood temperature. With this strategy, a blood sample will have a normal pH and P_{CO_2} when temperature-corrected gases are used, and acidotic pH and P_{CO_2} values when temperature-uncorrected gases are used. For practical purposes, pH-stat is maintained by adding CO_2 to the ventilating gas during hypothermic CPB to increase P_{CO_2} and decrease the pH. In contrast to *α*-stat regulation, in which total CO_2 content is kept constant, pH-stat regulation results in an increase in total CO_2 content. The cerebral vasculature maintains vasomotor responses to varying P_{CO_2} during hypothermic CPB. This response is maintained during both moderate and deep hypothermia despite the fact that deep hypothermia induces loss of cerebral blood flow autoregulation. It has been demonstrated clinically that when pH-stat regulation is used with moderate hypothermic CPB, there is uncoupling of cerebral blood flow and metabolism and loss of cerebral autoregulation. As a result, cerebral blood flow varies linearly with arterial blood pressure, and cerebral hyperperfusion exists with cerebral blood flow far in excess of that dictated by cerebral metabolic rate. This hyperperfusion state is the result of (1) reduced cerebral oxygen consumption induced by hypothermia and (2) cerebral

vasodilation resulting from a disproportionately high P_{CO_2} for the degree of hypothermia present. The potential danger of the hyperperfused state is that it may result in increased delivery of microemboli into the cerebral circulation.

C.9. What are the immediate post-CPB issues following ASO?

Hemorrhage from the extensive suture lines can require emergent surgical repair on CPB or can be caused by post-CPB coagulopathy. Temporarily reducing arterial blood pressure with vasodilating agents can be helpful. Aggressive blood component therapy is often required and may require 1 to 2 units of platelets (0.25 to 0.5 units per kg) to obtain a therapeutic platelet count increase in neonates. Because platelets are suspended in fresh frozen plasma, a platelet transfusion of this size usually results in a fresh frozen plasma transfusion of 10 to 15 mL per kg. Cryoprecipitate transfusion is sometimes necessary to restore fibrin levels to presurgical levels. Point of care assessment and characterization of coagulopathy using thromboelastography or rotational thromboelastometry may be helpful.

Myocardial ischemia following reimplantation of the coronary arteries is a potential problem following the ASO. Epicardial or transesophageal echocardiography is helpful to assess the patency of the reimplanted coronary arteries and to prevent coronary artery air emboli by ensuring adequate removal of air from the LA and LV before termination of CPB. Maintenance of high perfusion pressures on CPB after aortic

cross-clamp removal will facilitate the distal migration of air emboli. In other instances, kinking of the reimplanted artery or compromise of the implanted coronary ostia may require immediate surgical intervention. Pharmacologic intervention with traditional therapies to improve the balance of myocardial oxygen demand and delivery such as nitroglycerin and β-blockade are never a long-term alternative to prompt surgical revision of the appropriate anastomosis.

Despite comprehensive preoperative evaluation, the LV of patients undergoing an ASO may be marginal in its ability to support the systemic circulation in the post-CPB period. This may occur as the result of myocardial ischemia, inadequate LV mass, poor protection of the LV during aortic cross-clamping, or a combination of these variables. Echocardiography is useful in identifying and continuously evaluating both global and regional LV systolic dysfunction. It also detects mitral regurgitation, which may occur secondary to papillary muscle dysfunction or to dilation of the mitral valve annulus. Inotropic support of the LV and afterload reduction may be necessary to terminate CPB.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Whiting D, DiNardo JA. TEG and ROTEM: technology and clinical applications. *Am J Hematol*. 2014;89(2):228–232.

D. Postoperative Management

D.1. How is myocardial ischemia addressed in the intensive care unit (ICU) following the ASO?

Myocardial ischemia in the ICU following an ASO is usually heralded by ST-segment/T-wave changes or the development of atrial or ventricular arrhythmias. Myocardial ischemia should be considered to be mechanical in nature until proved otherwise.

Thrombin soaked absorbable gelatin pads are sometimes used for hemostasis around the coronary anastomoses and can compress the coronary ostia, as can adjacent thrombi. Surgical reexploration is indicated and likely to be immediately therapeutic.

LV dilation can initiate and exacerbate myocardial ischemia in patients who have undergone an ASO. Myocardial ischemia, afterload mismatch, or overzealous volume infusion can result in LV distension and LA hypertension. This is more likely if there is mitral insufficiency from either papillary muscle dysfunction or dilation of the mitral valve annulus. LV distention may result in stretching or kinking of the coronary reanastomosis sites causing a cycle of worsening myocardial ischemia and LV dilation. LA hypertension produces elevations in PA pressure and distention of the PA and can compress or place tension on the coronary ostia because the LeCompte maneuver brings the distal PA anterior to the ascending aorta. The resulting myocardial ischemia produces further LV dilation, progressive elevations in LA and PA pressures, and continuing compromise of coronary blood flow. Attempts to induce coronary vasodilation with nitroglycerin are unlikely to be beneficial in this setting, although the reduction in preload and afterload may be beneficial. Afterload reduction with nitroprusside or milrinone also might be helpful.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

D.2. What immediate postoperative problems would be anticipated following the Rastelli procedure?

Right (pulmonary) ventricular dysfunction related to the ventriculotomy used to close the VSD and create the new pulmonary outflow tract can occur, as can heart block given the

proximity of the VSD to the intraventricular conduction pathways. A residual VSD following repair is always possible, as is LV outflow tract obstruction around the tunnel used to create LV and aortic continuity.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Kreutzer C, De Vive J, Oppido G, et al. Twenty-five-year experience with Rastelli repair for transposition of the great arteries. *J Thorac Cardiovasc Surg*. 2000;120(2):211–223.

D.3. What intermediate and long-term surgical problems are seen after ASO?

Supravalvar pulmonary stenosis is probably the most common complication of ASO. This stenosis is usually caused by retraction of the tissue used to repair the PA in the area of the explanted coronaries, but in most patients is not extensive enough to result in valvular pulmonary stenosis. Series with long-term follow-up (15 years) confirms that the incidence of supravalvar stenosis severe enough to require reoperation (generally a gradient >50 to 60 mmHg) is approximately 4% to 8%.

The second most common complication of the ASO is aortic insufficiency and occurs in approximately 10% to 15% of patients at long-term follow-up, with the majority (96%) graded as trivial or mild. This is a rare source of morbidity or indication for reoperation following the ASO.

Early concerns of the long-term patency and growth potential of the reimplanted coronary arteries following the ASO have not materialized on a large scale.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Villafañe J, Lantin-Hermoso MR, Bhatt AB, et al. D-transposition of the great

arteries: the current era of the arterial switch operation. *J Am Coll Cardiol*. 2014;64:498–511.

D.4. What are the long-term outcomes after ASO?

Actuarial survival in experienced centers at 1 year is 90% for patients with D-TGA and IVS and 83% for patients with D-TGA and VSD. A review of 470 patients from one institution experienced in the ASO revealed a 1-year survival rate of 92% and an 8-year survival rate of 91% for patients with both D-TGA and IVS and D-TGA and VSD. A similar review of 1,200 patients from another experienced institution revealed a 1- and 15-year survival rate of 92% for patients with D-TGA and IVS, and 1- and 15-year survival of 81% and 80% for D-TGA and VSD, respectively. A recent multi-institution review of 631 patients with D-TGA and 167 patients with D-TGA and VSD revealed similar initial and long-term (15 years) outcomes. Freedom from adverse cardiovascular events has recently been shown to be 93% at 25 years.

Ninety to 97% of patients with D-TGA have normal-sized, patent coronary arteries as assessed by coronary angiography. A recent study of a large cohort demonstrated that survival without coronary events (death from myocardial infarction, sudden death, and reoperation for coronary stenosis) is 92.7% at 1 year and 88.2% at 15 years. The incidence of coronary events is bimodal with a high early and low late event rate. Eighty-nine percent of all coronary events occurred in the first 3 months after ASO. The event rate did not increase again until 6 years after ASO. Abnormal coronary, specifically a single coronary artery origin or two coronaries originating close to each other at a facing commissure were risk factors for a coronary event.

One of the potential advantages of the ASO over the atrial switch procedure is the use of the native LV as the systemic ventricle. Long-term follow-up indicates that patients who have undergone an ASO have higher systemic ventricular ejection

fractions than do patients who have undergone atrial switch procedures. In fact, patients who had D-TGA and IVS repaired in infancy and patients who had D-TGA and VSD repaired later have LV end-diastolic dimensions and contractile indices similar to normal patients. Myocardial contractility in patients having undergone a rapid or traditional two-stage arterial switch is mildly depressed as compared to patients having undergone a primary arterial switch. No progression of this ventricular dysfunction has been noted at either intermediate or long-term follow-up.

DiNardo JA, Shukla AC, McGowan FX. Anesthesia for congenital heart surgery. In: Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:633–698.

Villafañe J, Lantin-Hermoso MR, Bhatt AB, et al. D-transposition of the great arteries: the current era of the arterial switch operation. *J Am Coll Cardiol*. 2014;64:498–511.

D.5. What are the long-term outcomes after Rastelli repair for patients with D-TGA with left ventricular outflow tract (LVOT) obstruction?

Outcome following the Rastelli procedure for TGV with VSD and LVOT obstruction is good, with a near 100% early survival rate. A recent series reports survival to be 93% at 5, 10, and 20 years. The need for reintervention (either surgical or catheterization) increases over time. Intervention to relieve right ventricular outflow tract (RVOT) (RV to PA conduit) obstruction accounts for 75% of all interventions, with pacemaker insertion and relief of LVOT obstruction (aortic outflow) accounting for most of the remaining interventions. In an effort to reduce the need to intervene again for LVOT obstruction associated with the Rastelli procedure, some

institutions are making greater use of the LeCompte and Nikaidoh procedures.

D.6. What is long-term neurologic outcome like after ASO?

The best assessment of neurologic outcome following ASO is data from the Boston Circulatory Arrest Trial. In this trial, 171 infants undergoing ASO for D-TGA with IVS or VSD were randomized to strategy of either DHCA or LFCPB using α-stat pH management. Infants in the DHCA group underwent an average of 52 minutes of DHCA, whereas those in the LFCPB group underwent 14 minutes of DHCA.

Children in this cohort had overall physical and psychosocial health status similar to the general population. However, at age 8 years, parents of children in both groups reported more problems with attention, learning, speech, and the frequency of developmental delay than parents of children in a normative sample. There was no association between physical and psychosocial scores and the presence or absence of a VSD or the use of LFCPB versus DHCA. Neurodevelopmental outcome in this cohort was generally not adversely affected unless the duration of DHCA exceeded 41 minutes. Beyond 41 minutes, there was a nonlinear (steadily worsening) outcome with increasing duration of DHCA.

Eight-year and 16-year data from the trial also demonstrated that neurologic status, IQ, academic achievement, memory, problem solving, and visual–motor integration did not differ between the DHCA and LFCPB groups. Nonetheless, DHCA was associated with greater functional deficiencies in motor function, visual–motor tracking, phonic awareness and speech apraxia, whereas patients in the LFCPB exhibited more impulsive behavior and worse behavior in school as rated by teachers.

40 Pyloric Stenosis

Aarti Sharma and Vinod Malhotra

A 3-week-old first-born male infant had projectile vomiting, which contained the ingested formula but no bile. His body weight was 2.5 kg; serum electrolytes: K^+, 2.2 mEq per L; Cl^-, 86 mEq per L; and blood pH, 7.68. This infant was also noted to have a systolic murmur heard best at the second intercostal space along the left sternal border, which was assessed by a cardiologist and diagnosed as a ventricular septal defect (VSD).

A. Medical Disease and Differential Diagnosis

1. What is the diagnosis in this patient?
2. What is the differential diagnosis of pyloric stenosis?
3. What are the metabolic problems in this newborn secondary to his disease?
4. What are the adverse effects of metabolic alkalosis?
5. How would you treat this infant?
6. How would you determine fluid replacement in a newborn, and what fluids would you use?
7. How would you correct the metabolic alkalosis in this patient?
8. What causes a cardiac murmur?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. How would you evaluate a heart murmur?
3. How would you differentiate between functional versus organic murmur?
4. What are the types of VSD? What type of shunt do they cause?
5. What are the risks of surgery and anesthesia in a patient with VSD?
6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?
7. How would you prepare this patient for anesthesia?

C. Intraoperative Management

1. What induction–intubation sequence would you use?
2. What are the anatomic characteristics of the airway in the newborn and how do they differ from those in the adult?
3. How do you determine the size of an endotracheal tube in a pediatric patient?
4. What anesthesia system would you use and why?
5. What are the advantages and the disadvantages of commonly employed nonrebreathing systems?
6. How would you monitor this patient intraoperatively?
7. How does the pulse oximeter function?
8. What factors affect the measurement of oxygen saturation by the pulse oximeter?

D. Postoperative Management

1. What are the complications that can occur in the postanesthesia recovery period?
2. How would you treat postextubation “croup” in this infant?

A. Medical Disease and Differential Diagnosis

A.1. What is the diagnosis in this patient?

The most likely diagnosis in this patient is pyloric stenosis. The factors that favor the diagnosis are as follows:

- Age—3 weeks (average age at onset; range 5 days to 5 months)
- Boy child (boy-to-girl ratio = 4:1)
- Projectile vomiting (characteristic)
- Contents—ingested formula, no bile

The resultant biochemical abnormality in this patient is a hypokalemic, hypochloremic, metabolic alkalosis.

Pyloric stenosis occurs in 3 of 1,000 infants born in the United States; its incidence may be increasing. It is more common in Whites of Northern European ancestry, less common in Blacks, and rare in Asians. Reduced nitric oxide in pyloric tissue may contribute to the pathogenesis of pyloric stenosis.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

A.2. What is the differential diagnosis of pyloric stenosis?

Pyloric stenosis can be distinguished from other congenital anomalies that cause obstruction of the alimentary tract in the newborn. These other anomalies include chalasia of the esophagus, hiatus hernia, duodenal atresia, jejunal atresia, ileal atresia, pancreatic annulus, malrotation of the gut, intra-abdominal hernias, and Meckel diverticulum. Pathognomonic features of pyloric stenosis include absence of bile staining of the vomitus and visible gastric peristaltic waves on abdominal examination along with the palpable pyloric mass. The diagnosis is commonly made clinically. An “olive” is sometimes palpated in the epigastrium just to the right of the midline. The diagnosis can be confirmed by abdominal ultrasound. Occasionally, an upper gastrointestinal (GI) series with barium is necessary.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

A.3. What are the metabolic problems in this newborn secondary to his disease?

Metabolic changes occur secondary to protracted vomiting and characteristically include a hypokalemic, hypochloremic alkalosis, as evident in this infant. Hyponatremia, although present, may not be manifested in serum value determinations because of severe dehydration. Compensatory respiratory acidosis is a frequent finding; it results from hypoventilation that may be marked and associated with periods of apnea. In severe dehydration leading to circulatory shock, the lack of adequate perfusion coupled with impaired renal and hepatic function may produce an entirely different picture of metabolic acidosis with hyperventilation, resulting in respiratory alkalosis. Therefore, depending on the severity and duration of vomiting and the type of fluid replenishment, one can encounter wide variations in arterial blood gas and electrolyte determinations. However, the most frequent findings are hypokalemia, hyponatremia, hypochloremia, and primary metabolic alkalosis with secondary respiratory acidosis. The renal response to vomiting is twofold. Initially, serum pH is maintained by the excretion of alkaline urine with sodium and potassium loss. Then, after the depletion of these electrolytes, the kidneys secrete acidic urine (paradoxic acidosis), which exacerbates the metabolic alkalosis. These findings are summarized in **Table 40.1**.

TABLE 40.1 Metabolic Findings in the Newborn Secondary to Pyloric Stenosis

Severity of Dehydration	Arterial Blood Gases				Serum Electrolytes			
	pH	P_{CO_2}	C_{O_2}	P_{O_2}	NA	K	CL	HCO_3
Mild	↑	↑	↑	↔	↓↔	↓	↓↓	↑
Moderate	↑↑	↑↑	↑↑	↔	↓	↓↓	↓↓↓	↑↑
Severe	↓↓	↓	↓↓	↓	↓	↓↓	↓↓↓	↓↓

↔, no change; ↑/↓, slight change; ↑↑/↓↓, moderate change; ↑↑↑/↓↓↓, marked change.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:789–815.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

A.4. What are the adverse effects of metabolic alkalosis?

- An increase in pH results in shifting of the oxygen-dissociation curve to the left, thereby binding more oxygen to the hemoglobin and unloading less oxygen at the tissue level. This phenomenon assumes even more importance in newborns because at 3 weeks, they still have up to 70% fetal hemoglobin with an already low value of P50 (i.e., 20 to 22 mmHg).
- Respiratory compensation is affected by hypoventilation with increased potential for atelectasis as well as periods of apnea.
- Decrease in ionized calcium
- Increased potential for seizures

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

A.5. How would you treat this infant?

Medical management of this infant with pyloric stenosis is acutely urgent. The principles of management can be grouped under the following three categories: supportive therapy to stabilize the patient, diagnostic tests to confirm the diagnosis and monitor therapy, and surgery as the corrective therapy.

Supportive Therapy

- Circulatory support
- Correction of electrolyte imbalance
- Prevention of aspiration

Fluids

The infant with pyloric stenosis is hypovolemic and dehydrated secondary to persistent vomiting. Dehydration severity can vary

from mild hypovolemia to circulatory shock. The following parameters are good indicators of dehydration severity:

- Physical appearance—skin turgor, parched mucous membranes, sunken fontanels, sunken eyeballs
- Blood pressure—decreased
- Pulse—increased
- Urine output—decreased
- Weight (birth and present) and weight loss

Quantitative assessment of these parameters gives a fair estimate of the amount of total body fluid depletion. A wide-bore intravenous (IV) cannula should be placed and an infusion started immediately to correct the deficits and provide maintenance fluids.

Electrolytes

The patient is alkalotic, hypokalemic, hypochloremic, and hyponatremic and must be provided with necessary ions to replenish the deficit. Albumin or Ringer's lactate may be used to treat the shock first. Next, the deficit should be corrected, 0.45% to 0.9% saline in 5% to 10% dextrose. Potassium (usually 40 mEq per L) must be added to this to correct hypokalemia and aid in the correction of alkalosis. However, potassium infusion should be withheld until satisfactory renal function is established. Fluid therapy should be continued until the infant is rehydrated and serum bicarbonate concentration is less than 30 mEq per dL, which implies that the alkalosis has been corrected.

Prevention of Aspiration

A nasogastric tube should be inserted to thoroughly empty the stomach, and the upper airway reflexes should be preserved.

Diagnostic Tests

- To assess the severity of fluid and electrolyte derangement and to monitor therapy, the following should be evaluated:

complete blood count, serum electrolytes, blood gases, blood urea nitrogen (BUN), electrocardiogram (ECG) (for marked hypokalemia).

- To confirm the diagnosis: barium swallow, ultrasound imaging

Surgery

Pyloromyotomy is the definitive treatment for these infants. Ramstedt pyloromyotomy through a right upper quadrant transverse incision has been the traditional treatment for hypertrophic pyloric stenosis. Recently, laparoscopic and circumumbilical approaches have been introduced as alternative methods to improve cosmesis, but concerns about greater operative times, costs, and complications remain. Surgery should be carried out early but only after the patient has been stabilized satisfactorily.

Coran AG, Caldamone A, Adzick NS, et al. *Pediatric Surgery*. 7th ed. Philadelphia, PA: Elsevier Saunders; 2012:1021–1028.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

A.6. How would you determine fluid replacement in a newborn, and what fluids would you use?

The general principles of fluid therapy are based on fluid maintenance, correction of deficits, and replacement of losses.

Maintenance Fluids

In the newborn, maintenance fluids are as follows:

- First 48 hours of life—75 mL/kg/day or 3 mL/kg/hr
- 2 days to 1 month—150 mL/kg/day or 6 mL/kg/hr
- 1 month onward (up to 10 kg)—100 mL/kg/day or 4 mL/kg/hr

Estimation of the degree of dehydration in a newborn is shown in **Table 40.2**.

TABLE 40.2 Estimation of the Degree of Dehydration in a Newborn

	Mild	Moderate	Severe
Percentage fluid loss	5	10	15–20
Skin turgor	Poor	Very poor	Parched
Mucous membrane and tongue	Dry	Dry	Parched
Fontanel and eyes	Normal	Sunken fontanel	Sunken eyes
Urine	Concentrated oliguria	Oliguria	Oliguria, anuria
Pulse	Normal	Tachycardia	Marked tachycardia
Blood pressure	Normal	Hypotension	Marked hypotension, shock

The maintenance fluids take into account the fluid losses occurring normally through the kidney, bowel, skin, and lungs. At birth, the kidney is still undergoing maturation, and what may be called "a glomerular imbalance" exists. What it implies is that some mature glomeruli may be connected to the immature tubules and vice versa. Hence, the kidney is functionally limited at birth but undergoes rapid maturation during the first week of life.

Electrolytes

The newborn is an obligate sodium loser as well as a poor tolerator of excessive sodium overload. The maintenance electrolytes are as follows:

- Sodium—3 to 5 mEq/kg/day
- Potassium—2 to 3 mEq/kg/day
- Chloride—1 to 3 mEq/kg/day

Correction of Deficits

Deficits take into account the previous unreplaced losses because of a period of no intake by mouth and dehydration resulting from increased losses (e.g., from vomiting, diarrhea, and increased body temperature). The amount of deficit can be assessed by physical examination (**Table 40.2**), body weight loss, and hematocrit.

Replacement of Losses

Replacing losses covers ongoing abnormal losses not covered by maintenance fluids. Intraoperatively, it covers evaporative losses from the operative site, third spacing, and losses from the lungs if dry gases are used in nonrebreathing circuits (**Table 40.3**).

TABLE 40.3 Fluid Requirement to Replace Intraoperative Fluid Losses (Except Blood Loss) in the Newborn

	Fluid Replacement (mL/kg/hr)
Minor surgery (e.g., herniorrhaphy)	1–3
Moderate surgery (e.g., pyloromyotomy)	3–5
Major surgery (e.g., intestinal)	5–7
Respiratory water loss due to dry gases	2

The younger and more physically immature the patient, the higher the skin permeability, the ratio of body surface area to weight, and the metabolic demand. In addition, the use of radiant warmers and phototherapy increases insensible water loss.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2420–2458.

A.7. How would you correct the metabolic alkalosis in this patient?

To correct the metabolic alkalosis in this patient, the underlying electrolyte derangements (hyponatremia, hypokalemia, and hypochloremia) must be corrected. We correct the deficits by using calculated volumes of 5% dextrose in normal saline or Ringer's lactate solution, which helps to restore sodium and chloride mainly. Dextrose, 5%, with one-fourth strength normal saline may be used to provide maintenance fluids. Once renal function is established, potassium supplements are added to the infusion. Depending on the deficit, this therapy can require

anywhere from 12 to 72 hours. In severely alkalotic patients, HCl (hydrochloric acid) and NH_4Cl (ammonium chloride) have been used to correct the derangement. However, we have rarely found it necessary.

Barash PG, Cahalan MD, Cullen MD, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:385–386, 1213, 1407–1408.

A.8. What causes a cardiac murmur?

Cardiac murmurs are caused by turbulent blood flow across cardiac valves or septal defects and are audible sound waves in the range of 20 to 2,000 Hz. Most murmurs in pediatric patients are normal or innocent, occurring in almost 50% of all school-aged children but must be distinguished from those murmurs associated with significant structural heart disease. Auscultation is critically important in diagnosing these murmurs; however, echocardiography remains the gold standard.

Allen HD, Shaddy RE, Penny DJ, et al, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*. 9th ed. Philadelphia, PA: Wolters Kluwer; 2016:255–257.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

The following information is necessary in evaluating this patient:

History

Onset of illness, frequency and amount of vomiting, last feeding, diarrhea, urine output, activity of the newborn (active or lethargic), and birth weight

Physical Examination

Present body weight (to determine the weight loss), temperature, signs of dehydration (skin turgor, mucous membranes, fontanels,

eyeballs, blood pressure, pulse, color, and volume of urine), muscle tone, and level of consciousness

Laboratory Findings

Complete blood count, electrolytes, BUN and blood sugar, urinalysis, and arterial blood gases

Based on the data available, we can determine the fluid and electrolyte status of the patient and correct these accordingly to stabilize the patient for surgery and anesthesia.

B.2. How would you evaluate a heart murmur?

Heart murmurs can be innocent or organic. By definition, innocent murmurs occur in the absence of structural or physiologic cardiac disease. The clinical diagnosis of a normal or innocent murmur should occur in the setting of an otherwise normal history, physical examination, and appearance. The presence of a family history of hypertrophic cardiomyopathy; congenital cardiac disease; or unexplained infant, childhood, or early adult death is particularly worrisome. The perinatal history of prematurity, maternal diabetes, drug or toxin ingestion, fetal distress, or clearly definable chromosomal disorders has particular cardiorespiratory relevance. The initial approach to the evaluation of the cardiovascular system should include an assessment of the cardiorespiratory system functionality as a pump and delivery system. An index of exercise or play capacity should be sought as a component of assessing growth and development. We would ask about exercise tolerance, shortness of breath, cyanotic episodes, growth (because congestive heart failure may manifest as failure to thrive), and symptoms of congestive heart failure.

Allen HD, Shaddy RE, Penny DJ, et al, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*. 9th ed. Philadelphia, PA: Wolters Kluwer; 2016:255–257.

B.3. How would you differentiate between functional versus organic murmur?

Normal murmurs of childhood are composed of five systolic and two continuous types but never solely diastolic (**Table 40.4**). A functional murmur is usually soft, 1/6 or 2/6, and never associated with palpable thrill. Pathologic murmurs are usually louder, 3/6 or greater, and are associated with other cardiovascular pathologic features.

TABLE 40.4 Innocent Murmurs of Childhood

Systolic Murmurs	Continuous Murmurs
Vibratory Still murmur	Venous hum
Pulmonary flow murmur	Mammary arterial souffle
Peripheral pulmonary artery stenosis murmur	
Supraclavicular systolic murmur	
Aortic systolic murmur	

Park MK. *Park's Pediatric Cardiology for Practitioners*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2014:36–39.

B.4. What are the types of VSD? What type of shunt do they cause?

One common classification of VSD is based on anatomic location.

- Type I defects, or supracristal defects (5% of all VSDs), are outflow defects located above the crista supraventricularis just under the annulus of aorta.
- Type II defects, or infracristal defects (80% of all VSDs), are lower in membranous septum beneath the crista supraventricularis.
- Type III defects, or canal type (11% incidence), are inlet VSDs that accompany complete atrioventricular (AV) canal defects. They result from failure of the endocardial cushions to fuse.

- Type IV, or muscular, defects (2% to 7% incidence) probably result from excessive resorption of septal tissue during the muscular septal formation. They may be located anywhere in the muscular septum and may be multiple (also known as the Swiss cheese defect).

VSD is left-to-right shunt. Pathophysiologic effects of VSD include left-to-right shunting, pulmonary hypertension, and heart failure resulting from volume overload.

Allen HD, Shaddy RE, Penny DJ, et al, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*. 9th ed. Philadelphia, PA: Wolters Kluwer; 2016:784–792.

B.5. What are the risks of surgery and anesthesia in a patient with VSD?

Infective endocarditis is a complication of most congenital cardiac anomalies, so the patient requires antibiotic prophylaxis. There is also risk of increasing the flow in the shunt or reversing the flow in the shunt, resulting from decreases in pulmonary vascular resistance causing hypoxemia and congestive heart failure or acute and persistent increases in systemic vascular resistance. Right ventricular infundibular hypertrophy may be present in the patients with a VSD. Normally, this is a beneficial change because it increases the resistance to right ventricular ejection, leading to decrease in magnitude of the left-to-right shunt. Nevertheless, perioperative events that exaggerate this obstruction to right ventricular outflow, such as increased myocardial contractility or hypovolemia, must be minimized. Therefore, these patients are often anesthetized with a volatile anesthetic. In addition, intravascular fluid volume should be maintained by prompt replacement of blood loss. During the anesthetic, a normal end-tidal carbon dioxide (CO_2) should be maintained and routine air bubble precautions should be taken.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2017:130–133, 541–542.

B.6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?

Hypertrophic pyloric stenosis is a medical emergency and not a surgical emergency. Therefore, no newborn should be subjected to the additional hazards of anesthesia and surgery until stabilized medically.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1945–1949.

B.7. How would you prepare this patient for anesthesia?

Fluid and electrolyte replacement should be accomplished satisfactorily—this may take anywhere from 12 to 72 hours depending on the patient's status. The next step is to empty the stomach through a wide-bore nasogastric tube, lavaging out the gastric contents and any leftover barium. Alternatively, an oral-gastric approach allows for passage of a tube with wider lumen that ensures better stomach emptying. Premedication is usually atropine (0.01 to 0.02 mg per kg) IV or intramuscular if the patient does not have IV line.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:789–815.

C. Intraoperative Management

C.1. What induction–intubation sequence would you use?

These children should arrive to the operating room with an IV access. Standard monitors are placed. The stomach is emptied by inserting an orogastric tube (atropine may be used as premedication) to reduce the chance of regurgitation during

induction. Because the stomach may not be completely emptied, a rapid sequence induction and intubation with cricoid pressure is highly recommended to minimize the risk of aspiration. Awake intubation may be accomplished in skillful hands in a lethargic neonate or in a critically sick infant. In most cases, however, neonates presenting for this procedure are fit and do not require awake intubation, which can be more traumatic.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:795–797.

Jöhr M. Anesthesia for the child with full stomach. *Curr Opin Anaesthesiol*. 2007;20(3):201–203.

C.2. What are the anatomic characteristics of the airway in the newborn and how do they differ from those in the adult?

The special characteristics of the upper airway in the newborn are as follows:

- Nasopharynx—narrow nasal passages, obligate nasal breathers
- Oropharynx—large tongue, long and pendulous epiglottis
- Larynx—the distinctive features shown in **Table 40.5**

TABLE 40.5 Comparative Anatomy of the Larynx and Trachea in the Newborn and the Adult

Anatomic Features	Newborn	Adult
Size	4 cm	10–13 cm
Shape	Funnel	Cylindrical
Position of the glottis	C3–C4	C6
Narrowest point	1 cm below vocal cords	At vocal cords
Vocal cords	Slanting anteriorly	Transverse or slightly Slanting posteriorly
Mucous membrane	Loose (swells easily)	More firmly bound

It is apparent, therefore, that the newborn who has low

respiratory reserve can develop airway obstruction easily. The infant may present problems during intubation and tolerate airway trauma poorly.

Comparative anatomy of the larynx and trachea in the newborn and the adult is shown in **Table 40.5**.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:349–370.

C.3. How do you determine the size of an endotracheal tube in a pediatric patient?

The two parameters of endotracheal tube sizes are the tube length and diameter, depending on the age of the child, as shown in **Table 40.6**. However, these are approximate sizes and one must have one size bigger and one size smaller tube available when selecting any size tube. A simple way to remember these numbers is to know the sizes at newborn, 6 months, and 1 year. Between 2 and 12 years, the following guide may be used:

- Tube length from tip to incisor teeth (cm) = 11 + age in years
- Tube internal diameter (mm) = 4 + age / 4
- French size (French) = 18 + age
- External circumference (French) = ID (mm) × 4 + 2

TABLE 40.6 Endotracheal Tube Size for Pediatric Patient

Age	Length	Internal Diameter (mm)	French Sizes
Newborn	10	3.0	14
6 months	12	3.5	16
1 year	14	4.0	18
2 years	15	4.5	20
4 years	16	5.0	22
6 years	17	5.5	24
8 years	18	6.0	26
10 years	19	6.5	28
12 years	20	7.0	30

(French size means external circumference in millimeters, which equals π times external diameter; $\pi = 3.1416$.)

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:349–370.

C.4. What anesthesia system would you use and why?

We employ the circle system with a light circuit. The circle system is more advantageous because it maintains heat and humidification better and offers the freedom of choosing varying gas flows. The controversy about the increased resistance in the adult system is discounted by the fact that the respiration is assisted or controlled intraoperatively. Newer anesthesia machines use valves with much less resistance than older models. Dead space in these systems is no more than that of the Mapleson circuits.

Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:209–218.

C.5. What are the advantages and the disadvantages of commonly employed nonrebreathing systems?

Commonly used nonrebreathing systems include Bain Breathing circuit (Mapleson D system) and Jackson-Rees modification of Ayre T-piece. They offer the following advantages and disadvantages:

Advantages

- Minimal dead space
- No valves, low resistance
- Lightweight
- Reservoir bag to assist ventilation
- Good appreciation of patient's respiratory exchange

Disadvantages

- High flow of fresh gases required
- Low flows may allow rebreathing of gases without CO_2

absorption.

- Loss of heat and humidity because of high flow of cold, dry gases (Bain circuit allows some heating of inspired gases by surrounding fresh gas flow tubing with expired gas tubing.)
- Scavenging problems of waste gases

Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:191–208.

C.6. How would you monitor this patient intraoperatively?

Monitoring should include blood pressure, ECG, rectal temperature, precordial stethoscope, pulse oximeter, and an end-tidal CO_2 monitor.

C.7. How does the pulse oximeter function?

Commonly used pulse oximeters combine the scientific principles of spectrophotometric oximetry and plethysmography. Light of two wavelengths, 660 nm (red) and 920 nm (infrared), is emitted by a pair of light-emitting diodes (LED) and is passed through the tissue being measured to a photodetector. Because the saturated hemoglobin absorbs more blue light than unsaturated hemoglobin, the absorption of light for each color is an indication of the ratio of oxygen saturated blood to unsaturated blood. The pulsating vascular bed, by expanding and relaxing, creates a change in light-path length that modifies the amount of light detected. The microprocessor-controlled circuitry in the unit senses the pulsatile waveform, which is solely produced by the arterial blood, thereby allowing measurement of pulse rate and arterial saturation. The oximeter is reliably accurate in 60% to 100% saturation range.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:256–270.

Kim SH, Lilot M, Murphy LS, et al. Accuracy of continuous noninvasive

hemoglobin monitoring: a systematic review and meta-analysis. *Anesth Analg*. 2014;119:332–346.

Saraswat A, Simionato L, Dawson JA, et al. Determining the best method of Nellcor pulse oximeter sensor application in neonates. *Acta Paediatr*. 2012;101(5):484–487.

C.8. What factors affect the measurement of oxygen saturation by the pulse oximeter?

Dysfunctional hemoglobin, such as carboxyhemoglobin, sulfhemoglobin, and methemoglobin, can affect the accuracy of the oximeter. Intravascular dyes, such as indocyanine green and methylene blue, can also interfere with the accuracy of the instrument. Skin color, tissue thickness, venous blood, light intensity, and ambient light do not affect the accuracy of the instrument because they do not pulse.

Ehrenwerth J, Eisenkraft JB, Berry JM, eds. *Anesthesia Equipment: Principles and Applications*. 2nd ed. New York: Elsevier; 2013:256–270.

D. Postoperative Management

D.1. What are the complications that can occur in the postanesthesia recovery period?

The patient should be carefully observed for signs of respiratory depression and periods of apnea secondary to the combination of metabolic alkalosis, general anesthesia, and decreased body temperature. However, these infants do not appear to be at increased risk of postoperative apnea. Hypoventilation predisposes to atelectasis. These patients should be awake and responsive to avoid aspiration. Severe hypoglycemia resulting from depletion of liver glycogen stores has been reported 2 to 3 hours after surgery. Postextubation “croup” is a potentially dangerous complication in this age group.

Davis PJ, Cladis FP, eds. *Smith’s Anesthesia for Infants and Children*. 9th ed.

Philadelphia, PA: Elsevier; 2017:789–816.

D.2. How would you treat postextubation "croup" in this infant?

Treatment of the potentially catastrophic postextubation laryngeal edema should be immediate, vigorous, and carried out under direct observation of the anesthesiologists. It consists of the following:

- Increasing inspired oxygen concentration (50% to 60%)
- Humidification of inspired gases
- Adequate hydration using parenteral fluids
- Light sedation to calm the patient and allow for cooperation in therapy
- Avoidance of any significant respiratory depression
- Epinephrine through handheld nebulizer and mask, 50 μg/kg/min of active isomer
- Racemic epinephrine (2.25%) 0.05 mL per kg diluted in 5-mL saline solution delivered in 10 minutes

Treatment should be given over 10 minutes and may be repeated every 30 minutes, as necessary. Rebound phenomenon may be expected approximately 2 hours after cessation of this therapy.

- Steroids—dexamethasone, 0.5 to 1 mg per kg IV
- Reintubation—if signs of deterioration or hypoxia appear
- Tracheostomy, if necessary—rarely, subglottic edema may be so rapid and so severe that tracheostomy is the only choice

The age group most likely to manifest this complication is 1 to 4 years. Infants younger than 1 year are at most risk, mainly because of the size of their airway. Fortunately, an infant of this age is most amenable to early and vigorous intervention and should always be treated as an emergency requiring the continued presence of and evaluation by a physician who is adept at securing an airway for the child.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:789–816.

41 Inflammatory Airway Disease in Childhood: Laryngotracheobronchitis

Miles Dinner and Anthony Longhini

A 3-year-old boy was brought to the emergency room because of respiratory distress. He was noted to have stridor with substernal retractions and excessive drooling. He complained of a sore throat and had a fever of 39.5°C (103.1°F).

A. Medical Disease and Differential Diagnosis

1. What portion of the airway is affected in the croup syndrome and why?
2. What is stridor?
3. How does stridor correlate with anatomic location?
4. Define croup. What is the clinical presentation of laryngotracheitis?
5. What is the differential diagnosis of acute upper airway obstruction in children?
6. What is bacterial tracheitis?
7. What congenital problems can mimic features of croup?
8. How is the severity of croup assessed?
9. What is the medical management of croup? Does this have

implications for the anesthesiologist?

10. What is epiglottitis? What are its common causes? What is the incidence?
11. What are the clinical manifestations of epiglottitis?
12. How is the diagnosis of epiglottitis made?
13. What is postextubation croup? How is it managed?
14. What are the nonacute causes of partial airway obstruction in children?

B. Preoperative Evaluation and Preparation

1. Is intubation always required in children with epiglottitis?
2. Why is general anesthesia administered to a child with epiglottitis?
3. How would you prepare the patient for anesthesia?

C. Intraoperative Management

1. How is the airway of the child with epiglottitis best secured?
2. How would you induce anesthesia?
3. Should a child with epiglottitis undergo a rapid sequence induction?
4. Is awake intubation a practical alternative to secure the patient's airway?
5. What would you do if the airway cannot be secured with intubation?
6. Should this patient have a nasotracheal or orotracheal tube placed?
7. Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?

D. Postoperative Management

1. How long should this patient remain intubated? What criteria determine extubation time?
2. How would you make this patient comfortable during the

course of intubation?

3. What outcome can one expect for the child with acute epiglottitis?

A. Medical Disease and Differential Diagnosis

A.1. What portion of the airway is affected in the croup syndrome and why?

The subglottis is typically involved in infants and children presenting with croup. The subglottis is defined as the segment of the upper airway directly below the vocal cords fusing with the upper trachea. It contains pseudostratified columnar respiratory epithelium, which is loosely adherent and prone to swelling. Because this segment is fully cartilagenized in childhood, it lacks the ability to expand and thus can produce early symptoms due to even small degrees of inflammation.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2551.

Sobol SE, Zapata S. Epiglottitis and croup. *Otolaryngol Clin North Am*. 2008;41:551–566.

A.2. What is stridor?

Stridor is the high-pitched adventitious sound produced in the respiratory cycle by the turbulent flow of respiratory gases through a segmental narrowing in the airway. It can be biphasic, inspiratory, or expiratory, depending on the anatomic location.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2551.

A.3. How does stridor correlate with anatomic location?

Inspiratory stridor is characteristic of laryngeal or supraglottic obstruction. Conditions such as laryngeal papillomatosis, laryngeal web, laryngomalacia, and vocal cord paresis produce inspiratory stridor. Expiratory stridor is usually typical of intrathoracic processes such as extrinsic tracheal compression by a vascular ring or mass, tracheomalacia, or bronchotracheitis. Biphasic stridor is indicative of lesions or infections involving both the larynx and subglottis, such as the croup syndrome, subglottic stenosis, or intralaryngeal masses.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

A.4. Define croup. What is the clinical presentation of laryngotracheitis?

Croup is the constellation of inspiratory stridor, barking cough, and possible respiratory distress due to subglottic mucosal edema. The majority of croup cases is infectious and is termed laryngotracheobronchitis for the structures involved. Spasmodic croup is considered an allergic reaction to viral antigens. Patients with spasmodic croup are afebrile, lack severe laryngeal inflammation, and are typically managed as outpatients with supportive care. Infectious croup is caused by a number of viruses, including human rhinovirus; *Haemophilus parainfluenzae* virus types 1, 2, and 3; respiratory syncytial virus; influenza virus; or human corona virus. It commonly affects children between 6 months and 3 years of age, with a median age of 18 months. Most cases of infectious croup occur during the colder months, and there is a 1:1 male-to-female prevalence. It manifests subacutely as an exacerbation of cold symptoms with low fever, barking cough, noisy breathing, and hoarseness. Exudative inflammation of the upper airway may cause dyspnea and in extreme cases can lead to exhaustion and frank hypoxia. In most cases, it is self-limited and benign.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

van der Hoek L, Sure K, Ihorst G, et al. Human coronavirus NL63 infection is associated with croup. *Adv Exp Med Biol*. 2006;581:485–491.

A.5. What is the differential diagnosis of acute upper airway obstruction in children?

A full differential for this condition involves a host of infectious causes. Among the most important are bacterial tracheitis, diphtheria, retropharyngeal abscess, peritonsillar abscess, measles, and Epstein-Barr viral infection. Other causes to be considered are thermal burns, foreign body aspiration, laryngeal fractures, angioneurotic edema, vocal cord paralysis, and uvulitis.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Mandal A, Kabra SK, Lodha R. Upper airway obstruction in children. *Indian J Pediatr*. 2015;82(8):737–744.

Wald EL. Croup: common syndromes and therapy. *Pediatr Ann*. 2010;39:15–21.

A.6. What is bacterial tracheitis?

Bacterial tracheitis is a severe and potentially fatal disease of an infectious nature occurring as a consequence of infection with *Staphylococcus aureus*, various streptococcal species, and *H. influenzae*. It occurs in colder weather in young children as a secondary complication of viral laryngotracheitis. Although

presenting with the same symptoms as epiglottitis, it tends not to evolve as rapidly and generally does not have odynophagia and drooling, two characteristic signs of epiglottitis. Most of these children require intubation for thick and difficult-to-clear secretions, and during endoscopy, subglottic edema with mucosal ulceration is seen.

Mandal A, Kabra SK, Lodha R. Upper airway obstruction in children. *Indian J Pediatr*. 2015;82(8):737–744.

Wald EL. Croup: common syndromes and therapy. *Pediatr Ann*. 2010;39:15–21.

A.7. What congenital problems can mimic features of croup?

A host of anatomic problems can share similar signs and symptoms with the infectious agents causing airway compromise. These are distinguished from croup by the absence of fever and the chronicity of the illness. Vocal cord paralysis, vascular anomalies, laryngeal webs, laryngomalacia, subglottic masses (hemangiomas), and stenosis can all cause airway compromise.

Johnson DW. Croup. *BMJ Clin Evid*. 2014;2014:0321.

Wald EL. Croup: common syndromes and therapy. *Pediatr Ann*. 2010;39:15–21.

A.8. How is the severity of croup assessed?

The following parameters are evaluated in assessing severity of the illness: (1) Work of breathing: Is there tachypnea and/or retractions? (2) Chest wall motion: Is the tidal volume adequate with inspiration? (3) Overall appearance: Is the child cyanotic, obtunded, or comfortable? (4) Vocal quality: Is there stridor, diminished voice, or cry? Severe croup unresponsive to the medical therapy may require tracheal intubation. Once the diagnosis of croup has been established, the child is given a

croup score, which helps determine therapy (**Table 41.1**).

TABLE 41.1 The Westley Croup Score

	0	1	2	3	4	5
Cyanosis	None	—	—	—	With agitation	At rest
Level of consciousness	Normal, including sleep	—	—	—	—	Disoriented
Stridor	None	With agitation	At rest	—	—	—
Air entry	Normal	Decreased	Markedly decreased	—	—	—
Retractions	None	Mild	Moderate	Severe	—	—

Mild croup has a score <2, moderate is between 3 and 7, and severe has a score >8.

A.9. What is the medical management of croup? Does this have implications for the anesthesiologist?

Most cases of croup resolve with minimal intervention and less than 10% of patients require hospitalization. Mild croup is treated with inspired gas humidification, hydration, and oxygen to improve the attendant hypoxemia. Steroids and racemic epinephrine are the prime modalities of therapy.

If the patient has moderate retractions and appears dyspneic, 0.5 mL of a 2.25% racemic epinephrine solution in 2.5 mL of normal saline can be administered via nebulizer every 1 to 2 hours. Airway resistance can be high with the reactive transudation and intraluminal narrowing. By vasoconstricting the arterioles of the mucosal vasculature, racemic epinephrine relieves edema. Racemic epinephrine is a 1:1 mixture of the levo (L) and dextro (D) isomers to limit cardiac stimulation because only the L form is an active component. Patients often improve

markedly within 30 minutes, but edema may recur due to epinephrine's brief duration of action. Racemic epinephrine should be avoided in children with glaucoma and ventricular outflow obstruction.

Dexamethasone and budesonide when given early in viral croup can be beneficial in reducing inflammation and alleviating symptoms. This takes time to work, however, requiring hours for effective onset. The pediatric dose of dexamethasone is 0.5 to 1 mg per kg orally or intramuscularly. Clinical evaluation of topical steroids such as budesonide has shown effective improvement, especially with laryngeal edema. Nebulized budesonide has been shown to be as effective as dexamethasone in treatment. The role of heliox (helium–oxygen mixture) has yet to be defined but may be helpful in severe croup.

A.10. What is epiglottitis? What are its common causes? What is the incidence?

Epiglottitis is an inflammation of the epiglottis usually secondary to an infectious process. It can involve other supraglottic structures such as the arytenoid, false cords, and posterior tongue leading to obstruction of the airway. Progression of swelling can rapidly lead to complete airway occlusion and death. **Table 41.2** contrasts epiglottitis with

croup. Epiglottitis is most often bacterial in origin. The causative agent used to be *H. influenzae* type B. The *H. influenzae* type B vaccine has resulted in a remarkable decline in incidence, although epiglottis may still occur in vaccinated individuals. *Streptococcus pneumoniae* also has been infrequently associated with epiglottitis, and recently, group A *β*-hemolytic streptococci cases have been on the increase. Burn injury, neoplastic infiltration, caustic ingestion, lymphoproliferative disease, and angioneurotic edema are other causes. The incidence has declined to 1.8 per 10,000 admissions at The Children's Hospital of Philadelphia after the *H. influenzae* type B vaccine. In one study, five cases of epiglottitis occurred among children who had been immunized.

TABLE 41.2 Characteristics of Croup and Epiglottitis

	Croup	Epiglottitis
Etiology	Parainfluenza virus	*Haemophilus influenzae*
Age	4 months to 2 years	2–5 years
Onset	Subacute exacerbation of preexistent URI	Acute
Temperature	Low-grade fever	High fever
Course	Usually mild, stridor may worsen at night	Rapid progress of symptoms
Symptoms	Barky cough, stridor	Dysphagia, sore throat Dysphonia, respiratory distress

URI, upper respiratory infection.

A recent retrospective review reaffirms that epiglottitis remains a significant problem in the United States, with nearly 4,000 admissions in 2006. The demographics of the disease have shifted away from that of predominantly pediatric nature to one of adulthood. Surprisingly, the mean age in the study period from 1998 to 2006 was 45 years old, and the mortality was 36%.

A.11. What are the clinical manifestations of epiglottitis?

This illness presents acutely in the otherwise healthy child between 2 and 5 years of age with a fever as high as 40°C. Within a few hours, the epiglottic inflammation progresses, and the child becomes dyspneic. The child sits forward to use the accessory muscles of respiration and complains of a fullness and pain in the throat. Speech sounds are muffled, known as a "hot potato voice." Salivation often is characteristic and swallowing is difficult. The child appears anxious and concentrates only on breathing. The barking cough of croup usually is absent. The older child will assume a tripod posture with the neck extended to maximize air entry. As the child fatigues, cyanosis leading to complete asphyxia may ensue without intervention. Inspiratory effort is maximal with severe airway compromise, and thoracoabdominal asynchrony, otherwise known as paradoxical breathing, may be observed in the supine position; the abdomen protrudes and the chest wall retracts due to upper airway obstruction. Negative pressure pulmonary edema can occur. Chest auscultation may reveal decreased breath sounds.

A.12. How is the diagnosis of epiglottitis made?

Acute epiglottitis is a dire emergency, and any child whose clinical presentation warrants the diagnosis of epiglottitis must be evaluated promptly in a hospital.

Although epiglottitis and croup have similar features, the presence of drooling and absence of coughing are sensitive and specific signs of epiglottitis, whereas the absence of drooling and the presence of coughing are sensitive and specific signs of croup.

Pharyngoscopy to visualize an inflamed epiglottis should not be attempted in an office setting because this can stimulate upper airway reflexes and lead to increasing dyspnea. All medical centers should have in place a management protocol that standardizes the approach to this rapidly progressive and fatal disease and that involves a team of physicians and nurses from the specialties of pediatrics, otolaryngology, and anesthesiology. A logical approach is as follows:

- The child is kept calm with a parent in attendance at all times. Supplementary oxygen, maintenance of a sitting position, and reassurance are essential.
- If the patient clinically conforms to a classical presentation of epiglottitis, the operating room is alerted and the child is taken there immediately for intubation.
- With other diagnostic considerations, such as a foreign body in the upper airway, retropharyngeal abscess, congenital anomalies, and croup, the child may be escorted to radiology. The time taken for the x-ray examination obviously should be avoided in the critically ill child. A physician skilled in airway management should accompany the child with all necessary resuscitation equipment available.
- The classic thumb sign on a lateral x-ray film is an aptly named shape seen with epiglottic enlargement. However, the absence of this sign does not eliminate the diagnosis of epiglottitis. Croup is distinguished by the steeple sign representing a uniform narrowing of the subglottic airway by inflammation. Recently, magnetic resonance imaging has demonstrated the standard measurements for the

hypopharyngeal space in various age groups, and it has correlated this measurement with the change produced by epiglottic inflammation. This may be a useful tool in the future to assess the severity of airway involvement.

- Laboratory evidence is nonspecific, although a high white count with bands and polymorphonuclear leukocytes is more suggestive of epiglottitis than of croup.
- Fiberoptic pharyngoscopy can be most effective if performed gently by a skilled examiner; it immediately confirms or eliminates the diagnosis. Do not perform a laryngoscopy if anxiety is increased by the procedure and hence exacerbates airway obstruction.

A.13. What is postextubation croup? How is it managed?

Anesthesiologists are often in the position of treating patients with postextubation airway edema, which resembles croup in its symptomatology.

Pediatric patients undergoing general endotracheal anesthesia may mimic many of the physical signs of the croup syndrome following extubation. The tracheal and subglottic mucosa have become irritated by the plastic tube, which initiates an inflammatory response, causing airway luminal narrowing. Because airway resistance is inversely proportional to the fourth power of the tracheal radius (with turbulent flow, this increases to the fifth power), the pediatric airway is especially compromised by edema. Halving the lumen will increase laminar airflow resistance 16 times.

Postextubation croup may manifest more frequently in a patient who has received large quantities of fluid or transfusions; maintained unusual or strained lateral head positioning; has a history of smoke inhalation, restrictive congenital anomalies such as a tracheoesophageal fistula, or acquired subglottic stenosis secondary to prolonged intubation as a neonate; has a coexistent upper respiratory infection, especially bronchitis; or has a cuffed or uncuffed endotracheal tube with a high (>25 cm H_2O) leak pressure. The air leak test, which gauges the pressure needed to generate an audible leak in the presence of an endotracheal tube, may be predictive of postextubation stridor in children over 7 years of age. Ensuring an adequate air leak may decrease the risk of postextubation croup.

Management involves reducing airway constriction by administering nebulized racemic epinephrine, steroids, and humidification of inspired gases. On occasion, reintubating with a soft endotracheal tube one-half to one size smaller than previously used is necessary until the inflammation subsides. Note that topical lidocaine ointment can have vasodilatory actions and should not be used in patients with postextubation croup.

A.14. What are the nonacute causes of partial airway

obstruction in children?

Several congenital anomalies are associated with respiratory difficulties. These can be subdivided into intrinsic and extrinsic pathologies as follows.

Extrinsic Pathologies

- Cystic hygroma—a proliferation or expansion of lymphatic channels, usually in the cervical region, that can compress the airway and lead to enlargement of the tongue
- Vascular anomalies—abnormalities of the aortic arch usually caused by aberrant vessels lead to compression of the airway. This is often position-dependent and may be responsible for coughing and wheezing when the patient is supine.
- Neoplastic compression of the trachea by lymphoma, hemangioma, neurofibromatosis, rhabdomyosarcoma, and other neural tumors in the mediastinum may occur and enlarge or compress airway structures.

Intrinsic Pathologies

- Subglottic stenosis—especially as acquired in previously intubated neonates. This form of airway narrowing occurs below the vocal cords, and it can lead to marked airway obstruction with respiratory infections. The congenital form may not be appreciated until an upper respiratory infection is present, when stridor may occur.
- Vocal cord paralysis—considered the second most common laryngeal anomaly in children; it is associated with the Arnold-Chiari malformation.
- Laryngeal structural anomalies—webs, laryngoceles, and cysts

B. Preoperative Evaluation and Preparation

B.1. Is intubation always required in children with epiglottitis?

Adult patients often can be managed under very vigilant observation provided that there is no impending obstructive danger. However, contemporary practice warrants the establishing of an airway with an endotracheal tube in the vast majority of infants and children. Nasotracheal intubation is most often used for ease of maintaining the child's comfort and safety. Endoscopic evaluation using appropriate fiberoptic airway endoscopy is a major advance in the management of epiglottitis.

Shaw KN, Bachur RG, eds. *Fleisher & Ludwig's Textbook of Pediatric Emergency Medicine*. 7th ed. Philadelphia, PA: Wolters Kluwer; 2016:1421–1422.

B.2. Why is general anesthesia administered to a child with epiglottitis?

General anesthesia facilitates several activities. It gives the examiner a thorough look at the supraglottic area, which would be impossible and dangerous in the awake child. In addition, endotracheal intubation can be accomplished under controlled, relaxed conditions without trauma and laryngospasm. Intubation can be difficult because of the swelling and deformation of the paraepiglottic tissues. Clinicians who have no experience with

this unusual appearance will find it easier to visualize landmarks and secure the airway when the patient is in a surgical plane of anesthesia.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Jenkins IA, Saunders M. Infections of the airway. *Paediatric Anaesth*. 2009;19:118–130.

B.3. How would you prepare the patient for anesthesia?

Expedience is crucial. Once the diagnosis is made and the operating room alerted, the child is transported accompanied by parents and a physician with airway supportive equipment. An intravenous line can be placed more easily under anesthesia without upsetting the child. Anything that causes the child to cry will potentially worsen the obstruction and interfere with breathing. The child should, therefore, be kept calm and reassured. Nasal prong or face tent oxygen should be provided, and portable pulse oximetry should be used.

Airway equipment including a suitable mask and endotracheal tubes up to two sizes smaller than normally expected should be available. Lidocaine, succinylcholine, atropine, and ketamine in appropriate dilutions should be ready. A cricothyrotomy tray should be available as a precaution.

The parent should accompany the child into the operating room. Before induction, the parent is instructed on his or her role in comforting the child, encouraging complicity with mask breathing, and gently holding the child when the inhalation induction commences. When parents can provide their assistance in an emotionally controlled, supportive way, a smooth, safe anesthetic induction via mask can be well facilitated.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Tan GM. New way to mask induce a child. *Paediatric Anesth*. 2002;12:742–743.

C. Intraoperative Management

C.1. How is the airway of the child with epiglottitis best secured?

There is little debate over the safety and efficacy of endotracheal intubation provided that supportive staff is readily available. The endotracheal tube should be sized down 0.5 or 1.0 mm due to the inherent swelling and to protect against postextubation complications. Thick, copious secretions must be cleared frequently to prevent obstruction, and the child must be sedated to tolerate the endotracheal tube and to keep it secure in place.

Charles R, Fadden M, Brook J. Acute epiglottitis. *BMJ*. 2013;347:f5235.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Shaw KN, Bachur RG, eds. *Fleisher & Ludwig's Textbook of Pediatric Emergency Medicine*. 7th ed. Philadelphia, PA: Wolters Kluwer; 2016:1421–1422.

C.2. How would you induce anesthesia?

Verbal assurance is given continually. The child is seated on the parent's lap in the operating room and is oxygenated. Sevoflurane is a good choice of induction agent because it is less pungent and irritant than desflurane and is usually well tolerated. The inhalation drug should be initiated in low concentration and slowly increased as tolerated. As the child gets sleepy, he or she is placed in the supine position. The patient may undergo a brief period of excitement during which care is taken not to be overzealous with ventilation. Spontaneous, unassisted ventilation should continue as an intravenous line is placed. Glycopyrrolate 0.01 mg per kg is given intravenously as an antisialagogue. A crystalloid fluid bolus of 20 to 40 mL per kg

should be administered to treat dehydration. Ventilation may be assisted but not controlled. End-tidal gas is monitored continuously, and the airway is adjusted to provide maximal tidal exchange. Sevoflurane concentration is increased as tolerated to 8%, provided cardiovascular stability is maintained, to achieve an adequate depth of anesthesia. Airway obstruction will decrease ventilation and anesthetic uptake, requiring a longer induction time.

When the patient is in a deep plane of anesthesia (remember that the minimal alveolar concentration of sevoflurane in children is higher than in adults), a careful laryngoscopy is carried out. Paralysis is unnecessary in this deep plane of anesthesia. However, if several attempts are required with the possibility of the patient becoming light and reactive, a small dose of a neuromuscular blocker (e.g., rocuronium 0.4 mg per kg) will serve to maintain stable intubating conditions. This should be given only after it has been shown that the patient can be ventilated with a bag and mask.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Spalding MB, Ala-Kokko TI. The use of inhaled sevoflurane for endotracheal intubation in epiglottitis. *Anesthesiology*. 1998;89:1025–1026.

C.3. Should a child with epiglottitis undergo a rapid sequence induction?

In a child with a full stomach, a mask induction leaves the airway unprotected from aspiration of gastric contents. However, a rapid sequence induction may predispose the patient to severe hypoxia and hypoventilation should the clinician not be able to intubate expediently. Because the supraglottic landmarks are distorted by erythema and edema, recognition of the glottic inlet is obscured. In the spontaneously breathing patient, small air movements and the resultant secretional

bubbling may highlight the glottic opening. In addition, paralysis in no way assures ventilatability.

If the patient must be manually ventilated, it is possible to meet with complete obstruction secondary to invagination of the swollen supraglottic tissues into the laryngeal introitus. In such a case, positive end-expiratory pressure or the jaw-thrust maneuver may fail to correct the airway obstruction.

Should the child be too agitated to cooperate with an inhalational induction, an intramuscular dose of ketamine (2 to 3 mg per kg) will accomplish sedation and preserve ventilation. However, it may accentuate airway reflexes, and the clinician should be wary of laryngospasm. Videolaryngoscopy is the optimal choice whenever available.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Nagler J, Bachur RG. Advanced airway management. *Curr Opin Pediatr*. 2009;21(3):299–305.

Shaw KN, Bachur RG, eds. *Fleisher & Ludwig's Textbook of Pediatric Emergency Medicine*. 7th ed. Philadelphia, PA: Wolters Kluwer; 2016:1421–1422.

C.4. Is awake intubation a practical alternative to secure the patient's airway?

Awake intubation in these children is not generally recommended even though some authors have suggested awake intubation with topical anesthesia in the past. Risks of difficult visualization, agitation, trauma, worsening of epiglottic edema, and compromised ventilation far outweigh the benefits. Unless one has acquired great skill at awake pediatric intubation in the child with a normal airway, this technique should be avoided in these patients. In the adult, the awake GlideScope intubation has been reported with success.

Sinofsky AH, Milo SP, Scher C. The awake Glidescope intubation: an

additional alternative to the difficult intubation. *Middle East J Anesthesiol*. 2010;20:743–746.

C.5. What would you do if the airway cannot be secured with intubation?

Preemptive preparation is critical, and an otorhinolaryngologist should be present. In the event that the airway is lost, percutaneous transtracheal ventilation can be performed. This involves inserting a needle through the cricothyroid membrane as follows. Localize the cricothyroid membrane and topically cleanse the area with antiseptic. Anesthetize the skin with lidocaine (if time permits) and then insert a 16-gauge catheter (attached to needle) in the midline in the inferior portion of the cricothyroid membrane and directed caudally. Attach a 3-mL syringe to the needle barrel applying negative pressure. If the syringe contains a few milliliters of saline, air bubbles will be apparent when the trachea is entered. Following entry, advance the catheter into the trachea. Depending on the hub size, a 3.0-mm or 3.5-mm endotracheal tube adapter can be inserted into the catheter to interface with an Ambu bag. Alternatively, a 6.5- or 7.0-mm endotracheal tube adapter can be inserted into a 3-mL syringe without the plunger to interface with an Ambu bag or anesthesia circuit (**Fig. 41.1**). Jet ventilation can also be applied with high-pressure tubing keeping careful observation of respiratory dynamics and saturation. A tracheotomy in skilled hands also can be performed.

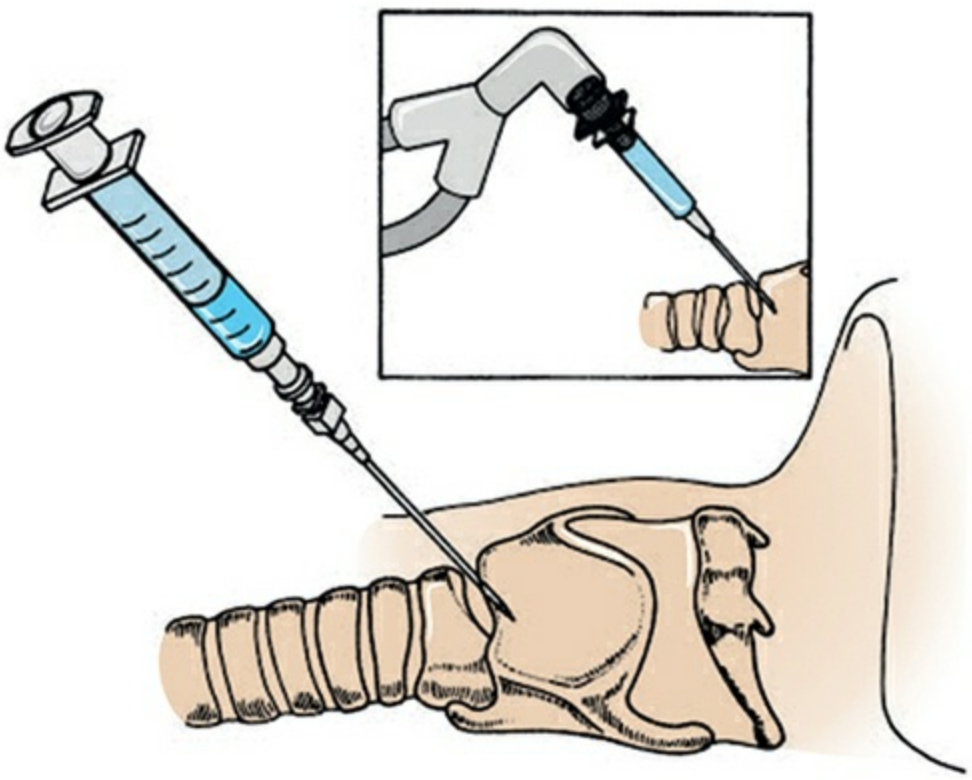

FIGURE 41.1. An emergency cricothyrotomy may be performed by passing a 14-gauge intravenous catheter through the cricothyroid membrane into the trachea. A 3-mL syringe with the plunger removed will accept a 15-mm endotracheal tube adapter that allows attachment of an oxygen-delivery system. Deutsch ES. Tracheotomy: pediatric considerations. *Respir Care*. 2010;55:1082–1090.

C.6. Should this patient have a nasotracheal or orotracheal tube placed?

The patient will better tolerate a nasal endotracheal tube for prolonged intubation. Oropharyngeal toilet will also be easier. However, because the intubation can be difficult with epiglottitis and may predispose the patient to the problems listed in section C.4, the orotracheal route is easier and safer. Once the airway is secured orally, a nasotracheal tube can be inserted with laryngoscopic guidance.

C.7. Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?

Davis et al. describe 7% of these patients as having pulmonary edema after intubation. This phenomenon relates to the transudation into the alveoli during periods of increased transpulmonary pressure. This occurs especially during obstructed inspiration. If the obstruction is complete, it is referred to as the "Müller" maneuver. The high negative pressures are buffered by the decreased venous return during exhalation. However, relief of the airway obstruction facilitates the extravasation of fluid for an increased venous return.

Treatment of this negative pressure pulmonary edema requires positive end-expiratory pressure. Diuretics and fluid restriction are not required because this condition generally is self-correcting. This can be administered by nasal bilevel means, mask continuous pressure, or intubation.

D. Postoperative Management

D.1. How long should this patient remain intubated? What criteria determine extubation time?

Earlier studies have shown a mean intubation duration of 36 hours in 23 patients with a range of 19 to 67 hours. These patients were treated with ampicillin or chloramphenicol, and the epiglottis was visualized before extubation. The current antibiotic regimen is cefazolin 75 to 100 mg/kg/day in three

divided doses or clindamycin 30 to 40 mg/kg/day in three divided doses with the addition of a third-generation cephalosporin such as cefotaxime or ceftriaxone.

Criteria for extubation include an increased air leak around the endotracheal tube as well as decreased erythema and edema. Vernon and Sarnaik, however, feel that instrumentation and examination of the child is unnecessary and extubation at 36 to 48 hours can be accomplished easily in all patients. Hopkins recommended that the flexible fiberoptic laryngoscope be used to visualize the epiglottis and determine extubation time.

Charles R, Fadden M, Brook J. Acute epiglottitis. *BMJ*. 2013;347:f5235.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

Vernon DD, Sarnaik AP. Extubation in epiglottitis. *Anesth Analg*. 1984;63:469–470.

D.2. How would you make this patient comfortable during the course of intubation?

The child must be kept sedated to minimize movement, to prevent inadvertent extubation, and to provide anxiolysis. There are several options. Midazolam (0.075 mg per kg) as a starting dose titrated upward to effect followed by a continuous infusion of 0.04 to 0.1 mg/kg/hr will be effective, often in combination with a fentanyl infusion of 1 to 3 μg/kg/hr. Alternatively, a short infusion of propofol can be given, taking care to monitor for propofol-related infusion syndrome. Dexmedetomidine is also a useful adjunct. A bilateral superior laryngeal nerve block in experienced hands may allow for better endotracheal tube toleration.

Appropriate respiratory care, humidification, suctioning, and

secretion mobilization also should be provided.

Charles R, Fadden M, Brook J. Acute epiglottitis. *BMJ*. 2013;347:f5235.

Coté CJ, Lerman J, Anderson BJ, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2018:754–789.

D.3. What outcome can one expect for the child with acute epiglottitis?

Residual airway problems are unusual in the vast majority of children. Most children who are diagnosed in time and intubated go on to a full recovery without sequelae. Complications are related to securing the airway and include associated pneumonia, respiratory failure, hypoxia, cardiac arrest, and death.

42 Cleft Palate

Aarti Sharma

A 3-month-old male infant was scheduled for repair of a cleft lip and a cleft palate. According to his pediatrician, the infant was born at full term and had no other medical problems.

A. Medical Disease and Differential Diagnosis

1. Describe the anatomic concept of a cleft palate and a cleft lip.
2. What is the cause of a cleft lip or a cleft palate?
3. What is the incidence of a cleft lip and a cleft palate?
4. Discuss the pathophysiology of a cleft lip and palate in the neonate and the older child (e.g., age >5 years).
5. What other conditions are associated with a cleft lip and a cleft palate?
6. What is Pierre Robin syndrome?
7. What is Treacher Collins syndrome?
8. What kind of specialized team care would these patients need?
9. Discuss indications and timing of closure of cleft lip and palate.
10. What is velopharyngeal incompetence, and how can it be diagnosed?
11. What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?

B. Preoperative Evaluation and Preparation

1. What information do you need before closure of a cleft lip and palate?
2. What preoperative orders are needed?

C. Intraoperative Management

1. What monitors will you need for cheiloplasty and palatoplasty?
2. Discuss the induction and the anesthetic management for cleft lip and palate.
3. What positioning is recommended for cleft palate repair surgery?
4. What are the reported complications of this type of surgery and anesthesia?
5. Briefly describe the surgical techniques used to repair cleft defects.
6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?
7. What is an Abbe flap? What are its anesthetic implications?
8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?

10. How would you manage the patient with laryngospasm?

D. Postoperative Management

1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?
2. How do you protect the airway postoperatively?
3. How would you control postoperative pain in patients following a cleft lip and cleft palate repair?

A. Medical Disease and Differential Diagnosis

A.1. Describe the anatomic concept of a cleft palate and a cleft lip.

Congenital clefts of upper lip occur because of failure of fusion of the maxillary, medial, and lateral nasal processes. They vary from a notch in the upper lip to a cleft through the lip and the floor of the nose involving the alveolar ridge, or they may present as a complete cleft of the lip and the palate.

The cleft palate is divided into prepalatal and postpalatal clefts. The incisive foramen marks the boundary between the two. They have different embryologic development. A prepalatal cleft involves the anterior palate, alveolus, lip, nostril floor, and ala nasi. Postpalatal clefts may extend anywhere from soft and hard palate to the incisive foramen. The third type is a submucosal cleft in which a bone defect exists without a mucosal defect. The most common cleft of the palate is a left complete cleft of the prepalatal and palatal structures. The second most common is a midline cleft of the entire soft palate and part of the hard palate without a cleft in the prepalatal area. Various degrees of the cleft palate and lip are shown in **Figure 42.1**.

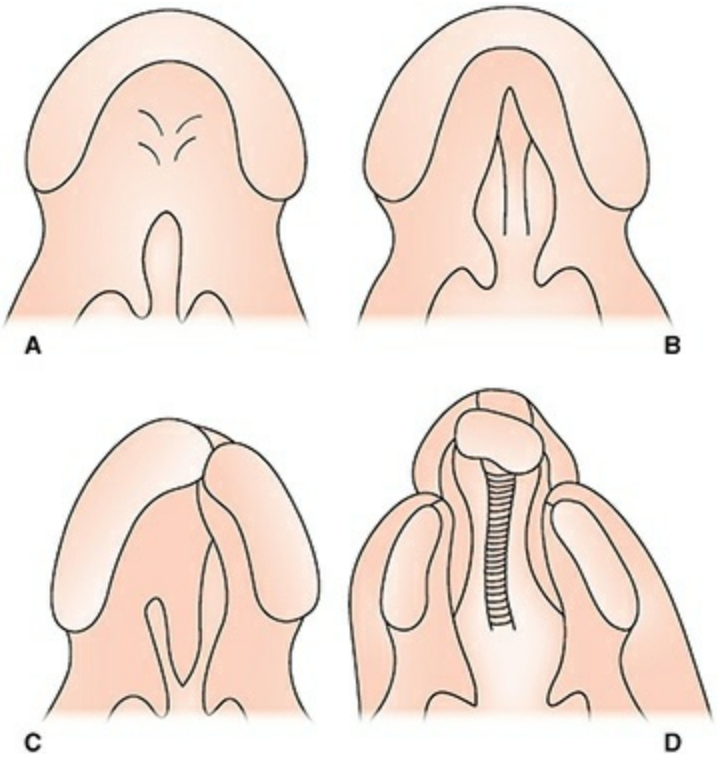

FIGURE 42.1. Various degrees of cleft palate and lip. A. Cleft of the soft palate only. **B.** Cleft of the soft and hard palate as far forward as the incisive foramen. **C.** Complete unilateral alveolar cleft, usually involving the lip. **D.** Complete bilateral alveolar cleft, usually associated with bilateral clefts of the lip. (*Modified from McCarthy JG, ed.* Cleft Lip and Palate and Craniofacial Abnormalities. *Philadelphia, PA: WB Saunders; 1990.* Plastic Surgery; *vol 4. Copyright © 1990 Elsevier. With permission.*)

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. Chichester, United Kingdom: Wiley-Blackwell; 2012:832–844.

A.2. What is the cause of a cleft lip or a cleft palate?

Major components of the face develop between 4 and 7 weeks of fetal life. There are three mesodermal islands, one central and two lateral. Prepalatal clefts are caused by the failure of these mesodermal elements to develop and fuse. Palatal clefts are caused when the palatal ridges fail to migrate medially, contact, and fuse (**Fig. 42.1**).

Chung KC, ed. *Grabb and Smith's Plastic Surgery*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2019:225–237.

A.3. What is the incidence of a cleft lip and a cleft palate?

A cleft lip and cleft palate may occur together or separately. A cleft lip with or without a cleft palate is more common in boys, whereas an isolated cleft palate is more common in girls. The overall prevalence of a cleft lip with or without a cleft palate is 9.92 per 10,000. The prevalence of a cleft lip is 3.28 per 10,000 and that of a cleft lip and palate is 6.64 per 10,000. There were 5,918 cases (76.8%) that were isolated clefts, 1,224 (15.9%) had malformations in other systems, and 562 (7.3%) occurred as part of recognized syndromes. Cases with greater dysmorphologic severity of cleft lip with or without cleft palate were more likely to include malformations of other systems.

The highest incidence of cleft lip and cleft palate occurs among Asians (1.61:1,000 births), whereas the lowest incidence is in African Americans (0.3:1,000 births). The incidence in Whites is intermediate (0.9:1,000 births).

IPDTOC Working Group. Prevalence at birth of cleft lip with or without cleft palate: data from the International Perinatal Database of Typical Oral Clefts (IPDTOC). *Cleft Palate Craniofac J*. 2011;48(1):66–81.

Samanich J. Cleft palate. *Pediatr Rev*. 2009;30(6):230–232.

A.4. Discuss the pathophysiology of a cleft lip and palate in the neonate and the older child (e.g., age >5 years).

A cleft palate is responsible for some major physiologic disorders. The pharynx communicates more extensively with the nasal fossae and the oral cavity. The complex mechanisms of swallowing, breathing, hearing (through the eustachian tube), and speech are, therefore, impaired.

The presence of a cleft lip and palate in a neonate results in feeding difficulties. The neonate cannot suck because the cleft makes the creation of a negative pressure difficult. Breastfeeding is improbable, and bottle-feeding is difficult.

Essentially, all children with a cleft palate have middle ear

disease because abnormal anatomy of the nasopharynx adversely affects eustachian tube function. Chronic middle ear effusions produce varying degrees of conductive hearing loss. Nasal septation between food and air is absent, creating a nonphysiologic mixing chamber in the nasopharynx. Not infrequently, this is associated with chronic rhinorrhea that must be distinguished preoperatively from infection.

Secondary defects of tooth development, growth of the ala nasi, and velopharyngeal function (contact between the soft palate and the posterior pharynx for speech and swallowing) can also occur.

Psychological problems may be considerable as this youngster approaches school age and peer association. The speech of these children is typically nasal with an inability to produce the so-called plosive (*p*/*k*/*d*/*t*) and fricative (*s*/*f*) sounds.

Kosowski TR, Weathers WM, Wolfswinkel EM, et al. Cleft palate. *Semin Plast Surg*. 2012;26(4):164–169.

A.5. What other conditions are associated with a cleft lip and a cleft palate?

Associated anomalies occur 30 times more frequently in the patient with isolated cleft palate than in the noncleft population.

The most common non–syndrome-related abnormalities are umbilical hernias, clubfoot, and limb and ear deformities.

The most common syndromes associated with a cleft lip and a cleft palate are the following:

- Velocardiofacial (Shprintzen) syndrome
- Van der Woude syndrome
- Stickler syndrome
- Pierre Robin syndrome
- Fetal alcohol syndrome
- Goldenhar syndrome (facioauriculovertebral syndrome or hemifacial microsomia)

- Treacher Collins syndrome
- Nager syndrome
- Down syndrome

Calzolari E, Pierini A, Astolfi G, et al. Associated anomalies in multi-malformed infants with cleft lip and palate: an epidemiologic study of nearly 6 million births in 23 EUROCAT registries. *Am J Med Genet A*. 2007;143A:528–537.

A.6. What is Pierre Robin syndrome?

This syndrome is characterized by retrognathia or micrognathia, glossoptosis, and airway obstruction. For facial cleft surgeons, Pierre Robin syndrome is defined by a triad of clinical criteria:

- Retrognathia
- Severe respiratory and/or digestive disorders in early infancy
- Cleft palate

An incomplete cleft of the palate is associated with the syndrome in approximately 50% of these patients. In patients with micrognathia (small jaw) or retrognathia, the chin is posteriorly displaced causing the tongue to fall backward toward the posterior pharyngeal wall. This results in obstruction of the airway on inspiration. Crying or straining by these children can often keep the airway open. However, when the child relaxes or sleeps, airway obstruction occurs. Because of these respiratory problems, feeding may become very difficult. This can lead to a sequence of events: glossoptosis, airway obstruction, crying or straining with increased energy expenditure, and decreased oral intake. This vicious cycle of events if untreated can led to exhaustion, cardiac failure, and ultimately death.

Jones KL, Jones MC, del Campo M, eds. *Smith's Recognizable Patterns of Human Malformation*. 7th ed. Philadelphia, PA: WB Saunders; 2013:314.

A.7. What is Treacher Collins syndrome?

It is a highly complex disease process consisting of the following:

- Hypoplastic cheeks, zygomatic arches, and mandible
- Microtia with possible hearing loss
- High-arched or cleft palate
- Macrostomia (abnormally large mouth)
- Antimongoloid slant to the eyes
- Colobomas (notching of the outer portion of the lower eyelid)
- Increased anterior facial height
- Malocclusion (anterior open bite)
- Small oral cavity and airway with normal-sized tongue
- Pointed nasal prominence

Jones KL, Jones MC, del Campo M, eds. *Smith's Recognizable Patterns of Human Malformation*. 7th ed. Philadelphia, PA: WB Saunders; 2013:334–335.

A.8. What kind of specialized team care would these patients need?

These patients need a pediatrician to maintain their overall health and a surgeon and an anesthesiologist to accomplish the various surgeries. They need a speech therapist to prevent or overcome the speech deficiencies and an orthodontist for early orthodontic intervention to develop and maintain a relatively normal bite and dentition. The care team should also include a geneticist, pediatric dentist, prosthodontist, psychologist, medical social worker, and public health nurse.

Kliegman RM, St. Geme JW III, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:1915–1917.

A.9. Discuss indications and timing of closure of cleft lip and palate.

Functional goals of cleft palate surgery are normal speech, hearing, and maxillofacial growth. It is thought that speech and hearing are improved by early cleft palate repair (before 24 months of age) and that the delayed closure (after 4 years) is associated with less retardation of midfacial growth. There is no

consensus in the exact timing of lip and palate closure. These variations likely reflect the anatomic situation in different patients as well as the personal preferences of the surgeon. An early two-stage palate repair is advocated in management of these patients. The recommended sequence involves closure of the soft palate at 3 to 6 months of age with secondary closure of the residual hard palate at 15 to 18 months of age. This sequence takes advantage of the early physiology and growth that occurs in the soft palate, which is vital in the development of speech. Furthermore, it avoids the potential pitfalls of the growth disturbance related to early periosteal undermining of palatal and vomerine tissue. This repair sequence also provides total palatal closure before speech evolves. If soft palate is repaired at the time of lip repair, an additional anesthetic is avoided.

Thiele OC, Kreppel M, Dunsche A, et al. Current concepts in cleft care: a multicenter analysis. *J Craniomaxillofac Surg*. 2018;46(4):705–708.

A.10. What is velopharyngeal incompetence, and how can it be diagnosed?

Velopharyngeal incompetence is the inability of the soft palate to fulfill its role in closing the nasopharynx, which seriously affects phonation.

To produce plosive sounds, *p*/*k*/*t*/*d*, or the sibilants, *s*/*sh*, the soft palate must touch the posterior pharyngeal wall to close the nose. Failure of closure results in the typical hypernasal speech. The most common cause of this is the cleft palate, but patients with congenitally short palates and no cleft can also have this typical speech pattern. Treatment consists of surgical lengthening of the palate by the pushback operation with or without pharyngeal flap. The diagnosis of velopharyngeal incompetence can be suggested by the child's speech. More objective diagnosis can be obtained by direct vision of the soft palate while the child is pronouncing certain keywords (*kah*,

kah), by the fogging of the hand mirror placed under the nose during speech, and from cinefluorographic x-ray films.

In patients with velopharyngeal incompetence, videofluoroscopy and nasopharyngoscopy can provide information that will help select the appropriate procedure, either pharyngoplasty or posterior pharyngeal flap.

Dudas JR, Deleyiannis FW, Ford MD, et al. Diagnosis and treatment of velopharyngeal insufficiency: clinical utility of speech evaluation and videofluoroscopy. *Ann Plast Surg*. 2006;56(5):511–517.

A.11. What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?

There is often a considerable mass of tonsillar and adenoidal tissue at the age when surgery is usually performed, and, in addition to the latent danger of infection, the flap used in pharyngoplasty creates an obstruction that seriously complicates their subsequent removal. Furthermore, bulky tonsils may hinder retrodisplacement of the soft palate or block the airflow by obstructing the cavum, which has already been reduced in volume by the retrodisplacement and the presence of the flap. It is, therefore, preferable to remove the tonsils and adenoids a few months before pharyngoplasty. The parents may wonder why this decision has been made because they have been repeatedly told that the adenoids should not be removed in the case of cleft palate because this might create or aggravate velar insufficiency. However, once velar inadequacy is confirmed, the parents are in a position to understand that these precautions are no longer justified and that the adenoids can represent a source of problems if not treated with radical measures. During tonsillectomy, it is important to leave the tonsillar pillars absolutely intact because their muscle structure has a vital physiologic role.

Milczuk HA. Effects of oropharyngeal surgery on velopharyngeal

competence. *Curr Opin Otolaryngol Head Neck Surg*. 2012;20(6):522–526.

B. Preoperative Evaluation and Preparation

B.1. What information do you need before closure of a cleft lip and palate?

Preoperative anesthetic evaluation is invaluable and includes the history and physical examination and suitable laboratory data. It gives a picture of the patient's general health. Hemoglobin level, which is often low in very young infants, should be obtained. If Treacher Collins or Pierre Robin syndrome is suspected, an x-ray film of the mandible may be helpful. Examination of the mouth may indicate potential intubation problems. The examination also offers a good opportunity to assess the family environment because parental cooperation is essential for proper postoperative care.

Most surgeons repair a cleft lip when the baby is 6 to 10 weeks old and repair a cleft palate at 6 to 12 months of age. The exact age of repair will depend on the size and health of the child and the surgeon's preference.

Because periosteoplasty and lip adhesions are carried out as soon as the segments are in alignment and the surgery is less extensive, the rule of 10 can be used with moderate license:

- *Weight*—approximately 10 lb
- *Hemoglobin*—10 g per dL or more
- *White blood cell count*—less than 10,000 per μL
- *Age*—can be less than 10 weeks

Of the rule of 10 metrics, only weight below 10 lb (4.5 kg) was identified as an independent predictor of overall complications in cleft patients. Preoperative screening is essential in cleft patients because underlying cardiac abnormalities dramatically increase the risk of perioperative morbidity.

With open cleft palate, however, it is common to have crusting and a low-grade infection of the nasopharynx because of food and fluid regurgitation through the cleft. It is nearly impossible to eliminate this completely. Unless an acute inflammatory process is present, this does not lead to complications.

Chow I, Purnell CA, Hanwright PJ, et al. Evaluating the rule of 10s in cleft lip repair: do data support dogma? *Plast Reconstr Surg*. 2016;138(3):670–679.

Chung KC, ed. *Grabb and Smith's Plastic Surgery*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2019:225–237.

B.2. What preoperative orders are needed?

Preoperative fasting has been a prerequisite for elective surgery. An issue of particular importance to the pediatric patient is the wonderful change that has taken place regarding preoperative fasting. Recent work has shown that prolonged fasting does not reduce the risk of aspiration pneumonitis during anesthesia. This has led to reduction in the fasting times. Reduced fasting increases patient comfort and may decrease the potential for intraoperative hypoglycemia. Fasting guidelines for infants and children are shown in **Table 42.1**.

TABLE 42.1 Minimum Fasting Period (Hours) for Pediatric Patients

	Clear Fluids	Breast Milk	Formula or Cow's Milk	Solids
Children	2	—	6	6
3–12 months	2	4	6	6
<3 months	2	4	4	6

Because multiple operations may be required, the emotional trauma of each hospital experience must be minimized. The most common premedication used at Weill Cornell Medical Center in pediatric patients is oral midazolam. The dose ranges from 0.25 to 0.5 mg per kg orally. Children younger than 8

months rarely require premedication. Children with anticipated difficulty in airway management and those with a propensity toward airway obstruction are better off without premedication.

Special orders include antibiotics if the infant or child has associated congenital heart disease and the typing and crossmatching of a unit of blood for palatal surgery.

Coté CJ. Preparation, premedication and induction of anesthesia in children. In: *ASA Annual Meeting Refresher Course Lectures*. Park Ridge, IL: American Society of Anesthesiologists; 2001:243.

C. Intraoperative Management

C.1. What monitors will you need for cheiloplasty and palatoplasty?

Heart rate, respiration, blood pressure, temperature, and oxygen saturation are monitored at all times. An electrocardiogram provides visual and audible evidence of the electrical activity of the heart. A precordial stethoscope monitors both heart and respiratory sounds. It is particularly important in this patient because once the surgery has begun, the anesthesiologist no longer has easy direct access to the airway. The use of pulse oximetry and an end-tidal carbon dioxide (CO_2) monitor is indispensable. Temperature should be monitored per rectum or axilla. A warming blanket should be used in these patients to avoid hypothermia. Blood loss determination should be made by a calibrated catchment trap in the suction line and by weighing sponges. Blood loss rarely exceeds 10% of circulating blood volume; however, properly crossmatched and screened blood should be available but used only if absolutely necessary.

C.2. Discuss the induction and the anesthetic management for cleft lip and palate.

After suitable monitors are attached, the anesthetic is induced

with oxygen, nitrous oxide, and either sevoflurane or halothane. Because the cardiac depressant effects of sevoflurane are less pronounced than those of halothane, we prefer to use sevoflurane for induction. In addition, the myocardium is more sensitive to exogenous epinephrine when halothane is used. The recommended maximal dose of lidocaine for palate or lip surgery is 5 mg per kg and of epinephrine is 10 μg per kg. This epinephrine dose is for hypocarbic or normocarbic patients.

Once the patient is asleep, an intravenous line is established and appropriate intravenous fluids are started. Intubation can be facilitated with a nondepolarizing muscle relaxant. Muscle relaxants should be withheld if any possibility of difficulty in intubation exists.

Laryngoscopy in patient with a cleft lip is generally straightforward, but the cleft palate has the capability to trap and immobilize a straight blade. Should this occur, the anesthesiologist must first recognize the problem and then consider inserting a gauze pack or a dental roll into the cleft before laryngoscopy.

To achieve a cosmetic repair, symmetry is essential, so the endotracheal tube should exit the mouth in the midline without facial distortion from either the tube or the securing tape. Some surgeons prefer to suture the tube to the lower gum.

An orogastric tube should be passed to empty the stomach of gas and secretions, and it should be removed before preparation of the surgical field.

A pharyngeal pack of moistened ribbon gauze is inserted for cleft lip repairs; as for a cleft palate repair, the surgeon inserts the gag before insertion of the pharyngeal pack. Following the gag and pack insertion, ventilation should be reassessed because tube compression may have occurred. To avoid eye injury, an ocular lubricant is placed in the eyes, and the upper eyelids are splinted shut with tape.

During the surgery, it is necessary to have good communication and cooperation between the surgeon and the anesthesiologist because the surgeon's tools and hands and the anesthesiologist's endotracheal tube and apparatus all occupy the same very small space.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. Chichester, United Kingdom: Wiley-Blackwell; 2012:832–834.

C.3. What positioning is recommended for cleft palate repair surgery?

Correct positioning of the child is important for the plastic surgeon, who sits at the head of the operating table. Head extension must be maximal for cleft palate surgery. The entire body is raised with a thick foam mat or folded blanket, allowing the head to drop back hyperextended into a stockinette head support. Not only does this position provide good exposure, but it also allows blood to flow away from larynx and toward the nasopharynx allowing it to be removed by suction.

C.4. What are the reported complications of this type of surgery and anesthesia?

Anesthetic complications include obstruction of the endotracheal tube, inadvertent extubation during the procedure, and cardiac arrest. Postanesthetic complications include airway obstruction, bleeding with or without aspiration, and pneumonia. Complications not related to anesthetic management are wound healing, diarrhea, and otitis media. The mortality rate has been reported to be less than 0.5%.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. Chichester, United Kingdom: Wiley-Blackwell; 2012:832–834.

C.5. Briefly describe the surgical techniques used to repair cleft defects.

The Furlow procedure is the most common technique for cleft palate closure. It involves opposing Z-plasties of the mucosa and the musculature of the soft palate. The goal is to separate the nonfunctioning attachments from the posterior border of the hard palate and to displace the mucosa and the musculature posteriorly.

Other basic surgical techniques include the von Langenbeck technique, Schweckendiek technique, two-flap technique, and three-flap/V-Y technique.

Although most of the repairs do not involve repairing the muscular sling, doing so allows better palatal and eustachian tube function.

A surgical robot may offer enhanced precision, visualization, and access and the potential to improve outcomes in cleft palate surgery in future.

Sadove AM, van Aalst JA, Culp JA. Cleft palate repair: art and issues. *Clin Plast Surg*. 2004;31(2):231–241.

C.6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?

The presence of this flap prohibits nasoendotracheal intubation and makes many nasal techniques difficult (e.g., insertion of nasogastric tube). The degree of obstruction is related to the width of the flap. Traumatic rupture of this flap secondary to attempted nasotracheal intubation could produce bleeding, aspiration, and laryngospasm.

Traumatic rupture of soft palate can occur from placement of laryngeal mask airway.

Knowledge of prior surgery is essential to good anesthetic management. Following the pushback and pharyngeal flap operation (pharyngoplasty), significant airway obstruction has been noted in the early postoperative period. Sleeping pulse

oximetry has demonstrated obstruction and desaturation in the first 48 to 72 hours.

Dearlove O, Perkins RJ, Briggs G. Anaesthesia after cleft palate repair. *Anaesthesia*. 2004;59(10):1032.

Somerville NS, Fenlon S, Boorman J, et al. Disruption of cleft palate repair following the use of the laryngeal mask airway. *Anaesthesia*. 2004;59(4):401–403.

C.7. What is an Abbe flap? What are its anesthetic implications?

An Abbe flap is a full-thickness pedicle flap taken from the lower lip and swung on its own artery to a position in the upper lip to replace a tissue deficit resulting from any cause, such as surgical excision of malignancy or loss of tissue in a bilateral cleft lip. The lips must remain closed until the flap "takes," and then it can be detached from its blood supply. Usually, this operation is performed in children of an older age under local anesthesia, but it occasionally requires general anesthesia if the patient is young. All the problems of a closed mouth, such as the possibility of vomiting and aspiration, are encountered in addition to those associated with preservation of the flap.

Koshy JC, Ellsworth WA, Sharabi SE, et al. Bilateral cleft lip revisions: the Abbe flap. *Plast Reconstr Surg*. 2010;126(1):221–227.

C.8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?

The establishment, maintenance, and protection of the airway are the crucial problems of anesthesia for palate surgery. Failure to establish, maintain, and protect the airway results in tachypnea, CO_2 retention, hypoxemia, increased bleeding, hypovolemia, arrhythmia, cardiac arrest, and death. The major cause of cardiac arrest in infants and children is hypoxia.

Positioning of the patient is usually supine with table rotated 90 to 180 degrees with a preformed oral RAE (Ring-Adair-Elwyn) or reinforced endotracheal tube extending down the midline of the jaw taped to the chin. The mouth gag that is used for surgical exposure may be released intermittently to allow reperfusion of tongue. However, each manipulation may affect the endotracheal tube. Blood that collects in the oropharynx should be carefully suctioned at the end of the procedure without disrupting the suture line. Residual blood and secretions in the oropharyngeal cavity may irritate the larynx and cause laryngospasm.

Jaffe RA, Schmiesing CA, Golianu B, eds. *Anesthesiologist's Manual of Surgical Procedures*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2014:1460–1462.

C.9. What is laryngospasm? How would you make a diagnosis of laryngospasm?

This is defined as glottic closure resulting from a reflex constriction of the laryngeal muscles. It is much more common in pediatric than adult anesthesia. The incidence is twice that of adults in older children and three times that of adults in younger children. Airway complications are further increased in children with upper respiratory tract infections. In the pediatric patient, the oxygen consumption is greater, so the consequences of laryngospasm in children are more serious. The oxygen consumption is highest in the youngest patients.

Laryngospasm seems to occur during anesthesia for two reasons: first, a lack of inhibition of glottic reflexes because of central nervous system depression, and second, an increased number of stimuli−such as manipulation of the airway, secretions or blood irritating the cords, and stimulation of visceral nerve endings at an inadequate depth of anesthesia.

Bingham R, Lloyd-Thomas A, Sury M, eds. *Hatch & Sumner's Textbook of*

Paediatric Anaesthesia. 3rd ed. London: Hodder Arnold; 2008:288–289.

C.10. How would you manage the patient with laryngospasm?

Laryngospasm may be partial or complete. Partial spasm will be diagnosed by a characteristic stridorous noise and a mismatch between the patient's respiratory effort and the disappointingly small movements of the reservoir bag. Methods of overcoming laryngospasm include applying positive pressure to the airway, deepening anesthesia, and administering muscle relaxants or a bolus of propofol. Recently, it was found that a bolus of propofol works extremely quickly, without the side effects of succinylcholine. The exact mechanism of action of propofol is not clear, but it could be due to increasing the depth of anesthesia or direct effect on the glottis. When there is complete laryngospasm, there will be silence with regard to air movement. The application of positive pressure may not be helpful in these circumstances and indeed may make the situation worse by forcing the false cords against the tightly closed true cords. It is much better to relax the cords before the hypoxia is severe. Succinylcholine can be given intramuscular or intravenous.

Bingham R, Lloyd-Thomas A, Sury M, eds. *Hatch & Sumner's Textbook of Paediatric Anaesthesia*. 3rd ed. London: Hodder Arnold; 2008:288–289.

D. Postoperative Management

D.1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?

Complications include airway obstruction, bleeding, neurosensory disturbance, and hypothermia. Airway obstruction is the result of closure of the cleft structures plus some edema secondary to trauma. In the case of a pushback procedure with or without a pharyngeal flap, the obstruction is due to the new

posterior position of the palate and the pharyngeal flap. Combination of a closed palate, a small mandible pushing the tongue into a small pharynx, edema, blood, and the residual effects of anesthesia make postextubation airway obstruction more likely. There could also be swelling of the tongue due to mouth gag placement during surgery. The anesthesiologist must be aware of the potential problems such as subglottic edema, flap edema, increased oral secretions, posterior displacement of tongue, mucosal swelling of hypopharynx, and an overlooked throat pack.

Blood loss is not an anesthetic complication, but its replacement is an anesthesiologist's responsibility, as is prevention of aspiration.

Patients may experience paresthesia in the cheek after surgery, very rarely the sensory disturbance may be permanent.

Hypothermia delays emergence and produces metabolic acidosis and respiratory and myocardial depression. The most important problem for the anesthesiologist is maintenance of airway.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:817–843.

Neligan PC, Rodriguez ED, Losee JE, et al, eds. Cleft and craniofacial orthognathic surgery. In: *Craniofacial, Head and Neck Surgery and Pediatric Plastic Surgery*. 4th ed. London: Elsevier; 2018:660–677. *Plastic Surgery*; vol 3.

D.2. How do you protect the airway postoperatively?

Following palatoplasty, the pharynx and nasopharynx are suctioned before extubation. Some anesthesiologists advocate that this be done with the aid of a laryngoscope to ensure removal of any mucus, blood, or clots. If suctioning is done before removing the Dingman gag, the laryngoscope may not be necessary. The infant should be as awake as possible. A long traction suture is placed through the tongue and tied loosely.

Traction on the suture stimulates respiration and clears the airway. Neither an oral nor a nasal airway should be inserted unless absolutely necessary; either one could disrupt the sutures and undo all the surgical work. The traction suture is removed when the infant leaves the recovery room.

Following palate surgery, the infant is placed in prone or lateral position with the head dependent, turned to the side, and hyperextended. This position can be achieved with a jack placed under the foot of the crib or by placing a bulky bath blanket under the hips of the infant. Any blood or mucus will accumulate in the dependent cheek or roll out of the mouth.

Following cleft lip surgery, a Logan bow is frequently used to take the tension off the newly sutured lip. The infant can still be placed in the lateral position. Elbow restraints are essential, and they are placed on the infant or the child before leaving the operating room. A high-humidity atmosphere is recommended postoperatively to reduce the incidence of tracheitis, but others have failed to show any correlation between the use of humidity and the incidence of tracheitis.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:817–843.

D.3. How would you control postoperative pain in patients following a cleft lip and cleft palate repair?

In patients with cleft lip or cleft palate repair, the continuum of pain management continues through to the recovery room, the pediatric intensive care unit, or to an inpatient bed. No child should be discharged from recovery room with uncontrolled pain. Cleft palate repair is associated with the risk of postoperative airway obstruction, which may be increased with administration of opioids. Nerve blocks may be used to improve pain relief, to decrease perioperative consumption of opioids, and to favor early feeding resumption after repair.

Infraorbital nerve block can be used for pain control after cleft lip repair. Nasopalatine and palatine nerve block will provide palatal hard and soft tissue anesthesia. Recently, bilateral maxillary nerve blocks using a suprazygomatic approach have been used for effective pain relief.

Opioid analgesics that can be used postoperatively are shown in **Table 42.2**.

TABLE 42.2 Opioid Analgesics for Pediatric Patients

Drugs	Dosage	Form
Fentanyl	1 μg/kg	IV
Morphine	0.05–0.1 mg/kg	IV
Meperidine	1 mg/kg	IV
Oxycodone	0.15 mg/kg	PO: 5-mg tablets; syrup 5 mg/mL

IV, intravenous; PO, by mouth.

Nonopioid analgesics that can be used postoperatively are shown in **Table 42.3**.

TABLE 42.3 Nonopioid Analgesics for Pediatric Patients

Drug	Dosage	Forms Available
Acetaminophen (Tylenol)	10–15 mg/kg PO maximum 2,600 mg/day	Tablets: 80 mg Syrup: 325 mg/5 mL Suppositories: 120 mg, 325 mg, 650 mg
Ibuprofen (Motrin)	10–20 mg/kg PO q6h	Tablets: 300 mg, 400 mg Syrup: 100 mg/5 mL
Ketorolac (Toradol)	0.5 mg/kg IV to load (maximum dose 30 mg) 0.5 mg/kg q8h intramuscularly or intravenously (limit use to 48 hr)	Parenteral form used intramuscularly/intravenously

IV, intravenous; PO, by mouth.

43 Congenital Heart Disease with a Cervical Mass in Infancy

Miles Dinner and Elizabeth Q. Starker

A 1-week-old male infant was diagnosed shortly after birth with an interrupted aortic arch (IAA). The workup revealed the child to have a 22q11 deletion syndrome (formerly known as *DiGeorge syndrome*). An enlarging cervical mass was noted, and the child was brought to the operating room for exploration.

A. Medical Disease and Differential Diagnosis

1. What is 22q11 deletion syndrome?
2. What are the associated cardiovascular defects in 22q11 deletion syndrome?
3. What are the metabolic and endocrine abnormalities in patients with 22q11 deletion syndrome and the attendant manifestations?
4. What are the immunologic findings in 22q11 deletion syndrome?
5. What is the differential diagnosis of cervical masses in infancy?
6. What is a cystic hygroma? What are the complications? What

is the treatment?

7. What is the IAA anomaly?
8. What is the pathophysiology of the IAA syndrome?
9. How is ductal patency maintained?
10. What are the side effects of prostaglandin infusion?
11. What is the hyperoxia test?

B. Preoperative Evaluation and Preparation

1. What preoperative studies should be obtained to evaluate the neck mass?
2. How would you categorize the difficult airway in children?
3. What features of the difficult airway can be noted on physical examination?
4. How would you preoperatively optimize the ability to secure the airway in the operating room?
5. What laboratory studies are necessary before surgery?
6. What are the causes of heart failure (HF) in the infant? How would you assess this infant in your preoperative evaluation for signs of HF?
7. How would you optimize the preoperative treatment of HF?
8. How would you premedicate this infant?
9. When is premedication useful in infants and children?
10. Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to ensure that the baby remains immobile for 20 minutes to perform the scan adequately. How would you accomplish this?

C. Intraoperative Management

1. What anesthesia equipment, circuit, and monitors would you use?
2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this baby.
3. How would you monitor blood loss in this patient?
4. What anesthetic technique should be used in a patient who

may experience severe loss of blood intraoperatively?

5. How would you induce and maintain anesthesia in this neonate?
6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?

D. Postoperative Management

1. How would you manage this patient postoperatively?

A. Medical Disease and Differential Diagnosis

A.1. What is 22q11 deletion syndrome?

The 22q11 deletion syndrome is one of the most common multiple anomaly syndromes in humans and has historically been referred to as velocardiofacial syndrome, DiGeorge sequence, conotruncal anomalies face syndrome, CATCH 22, and Sedlackova syndrome—different names describing the same disorder. This syndrome has an expansive phenotype with more than 180 clinical features that can involve every organ and system. The syndrome is caused by a microdeletion of chromosome 22 at the q11.2 band. The syndrome has a prevalence of approximately 1 in 4,000 in the United States. The majority of patients have a constellation of abnormalities resulting from an embryogenic disruption in the formation of the third and fourth aortic arches. The common clinical features are hypocalcemia, immunodeficiency, dysmorphic facial features, palatal and velopharyngeal dysfunction, renal anomalies, and congenital heart disease (CHD). The DiGeorge variant is characterized by thymic and parathyroid aplasia and/or hypoplasia, cardiovascular defects, and dysmorphic facies. Depending on the extent of the thymic hypoplasia, clinical manifestations can range from frequent upper respiratory tract

infections to severe immunodeficiency that can only be corrected with T-cell–replete hematopoietic stem cell transplantation (HSCT) or thymus transplantation.

Zucker EJ. Syndromes with aortic involvement: pictorial review. *Cardiovasc Diagn Ther*. 2018;8(suppl 1):S71–S81.

A.2. What are the associated cardiovascular defects in 22q11 deletion syndrome?

Congenital heart defects are found in 80% of patients with this syndrome. Most of these patients have conotruncal defects with additional anomalies of the aortic arch, pulmonary arteries, infundibular septum, and semilunar valves. The most common abnormalities include tetralogy of Fallot, pulmonary atresia with ventricular septal defect (VSD), truncus arteriosus, IAA, isolated anomalies of the aortic arch, and VSD. These defects arise during the crucial developmental stages of the truncoconal parts of the heart from the pharyngeal pouch derivatives. Echocardiography, computed tomography (CT), and cardiac MRIs are important in defining the cardiac and associated anatomy in detail. These modalities can provide an invaluable understanding of the anatomy required for presurgical planning.

A.3. What are the metabolic and endocrine abnormalities in patients with 22q11 deletion syndrome and the attendant manifestations?

Because of errors of embryogenesis of the third and fourth pharyngeal arches, parathyroid hypoplasia and/or aplasia is common and results in hypocalcemia. This can be transient in neonates or may be permanent requiring calcium and vitamin D supplementation. Because hypocalcemia can be difficult to detect in the neonate, a high index of suspicion is necessary if a neonate exhibits irritability, jitteriness, twitching, seizure activity, failure to thrive, tachycardia, and hypotension. Stridor (which needs to be differentiated from laryngeal web, which is also prevalent in 22q11 deletion syndrome) and carpopedal spasm may also occur. It is important to remember that in patients with this syndrome, hypocalcemia may be precipitated by the stress of surgery and by increased needs during puberty or pregnancy. Chronic hypocalcemia may result in poor dentition that is prone to caries.

The prevalence of thyroid disease is significantly higher in the pediatric population with 22q11 deletion syndrome than in the general pediatric population. Some sources suggest that screening for thyroid disease should be added into the routine medical management of these children.

Levy-Shraga Y, Gothelf D, Goichberg Z, et al. Growth characteristics and endocrine abnormalities in 22q11.2 deletion syndrome. *Am J Med Genet A*. 2017;173(5):1301–1308.

Sperling MA, ed. *Pediatric Endocrinology*. 4th ed. Philadelphia, PA: Elsevier Saunders; 2014:734–754.

A.4. What are the immunologic findings in 22q11 deletion syndrome?

Patients with this syndrome demonstrate marked variability in their immune system ranging from complete thymic aplasia to reduced T-cell counts and function. The majority of patients (approximately 75%) have a decrease in the total number of T cells, and approximately 1.5% of patients have complete thymic aplasia requiring transplant. Reduced levels of immunoglobulin A (IgA) and immunoglobulin M (IgM) also occur more frequently compared to the general population. Almost all patients have a tendency toward infection, particularly of the respiratory tract. As long as there is a working thymus, patients with 22q11 deletion syndrome can be immunized and generate a good antibody response because humoral immunity is usually intact. However, poor vaccine-specific antibody responses have been described. Neonatal diagnosis historically relied on fluorescence in situ hybridization (FISH) testing and phenotype recognition. However, T-cell receptor excision circles (TRECs) are now being included in the newborn screening panel for severe combined immunodeficiency (SCID). This allows for early identification of 22q11.2 deletion syndrome patients with severe T-cell lymphopenia. Autoimmune conditions are found in up to a third of patients, the most common being juvenile chronic arthritis, autoimmune thrombocytopenia, hemolytic anemia, Raynaud phenomena, and autoimmune thyroid disease.

A.5. What is the differential diagnosis of cervical masses

in infancy?

Neck masses can originate from a congenital anatomic anomaly, infection, or neoplasm. Congenital anomalies consist of branchial and thyroglossal duct cysts and failed thymic descents. In the embryo, branchial cysts arise from the thymic stalk or the pharyngeal pouch and may be present at birth or develop later. They lie beneath the sternocleidomastoid muscle and may bulge out from its anterior border. The branchial cysts can become infected and enlarge to the extent that they compress the airway or upper esophagus. Thyroglossal duct cysts are spherical, midline masses that may extend back to the base of the tongue and may represent all of the neonate's thyroid tissue. In the embryo, the thymus gland arises high in the neck and descends into the anterior mediastinum. If there is any interruption of this caudad movement, the thymus can appear as a soft, compressible mass anywhere along the anterior border of the sternocleidomastoid muscle.

Infectious masses can be due to tuberculosis, Kawasaki disease, Epstein-Barr viral infection, cellulitic facial infections (Ludwig angina), and subacute regional lymphadenitis (catscratch disease).

Neoplastic masses in the cervical region can be teratomas, hemangiomas, neurofibromas, lymphomas, goiters, or cystic hygromas. Teratomas are firm, midline masses arising adjacent to the thyroid isthmus. Hemangiomas may be extensive, consequently compressing vital structures. Neurofibromas may arise individually or as a consequence of neurofibromatosis (von Recklinghausen disease) and can be very large. Goiters are enlarged thyroid glands that may present a hypothyroid, hyperthyroid, or euthyroid state. Ultrasound, CT, and MRI are the imaging modalities used most often to determine the nature of a neonatal neck mass.

Tranvinh E, Yeom KW, Iv M. Imaging neck masses in the neonate and young infant. *Semin Ultrasound CT MR*. 2015;36:120–137.

A.6. What is a cystic hygroma? What are the complications? What is the treatment?

Cystic hygroma is a developmental malformation of the lymphatic system found most often in the posterior triangle of the neck and axilla of children. They are divided into suprahyoid and subhyoid masses. They are compressible masses that are most often found in infants younger than 1 year and can intermittently enlarge. Suprahyoid masses can be extremely difficult to manage because of the associated obstructive symptoms, feeding difficulties, and potential for infection, which further can compromise airway patency. Surgical removal is the treatment of choice in these patients. Complete surgical removal of these masses is often impossible. Repeat debulking is sometimes the only treatment. The mortality of a prenatally diagnosed cystic hygroma remains high, due to other comorbidities and the risk of airway obstruction. Therefore, intubation of the neonate during delivery while maintaining uninterrupted maternal–fetal circulation until the airway is secured (ex utero intrapartum treatment [EXIT] procedure) has been performed to prevent the fatal consequences of immediate postnatal airway obstruction. Other treatment modalities include radiofrequency ablation, CO_2 laser, and percutaneous sclerotherapy. Bleomycin, doxycycline, or derivatives of *Streptococcus pyogenes* have been used as sclerosing agents with favorable results.

A.7. What is the IAA anomaly?

An IAA anomaly is extremely rare and represents approximately 1% of CHD. In IAA, there is complete aorta atresia somewhere along its arch, which is usually associated with a VSD and other complex cardiovascular anomalies. This defect is categorized into three types depending on where the atresia occurs. Left untreated, it is uniformly lethal within 1 week of life, as a result of closure of the ductus arteriosus. In type A (30%), the aorta is interrupted between the left subclavian artery and the aortic isthmus. In type B (the most common, 65% to 70%), the interruption lies between the left common carotid and the left subclavian arteries. With type C (least common type, <1%), the arch is interrupted between the innominate and the left common carotid arteries. One in three patients with IAA has the 22q11.2 deletion, which is usually associated with a more proximal location of the arch interruption (type C or B).

Zucker EJ. Syndromes with aortic involvement: pictorial review. *Cardiovasc Diagn Ther*. 2018;8(suppl 1):S71–S81.

A.8. What is the pathophysiology of the IAA syndrome?

IAA is a neonatal medical emergency. It warrants immediate infusion of prostaglandin E_1 (PGE_1) to maintain ductal patency

as well as stabilization of coexisting HF. Due to the discontinuity between the descending aorta and the arch, blood flow to the descending aorta and its tributaries cannot occur unless the ductus arteriosus stays open. After medical stabilization, surgical correction should occur as soon as possible because of the risk of mortality in untreated IAA. The cause of death is usually a combination of greatly increased left-to-right shunt with increased pulmonary blood flow (which results in biventricular failure and pulmonary edema), ductal stenosis, the sequelae of renal failure, and metabolic acidosis. Pulse oximetry will reveal normal saturation in the right arm, with a decreased saturation in the lower extremities. If there is inadequate perfusion to the lower body because of ductal closure, death quickly ensues from the combination of increased left-to-right shunt with increased pulmonary blood flow via the VSD, biventricular congestive heart failure (CHF), pulmonary edema, renal insufficiency, severe metabolic acidosis, and shock. Symptoms of ductal closure include tachypnea, lethargy, and poor feeding. A transthoracic echocardiography is diagnostic. Cardiac CT, MRI, and catheterization are also utilized in the diagnosis of IAA.

Friedman, K. Preoperative physiology, imaging, and management of interrupted aortic arch. *Semin Cardiothorac Vasc Anesth*. 2018;22(3):265–269.

Jonas RA. Management of interrupted aortic arch. *Semin Thorac Cardiovasc Surg*. 2015;27:177–188.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:2384–2393.

A.9. How is ductal patency maintained?

The ductus arteriosus is kept open by the infusion of PGE_1. Both PGE_1 and prostaglandin E_2 are produced endogenously in the ductus and are metabolized in the lungs. Among the endogenous

prostaglandins, prostaglandin E_2 is the most important. Postnatally, the levels fall dramatically secondary to increased metabolism resulting from the increase in pulmonary blood flow. A prostaglandin infusion will delay the natural closure of the ductus and improve systemic arterial perfusion and oxygenation. Less acidosis will also be seen in arterial blood gases compared to those obtained prior to PGE_1 infusion administration. In the case of an IAA, circulation to the lower body is completely dependent on the patency of the ductus; therefore, PGE_1 must be continuously infused to keep the infant alive. Of note, the PGE_1 infusion has a relatively long half-life; its inadvertent discontinuation will not acutely cause ductal closure, but it should be maintained until surgical repair is complete.

Burbano-Vera N, Zaleski KL, Latham GJ, et al. Perioperative and anesthetic considerations of interrupted aortic arch. *Semin Cardiothorac Vasc Anesth*. 2018;22(3):270–277.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:2384–2393.

A.10. What are the side effects of prostaglandin infusion?

Prostaglandin has a wide array of side effects including fever, seizure-like activity, hypotension, flushing, and edema. Platelet aggregation may also be reduced, and apnea with associated bradycardia can occur. This is most often seen in neonates weighing less than 2 kg at birth and usually appears during the first hour of initiating the drug infusion. Therefore, respiratory status should be monitored throughout treatment with mechanical ventilation as a consideration. It is recommended that a prostaglandin infusion be continuously administrated via a separate intravenous line that can be monitored for any disruptions in flow.

Kliegman RM, St. Geme JW, Blum NJ, et al, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:2407–2420.

A.11. What is the hyperoxia test?

This test is performed to distinguish pulmonary causes from cardiac causes of cyanosis. To perform the test, the patient is first placed on 100% oxygen for 10 minutes. A preductal arterial blood gas is then taken from the patient's right arm. In patients with pulmonary disease, this supplemental oxygen significantly augments systemic oxygenation, which is not the case in cyanotic congenital heart defects. However, in some pulmonary conditions, the oxygen tension may not rise significantly. In these patients, a chest radiograph is invaluable for affirming pulmonary pathology. In some congenital heart lesions with mixing (i.e., truncus arteriosus), the supplemental oxygen decreases the pulmonary vascular resistance, which results in an increase in oxygen tension but is rarely greater than 150 mmHg.

Keane JF, Lock JE, Fyler DC, eds. *Nadas' Pediatric Cardiology*. 2nd ed. Philadelphia, PA: Saunders Elsevier; 2006:141–142.

B. Preoperative Evaluation and Preparation

B.1. What preoperative studies should be obtained to evaluate the neck mass?

Because cervical masses have a variable nature and the potential for airway compression, studies need to be done preoperatively. A flexible neonatal bronchoscopy can define any extrinsic compressive deformations of the airway. Ultrasound and MRI of the head and neck can define the nature of the cystic hygroma and elucidate the degree of airway compression. These cysts are known to invade the anterior mediastinum and can cause extrinsic distortion of the lower airway anywhere from the cricoid ring to the carina. Under sonographic guidance, cystic

fluid can be aspirated to reduce the size of the mass and potentially relieve compressive symptoms. Rarely, there may be invasion into the pericardium and displacement of the lung. If the mass is suprahyoid, radiologic studies will reveal the degree of laryngeal compression and retropharyngeal involvement, which are vital to know prior to intubation.

Vijayasekaran S, Lioy J, Maschhoff K. Airway disorders of the fetus and neonate: an overview. *Semin Fetal Neonatal Med*. 2016;21:220–229.

B.2. How would you categorize the difficult airway in children?

Children with difficult airways can be grouped into four main groups. The first group includes children who have congenital anomalies affecting the airway such as vascular rings, laryngomalacia, micrognathia, or neurofibromatosis. The second group includes patients with an acutely acquired obstruction of the airway such as trauma or foreign body. The third group includes infectious etiologies such as retropharyngeal abscess, laryngotracheobronchitis, or peritonsillar abscess. The last group is composed of children without known congenital or anatomic abnormalities that have unanticipated difficulty with intubation secondary to glottic visualization problems on direct laryngoscopy.

Belanger J, Kossick M. Methods of identifying and managing the difficult airway in the pediatric population. *AANA J*. 2015;83(1):35–41.

Vijayasekaran S, Lioy J, Maschhoff K. Airway disorders of the fetus and neonate: an overview. *Semin Fetal Neonatal Med*. 2016;21:220–229.

B.3. What features of the difficult airway can be noted on physical examination?

Many anatomic abnormalities can be noted simply by

performing a thorough airway exam. Visual inspection of the size of the patient's mouth can alert the anesthesiologist to a constricted oral opening that may be seen in conditions, such as scleroderma, epidermolysis bullosa, or congenital microstomia, which could prevent insertion of the laryngoscope. Micrognathia or maxillary protrusion often accompanies an anterior larynx, making glottic visualization during direct laryngoscopy impossible. This is seen in children with craniofacial syndromes, such as Pierre Robin sequence, Treacher Collins syndrome, Apert syndrome, or Crouzon syndrome. Macroglossia as a consequence of certain metabolic storage diseases (i.e., Hurler syndrome, Hunter syndrome), cystic abnormalities, and/or hamartomatous tumors of the tongue (Goltz syndrome) can also make effective laryngoscopy impossible. Assessing the temporomandibular joint can reveal signs of ankylosis, which can occur in patients with juvenile rheumatoid arthritis and other autoimmune processes that may prevent adequate mouth opening. A narrow, high-arched palate may also suggest a difficult intubation. One should evaluate range of motion of the neck to reveal any decreased neck extension, which may accompany some neuromuscular disorders, arthritic conditions, trauma, Klippel-Feil syndrome, or Goldenhar syndrome. Lastly, one should attempt to palpate the patient's neck to access for tracheal deviation. A preoperative chest radiograph may better serve to note tracheal deviation as well as provide a baseline for the state of the lungs.

Wetmore RF, Muntz HR, McGill TJ. *Pediatric Otolaryngology: Principles and Practical Pathways*. 2nd ed. New York: Thieme Medical; 2012:501–512.

B.4. How would you preoperatively optimize the ability to secure the airway in the operating room?

Because there are inherent risks in inducing anesthesia and securing the airway in this neonate, one would prepare for a fiberoptic-guided intubation. The infant bronchoscope is so small in diameter that it does not allow the presence of a suction port, which can impair visualization if there are excessive secretions. An antisialagogue should be given at least 15 to 20 minutes before beginning the fiberoptic intubation to facilitate recognition of the anatomy. Glycopyrrolate (0.01 mg per kg intravenous and/or intramuscular [IM]) will limit secretions without causing the excessive tachycardia that may occur with atropine. In this neonate with cardiac compromise, any unnecessary stress on the heart should be avoided. In addition to the fiberoptic bronchoscope being available, an appropriate laryngeal mask airway (LMA) and equipment trays for an emergency cricothyrotomy should also be ready. Having a pediatric otolaryngologist present for the induction of anesthesia as well as a rigid infant bronchoscope with video imaging capability should also be strongly considered. The rigid bronchoscope cannot only facilitate visualization of the laryngeal inlet, but it can also provide a route to temporarily ventilate the patient and hold the endotracheal tube as an introducing stylet to facilitate intubation.

Apfelbaum JL, Hagberg CA, Caplan RA, et al. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of Difficult Airway. *Anesthesiology*. 2013;118(2):251–270.

Enterlein G, Byhahn C. Practice guidelines for management of difficult airway: update by the American Society of Anesthesiologists Task Force [in German]. *Anaesthesist*. 2013;62(10):832–835.

B.5. What laboratory studies are necessary before surgery?

Serum calcium should be measured because of the strong association of 22q11 deletion syndrome with hypocalcemia. Serum glucose and sodium levels should be reviewed, as the infant will have been started on total parenteral nutrition due to the inability of oral feeding due to dysphagia caused by the cystic hygroma. Because there is also the potential for severe metabolic acidosis secondary to inadequate perfusion of the lower body as a result of the IAA, serum pH and bicarbonate concentrations must be obtained. The $Paco_2$ level will indicate the baseline adequacy of ventilation in the face of a potentially obstructing mass, and the Pao_2 level will serve as a guide in assessing the neonate's degree of CHF, pulmonary insufficiency, and central shunting. Because the surgery can be extensive, with a significant loss of blood, a baseline complete blood count with hematocrit should be obtained. In addition, the prothrombin time and partial thromboplastin time should be obtained before surgery because of the possibility of baseline immaturity in coagulation factor production and the inherent bleeding potential from the large dissection that will be done.

B.6. What are the causes of heart failure (HF) in the infant? How would you assess this infant in your preoperative evaluation for signs of HF?

The causes of HF can be divided into five major areas:

- Cardiac rhythm disturbances (heart block and supraventricular tachycardia)
- Volume overload (anemia, sepsis, and VSD)
- Systolic ventricular dysfunction (myocarditis, malnutrition, and dilated cardiomyopathy)
- Pressure overload (aortic stenosis and coarctation)
- Diastolic ventricular dysfunction (pericardial tamponade and restrictive cardiomyopathy)

HF occurs either in response to an excessive volume or

pressure load or as a consequence of myocardial muscle impairment. Volume overload is due to factors causing a large increase in cardiac output (e.g., large VSD or ductus arteriosus). In these circumstances, there must be a sufficiently large left-to-right shunt to cause a severe strain on the heart. In the normal newborn, these lesions do not usually produce HF until 1 to 2 months of age because it takes longer than usual for the pulmonary vascular resistance to fall. The elevated pulmonary vascular resistance protects the left ventricle from the stress of overcirculation. This is not true in premature neonates who do not manifest the same degree of pulmonary arteriolar constriction; therefore, they are susceptible to large left-to-right shunts early and show HF more readily.

Regurgitant valvular lesions can also lead to HF. In complex CHD (i.e., truncus arteriosus or tricuspid atresia with transposition), the additional stress of hypoxemia or univentricular overload may herald the early onset of HF. Large arteriovenous malformations may also occur intracranially and cause HF. Excessive pressure loads are seen in obstruction to cardiac output from aortic stenosis, aortic coarctation, and aortic interruption.

In the immediate newborn period, right-sided HF is seen with greater frequency because of severe pulmonary hypertension. Pulmonary hypertension has many causes including intrinsic lung parenchymal insufficiency or pathology (i.e., diaphragmatic hernia, meconium aspiration, or hyaline membrane disease), chronic hypoxemia, hypervolemia, and polycythemia.

Primary myocardial failure is unusual and rare in the newborn. If it occurs, it is likely due to endocardial fibroelastosis and anomalous coronary circulation. Nonetheless, the myocardium in the infant is susceptible to depression from metabolic derangements such as hypoglycemia, hypocalcemia,

hypoxemia, and hypercarbia. Also, severe anemia with the associated decreases in systemic and myocardial oxygen supply forces an increase in myocardial work that can lead to HF.

Infants are different from adults in their manifestations of HF. Signs of cardiac dilation may be absent because of decreased systemic venous return from the elevated intrathoracic pressure as a consequence of coexisting lung disease in premature infants. Although immature, the carotid baroreceptors still initiate an increase in sympathetic outflow in response to reduced perfusion. The increased α-adrenergic stimulation impairs blood flow to the systemic arteriolar beds, resulting in cold, underperfused extremities, and diminished splanchnic perfusion. Fatigue, loss of appetite, and failure to thrive quickly follow. Tachycardia from β-adrenergic receptor stimulation occurs. Generalized sweating results from sympathetic cholinergic fiber stimulation. Extracellular water increases because of decreased renal excretion of sodium due to a decreased glomerular filtration rate; however, peripheral pitting edema is much less common in infants compared to older children and adults. The venous system in infants is extremely distensible, so much so that elevated right atrial pressures may not show jugular venous engorgement. The most prominent manifestation of HF in the infant is tachypnea. Because pulmonary venous pressure is elevated from left ventricular failure, the lung compliance decreases because of the augmented interstitial fluid. Breathing becomes rapid and shallow further increasing the body's oxygen requirement, which leads to a cyclic dependency to maintain both tachycardia and tachypnea. It is common to see subcostal retractions due to the increase in respiratory effort in infants with HF.

Infants have a greater lymphatic drainage capacity compared to adults and can clear interstitial accumulations more readily. Therefore, rales are less often appreciated in infants with HF, as

opposed to adults with HF. The bronchial mucosa may become swollen because of engorgement of the bronchial venous system resulting in narrowing of the airway lumen. This can produce an audible wheeze that is often seen in infantile HF. Lastly, hepatomegaly is a cardinal sign of right ventricular failure in infants.

B.7. How would you optimize the preoperative treatment of HF?

The typical manifestations of CHF in infants (i.e., tachycardia, tachypnea, subcostal retractions, and rhonchi) are also cardinal signs of pulmonary infection in this age group. They can be difficult to distinguish. Often, they coexist and treatment must address both conditions. In this patient, the structural abnormality of the IAA needs surgical correction; however, correction must be deferred until the neck mass is resected. In this infant, the CHF is caused by pressure overload from the IAA, and the hypocalcemia is due to parathyroid hormone insufficiency. Calcium must be normalized by intravenous infusion. If glucose is low, as would be expected in an infant who is unable to feed by mouth, has glycogen depletion from the stress of illness, has an immature liver that is unable to generate sufficient gluconeogenesis, and has an increased utilization from a baseline higher metabolic rate (compared to adults), a glucose source should be continuously supplemented by slow intravenous administration. Myocardial work is compromised by the presence of metabolic acidosis, which occurs as a

consequence of the increased lactic acid production during anaerobic metabolism resulting from lower body hypoperfusion. The pH should be normalized with sodium bicarbonate.

With the guidance of a pediatric cardiologist, myocardial function should be optimized with ace inhibitors, β-blockers, and digoxin in infants with HF. A catecholamine (e.g., dopamine or dobutamine) can be infused to boost contractility. Pulmonary symptoms should be treated with antibiotics and positive pressure ventilation (i.e., high-flow nasal cannula, nasal continuous positive airway pressure [CPAP]) with oxygen titrated to arterial blood gas measurements. Intubation and mechanical ventilation may be necessary in many infants with HF. Diuresis, with furosemide in conjunction with fluid restriction, will promote restoration of pulmonary compliance by decreasing lung water.

Das BB. Current state of pediatric heart failure. *Children (Basel)*. 2018;5(7):88. doi:10.3390/children5070088.

McMillan JA, Feigin RD, DeAngelis C, et al, eds. *Oski's Pediatrics: Principles & Practice*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:357.

B.8. How would you premedicate this infant?

Infants younger than 2 years do not routinely require preoperative anxiolytics or narcotics. An infant with a compromised airway and abnormal circulation cannot tolerate any degree of respiratory depression; therefore, no sedative premedication should be given at all. Because a fiberoptic intubation is planned, glycopyrrolate should be given preoperatively for its antisialagogue activity.

B.9. When is premedication useful in infants and children?

Patients with dynamically responsive cyanotic CHD (i.e., tetralogy of Fallot) benefit from premedication before coming to

the operating room. In these children, the inherent anxiety of transfer to unfamiliar surroundings, change in temperature, and parental separation may trigger infundibular spasm and reduce pulmonary blood flow, thereby leading to a "tet spell." This transient increase in pulmonary vascular resistance dramatically decreases pulmonary blood flow and increases the flow of desaturated blood to the body via VSD. Acute hypoxemia is not an optimal state in which to initiate an anesthetic induction. Therefore, sedation with oral midazolam or nasal dexmedetomidine is useful to allay preoperative anxiety and reduce the risk of provoking a hypoxemic spell. Premedication can make the perioperative experience for a child less frightening, produce variable degrees of amnesia, and decrease the risk of emergence delirium. Pharmacologic premedication is one of many tools a pediatric anesthesiologist has at his or her disposal to ensure a positive perioperative experience for the patients and their family. Studies have shown promising results with nonpharmacologic interventions including handheld video games or low sensory stimulation.

B.10. Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to ensure that the baby remains immobile for 20 minutes to perform the scan adequately. How would you accomplish this?

Because this neonate has an already severely compromised

airway while awake, the safest anesthetic plan to assure immobility and adequate ventilation is to perform a general anesthetic via an endotracheal tube. Any form of sedation without an endotracheal tube already in place puts this patient at risk for complete airway obstruction and should not be used here. If the neonate has demonstrated a postprandial sleep cycle and can take oral fluids, it may be well worth an attempt to perform the MRI scan while the neonate is swaddled in a warm baby blanket sucking on a pacifier filled with dextrose solution ("Sweetie Soother pacifier"). In this manner, the patient remains "motionless" from the inherent feeling of comfort of being able to feed and bundled in a warm blanket.

Salerno S, Granata C, Trapenese M, et al. Is MRI imaging in pediatric age totally safe? A critical reprisal. *Radiol Med*. 2018;123:695–702.

C. Intraoperative Management

C.1. What anesthesia equipment, circuit, and monitors would you use?

This patient is especially susceptible to infection because of the baseline depressed cellular immunity. As with every patient, strict attention must be paid to maintaining a sterile technique during the central line placement and instrumentation of the patient. The anesthesiologist must wear a sterile gown and gloves to protect the neonate. Sterility of the disposable circle system, mask, endotracheal tube, fiberoptic bronchoscope, and laryngoscope should be ensured. Routine monitors for all surgery on infants include pulse oximetry, electrocardiogram, blood pressure, capnograph, spirometer, and temperature probe. Multiple pulse oximeters should be available to offer flexibility in the event of monitor dysfunction. In this neonate, the IAA prevents the ability to obtain saturation data from the lower body

and left arm. End-tidal expired gas concentrations should be recorded for anesthetic gases, nitrogen, and oxygen. Accurate capnography in small infants may be hampered by sidearm gas sampling resulting from the relatively high gas flows relative to the expired gas flow from the infant.

In this procedure, an arterial line should be inserted in the right upper extremity because the IAA will not allow for blood pressure determination on the left side. Because there is potential for significant blood loss, a central line should be placed under ultrasound guidance at the best available site (i.e., internal jugular, subclavian, or femoral). Obtaining central access in such a small patient with distorted anatomy may prove very difficult. If an internal jugular or subclavian central line is placed, a chest radiograph should be obtained after placement and reviewed for correct positioning and to rule out pneumothorax before proceeding with this complicated case. Catheter length must be taken into consideration during placement to avoid inadvertently inserting the central line inside the right atrium or across the tricuspid valve, leading to arrhythmias and misleading right ventricular pressures. The arterial line and central venous pressure (CVP) transducers should be placed at the approximate level of the right atrium and adjusted accordingly as the table height is changed. Cerebral and somatic oximetries are useful in providing early recognition of intraoperative hypoperfusion to the brain and body.

C.2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this

baby.

It is highly unlikely that glottic visualization could be accomplished in this neonate with direct laryngoscopy alone. The following alternative forms of securing the airway can be used when direct laryngoscopy is not expected to provide easy visualization of the glottis.

Infant Video Laryngoscope

The various forms of this device on the market allow for excellent glottic visualization and facilitation of intubation if the patient's mouth opening is large enough to accommodate the blade and may provide a superior visualization compared to conventional direct laryngoscopy in some patients.

Intubation through a Laryngeal Mask Airway

First, securing the airway with an LMA and demonstrating that one can ventilate through it can add an extra margin of safety when performing an anticipated difficult pediatric intubation. The LMA is then used as a conduit for insertion of the fiberoptic-guided endotracheal tube into the glottis.

Retrograde Cricothyroid Wire

This technique is not ideal for this patient for many reasons. First, the size of the patient would make it technically difficult. Second, the large cystic hygroma is distorting the external anatomy landmarks that facilitate this type of intubation; nonetheless, for completeness, this method will be described. The retrograde cricothyroid wire technique is best for oral intubations. A guidewire is inserted through a large-gauge needle that is used to puncture the cricothyroid membrane. The guidewire is threaded cephalad until it visualized and retrieved through the mouth. Then, the guidewire is tied to "Murphy eye" of the endotracheal tube. Then, the other end of the guidewire (that is sticking out through the cricothyroid membrane) is

slowly pulled caudally to guide the endotracheal through the vocal cords. Even after the endotracheal tube is in correct position, the guidewire remains attached externally to the neck in case of unplanned extubation (to facilitate reintubation).

Blind Nasal Intubation

Although very successful in adult patients, the blind nasal intubation technique can be very challenging in infants or small children. Certainly, performing an awake, sedated intubation in this manner mandates giving adequate topical anesthesia to a less than cooperative infant. In addition, the smaller endotracheal tubes used in pediatrics are far more compliant than adult-sized tubes, especially when warmed with nasopharyngeal respiratory gases, which makes it difficult to maintain the anterior curve on the tube to enter the larynx.

Nasal Intubation with Laryngoscope and Magill Forceps

If the larynx cannot be visualized by direct laryngoscopy, an anesthetized, spontaneously breathing nasal intubation with laryngoscopic assistance can be carried out in some patients. In this case, great care is taken to ensure that the patient continues to maintain spontaneous and adequate ventilatory exchange during the inhalational induction. Sevoflurane is used for pediatric inhalational inductions because it is less pungent and more easily tolerated than other agents. The pediatric anesthesiologist should be mindful that total airway obstruction can happen at any point during the inhalation induction due to relaxation of pharyngeal tone and other airway abnormalities. If spontaneous breathing can be maintained, the intubation should be attempted after a surgical plane of anesthesia is achieved. The laryngoscope is then used to visualize the epiglottis. Using Magill forceps, the tip of the endotracheal tube is aligned with the subepiglottic region and slowly advanced. Capnographic

monitoring during this maneuver can help verify the direction of the endotracheal tube tip.

Fiberoptic Intubation

Fiberoptic intubation is most successful when it is carried out as the initial maneuver before the airway is traumatized from previous attempts at intubation. It may be nearly impossible to use after several unsuccessful attempts because the upper airway becomes hypersecretory and may ooze blood. The appropriate fiberoptic technology may not be widely available unless one is practicing at a tertiary pediatric hospital with a wide range of bronchoscopes on hand (including the smallest, "ultrathin" 2.2 mm in diameter scope necessary for this neonate). Due to their small size, pediatric bronchoscopes lack a suction port and need to be lubricated to facilitate the sliding of the endotracheal tube off the scope once it is through the glottis.

In older patients, three specialized fiberoptic methods can be useful in intubating pediatric patients with difficult airways. First, the clinician can pass a guidewire through the suction port of the larger instrument to serve as a stylet for the endotracheal tube. Second, the scope can be used to visualize and guide a nasal endotracheal tube inserted into the opposite nostril. Finally, a 4.5-mm tube can be placed at the laryngeal orifice to be used as a stent for inserting a small guidewire, which can in turn be used to place a smaller endotracheal tube.

Transtracheal jet ventilation can be used when applicable. In this technique, a 16-gauge intravenous catheter is placed through the cricothyroid membrane and jet ventilation with 100% oxygen is provided. A second intravenous catheter is placed through the cricothyroid membrane and a guidewire (0.021-in. diameter J-tip) is introduced with cephalad angulation. Jet ventilation continues as the guidewire is threaded through the nose and connected to the working part of a fiberoptic scope.

The scope is then advanced through the laryngeal inlet, and a tube is threaded over the scope and then the guidewire is removed. Sedation can be provided with a remifentanil drip (0.1 to 0.2 μg/kg/min). Because patient safety is the foremost consideration in any technique for inserting an artificial airway, the anesthesiologist and/or otolaryngologist should be immediately available to perform an emergent cricothyrotomy in case of a life-threatening loss of airway.

Of note, in the pediatric patient with a known difficult airway, a preemptive collaborative approach of securing the airway with a pediatric otolaryngologist can greatly increase the degree of safety and minimize harm done to the patient. When performing an emergency cricothyrotomy, a longitudinal incision is made in the skin and fascia above the cricothyroid membrane, after which the cricothyroid membrane is punctured and entered with a small endotracheal tube. Another technique utilizes an 18-gauge angiocatheter (or larger), which is inserted into the cricothyroid membrane. Intratracheal location is verified by the loss of resistance with an attached syringe and the aspiration of air. The catheter is attached to a 3-mL syringe (without plunger), which is then connected to the Y-piece of the anesthesia circuit by an adapter from a 3.0-mm internal diameter endotracheal tube.

C.3. How would you monitor blood loss in this patient?

In many of these procedures, the blood loss can be significant and easily exceed the patient's calculated blood volume. It is difficult to accurately measure blood loss when it is lost under

the drapes or irrigated away. Meticulous weighing of the sponges and observation of suction canisters are important, but blood loss can be continuous from the time of skin incision and may be seemingly relentless for an inexperienced clinician. Absolute changes in the CVP are a relative guide to the volume in the central compartment, but no one isolated value correlates with a known blood volume. A steady decrease in CVP in association with a downward trend in mean arterial pressures (MAPs) during periods of surgical intervention known to produce significant bleeding should be treated aggressively with crystalloid (20 mL per kg) or colloid (i.e., 5% albumin) replacement first, followed by a vasopressor supplementation as necessary. Ideally, with an arterial line in place and point of care testing, one can trend the hemoglobin and/or hematocrit prior to the initiation of a blood transfusion. Persistent hypotension with a normal hematocrit could be due to hypocalcemia either from parathyroid hormone insufficiency and/or from the citrate (used as an anticoagulant in the blood products), which binds ionized calcium if the patient was recently transfused.

C.4. What anesthetic technique should be used in a patient who may experience severe loss of blood intraoperatively?

Blood loss should be replaced milliliter for milliliter to prevent falling behind in volume. It is wise to choose an anesthetic technique that produces a relatively stable blood pressure throughout the surgery so that any new downward trend in blood pressure can be easily attributable to blood loss and not to pharmacologic action. For instance, if a steady level of desflurane or sevoflurane is given at 1.25 minimal alveolar concentration (MAC) with a resultant MAP 15% lower than awake, further dips in MAP during surgical intervention can be taken as intravascular volume depletion secondary to bleeding

and replaced accordingly. This interpretation would be obscured if there were frequent anesthetic interventions associated with MAP changes, such as intermittent narcotization, relaxant titration, or up and down titration of hypotension-inducing agents. An important clue to the blood volume loss of the patient is the blood pressure at an MAC of anesthesia. If a stable pressure is established at a given MAC of inhalational agent, a lower than expected blood pressure at this MAC is almost always indicative of hypovolemia and therefore calls for fluid or blood replacement. Another anesthetic technique for this procedure on a neonate is to use a high-dose narcotic technique with paralysis, which will lessen the impact of inhalational agents on the MAP. Serial hematocrit determinations drawn throughout the case should guide management. It is most unusual in an otherwise healthy infant to produce hypotension with intravascular overload unless there are other attendant problems.

C.5. How would you induce and maintain anesthesia in this neonate?

After securing the airway and verifying bilateral breath sounds, narcotic titration with fentanyl should be given in repeated doses. Remember, this neonate may be sensitive to any anesthetic agent because of his cardiovascular anomalies; therefore, titrating fentanyl to the patient's arterial blood pressure via the arterial line decreases the chance of inadvertent drops in perfusion. Because the neonate is not going to be extubated, fentanyl can be dosed safely at 50 μg per kg or higher to allow for dense analgesia. Neuromuscular blocking agents such as vecuronium and cisatracurium can be given and redosed at regular intervals to facilitate the surgical dissection. If tolerated, small concentrations of approximately 0.5% to 4% desflurane or sevoflurane 0.25% to 1.5% can be administered to

synergize with the narcotic. The prostaglandin infusion should be maintained throughout the entire surgery.

C.6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?

Double-lumen tubes are not used in the neonatal age group because of the exceedingly small lumen and the technical difficulties of securing both lungs. Instead, a single-lumen endotracheal tube can be advanced into the right or left mainstem bronchus to allow for one-lung ventilation. This may be fraught with consequences in this infant with IAA, but it can still be attempted. Keep in mind that hypoxic pulmonary vasoconstriction may not occur readily in the neonate and excessive shunting may happen. In addition, having an infant on one-lung ventilation may lead to an elevated $PaCO_2$ from the pulmonary insufficiency. During thoracotomies in infants for pulmonary banding or Blalock-Taussig shunts, it is not uncommon to see extremely elevated $PaCO_2$ values from lung retraction, especially of the right side, which has almost 60% of the total lung surface area.

Cerchia E, Ferrero L, Molinaro F, et al. Pediatric thoracoscopy and bronchia blockers: the continued search for the ideal one-lung ventilation. *J Laparoendosc Adv Surg Tech A*. 2016;26(2):153–156.

Engum SA. Minimal access thoracic surgery in the pediatric population. *Semin Pediatr Surg*. 2007;16:14–26.

D. Postoperative Management

D.1. How would you manage this patient postoperatively?

Multiple factors about this case mandate that the neonate remain intubated or have a tracheostomy placed at the end of the case.

This surgery involves an extensive dissection of the patient's neck and upper thorax that will result in a tremendous amount of upper airway and neck edema. Consequently, this would make extubation life-threatening. High-dose narcotics and paralytics have been used, which also hamper safe extubation. The neonate should continue to remain well-narcotized and paralyzed to coordinate effective mechanical ventilation. Artificial ventilation and oxygen supplementation should be titrated to serial arterial blood gases. In addition, the prostaglandin drip must be continued to ensure ductal patency. Generous narcotic supplementation will ensure that the pulmonary vascular resistance stays in a state of relative quiescence. Approximately 24 hours postoperatively, a leak test can be performed to assess residual vocal cord edema. Fiberoptic visualization of the laryngeal inlet can provide useful information about the state of the laryngeal inlet for extubation.

Anatomic airway factors aside, the IAA and associated HF will make extubation of this baby more challenging. Assuming all other factors are under control, the following ventilatory parameters should be met before extubation: normal arterial blood gases with satisfactory oxygenation on 28% oxygen, spontaneous tidal volume greater than 5 mL per kg, and an inspiratory force greater than 12 cm H_2O. One needs to be vigilant for early signs of airway obstruction and be ready to reintubate or perform an emergent tracheostomy if prompt desaturation occurs.

44 Patent Ductus Arteriosus and Prematurity

Albert C. Yeung and Fun-Sun F. Yao

A 2-week-old male infant weighing 900 g is scheduled for ligation of patent ductus arteriosus (PDA). He was born at 27 weeks' gestation as part of a triplet pregnancy complicated by preterm labor. Immediately after delivery, he was intubated because of respiratory distress. He was given indomethacin prophylactically because of his prematurity and presumed PDA. A transthoracic echocardiogram (TTE) confirmed the patency of the ductus arteriosus and demonstrated its closure after one course of indomethacin. His respiratory function was gradually improving with ventilatory support until 2 weeks later when his oxygenation and ventilation suddenly worsened. A murmur was heard over his chest. A repeat TTE demonstrated left-to-right shunting through the ductus arteriosus. Another course of indomethacin was administered, but the ductus remained patent. His blood pressure was 50/20 mmHg and heart rate was 165 beats per minute. The laboratory data were as follows: white blood cell (WBC) count, 17,000 per μL; hemoglobin, 11 g per dL; hematocrit, 34%; urine specific gravity, 1.005; protein, 1+; sugar, 1+; serum calcium, 6.0 mg per dL; blood glucose, 60 mg per dL; arterial blood gases: pH, 7.30; $Paco_2$, 60 mmHg; Pao_2, 49 mmHg on fraction of inspired

oxygen (FIO_2) 50%; inspiratory pressure, 19/6 cm H_2O; and ventilation rate, 40 breaths per minute.

A. Medical Disease and Differential Diagnosis

1. How would you classify prematurity? What are the common problems associated with prematurity?
2. What are the survival rates of preterm infants?
3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.
4. What is bronchopulmonary dysplasia (BPD)? How would you treat it?
5. What are apnea spells? What are the possible causes of apneic spells?
6. Discuss the incidence and pathophysiology of PDA in preterm infants.
7. How would you make a diagnosis of PDA? Describe its treatment.
8. Would you give digitalis to treat congestive heart failure in preterm infants? Why?
9. How does indomethacin close the ductus? What are the adverse effects of indomethacin?
10. When is surgical closure indicated? What are the complications associated with surgical ligation?
11. What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, prevention, and treatment.
12. Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?

2. What are the normal values of arterial blood gases and pH in neonates and infants?
3. Interpret the arterial blood gases: pH, 7.30; $Paco_2$, 60 mmHg; Pao_2, 49 mmHg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?
4. What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm infants?
5. What are the normal values of WBC, red blood cells (RBCs), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?
6. Would you transfuse blood to this patient preoperatively?
7. How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1+; and protein, 1+?
8. Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?
9. How would you premedicate this patient?

C. Intraoperative Management

1. Where should the procedure take place? In the neonatal intensive care unit (NICU) or the operating room?
2. What monitors would you use for this child during surgery?
3. How does the oxygen analyzer work?
4. What is the Doppler effect? How does the Doppler transducer measure blood pressure?
5. What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?
6. How would you maintain the patient's body temperature?
7. How do the anesthetic requirements of the preterm infant differ

from those of the adult?

8. What size endotracheal tube would you have used if the patient had not been intubated?
9. How would you have induced anesthesia if the patient had not been intubated?
10. How would you maintain anesthesia?
11. How would you ventilate the patient? What tidal volume, respiratory rates, and FIO_2 would you set for the infant?
12. Discuss blood and fluid therapy in this preterm infant.
13. During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?

D. Postoperative Management

1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?
2. How can one minimize the risk of transporting the patient to the NICU after surgery?
3. The patient's condition deteriorated postoperatively in the intensive care unit (ICU). Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?

A. Medical Disease and Differential Diagnosis

A.1. How would you classify prematurity? What are the common problems associated with prematurity?

Live born infants delivered before 37 weeks from the first day of the last menstrual period are termed premature by the World Health Organization. Preterm infants can be classified into three groups, as shown in **Table 44.1**. Infants of borderline prematurity usually require no special care, but, because of their susceptibility to RDS, they should be observed closely for 24 to

48 hours in the newborn nursery. Furthermore, those with a poor suck reflex may require gavage feedings. Infants classified as moderately premature require intense neonatal care, and neonatal mortality correlates inversely with gestational age. Neonates of extreme prematurity constitute only 1% of all preterm infants; however, mortality in this group is extremely high, accounting for greater than 70% of all neonatal deaths. Furthermore, morbidity in surviving infants is substantial, often secondary to irreversible neurologic or respiratory insult.

TABLE 44.1 Classification of Prematurity

	Borderline Prematurity	Moderate Prematurity	Extreme Prematurity
Gestational age (weeks)	36–37	31–35	24–30
Percentage live births	16%	6%–7%	<1%
Weight (g)	2,500–3,200	1,500–2,500	500–1,500
Associated problems	Poor suck RDS Temperature regulation	Poor suck RDS Temperature regulation Sepsis Intracranial hemorrhage	Poor suck RDS Temperature regulation Sepsis Intracranial hemorrhage Necrotizing enterocolitis Congestive heart failure Birth asphyxia
Level of care	Careful observation in newborn nursery	Neonatal ICU	Neonatal ICU

ICU, intensive care unit; RDS, respiratory distress syndrome.

Kliegman RM, St. Geme JW III, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:897–909.

A.2. What are the survival rates of preterm infants?

The survival rates of preterm infants depend mainly on their

maturity or birth weights. Because of the advancement in neonatal care, survival rates have continued to improve for extremely premature infants. Over the past 20 years, survival has increased for infants born at 23 and 24 weeks' gestation and survival without major comorbidities increased for infants born at 25 to 28 weeks. In a recent study looking at trends in the mortality of extremely premature infants, survival rates of infants born at 22, 23, 24, 25, and 26 weeks' gestation are 7%, 32%, 62%, 77%, and 85%, respectively.

Kliegman RM, St. Geme JW III, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:897–909.

Stoll BJ, Hansen NI, Bell EF, et al. Trends in care practices, morbidity, and mortality of extremely preterm neonates, 1993-2012. *JAMA*. 2015;314(10):1039–1051.

A.3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.

RDS, formerly called hyaline membrane disease, is common in preterm infants. RDS is a life-threatening condition associated with 50% to 75% of all deaths of premature infants. The incidence of RDS is inversely related to gestational age and birth weight. RDS occurs in 60% to 80% of infants born at <28 weeks gestational age and 15% to 30% of infants between 32 and 36 weeks. The risk increases with maternal diabetes, multiple gestation, cesarean delivery, and precipitous delivery.

Survival depends on the infant's size and gestational age. Eighty percent of those weighing less than 750 g, 85% of those weighing less than 1,000 g, and >95% of those weighing 1,500 to 2,500 g survive. Maternal corticosteroid administration and administration of exogenous surfactant into the lungs of neonates of less than 28 weeks' gestation at birth has been associated with in an increase in survival and a decrease in

severity of RDS.

Deficiency of the alveolar phospholipid surfactant is thought to be the cause of RDS. The surfactant is produced by the type II alveolar cells and is necessary for the maintenance of alveolar stability. Surfactant production is usually inadequate before 35 weeks of gestational age. In its absence, alveolar collapse and a decrease in functional residual capacity (FRC) occur, with consequent right-to-left shunting, arterial hypoxemia, and metabolic acidosis. Administration of betamethasone to women 48 hours before the delivery of fetuses less than 34 weeks' gestation significantly reduces the incidence, mortality, and morbidity of RDS.

Physical examination of the infant with RDS will likely reveal cyanosis, tachypnea, intercostal retractions, and bilateral rales that fail to clear with suctioning. An arterial blood gas sample will demonstrate hypoxemia, metabolic acidosis, and respiratory alkalosis; a chest radiograph will show diffuse, hazy ("ground glass") infiltrates. RDS causes a decrease in lung volume and lung compliance, which may pose a problem for the anesthesiologist if these patients require surgery. Ventilation with high positive pressures and large volumes increases the likelihood of pneumothorax and lung injury.

A.4. What is bronchopulmonary dysplasia (BPD)? How would you treat it?

BPD is a chronic lung disease of prematurity. BPD is defined as

oxygen dependence at 36 weeks' postconceptual age with oxygen requirements to maintain Pa_{O_2} >50 mmHg beyond 28 days of life in infants with birth weight less than 1,500 g. BPD is thought to be a result of mechanical ventilation, oxygen toxicity, infection, or a combination of these factors that cause a lung injury–induced increase in cytokine production. Lung injury in the premature infant disrupts pulmonary maturation that normally occurs around 36 weeks' gestation, resulting in larger but fewer alveoli, decreased surface area for pulmonary gas exchange, and abnormal muscularization of peripheral pulmonary vessels. Infants with BPD may have interstitial fibrosis, lobar emphysema, and components of reactive airway disease. BPD results in mismatch of ventilation and perfusion, resulting in hypoxemia and hypercarbia. With progressive disease, it may lead to pulmonary hypertension and right heart failure.

The treatment for BPD is supportive ventilatory and medical therapies. Ventilatory goals include avoidance of intubation and hyperoxia if possible and use of smaller tidal volumes with permissive hypercapnia to avoid barotrauma. Medical therapies include diuretics (furosemide 5 to 10 mg per kg every 6 hours) to decrease pulmonary edema, bronchodilators to reduce airway resistance, corticosteroids, and inotropes as needed to support cardiac contractility.

Kliegman RM, St. Geme JW III, eds. *Nelson Textbook of Pediatrics*. 21st ed. Philadelphia, PA: Elsevier; 2019:936–940.

A.5. What are apnea spells? What are the possible causes of apneic spells?

Apnea spells are defined as cessation of breathing lasting more than 20 seconds or more than 10 seconds and produces oxygen desaturation and bradycardia. Apneic spells are common in preterm infants, especially after the first week of life and almost universal in infants who are less than 1,000 g at birth. Failure to breathe (central apnea) or failure to maintain a patent airway (obstructive apnea) may both be present. The causes are multiple and include the following:

- Hypothermia or hyperthermia
- Hypoglycemia or hyperglycemia
- Hypocalcemia or hypercalcemia
- Hypovolemia or hypervolemia
- Anemia
- Decreased FRC
- PDA
- Constipation
- Hypothyroidism
- Immature brainstem function
- Lack of type I muscle fibers in diaphragm
- Excessive handling
- Sepsis
- Gastroesophageal reflux disease

Repeated apnea increases the likelihood of central nervous system damage because of repeated episodes of hypoxemia. Infants who have apneic spells may not breathe during anesthesia; therefore, they should be ventilated throughout anesthesia, including the induction phase. Inhaled and intravenous anesthetics affect the control of breathing and contribute to upper airway obstruction, thereby increasing the likelihood of apnea during the postoperative period, especially in preterm infants less than 60 weeks postconception age.

A.6. Discuss the incidence and pathophysiology of PDA in preterm infants.

In term infants, the ductus arteriosus closes soon after birth in response to the increased arterial oxygen tension. Closure is delayed in preterm infants, with the ductus remaining open on day 7 after birth in 2% of infants born at 30 through 37 weeks' gestation, 65% of those born at 25 through 29 weeks' gestation, and 87% of those born at 24 weeks' gestation. Compared to term infants, the ductus arteriosus in preterm infants has a thinner, more poorly contractile muscular layer with diminished responsiveness to the increasing oxygen levels after birth. In addition, preterm infants often suffer from hypoxemia because of RDS so that there are both a reduced stimulus to and a reduced response to physiologic closure. Shunting from the systemic to the pulmonary circulation results in pulmonary vascular overload and ultimately left heart failure. The pulmonary congestion worsens respiratory failure, resulting in further hypoxemia and carbon dioxide (CO_2) retention.

Prolonged patency is associated with increased mortality, BPD, pulmonary hemorrhage, necrotizing enterocolitis, and intraventricular hemorrhage.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:723–726.

A.7. How would you make a diagnosis of PDA? Describe its treatment.

The diagnosis of PDA in preterm infants may be suspected when there is sudden increase in respiratory failure, tachycardia, tachypnea, and a widened pulse pressure. The classic continuous or machinery murmur of PDA is usually not present in this population, but a systolic murmur, sometimes extending into diastole, and a hyperdynamic precordium are nearly always present. The diagnosis is confirmed by echocardiography to assess PDA diameter, shunt pattern, and shunt volume. Continuous-wave Doppler can detect abnormal flow in the pulmonary artery. Color Doppler can visualize the jet of abnormal flow.

The initial treatment of PDA is medical. It includes fluid restriction and administration of diuretics and indomethacin. Indomethacin, 0.1 to 0.2 mg per kg, three doses for every 12 hours, usually closes the ductus within 24 hours. If the ductus fails to close with medical treatment, surgical ligation may be indicated. Percutaneous closure with coils or occlusion devices in the catheterization laboratory may also be performed at some centers, but there are size limitations in small infants.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:723–726.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:479.

A.8. Would you give digitalis to treat congestive heart failure in preterm infants? Why?

Although digitalis was once a mainstay in treatment of congestive heart failure in both children and adults, there is controversy over digitalis use as newer therapies with fewer potential toxicities have been introduced. Digitalis should not be given to small preterm infants because it does not effectively

improve stroke volume or ventricular emptying. However, it does decrease the heart rate, resulting in detrimental decrease in cardiac output. Digitalis toxicity increases mortality in preterm infants.

A.9. How does indomethacin close the ductus? What are the adverse effects of indomethacin?

The ductus arteriosus functionally closes shortly after birth in term infants when the vascular smooth muscle contracts. The muscular contraction of the ductus is initiated by the increased oxygen content and is influenced by other factors, such as release of vasoactive substances, the relative resistances in the aorta and pulmonary artery, and the differences in sensitivity of the vessel to oxygen. The ductus arteriosus produces several prostaglandins, including prostaglandin I_2 (PGI_2) and prostaglandin E_2 (PGE_2); both prostaglandins relax the smooth muscle of the ductus and keep the ductus patent. Meanwhile, the ductus of preterm infants is far more sensitive to the vasodilating effects of prostaglandins than is the ductus of term infants. Indomethacin is one of the most potent inhibitors of the prostaglandin-forming cyclooxygenase. Therefore, indomethacin decreases the synthesis of prostaglandins, resulting in closure of the ductus.

Adverse effects of indomethacin include decreased mesenteric, renal, and cerebral blood flow. Ibuprofen is another nonselective cyclooxygenase inhibitor that can be used effectively to treat PDA and has less side effects on organ blood circulation than indomethacin. When the agents are compared with each other, no differences were observed in the rate of PDA

closure, neonatal outcomes, or adverse effects.

A.10. When is surgical closure indicated? What are the complications associated with surgical ligation?

Surgical ligation is indicated for infants with hemodynamically significant PDA where medical treatment has failed and the infant is unable to be weaned from respiratory support. Recently, the role of surgical ligation has come under scrutiny because of associations with adverse neonatal and neurodevelopmental outcomes. Systematic reviews have found that surgical ligation is associated with higher morbidity with lower mortality. Complications associated with surgical ligation include pneumothorax, chylothorax, vocal cord palsy, postligation cardiac syndrome, and abnormal neurodevelopmental outcome.

Jain A, Shah P. Diagnosis, evaluation, and management of patent ductus arteriosus in preterm neonates. *JAMA Pediatr*. 2015;169(9):863–872.

A.11. What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, prevention, and treatment.

ROP is a retinal disorder affecting preterm infants that can result in blindness if untreated. Some degree of ROP occurs in approximately 50% of infants weighing 1,000 to 1,500 g at

birth, 78% of those weighing 750 to 999 g, and more than 90% of those weighing less than 750 g. ROP is thought to be initiated by oxygen-induced retinal vasoconstriction with retinal vascular obliteration, which is followed by increased vascularity, hemorrhage, cicatrization, and finally retinal detachment. ROP refers to all stages of the disease and its sequelae. RLF, the term previously used for this disease, described only the cicatricial stages.

The factors that cause ROP and determine its outcome are not fully known, but prematurity, the degree of retinal immaturity at birth, and days on supplemental oxygen therapy are major factors. Other contributing factors include respiratory distress, apnea, bradycardia, heart disease, infection, hypoxia, hypercarbia, acidosis, anemia, and the need for transfusion. Generally, the lower the birth weight and the sicker the infant, the greater the risk for ROP.

The retinal vasculature in the developing fetus spreads outward from the optic disc, reaching the nasal side of the retinal periphery by 36 weeks' gestational age and the temporal side at 40 weeks. Classically, it was postulated that hyperoxia constricts the retinal arterioles, resulting in swelling and degeneration of the endothelium. This causes paradoxical retinal ischemia in spite of systemic hyperoxia. When normoxic conditions are restored, vascularization resumes in an aberrant manner, leading to retinal detachment and blindness.

ROP is divided into five stages:

Stage 1: A thin, white line separates the posterior vascularized portion of the retina from the anterior avascular retina.

Stage 2: The demarcation line increases in volume and elevates. At this point, it is known as the "ridge." The changes in stage 1 and 2 regress in 80% of patients. Between 5% and 10% of premature infants with stage 1 and 2 disease progress to stage 3.

Stage 3: Tissue proliferation develops from the ridge, usually posteriorly. Stage 3 can be mild, moderate, or severe, depending on the volume of the extraretinal tissue.

Stage 4: Partial retinal detachment occurs with the macula still attached (stage 4a). The macula is detached in stage 4b.

Stage 5: Total retinal detachment occurs.

Eighty-five percent of ROP cases undergo spontaneous recovery. Mild ROP regresses in 2 to 3 months, and moderate ROP in 6 months. The most severe ROP usually results in blindness or limited vision.

It is unclear what level of Pa_{O_2} causes ROP, but a Pa_{O_2} of 150 mmHg for as short a time as 1 to 2 hours can do so. Furthermore, the retinal vessels of these neonates certainly constrict maximally with a Pa_{O_2} of 100 mmHg. In addition, it is also possible that ROP will develop at lower Pa_{O_2} levels because infants of this age are normally exposed to a much lower Pa_{O_2} (30 to 40 mmHg) in utero than the levels found during the neonatal period. Therefore, in order to reduce the possibility of ROP, it is wise to maintain the Pa_{O_2} levels between 50 and 70 mmHg or the saturation of oxygen (Sa_{O_2}) between 87% and 92% for infants <44 to 50 weeks' gestation.

However, prevention of ROP ultimately depends on the prevention of premature birth and its attendant problems. Oxygen alone is neither sufficient nor necessary to produce ROP, and no safe level of oxygen has yet been determined. Therefore, each infant must be treated with whatsoever is necessary to sustain life and neurologic function. Treatment of ROP includes cryotherapy and laser photocoagulation for moderate disease and scleral buckling surgery and vitrectomy for severe disease.

A.12. Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.

Neutral temperature is the ambient temperature that results in minimal oxygen consumption. Critical temperature is the ambient temperature below which an unclothed, unanesthetized individual cannot maintain a normal core temperature (**Table 44.2**).

TABLE 44.2 Neutral and Critical Temperature

	Neutral Temperature (°C)	Critical Temperature (°C)
Preterm neonate	34	28
Term neonate	32	23
Adults	28	1

Normally, body heat is lost by conduction, convection, radiation, and evaporation. The neonate is particularly susceptible to heat loss owing to a large surface: volume ratio, lack of insulating fat, and naturally flaccid and open posture. When stressed by a cold environment, vasoconstriction occurs, but the neonate is unable to shiver and relies on nonshivering thermogenesis. Cold stress stimulates norepinephrine release, promoting the exothermic metabolism of brown fat deposits in an attempt to maintain core temperature. However, under anesthesia nonshivering thermogenesis appears to be inhibited. Hypothermia can result in bradycardia, apnea, hypoglycemia, or metabolic acidosis and is a risk factor for infant mortality.

When the infant's rectal temperature reaches 36.6°C (97.88°F) to 37.3°C (99.14°F), dilation of peripheral vessels occurs. The term neonate will perspire at 37.2°C (98.96°F) in an attempt to maintain a normal core temperature, whereas those infants born before 37 weeks' gestation are unable to sweat.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:477.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

The preoperative evaluation of preterm infants should be based on a clear understanding of the pathophysiology of prematurity. The preoperative evaluation of this patient should begin with a careful review of the medical record, followed by a systematic physical examination and laboratory evaluation, specifically:

- *History*—birth trauma, asphyxia, maternal drug history, respiratory, cardiovascular, and fluid status
- *Physical examination*—evaluation of the airway, cardiopulmonary system, fluid status (skin texture, turgor, mucous membranes, and fontanelles), and abdominal examination
- *Laboratory data*—WBC count; hemoglobin and hematocrit; serum electrolytes; serum coagulation profile, including prothrombin time, partial thromboplastin time, and platelet count; serum calcium and serum protein; arterial blood gases; urinalysis and urine specific gravity; and chest and abdominal radiographs

B.2. What are the normal values of arterial blood gases and pH in neonates and infants?

The normal blood gas and pH values for pediatric patients are shown in **Table 44.3**. The normal pH and $PaCO_2$ values for pediatric patients are similar to those for adults, whereas the normal PaO_2 values are lower in pediatric patients than in adult patients.

TABLE 44.3 Normal Values of Arterial Blood Gases and pH in Pediatric Patients

Age	Preterm	Term	1 Month	1 Year
pH	7.37 ± 0.03	7.40 ± 0.02	7.41 ± 0.04	7.39 ± 0.02
PaO_2 (mmHg)	60 ± 8	70 ± 11	95 ± 8	93 ± 10
$PaCO_2$ (mmHg)	37 ± 6	39 ± 7	40 ± 6	41 ± 7

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:1302–1303.

B.3. Interpret the arterial blood gases: pH, 7.30; $PaCO_2$, 60 mmHg; PaO_2, 49 mmHg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?

The blood gases show respiratory and metabolic acidosis. The PaO_2 of 49 mmHg is low but acceptable for preterm infants with chronic lung disease. In order to prevent ROP, PaO_2 between 50 and 70 mmHg should be maintained. $PaCO_2$ of 60 mmHg indicates hypoventilation, which can be corrected by increasing respiratory rate or tidal volume. In order to avoid the pulmonary oxygen toxicity, FIO_2 should be lowered to less than 40% by increasing levels of PEEP. Mild metabolic acidosis may be corrected by improving fluid balance and circulation.

B.4. What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm

infants?

The blood pressure is related to the size of infants, as shown in **Table 44.4**. The heavier the birth weight, the higher the blood pressure is. The normal heart rate is 120 to 160 beats per minute. The respiratory rate is normally between 30 and 60 breaths per minute. However, it can increase to 100 to 150 breaths per minute depending on how severely the lung compliance is decreased.

TABLE 44.4 Normal Blood Pressure of Infants Weighing between 1,000 and 4,000 g

	Birth Weight (g)			
	1,000	2,000	3,000	4,000
Systolic BP (mmHg)	50	55	60	70
Diastolic BP (mmHg)	25	30	35	40
Mean BP (mmHg)	35	40	45	50

BP, blood pressure.

Coté C, Lerman J, Anderson B, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier; 2019:18.

Versmold HT, Kitterman JA, Phibbs RH, et al. Aortic blood pressure during the first 12 hours of life in infants with birth weight 610 to 4,220 grams. *Pediatrics*. 1981;67(5):607–613.

B.5. What are the normal values of WBC, red blood cells (RBCs), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?

The WBC count usually ranges from 9,000 to 30,000 per μL at birth and decreases to 5,000 to 20,000 per μL during the fifth week of life.

The normal RBC and hemoglobin are $5.1 \pm 1.0 \times 10^6$ per μL and 19.5 ± 5.0 g per dL, respectively, at birth and decrease to $4.5 \pm 0.7 \times 10^6$ per μL and 12.2 ± 2.3 g per dL, respectively, at 3

months of age. At birth, most of the hemoglobin is fetal hemoglobin, which has a greater affinity for oxygen. Therefore, the oxygen saturation (and content) of blood for a given Pa_{O_2} is higher. By 7 months of age, the circulating hemoglobin is of the adult type.

The normal blood glucose level is between 45 and 90 mg per dL. A glucose level below 40 mg per dL is common in preterm infants. It should be corrected with a bolus of 10% to 20% glucose (2 to 5 g per kg) given over 5 minutes, followed by a continuous infusion of glucose. Severe hypoglycemia (<10 mg per dL) may cause brain damage.

The serum calcium concentration of preterm infants is normally lower than that of term infants because preterm infants have decreased serum proteins. Normal calcium level is over 8.0 mg per dL.

The normal values of sodium, potassium, and chloride are 135 to 145, 3.0 to 5.0, and 105 to 115 mEq per L, respectively.

The creatinine levels of term infants at birth are 0.6 to 1.2 mg per dL but, within 1 month, fall to levels of 0.1 to 0.2 mg per dL. Preterm infants have relatively high serum creatinine levels compared with term infants. They are 0.8 to 1.8 mg per dL at birth and fall to 0.2 to 0.8 mg per dL in 1 month.

The normal blood urea nitrogen level is 10 to 20 mg per dL in term infants, whereas it is 16 to 28 mg per dL in preterm infants.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:1300–1314.

B.6. Would you transfuse blood to this patient preoperatively?

The patient has a hemoglobin of 11 g per dL; a transfusion is not indicated at this time. To ensure oxygen-carrying capacity, most clinicians agree that a hemoglobin of 10 g per dL is the lowest acceptable level if cardiorespiratory disease exists. If infants are

well, a hemoglobin level of above 7.0 g per dL is usually tolerable.

Coté C, Lerman J, Anderson B, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier; 2019:218–219.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:244.

B.7. How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1+; and protein, 1+?

Normal urine specific gravity is 1.001 to 1.035. A higher specific gravity may be suggestive of dehydration. Mild glucosuria may be present in preterm infants, likely due to decreased renal tubular reabsorption of glucose. Albumin is normally filtered by the glomerulus and is completely reabsorbed. However, because of tubular immaturity, preterm infants have mild proteinuria.

Hughes H, Kahl I. *The Harriet Lane Handbook*. 21st ed. Philadelphia, PA: Elsevier; 2018:516–518.

B.8. Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?

Normally, the serum calcium is maintained at 8.0 mg per dL; however, in the preterm infant, a level of 7.0 mg per dL is acceptable. This child's serum calcium is 6.0 mg per dL. Therefore, supplementation with 30 to 100 mg per kg of calcium gluconate or 10 to 20 mg per kg of calcium chloride is appropriate.

Hypocalcemia in neonate is defined as serum calcium less than 3.5 mEq per L or serum ionized calcium less than 1.5 mEq

per L. When evaluating the serum calcium levels, it is important to know the serum protein concentration; neonatal hypocalcemia is usually due to hypoproteinemia. It is also important to determine the ionized calcium concentration (usually 45% of the total calcium concentration) because this is the calcium immediately available at the cellular level. The chloride molecule is approximately one-third the weight of the gluconate molecule. For this reason, approximately three times more calcium is given when an equivalent volume of calcium chloride is administered instead of 10% calcium gluconate. Respiratory alkalosis following hyperventilation will reduce serum ionized calcium levels and, for this reason, should be avoided in this infant.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:137–139.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:481.

B.9. How would you premedicate this patient?

Children under 1 year of age do not usually need sedation or anxiolysis. However, atropine, 0.01 to 0.02 mg per kg, may be given to attenuate the vagal response to a host of different stimuli.

Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:412–416.

C. Intraoperative Management

C.1. Where should the procedure take place? In the neonatal intensive care unit (NICU) or the operating room?

Surgical ligation of the PDA can occur either in the operating room or in the NICU. The decision is frequently institution

dependent. Studies have demonstrated the safety of PDA ligation in the NICU setting when performed by an experienced team. Advantages of performing ligation in the NICU include minimizing transport, continuity of care, and continuation of NICU interventions such as specialized ventilator settings or nitric oxide. Advantages of performing ligation in the operating room include familiarity of the environment for the surgical and anesthesia teams, availability of familiar equipment, potential for improved sterility, and proximity to other surgical and anesthesia personnel.

Gould DS, Montenegro LM, Gaynor JM, et al. A comparison of on-site and off-site patent ductus arteriosus ligation in premature infants. *Pediatrics*. 2003;112:1298–1301.

Jenkins IA, Kelly Ugarte LR, Mancuso TJ. Where should we operate on the preterm neonate? *Paediatr Anaesth*. 2014;24(1):127–136.

C.2. What monitors would you use for this child during surgery?

Proper monitoring of this child for safe administration of anesthesia includes the following:

- *Respiratory*—precordial or esophageal stethoscope, end-tidal CO_2, inspiratory oxygen monitor, pulse oximeter, arterial blood gases, inspiratory pressure gauge
- *Cardiovascular*—precordial or esophageal stethoscope, electrocardiogram, blood pressure cuff and Doppler transducer, and urinary bag
- *Thermoregulatory*—esophageal or axillary temperature probe with servo loop overhead heater and thermal blanket

If the patient has an umbilical artery catheter in place, it is useful for the measurement of blood pressure and arterial blood gases. However, it is probably unnecessary to establish an arterial line for the surgery alone because invasive monitoring in this age group is not without risk.

C.3. How does the oxygen analyzer work?

Oxygen analysis can be done by either parametric or amperometric analysis. Parametric analysis is based on the fact that oxygen is a dipole molecule. When a gas containing oxygen is passed through a magnetic field, the gas is deflected in proportion to the concentration of oxygen. Sensors can detect this deflection and give a readout of oxygen concentration. Amperometric analysis can be done with one of the two devices: the galvanic cell analyzer and the polarographic cell analyzer. In the galvanic or fuel cell analyzer, oxygen diffuses through a membrane of the sensor into an electrolyte solution from which the oxygen absorbs electrons and forms hydroxide ions. The hydroxide ions then diffuse to a lead anode where oxidation to lead oxide and water occurs with the resultant liberation of free electrons. An electron flow (current) is thereby generated between the anode and the cathode, which is proportional to the oxygen level at the sensor. This current is directly displayed by a meter that indicates oxygen percentage. These devices are relatively inexpensive to purchase but carry a high operating cost because the sensor is eventually exhausted and must be replaced.

The polarographic cell, or Clark electrode, uses a battery to induce a negative potential of 0.75 V between the anode and the cathode. As oxygen diffuses across a membrane and into the electrolyte solution separating the anode and cathode, the polarizing voltage at the cathode causes electrons to combine with oxygen molecules, reducing them to hydroxide ions. The hydroxide ions then move to the anode, causing electron flow (current) that is proportional to the initial oxygen concentration. This flow is read by a meter that translates to oxygen percentages. These monitors are initially more expensive than galvanic cell monitors, but they are less expensive to maintain, requiring only inexpensive electrolyte solution and battery

replacement.

Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia*. 3rd ed. Boston, MA: Butterworth-Heinemann; 1993:384.

C.4. What is the Doppler effect? How does the Doppler transducer measure blood pressure?

In 1841, Christian Doppler noted the change in observed frequency from a constant frequency sound generator when the source moved with respect to the observer. Ballot confirmed this "Doppler effect" in 1845 with the simple example of the frequency increase in a train's steam whistle as the train approached an observer. In the 1960s, a practical ultrasonic system for transducing arterial wall motion was described to obtain blood pressure. The ultrasonic system consists of an occlusive cuff and a dual crystal ultrasonic transducer placed over the artery distal to the occlusion. One crystal transmits the ultrasonic signal, whereas the other receives the signal reflected from the artery. Although the cuff occludes the artery, there is no arterial wall movement and the crystal receives a signal with an unchanged frequency. When the cuff pressure falls below systolic pressure, arterial wall motion occurs, causing a Doppler frequency shift, indicating systolic blood pressure. When the cuff pressure falls to diastolic pressure, the artery is open throughout the cycle: Rhythmic arterial opening and closing does not occur, and there is a loss of Doppler frequency shift. Therefore, one can easily and accurately obtain systolic and diastolic blood pressure.

Saidman LJ, Smith NT, eds. *Monitoring in Anesthesia*. 3rd ed. Boston, MA: Butterworth-Heinemann; 1993:121.

C.5. What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?

The mechanism of pulse oximetry is described in Chapter 2, section C.10, and Chapter 59, section A.5.

Safe anesthesia practice requires the monitoring of arterial oxygen saturation in all patients to prevent hypoxia. However, in ex-premature infants less than 44 weeks' postconceptional age, it is also vital to guard against hyperoxia, which may cause ROP.

The arterial oxygen saturation should be kept between 85% and 95% during the neonatal period.

C.6. How would you maintain the patient's body temperature?

Hypothermia greatly increases the metabolic rate and oxygen consumption of preterm infants. The preterm infant is particularly susceptible to heat loss because of a large surface-to-volume ratio, lack of insulating fat, and a naturally flaccid and open posture. In addition, the preterm infant often has impaired thermal regulatory ability; therefore, all precautions must be taken to ensure normothermia. The patient should be transported to the operating room in a heated isolette. If unavailable, the infant should be covered with a plastic sheet or warm blanket, and a cap should be put on the head to prevent heat loss. The operating room should be warmed to >27°C

(80°F) and a servo-controlled infrared heater placed over the operating table. A water-circulating heating blanket or forced air warmer should be used. All extremities should be covered if possible. All intravenous fluids and inspired gases should be warmed and humidified to help maintain the patient's body temperature. If the appropriate setup and equipment are available, then in very low birth weight infants, the procedure can be done at the bedside using the ICU ventilator for airway management. This helps minimize the risks associated with transportation and also minimize the incidence of hypothermia.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:341–342.

C.7. How do the anesthetic requirements of the preterm infant differ from those of the adult?

Achieving proper anesthetic depth in the preterm infant presents a unique challenge to the anesthesiologist. Anesthetic requirements (as determined by minimal alveolar concentration) are decreased in the preterm infant as compared with the adult, possibly due to immaturity of the central nervous system and to increase circulating concentrations of progesterone and β-endorphins. Cardiovascular sensitivity is greatly pronounced because of greater myocardial depression and a reduced peripheral response to catecholamines. Furthermore, the baroreceptor reflex that maintains blood pressure is often poorly developed in the preterm infant and can be abolished by even light levels of inhalation anesthesia. Therefore, the preterm infant is extremely susceptible to anesthetic overdose, which produces cardiovascular depression leading to hypotension or cardiovascular collapse.

Unfortunately, an inadequate depth of anesthesia is also

uniquely hazardous in the neonate. Because there is a lack of cerebral autoregulation, systemic hypertension from inadequate depth of anesthesia may be transmitted directly to the cerebral circulation, resulting in intraventricular hemorrhage.

For these reasons, it is essential to carefully tailor anesthetic depth to surgical conditions because the therapeutic margin between underdose and overdose is extremely narrow.

Lou HC, Lassen PH, Friis-Hansen B. Impaired autoregulation of cerebral blood flow in the distressed newborn infant. *J Pediatr*. 1979;94:118–121.

C.8. What size endotracheal tube would you have used if the patient had not been intubated?

The larynx of a full-term neonate usually accommodates a 3.0- or 3.5-mm endotracheal tube, whereas infants weighing less than 3,500 g tolerate a 3.0-mm tube. In infants weighing less than 1,500 g, a 2.5-mm (internal diameter) tube is usually recommended. The endotracheal tube should be large enough to allow easy ventilation but small enough to permit leaking of gas between the tube and trachea when the lung is ventilated with 15 to 20 cm H_2O pressure. However, a higher leak pressure of 25 to 35 cm H_2O may be necessary if high peak inspiratory pressures are required during anesthesia such as during a thoracotomy or an upper laparotomy or if the patient has decreased pulmonary compliance.

Coté C, Lerman J, Anderson B, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier; 2019:841–842.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed.

West Sussex, United Kingdom: Wiley-Blackwell; 2012:314–315.

C.9. How would you have induced anesthesia if the patient had not been intubated?

Preterm infants require adequate anesthesia and analgesia for painful procedures. Although use of premedication for intubation in the NICU may be institution dependent, studies have demonstrated that premedication in the newborn improves intubating conditions, decreases the time and number of attempts to secure airway, decreases potential intubation-related airway injury, and attenuates the physiologic responses to laryngoscopy and intubation. After preoxygenation with 100%, premedication with fentanyl 1 to 4 μg per kg and 0.05 to 0.1 mg per kg of pancuronium or 0.6 to 1.2 mg per kg of rocuronium can be used to facilitate intubation. After intubation, breath sounds should be checked bilaterally to ensure that the tube is properly positioned.

Alternatively, anesthesia may be induced in the operating room with an inhalation anesthetic such as sevoflurane followed by muscle relaxation with pancuronium or rocuronium before intubation.

Kumar P, Denson SE, Mancuso TJ. Clinical report—premedication for nonemergency endotracheal intubation in the neonate. *Pediatrics*. 2010;125:608–615.

C.10. How would you maintain anesthesia?

Because preterm infants are extremely sensitive to cardiovascular depression from volatile anesthetics, an intravenous anesthetic technique using opioids such as fentanyl and a neuromuscular blocker can be used for maintenance of anesthesia. Increments of fentanyl, 3 to 5 μg per kg, are titrated to maintain hemodynamic stability. A bolus injection of high-dose fentanyl, 30 to 50 μg per kg, often causes hypotension because the infant is usually dehydrated as a result of fluid

restriction and diuretic therapy for congestive heart failure from PDA.

Pancuronium, 0.1 mg per kg, is an attractive choice for muscle relaxation because it causes mild tachycardia and the infant's blood pressure is dependent on heart rate.

Robinson S, Gregory GA. Fentanyl-air-oxygen anesthesia for ligation of patent ductus arteriosus in preterm infants. *Anesth Analg*. 1981;60:331–334.

C.11. How would you ventilate the patient? What tidal volume, respiratory rates, and FIO_2 would you set for the infant?

Controlled ventilation should be employed because preterm infants do not breathe well under anesthesia. The patient may be ventilated by hand with a Jackson-Rees device. This technique potentially allows for instantaneous compensation for changes in pulmonary compliance and resistance, especially during thoracotomy. It also permits the use of PEEP. However, manual ventilation may be unreliable for sensing changes in compliance. Mechanical ventilation, preferably with a pediatric bellows or NICU ventilator, may be used to ventilate the infant.

During spontaneous respiration, normal tidal volume is 7 mL per kg for all ages. However, the ventilator tidal volumes calculated on the basis of body weight for adult patients, such as 10 mL per kg, may not be applicable for pediatric patients, especially small infants. A ventilator-delivered tidal volume may be lost from the leak around the uncuffed endotracheal tube. Traditional anesthesia ventilators were not designed to deliver

small tidal volumes accurately, but modern ventilators can compensate for the compliance of the breathing system. However, most modern anesthesia ventilators have a minimal tidal volume of 20 mL, which might not be appropriate for the smallest patients. In cases where a leak cannot be eliminated such as with an uncuffed tube, or the desired tidal volumes are below the limitations of the ventilator, pressure control ventilation is appropriate. Usually, the peak inspiratory pressures are set between 15 and 25 cm H_2O, depending on the patient's respiratory condition, to ensure adequate chest expansion.

The respiratory rates and inspiratory pressures are adjusted as needed to maintain the $PaCO_2$ between 35 and 40 mmHg or the end-tidal CO_2 between 30 and 35 mmHg. The FIO_2 is adjusted to keep the PaO_2 between 50 and 70 mmHg or the arterial oxygen saturation between 87% and 95%.

C.12. Discuss blood and fluid therapy in this preterm infant.

Fluid therapy should be aimed at correcting the preoperative deficit; providing maintenance fluid; and replacing intraoperative evaporative, third space, and blood loss.

Intraoperative blood loss must be carefully estimated by weighing the sponges and using small-calibrated suction bottles in plain view of the anesthesiologist. The preterm infant's blood volume is only 80 to 95 mL (85 to 100 mL per kg); therefore, even a 10-mL blood loss can be critical. Despite these precautions, estimation of blood loss is inevitably inaccurate because of the unmeasured loss in the drapes and tissues. For

this reason, it is recommended that 125% to 150% of measured blood loss be replaced. Each milliliter of estimated blood loss is replaced with 3 mL of Ringer's lactate or 1 mL of 5% albumin in saline. If the hematocrit is low (<30%) to begin with, blood losses are replaced with packed RBC.

Maintenance fluids consisting of 5% dextrose in one-fourth strength normal saline are given at 4 mL/kg/hr, whereas evaporative and third-space losses are replaced with Ringer's lactate at 8 to 12 mL/kg/hr for abdominal or thoracic procedures. The adequacy of blood and fluid therapy may be ensured by stable blood pressure, normal central venous pressure (over 3 cm H_2O), and adequate urine output of >0.75 mL/kg/hr and specific gravity of less than 1.010. In addition, the infant's fontanel should be above the inner table of the skull if there is no volume depletion.

Coté C, Lerman J, Anderson B, eds. *A Practice of Anesthesia for Infants and Children*. 6th ed. Philadelphia, PA: Elsevier; 2019:205–209.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:352–354.

C.13. During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?

Pediatric patients, especially preterm infants, develop hypoxemia quickly after hypoventilation because they have high metabolism (increased oxygen demand) and low FRC (decreased oxygen reserve). During dissection of the ductus arteriosus, the ipsilateral lung is retracted and compressed by the surgeon. Therefore, the pulmonary resistance increases and pulmonary compliance decreases. Consequently, the delivered tidal volume to the patient decreases, and the gas leak around the

endotracheal tube increases if the inspiratory pressures remain unchanged. Decreasing tidal volume causes hypoventilation, resulting in hypoxemia and CO_2 retention. In addition, compressing the lung tissue increases intrapulmonary shunt, which causes further hypoxemia. In pediatric patients, bradycardia is most commonly caused by hypoxemia. During dissection of the ductus arteriosus, surgical manipulation of the vagus nerve and lung tissue may initiate vagal reflex, with resultant bradycardia.

The infant should be manually ventilated with 100% oxygen to correct hypoxemia and bradycardia. If bradycardia persists, atropine, 0.01 to 0.02 mg per kg, should be given. The surgical manipulation should be stopped and the collapsed lung reexpanded. Blood loss or hypovolemia should also be corrected.

When the hemodynamic status and oxygenation are stabilized, the F_{IO_2} and respiratory pressures should be adjusted to ensure adequate ventilation and oxygenation.

D. Postoperative Management

D.1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?

No. Postoperative ventilatory support would be necessary for this preterm infant with RDS; therefore, reversal of muscle relaxation and extubation are not indicated.

D.2. How can one minimize the risk of transporting the patient to the NICU after surgery?

The anesthesiologist's responsibilities do not end with the successful completion of the operative procedure. Removal of the surgical drapes must be done with caution to prevent inadvertent extubation or removal of the arterial or venous

cannula. Transportation of the infant to the NICU is an extremely hazardous transition and requires watchful vigilance.

Arrangements must be made in advance so that elevators are waiting and the nursery is ready to accept the patient. The anesthesiologist must accompany the child until satisfied that care has been appropriately transferred to the neonatal nursery staff.

The same monitors that were employed for surgery must be used in transport, including electrocardiogram and monitors for arterial blood pressure and oxygen saturation. Ventilation should be maintained by hand with a Jackson-Rees device or by a battery-operated transport ventilator, and the child should not be transported with 100% oxygen unless it was used for the operative procedure. A precordial stethoscope is especially helpful to monitor the adequacy of respiration and heart sounds. Finally, every effort to ensure thermal stability must be made, including the use of a heated Isolette (if possible), plastic sheet, warm blankets, and a cap on the infant's head.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. West Sussex, United Kingdom: Wiley-Blackwell; 2012:488–489.

D.3. The patient's condition deteriorated postoperatively in the intensive care unit (ICU). Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?

It has been reported that a large ductus arteriosus arising from the aortic arch proximal to the subclavian artery creates the illusion of the arch, leading to surgical closure of the distal left pulmonary artery instead of ductus arteriosus (**Fig. 44.1**). A sign of successful PDA ligation is an increase in diastolic blood pressure from the elimination of pulmonary runoff during diastole. To help identify the ductus, some surgeons place a temporary clip on what they believe is the ductus and observe

whether the diastolic pressure increases correspondingly.

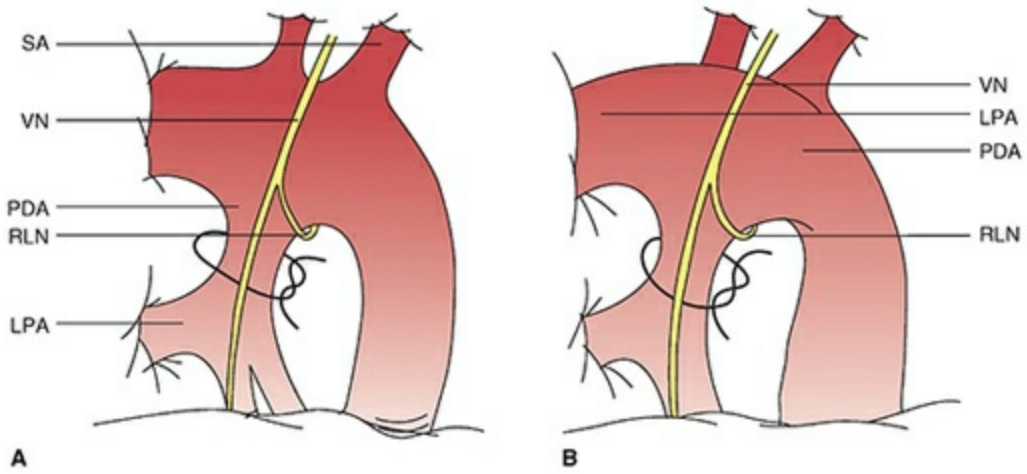

FIGURE 44.1. A. Anatomically, atypical patent ductus arteriosus (PDA) arising proximal to the left subclavian artery (SA). **B.** Large patent ductus arteriosus sweeping into the descending aorta and appearing to be the arch. The ductus overlies the arch and hides it from view. A large distal left pulmonary artery is misinterpreted as the patent ductus (encircled by ligature). LPA, left pulmonary artery; RLN, recurrent laryngeal nerve; VN, vagus nerve. (*Adapted from Pontius RG, Danielson GK, Noonan JA, et al. Illusions leading to surgical closure of the distal left pulmonary artery instead of the ductus arteriosus.* J Thorac Cardiovasc Surg*. 1981;82[1]:107–113. Copyright © 1981 Elsevier. With permission.*)

In this case, the ductus arteriosus was not ligated; therefore, the ductus murmur persisted. Inadvertent ligation of the distal left pulmonary artery resulted in pulmonary ischemia distal to the ligation. Meanwhile, the right lung was further flooded with the shunted blood through the unligated PDA. The resultant ventilation/perfusion mismatch caused further hypoxemia and CO_2 retention in this infant. The patient should be brought to the operating room for repair of the left pulmonary artery and ligation of the ductus arteriosus.

45 Post-tonsillectomy Hemorrhage

Dana L. Gurvitch, Jessica A. Latzman, and Hugh C. Hemmings Jr.

The patient is a 10-year-old male with a history of diagnosed obstructive sleep apnea (apnea–hypopnea index [AHI] of 27) who presents to the emergency department with bleeding in the posterior oropharynx 7 days post-tonsillectomy. On physical exam, the patient is lethargic with pallor and decreased capillary refill. His vital signs are significant for tachycardia to 140 beats per minute, hypotension with blood pressure of 70/40 mmHg, and tachypnea with a respiratory rate of 25 breaths per minute. His oxygen saturation is 97%. The patient is accompanied by his mother, who states that the bleeding started 2 hours ago after the child ate a sandwich.

A. Medical Disease and Differential Diagnosis

1. Approximately how many pediatric tonsillectomies are performed in the United States each year? What are the indications for tonsillectomy?
2. What is the differential diagnosis for this patient?
3. What is the treatment for a patient with von Willebrand disease?

4. Describe the vascular anatomy of the tonsils. What is the incidence of post-tonsillectomy hemorrhage?
5. What are the risk factors for post-tonsillectomy hemorrhage? Does age matter?
6. Describe the morbidity and mortality of post-tonsillectomy hemorrhage.

B. Preoperative Evaluation and Preparation

1. What is your approach to assessing this patient?
2. What will you set up in the operating room for this patient? How will your preparation be different from a routine general anesthetic set up?
3. Should you plan to use vasopressors?
4. The patient seems anxious. Will you administer a sedative to calm the patient down?
5. How do you plan on interpreting this patient's laboratory results?
6. What are your expectations of the surgeon, specifically as it relates to induction of anesthesia?

C. Intraoperative Management

1. What is your plan for induction of anesthesia? During the initial procedure, this patient underwent an uneventful inhalational induction, with postinduction intravenous (IV) placement. Would you perform an inhalational induction again? Why or why not?
2. What is your plan for management of blood in the oropharynx?
3. What is your plan for airway management?
4. Laryngoscopy and intubation prove challenging due to blood in the airway. What options do you have now?
5. What is your plan for maintenance of the anesthetic? What other medications might you want to give?
6. Assuming the surgical intervention is successful, what is your plan for emergence and extubation?

D. Postoperative Management

1. Is postoperative management in the pediatric intensive care unit (PICU) indicated?
2. What would you require for safe transport from the operating room to the PICU?
3. Discuss potential postoperative complications for this patient.
4. What discharge instructions should be given post-tonsillectomy?

A. Medical Disease and Differential Diagnosis

A.1. Approximately how many pediatric tonsillectomies are performed in the United States each year? What are the indications for tonsillectomy?

Approximately 500,000 pediatric tonsillectomies are performed in the United States each year, making it the second most common pediatric ambulatory procedure (behind myringotomy tube insertion).

There are two indications for tonsillectomy in children: sleep-disordered breathing (SDB) and infection. SDB exists on a continuum, with the mildest end being snoring. Obstructive sleep apnea syndrome (OSAS) exists on the severe end of the spectrum and is now the most common indication for tonsillectomy in the pediatric population. The severity of OSAS can be evaluated via polysomnography. Results of polysomnography are graded by the AHI (i.e., the average number of apneic and hypopneic episodes per hour). The AHI allows OSAS to be classified as mild ($1 < \text{AHI} \leq 5$), moderate ($5 < \text{AHI} \leq 10$), or severe ($\text{AHI} > 10$). Patients with SDB and OSAS can exhibit problems such as enuresis, daytime sleepiness or hyperactivity, poor concentration, aggression, anxiety, depression, and other behavioral disorders. In addition, patients

with SDB may have a lower intelligence quotient (IQ) and quality of life.

A second indication for tonsillectomy in children is infection. This can include recurrent tonsillitis, chronic tonsillitis, or peritonsillar abscess. The American Academy of Otolaryngology-Head and Neck Surgery recommends tonsillectomy for recurrent throat infections (7 infections in the past year, 5 infections per year for the last 2 years, or 3 infections per year for at least 3 years, also known as the Paradise Criteria) with documentation of either temperature greater than 38.3°C, cervical adenopathy, tonsillar exudates/erythema, or a positive test for Group A β-hemolytic streptococcus.

A.2. What is the differential diagnosis for this patient?

Blood in the posterior oropharynx could have several etiologies, and it is important to start with a broad differential. Given this patient's recent tonsillectomy, postoperative bleeding from the surgical site is the most likely diagnosis. However, other possible causes of bleeding may be due to trauma, underlying coagulopathy or vascular malformations, or it may be

spontaneous. Bleeding from the tonsillar bed is the most likely cause of this patient's surgical bleeding. However, damage to nearby structures, including the uvula, should not be overlooked. Epistaxis secondary to trauma, and possibly unrelated to the prior surgery, may also be a cause of bleeding into the posterior pharynx. Additionally, underlying coagulopathies, such as von Willebrand disease (incidence of 1% in the general population), may be a cause for continued bleeding postsurgery. And finally, spontaneous hemorrhage has also been reported.

Centers for Disease Control and Prevention. Data & Statistics on von Willebrand Disease. Centers for Disease Control and Prevention Web site. https://www.cdc.gov/ncbddd/vwd/data.html. Accessed December 18, 2018.

Salem A, Healy S, Pau H. Management of spontaneous tonsillar bleeding: review. *J Laryngol Otol*. 2010;124:470–473.

A.3. What is the treatment for a patient with von Willebrand disease?

To combat the dual defects of hemostasis (abnormal coagulation due to low levels of expressed factor VIII and abnormal platelet adhesion), there are three main treatment options:

- Desmopressin (raises endogenous factor VIII and von Willebrand factor levels)
- von Willebrand factor concentrate
- Transfusion therapy with blood products

Eighty percent of patients with von Willebrand disease have type 1 von Willebrand disease, which is responsive to desmopressin. In patients with type 2 or type 3 von Willebrand disease, desmopressin is not effective, and plasma concentrates containing factor VIII and von Willebrand factor concentrate must be used.

https://www.uptodate.com/contents/treatment-of-von-willebrand-disease. Accessed December 19, 2018.

A.4. Describe the vascular anatomy of the tonsils. What is the incidence of post-tonsillectomy hemorrhage?

The arterial blood supply of the tonsils comes from several branches of the external carotid artery, including the ascending pharyngeal artery, descending palatine artery, ascending palatine artery, facial artery branches, and dorsal lingual artery (**Fig. 45.1**). The internal carotid artery may have an aberrant course, allowing it to run close to the tonsillar bed. Venous return is to the peritonsillar plexus, the lingual vein, and the pharyngeal plexus. Sources of tonsillar bleeding can be arterial, venous, or involve vascular anomalies.

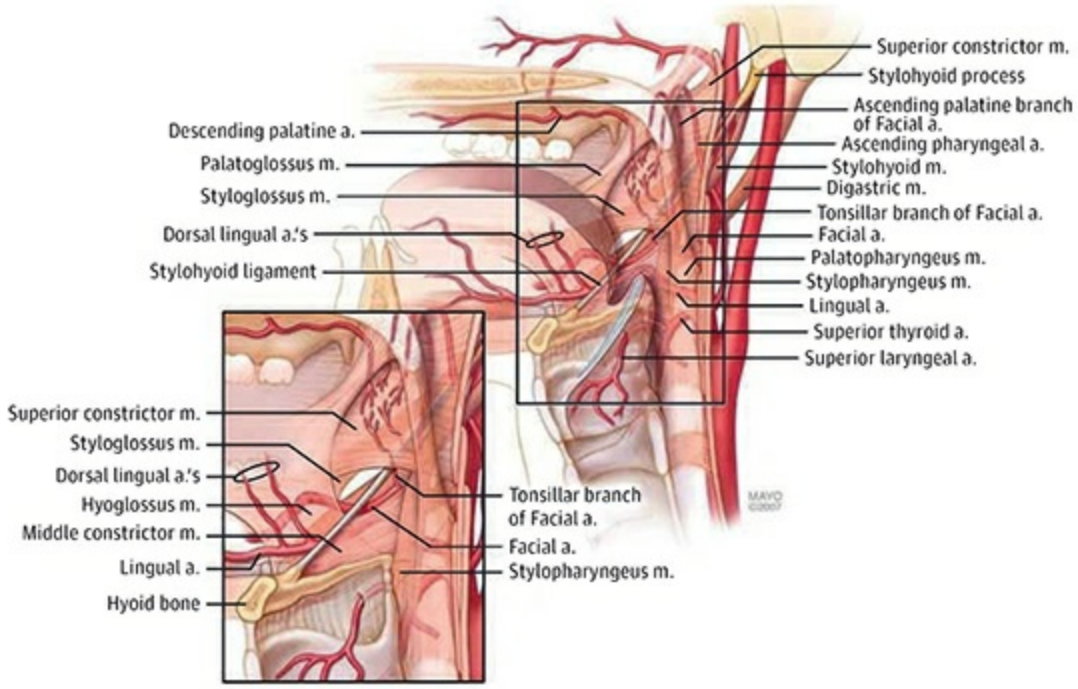

FIGURE 45.1. Blood supply to the lateral oropharynx. a, artery; m, muscle. (*From Pollei TR, Hinni ML, Moore EJ, et al. Analysis of postoperative bleeding and risk factors in transoral surgery of the oropharynx*. Stages of tonsillectomy healing are shown in **Figure 45.2**.

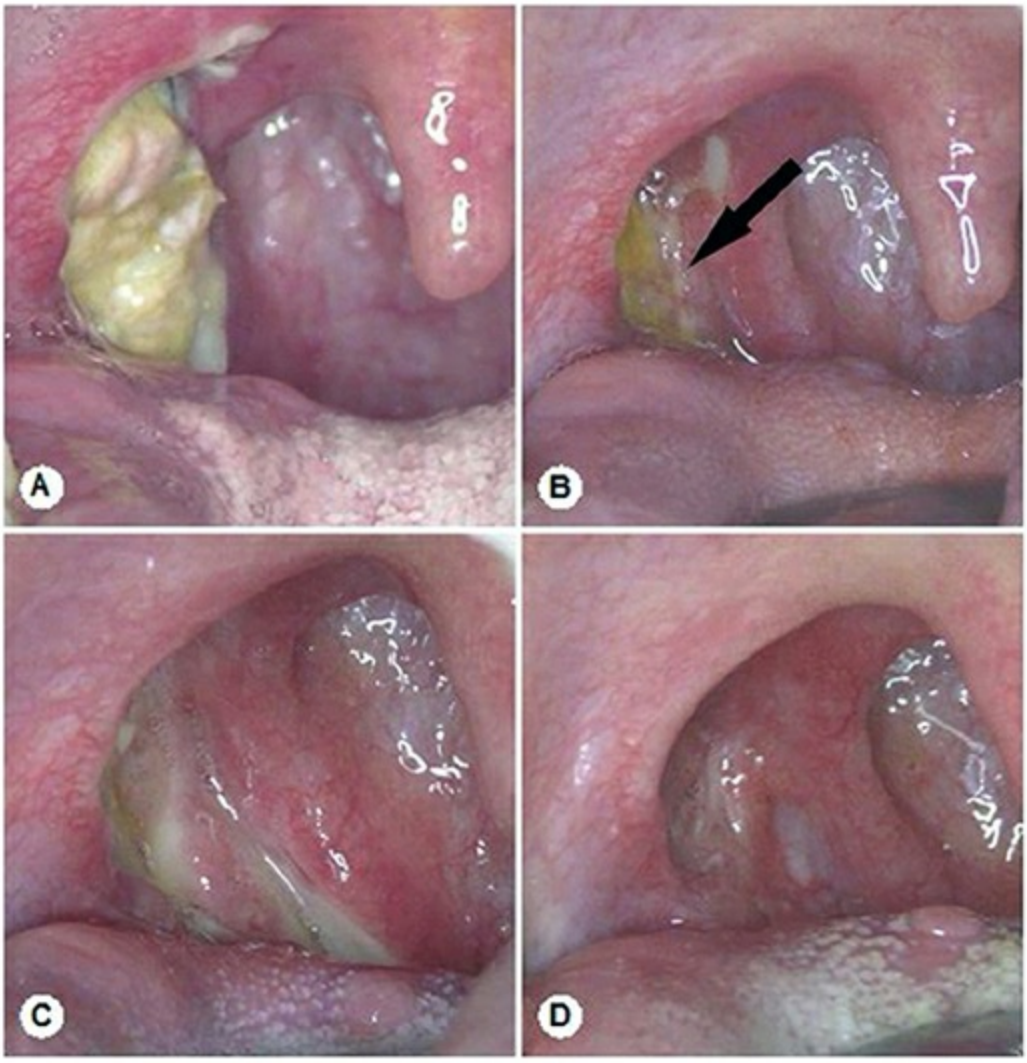

FIGURE 45.2. Stages of tonsillectomy healing. A. Postoperative day (POD) 5: Exudative fibrin clot fills tonsillar fossa, protruding beyond tonsillar pillars. **B.** POD 7: Fibrin clot has separated from tonsillar fossa. New stroma lines the tonsillar fossa. Initial ingrowth of posterior pillar epithelium is discernible (*arrow*). **C.** POD 9: Bridge of epithelium has widened, advancing laterally across tromal bed. **D.** POD 17: Tonsillar fossa is covered by layer of epithelium. Initial epithelium bridge has thickened and resembles normal mucosa. (*Reprinted with permission from Isaacson G. Tonsillectomy healing*. Ann Otol Rhinol Laryngol. *2012;121[10]:645–649. Copyright © 2012 SAGE Publications*.)

Post-tonsillectomy hemorrhage occurs at an overall rate of 3.5% and can be a surgical emergency. Primary bleeding occurs within 24 hours of surgery in approximately 0.55% of cases, with ranges reported in the literature of 0.2% to 2.2% of tonsillectomy patients. Secondary bleeding occurs in approximately 3% of patients (ranges have been reported from

0.1% to 4.8%) and occurs more than 24 hours after surgery, usually between postoperative days 5 through 7. Primary hemorrhage is usually a result of inadequate surgical hemostasis, whereas secondary hemorrhage occurs when the fibrin clot, or eschar, sloughs off of the tonsillar bed.

Windfuhr JP, Chen YS, Remmert S. Hemorrhage following tonsillectomy and adenoidectomy in 15,218 patients. *Otolaryngol Head Neck Surg*. 2005;132(2):281–286.

A.5. What are the risk factors for post-tonsillectomy hemorrhage? Does age matter?

Risk factors for post-tonsillectomy hemorrhage include age, male sex, history of recurrent tonsillitis/peritonsillar abscess, and, in rare cases, underlying coagulopathies (such as von Willebrand disease). There are also rare cases of unsuspected vascular anomalies. The incidence of post-tonsillectomy bleeding increases with age, particularly after age 12 years. Patients age 12 years and older are 1.5 times more likely to experience primary hemorrhage and 3.3 times more likely to experience secondary hemorrhage following tonsillectomy.

Tomkinson A, Harrison W, Owens D, et al. Risk factors for postoperative hemorrhage following tonsillectomy. *Laryngoscope*. 2011;121:279–288.

A.6. Describe the morbidity and mortality of post-tonsillectomy hemorrhage.

Efficient and early intervention and resuscitation should be implemented in the face of active bleeding post-tonsillectomy to prevent hypovolemia, decreased cardiac output, and airway obstruction. Morbidity and mortality occur secondary to aspiration, laryngospasm, and hemorrhagic shock. Mortality rates range from 1 in 10,000 to 1 in 35,000.

B. Preoperative Evaluation and Preparation

B.1. What is your approach to assessing this patient?

The preoperative assessment must be focused and efficient, with emphasis on the airway, vital signs, and cardiovascular status. Important questions to ask yourself during preoperative assessment include the following:

- Is the patient alert and maintaining his or her airway?
- Is the bleeding active?
- Has the patient been adequately resuscitated?

Inadequate volume resuscitation, anemia, swallowing of blood (increasing the risk of aspiration), and compromised airway visualization are all critical issues. As the patient continues to manifest hypotension and tachycardia, more aggressive volume resuscitation should be employed. Laboratory values will help identify the severity of anemia (and thus the need for preoperative transfusion), coagulation issues (platelet count, prothrombin time, partial thromboplastin time, and international normalized ratio values), and the need to order clotting factors or platelets. Additionally, laboratory values can help determine acidosis and volume contraction necessitating

additional crystalloid administration.

B.2. What will you set up in the operating room for this patient? How will your preparation be different from a routine general anesthetic set up?

Along with standard operating room equipment, additional items to have prepared in the procedure room include the following:

- Blood transfusion tubing along with a fluid warmer
- Double suction set up with Yankauer suction tips, as one may become occluded with blood clots)
- Multiple sizes of stylet cuffed endotracheal tubes
- Backup laryngoscope blades/handles
- Emergency airway equipment (McGrath videolaryngoscope, GlideScope, fiberoptic intubation equipment)
- Resuscitation medications
- A tracheostomy set in the unlikely need of an emergency surgical airway

The temperature in the operating room should also be increased to minimize heat loss in the patient.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:828–829.

Fields R, Gencorelli F, Litman R. Anesthetic management of the pediatric bleeding tonsil. *Paediatr Anaesth*. 2010;20(11):982–986.

B.3. Should you plan to use vasopressors?

If the patient is hemodynamically unstable, vasopressors can be titrated until the patient is able to be adequately volume resuscitated. A blood type and crossmatch should be done, laboratory tests should be sent, and the patient should be given fluids and/or blood products in the operating room. Vasopressors should also be considered if the patient has a cardiac history, pulmonary hypertension, or if there is a need to manage the blood pressure tightly.

B.4. The patient seems anxious. Will you administer a sedative to calm the patient down?

The decision to administer preoperative sedation should be weighed against the patient's increased risk for regurgitation and aspiration as well as the potential for respiratory depression. Thus, preoperative sedation in this patient is likely not a wise decision.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2013:1359.

B.5. How do you plan on interpreting this patient's laboratory results?

The need for blood transfusion should be based on hemoglobin/hematocrit assessment and ongoing blood loss. Although recognizing optimal oxygen-carrying capacity is imperative, the threshold for transfusion should be addressed and discussed with the parents and surgical team preoperatively.

B.6. What are your expectations of the surgeon, specifically as it relates to induction of anesthesia?

The surgeon should be gowned and gloved with a headlight on when the patient enters the operating room. The surgeon should have a rigid bronchoscope and a tracheotomy set ready in addition to standard surgical equipment.

Windfuhr JP, Schloendorff G, Sesterhenn AM, et al. A devastating outcome after adenoidectomy and tonsillectomy: ideas for improved prevention and management. *Otolaryngol Head Neck Surg*. 2009;140:191–196.

C. Intraoperative Management

C.1. What is your plan for induction of anesthesia? During the initial procedure, this patient underwent an uneventful inhalational induction, with postinduction intravenous (IV) placement. Would you perform an inhalational induction again? Why or why not?

Adequate preoxygenation is essential to ensuring maximal oxygen reserves in the functional residual volume in the unlikely event of an airway issue. A preinduction nasogastric tube should also be placed to evacuate any gastric contents and/or blood. Rapid sequence induction should be performed with cricoid pressure (Sellick maneuver) using IV propofol if the patient is hemodynamically stable, or etomidate or ketamine if the patient is unstable. High-dose rocuronium or succinylcholine can be administered for rapid paralysis. If succinylcholine is deemed appropriate and safe, an anticholinergic, such as glycopyrrolate, should be administered prior to succinylcholine to minimize vagal response.

Curley GF. Rapid sequence induction with rocuronium—a challenge to the gold standard. *Crit Care*. 2011;15(5):190.

Davis PJ, Cladis FP, eds. *Smith's Anesthesia for Infants and Children*. 9th ed. Philadelphia, PA: Elsevier; 2017:828–829.

C.2. What is your plan for management of blood in the oropharynx?

There should be two large-bore suction catheters ready prior to anesthesia induction and intubation. Suctioning should be done

carefully, as disruption of formed clots may cause an exacerbation of the bleeding. If suctioning is needed, the suction catheter should be directed into the midline of the oropharynx, avoiding the tonsillar fossae. Once the bleeding is surgically controlled, suctioning of the stomach can be done carefully and with direct visualization of the oropharynx.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. Chichester, United Kingdom: Wiley-Blackwell; 2012:786.

C.3. What is your plan for airway management?

Airway management must proceed with a plan. Airway adjuvants, including a fiberoptic bronchoscope and a videolaryngoscope (if the patient's size warrants) should be in the operating room and ready for use. Multiple styleted, cuffed endotracheal tubes should also be in the operating room. Additionally, a double suction set up, a backup anesthesiologist, and an ear, nose and throat (ENT) surgeon should be present.

Fields R, Gencorelli F, Litman R. Anesthetic management of the pediatric bleeding tonsil. *Paediatr Anaesth*. 2010;20(11):982–986.

Weiss M, Dullenkopf A. Cuffed tracheal tubes in children: past, present and future. *Expert Rev Med Devices*. 2007;4:73–82.

C.4. Laryngoscopy and intubation prove challenging due to blood in the airway. What options do you have now?

Gently pressing on the chest to simulate respiration can create air bubbles at the glottic opening to guide placement of the endotracheal tube. Simultaneous suctioning of blood in the oropharynx by a second anesthesia provider may also be warranted to help the laryngoscopist focus on intubation.

Gregory GA, Andropoulos DB, eds. *Gregory's Pediatric Anesthesia*. 5th ed. Chichester, United Kingdom: Wiley-Blackwell; 2012:786.

C.5. What is your plan for maintenance of the anesthetic? What other medications might you want to give?

Maintenance of the anesthetic will depend both on the patient's hemodynamic stability and surgical cessation of bleeding. Given the usual brevity of these procedures, it is important to exercise caution when choosing to administer IV narcotics as this can prolong respiratory depression. As such, IV acetaminophen (12.5 mg/kg) might be considered a better alternative for analgesia. Inhalational anesthetics are appropriate for maintenance. Antiemetics, such as ondansetron (0.15 mg/kg) and dexamethasone (0.15 mg/kg) should also be administered.

Baugh RF, Archer SM, Mitchell RB, et al. Clinical practice guideline: tonsillectomy in children. *Otolaryngol Head Neck Surg*. 2011;144(suppl 1):S1–S30.

C.6. Assuming the surgical intervention is successful, what is your plan for emergence and extubation?

Once hemostasis and hemodynamic stability are achieved, and the decision is made to extubate, gastric contents should be suctioned, paralysis reversal should be confirmed by a twitch monitor, and the patient should be awake and responsive with laryngeal reflexes.

Fields R, Gencorelli F, Litman R. Anesthetic management of the pediatric bleeding tonsil. *Paediatr Anaesth*. 2010;20(11):982–986.

Tomkinson A, Harrison W, Owens D, et al. Postoperative hemorrhage following adenoidectomy. *Laryngoscope*. 2012;122:1246–1253.

D. Postoperative Management

D.1. Is postoperative management in the pediatric intensive care unit (PICU) indicated?

Deciding whether to admit patients to the PICU status post-tonsillectomy hemorrhage should be jointly determined by the

anesthesiologist and surgeon. Assuming the patient does not have significant comorbidities and had an uneventful intraoperative course, admission to the postanesthesia care unit (PACU) is appropriate and safe for management until discharge criteria are met and the patient is able to go home (**Table 45.1**).

TABLE 45.1 PACU Discharge Criteria for the Pediatric (Under 13 Years of Age) Patient

Infant <1 Year			
Optimal Pain Relief Achieved	□ YES	□ NO	
1. BP within Pre-op Value/Age-specific range	□ YES	□ NO	
2. HR 120-160	□ YES	□ NO

Windfuhr JP. Lethal post-tonsillectomy hemorrhage. *Auris Nasus Larynx*. 2003;30:391–396.

D.2. What would you require for safe transport from the operating room to the PICU?

Positioning the patient in the left or right lateral position can reduce the risk of airway obstruction. Supplemental oxygen, emergency airway equipment, and emergency medications are essential for safe transport. If transport over a long distance is required, monitoring equipment should also be employed.

Randall DA, Hoffer ME. Complications of tonsillectomy and adenoidectomy. *Otolaryngol Head Neck Surg*. 1998;118(1):61–68.

D.3. Discuss potential postoperative complications for this patient.

Potential postoperative complications include fever, intravascular volume depletion, airway edema, coagulopathy, anemia, and electrolyte disturbances. Although rare, a rebleed may also occur. If stridor is present postextubation, humidified oxygen and nebulized racemic epinephrine (0.25 mL of 2.25% solution diluted to 3 mL with normal saline) should be promptly administered.

Guida RA, Mattucci KF. Tonsillectomy and adenoidectomy: an inpatient or outpatient procedure? *Laryngoscope*. 1990;100(5):491–493.

Leach J, Manning S, Schaefer S. Comparison of two methods of tonsillectomy. *Laryngoscope*. 1993;103:619–622.

D.4. What discharge instructions should be given post-tonsillectomy?

After discharge criteria are met, patients (and their parents) should be instructed to visit the nearest emergency room in the event of ongoing bleeding. In addition, patients should be encouraged to hydrate and add soft solids to their diet as tolerated. Pharmacologic interventions for pain management should be determined on an individual basis but should aim to minimize the use of narcotics and maximize the use of acetaminophen.

Baugh RF, Archer SM, Mitchell RB, et al. Clinical practice guideline: tonsillectomy in children. *Otolaryngol Head Neck Surg*. 2011;144(suppl 1):S1–S30.

SECTION 11 Pain Management and Neuraxial Blocks

46 Brachial Plexus Block

Tiffany Tedore and William Urmey

A 72-year-old man presents after sustaining a fall and right proximal humeral fracture. The patient's history is remarkable for hypertension and significant chronic obstructive pulmonary disease (COPD). He has a 30 pack-year cigarette smoking history. His only other remarkable history is that he claims to have fainted several times in his life. Recent pulmonary function tests 6 months before admission include a forced vital capacity (FVC) of 1.4 L (33% predicted). The patient's routine medications include atenolol and chlorthalidone. Hydromorphone 1 mg was administered intravenously in the emergency room.

A. Medical Disease and Differential Diagnosis

1. What are the presenting problems in this patient?
2. What additional medical history would you want to obtain?
3. What implications does the use of atenolol have on the

patient's coexisting medical condition?

4. Why is immobilization of the arm important following humeral fracture?
5. What nerve is at particular risk for injury from humeral fracture?

B. Preoperative Evaluation and Preparation

1. What testing would be helpful to elucidate the cause of this patient's fainting spells?
2. What premedication would you order?
3. What are the respiratory effects of benzodiazepines?

C. Intraoperative Management

1. What anesthetic technique would you use?
2. Describe the relevant anatomy of the brachial plexus.
3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?
4. What regional technique would you choose to block the brachial plexus in this patient?
5. What are the advantages and disadvantages of the following blocks?
   a. Interscalene block
   b. Supraclavicular block
   c. Infraclavicular block
   d. Axillary block
6. Describe the landmarks and procedures for nerve stimulator and ultrasound-guided interscalene block.
7. Describe the landmarks and procedures for supraclavicular block.
8. Describe the landmarks and procedures for infraclavicular block.
9. Describe the landmarks and procedures for axillary block.
10. The patient requests to have the brachial plexus block

performed after you administer general anesthesia. Would you agree to this request?

11. What relevant respiratory complications or side effects are you concerned about in this patient?
12. What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by decreasing the volume or concentration of local anesthetic injected or by using ultrasound-guided supraclavicular block?
13. Describe the pulmonary function changes that occur after interscalene brachial plexus block.
14. What would you do if the patient complained of dyspnea after you performed an interscalene or supraclavicular block?
15. The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?
16. Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block? With all brachial plexus blocks?
17. What is the expected duration of brachial plexus block with 30 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?
18. What is the maximum safe dose of local anesthetic for brachial plexus block?

D. Postoperative Management

1. What regimen would you suggest for postoperative pain management?
2. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?
3. On the third postoperative day after removal of the brachial plexus catheter, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How would you manage neurologic

dysfunction after brachial plexus block that persists for 1 week?

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting problems in this patient?

The patient presented for urgent surgery for a proximal humeral fracture and may have some internal bleeding. The patient has significant COPD, most likely secondary to his long cigarette smoking history, and has a history of multiple fainting episodes in the past. He also has chronic hypertension.

A.2. What additional medical history would you want to obtain?

It is important to know if the patient's fall was precipitated by a fainting episode or if the patient simply tripped or lost footing. The patient should be questioned whether any additional trauma occurred at the time of the fall. Has the patient's history of fainting been evaluated in the past? Does the patient have any known cardiac problems? Does he have any history of stroke or carotid disease?

A.3. What implications does the use of atenolol have on the patient's coexisting medical condition?

The patient's use of atenolol may exacerbate COPD, especially if there is a reversible component of airway disease. It would be useful to determine whether the atenolol is being taken for the treatment of hypertension or syncope. Although β-blockers have been commonly used for vasovagal reflex syncope, large long-term controlled trials do not support their efficacy. The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) and the European Society of Cardiology (ESC) guidelines do not

recommend their use. There is some evidence that in adults older than 42 years of age, β-blockers may be protective with regard to development of severe bradycardia or sudden asystole during surgical procedures performed in the "beach chair" or head-up position.

Brignole M, Moya A, deLange FJ, et al. 2018 ESC guidelines for the diagnosis and management of syncope. *Eur Heart J*. 2018;39:1883.

Shen WK, Sheldon RS, Benditt DG, et al. 2017 ACC/AHA/HRS guideline for the evaluation and management of patients with syncope: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation*. 2017;136(5):e60–e122.

A.4. Why is immobilization of the arm important following humeral fracture?

Immobilization of the arm following humeral fracture is important to avoid injury to the brachial plexus or its terminal branches.

A.5. What nerve is at particular risk for injury from humeral fracture?

The axillary nerve is at greatest risk from a proximal humerus fracture, and the radial nerve is at risk with midshaft humeral fracture. Following proximal humeral fracture, the shoulder can be dislocated and malpositioning can cause stretching or pressure on components of the brachial plexus, especially the axillary nerve. To this extent, it is important to verify and document any preexisting neurologic findings on examination, especially if brachial plexus block is being considered.

B. Preoperative Evaluation and Preparation

B.1. What testing would be helpful to elucidate the cause of this patient's fainting spells?

Syncope is defined by a complete loss of consciousness that is of rapid onset and short duration, accompanied by loss of postural tone and a complete and spontaneous recovery. The major categories of syncope include reflex or neurally mediated syncope (vasovagal, situational, carotid sinus), orthostatic syncope (autonomic failure, drug-induced, hypovolemia), and cardiac syncope (arrhythmia, drug-induced, structural disease). Syncope is fairly common, affecting approximately 11% of the population. Vasovagal syncope is the most common cause, accounting for 21% of cases. Most affected patients experience a first episode between the ages of 10 and 30 years; only 5% of patients experience their first episode after age 40 years. The incidence of syncope increases with age, peaking after the age of 65 years.

The workup of syncope should include a detailed history and physical examination, including a measurement of orthostatic blood pressure and an electrocardiogram. An echocardiogram is indicated if the history or physical exam is suggestive of cardiac disease. Tilt-table testing or a neurologic workup may also be appropriate depending on the history and physical exam.

This patient had a prior evaluation that documented an abnormal response to head-up tilt-table testing during isoproterenol infusion and received a diagnosis of reflex (vasovagal) syncope. He has managed this conservatively with physical maneuvers (sitting, leg crossing) upon feeling faint and has not experienced a complete loss of consciousness for over 20 years.

Brignole M, Moya A, deLange FJ, et al. 2018 ESC guidelines for the diagnosis and management of syncope. *Eur Heart J*. 2018;39:1883.

Shen WK, Sheldon RS, Benditt DG, et al. 2017 ACC/AHA/HRS guideline for the evaluation and management of patients with syncope: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *Circulation*. 2017;136(5):e60–e122.

Soteriaces E, Evans J, Larson M, et al. Incidence and prognosis of syncope. *N Engl J Med*. 2002;347:878–885.

B.2. What premedication would you order?

This patient has already received a recent significant intravenous dose of hydromorphone in the emergency room. The patient may not require any additional medication. If the patient is anxious, and assuming that a careful history rules out any significant problems or other drug intake, intravenous midazolam can be carefully administered in the operating room while the patient is monitored with pulse oximetry in the presence of the anesthesia practitioner. Additional opioids may be avoided if he is not in pain.

B.3. What are the respiratory effects of benzodiazepines?

Although benzodiazepines cause a dose-related, centrally mediated respiratory depression, overall respiratory depression is not nearly as profound as with the administration of intravenous opioids. Use of carefully administered smaller therapeutic doses of midazolam is usually well tolerated, without significant respiratory depression. Use of benzodiazepines has been shown to elevate the seizure threshold during local anesthetic administration.

Arcangeli A, Antonelli M, Mignani V, et al. Sedation in PACU: the role of benzodiazepines. *Curr Drug Targets*. 2005;6:745–748.

C. Intraoperative Management

C.1. What anesthetic technique would you use?

Both interscalene and supraclavicular brachial plexus blocks provide excellent operating conditions and allow for postoperative analgesia. Interscalene block may provide better coverage if arthrotomy is required. Concomitant intravenous sedation and oxygen via nasal cannula may be appropriate, or

laryngeal mask airway or endotracheal intubation may be preferred depending on the surgical positioning and access to the airway.

C.2. Describe the relevant anatomy of the brachial plexus.

The brachial plexus supplies the nerves to the upper limb. It is formed by the ventral primary divisions of the fifth to the eighth cervical and the first thoracic nerves, with possible contributions from the fourth cervical and second nerve thoracic roots. The roots join to form the superior, middle, and inferior trunks, which divide into anterior and posterior divisions (**Fig. 46.1**). The three posterior divisions form the posterior cord, whose major branches are the radial and the axillary nerves. The upper two anterior divisions form the lateral cord, whose major branches are the musculocutaneous nerve and the lateral root of the median nerve. The lowest anterior division forms the medial cord, which gives the medial root to the median nerve and terminates as the ulnar nerve. The sympathetic contributions to the brachial plexus are derived from the middle cervical ganglion and the stellate ganglion.

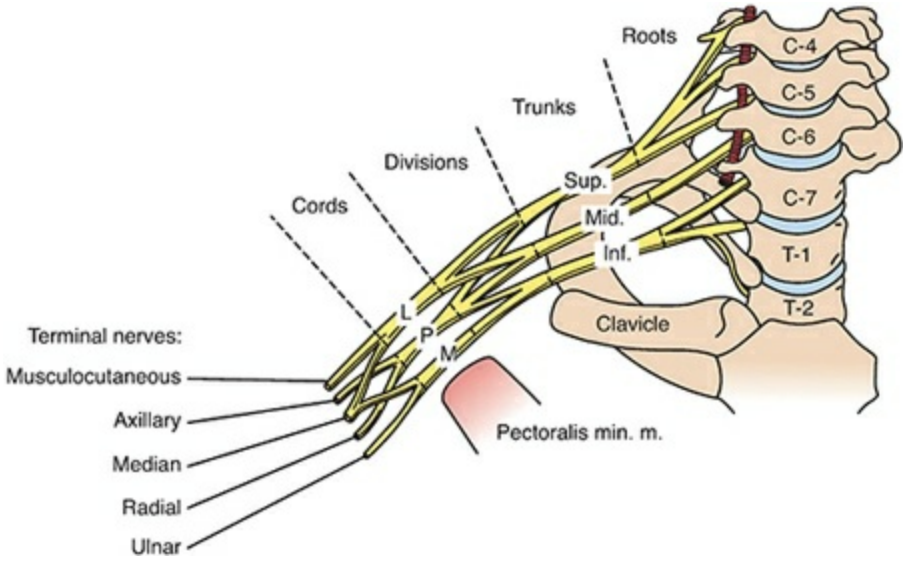

FIGURE 46.1. The brachial plexus. The roots join to form the superior (Sup.), middle (Mid.), and inferior (Inf.) trunks, which divide into anterior and posterior divisions. L, lateral; M, medial; P, posterior.

The brachial plexus begins at the level of the nerve roots, usually at C5–T1. It is at this level that the interscalene brachial plexus block, first described by Winnie, is performed. Injections at this level result in a block with central characteristics, much like a one-sided neuraxial block. Resulting sensory block at this level is characterized by a dermatomal pattern. If the block is incomplete, the typical cause is inadequate spread of local anesthetic to certain nerve roots. For example, the C8–T1 nerve roots are often spared during interscalene block anesthesia because local anesthetic distribution fails to include the lower, most caudal, nerve roots of the brachial plexus. As the brachial plexus courses more peripherally from the neck to the axilla, the nerve roots transform to trunks, divisions, and cords and finally form fully differentiated peripheral nerves. At the level of the axilla, where axillary block is performed, the plexus is composed of terminal nerves that include the median, radial, ulnar, and musculocutaneous nerves. At this level, an incomplete block typically spares sensory or motor blockade in the distribution of a given peripheral nerve, for example, the lateral antebrachial cutaneous nerve (the terminal sensory branch of the musculocutaneous nerve), which exits the surrounding fascia high in the brachial plexus. At this level, the nerves are spread out anatomically around the axillary artery and, depending upon the location of the needle tip during injection and the volume of local anesthetic, any of the four nerves could be spared. This has resulted in the description of multiple injection techniques for axillary block to ensure complete brachial plexus anesthesia.

At the level of the nerve roots or trunks, the brachial plexus is simply a neural plexus, being devoid of major consistently identifiable blood vessels. At this level, brachial plexus identification (i.e., needle tip location) relies on a neural response (paresthesia or motor response to electrical nerve

stimulation) or direct imaging (e.g., using ultrasonographic guidance) of the neural tissue itself. At the level of the clavicle and first rib, the plexus is adjacent to the subclavian artery, which continues as the axillary artery. At this level or below, one can use the blood vessels as landmarks by palpation, Doppler flow guidance, or ultrasonographic guidance to assist in the performance of brachial plexus block.

Winnie AP. Interscalene Brachial Plexus Block. *Anesth Analg*. 1970;49:455–466.

C.3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?

The brachial plexus in the neck has multiple significant anatomic relationships that include the phrenic nerve, subarachnoid space, epidural space, spinal cord, proximal nerve roots, vertebral artery, jugular veins, and the apex of the lung. Errant needle passes can hit any one of these, and in fact, there are published case reports of complications from needle injury or local anesthetic injection for each of these anatomic structures.

Below the neck, the major relevant structures are the blood vessels in the neurovascular plexus, which include the subclavian artery and vein, which more distally become the axillary artery and vein, as well as the parietal pleural, visceral

pleural, and lung.

Mian A, Chaudhry I, Huang R, et al. Brachial plexus anesthesia: a review of the relevant anatomy, complications, and anatomical variations. *Clin Anat*. 2014;27(2):210–221.

C.4. What regional technique would you choose to block the brachial plexus in this patient?

Interscalene block provides the most complete anesthetic block for shoulder surgery. The supraclavicular block has not historically been used for shoulder surgery due to the concern that it may spare the supraclavicular (C3–C4) and suprascapular (C5–C6) nerves and thus not provide anesthesia for the entire shoulder joint and skin over the cape of the shoulder. Recent experience suggests that at higher volumes of local anesthetic (50 mL), supraclavicular block provides equivalent anesthetic conditions to interscalene block. The supraclavicular block may also have a decreased incidence of phrenic nerve blockade when compared to the interscalene block when lower volumes of local anesthetic (20 mL) are used, although this is not guaranteed. If coverage of the shoulder cape is a concern with the use of lower volumes of local anesthetic, the supraclavicular nerve can be anesthetized separately with a superficial cervical plexus block. If the avoidance of phrenic nerve block is to be assured, a combination of more distal blocks, such as the suprascapular and axillary nerve blocks, can be used for shoulder analgesia but will not provide full anesthetic coverage.

Tran DQ, Elgueta MF, Aliste J, et al. Diaphragm-sparing nerve blocks for shoulder surgery. *Reg Anesth Pain Med*. 2017;42:32–38.

C.5. What are the advantages and disadvantages of the following blocks?

a. Interscalene block
b. Supraclavicular block
c. Infraclavicular block
d. Axillary block

Interscalene Block

One advantage of the interscalene block is a superficial location that makes it easily accessible by paresthesia, nerve stimulation, or ultrasonographic guidance techniques. Injection of an adequate volume of local anesthetic at the interscalene level results in reliably complete anesthesia or analgesia for surgery on or about the shoulder, including proximal humeral surgery. A single injection results in success rates approaching 100%. A catheter can be easily placed at this site. This technique blocks the axillary nerve to the deltoid and the musculocutaneous nerve to the biceps brachialis derived from the C5–C6 nerve roots and therefore guarantees reliable relaxation of the deltoid and biceps muscles. This block also reliably anesthetizes the distribution of the supraclavicular nerve (C3–C4), which supplies sensory innervation to the cape of the shoulder, as well as the suprascapular (C5–C6) and lateral pectoral nerves (C5–C7), which innervate the shoulder joint, adjacent ligaments, and soft tissues. This allows optimal surgical exposure and facilitates dislocation of the humeral head from the glenoid socket. If performed properly, it is unlikely to cause a pneumothorax with an appropriate-sized needle using this approach.

Disadvantages include the close proximity of the phrenic

nerve, or perhaps nerve root marginalization of those fibers contributing to phrenic nerve formation, which has rarely resulted in injury to these structures and reported cases of permanent phrenic nerve palsy. Interscalene block with a volume of local anesthetic adequate for surgery results in 100% incidence of ipsilateral hemidiaphragmatic paresis.

Supraclavicular Block

The supraclavicular block is used for surgeries distal to and including the shoulder, although this block may spare the supraclavicular nerve (C3–C4) supplying sensation to the skin over the top of the shoulder, as well as the suprascapular nerve (C5–C6), which innervates the shoulder joint and adjacent ligaments and soft tissues. If being performed for shoulder surgery, the supraclavicular block may be supplemented with a superficial cervical plexus block and/or a suprascapular block. The supraclavicular block is most commonly performed using ultrasound guidance. It can also be performed with the subclavian perivascular or "plumb-bob" approaches. Advantages of ultrasound-guided supraclavicular block include superficial location of the artery and plexus that allow for easy imaging and perivascular block. Also, one is able to visualize two-dimensional local anesthetic distribution and can avoid inadvertent puncture or injection into the vessels. Disadvantages include the intimate proximity to the apex of the lung with a risk of pneumothorax following this block. Supraclavicular block is associated with a variable incidence of diaphragmatic paresis.

Infraclavicular Block

The infraclavicular block is used for procedures distal to the shoulder. It can be performed with nerve stimulation or ultrasound guidance. One advantage of the ultrasound-guided infraclavicular block is the visualization of the artery, which facilitates imaging for perivascular brachial plexus block. The

block does not require positioning of the upper extremity. It is easy to place a catheter at a central location of the plexus via this approach. Disadvantages are related to the depth of the plexus at this level. This may cause more discomfort during placement as the needle must pass through both the pectoralis major and minor muscles.

Axillary Block

The axillary block is utilized for anesthesia distal to the elbow. This block is characterized by the major advantage of the superficial location of the individual terminal branches of the brachial plexus. Thus, one can target the fully differentiated terminal nerves by using either nerve stimulation, paresthesia, or ultrasound-guided techniques. Disadvantages include the need to locate more than one nerve to guarantee successful brachial plexus block at this level. The musculocutaneous nerve is often located relatively distant to the other terminal nerves, lying within the body of the coracobrachialis muscle or between the coracobrachialis and biceps muscles and usually requires a separate injection.

C.6. Describe the landmarks and procedures for nerve stimulator and ultrasound-guided interscalene block.

For interscalene block by electrical nerve stimulation, the patient's head is turned away from the side of the block at an approximately 45-degree angle with the surface of the bed or table. The interscalene groove (between the anterior and middle scalene muscles) is located by palpation just posterior to the lateral border of the sternocleidomastoid muscle. The electrically shielded stimulating needle is introduced in a dorsal, medial, and caudal direction until an appropriate motor response is elicited. Because of the orientation of the nerve roots in a cephalocaudad plane, a response from C5–C6 nerve roots is most frequently obtained first. C5–C6 motor response is characterized by deltoid, biceps, or brachioradialis muscle contractions. Reduction of electrical current amplitude below 0.5 mAmp at a pulse duration of 0.1 millisecond results in a success rate with single injection close to 100%.

For interscalene block by ultrasonographic guidance (**Figs. 46.2** to **46.4**, **Video 46.1**), either an in-plane or out-of-plane approach can be used, depending on the experience and preference of the operator. For an in-plane approach, the needle is inserted in a posterolateral to anteromedial direction along the long axis of a high-frequency linear array transducer with the needle shaft and tip visualized. The middle and anterior scalene muscles should be visualized, and the hypoechoic nerve roots

are usually stacked in a somewhat cephalocaudad arrangement. Injection should be made so that real-time spread of anesthetic can be visualized within the brachial plexus sheath spreading the cross-sectional nerve roots apart.

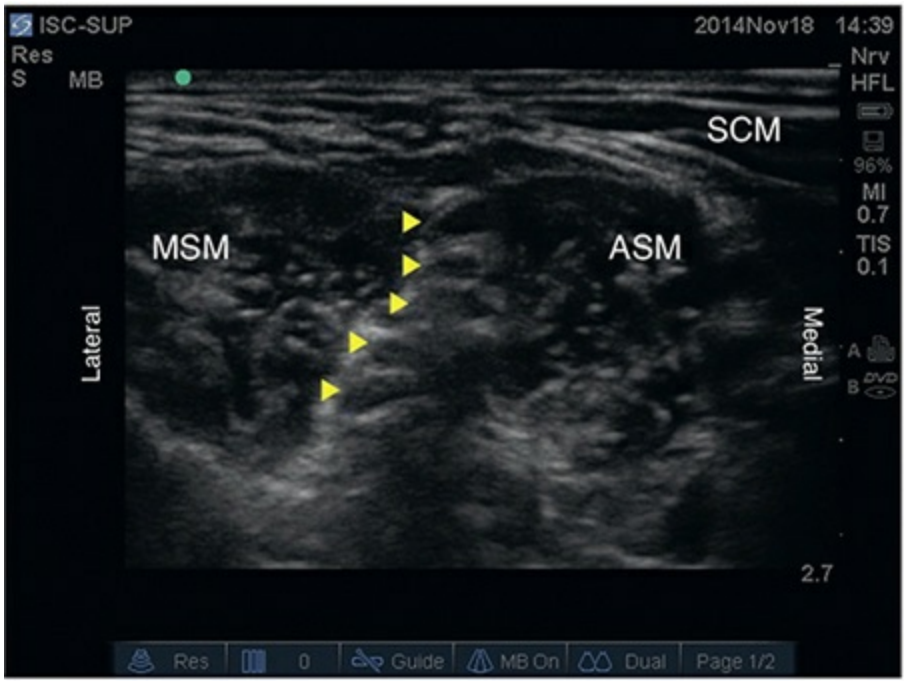

FIGURE 46.2. Ultrasound image of interscalene groove. The hypoechoic nerve roots of the brachial plexus *(yellow arrowheads)* can be seen between the anterior scalene muscle (ASM) and middle scalene muscle (MSM). SCM, sternocleidomastoid muscle.

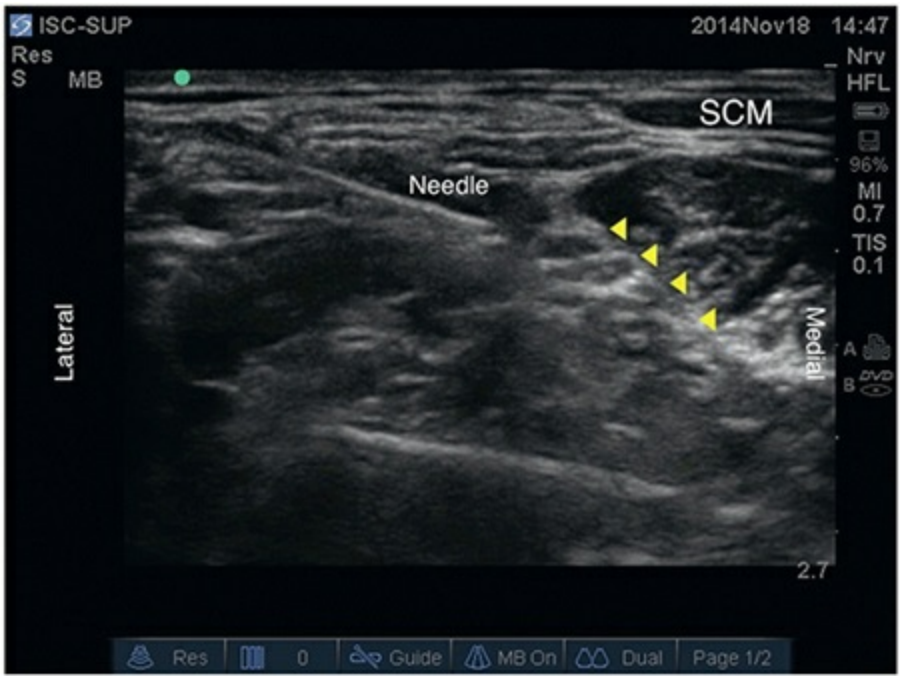

FIGURE 46.3. Ultrasound-guided interscalene block. The needle can be seen approaching the nerve roots *(yellow arrowheads)* in the interscalene groove from the lateral to medial direction. SCM, sternocleidomastoid muscle.

FIGURE 46.4. Ultrasound-guided interscalene block. Hypoechoic local anesthetic *(white arrowheads)* can be seen surrounding the brachial plexus in the interscalene groove. SCM, sternocleidomastoid muscle.

For an out-of-plane approach, the high-frequency linear array

transducer may be placed just caudal to the conventional interscalene block injection point and just above the clavicle. The longitudinal axis of the transducer is oriented in a posterolateral to anteromedial direction, with the center of the probe overlying the interscalene space and the image of the nerve roots, which again will be hypoechoic in cross-section. The needle is introduced in a slightly dorsal, medial, and caudal direction, as originally described in the conventional technique by Winnie. It is technically challenging to observe the needle tip when using the out-of-plane approach. Tissue movement as seen on the ultrasound image can be used to guide needle placement, as can intermittent injection of small volumes of local anesthetic. Nerve stimulation can also be used to confirm position of the needle tip within the brachial plexus.

C.7. Describe the landmarks and procedures for supraclavicular block.

The divisions of the brachial plexus in the supraclavicular area are located cephaloposterior to the subclavian artery and superior to the first rib. Due to the high risk of subclavian artery puncture and pneumothorax with the perivascular and "plumb-bob" techniques, this block is predominately performed using ultrasound guidance. A high-frequency linear array transducer is

placed just above and parallel to the clavicle in the supraclavicular fossa (**Figs. 46.5** and **46.6**). In the resulting ultrasound image, the plexus can be visualized superior and lateral to the subclavian artery and directly above the first rib. The dome of the lung can be seen medial to the first rib. An in-plane posterolateral to anteromedial technique is generally used, making sure that the needle tip and shaft are visualized throughout manipulation of the needle and that the pleura is clearly seen. Local anesthetic is deposited at the superior aspect of the plexus for proximal procedures (shoulder, humerus) and in the "eight ball, corner pocket" between the subclavian artery, first rib, and brachial plexus for distal procedures (forearm, hand).

FIGURE 46.5. Ultrasound image of the supraclavicular fossa. The hypoechoic divisions of the brachial plexus *(yellow arrowheads)* can be seen superior and lateral to the subclavian artery (SA).

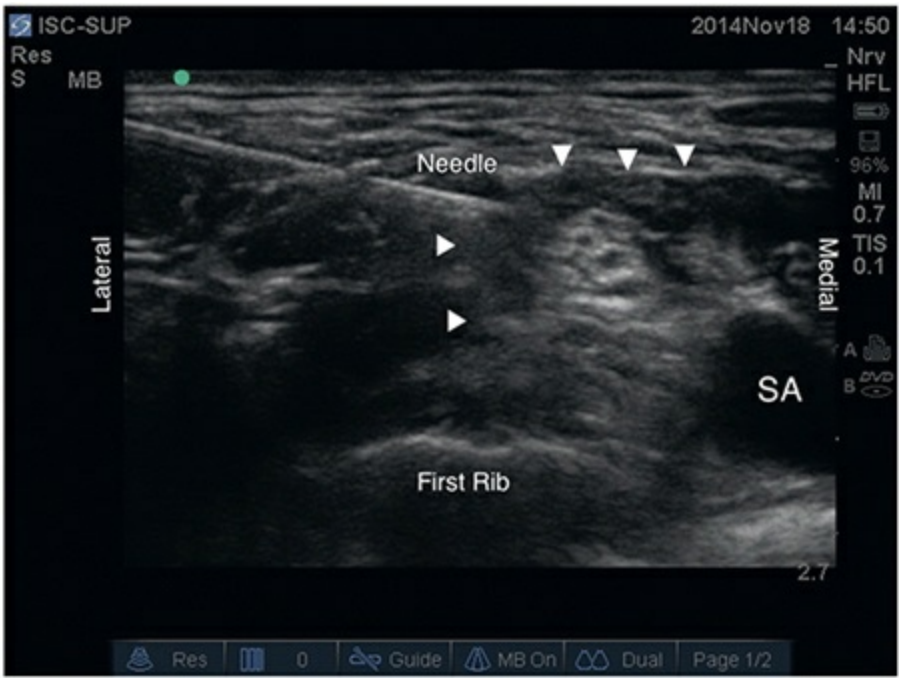

FIGURE 46.6. Ultrasound-guided supraclavicular block. The needle is positioned just superior and lateral to the brachial plexus. Hypoechoic local anesthetic *(white arrowheads)* can be seen surrounding the plexus. SA, subclavian artery.

C.8. Describe the landmarks and procedures for infraclavicular block.

The infraclavicular block is performed at the cord level of the brachial plexus near the second portion of the axillary artery. For the nerve stimulator approach, the patient is placed supine with the arm to be blocked abducted 90 degrees at the elbow. The coracoid process is palpated, and the needle insertion site is located 2 cm medial and 2 cm caudad to the process. The needle is inserted in a vertical parasagittal plane until a distal upper extremity motor response is elicited. The needle may be

redirected in a cephalocaudad arc if a response is not elicited on the initial attempt. The depth of the brachial plexus can vary from 3 to 10 cm depending on patient size.

The ultrasound-guided infraclavicular block (**Fig. 46.7**) is usually performed with the patient supine and with the arm either adducted at the side or abducted 90 degrees at the elbow. The ultrasound probe is placed in the deltopectoral groove just medial to the coracoid process. There is a large amount of variation in the precise location of the cords, but in this position, the lateral cord is most often located cephalad, the posterior cord posterior, and the medial cord caudad to the axillary artery. The medial cord may lie between the axillary artery and vein. Abduction of the arm to 90 degrees may improve visualization of the cords and will pull the clavicle down and away from the needle insertion site. A 10-cm needle is inserted in-plane and cephalad to the long axis of the probe, and the tip is positioned posterior to the axillary artery near the posterior cord. The steep insertion angle required and the depth of the brachial plexus at this level often results in poor visualization of the needle. The use of a small curvilinear probe and an echogenic needle may enhance needle visualization. The curvilinear probe allows greater room for needle entry and a wide sector view of the involved structures at the expense of reduced resolution when compared to a high-frequency linear probe. If all three cords are not easily identifiable, deposition of a ring of local anesthetic surrounding the axillary artery is associated with an effective block in 95% of cases. It may be necessary to reposition the needle and give multiple injections in order to surround all three cords.

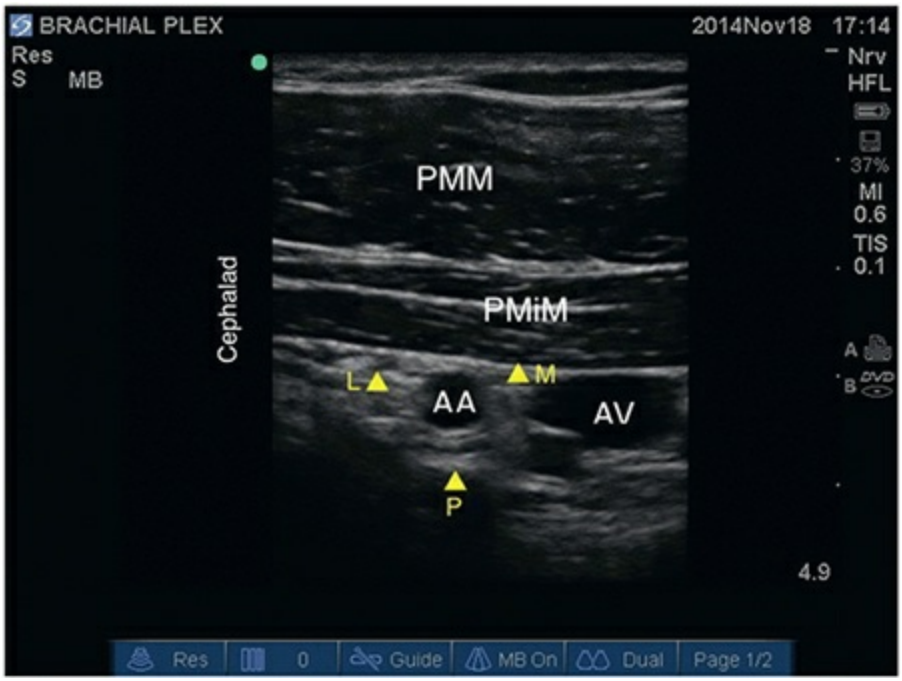

FIGURE 46.7. Ultrasound image of the infraclavicular region using a high-frequency linear probe. The lateral (L), posterior (P), and medial (M) cords can be seen surrounding the axillary artery (AA). AV, axillary vein; PMiM, pectoralis minor muscle; PMM, pectoralis major muscle.

C.9. Describe the landmarks and procedures for axillary block.

In the axilla, the median, ulnar, and radial nerves lie close to the axillary artery and are surrounded by the biceps, triceps, and coracobrachialis muscles. The radial nerve generally lies between the axillary artery and the humerus. The musculocutaneous nerve separates from the lateral cord

proximal to the axilla and is often found between the biceps and coracobrachialis muscles.

For the nerve stimulator technique, the patient is positioned supine and the arm is abducted to 90 degrees and bent at the elbow. The patient's axillary artery is palpated, and a small-gauge electrically shielded stimulating needle is introduced just below the artery to elicit motor response from the radial nerve (deep to the artery) or ulnar nerve (medial to the artery; i.e., immediately below with the arm in this position). The needle is repositioned and advanced superficial to the artery for a median nerve motor response. Highest success rate correlates with at least two motor responses in which one response is from radial nerve stimulation. By insisting on current amplitude levels of 0.5 mAmp or below, at short pulse duration (0.1 millisecond), success rates in the 95% to 100% range can be expected.

The ultrasound-guided axillary block (**Fig. 46.8**) utilizes the same patient position as the nerve stimulator technique. The ultrasound probe is placed along the axillary crease in order to obtain a transverse view of the vessels and nerves. Care should be taken to identify the location of axillary veins because even slight pressure from the ultrasound transducer can collapse these vessels and obscure their identification. The nerves will appear hyperechoic with a honeycomb-like texture and can be traced distally in the arm to confirm their identification. The block is usually performed in-plane with a 5-cm needle oriented from lateral to medial, or out-of-plane with the needle oriented perpendicular to the long axis of the transducer. A shallow needle angle is utilized due to the superficial location of the nerves in the axilla and generally results in a clear image of the needle. If an out-of-plane technique is used, injections of small amounts of local anesthetic during needle advancement can assist in identifying the location of the needle tip. If the individual radial, median, and ulnar nerves are difficult to

identify, a perivascular ring of local anesthetic surrounding the axillary artery usually ensures a successful block of these nerves.

FIGURE 46.8. Ultrasound image of the axilla. The median (M), radial (R), and ulnar (U) nerves can be seen surrounding the axillary artery (AA). The musculocutaneous nerve (MC) lies between the body of the biceps and the coracobrachialis muscles.

C.10. The patient requests to have the brachial plexus block performed after you administer general anesthesia. Would you agree to this request?

In a landmark publication, Benumof reported four cases of permanent injury to the cervical spinal cord resulting from interscalene block performed during general anesthesia. Imaging

of the cervical spinal cord showed vacuolization of the cord or the presence of a syrinx. Intraneural injection of local anesthetic under pressure has been found to spread along the longitudinal axis along the nerve during experimental studies. Thus, theoretically, injection into a proximal nerve root can spread and disrupt the cervical spinal cord.

Performance of regional anesthesia in the anesthetized patient does not allow the patient to report painful paresthesia or other sensations. Sudden severe pain on injection during peripheral nerve block is a time-honored signal that neural tissue is endangered and that the needle should be promptly withdrawn and repositioned. It has been shown that needle contact with the nerve is often not associated with the ability to elicit a motor response during electrical stimulation. Reports of accidental intraneural injection during ultrasonographic needle guidance have been published. Therefore, no available modality can ensure against this complication and hence the caution that regional blocks not be performed in patients who are heavily sedated or following induction of general anesthesia. There are certain important exceptions to this rule, including children and adults who may suffer from dementia, developmental delay, or for other reasons are unable to tolerate regional block under only minimal sedation.

C.11. What relevant respiratory complications or side effects are you concerned about in this patient?

Ipsilateral hemidiaphragmatic paresis is a consistent side effect associated with interscalene block. It occurs with an incidence of 100% when utilizing local anesthetic volumes of 20 mL or greater. It is also a variable side effect of supraclavicular block. This expected side effect takes on added importance if the patient has respiratory comorbidities, including contralateral phrenic or diaphragmatic pathology, severe chronic obstructive cardiopulmonary disease, neuromuscular disorders in which a 25% reduction in FVC would not be tolerated, or conditions that restrict rib cage motion such as ankylosing spondylitis. If these conditions are present, significant atelectasis or respiratory failure can occur. With proper technique and needle size, the risk of pneumothorax is minimal. Introduction of a catheter, nevertheless, could theoretically reach the apex of the lung.

Urmey W, Talts K, Sharrock N. One hundred percent incidence of hemidiaphragmatic paresis associated with interscalene brachial plexus anesthesia as diagnosed by ultrasonography. *Anesth Analg*. 1991;72:498–503.

C.12. What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by decreasing the volume or concentration of local anesthetic injected or by using ultrasound-guided supraclavicular block?

Hemidiaphragmatic paresis cannot be reliably avoided by reducing the volume of local anesthetic injected. Volumes as

low as 5 mL (which is inadequate for surgical anesthesia) have been associated with a 45% incidence of hemidiaphragmatic paresis. Similarly, reductions in local anesthetic concentration do not avoid this side effect, with concentrations of bupivacaine as low as 0.125% being associated with 100% incidence of hemidiaphragmatic paresis. The use of ultrasound-guided supraclavicular blocks can reduce the incidence of hemidiaphragmatic paresis from 100% but will still be expected to be associated with a variable incidence. Blocks above the clavicle are associated with spread of local anesthetic into the cervical plexus. The mechanism for phrenic nerve paresis is motor blockade of the C3–C5 nerve roots before forming the phrenic nerve. The main nerve root contributing to formation to the phrenic nerve is the C4 nerve root. Any block causing sensory blockade of C5, C4, or C3 would be expected to have associated phrenic paresis. A recent publication suggests that with careful deposition of lower volumes of local anesthetic by ultrasonographic guidance at the intersection of the first rib and subclavian artery, the incidence of hemidiaphragmatic paresis may indeed be avoided during supraclavicular block.

C.13. Describe the pulmonary function changes that occur after interscalene brachial plexus block.

Pulmonary function (such as FVC and forced expiratory volume in 1 second) reductions of 25% to 30% occur routinely. These changes are usually complete within 15 minutes of completion of the injection. Increased upper rib cage expansion and ipsilateral paradoxical inward motion of the hemiabdomen have been reported. The combined effect of these changes is a reduced ability to cough and clear secretions, which may be poorly tolerated by a patient with severe COPD.

Urmey W, McDonald M. Hemidiaphragmatic paresis during interscalene brachial plexus block: effects on pulmonary function and chest wall mechanics. *Anesth Analg*. 1992;74:352–357.

C.14. What would you do if the patient complained of dyspnea after you performed an interscalene or supraclavicular block?

The patient should be reassured and observed. Most patients complaining of dyspnea will have more than adequate pulmonary function for normal respiration. Symptoms of dyspnea may be relieved by placing the patient in the upright or sitting position as tolerated. This position optimizes diaphragmatic geometry and function and increases functional

residual capacity. Auscultation often reveals diminished or silent breath sounds on the side of the block. Chest radiography may be obtained if pneumothorax is suspected. Application of a face mask to assess ventilation or end-tidal carbon dioxide may be done, and assisted or controlled ventilation can be used if necessary. Endotracheal intubation should be performed if clinically indicated.

C.15. The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?

As discussed earlier, the seated position optimizes chest wall mechanics. The sitting position also allows easier access to the airway and is more comfortable for the patient if sedation is preferred over general anesthesia. However, placing the patient in the seated position may be associated with hypotensive bradycardiac episodes (HBE). Severe bradycardia or asystole may occur. It is suggested that these events occur as a result of the Bezold-Jarisch reflex (paradoxical cardiac inhibition and bradycardia in response to decreased ventricular volume resulting from venous pooling in sitting position). The sitting position may be thought of as a variation of the tilt-table test. This patient would be at particular risk for developing intraoperative bradycardia in the sitting position because of the history of syncopal episodes and positive findings on the tilt test. The use of β-blockers to decrease the likelihood of HBEs advocated on basis of observational studies has not been corroborated by large randomized studies in the literature. Ephedrine appears to be the drug of choice for HBEs. Epinephrine, atropine, α-agonists, and intravenous fluids are effective treatments for hypotension and bradycardia. Vigilance and rapid response are of critical importance.

The seated position has also been associated with case reports of stroke and neurologic deficit following shoulder surgery. There is some evidence to suggest improved cerebral perfusion when spontaneous, rather than positive pressure, ventilation is used for shoulder procedures in the upright position.

C.16. Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block? With all brachial plexus blocks?

Axillary brachial plexus block commonly misses the musculocutaneous nerve, which arises from C5–C6 nerve roots and exits the plexus above the axilla. The interscalene block commonly spares the ulnar nerve, which is formed by the C8–T1 nerve roots at the lower extent of the brachial plexus. The intercostobrachial nerve is a branch of the second thoracic nerve and is not anesthetized by brachial plexus blocks. A separate injection is required for procedures involving the medial upper arm or axilla, or if a tourniquet will be inflated for extended periods on the upper arm.

C.17. What is the expected duration of brachial plexus block with 30 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?

Such an injection typically lasts 4 to 5 hours for surgical anesthesia.

C.18. What is the maximum safe dose of local anesthetic for brachial plexus block?

There is no absolute maximum safe dose of local anesthetic. The brachial plexus is characterized by relatively low systemic absorption compared to that of other blocks, such as epidural or intercostal. Absorption of local anesthetic following regional anesthetic injection is site specific. The American Society of Regional Anesthesia and Pain Medicine has published guidelines for local anesthetic toxicity. One should be cognizant of the recent publications demonstrating the efficacy of intravenous infusion of lipid emulsion in reversing local anesthetic–induced cardiac toxicity in animals and in multiple case reports involving human patients. Background information as well as advice concerning resuscitation equipment and procedure, including recommended dosing of lipid emulsion, can be obtained by accessing lipidrescue.org.

D. Postoperative Management

D.1. What regimen would you suggest for postoperative pain management?

Patient-controlled regional analgesia with a continuous infusion of local anesthetic is superior to intravenous patient-controlled analgesia for the treatment of pain after major shoulder surgery and also results in a faster time to discharge and increased patient satisfaction when used as part of a multimodal pain regimen. A supraclavicular or interscalene infusion of 0.2% ropivacaine at 4 to 8 mL per hour with patient administered boluses of 2 to 4 mL every 20 to 30 minutes is a good starting point. This can be combined with standing acetaminophen, COX-2 selective nonsteroidal anti-inflammatory drugs, gabapentinoids, and oral or intravenous opioids as needed.

D.2. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?

The patient's vital signs should be monitored, including the oxygen saturation. Duration of hemidiaphragmatic paresis following brachial plexus block with mepivacaine or bupivacaine with added epinephrine lasts 3 to 4 hours or 9 to 18

hours, respectively. If a catheter has been placed, it should be checked via imaging to ascertain that it is not in the cervical plexus. Chest radiography should be performed to rule out pneumothorax or significant atelectasis. The patient should be supported by placement into the sitting position and ventilation assisted or controlled if necessary.

Urmey W, Gloeggler P. Effects of bupivacaine 0.5% compared with mepivacaine 1.5% used for interscalene brachial plexus block (abstract). *Reg Anesth*. 1992;17:13.

D.3. On the third postoperative day after removal of the brachial plexus catheter, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How would you manage neurologic dysfunction after brachial plexus block that persists for 1 week?

Postoperative neurologic symptoms may be due to block-, surgical-, or patient-related factors. Causes unrelated to the brachial plexus block can include restrictive casts, compartment syndrome, or surgical causes such as tourniquet or traction injuries. The incidence of peripheral nerve injury after general anesthesia is approximately 0.04%. The incidence of block-related neurologic symptoms in the first several postoperative days ranges from 0.9/1,000 to 3/100 (0.18% to 3%). The incidence of symptoms lasting longer than 6 months ranges from 0.14 to 0.9/1,000 (0.014% to 0.09%).

It is appropriate to reassure the patient and tell him that these symptoms will likely resolve over time. If the symptoms persist for more than 1 week, a neurologist should be consulted to evaluate for neuropathy or brachial plexopathy. Electromyography (EMG) studies provide information on the location and degree of injury. It can take up to 4 weeks for an injury to cause sufficient wallerian degeneration of axons to

result in muscle denervation. EMG testing immediately after the injury can help to define any preexisting neurologic injury but should be repeated after 3 to 4 weeks. Serial testing can help to assess the evolution or recovery of the initial injury. Magnetic resonance imaging (MRI) is also considered a standard tool for the workup of neurologic injuries. It is especially suited to image the brachial plexus, where injuries often present with enhancement. The diagnostic ability of MRI is limited due to the fact that abnormalities seen on MRI can be nonspecific.

47 Nerve Blocks of the Lower Extremity

Roniel Weinberg, Melvin La, and Danielle M. Gluck

A 60-year-old male was struck by a car while walking across a street. Upon arrival to the emergency room (ER), he complained of severe right lower extremity pain. His Glasgow Coma Score was 13 because he was slightly confused and only opened his eyes to speech. His past medical history was significant for paroxysmal atrial fibrillation and chronic low back pain. Prior surgeries include a right anterior cruciate ligament (ACL) repair 4 years ago and an L4–S1 fusion. His medications include dabigatran (Pradaxa), methadone 15 mg every 6 hours, and oxycodone 15 to 30 mg every 6 hours as needed for breakthrough pain. The patient's heart rate is irregular at a rate of 85 beats per minute, and his blood pressure is 130/70 mmHg. An electrocardiogram shows atrial fibrillation. Head computed tomography (CT) scan in the ER reveals a small subdural hematoma. He has lacerations of the skin on both the medial and lateral aspects of his right ankle, and plain film x-rays show a high right ankle fracture of the tibia and fibula. The consulting neurosurgical service has determined that the patient does not require immediate interventions and will be followed with close observation. The orthopedic surgery team wants to take the patient for an open reduction and internal fixation (ORIF) of his ankle as soon as medical conditions allow.

A. Preoperative Evaluation

1. What is the Glasgow Coma Scale and its significance in this patient?
2. Should surgery be allowed to proceed in this patient who has a subdural bleed?
3. Does the patient's atrial fibrillation need to be addressed prior to surgery, and if so, how?

B. Preoperative Preparation

1. What is dabigatran (Pradaxa)? How is its effect measured? How far in advance of elective surgery should it be stopped? Can its effect be reversed?
2. What concerns do you have regarding neuraxial anesthesia in this patient who has a subdural hematoma?
3. What concerns do you have regarding neuraxial anesthesia in this patient who has prior back surgery?
4. The surgeon is willing to wait a few days prior to surgery while the swelling around the injury decreases. When would you feel comfortable proceeding with surgery in this patient?

C. Intraoperative Management

The patient presents to the operating room (OR) 72 hours after his injury. He was medically cleared for the ORIF of his right ankle. You have decided to proceed with a regional nerve block anesthetic technique.

1. What two nerve plexuses need to be blocked in this case? What nerve roots contribute to each plexus? Name the major nerves that come from each plexus.
2. What is the innervation to the medial and lateral aspects of the ankle? What nerves need to be blocked for his surgery?
3. What nerves are blocked with an ankle block? Would you do an ankle block in this case?
4. Explain the posterior landmark technique to blocking the lumbar plexus. What motor response would be elicited with a

nerve stimulator? At what stimulation level would you feel safe injecting the patient? Why not at a lower level of stimulation? Can ultrasound guidance be utilized for this injection?

5. What is a fascia iliaca block (three-in-one block)?
6. Describe the different ultrasound approaches to blocking the saphenous nerve above the knee.
7. What benefits might a saphenous nerve block above the knee provide compared to a femoral nerve block?
8. How would pain from a midthigh tourniquet dictate which peripheral nerve blocks to use in this patient? Describe the landmark technique of sciatic nerve block in the gluteal region. What is seen while performing an ultrasound technique to block the sciatic nerve?
9. Why does a popliteal nerve block have a high failure rate if performed too proximate to the popliteal fossa when using a landmark/nerve stimulator technique? Describe how this can be avoided when using ultrasound-based popliteal block.
10. What is the IPACK block? In what situations would this block be useful?

D. Postoperative Pain Management

1. Describe compartment syndrome and how that risk would influence your postoperative plan for peripheral regional analgesia.
2. How would the addition of dexamethasone to your local anesthetic influence the duration of the blocks placed in the OR?
3. What is liposomal bupivacaine?
4. What benefit would a peripheral nerve catheter provide over a long-acting local anesthetic? Are there any downsides?
5. You were able to perform a continuous spinal epidural (CSE) at L3–L4 and used 0.125% bupivacaine via epidural route for

postoperative pain control. The patient reports that he is comfortable regarding both his back pain and his ankle pain. What benefit would continuing the patient's methadone confer in this case?

6. How can regional analgesia aid in fast-track postoperative care?

A. Preoperative Evaluation

A.1. What is the Glasgow Coma Scale and its significance in this patient?

The Glasgow Coma Scale (Score) was developed as a practical structured assessment of consciousness in patients following acute brain trauma. The scale, first described in 1974 and later revised in 1979, scores three different components of responsiveness for a score range of 3 to 15. The levels of response include eye opening (none, to pressure, to speech, spontaneous), verbal response (none, sounds, words, confused, oriented), and best motor response (none, extension, abnormal flexion, normal flexion or withdrawal, localizing, obeying commands), with the worse response receiving a lower number. Generally, scores of 13 to 15 signify mild head injury, 9 to 12 as moderate, and 8 and below as severe. Components of the scale and the overall score seem to strongly correlate to outcome after acute brain injury. A baseline score should be established upon patient presentation, with a revised and more predictive score upon stabilization of respiratory, circulatory, and metabolic abnormalities.

Teasdale G, Maas A, Lecky F, et al. The Glasgow Coma Scale at 40 years: standing the test of time. *Lancet Neurol*. 2014;13:844–854.

A.2. Should surgery be allowed to proceed in this patient who has a subdural bleed?

Although the patient suffered acute brain trauma and appears stable, he remains at risk for sudden deterioration secondary to increased hematoma formation or cerebral edema. Following acute brain trauma, preservation of normal intracranial pressures and avoiding hypotension while maintaining cerebral perfusion pressure between 60 and 70 mmHg are essential to decrease poor outcomes. Subdural hematomas are the result of bleeding from bridging veins into the space between the dura and arachnoid. These can develop over the course of a few days and may often result from a seemingly benign injury or spontaneously. Patients will complain of a headache and often appear drowsy or obtunded. The diagnosis is via CT scan, and the patient can be managed conservatively or with surgical evacuation. Assuming the patient's medical condition does not change over the course of 24 to 48 hours, it would then be safe to proceed with repair of the ankle fracture.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:290–291.

A.3. Does the patient's atrial fibrillation need to be addressed prior to surgery, and if so, how?

This patient has preexisting paroxysmal atrial fibrillation. Prior to surgery, he should be asked if he knows when his last episode of atrial fibrillation was, if he has symptoms when it occurs, if he is typically rate controlled, if he has ever taken medications for rate control, and if he ever required a cardioversion or an ablation. Because these patients are more likely to have cardiac disease, a preoperative transthoracic echocardiogram in non-emergent cases is often helpful in evaluating cardiac and valvular functions. Although our patient's heart rate is controlled, consider the addition of a β-blocker or calcium

channel blocker in non–rate-controlled patients, as tolerated by their blood pressure. In addition to inquiring about our patient's last dabigatran (Pradaxa) use, discuss with the surgical team the plan for possible perioperative anticoagulation.

January CT, Wann LS, Alpert JS, et al. 2014 AHA/ACC/HRS guideline for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *Circulation*. 2014;130:e199–e267.

B. Preoperative Preparation

B.1. What is dabigatran (Pradaxa)? How is its effect measured? How far in advance of elective surgery should it be stopped? Can its effect be reversed?

Patients with atrial fibrillation will often take an oral anticoagulant to reduce their risk of stroke. Dabigatran etexilate (Pradaxa) is a direct thrombin (factor IIa) inhibitor that is among a group of drugs known as direct oral anticoagulants (DOACs). Unlike warfarin, DOACs are generally easier to manage and do not require laboratory monitoring, but until recently, specific reversal agents for these drugs did not exist. Thrombin activates factors V, VIII, and IX; helps convert fibrinogen to fibrin; and stimulates platelet aggregation. Dabigatran inhibits both free and clot-bound thrombin. It is a prodrug that is hydrolyzed by serum esterases into its active form. Peak plasma level occurs within 0.5 to 2 hours of administration, and its half-life is 12 to 17 hours in healthy patients and up to 28 hours in patients with end-stage renal disease. Eighty percent of the medication is excreted unchanged via the kidneys. In patients with normal renal function, the medication should be stopped 24 hours prior to

low-risk surgery and 48 hours prior to high-risk surgery. These time intervals are extended up to 4 times depending on the patient's renal impairment. In terms of anesthetic management, it is recommended that dabigatran be discontinued 120 hours (5 days) prior to neuraxial block. However, in patients with a normal creatinine clearance and no additional risk factors for bleeding (e.g., elderly patients, concomitant antiplatelet medications, hypertension), it may be appropriate to wait 72 hours (i.e., 4 to 6 half-lives) from cessation of dabigatran prior to neuraxial injection.

Prothrombin time (PT) and international normalized ratio (INR) cannot be used reliably to determine anticoagulation status in a patient receiving dabigatran. Although activated partial thromboplastin time (aPTT) has a nonlinear correlation to dabigatran plasma levels and can be used to provide some qualitative measure of anticoagulation status in emergency situations, there remains considerable variability between patients. The most sensitive assays to monitor quantitative dabigatran activity are thrombin time (TT) and dilute thrombin time (dTT), but the availability of these specialized tests may be limited. Idarucizumab (Praxbind) is a monoclonal antibody fragment that binds to dabigatran and can be used for the emergency reversal of life-threatening bleeding in patients on dabigatran. The recommended dose is 5 g via intravenous infusion. If idarucizumab is not available, activated prothrombin complex concentrate (PCC) or unactivated three-factor or four-factor PCC has been suggested for reversal of dabigatran associated bleeding. In addition, gastric lavage with activated charcoal within 2 hours of administration can be attempted. Ultimately, dialysis will remove the anticoagulant effects of dabigatran.

B.2. What concerns do you have regarding neuraxial anesthesia in this patient who has a subdural hematoma?

The sheering of bridging veins, generally at their thinnest point in the subdural space, is the likely etiology in the development of subdural hematomas associated with trauma and those associated with postdural puncture headaches and low cerebrospinal fluid (CSF) pressure. A review documented 46 cases of subdural hematoma, which developed following intentional dural puncture during spinal procedures or unintentional violation of the dura mater during epidural catheter placement. Given that this patient has already developed a subdural hematoma, neuraxial anesthesia would need to be undertaken with great care, and if done, a spinal should be avoided in favor of an epidural technique.

Zeidan A, Farhat O, Maaliki H, et al. Does postdural puncture headache left untreated lead to subdural hematoma? Case report and review of the literature. *Int J Obstet Anesth*. 2006;15:50–58.

B.3. What concerns do you have regarding neuraxial

anesthesia in this patient who has prior back surgery?

Neuraxial anesthesia should be considered with caution in this patient with a history of a lumbar fusion at L4–S1. Neuraxial anesthesia can be challenging in this patient population due to abnormalities of the usual landmarks, scar formation, presence of hardware, and bone grafts. These patients are at higher risk for false loss of resistance, inability to access the epidural or subarachnoid space, patchy and failed blocks, unintentional dural puncture, and traumatic needle placement. In a retrospective review of 937 patients with a history of spinal stenosis and/or lumbar disc disease, Hebl et al. showed that prior spinal surgery in 207 of the patients did not affect the block success rate or the frequency of complications. However, of the 207 patients, only 5 had prior spinal fusion. Care should be taken to confirm that the fusion is at the level that the patient reports. If available, imaging of the patient's spine should be reviewed to identify relevant anatomy, deformity, or surgical implants. In addition, ultrasound can be helpful in determining the best interspace, correct level, midline, and epidural space depth.

B.4. The surgeon is willing to wait a few days prior to surgery while the swelling around the injury decreases. When would you feel comfortable proceeding with surgery in this patient?

After assessing the patient's current medical status and prior medical history, an anesthetic plan of general, regional, or neuraxial should be considered. If choosing an anesthetic plan of neuraxial anesthesia or one involving deep regional blocks, the anticoagulation status of the patient must be taken into account. The most recent guidelines from the American Society of Regional Anesthesia and Pain Medicine (ASRA) recommend waiting 120 hours from the last dose of dabigatran prior to neuraxial block. However, these same guidelines also suggest that patients with stable renal function, creatinine clearance of 80 mL per minute or greater, and no other risk factors for bleeding need only wait 72 hours prior to neuraxial block. Otherwise, for a general anesthetic or superficial peripheral nerve block, surgery can proceed within 24 to 48 hours, assuming that his atrial fibrillation is stable with preserved cardiac function and that his mental status does not deteriorate secondary to his subdural hematoma.

C. Intraoperative Management

The patient presents to the operating room (OR) 72 hours after his injury. He was medically cleared for the ORIF of his right ankle. You have decided to proceed with a regional nerve block anesthetic technique.

C.1. What two nerve plexuses need to be blocked in this case? What nerve roots contribute to each plexus? Name the major nerves that come from each plexus.

Peripheral regional anesthesia for almost all major orthopedic surgery of the lower extremity involves blocking the whole or branches of both the lumbar and the lumbosacral plexuses. In broad terms, the lumbar plexus innervates the ventral aspect of the lower extremity, whereas the sacral plexus innervates the dorsal aspect. The lumbar plexus is made up of the ventral rami of L1–L3, part of L4, and, in 50% of patients, a branch from T12. The plexus is located within the psoas muscle, anterior to the transverse processes of the lumbar vertebra. The plexus gives off the iliohypogastric (T12–L1), ilioinguinal (L1), genitofemoral (L1–L2), lateral femoral cutaneous (L2–L3), femoral (L2–L4), and obturator nerves (L2–L4) (**Fig. 47.1**).

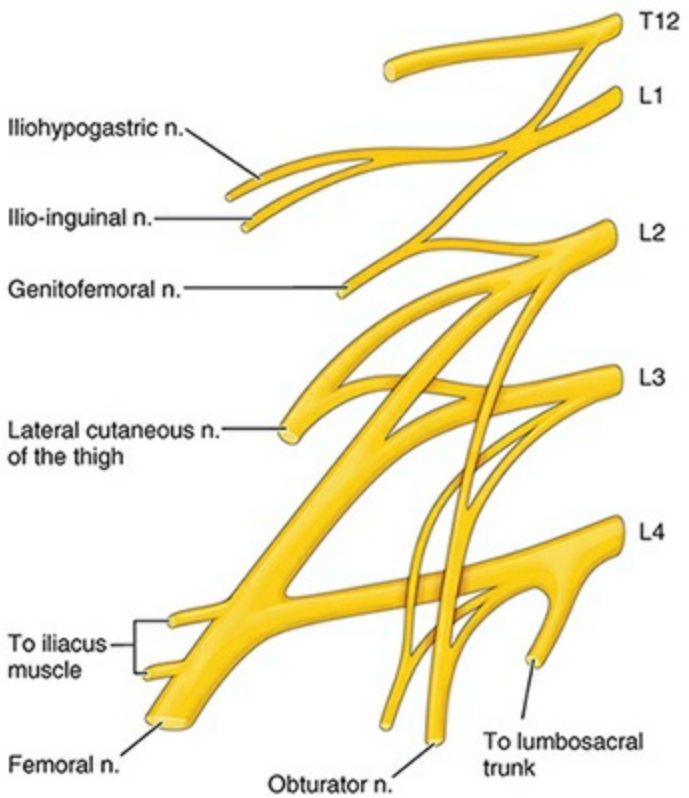

FIGURE 47.1. Lumbar plexus. (*From Drake RL, Vogl AW, Mitchell AWM*. Gray's Anatomy for

Students. *3rd ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2014: Fig. 4.160, 253–420, with permission*.)

The lumbosacral trunk is formed from ventral rami of L4 and L5 and the anterior branch of S1. The sacral plexus is composed of the union of the lumbosacral trunk with S1–S3 and occasionally S4. The sciatic nerve contains the tibial nerve, which is made up of the anterior divisions of the ventral rami of L4, L5, and S1–S3, and the common peroneal nerve, which is made of the dorsal branches of the same nerve roots. The sciatic nerve splits into the tibial and common peroneal nerves in the popliteal fossa. The common peroneal nerve branches into the superficial and deep tibial nerves. The tibial nerve branches into the medial plantar, calcaneal, and sural (with contribution from communicating superficial peroneal branches) nerves. Other nerves from the lumbosacral plexus include the superior gluteal (L4–S1), inferior gluteal (L5–S2), posterior femoral cutaneous (S1–S3), piriformis (S1–S2), obturator internus (L5, S1–S2), and quadratus femoris (L4–L5, S1) (**Fig. 47.2**).

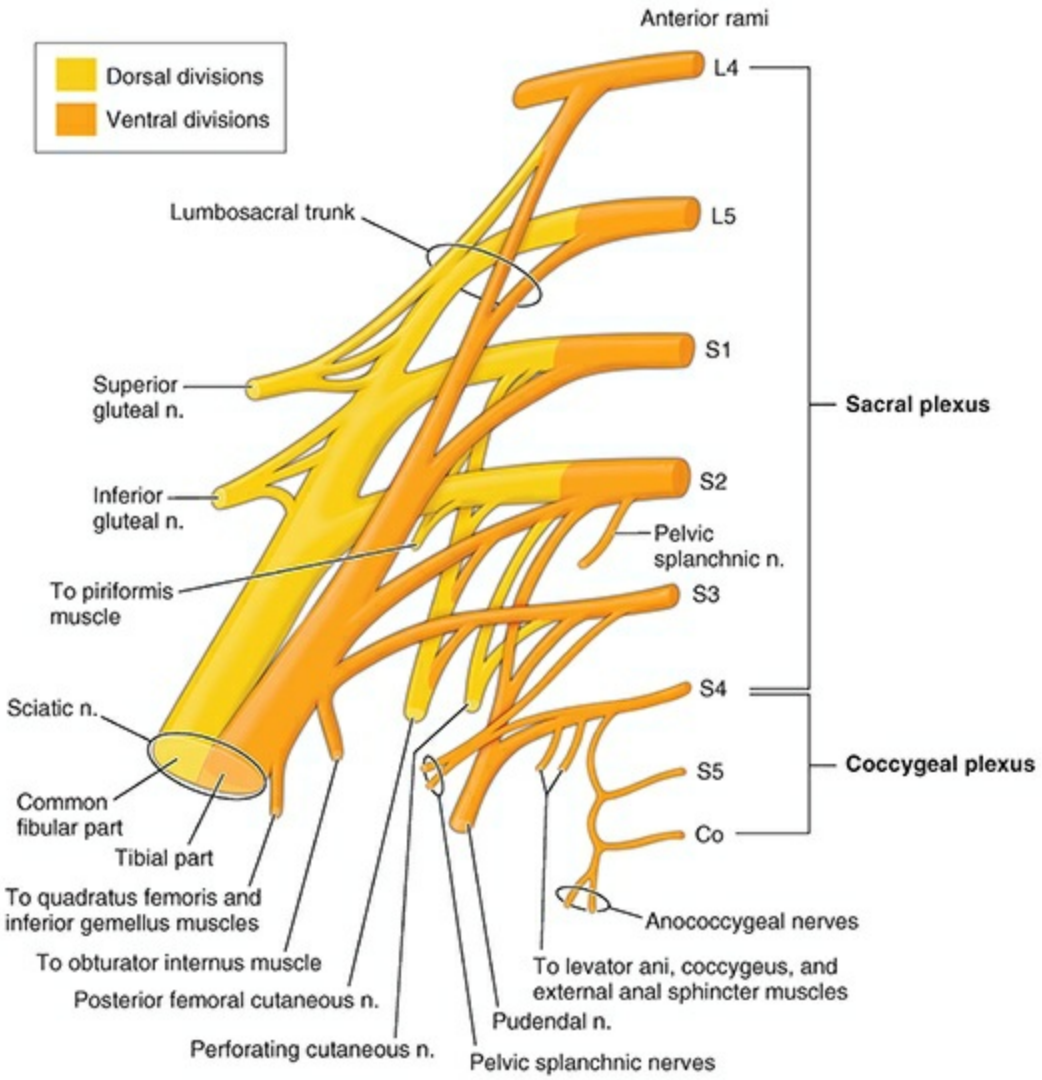

FIGURE 47.2. Sacral plexus.

Narouze SN, ed. *Atlas of Ultrasound-Guided Procedures in Interventional Pain Management*. New York: Springer; 2011:240–258.

C.2. What is the innervation to the medial and lateral aspects of the ankle? What nerves need to be blocked for his surgery?

Below the knee, the saphenous nerve provides innervation to the medial aspect of the lower extremity. The lateral aspect is innervated by the common peroneal nerve, with the tibial nerve providing innervation in the posterior aspect. The superficial peroneal nerve innervates the dorsal aspect of the foot, whereas the deep peroneal nerve provides innervation to the deep dorsal structures and the web space between the first and second digits. The sural nerve innervates the lateral aspect of the foot, whereas the calcaneal and medial plantar nerves innervate the plantar aspect of the foot.

In our case, to provide effective surgical anesthetic peripheral nerve blockade, both the medial and lateral aspects of the ankle would need to be anesthetized. Thus, the tibial, common peroneal, and the saphenous branch of the femoral nerve would require surgical blockade.

Narouze SN, ed. *Atlas of Ultrasound-Guided Procedures in Interventional Pain Management*. New York: Springer; 2011:240–258.

C.3. What nerves are blocked with an ankle block? Would you do an ankle block in this case?

The posterior tibial, deep and superficial peroneal, sural, and saphenous nerves require blockade for anesthesia of the foot. Typically, an ankle block is performed at the level of the medial and lateral malleoli. The posterior tibial nerve is blocked by inserting a fine needle along the medial aspect of the Achilles tendon at the level of the medial malleolus and advanced until the posterior tibia/medial malleolus is contacted (**Fig. 47.3**). Three to 5 mL of local anesthetic is deposited superficial to the periosteum. The deep peroneal nerve at the level of the malleoli

lies deep between the tendons of the tibialis anterior and the extensor hallucis longus (EHL). These tendons are identified by asking the patient to dorsiflex the big toe (EHL) and the foot (tibialis anterior). Another 2 to 3 mL of local anesthetic can be deposited here just superficial to the periosteum. The deep peroneal nerve can also be blocked distal to the level of the malleoli on the dorsum of the foot by injecting local anesthetic deep to the fascia lateral to the EHL and medial to the dorsalis pedis artery (**Fig. 47.4**). At the level of the malleoli, the needle can be redirected to block the branches of the superficial peroneal and saphenous nerves by making a subcutaneous ring across the dorsum of the foot using 5 to 10 mL of the anesthetic solution. The sural nerve can be blocked by inserting a needle lateral to the Achilles tendon at the level of the lateral malleolus. The needle is advanced until the periosteum is contacted and another 3 to 5 mL of local anesthetic is deposited superficial to the periosteum.

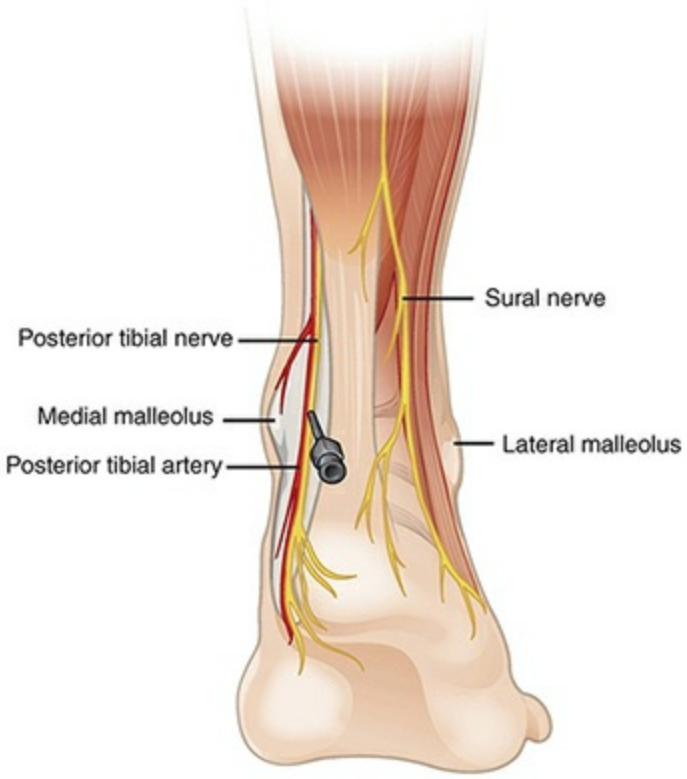

FIGURE 47.3. The posterior tibial nerve block.

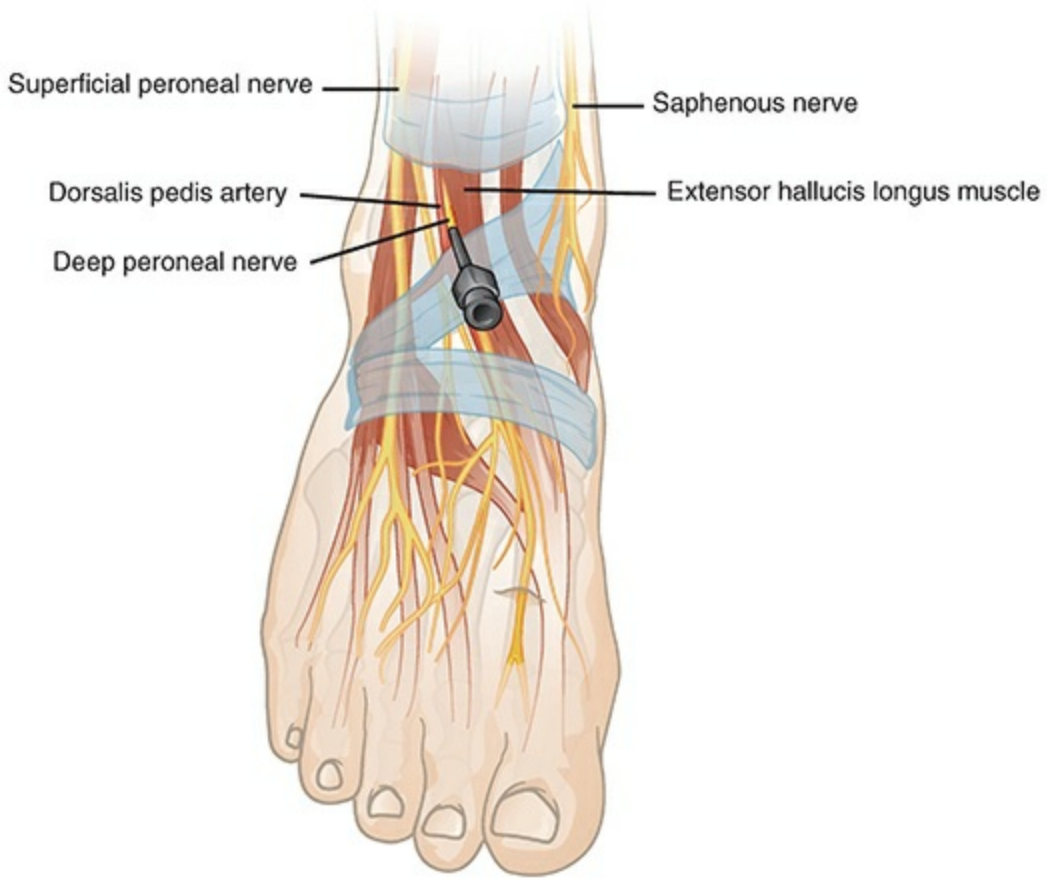

FIGURE 47.4. The deep peroneal nerve block.

Our patient would require anesthesia cephalad to the level of the malleoli, given that he has sustained a high ankle fracture. Thus, an ankle block would likely not provide adequate surgical anesthesia and should not be employed as the primary anesthetic in this case.

Sharrock NE, Waller JF, Fierro LE. Midtarsal block for surgery of the forefoot. *Br J Anaesth*. 1986;58:37–40.

C.4. Explain the posterior landmark technique to blocking the lumbar plexus. What motor response

would be elicited with a nerve stimulator? At what stimulation level would you feel safe injecting the patient? Why not at a lower level of stimulation? Can ultrasound guidance be utilized for this injection?

The posterior approach to the lumbar plexus block, also known as a psoas compartment block, is performed by injecting 20 to 40 mL of local anesthetic into a lumbar paravertebral location. For this injection, the patient should be in the lateral decubitus position. The classic approach was described by Winnie et al. at the L4 level using a paresthesia technique that can be modified with the use of a nerve stimulator. The point of puncture is at the intersection of the intercristal line (line joining the iliac crests) and a caudad-cephalad line that passes through the posterior superior iliac spine (PSIS) and is parallel to the spinal column. If the lumbar plexus is not located, the needle should be directed more medially. Mannion et al. recommended a medial needle redirection of no more than 15 degrees to reduce the risk of bilateral spread. Capdevila et al. described a modification of this approach by using a point of puncture at the lateral two-thirds of the distance between the spinous process and the PSIS and 1 cm above the intercristal line. The needle should be advanced in a perpendicular plane and contact made with the L4 transverse process. The needle should then be redirected caudally, until a quadriceps femoris twitch is obtained, usually at the depth of another 18 mm.

With the near ubiquitous use of ultrasound for peripheral nerve blocks, ultrasound can similarly be utilized to image the relevant anatomy and to guide needle placement in the lumbar plexus block. First described by Kirchmair et al., ultrasound technique allows for the visualization of the lumbar paravertebral region, which includes the psoas major muscle, erector spinae muscle, and quadratus lumborum muscle. For

most techniques, the block needle is advanced under ultrasound guidance to the posterior aspect of the psoas muscle. Because the lumbar plexus nerves cannot always be delineated within the psoas muscle, ultrasound-guided approaches are often combined with nerve stimulation.

Although inadvertent spinal anesthesia, intravascular injections, incorrect catheter placement, and renal and psoas hematoma have all been reported, the most common complication of a lumbar plexus block is inadvertent epidural anesthesia and bilateral spread. Motor stimulation should be elicited between 0.5 and 1.0 mA, as twitches evoked at lower currents may indicate needle placement in a dural sleeve, which might increase the risk of epidural or spinal spread.

C.5. What is a fascia iliaca block (three-in-one block)?

The femoral, lateral femoral cutaneous, and obturator nerves can be blocked separately (**Fig. 47.5**). The three-in-one block is a

large-volume block, first described by Winnie et al., intended as an anterior approach to block all three nerves with one needle. The intention is to provide analgesia to the anterior and lateral thigh, as opposed to only the anterior thigh, by blocking the femoral and lateral cutaneous nerves, which lay together under the iliacus fascia, as they travel through the pelvis. The fascia iliaca block has been shown to provide good pain relief in elderly patients with hip fractures, in post-hip surgery patients, and in anterior thigh and knee surgery.

Anatomically, the nerves of the lumbar plexus run posterior to the iliacus fascia. The fascia iliaca is continuous with the posterior aspect of the inguinal ligament, passes behind the femoral vessels, and laterally attaches to the anterior superior iliac spine. It is covered by the fascia lata and forms the top of a fat-filled space called the lacuna musculorum (lateral to the lacuna vasorum; the femoral vessels sheath). Using the landmark-based technique, a line, mimicking the inguinal ligament, is drawn from the pubic bone to the anterior superior iliac spine. The puncture site is 0.5 cm caudal to a point at the lateral two-thirds of that line. The anesthetic is injected on the second "give" or loss of resistance as needle passes through the fascia lata and fascia iliaca, with pressure caudad to the needle.

Although the landmark-based technique is quick and easy to perform, complete sensory block of the anterior, medial, and lateral aspects of the thigh increased from 47% with loss of resistance technique to 82% using ultrasound guidance.

One technique to an ultrasound-guided fascia iliaca block utilizes placement of the ultrasound probe in the transverse position, similar to the standard ultrasound-guided femoral nerve block. Once the femoral artery is located, the hyperechoic femoral nerve is identified lateral to that with the fascia iliaca running above it (**Fig. 47.6**). The probe is moved laterally, tracing the fascia iliaca until the sartorius muscle is identified

(Fig. 47.7). The needle is passed in-plane under the fascia iliaca and local anesthetic injected while the distal femoral sheath is compressed. For the second technique, the probe is placed in the sagittal plane above the iliac bone, located where the sartorius muscle and the external oblique muscle come together above the iliacus (Fig. 47.8). Injecting the local anesthetic under the fascia iliaca with the needle in plane in a cephalad direction at this location theoretically results in a more proximal spread of the anesthetic in the direction of the lumbar plexus. Unfortunately, the obturator nerve is not blocked reliably using either approach.

C.6. Describe the different ultrasound approaches to blocking the saphenous nerve above the knee.

The saphenous nerve is a sensory branch of the femoral nerve, which when blocked in combination with a sciatic nerve block, provides anesthesia for surgeries distal to the knee. Traditionally, this nerve was blocked via a subcutaneous wheel

of local anesthetics from the medial aspect of the tibial tuberosity to the anterior aspect of the tibia. The nerve lays lateral to the femoral artery while exiting the femoral triangle and then crosses over the roof of the adductor canal (subsartorial canal) and lays medial to the artery at the distal aspect of the adductor canal. The canal is bound anterolaterally by the vastus medialis muscle, anteriorly by the sartorius muscle, and posteromedially by the adductor magnus muscle. The saphenous nerve emerges from the adductor canal with the saphenous branch of the descending genicular artery and divides into the infrapatellar and sartorial branches. The sartorial branch courses through the fascia between the sartorius and gracilis muscles and emerges subcutaneously below the knee. Studies have proven ultrasound techniques to be quite reliable and effective in blocking this nerve, as the saphenous nerve emerges from the adductor canal. Just above the level of the knee, the nerve can be blocked between the sartorius and gracilis muscles in close proximity to the saphenous branch of the descending genicular artery. Krombach and Gray described blocking the saphenous nerve about 5 to 7 cm proximal to the popliteal crease, in the vastoadductor membrane (facial plane adjacent to the vastus medialis) deep to the sartorius muscle. Manickam et al. described blocking the saphenous nerve more proximally, in the distal adductor canal deep to the sartorius and anteromedial to the femoral artery (**Figs. 47.9** and **47.10**, **Video 47.1**).

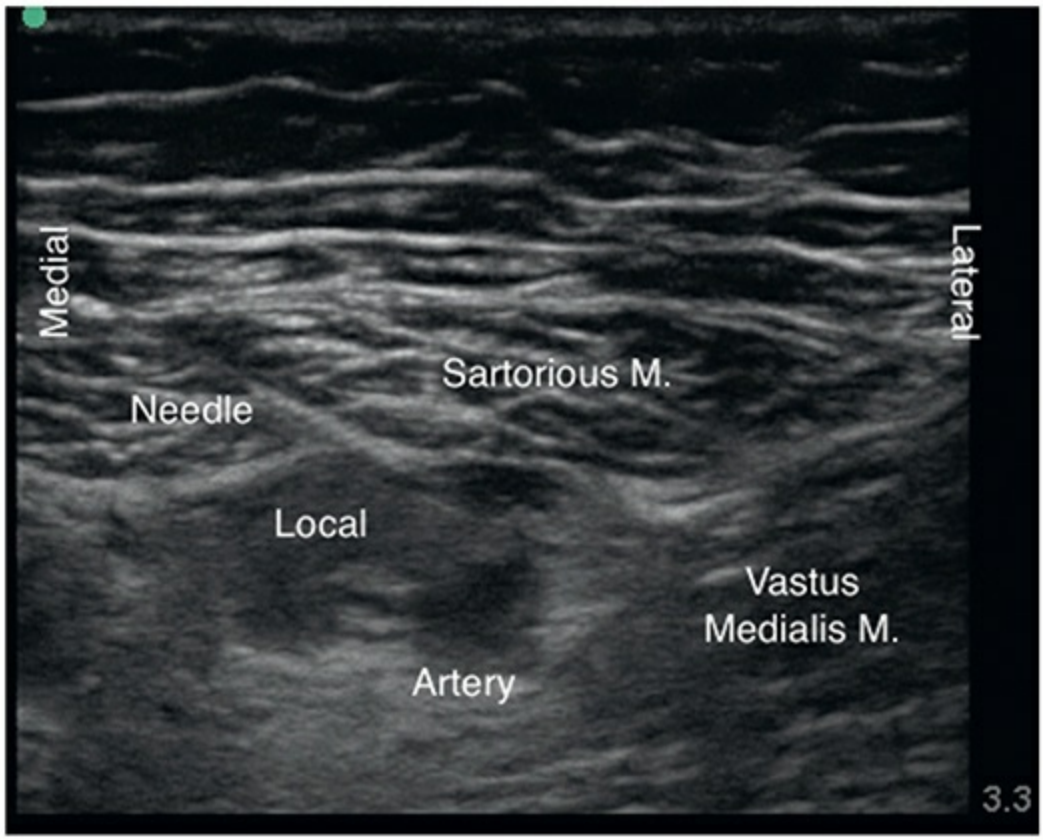

FIGURE 47.9. Post-periarterial saphenous nerve injection in the adductor canal.

C.7. What benefits might a saphenous nerve block above the knee provide compared to a femoral nerve block?

Femoral and saphenous nerve blocks have been shown to

provide effective analgesia at the level of the knee and below. However, as a femoral nerve block provides analgesia to all the branches of the femoral nerve, it confers significant motor blockade to the quadriceps and has been associated with a small risk of falls during postoperative ambulation. Ideally, in cases where early ambulation and mobilization is desired, such as "fast-track" joint replacements, an analgesic block with motor preservation would be advantageous. Studies have shown that adductor canal saphenous nerve block provides equivalent analgesia compared to femoral block with improved quadriceps function in cases of knee arthroscopy, as well as ACL repair. In a group of healthy volunteers, Jaeger et al. demonstrated that a saphenous nerve block in the adductor canal reduced quadriceps strength 8% from baseline, whereas a femoral nerve block caused a 49% reduction from baseline. Although 100% could mobilize after a saphenous nerve block, only about 50% were mobile following a femoral nerve block. A possible basis for improved strength is that analgesia decreases centrally mediated inhibition of voluntary muscle contraction. Although a midthigh saphenous nerve block in the adductor canal will often spread to the nerve to the vastus medialis (sensory and motor), there would be less reduction in quadriceps muscle strength compared to a femoral nerve block.

C.8. How would pain from a midthigh tourniquet dictate which peripheral nerve blocks to use in this patient? Describe the landmark technique of sciatic nerve block in the gluteal region. What is seen while performing an ultrasound technique to block the sciatic nerve?

A midthigh tourniquet will have implications in determining what blocks should be performed for lower extremity surgery. Although a tourniquet is used to decrease intraoperative blood loss, it occasionally has the unintended consequence of causing considerable pain in the thigh. The tourniquet is wrapped entirely around the leg and can affect both the femoral and sciatic nerves. Thus, it is important to block these nerves more proximal than at the adductor canal or the popliteal fossa. The mechanism of tourniquet pain is more complex than just secondary to pressure from the tourniquet and involves both unmyelinated C fibers and myelinated A fibers. The C fibers are more resistant to local anesthetic blockade, so when either neuraxial anesthesia or a regional block begins to wear off, or if they are incomplete to begin with, the C fibers will conduct resulting in the sensation of dull pain. This dull pain is experienced even with an “adequate” sensory block of the A fibers. C fibers are more readily blocked during general anesthesia, offering the lowest likelihood of tourniquet pain.

To perform a transgluteal sciatic nerve block with the landmark technique, the patient should be positioned in the lateral decubitus position with the leg to be blocked uppermost and flexed at the hip and knee. The landmarks are the greater trochanter and the PSIS. The distance between the greater

trochanter and the PSIS is measured, and the skin at 4 cm distal to the midpoint is marked as the insertion site. Alternatively, that point lies on a line from the greater trochanter to the sacral hiatus (**Fig. 47.11**). Once this site is located and the skin is prepped, the block needle is introduced at 90 degrees to the skin. Using a nerve stimulator, muscle twitches of the gluteal muscles are initially seen, and with further advancement, hamstring or calf twitches are seen. Ideally, the twitch remains at about 0.2 to 0.5 mA, indicating appropriate closeness to the nerve. When negative aspiration is confirmed, the local anesthetic of choice can then be injected.

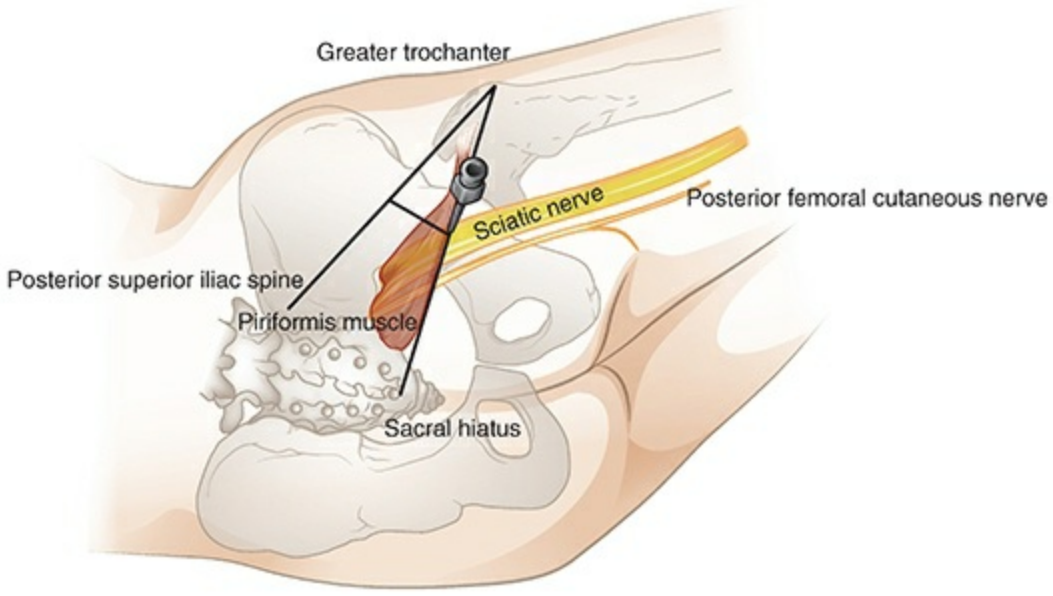

FIGURE 47.11. Sciatic nerve block, the Labat approach.

When utilizing an ultrasound-guided subgluteal approach, the nerve can be visualized between the ischial tuberosity and the greater trochanter. The patient is positioned either in the prone or lateral decubitus position; again, the leg and knee are flexed. Once the skin is cleaned, the curved transducer probe is placed over the skin. The nerve will be visualized between the two osseous structures, frequently described as being in a

"hammock" under the gluteus muscle. The local anesthetic solution will usually push the nerve away and actually improve the visualization of the nerve.

C.9. Why does a popliteal nerve block have a high failure rate if performed too proximate to the popliteal fossa when using a landmark/nerve stimulator technique? Describe how this can be avoided when using ultrasound-based popliteal block.

The landmark technique for performing a popliteal fossa block involves delineating the biceps femoris tendon, the semitendinosus and semimembranosus tendons, as well as the popliteal fossa crease. Needle insertion is at a point 7 cm above the popliteal crease at the midpoint between the lateral and medial tendons. Although this technique will work for a large majority of patients, a high failure rate does occur as a significant portion of the population has variant anatomy where the division of the sciatic nerve into the common peroneal nerve and the tibial nerve occurs more proximal to the level of the needle insertion point (**Fig. 47.12**). Thus, an incomplete blockade could occur if only one branch of the sciatic nerve is effectively blocked. The use of an ultrasound-guided technique allows for visualization of the nerve and the exact location of the division helping prevent such failure (**Fig. 47.13**, **Video 47.2**).

C.10. What is the IPACK block? In what situations would this block be useful?

IPACK stands for infiltration between the popliteal artery and the capsule of the knee. The IPACK block provides analgesia to the posterior compartment of the knee by anesthetizing the medial and lateral superior genicular nerves. It is typically performed under ultrasound guidance by first identifying the popliteal artery just proximal to the level of the femoral condyles (Fig. 47.14). The needle is placed between the popliteal artery and the femur in close proximity to the periosteum and 20 to 25 mL of local anesthetic is infiltrated in

the area and also as the needle is withdrawn (**Fig. 47.15**).

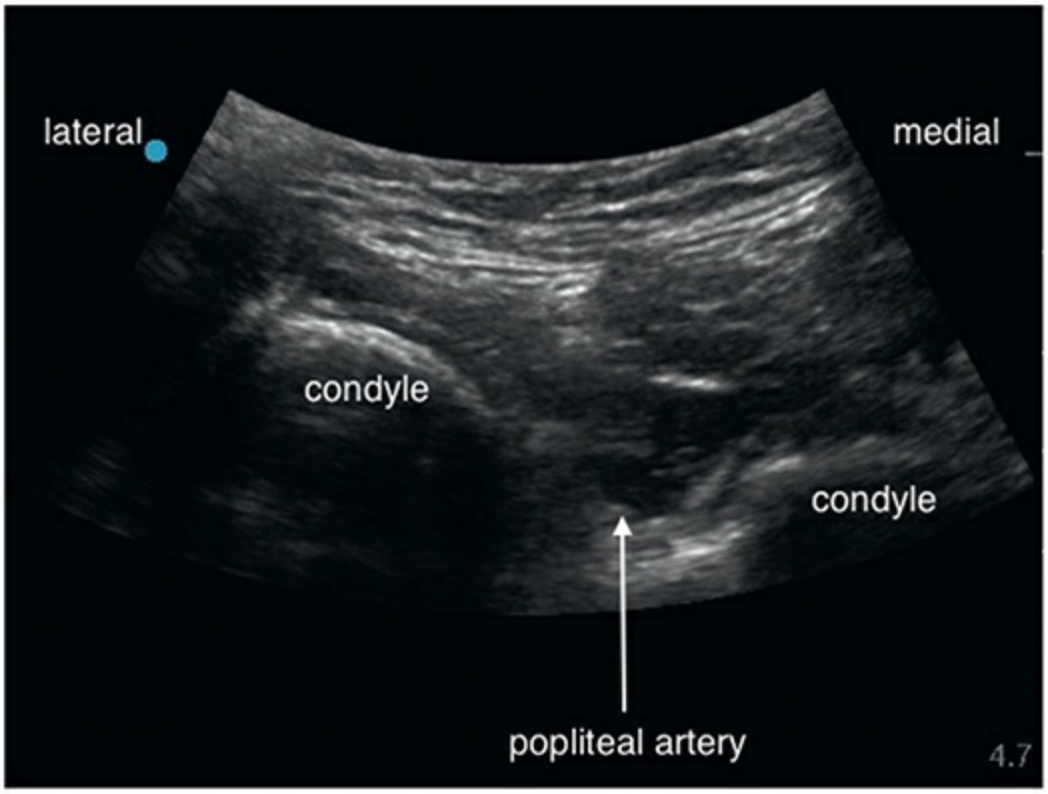

FIGURE 47.14. IPACK block—scanning at the level of the femoral condyles.

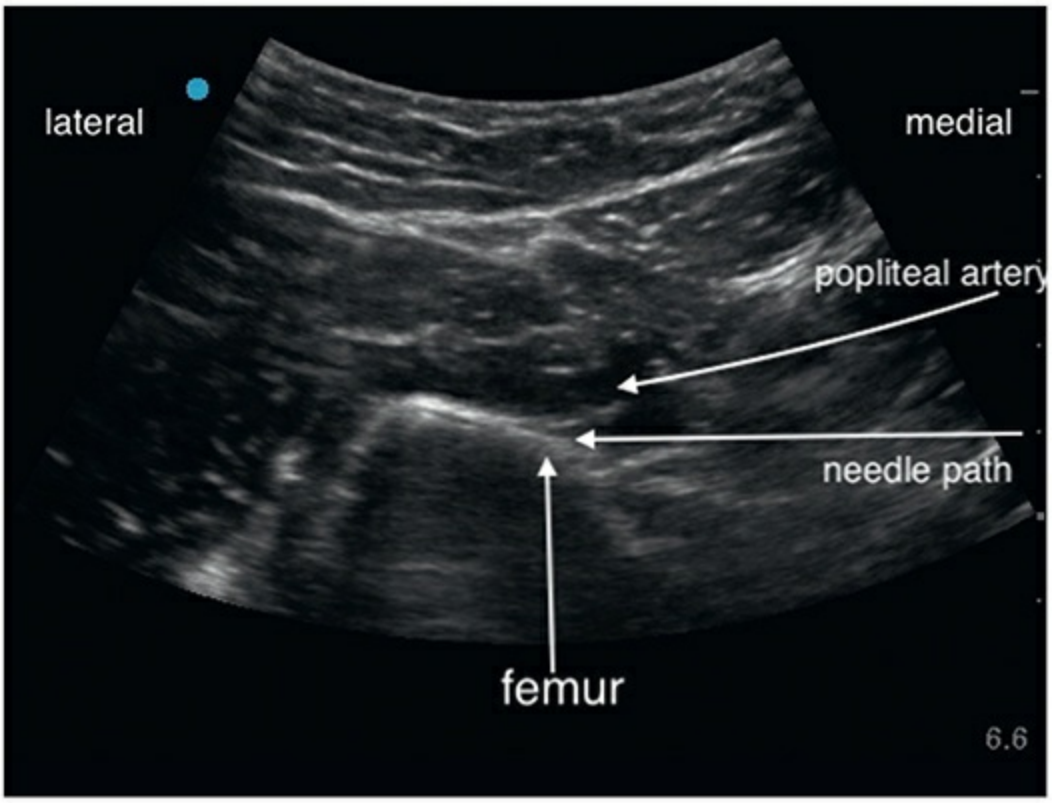

FIGURE 47.15. IPACK injection—location of IPACK injection between the popliteal artery and the femur, proximal to the femoral condyles.

The IPACK block is increasingly being used in conjunction with an adductor canal block to provide pain control after total knee arthroplasty (TKA) in the setting of "fast-track" recovery protocols. Although a sciatic block can also provide analgesia to the posterior knee, it is associated with significant motor block of the foot and ankle, delaying early mobilization after surgery and potentially masking a surgical injury to the peroneal nerve, which is not uncommon after TKA. Therefore, much like the adoption of the saphenous nerve block over the femoral nerve block, the IPACK block is being increasingly incorporated as a motor-sparing peripheral nerve block to enhance recovery after TKA. In a randomized trial of 86 patients undergoing TKA, Kim et al. demonstrated that the addition of the IPACK and adductor canal block significantly improved postoperative analgesia and reduced opioid consumption compared to periarticular injection

by the surgeon alone.

D. Postoperative Pain Management

D.1. Describe compartment syndrome and how that risk would influence your postoperative plan for peripheral regional analgesia.

Compartment syndrome develops when there is an increase in pressure within a fixed compartment. Patients often have a collection of signs and symptoms including pain out of proportion to the injury, paresthesia, pallor, decreased sensation, weakness, and a late finding of paralysis. It is typically seen after trauma, especially long bone fractures, and specifically after any injury that increases the volume of a compartment of limited size. Tibial fractures are the most common cause, with an incidence of 1% to 10%. The pathophysiology has been described as cellular anoxia due to the inability of the blood flow in an injured area to meet the metabolic demands of local tissue. The resultant swelling and obstruction to venous outflow further decreases the arteriovenous gradient.

The use of regional anesthesia in patients at risk for compartment syndrome remains controversial. Theoretically, neuraxial blockade could prevent recognition of an acute compartment syndrome. Case reports have shown that signs and symptoms of acute compartment syndrome were present in

patients given high concentrations of local anesthetic for neuraxial analgesia but that the significance of the symptoms were not appropriately recognized. Other case reports have demonstrated that patients with dense motor and sensory blocks who are later diagnosed with acute compartment syndrome still reported severe pain in the distribution of the peripheral nerve block. A recent systematic review article concluded that regional anesthesia does not increase the risk of delayed diagnosis of compartment syndrome. Still, one should consider the risks of compartment syndrome, the exact location of the fracture, positioning during surgery, and the benefits of a regional anesthetic in this patient, taking into account his chronic pain issues.

D.2. How would the addition of dexamethasone to your local anesthetic influence the duration of the blocks placed in the OR?

The addition of dexamethasone to local anesthetic for peripheral nerve blockade has been shown to increase the duration of blockade. When dexamethasone is added to bupivacaine or ropivacaine 0.5%, the duration of sensory block increases from approximately 12 to 24 hours. There is some evidence that

giving an equivalent dose of intravascular dexamethasone concomitant to the block will prolong the duration of the sensory block to 24 hours. Recent meta-analysis has shown that perineural dexamethasone prolongs analgesia by 3.77 hours with a slight decrease of opioid consumption when compared with intravascular dexamethasone while providing a similar duration of prolonged motor blockade.

D.3. What is liposomal bupivacaine?

Liposomal bupivacaine is a slow-release form of the local anesthetic bupivacaine that has U.S. Food and Drug Administration (FDA) approval to be used for local infiltration and, most recently, for interscalene block to decrease postoperative pain. Each liposome has internal chambers with encapsulated bupivacaine that are released over an extended period of time. Some studies reported a duration of blockade of up to 72 hours as part of a peripheral or neuraxial technique, giving promise that this agent can be a potential substitute for the peripheral catheter. There has been evidence showing modest improvements in pain scores and patient satisfaction using liposomal bupivacaine compared to bupivacaine alone for major shoulder surgery.

D.4. What benefit would a peripheral nerve catheter provide over a long-acting local anesthetic? Are there any downsides?

Peripheral nerve catheters are a proven method for prolonging postoperative pain control with decreased intravenous or oral opioid use and hence their related side effects. They also have been shown to decrease the incidence and/or severity of chronic postsurgical pain syndromes. A peripheral nerve catheter gives patients the ability to have some control over their own pain management. As compared with long-lasting single-shot injections with additives, a catheter technique could provide analgesia beyond the first 24 hours, which is essentially the limit of duration of a single-shot block, aside from the use of liposomal bupivacaine. As compared to a long-lasting single-shot injection, peripheral catheters can be stopped and/or removed if needed. Peripheral nerve catheters are increasingly being used in the ambulatory and outpatient settings, with patients being discharged to home with an infusing peripheral nerve catheter in place. Large studies continue to show a low-risk profile with the use of at-home patient management of catheters. Some limitations to the placement of peripheral nerve catheters include the risk of infection, technical challenges inherent in their placement, time of placement, and the need for their management and supervision by anesthesiologists and other health care providers. Other risks of peripheral nerve catheters include damage to the nerve itself from direct contact

or nerve entrapment, damage to nearby structures, and intravascular placement and migration. Although these risks are recognized and need to be monitored, a recent comprehensive review article reports them to be exceedingly rare. Although there are no studies, at this time, directly comparing the use of peripheral nerve catheters to liposomal bupivacaine, the recent FDA approval of liposomal bupivacaine for interscalene block will add another dimension to the ongoing discussion regarding peripheral nerve catheters.

D.5. You were able to perform a continuous spinal epidural (CSE) at L3–L4 and used 0.125% bupivacaine via epidural route for postoperative pain control. The patient reports that he is comfortable regarding both his back pain and his ankle pain. What benefit would continuing the patient's methadone confer in this case?

The use of chronic opioid regimens for patients suffering from chronic nonmalignant pain has increased dramatically over the past two decades. Acute postoperative pain control in patients who are taking maintenance opioids for addiction and dependence presents a challenge for health care providers. Studies have shown that these patients require opioid doses that are multiples of the doses needed by patients not exposed to

opioids chronically. Aside from tolerance to opioids, these patients often exhibit increased pain to surgical stimuli, when compared to an opioid-naive population. This may be secondary to increased anxiety and depression, the development of opioid-induced hyperalgesia, and changes in the endogenous opioid system. Multimodal analgesia, including regional techniques and nonopioid adjuvants, such as ketamine, nonsteroidal anti-inflammatory drugs, gabapentinoids and acetaminophen, greatly aid in controlling their pain postoperatively. Nonetheless, continuation of maintenance opioids (50% to 100%) is essential to avoid withdrawal symptoms. Approaches to maintaining opioid levels include continuation of the same preoperative opioid and route, changing the route of administration while continuing the same opioid, or using an equianalgesic conversion to a different opioid with a likely dose reduction secondary to lack of 100% cross tolerance. In addition, patients should generally receive their usual dose of opioids prior to surgery. Withdrawal from methadone may present 12 to 24 hours after the last doses, whereas withdrawal from medications such as morphine may fall within 6 to 18 hours. Withdrawal syndrome can present with agitation, diaphoresis, hypertension, diarrhea, nausea, emesis, abdominal cramps, and even seizures.

D.6. How can regional analgesia aid in fast-track postoperative care?

Fast-track programs are used to help decrease morbidity by

decreasing perioperative hospitalization. Both neuraxial and peripheral blockade can be utilized as an effective modality to aid in fast-track programs. Regional anesthesia can attenuate the inflammatory, endocrine, and metabolic responses to surgical stress and thus decrease perioperative complications. The blockade of the sympathetic response helps with improved blood flow, decreased thromboembolic events, and decreased blood loss. It also tempers the shivering response, which can potentially prolong postanesthetic care unit stays. Regional techniques can be used to minimize inhalational agents, muscle relaxants, and opioids with a resultant earlier awakening from general anesthesia or complete avoidance of general anesthesia. It improves immediate postoperative analgesia and has been shown to decrease the risk of infection. In addition, there is often earlier return of bowel function. Specifically, for lower extremity surgery, regional anesthesia can improve patient satisfaction with decreasing time to home readiness, opioid consumption, pain scores, time to ambulation, and postoperative nausea and vomiting. Regional anesthesia is the cornerstone of the new movement toward total joint replacement in the ambulatory setting.

48 Complex Regional Pain Syndromes

Mohammad M. Piracha, Neel D. Mehta, Sudhir A. Diwan, and Vinod Malhotra

A 35-year-old woman complains of diffuse burning pain in the left arm and hand for the last 6 months. She recalls spraining her left wrist while playing volleyball. Her left hand feels colder than the right, and her fingertips are blue. She is a recently divorced high-profile executive.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of pain in this patient?
2. What is complex regional pain syndrome (CRPS)?
3. What are the two types of CRPS?
4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?
5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.
6. What are the stages of CRPS?
7. What are the possible etiologies of CRPS?
8. Explain the pathophysiology of the development of CRPS.
9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).

10. How does CRPS differ from neuralgia?
11. What is central pain? How will you differentiate central pain from CRPS?
12. Is the social history of this patient relevant to the development of chronic pain syndrome?

B. Pain Management

1. How will you work up CRPS types I and II?
2. Describe the sympathetic nerve supply to the arm?
3. Where is the stellate ganglion located?
4. What are the anatomic landmarks used in the stellate ganglion block?
5. What are the clinical signs of stellate ganglion block?
6. What is Horner syndrome?
7. After a stellate ganglion block, this patient reports no significant change in the degree of pain despite developing Horner syndrome. Is the pain psychogenic in this patient?
8. What types of nerve fibers are interrupted in stellate ganglion block?
9. What is a differential block?
10. What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.

17. What roles does ketamine infusion play in the treatment of CRPS? Is there a guideline for ketamine infusion in treating CRPS?
18. What is neuromodulation? What is the role of spinal cord stimulation (SCS) in treating CRPS?
19. What is the role of surgical sympathectomy?
20. What role does intrathecal (IT) therapy play in managing CRPS?
21. If opioids are prescribed as treatment for CRPS patients, what is the Centers for Disease Control and Prevention (CDC) guideline of chronic opioid therapy?

C. Complications

1. What are the complications of stellate ganglion block?
2. What is the systemic toxicity of local anesthetics?
3. How do you treat the systemic toxicity of local anesthetic drugs?
4. What are the possible complications of SCS?
5. What are the possible complications of IT therapy?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of pain in this patient?

Pain accompanied by burning and temperature change in this patient is most likely due to CRPS. The differential diagnosis may also include the following:

1. Peripheral neuropathy
2. Soft tissue injury
3. Vascular insufficiency (Raynaud disease)
4. Nerve entrapment syndrome (carpal tunnel syndrome)
5. Brachial plexopathy

Over the years, CRPS has been referred to as *reflex*

sympathetic dystrophy (RSD), causalgia, SMP, and chronic peripheral pain syndrome. The term *CRPS* was introduced in 1994 by the International Association for the Study of Pain subcommittee on taxonomy. It is subdivided into CRPS type I (formerly described as *RSD*) and CRPS type II (formerly described as *causalgia*).

Dutton K, Littlejohn G. Terminology, criteria, and definitions in complex regional pain syndrome: challenges and solutions. *J Pain Res*. 2015;8:871–877.

Stanton-Hicks MD. CRPS: what's in a name? Taxonomy, epidemiology, neurologic, immune and autoimmune considerations. *Reg Anesth Pain Med*. 2019;44:376–387.

A.2. What is complex regional pain syndrome (CRPS)?

CRPS is characterized by pain associated with sensory, autonomic, trophic, and motor abnormalities. CRPS is triggered by *noxious stimuli* (type I) or by *nerve injury* (type II). It is not limited to the distribution of a single peripheral nerve and is disproportionate to the inciting event.

RSD, causalgia, algodystrophy, Sudeck atrophy, and various other conditions are all grouped under CRPS. This diagnosis better describes the wide range of clinical signs and symptoms and the complexity of the pathophysiology responsible for the clinical picture.

Dutton K, Littlejohn G. Terminology, criteria, and definitions in complex regional pain syndrome: challenges and solutions. *J Pain Res*. 2015;8:871–877.

Stanton-Hicks MD. CRPS: what's in a name? Taxonomy, epidemiology, neurologic, immune and autoimmune considerations. *Reg Anesth Pain Med*. 2019;44:376–387.

A.3. What are the two types of CRPS?

CRPS-I is defined as a clinical syndrome triggered by a *noxious stimulus* that is not limited to the distribution of a single peripheral nerve; no nerve lesion can be identified. CRPS-II is

defined as a clinical syndrome that is due to a *nerve injury* and is mostly limited to the distribution of the injured nerve. The diagnostic criteria are the same for CRPS-I and II.

Marinus J, Moseley GL, Birklein F, et al. Clinical features and pathophysiology of complex regional pain syndrome. *Lancet Neurol*. 2011;10:637–648.

Stanton-Hicks MD, Burton AW, Bruehl SP, et al. An updated interdisciplinary clinical pathway for CRPS: report of an expert panel. *Pain Pract*. 2000;2(1):1–16.

A.4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?

The diagnosis of CRPS can be made in the following context: a history of trauma to the affected area associated with pain that is disproportionate to the inciting event plus one or more of the following as defined by either the Orlando criteria or a modified version referred to as the Budapest criteria.

- Abnormal function of the sympathetic nervous system (vasomotor changes, skin color changes)
- Swelling
- Movement disorder
- Changes in tissue growth (dystrophy and atrophy)
- Sensory disturbances (hyperalgesia or allodynia)

The main features include pain that is continuous, burning in nature, independent of type and severity of injury, and not limited to a dermatomal distribution. Patients may complain of allodynia, dysesthesia, or hyperalgesia. Movement or stress exacerbates pain. Edema is usually present. Abnormal sudomotor activity, limb discoloration, and local temperature changes are common but inconsistent.

It affects between 200,000 and 1.2 million Americans. This syndrome may follow as many as 5% of all traumatic injuries with the arms being affected in approximately 60% of cases and the legs about 40%.

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:314–331.

Marinus J, Moseley GL, Birklein F, et al. Clinical features and pathophysiology of complex regional pain syndrome. *Lancet Neurol*. 2011;10:637–648.

A.5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.

- *Allodynia*: pain caused by a stimulus that normally does not provoke pain (i.e., touching with a cotton swab)
- *Hyperalgesia*: an increased response to a stimulus that is normally painful (i.e., increased response to pinprick)
- *Hyperesthesia*: increased sensitivity to a stimulus either due to a diminished threshold or an increased response to stimuli that are normally recognized. Hyperesthesia includes both allodynia and hyperalgesia.
- *Dysesthesia*: an abnormal sensation that is unpleasant to the patient. It may be either spontaneous or evoked (i.e., lumbar radiculopathy).

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:314–331.

A.6. What are the stages of CRPS?

Stage I

- Onset of severe pain limited to the site of injury
- Increased sensitivity of skin to touch and light pressure (hyperesthesia)
- Localized swelling
- Muscle cramps
- Stiffness and limited mobility

At the onset, the skin is usually warm, red, and dry; then it may change to blue (cyanotic) in appearance and become cold and sweaty.

- Increased sweating (hyperhidrosis)

- In mild cases, this stage lasts a few weeks and then subsides spontaneously or responds rapidly to treatment.

Stage II

- Pain becomes even more severe and more diffuse.
- Swelling tends to spread and it may change from a soft to hard (brawny) type.
- Hair may become coarse then scant; nails may grow faster and become brittle, cracked, and heavily grooved.
- Spotty wasting of bone (osteoporosis) occurs early but may become severe and diffuse.
- Muscle wasting begins.

Stage III

- Marked wasting of tissue (atrophic) eventually becomes irreversible.
- For many patients, the pain becomes intractable and may involve the entire limb.
- A small percentage of patients have developed generalized CRPS affecting the entire body.

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:314–331.

A.7. What are the possible etiologies of CRPS?

CRPS may follow relatively minor trauma with or without nerve injury. Causes leading to CRPS include the following:

- Injuries to peripheral tissues (e.g., fractures, dislocations, and postoperative state)
- Inflammatory conditions (e.g., fasciitis, tendonitis, bursitis, and arthritis)
- Immobilization as a result of injury or cast application
- Peripheral nerve injury resulting from direct compression or ischemia (e.g., brachial plexopathy, postherpetic neuralgia, and nerve root injury)

- Central nervous system insults (e.g., head injury, ischemia, and brain tumor)
- Spinal cord lesions
- Idiopathic

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:314–331.

A.8. Explain the pathophysiology of the development of CRPS.

Several hypotheses have been postulated, but none can explain all the findings and the varying responses to treatment in these patients. These hypotheses include the following:

- Abnormal discharges in sympathetic and nociceptive afferents produced by trauma
- Sensitization of peripheral sensory receptors produced by sympathetic hyperactivity
- Formation of ephapses (artificial synapses) after peripheral nerve injury
- Spontaneous neuronal ectopy at the site of demyelination or axonal injury
- Central reorganization of pain processing (central sensitization)

More than one sequence of events likely take place in a patient, giving rise to a mixed clinical picture. A dynamic change in the physiology and structure of central pain projecting neurons mediated through the *N*-methyl-D-aspartate (NMDA) receptor. Injury initiates and maintains a state of central sensitization in the central pain pathways, resulting in a lower threshold to fire pain transmission neurons and an increase in their receptive fields. This may involve disinhibition of spinal and trigeminal nociceptive neurons. This often precedes thermal and mechanical allodynia and spontaneous pain. Finally, the psychological component and neuromodulation cannot be

discernibly separated.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Marinus J, Moseley GL, Birklein F, et al. Clinical features and pathophysiology of complex regional pain syndrome. *Lancet Neurol*. 2011;10:637–648.

McMahon SB, Koltzenburg M, Tracey I, et al, eds. *Wall and Melzack's Textbook of Pain*. 6th ed. New York: Churchill Livingstone; 2013:961–977.

A.9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).

The pain that is maintained by sympathetic innervation or circulating catecholamines is defined as SMP. It describes a pain mechanism, not a clinical syndrome. Therefore, by definition, patients with CRPS who report pain relief after a sympathetic block (e.g., stellate ganglion block) have SMP. Conversely, pain conditions that show features of sympathetic overactivity, yet fail to respond to sympathetic blocks, are described as SIP.

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:314–331.

A.10. How does CRPS differ from neuralgia?

The chronic pain seen in neuralgia is usually paroxysmal in nature and follows the distribution of nerve. The pain is sharp and shooting without associated vasomotor or sudomotor changes. The chronic pain syndrome of CRPS is a sustained, diffuse, burning pain that is independent of nerve distribution and is associated with vasomotor and sudomotor changes, edema, allodynia or hyperalgesia, and changes in skin color.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

A.11. What is central pain? How will you differentiate central pain from CRPS?

Central pain is regional pain initiated or caused by a primary lesion or dysfunction in the central nervous system; it is usually associated with abnormal sensitivity to temperature and to noxious stimulus. Central pain, also referred to as *deafferentation pain*, is a difficult pain syndrome to treat because the pathophysiology is not well understood. Regional pain not relieved by peripheral nerve blocks, either sympathetic or somatic, is more likely to be central pain. Central pain may be associated with various neurologic symptoms and signs such as monoparesis, hemiparesis, or paraparesis. Central pain conditions typically include partial or complete loss of sensation, involvement of spinothalamic functions, and development of hypersensitivity in body parts that have loss normal somatosensory feedback as a result of a central nevous system lesion.

Abram SE, Haddox JD, eds. *The Pain Clinic Manual*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000:253–259.

McMahon SB, Koltzenburg M, Tracey I, et al, eds. *Wall and Melzack's Textbook of Pain*. 6th ed. New York: Churchill Livingstone; 2013:990–1002.

A.12. Is the social history of this patient relevant to the development of chronic pain syndrome?

In patients with CRPS, the disproportionate pain and dysfunction and the absence of clear pathogenesis and pathophysiology have led to examination of potential psychological etiology. Also noted is the fact that as the CRPS progresses, patients' personality measures such as Minnesota Multiphasic Personality Inventory (MMPI) profiles tend to resemble those of patients experiencing chronic pain and psychological distress as evidenced by hypochondriasis, depression, and hysteria scales. Certainly, stress has been implicated in increasing sympathetic outflow. The literature suggests that the presence of psychological disorders,

particularly anxiety and depression, may predispose the patient to the development of CRPS. However, a large case-control study reported no differences in psychological variables between those with CRPS and those without CRPS after controlling for age, sex, and trauma. Furthermore, anxiety and stress can augment nociception, and therefore, antidepressive treatments can be useful.

B. Pain Management

B.1. How will you work up CRPS types I and II?

CRPS is diagnosed clinically with a detailed history and physical examination. Because it is a clinical diagnosis of exclusion, other specific conditions that could account for the degree of pain and dysfunction must be ruled out. Objective signs are variable but almost universally include loss of function of the affected part due to pain. Allodynia and hyperalgesia are extremely common. Change in temperature and sweating may vary depending on the stage of the disease. Several diagnostic studies may aid in the diagnosis of CRPS but are seldom pathognomonic.

A quantitative sweat test may show excessive sweating, and thermography may demonstrate abnormal heat regulation and disparity in temperature between affected and normal regions. Radiologic studies may reveal patchy osteoporosis in early stages. Triple-phase bone scintigraphy using technetium-99m

may show increased periarticular uptake in the affected extremity illustrated by unilateral hyperperfusion in the perfusion and blood pool phases. Negative triple-phase bone scan results do not rule out CRPS. Thermographic, radiologic, or scintigraphic findings can be nonspecific and should be correlated with the clinical findings. Positive diagnostic sympathetic blocks can confirm the sympathetically mediated component of CRPS.

McMahon SB, Koltzenburg M, Tracey I, et al, eds. *Wall and Melzack's Textbook of Pain*. 6th ed. New York: Churchill Livingstone; 2013:990–1002.

Stanton-Hicks MD. CRPS: what's in a name? Taxonomy, epidemiology, neurologic, immune and autoimmune considerations. *Reg Anesth Pain Med*. 2019;44:376–387.

B.2. Describe the sympathetic nerve supply to the arm?

The preganglionic sympathetic outflow to the upper extremity is derived from T2–T9. These fibers synapse with postganglionic neurons in the stellate ganglion. Therefore, a stellate ganglion block interrupts sympathetic outflow to the upper extremity.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

B.3. Where is the stellate ganglion located?

The stellate ganglion is formed by the fusion of the inferior cervical and the first thoracic ganglia. It usually measures 2.5 cm × 1.5 cm × 0.5 cm and lies between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib. It is situated behind the carotid sheath, ventral to the longus colli muscle, behind the vertebral artery, and lateral to the body of the vertebra. The vertebral, subclavian, inferior thyroid, and the first intercostal arteries are in close proximity to the ganglion and so is the recurrent laryngeal nerve. The left pleura is 1 to 2 cm below it, whereas the right pleura is in closer proximity.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2416.

B.4. What are the anatomic landmarks used in the stellate ganglion block?

The landmarks used in the stellate ganglion block are the jugular notch of the sternum, the sternocleidomastoid muscle, the cricoid cartilage, and Chassaignac tubercle. In a supine patient with the neck extended, a mark placed approximately 3.5 cm from the midline along the jugular notch and the same distance above the clavicle should overlie the transverse process of the seventh vertebra and the medial border of the sternocleidomastoid muscle. This marking is further confirmed by palpating the cricoid cartilage, which lies at the level of the sixth cervical vertebra, and the anterior tubercle on the vertebral transverse process, which is the most prominent tubercle in the neck (Chassaignac tubercle).

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

B.5. What are the clinical signs of stellate ganglion block?

A stellate ganglion block results in the following ipsilateral signs:

- *Eye*: ptosis, narrowing of the palpebral fissure, miosis, enophthalmos, conjunctival injection, and lacrimation
- *Face and neck*: anhidrosis, elevated local temperature, and nasal stuffiness
- *Arm*: increased temperature and plethysmographic evidence of improved cutaneous blood flow

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2416.

B.6. What is Horner syndrome?

Horner syndrome is a clinical entity characterized by ptosis, miosis, anhidrosis, and enophthalmos. It is usually seen with disease processes involving the cervical sympathetics and is the classic sign of a successful stellate ganglion block.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2416.

B.7. After a stellate ganglion block, this patient reports no significant change in the degree of pain despite developing Horner syndrome. Is the pain psychogenic in this patient?

Not necessarily. The Horner syndrome indicates only the interruption of sympathetic supply to the head and neck. Unless it is accompanied by objective changes in the arm, it does not indicate a sympathetic nerve block of the upper extremity. Furthermore, SMP will respond to sympathectomy, whereas SIP will not.

McMahon SB, Koltzenburg M, Tracey I, et al, eds. *Wall and Melzack's Textbook of Pain*. 6th ed. New York: Churchill Livingstone; 2013:990–1002.

B.8. What types of nerve fibers are interrupted in stellate ganglion block?

The stellate ganglion block results in interruption of the preganglionic, thinly myelinated type B fibers as well as the postganglionic, unmyelinated type C fibers.

Casale R, Glynn CJ, Buonocore M. Autonomic variations after stellate ganglion block: are they evidence of an autonomic afference? *Funct Neurol*. 1990;5:245–246.

B.9. What is a differential block?

The variable effects of local anesthetics on fibers performing different functions are termed as *differential block*. The

diagnostic distinction can be made by selectively blocking the function of these nerve fibers. The mechanism that results in a differential block is best explained by fiber size and myelination because these factors determine different sensitivities of nerve fibers to local anesthetics. By using different concentrations of local anesthetic, sympathetic and somatic fibers can be selectively blocked. A differential block may be helpful in differentiating somatic versus sympathetic pain and peripheral versus central pain.

Cousins MJ, Carr DB, Horlocker TT, et al, eds. *Cousins & Bridenbaugh's Neural Blockade: In Clinical Anesthesia and Pain Medicine*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:838–840.

B.10. What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.

The two major classes of clinically employed local anesthetics are esters and amides. The esters are hydrolyzed in the plasma by pseudocholinesterase; the amides are biotransformed in the liver. Although infrequent, local anesthetic toxicity is encountered more commonly in the ester group because of the para-aminobenzoic acid moiety. True allergic reactions to amides are rare and in most instances are caused by the preservatives in the solution. Each of the two groups of local anesthetics contains drugs with varying degrees of rate of onset, duration of neural blockade, potency, and toxicity.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

B.11. What factors determine the onset, potency, and duration of a local anesthetic block?

- Onset correlates with pK_a.
- Potency correlates with lipid solubility.

- Duration correlates with degree of protein binding.

The commonly used local anesthetics are weakly basic tertiary amines that are lipid soluble and unstable in water. They are prepared as acidic salts because the ionized form, which is soluble in water, is stable. Therefore, the aqueous solution contains the ionized (cation) form of the local anesthetic in dissociation equilibrium with the unionized (free base) form depending on the pH of the medium.

$$\underset{\text{Cation}}{R{=}NH^{+}} \rightleftharpoons \underset{\text{Base}}{R{=}N} + H^{+}$$

When injected into the body, the relative rise in pH will allow the local anesthetic to convert to the uncharged base. The free base, being lipid soluble, will diffuse across the neural membrane and is responsible for neural blockade. With the exception of procaine and chloroprocaine, the commonly employed local anesthetics are highly protein bound and are therefore longer acting (**Table 48.1**).

TABLE 48.1 Physiochemical Properties of Commonly Used Local Anesthetics

Local Anesthetic	pK_a	Protein Binding (%)
Esters		
Procaine	8.9	5.8
Chloroprocaine	8.7	—
Tetracaine	8.5	75.6
Amides		
Lidocaine	7.9	64.3
Mepivacaine	7.6	77.5
Bupivacaine	8.1	95.6
Etidocaine	7.7	94.0

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

B.12. How does the addition of epinephrine to commercially available premixed solutions affect the efficacy of local anesthetics?

The addition of epinephrine to a local anesthetic increases the duration and intensity of a block. However, in commercially available premixed solutions containing epinephrine, antioxidants are added to preserve epinephrine, and the result is a lower buffered pH level of the solution. This lowering of the pH level can result in decreased efficacy of the local anesthetic. Best results are achieved by adding the desired concentration of epinephrine to the local anesthetic solution just before injection.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

B.13. How will you treat this patient?

Early diagnosis and aggressive physical therapy with pharmacologic control of pain form the basis of the treatment of CRPS. Physical therapy is widely recommended and accepted as a first line of treatment. The treatment of CRPS will differ depending on whether the pain is SMP or SIP. A series of sympathetic blocks has been shown effective in treating SMP of CRPS. A multidisciplinary approach including physiotherapy and symptom-specific psychological treatments (e.g., biofeedback and hypnosis) may be beneficial. Many patients have a component of both SMP and SIP, and a combination of sympathectomy and analgesic treatment is recommended. However, no single treatment is consistently successful. Therefore, the treatment plan should be individualized.

McMahon SB, Koltzenburg M, Tracey I, et al, eds. *Wall and Melzack's Textbook of Pain*. 6th ed. New York: Churchill Livingstone; 2013:990–1002.

Stanton-Hicks MD. CRPS: what's in a name? Taxonomy, epidemiology, neurologic, immune and autoimmune considerations. *Reg Anesth Pain Med*. 2019;44:376–387.

B.14. What is the pharmacologic management of CRPS?

SMP of CRPS is treated with the drugs that deplete norepinephrine from the sympathetic nerve terminals. Oral sympatholytic agents include phenoxybenzamine, prazosin, and terazosin. Topical clonidine, a selective α_2-agonist, has been successfully used to treat SMP. Tricyclic antidepressants have been effective in approximately half the number of patients and have been recommended as first-line agents. Other drugs that have been successfully used to treat CRPS are anticonvulsants (e.g., gabapentin, pregabalin, carbamazepine, and topiramate), local anesthetics such as lidocaine and mexiletine, calcitonin, corticosteroids, and high-dose opioids. Anecdotal reports suggest that methadone (opioid with anti-NMDA receptor effect) has been more effective than other opioids. Long-term IT morphine has been reported to produce analgesic effects in CRPS. Nonsteroidal anti-inflammatory drugs have also been used successfully.

Abram SE, Haddox JD, eds. *The Pain Clinic Manual*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2000:177–184.

Becker WJ, Ablett DP, Harris CJ, et al. Long term treatment of intractable reflex sympathetic dystrophy with intrathecal morphine. *Can J Neurol Sci*. 1995;22:153–159.

B.15. What is the role of intravenous regional block (Bier method) in diagnosis and treatment of CRPS?

Intravenous regional block (Bier method) with guanethidine, reserpine, bretylium, and phentolamine has been used to achieve temporary sympatholytic effect and relieve SMP of CRPS. Intravenous guanethidine and reserpine have been reported to relieve pain in more than 50% of patients as compared with a control group in one study. However, guanethidine and reserpine are not commercially available in the United States. The combination of bretylium and lidocaine is more effective than

lidocaine alone. α-Adrenergic blockade with intravenous phentolamine is a sensitive test to identify patients with SMP. Phentolamine has been used as a predictor agent before more invasive sympathetic blocks.

Blanchard J, Ramamurthy S, Walsh N, et al. Intravenous regional sympatholysis: a double-blind comparison of guanethidine, reserpine, and normal saline. *J Pain Symptom Manage*. 1990;5:357–361.

Raja SN, Treede RD, Davis KD, et al. Systemic alpha-adrenergic blockade with phentolamine: a diagnostic test for sympathetically maintained pain. *Anesthesiology*. 1991;74:691–698.

B.16. Compare and contrast the mechanism of actions of ketamine and methadone.

Methadone is a strong, long-acting opioid analgesic, whereas ketamine is a dissociative anesthetic. Methadone is used as an opioid but has mild NMDA receptor antagonist properties—the only strong opioid that has this quality. Ketamine is used in oral preparations, intravenous delivery systems, in skin preparations, and other delivery methods including being compounded in various percentages. These medications can block NMDA glutamate receptors and decrease the windup pain and central sensitization typical of chronic intractable pain. Windup causes an amplification of the incoming pain signal at the level of second-degree neurons in the dorsal horn of the spinal cord. By blocking these receptors, not only is windup pain decreased but also tolerance to opioid medications can also be decreased. Ketamine has the added effect of blocking sodium channels.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Chizh BA. Low dose ketamine: a therapeutic and research tool to explore N-methyl-D-aspartate (NMDA) receptor-mediated plasticity in pain pathways. *J*

Psychopharmacol. 2007;21(3):259–271.

B.17. What roles does ketamine infusion play in the treatment of CRPS? Is there a guideline for ketamine infusion in treating CRPS?

Although ketamine may have more than one mechanism of action, the basis for using it to treat CRPS may reside in its strong ability to block NMDA receptors. Ketamine is the only potent NMDA-blocking drug currently available for clinical use. An appropriately prolonged infusion of ketamine appears to maintain a level of ketamine in the central nervous system long enough to reverse the effects of the sensitization process and associated pain.

Currently, three methods of ketamine administration have been used for treatment including an outpatient low-dose ketamine administration; a low-dose awake inpatient technique; and a ketamine "coma" technique, which is a controversial treatment not currently allowed in the United States. Although studies are continuing, ketamine therapy has been shown to be effective for relief of pain CRPS-I; to date, no adverse cognitive effects of extended ketamine infusion treatment have occurred. Side effects, however, can occur in the high-dose setting; the infusion can be associated with significant risks including chronic catheterization, the need for parenteral nutrition, and endotracheal intubation. The outpatient therapy requires the patient to return for a 10-day period of time and often losses effectiveness after 6 to 12 weeks.

The guideline currently available for ketamine infusion is mainly focused on chronic neuropathic pain. Although there is moderate evidence showing ketamine infusion can provide effective short-term relief of CRPS-I pain, there is no consensus on the role of ketamine infusion in long-term management of the disease.

Cohen SP, Bhatia A, Buvanendran A, et al. Consensus guidelines on the use of intravenous ketamine infusions for chronic pain from the American Society of Regional Anesthesia and Pain Medicine, the American Academy of Pain Medicine, and the American Society of Anesthesiologists. *Reg Anesth Pain Med*. 2018;43:521–546.

Zhao J, Wang Y, Wang D. The effect of ketamine infusion in the treatment of complex regional pain syndrome: a systemic review and meta-analysis. *Curr Pain Headache Rep*. 2018;22:12.

B.18. What is neuromodulation? What is the role of spinal cord stimulation (SCS) in treating CRPS?

Neuromodulation, per International Neuromodulation Society definition, is "the alteration of nerve activity through the delivery of electrical stimulation or chemical agents to targeted sites of the body." Randomized controlled studies support the efficacy of SCS in treating pain of CRPS, and SCS has been shown to be superior to conventional medication management. Neurostimulation Appropriateness Consensus Committee (NACC) guidelines suggest the use of SCS for treating both CRPS-I and CRPS-II (evidence I, recommend strength A).

While the effectiveness and efficiency of different SCS stimulation modes are being investigated, dorsal root ganglion (DRG) stimulation has also significantly improved the management of CRPS and been proven to be noninferior in managing pain of CRPS, with less paresthesia in undesired body locations. Peripheral nerve stimulation (PNS) has also been reported to successfully achieve analgesia in CRPS patients. PNS would require that the injured nerve(s) would need to be known and identifiable for targeted stimulation but offers a

smaller and less invasive option for patients.

Deer TR, Krames E, Mekhail N, et al. The appropriate use of neurostimulation: new and evolving neurostimulation therapies and applicable treatment for chronic pain and selected disease states. Neuromodulation Appropriateness Consensus Committee. *Neuromodulation*. 2014;17:599–615.

Sokal P, Harat M, Zieliński P, et al. Tibial nerve stimulation with a miniature, wireless stimulator in chronic peripheral neuropathic pain. *J Pain Res*. 2017;10:613–619.

B.19. What is the role of surgical sympathectomy?

Surgical, chemical, or radiofrequency sympathectomy produces short-term pain relief, but long-term results are poor and inconsistent. Delayed failure of sympathectomy may be due to regeneration of ipsilateral nerves or reinnervation from the contralateral sympathetic nerves.

Kumar K, Nath RK, Toth C. Spinal cord stimulation is effective in the management of reflex sympathetic dystrophy. *Neurosurgery*. 1997;40(3):503–508.

Rocco AG. Radiofrequency lumbar sympatholysis. The evolution of a technique for managing sympathetically maintained pain. *Reg Anesth*. 1995;20(1):3–12.

B.20. What role does intrathecal (IT) therapy play in managing CRPS?

As a form of neuraxial analgesia, IT therapy bypasses first-pass metabolism and the blood–brain barrier, allowing lower effective doses and decreased systemic adverse effects. It is

usually achieved through an IT drug delivery system/device and should be considered only as a salvage approach after failing high doses of systemic opioids.

Polyanalgesic Consensus Conference (PACC) guidelines recommend both morphine (evidence level IIIB) and ziconotide (evidence level IA) as first-line IT monotherapy for either cancer- or non–cancer-related chronic pain, including CRPS; however, each of the medication has their own limitation and thus require monitoring. PACC guidelines recommend trialing before a permanent device is placed and that the pros and cons of the therapy must be thoroughly discussed with patients before initiating the treatment.

Deer TR, Pope JE, Hanes MC, et al. Intrathecal therapy for chronic pain: a review of morphine and ziconotide as firstline options. *Pain Med*. 2019;20(4):784–798.

Deer TR, Pope JE, Hayerk SM, et al. The Polyanalgesic Consensus Conference (PACC): recommendations on intrathecal drug infusion systems best practices and guidelines. *Neuromodulation*. 2017;20:96–132.

B.21. If opioids are prescribed as treatment for CRPS patients, what is the Centers for Disease Control and Prevention (CDC) guideline of chronic opioid therapy?

In 2016, CDC has published a guideline to address the (1) timing, (2) strategies, and (3) risk–benefit assessment of prescribing opioids for chronic pain other than cancer treatment, palliative care, or end-of-life care. Other resources including checklist, fact sheets, and mobile application are also available.

CDC guidelines also recommend thoroughly discussing risks and benefits with patients before starting therapy, initiating therapy with immediate-release opioids, and reevaluating benefits and harms frequently. Last but not least, offer treatment for opioid use disorder when aberrant behavior of opioid use is

perceived.

Dowell D, Haegerich TM, Chou R. CDC guideline for prescribing opioids for chronic pain—United States, 2016. *MMWR Recomm Rep*. 2016;65:1–49.

C. Complications

C.1 What are the complications of stellate ganglion block?

Although complications appear infrequently, the more common complications of stellate ganglion block are as follows:

- Intra-arterial injection: seizure and hematoma
- Recurrent laryngeal nerve paralysis: hoarseness of voice
- Brachial plexus block: motor weakness
- Accidental epidural or subarachnoid injection
- Esophageal injury
- Pneumothorax: respiratory distress

To avoid complications, aspiration of the needle should be performed before, during, and after administration of local anesthetics to look for (1) air, (2) blood, and (3) cerebrospinal fluid.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:2416.

C.2 What is the systemic toxicity of local anesthetics?

The systemic toxic effects of local anesthetics are related to drug levels in blood, and they are manifested mainly in the central nervous system and the cardiovascular system. As a rule, the central nervous system effects precede the cardiovascular toxic manifestations.

Central Nervous System Effects

Central nervous system effects include light-headedness,

dizziness, tinnitus, visual disturbances, drowsiness, disorientation, slurred speech, muscle twitching, generalized grand mal seizures, and electroencephalographic changes. The blood levels of local anesthetics associated with central nervous system changes in humans are as follows:

- Procaine: 20 μg per mL
- Lidocaine, mepivacaine, and prilocaine: 5 to 10 μg per mL
- Tetracaine, bupivacaine, and etidocaine: 1.5 to 4 μg per mL
- Lowering the $Paco_2$ by hyperventilation decreases the convulsive threshold dose of a local anesthetic drug.

Cardiovascular Effects

Ventricular arrhythmias are reported with intravenous bupivacaine only. Cardiac resuscitation is extremely difficult in patients with bupivacaine-induced cardiac arrhythmias. Ropivacaine is less toxic than bupivacaine but more toxic than lidocaine. The mechanism of enhanced cardiotoxicity in pregnant patients is not well understood; nevertheless, 0.75% bupivacaine is no longer recommended in pregnant patients in the United States (**Table 48.2**).

TABLE 48.2 Cardiovascular Effects of Lidocaine

Blood Level Lidocaine (μg per mL)	Electrocardiographic Changes	Hemodynamic Effects
<5	—	—
5–10	↑ PR interval	↓ Myocardial contraction
	↑ QRS duration	↓ Cardiac output
	Sinus bradycardia	Vasodilatation
>10	↑ PR interval	↓ Myocardial contraction
	↑ QRS duration	↓ Cardiac output
	Sinus bradycardia	Circulatory collapse
	Atrioventricular block	
	Asystole	

↑, increase; ↓, decrease.

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:865–891.

C.3 How do you treat the systemic toxicity of local anesthetic drugs?

The principles of treatment include the following:

- Secure and maintain the airway.
- Ensure adequate oxygenation and ventilation.
- Treat hypotension and bradycardia promptly.

For patients in cardiac arrest or with severe, refractory arrhythmias, intravenous fat emulsions should be given. The suggested bolus dose is 1.5 mL per kg of 20% fat emulsion (Intralipid) over 1 minute followed by a continuous infusion at 0.25 mL/kg/min. If there is no clinical improvement, the bolus dose should be repeated and the infusion should be increased to 0.5 mL/kg/min. The infusion should be continued for at least 10 minutes after hemodynamic stability is restored but discontinued within an hour.

- Perform immediate cardiopulmonary resuscitation for profound cardiovascular collapse.
- Perform electrical cardioversion for ventricular tachycardia or fibrillation.
- Control seizures with the following:
  - Diazepam, 0.1 to 0.2 mg per kg, intravenously
  - Thiopental sodium, 1 to 2 mg per kg, intravenously

Benzon H, Rathmell JP, Wu CL, et al, eds. *Practical Management of Pain*. 5th ed. St. Louis, MO: Mosby; 2013:346–360.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:883–887.

C.4 What are the possible complications of SCS?

Epidural SCS is a simple procedure and carries low morbidity. The majority of complications are associated with the implants involving electron fracture or lead migration, which are correctable. Other more serious complications include epidural hematoma, epidural abscess, permanent neurologic deficits, or serious spinal cord injury; however, the risk of these adverse events are less than spine surgery.

Deer TR, Krames E, Mekhail N, et al. The appropriate use of neurostimulation: new and evolving neurostimulation therapies and applicable treatment for chronic pain and selected disease states. Neuromodulation Appropriateness Consensus Committee. *Neuromodulation*. 2014;17:599–615.

Deer TR, Mekhail N, Provenzano D, et al. The appropriate use of neurostimulation of the spinal cord and peripheral nervous system for the treatment of chronic pain and ischemic diseases: the Neuromodulation Appropriateness Consensus Committee. *Neuromodulation*. 2014;17:515–550.

Deer TR, Pope JE, Lamer TJ, et al. The Neuromodulation Appropriateness Consensus Committee on best practices for dorsal root ganglion stimulation. *Neuromodulation*. 2019;22(1):1–35.

C.5. What are the possible complications of IT therapy?

Based on the characteristics, there are five classes of potential IT therapy complications, including mechanical system, pharmacologic, surgical, patient-specific, and refill complications. The severity of the results can range from local hygroma to life-threatening anaphylaxis, respiratory depression, or arrest. It is also worth noting that ziconotide may cause neuropsychiatric adverse effect and is contraindicated in patients with preexisting history of psychosis or suicidal ideation.

49 Cancer Pain

Shakil Ahmed and Sudhir A. Diwan

A 44-year old man was referred to the pain clinic for evaluation and management of abdominal pain. He was recently diagnosed with adenocarcinoma of the pancreas with retroperitoneal lymph nodes in the paraaortic region. His pain is localized in the epigastric region and is worse during the night and decreased during the day. He is taking sustained-release morphine sulfate (MS Contin), 100 mg orally every 8 hours, and immediate-release morphine sulfate, 30 mg orally every 3 hours as needed, for breakthrough pain. The patient reports inadequate pain control, nausea, vomiting, and constipation.

A. Medical Disease and Differential Diagnosis

1. What is the definition of pain?
2. How significant is the problem of pain in patients with cancer?
3. What are the components of cancer pain?
4. How does the pain contribute to the suffering of patients with cancer?
5. How do psychological factors affect pain in patients with cancer?
6. What are the causes of pain in patients with cancer?
7. How do you classify pain in patients with cancer?
8. What are the characteristics of pancreatic cancer pain?

9. How do you assess pain in patients with cancer?
10. What is the differential diagnosis of abdominal pain?

B. Pharmacologic Treatment of Pain

1. What is the World Health Organization stepladder approach for cancer pain management?
2. What class of drugs does morphine sulfate belongs to?
3. What is the difference between morphine and synthetic opioids?
4. How does mixed opioid agonist/antagonist differ from opioid agonist?
5. Describe the role of methadone in the management of cancer pain.
6. What are the advantages and disadvantages of methadone?
7. What is the mechanism of action of opioids?
8. What are the side effects of opioid therapy?
9. Define tolerance and physical dependence.
10. How would you treat the side effects of opioid therapy?
11. What is tramadol? Is it an opioid?
12. When would you consider adjuvant analgesics as part of the treatment plan?
13. The patient and his family are worried about addiction. How would you approach this problem?
14. Describe different routes of opioid administration.
15. Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?
16. What is meperidine? How is it different from other opioids?
17. What is rotation of opioids? When would you consider rotation of opioids?

C. Invasive Therapy

1. Describe the role of peripheral nerve blocks in cancer pain management.

2. Describe the role of celiac plexus block in cancer pain management.
3. What are the complications of celiac plexus block?
4. Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.
5. Which medications can be used intrathecally? What is ziconotide?
6. What is a Personal Therapy Manager (PTM), and what role does it play in neuraxial pain relief?
7. Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.
8. Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?
9. Describe the role of radiation therapy in cancer pain.

D. Nonpharmacologic Management

1. What are the various nonpharmacologic techniques of cancer pain management?
2. What physical modalities have been successfully tried in cancer pain management?
3. Describe the role of neuromodulation in cancer pain management.
4. What psychological techniques have been promoted for comfort care and pain relief?
5. What are distraction and reframing techniques? What is the role of hypnosis in cancer pain?

A. Medical Disease and Differential Diagnosis

A.1. What is the definition of pain?

According to the International Association for the Study of Pain, pain is defined as “an unpleasant, sensory and emotional

experience associated with actual or potential tissue damage or described in terms of such damage."

Williams and Craig proposed another definition in light of the new understanding of pain, "Pain is a distressing experience associated with actual or potential tissue damage with sensory, emotional, cognitive and social components."

Anand KJS, Craig KD. New perspectives on the definition of pain. *Pain*. 1996;67:3–6.

Merskey H, Bogduk N, eds. *Classification of Chronic Pain: Descriptions of Chronic Pain Syndromes and Definitions of Pain Terms*. 2nd ed. Seattle, WA: IASP Press; 1994:210.

Williams AC, Craig KD. Updating the definition of pain. *Pain*. 2016;157(11):2420–2423.

A.2. How significant is the problem of pain in patients with cancer?

There are 1,762,450 new patients with cancer annually in 2019. Cancer causes 606,880 deaths per year, making it the second leading cause of death in the United States. Thirty percent of the patients with cancer have pain at the time of diagnosis, and 65% to 85% of patients with cancer have pain at advanced stages. Thirty-six percent have pain severe enough to impair their ability to function.

Vainio and Auvinen studied 1,840 patients with advanced cancer and found 24% with no pain, 24% with mild pain, 30% with moderate pain, and 21% with severe pain.

Van den Beuken-van Everdingen and colleagues showed in a pooled meta-analysis of 52 studies that more than one-third of cancer patients graded their pain as moderate or severe. Pooled prevalence of pain was >50% in all cancer types including gastrointestinal, lung, breast, and urogenital, with the highest prevalence in head/neck cancer patients (70%).

Daut and Cleeland found pain to be an early symptom of cancer in 48% to 50% of patients with cancer of breasts, ovary,

prostate, colon, and rectum and in 20% of patients with uterus and cervical cancer.

A.3. What are the components of cancer pain?

The components of cancer pain are sensory, affective, and psychological.

The sensory components could be nociceptive pain elicited by activation of sensory nerve endings, by mechanical, chemical, radioactive, or thermal energy. It is often associated with ongoing tissue damage and may be of somatic or visceral origin. Somatic pain may be superficial, well localized, sharp, pricking, burning or deep diffused, dull, and aching. Visceral pain is usually diffuse, referred to body surface, and has a sickening quality to it.

Neuropathic pain is due to pathologic change in the discharge properties of the neurons because of invasion, compression, or damage caused by various cancer treatment modalities. It is typically described as burning, lancinating, painful numbness, or itching sensations. Phantom pain is a pain referred to the amputated part of the body. Psychological pain is usually due to fear, anxiety, depression, existential questions, anger, social and financial issues, social support, and the impact the pain has on the family and caregivers. Most cancer patients report more than

one site of pain.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

Sela RA, Bruera E, Conner-Spady B, et al. Sensory and affective dimensions of advanced cancer pain. *Psychooncology*. 2002;11:23–34.

A.4. How does the pain contribute to the suffering of patients with cancer?

Sustained pain on its own can create complex, enduring, unpleasant emotional suffering by its ability to create awareness of the perceived threat to one's life. It causes helplessness in the face of the inevitability of demise as well as exhaustion of hope. Patients with cancer usually identify pain as an indicator of disease progression. Suffering may be attributable to many factors besides physical complaints. Psychological factors include financial issues, lack of social support, loss of job or social position in society, loss of independence, effect on family and friends, social isolation, and fear of death.

A.5. How do psychological factors affect pain in patients with cancer?

The ultimate perception of pain depends on the nociceptive stimulus and psychological fear, anger, anxiety, or depression. Twenty-five percent of patients with cancer meet criteria for major depressive syndromes at some point in their illness, with an overall prevalence of 53% in hospitalized patients with cancer. Psychological factors may significantly exacerbate pain. The psychological suffering is associated with the disease and the imminence of death.

Symptoms usually include anxiety, restlessness and irritability, sleep disorders, obsessive thinking, slowness in motor responses, and hopelessness. Psychological suffering is most typically manifested in depression, which most of the

patients suffer during the initial stages of the disease, when the disease metastasize, and when they are in a particularly poor condition. These factors affect overall pain behavior and suffering. General deterioration causes them to withdraw into their home or the hospital. Also, a meta-analysis of studies showed that depression predicts mortality, but not progression, in cancer patients.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

Speigel D, Giese-Davis J. Depression and cancer: mechanisms and disease progression. *Biol Psychiatry*. 2003;54:269–282.

A.6. What are the causes of pain in patients with cancer?

Pain in patients with cancer may be due to (1) presence and progression of the tumor itself, for example, bone involvement, viscus obstruction, and nerve compression; (2) indirect effect of the tumor, for example, metabolic imbalance, infection, and venous or lymphatic obstruction; (3) consequence of cancer treatment, such as chemotherapy, radiation therapy, or surgery; or (4) unrelated mechanisms such as migraine and myofascial pain.

Localized invasion of peripancreatic structures most commonly causes back pain, which stems from tumor invasion of the splanchnic plexus, common bile duct obstruction, retroperitoneum, or pancreatitis. This pain is described as severe, gnawing, epigastric, upper abdominal radiating to the middle of the back, worse on lying down and improved with upright position.

Grond and colleagues found in a prospective study of 2,266 patients with cancer that 30% had one pain syndrome, 39% had two pain syndromes, 31% had three pain syndromes, 85% by the

cancer itself (bone, 35%; soft tissue, 45%; and visceral, 34%), and 17% by anticancer treatment.

The bone cancer pain has both nociceptive and neuropathic components, which evolve with disease progression. The tumor and associated cells release factors that sensitize and activate bone nociceptors, injure the sensory nerve fibers, and release growth factors that drive ectopic sprouting of nerve fibers and neuroma formation, all of which can contribute to peripheral and central sensitization.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

Grond S, Zech D, Diefenbach C, et al. Assessment of cancer pain: a prospective evaluation in 2266 cancer patients referred to a pain service. *Pain*. 1996;64:107–114.

Mantyh PW. Bone cancer pain: from mechanism to therapy. *Curr Opin Support Palliat Care*. 2014;8(2):83–90.

A.7. How do you classify pin in patients with cancer?

Pain, in patients with cancer, may be classified on the basis of the following:

- Chronicity: acute or chronic
- Intensity and severity: visual analog score, numeric pain score; and verbal: mild, moderate, severe, or worst possible pain
- Pathophysiology and mechanism: nociceptive or neuropathic, tumor infiltration of nerves, infiltration of soft tissue or hollow organs, serosa, solid organ necrosis, and destruction of bone
- Individual type and stage of disease: pancreatic, ovarian, prostatic, breast, or lung
- Pattern of pain: incidental pain related to an event or activity; spontaneous pain unrelated to an event or activity and end-of-dose failure
- Pain syndromes: tumor invasion of bone, nerves, spinal cord,

viscera, blood vessels, postsurgical, and postchemotherapy and postradiation therapy pain

The pancreatic carcinoma usually presents with vague symptoms of anorexia, weight loss, abdominal discomfort, new-onset diabetes mellitus, or thrombophlebitis. The vague nature of symptoms may result in delay of diagnosis.

Ochoa JL. Neuropathic pain: redefinition and a grading system for clinical and research purposes. *Neurology*. 2009;72(14):1282–1283.

A.8. What are the characteristics of pancreatic cancer pain?

Pancreatic cancer affects 12 or 13 patients per 100,000 in the Western world, men more than women, and Blacks more than Whites. In 2019, an estimated 56,770 adults (29,940 men and 26,830 women) in the United States will be diagnosed with pancreatic cancer. If the cancer is detected at an early stage when surgical removal of the tumor is possible, the 5-year survival rate is 37.4%. About 10% of people are diagnosed at this stage. If the cancer has spread to surrounding tissues or organs, the 5-year survival rate is 12%. For the 53% of people who are diagnosed after the cancer has spread to a distant part of the body, the 5-year survival rate is 3%.

About 30% to 60% of patients present with pain, and 80% of the patients with advanced cancer complain of pain. Patients complain of diffuse epigastric pain radiating to the back that is increased on lying down and improved on sitting. About 90% of pancreatic tumors are of the adenocarcinoma type. Cancer in the

head of the pancreas usually invades the stomach, duodenum, gall bladder, and peritoneum, whereas tumors in the body spreads to liver, spleen, lymph nodes, and left adrenal gland. A study of 42 Japanese patients on clinical characteristics of Japanese patients with epithelioid hemangioendothelioma showed tumor size >3.0 cm is an independent indicator of a poor prognosis in epithelioid hemangioendothelioma. The presence of symptoms at the time of diagnosis and high Ki-67 index implies poor survival.

Siegel RL, Miller KD, Jemal A. Cancer statistics, 2019. *CA Cancer J Clin*. 2019;69(1):7–34.

A.9. How do you assess pain in patients with cancer?

A stepwise approach is required for the assessment of pain. It includes history, physical examination, and data collection ending with clinical diagnosis. It helps the clinician achieve goals of providing pain relief. Assessment involves identifying features of pain, such as location, intensity, quality, timing, exacerbating/relieving factors, response to previous analgesics, and disease-modifying treatments; effects of pain on daily activities and psychological state; associated symptoms; complete physical examination; and laboratory data and imaging.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

A.10. What is the differential diagnosis of abdominal pain?

Although abdominal pain could arise from different structures within the peritoneal cavity, the retroperitoneal organs can cause similar pain syndromes. Location and radiation of the pain can give important clues to make the diagnosis. Retroperitoneal

structures present with dull or sharp back pain that is increased on lying down and relieved on sitting hunched up. Abdominal tumors are frequently characterized by colicky pain associated with nausea that is worse after eating. Abdominal pain may be referred to distant areas like shoulder, neck, or back depending on the organ involved. Tumors of the small bowel or large bowel may present with symptoms of obstruction (e.g., abdominal distention, nausea, and bilious vomiting) or hematemesis or melena. Other common causes of abdominal pain include omental metastasis, volvulus of intestine, infectious peritonitis, radiation enteritis, and peritoneal carcinomatosis. Mesenteric ischemia presents with diffuse pain that is increased with meals and weight loss.

Nonmalignant causes of abdominal pain such as appendicitis, cholecystitis, and pancreatitis can occur in patients with cancer coincidentally and may complicate the diagnostic process. Opioid analgesics may not be used in these patients because they may exacerbate symptoms of colicky pain (due to spasm of sphincter of Oddi), nausea, vomiting, paralytic ileus, and constipation.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

B. Pharmacologic Treatment of Pain

B.1. What is the World Health Organization stepladder approach for cancer pain management?

The World Health Organization advocated a stepladder approach to manage cancer pain exclusively with oral medications depending on the pain intensity and, to some extent, the pain mechanism (**Fig. 49.1**).

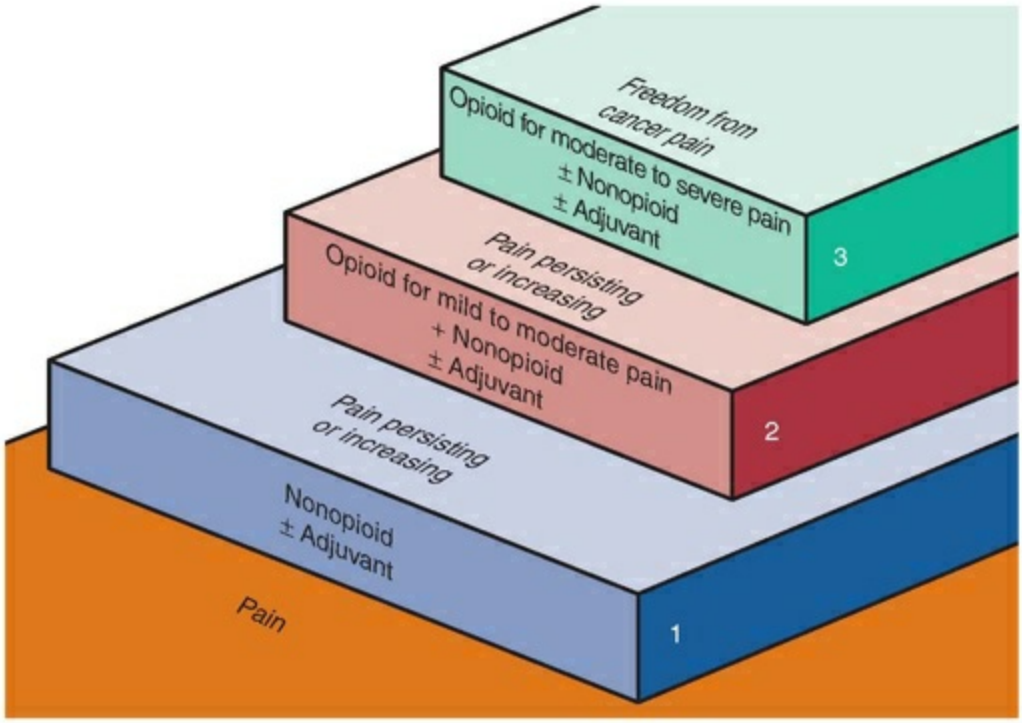

FIGURE 49.1. World Health Organization–advocated stepladder approach to management of cancer pain.

Step 1. Manage the pain by nonopioid medications with or without adjuvants.
Step 2. If pain is persisting or increasing, add weak opioids to nonopioid analgesics and adjuvants.
Step 3. Strong opioids are used with nonopioid analgesics and adjuvants until the patient achieves complete analgesia.

Noninvasive routes of drug delivery should be maintained as long as possible because of its simplicity, convenience, and cost. A fourth step has been added for patients who still have significant pain despite maximum medical management. At this point, interventional procedures including neuromodulation, drug delivery systems, and/or neurolysis should be employed.

Cuomo A, Bimonte S, Forte CA, et al. Multimodal approaches and tailored therapies for pain management: the trolley analgesic model. *J Pain Res*. 2019;12:711–714.

Mercadante S. Management of cancer pain. *Intern Emerg Med*. 2010;5(suppl

1):S31–S35.

Pazdur R, Wagman L, Camphausen KA, et al, eds. *Cancer Management: A Multidisciplinary Approach. Medical, Surgical, & Radiation Oncology*. 13th ed. Philadelphia, PA: FA Davis; 2010:731–746.

B.2. What class of drugs does morphine sulfate belongs to?

Morphine is classified as a μ-receptor opioid agonist because of its high specificity for activation of μ-receptors. An ideal opioid agonist would have a high specificity for receptors producing desirable effects (analgesia and minimal or no specificity for other receptors that cause side effects). Opioids are unique in producing analgesia without loss of consciousness.

Brunton LB, Hilal-Dandan R, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:368–372.

B.3. What is the difference between morphine and synthetic opioids?

Morphine is the principal phenanthrene alkaloid present in opium. It is highly ionized and water soluble. The most active molecule of morphine is the levorotatory isomer of stereochemical structure. The synthetic opiates contain the phenanthrene nucleus of morphine and are manufactured by synthesis, rather than chemical modification. Clinically, histamine release by morphine differentiates it from the synthetic opioids. This may cause urticaria, allergic reactions, and hemodynamic instability, particularly in volume-depleted patients.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

B.4. How does mixed opioid agonist/antagonist differ from opioid agonist?

The mixed-action opioids bind to μ-receptors, where they are partial agonists or competitive antagonists. Antagonistic properties of these drugs can attenuate the efficacy of subsequently administered opioid agonists and cause withdrawal symptoms in patients already receiving opioid agonists. The advantages of these drugs include low potential for respiratory depression and physical dependence. A dysphoric reaction is very common with mixed-action opioids. Their use is limited because of a ceiling effect whereby progressive escalation in doses does not increase analgesia as with opioid agonists.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2018:599–620.

Brunton LB, Hilal-Dandan R, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:368–377.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:680–741.

B.5. Describe the role of methadone in the management of cancer pain.

The efficient oral and rectal absorption with prolonged duration of analgesic action of methadone makes it a highly effective and attractive oral drug for cancer pain management.

Methadone is a synthetic opiate drug with a unique agonist/antagonist action. Methadone is a μ-receptor agonist and an *N*-methyl-d-aspartate (NMDA) receptor antagonist. Activation of NMDA receptors is involved in the development of hypersensitivity and central sensitization in neuropathic pain and tolerance to opioids. Because of the antagonistic effect at the NMDA receptor site, methadone is very effective in neuropathic pain secondary to cancer-related pathology and therapeutic interventions. The same antagonistic action of methadone minimizes the development of tolerance to opioids.

Manfredi PL, Gonzalez GR, Cheville AL, et al. Methadone analgesia in cancer pain patients on chronic methadone maintenance therapy. *J Pain Symptom Manage*. 2001;21:169–174.

B.6. What are the advantages and disadvantages of methadone?

Methadone has several advantages including oral and rectal absorption with bioavailability to 95%, high potency, high lipid solubility, low cost, and no active metabolites. Methadone has a long half-life, and its analgesic effect lasts 6 to 8 hours. However, methadone has been used for a long time for heroin abusers as detoxification and maintenance; it carries a social stigma, which can interfere with adequate pain management. Methadone has an irregular elimination half-life with inter individual variation between 20 and 60 hours. Because of that, the cumulative effect of methadone causes sedation, makes titration difficult, and has led to the concept of individualization of methadone dosing.

Ballantyne JH, Fishman SM, Rathmell JPC, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2019:687–792.

Brunton LB, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:368–374.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:680–741.

B.7. What is the mechanism of action of opioids?

Opioids act as agonists at stereospecific opioid receptors that are

normally activated by endogenous ligands known as endorphins in brainstem and spinal cord. Binding of opioid to the receptor inhibits adenylate cyclase activity and causes hyperpolarization of neurons, which results in suppression of spontaneous discharge and evoked potential. Opioids also interfere with transmembrane transport of calcium ion and interfere with the release of neurotransmitters like acetylcholine, dopamine, norepinephrine, and substance P. Inhibition of acetylcholine release from nerve endings is the basis of analgesic activity of opioids.

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2019:1333–1343.

Brunton LB, Chabner B, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:355–377.

Gropper MA, Cohen NH, Eriksson L, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:680–741.

B.8. What are the side effects of opioid therapy?

The opioid-related side effects occur because of opioid receptor pharmacodynamics, metabolites, or both. Sedation and respiratory depression are due to μ-receptor activation. Tolerance to these side effects is developed within a very short period of treatment. The dysphoric reaction is due to activation of κ-receptors. Psychotomimetic and depersonalization reactions are due to activation of σ-receptors. Nausea and vomiting are caused by direct stimulation of the chemoreceptor trigger zone. Increased intrabiliary pressure is due to spasm of the sphincter of Oddi. Other side effects commonly observed are constipation, pruritus, and myoclonus. Almost all side effects diminish with time, except constipation and myoclonus. Patients with cancer who develop constipation secondary to opioid therapy are required to be on a regular bowel regimen to avoid subsequent serious consequences. In patients with compromised renal

function, metabolites of morphine (M3G, M6G) cause excessive sedation and metabolites of meperidine (normeperidine) lower the seizure threshold. The most commonly reported adverse events in the MERITO study of 159 cancer patients were somnolence (24% of patients), constipation (22%), vomiting (13%), nausea (10%), and confusion (7%).

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2019:1333–1335.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:680–741.

B.9. Define tolerance and physical dependence.

Tolerance occurs with the development of the need to gradually escalate the dose to achieve the same pain control, and it can develop in 2 to 3 weeks. Tolerance does not indicate abuse or addiction, it is commonly associated with increasing pain or disease progression. Physical dependence develops after chronic use of opioids, and it is characterized by development of withdrawal syndrome after administration of an opioid antagonist or abrupt discontinuation of the medication. The potential for tolerance is an agonistic effect of opioids.

Fishman SM, Ballantyne JC, Rathmell JP, eds. *Bonica's Management of Pain*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:418–423.

B.10. How would you treat the side effects of opioid therapy?

Oversedation and respiratory depression are treated with a specific μ-receptor antagonist, naloxone, as well as supplemental oxygen. Naloxone, in a 1 to 4 μg per kg intravenous bolus, promptly reverses sedation, respiratory depression, and analgesia. Continuous intravenous infusion at the rate of 2 to 4

μg/kg/hr will reverse only side effects without reversing analgesia. Nausea and vomiting should be managed by antiemetics. Constipation should be treated with a regular bowel regimen of laxatives and stool softener. Peripherally acting μ-opioid receptor antagonists (PAMORA; methylnaltrexone, naloxegol, naldemedine) and a chloride channel activator (lubiprostone) improve opiate-induced bowel dysfunction without reversing analgesia. Generalized pruritus may respond to one or more doses of antihistamine; however, pruritus may not be related to histamine release.

B.11. What is tramadol? Is it an opioid?

Tramadol (Ultram) is a nonopioid synthetic analgesic with weak μ-receptor agonistic activity and is thought to exert its analgesic effects by inhibition of reuptake of norepinephrine and serotonin. It should be started at 50 to 100 mg every 6 to 8 hours. It may exhibit μ-receptor–related clinical side effects like respiratory depression and constipation. Prolonged use may lead to physical and psychological dependence. Tramadol was placed into schedule IV of controlled substances effective August 18, 2014.

Tapentadol is a centrally acting pain reliever, with agonist

activity at the μ-receptor and inhibition of norepinephrine reuptake. Compared to oxycodone IR, tapentadol showed a reduction in gastrointestinal side effects, specifically nausea, constipation, and vomiting. Tapentadol should be administered first in the 50-mg strength and can be increased to 100 mg every 4 to 6 hours as needed. Of note, it too can also cause respiratory depression because it shows μ-opioid agonist activity and is a controlled substance.

Both tramadol and tapentadol can cause life-threatening serotonin syndrome with the use of other serotonin-norepinephrine uptake inhibitors, selective serotonin reuptake inhibitors, tricyclic antidepressants, or monoamine oxidase inhibitors and, therefore, should be used with caution in patients on these medications.

There is limited, very low quality, evidence from randomized controlled trials that tramadol produced pain relief in some adults with pain due to cancer and no evidence at all for children.

B.12. When would you consider adjuvant analgesics as part of the treatment plan?

In cancer pain management, adjuvant drugs are considered to enhance pain relief. The adjuvant analgesics are a heterogeneous group of medications originally developed for purposes other than pain relief. These drugs may become necessary in the multimodal approach to treat pain, the adverse effects of

analgesic medications, or to treat concomitant psychological disturbances such as insomnia, anxiety, depression, and psychosis. The most useful adjuvants used clinically to manage cancer pain are as follows:

- Corticosteroids
- Tricyclic antidepressants (e.g., amitriptyline)
- Anticonvulsants (e.g., gabapentin)
- Amphetamines
- *N*-methyl-D-asparate (NMDA) receptor antagonists (e.g., methadone, ketamine)
- α_2-Agonists (e.g., clonidine)
- Antihistaminics
- Phenothiazines

B.13. The patient and his family are worried about addiction. How would you approach this problem?

Unfortunately at times, it becomes difficult to differentiate between drug abuse and the deterioration in physical or psychosocial functioning caused by the disease and its treatment. For example, questionable drug-related behaviors would be difficult to recognize in a patient who develops social withdrawal or cognitive changes following brain irradiation for metastases.

Addiction is defined as a persistent pattern of dysfunctional use of opioids that may involve adverse consequences associated with continued use, loss of control over use of opioids,

compulsive use of drug, craving for the drug, and a typical drug-seeking behavior. Patients with chronic pain who are using opioids are not at higher risk of addiction than the general population. The goals of treatment including palliation of pain and improvement in the patient's quality of life must be clearly defined and explained to the patient and his relatives. At no time should patients with cancer pain be undertreated because of the fear of addiction. The patient and his family should be educated about the common misconception that addiction is a common outcome of opioid therapy.

Opioid analgesic therapy must be tailored to carefully monitor all patients in order to minimize misuse and abuse and every patient is potentially at some degree of risk for opioid misuse. This is affected by patient's disease progression, tolerance, changes in pain quality, mental health, comorbidities, other drug therapies, and changes in the patient's lifestyle.

B.14. Describe different routes of opioid administration.

Oral medications should be used as the first-line approach in most patients with cancer pain who are receiving opioid analgesics. **Table 49.1** outlines the routes of opioid administration and available opioid preparations.

TABLE 49.1 Routes of Opioid Administration

Route of Administration	Available Opioid Preparation
Oral	Morphine

	Hydromorphone (Dilaudid) Methadone (Dolophine) Oxycodone, hydrocodone Codeine, meperidine Levorphanol
Rectal	Suppositories containing morphine Hydromorphone, oxycodone
Transdermal	Fentanyl patch
Sublingual	Fentanyl, methadone, buprenorphine
Intramuscular/subcutaneous	Morphine, hydromorphone, methadone Meperidine, levorphanol
Intravenous	Morphine, meperidine, methadone, fentanyl Hydromorphone, oxymorphone
Epidural/intrathecal	Morphine, methadone, hydromorphone Fentanyl, sufentanil, meperidine

The rectal or transdermal route should be chosen before considering invasive therapy for cancer pain. The sublingual route is limited by the inability to deliver large doses.

The intramuscular route is not preferred for long-term administration because it requires repeated painful injections and offers no pharmacodynamic advantages. Intravenous administration provides quick onset and is ideal for painful crises in patients with cancer as PCA.

The equianalgesic doses of opioids used orally and parenterally are listed in **Table 49.2**.

TABLE 49.2 Opioids Used Orally or Parenterally to Treat Cancer Pain

	Equianalgesic Dose (mg)[a]	
Drug	**Oral**	**Parental**
Morphine	30	10
Hydromorphone	6	2
Oxycodone	20–30	NA
Methadone	10[b]	10[b]
Levorphanol	2–3[b]	2[b]
Codeine	130[c]	75

NA, not available in the United States.

[a]Suggested doses are guidelines only. Doses are based on chronic opioid use.

[b]Particular care with titration is recommended because doses may need to be reduced significantly when steady-state levels are reached after 2 to 3 days.

[c]Codeine doses greater than 65 mg may be associated with significant constipation.

B.15. Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?

Intravenous PCA is very advantageous for patients with chronic cancer pain because it allows patients to self-administer medication and find their own comfort zone between side effects and pain control within limits set by the physician. The PCA device is a computerized, programmable, lightweight, battery-operated portable pump with the capability of storage and retrieval of data by the microprocessor. The pump is programmed for three modes of drug delivery: (1) continuous per hour rate infusion only, which is preset by the physician and the patient has no control over it; (2) continuous with boluses for breakthrough pain, boluses controlled by the patient; and (3) boluses with lockout time in minutes set by the physician and the patient can control his or her own requirement. If required, the physician or nurse can deliver extra boluses. Intermittent rescue doses for breakthrough pain, along with continuous

infusion, decrease the total requirement of opioids. Only rescue-dose delivery mode is safer because patients will not take medication if there is no pain. However, continuous-delivery mode carries risks of oversedation and respiratory depression. The initial cost of the drug-delivery device and training of the health care provider could be expensive. PCA can also be provided by subcutaneous, epidural, or intrathecal route.

MEAC is the minimum effective analgesic concentration of the opioid that is the lower level of the therapeutic window.

Functional impairment of excretory organs is common in the elderly, half-life of the active drug and metabolites is increased in the elderly and in patients with renal dysfunctions except buprenorphine, therefore doses be reduced, a longer time interval be used between doses, and creatinine clearance be monitored except for buprenorphine.

B.16. What is meperidine? How is it different from other opioids?

Meperidine is a synthetic opioid that pharmacologically resembles morphine. Meperidine is not an ideal drug for chronic pain because of its short duration of action and its high potential for abuse. The by-product normeperidine is exclusively excreted via the kidney with an elimination half-life of 36 to 40 hours. In

patients with compromised renal function, by-product accumulation has been associated with central nervous system toxicity, including myoclonus, tremulousness, hallucinations, and seizures. Meperidine possesses anticholinergic activity similar to atropine, causing mydriasis, orthostatic hypotension, and tachycardia. Compared with other opioids, meperidine very rarely causes pruritus when given neuraxially. It is extremely effective in the treatment of postoperative shivering. Meperidine also demonstrates local anesthetic actions. It is contraindicated in patients who are receiving monoamine oxidase inhibitors because of the risk of a potentially fatal syndrome characterized by hyperthermia, rigidity, and seizures.

Brunton LB, Hilal-Dandan R, Knollman B. *Goodman and Gilman's The Pharmacological Basis of Therapeutics*. 13th ed. New York: McGraw-Hill; 2018:372–373.

B.17. What is rotation of opioids? When would you consider rotation of opioids?

The sequential trial of changing one opioid to another when either treatment-limiting toxicity or poor responsiveness develops has become known as *opioid rotation*. The variable response from opioid to opioid in an individual has led to this approach; changing to an alternative opioid may yield a far better balance between side effects and analgesia.

For those patients in whom pain control is inadequate and who have intolerable side effects, different strategies are implemented to improve analgesia. Opioid rotation is a simple strategy that almost all physicians can implement. Depending on equianalgesic potency ratio guidelines, switch is made to other opioids such as methadone or transdermal fentanyl patch. This should be done under close supervision and preferably in an inpatient environment.

C. Invasive Therapy

C.1. Describe the role of peripheral nerve blocks in cancer pain management.

Some patients experience inadequate pain despite control, maximal medical management, or because of intolerable side effects. Interventional techniques may significantly reduce the level of pain allowing a significant decrease in analgesic requirement. Interventional therapies that can be considered depending on the location and distribution of the thoracic or abdominal pain and the involvement of viscera are the following:

- Intercostal nerve blocks
- Intrapleural blockade
- Splanchnic nerve blocks
- Celiac plexus block
- Hypogastric plexus block
- Thoracic and lumbar paravertebral blocks
- Rectus abdominis block
- Transversus abdominis plane (TAP block)
- Iliac crest block
- Ilioinguinal and iliohypogastric nerve block
- Cave of Retzius (space between urinary bladder and

symphysis pubis) block

The most useful blocks for the upper abdomen and thorax are intercostal nerve blocks and celiac plexus blocks and splanchnic nerve block and superior hypogastric and ganglion impair blocks for the lower abdomen, pelvic, and perineal pain. Thoracic and lumbar paravertebral blocks are performed to obtain spinal nerve segmental analgesia. The intercostal and thoracic paravertebral nerve blocks carry the risk of pneumothorax due to proximity of the pleura and lung. The peripheral nerve blocks are performed at anatomic sites away from the central neuraxis.

Patients with pancreatic cancer who was not tolerating opioids or not receiving adequate analgesia may benefit from a neurolytic celiac plexus block.

Neuraxial infusion of epidural and intrathecal analgesics reduces the doses of drugs required to provide adequate analgesia thereby reducing the adverse effects of systemic administration. It also benefits the patients with intolerable sedation, confusion, and/or inadequate pain control with systemic opioid administration or patients who have pain from a variety of anatomic locations.

Percutaneous kyphoplasty and vertebroplasty might be helpful for painful spinal metastases or in cases of vertebral compression fractures in, for example, multiple myeloma.

Neurodestructive procedures may be used for visceral pain from abdominal or pelvic malignancy.

Neurostimulation procedures have been useful for painful chemotherapy induced peripheral neuropathies, neuralgias, and complex regional pain syndrome.

Interventions are not appropriate if technical expertise is not available.

C.2. Describe the role of celiac plexus block in cancer pain management.

Diagnostic celiac plexus block with a local anesthetic is performed to precisely differentiate sympathetically maintained pain and localize retroperitoneal or upper abdominal pain. A positive result of the diagnostic block is an indication for more definitive neurolysis in chronic cancer and nonmalignant pain. Success rates of celiac plexus neurolysis are lower in patients suffering from chronic nonmalignant abdominal pain than in those suffering from abdominal pain due to neoplasms involving the upper abdominal viscera. Neurolysis of celiac plexus with alcohol or phenol is performed under fluoroscopic guidance or computed tomography–guided technique and strict sterile condition by using a single- or two-needle periaortic technique, single-needle transaortic technique, single-needle anterior technique, or endoscopic ultrasound (EUS)-guided technique. Individual skills of the treating physician, available facilities, patient's general condition, and extent of the spread of tumor should be considered in determining the type of technique to use.

Computed tomography (CT) guidance provides better visibility of tumor, lymph nodes, and the celiac plexus.

Pain physicians for celiac plexus neurolysis commonly use 40 to 50 mL of 50% to 70% alcohol or 6% to 10% phenol. Smaller volumes are recommended for absolute alcohol and higher concentration of phenol. Neurolysis with phenol is less painful because of its local anesthetic action, whereas alcohol neurolysis

is very painful and should be blocked with pretreatment with local anesthetics.

A Cochrane review from 1990 to 2010 to determine the efficacy and safety of celiac plexus neurolysis in reducing pancreatic cancer pain found that there is minimal statistical evidence for the superiority of pain relief over analgesic therapy; however, because celiac plexus block causes fewer adverse effects than opioids, it is important to consider for patients.

C.3. What are the complications of celiac plexus block?

Serious complications should rarely occur in the hands of a skilled clinician. Hypotension and increased gastrointestinal motility are the most common complications of this block. Neurologic complications include subarachnoid or epidural injection and lumbar nerve root injury, causing long-lasting paresthesia. A potentially severe complication can occur as a result of accidental injection into the nutrient artery of the spinal cord (artery of Adamkiewicz), causing paraplegia. Injury to the kidney may cause temporary hematuria that may not need any treatment. Other complications have been reported due to proximity of other vital structures include pneumothorax, chylothorax, intradiscal injection, retroperitoneal hematoma, and failure to ejaculate.

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2019:717–719.

C.4. Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.

In properly selected patients, epidural, intrathecal (subarachnoid), or intraventricular infusions of opioids have the advantage of producing profound analgesia without motor, sensory, or autonomic blockade. These routes are considered to deliver preservative-free medications when pain is not well controlled by noninvasive (oral, subcutaneous, or intravenous) routes and escalation of doses is limited by intolerable side effects. The potency ratio of oral to epidural morphine is 1:30 and that from oral to intrathecal morphine is 1:300. The decrease in the size of dose from oral to intrathecal greatly reduces the side effects and improves pain control and quality of life. The PCA technique can also be employed for epidural routes. Programmable intrathecal pumps can deliver medications at the prescribed dose. Fixed or flexible doses of morphine can deliver via the intrathecal pumps. Recently approved patient-controlled device allows patient-activated doses via the intrathecal pump (Personal Therapy Manager or PTM, Medtronic Neurological, Minneapolis, MN). Morphine is the most commonly used drug. Other opiates, local anesthetics, ziconotide, α_2-agonists, etc can be used as recommended by the Polyanalgesic Consensus panel.

These routes require a skilled experienced clinician, meticulous technique, and family and facility support in which close monitoring and follow-ups can be done. These procedures are reversible but involve an initial expense for specialized care and operating room costs. Intraspinal opioids may produce the same side effects of nausea, mental clouding, and sedation as in oral and parenteral dosing. Infection (e.g., meningitis and epidural abscess) and hematoma are potentially devastating complications that can cause permanent neurologic deficit if not dealt with in a timely basis. Pruritus and urinary retention are

more common than with oral or parenteral administration.

Stearns L, Boortz-Marx R, Du Pen S, et al. Intrathecal drug delivery for the management of cancer pain: a multidisciplinary consensus of best clinical practices. *J Support Oncol*. 2005;3:399–408.

C.5. Which medications can be used intrathecally? What is ziconotide?

Morphine is the most commonly used drug; other opiates such as hydromorphone, fentanyl, and sufentanil can be used intrathecally. In addition, local anesthetics, α-agonist such as clonidine, and baclofen can be used as recommended by the Polyanalgesic Consensus panel.

Recently, Prialt (ziconotide), a synthetic equivalent of a naturally occurring peptide found in marine snails, has been shown to be effective in pain relief when used intrathecally. It is a selective voltage-gated calcium channel blocker that inhibits release of pyroglutamate, calcitonin, and substance P in the brain and spinal cord. Side effects include dizziness, nausea, confusion, and psychosis, and therefore, patients trailed on ziconotide should be monitored for cognitive impairment, hallucinations, or changes in mood and consciousness.

Only morphine, baclofen, and ziconotide has been approved by the U.S. Food and Drug Administration (FDA).

C.6. What is a Personal Therapy Manager (PTM), and what role does it play in neuraxial pain relief?

Increasingly being used is a patient-controlled device that allows patient-activated doses via the intrathecal pump (PTM, Medtronics Neurological, Minneapolis, MN). The PTM enables the patient to activate delivery of physician-programmed supplemental doses of intrathecal medication. This is especially useful for patients experiencing intermittent pain of carrying intensity that cannot be adequately managed with a simple continuous infusion, have an unpredictable need for varying doses of drug, or experience inadequate pain relief or intolerable side effects from supplemental systemic breakthrough pain medications. Nevertheless, risk of sedation, respiratory depression, and other adverse effects are just as possible as when taking oral opiate supplementation, and therefore, caution and careful programming should be ensured. Also see section C.4.

C.7. Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.

Due to physical separation of motor and sensory nerve roots in the spinal canal and intrathecal space, chemical neurolytic procedures allow sensory blockade without loss of motor functions. Inadequate pain control with intolerable side effects makes this patient an ideal candidate for neuraxial neurolysis; however, complications of the procedure should be weighed against benefits. Epidural or intrathecal (subarachnoid) neurolytic blocks are considered for severe intractable pain from advanced cancer as an adjuvant to relieve pain and suffering and improve quality of life. These blocks are primarily effective in relieving pain of somatic origin and less effective for visceral and neuropathic pain.

In selected patients in whom pain relief is not achieved by less invasive measures, these blocks can provide rapid analgesia and allow dosage (and side effects) reduction of systemic drugs. However, risks of postural hypotension, bowel and bladder incontinence, and motor and sensory deficit in the lower extremities cannot be overemphasized. These blocks are irreversible and require a skilled clinician to perform the procedure.

C.8. Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?

Based on the location and type of pain (somatic, visceral, deafferentation), the general condition of the patient, the stage of tumor and metastasis, the life expectancy, and the expertise available, the following neurosurgical procedures could be considered:

- Peripheral neurectomy
- Dorsal rhizotomy
- Anterolateral cordotomy (spinal tractotomy)
- Commissural myelotomy
- Hypophysectomy

Ballantyne JC, Fishman SM, Rathmell JP, eds. *Bonica's Management of Pain*. 5th ed. Philadelphia, PA: Wolters Kluwer; 2019:1698–1707.

C.9. Describe the role of radiation therapy in cancer pain.

Radiation therapy can be curative or palliative to relieve pain from metastasis and symptoms from local extension of the disease. Radiation therapy is complementary to chemotherapy, surgery, and analgesic drug therapies to enhance the effectiveness of pain control. Radiating therapy can palliate when disease can not be controlled. Along with therapeutic effectiveness of radiation treatment, the absence of complete specificity for disease may exacerbate or even cause new pain. It is most commonly used for bone metastasis. The radiation dosage should be administered in the fewest fractions possible to promote pain control during and after treatment.

D. Nonpharmacologic Management

D.1. What are the various nonpharmacologic techniques of cancer pain management?

Eisenberg and colleagues demonstrated that cancer and other chronic pain syndromes like AIDS and arthritis may get benefit from alternative modalities. Practicing physical activity and

sport during cancer modifies fatigue and quality of life and reduces symptoms of depression.

The common therapies offered are as follows:

- Physical therapy and physical modalities
- Physical activity and sport
- Relaxation and massage
- Chiropractic manipulation
- Spiritual healing
- Biofeedback and hypnosis
- Magnetic and low-power laser therapy
- Transcutaneous electrical nerve stimulation (TENS)
- Homeopathy
- Acupuncture
- Prayer

D.2. What physical modalities have been successfully tried in cancer pain management?

Physical modalities may be useful in conjunction with conventional systemic and interventional treatments used to control cancer-related pain, especially in patients with movement-associated pain. Physical modalities may help decrease stiffness, increase blood flow to the part, help relax the patient, and reduce the dose of analgesics. They include

cutaneous stimulation, superficial heat and cold therapy, massage, vibration, and pressure. Cold therapy (cryotherapy) causes vasoconstriction, reduces inflammation, and decreases muscle spasm. Superficial application of heat (thermotherapy) acts through conduction or convection to increase blood flow to the skin and superficial organs. Heat also decreases joint stiffness and increases muscle flexibility. Physical therapy and exercise help to strengthen weak muscles, mobilize stiff joints, and restore coordination. Exercise may reduce pain by 25%. Weight-bearing exercises are avoided if an impending fracture is suspected.

D.3. Describe the role of neuromodulation in cancer pain management.

Neuromodulation techniques like spinal cord stimulation and deep brain stimulation have not been popular in cancer pain management because of incompatibility with magnetic resonance imaging (MRI). But this therapy is now being used more frequently since the availability of the MRI compatible spinal cord stimulator systems. Neuromodulation techniques have variable outcome results with success rates between 18% and 80% depending on the study cited. Much of the literature is about chronic nonmalignant pain syndromes. The consensus among most pain physicians is that neuropathic pain syndromes are more effectively treated as spinal cord syndromes than as nociceptive pain syndromes.

TENS and acupuncture are believed to activate endogenous pain-relieving pathways. Low-voltage stimulation to large myelinated peripheral nerves via cutaneous electrodes may significantly reduce pain. Spinal cord stimulation appears to be a promising therapy for intractable cancer pain and can offer relief of neuropathic pain, which is present in 15% to 40% of cancer pain patients. Recently, high-frequency spinal cord stimulation, burst stimulation and dorsal root ganglion, and MRI compatible spinal cord stimulation systems may increase the role of this therapy in cancer patient. Studies have shown significant pain relief in postthoracotomy pain, back pain, leg pain, groin pain, and testicular pain related to carcinoma. Based on the evidence, motor cortex stimulation should be abandoned.

D.4. What psychological techniques have been promoted for comfort care and pain relief?

Psychological distress impacts pain. Depression, anxiety, anger, and mood disturbances have been correlated with higher levels of perceived cancer pain. Also, there has been increase in the number of people surviving with cancer, as result of advances in cancer treatment, who are suffering from intractable pain. Psychological interventions are an important part of a multimodal approach to pain management in patients with cancer. Some techniques that are used are relaxation, biofeedback, hypnosis, imagery, and cognitive-behavioral therapy. They help patients gain a sense of control over pain. Cognitive and behavioral techniques are designed to influence

the interpretation of events and bodily sensations. Cognitive techniques help patients think differently about their pain and its management. Behavioral techniques help patients develop skills to cope with pain and help modify their reactions to pain. Patients who undergo psychotherapy report less pain. Relaxation therapy is a well-established modality in managing cancer pain. Several variations of relaxation strategies and techniques have been widely practiced in patients suffering from advanced cancer and have proven effective. Relaxation strategies like deep breathing, muscle relaxation, and imagery are recommended for the promotion of comfort and relief of pain in hospitalized patients.

Relaxation and imagery are used to achieve a state of mental and physical relaxation, thereby relieving anxiety and muscle tension.

Patients with higher levels of social support have reported lower intensity of cancer pain.

These interventions have medium-size effects on both pain severity and interference per meta-analysis by Gorin. Therefore, quality controlled psychosocial interventions should be part of a multimodal approach to managing pain in cancer patients.

D.5. What are distraction and reframing techniques?

What is the role of hypnosis in cancer pain?

Distraction and reframing techniques encourage focused attention on stimuli other than pain. This involves singing, talking, praying, and watching television. Reframing helps monitor and evaluate negative thoughts and images while encouraging positive thoughts and behavior.

Hypnosis by a skilled person decreases pain and anxiety in patients who have difficulty managing their pain. It also increases coping skills. This technique allows heightened awareness and focused concentration to manipulate perception of pain and has been effective in the management of cancer-related pain syndromes.

50 Low Back Pain and Sciatica

David Y. Wang

A 57-year-old former factory worker was injured on the job 8 years ago. He experienced severe low back and right leg pain after lifting a heavy piece of equipment and was found to have a herniated L4–L5 intervertebral disc with compression of the right L5 nerve root. He underwent a lumbar laminectomy and decompression surgery; nevertheless, he has continued to complain of back pain and right sciatica.

A. Medical Disease and Differential Diagnosis

1. How great an issue is low back pain in the general population?
2. What is the prevalence of low back pain?
3. What is the societal cost of low back pain?
4. What causes low back pain?
5. What are the risk factors for low back pain?
6. What are the potential sources of pain in the spine?
7. What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?
8. What is the anatomy of the spinal facets? How do the facet joints cause pain?
9. What are the important findings through history and physical examination?

10. What are the appropriate diagnostic studies for low back pain?
11. What is the differential diagnosis of low back pain?
12. What are the causes of persistent back pain after multiple spine surgeries?

B. Management of Low Back Pain and Sciatica

1. What are the noninterventional treatments available?
2. What traditional interventional treatments are available and how should they be used?
3. What are some of the recent safety improvements recommended for lumbar epidural steroid injection?
4. What are some of other approaches in minimally invasive interventions?
5. What are the concerns about magnetic resonance imaging (MRI) safety in patients with a spinal cord stimulator (SCS)?
6. When should surgery be considered?
7. What surgical options are available for the treatment of disc disease?

A. Medical Disease and Differential Diagnosis

A.1. How great an issue is low back pain in the general population?

Disorders of the lumbosacral spine cause pain, disability, suffering, public health issues, and socioeconomic issues. Most adults will experience several episodes of low back pain during their lifetime. It is estimated that 80% of workers will lose work time because of this complaint. On the basis of primary diagnosis only, a National Ambulatory Medical Care Survey from 1989 to 1990 ranked low back pain as the fifth most frequent reason for adults to visit an office-based medical practice. In 2010, low back pain was ranked third behind only ischemic heart disease and chronic obstructive pulmonary

disease in causing poor health and mortality burden in United States. Lower back pain has been ranked the highest in terms of causing disability and fifth in the overall burden per the Global Burden of Disease 2010 study.

Hart LG, Deyo RA, Cherkin DC. Physician office visits for low back pain. Frequency, clinical evaluation, and treatment patterns from a U.S. national survey. *Spine (Phila Pa 1976)*. 1995;20:11–19.

National Institute of Neurological Disorders and Stroke. *Low Back Pain Fact Sheet*. Bethesda, MD: National Institute of Neurological Disorders and Stroke; 2014:1–50. NIH publication 15-5161.

A.2. What is the prevalence of low back pain?

A global review of the prevalence of low back pain in the adult general population has shown its point prevalence to be approximately 12%, with a 1-month prevalence of 23%, a 1-year prevalence of 38%, and a lifetime prevalence of approximately 40%. Furthermore, as the population ages over the coming decades, the number of individuals with low back pain is likely to increase substantially. Low back pain usually begins in early life, with the highest frequency of symptoms occurring between ages 35 and 55 years. Of all adults in industrialized societies, 60% to 80% are affected at some point in their lives. Work absence and symptom duration increase with aging. An acute episode of low back pain usually resolves within 6 weeks. More persistent pain lasting beyond 3 to 6 months occurred in only 5% to 10% of patients with back pain. The U.S. Agency for Health Care Policy and Research reported that 90% of patients with acute low back pain recover their usual activity tolerance within 4 weeks of injury. The remaining 10% of patients who do not recover with time or routine therapy go on to develop chronic symptoms and secondary problems. At 1 year, the

incidence of acute back pain converting to chronic back pain is 20%. Recurrences of low back pain are also common, with the percentage of subsequent low back pain episodes ranging from 20% to 44% within 1 year for working populations to lifetime recurrences of up to 85%.

A.3. What is the societal cost of low back pain?

The costs of low back pain include functional impairment, activity limitations, reduced quality of life, disability, underemployment, reduced work productivity, and direct medical cost. It appears that the societal perception of disability has changed dramatically over time. This has resulted in an increased rate and cost of disability and overutilization of medical care, including surgical treatments. Back pain in workers 40 to 65 years of age costs employers an estimated $7.4 billion per year. Duke University Medical Center researchers found that patients suffering from back pain consume more than $90 billion annually in health care expenses, with approximately $26 billion of that amount directly attributable to treating the back pain. Their results demonstrate the enormous economic impact of back pain. The total $90 billion spent in 1998 represented 1% of the U.S. gross domestic product (GDP), and

the $26 billion in direct back pain costs accounted for 2.5% of all health care expenditures for that year. These data came from the Medical Expenditure Panel Survey (MEPS) in 1998. The team found that 25.9 million adults reported back pain in 1998, with 172.7 million reporting no back pain. The figures do not include information about back pain in nursing home patients, who in the 1977 research accounted for about 20% of medical costs. As a result, the costs of care for back pain almost certainly top $100 billion annually. A study in the *Journal of the American Medical Association* found that chronic pain conditions, including arthritis, back problems, and other ailments, drain $61.2 billion a year from the U.S. economy. Back pain accounted for about a quarter of the lost or unproductive work and is second only to headaches as the most frequent pain complaint of workers. The annual cost to U.S. employers is $100 billion for spine-related disabilities.

A.4. What causes low back pain?

Majority of low back pain is mechanical in nature caused by injury, compression, tears, and bone and disc degeneration. Common causes include the following:

- Sprains and strains

- Intervertebral disc degeneration/internal disc disruption (IDD)
- Herniated disc (bulge, protrusion, extrusion, sequestration of disc)
- Radiculopathy
- Spondylosis/facet joint arthrosis
- Spondylolisthesis
- Traumatic injury
- Spinal stenosis/foraminal stenosis/lateral recess stenosis
- Skeletal irregularity (scoliosis, kyphosis)
- Compression fracture/end plate fracture
- Cluneal nerves entrapment (superior and middle cluneal nerves)
- Sacroiliac joint dysfunction
- Other underlying conditions
  - Infections
  - Tumors
  - Abdominal aortic aneurysms
  - Kidney stones
  - Endometriosis
  - Fibromyalgia

A.5. What are the risk factors for low back pain?

Traditional beliefs suggested that heavy physical jobs required high-energy demand and significant stress and strain on the spine, whereas light jobs required low-energy demand. Many low-energy jobs, however, are static, which is an inherent risk factor for low back pain. Low back pain, degenerative disc disease, and disc herniation are associated with the following:

- Repetitive heavy lifting
- Static work posture (sitting or standing)
- Frequent twisting and bending
- Vibration (operation of motor vehicle or industrial device)
- The common vibration of construction vehicles and industrial devices ranging in frequency from 3.5 to 8.9 Hz.
- Low-frequency vibration, especially around 5 Hz, in conjunction with a prolonged seated position is associated with spine problems.
- The potential for damage to the disc through mechanical resonance is analogous to the high notes of an opera soprano shattering a wine glass.
- Fatigue of the abdominal and paraspinal muscles has been demonstrated when subjected to 30 minutes of vibration. In the absence of this support, the spine is further susceptible to injury.
- A meta-analysis of 17 studies revealed that whole-body vibration is associated with an increased risk of low back pain, sciatica, and lumbar intervertebral disc disorders.
- Cigarette smoking is linked to low back pain, sciatica, and lumbar disc herniation. In an animal model, cigarette smoking significantly affects the vasculature outside the intervertebral disc, where the most pronounced effect is the reduction of solute-exchange capacity, cellular uptake, and metabolism within the disc.
- Cross-country skiing. In a study of skiing and spinal trauma, the diagonal body position required for cross-country skiing was the most common back pain–inducing stance, whereas no skier experienced back pain when only downhill skiing.

The “oxidative stress hypothesis of aging” theory proposed that enhancement of oxygen consumption resulting from increased physical activity may accelerate disc degeneration. On the other hand, strenuous exercises may contribute to positive

nutritional effect by facilitating the transport of small solutes into and out of the disc. Generally, it is believed that people who are physically fit or who maintain a balanced exercise program appear to have a lower risk for chronic low back pain and a more rapid recovery after an episode of acute back pain.

A.6. What are the potential sources of pain in the spine?

In order to more easily identify the various sources of pain, the spine may be divided into three compartments: anterior, middle, and posterior.

The anterior compartment consists of the vertebral body and intervertebral disc. The anterior unit is bound together by cephalocaudal ligaments: anterior longitudinal ligament and posterior longitudinal ligament (PLL). The anterior longitudinal ligament is anatomically much broader and stronger than the PLL. The PLL is intact throughout the length of the vertebral column until it reaches the lumbar vertebrae. From L1, it becomes progressively narrower until at L5–S1 it is only half of its original width. This anatomic feature contributes to an inherent structural weakness in the lumbar spine. Hence, the lower lumbar spine is the region subjected to the greatest static stress and most spinal movement resulting in the greatest kinetic strain.

The middle (neuraxial) compartment contains all of the structures within the bony and ligamentous boundaries of the spinal canal. This includes the PLL, epidural space, meninges, spinal cord, dorsal and ventral nerve roots, root sleeves, dorsal

root ganglia, and ligamentum flavum.

The posterior compartment contains the facet joints, laminae, vertebral arches, and structures posterior to the plane of the transverse processes and innervated by the dorsal rami of the spinal nerves. The ligaments are extremely important in stabilizing the vertebral column. The ligamentum flavum (yellow ligament), which connects the laminae of adjacent vertebrae, is the thickest and strongest ligament in the lumbar region. It can contribute to spinal stenosis by folding inward during an upright posture, extension of the back, and hypertrophying.

The sinuvertebral nerve (also known as recurrent meningeal nerve) originates lateral to the neural foramina and enters the spinal canal anterior to the dorsal root ganglion (DRG). It is a branch of the somatic ventral nerve root and the sympathetic grey ramus communicans. This specific nerve, the nerve of Luschka, innervates the outer one-third of the disc annulus, PLL, epidural membranes, and dura at the segmental level of origin and adjacent levels. Therefore, it has the ability to transmit pain messages from a problematic disc to the brain. It is important to note that central low back pain, with or without referred pain to the buttocks, may derive from the irritation of the outer part of the annulus fibrosis or the PLL.

In summary, the potential sources of low back and radicular pain include the bony structure of vertebrae, muscles attached to the spine and hips, fasciae, ligaments, discs, facet joints, meninges, vessels, nerve roots, DRG, and nerves in the surrounding areas.

The natural wear and tear on the discs and facet joints results in microtrauma and degeneration. This can induce the release of neurohumoral mediators such as phospholipase A_2, serotonin, H^+, substance P, prostaglandin E_2, and so on, to produce

inflammation of the nerve roots or meninges and to sensitize local nociceptors. Furthermore, it has been theorized that material from the nucleus pulposus, sheltered from the immune system by the presence of the annulus fibrosus, might act as a foreign protein and trigger an autoimmune reaction. The demonstration of an activated immunocompetent cellular response at the epidural interface of the herniation of the nucleus pulposus supports the concept of the immunogenic capacity of the nucleus pulposus. Tissue injury or inflammation can cause a barrage of nociceptive input into the spinal cord. This may lead to a phenomenon called *central sensitization* or *windup* of neurons in the dorsal horn of the spinal cord. The release of excitatory amino acids and neuropeptides in the dorsal horn is thought to be the mechanism underlying the phenomenon of central sensitization. At the cellular level, there is an increase in spontaneous discharge and an expansion of neural receptive fields of wide-dynamic-range (WDR) neurons located in Rexed lamina V of the spinal cord. Clinically, this is characterized by the sensation of pain when exposed to nonnoxious stimuli (allodynia), a significantly increased response to painful input (hyperalgesia), and an increased response to repetitive stimulation (hyperpathia).

A.7. What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?

The intervertebral disc is a ring-like structure composed of a centrally located well-hydrated pliable proteoglycan matrix, the nucleus pulposus, which comprises two-thirds of the surface area of the disc. Surrounding the nucleus is a fibrocartilaginous ring composed predominantly of type I collagen, the annulus fibrosus, which makes up the remaining one-third of the surface area of the disc. The annulus fibrosus is stronger anteriorly but often defective posteriorly. As a self-contained fluid system, the disc absorbs shock, permits transient compression, and allows movement. It provides a cushion between the vertebral bodies and allows for greater flexibility.

As the disc ages, the number of viable cells in the nucleus pulposus decreases, and the proportion of cells that exhibit necrosis changes from 2% in infancy to 50% in young adults and 80% in the elderly. The water content in the young disc is 80% to 90% in the nucleus pulposus. With aging, the discs tend to dehydrate, losing up to 70% of their water content. As the nucleus pulposus further dehydrates, it becomes more fibrous and less compliant. A disc will usually herniate under strain and pressure. When overstressed, it will protrude along in the path of least resistance, usually posterolaterally. This can cause direct mechanical pressure on the nerve roots resulting in radiculopathy.

In the healthy back, only the outer third of the annulus fibrosus is innervated. In the degenerative or disrupted disc, small unmyelinated nerve fibers grow into the inner third of the annulus fibrosus and even into the nucleus pulposus. IDD is a condition characterized by a degenerated nucleus pulposus with radial fissures extending into the peripheral annulus fibrosus.

Upon rupture of the disc, the release of irritative material near the meninges can induce radiculitis and symptoms of radiculopathy without actual herniated disc material compressing the nerve roots. Under such circumstances, significant disc herniation might not be visualized on MRI or computed tomography (CT) scan. In brief, the proposed mechanisms of radiculopathy include direct pressure on nerve fibers as a result of compression injury and indirect impact through impairment of microcirculation, chemical irritation and inflammation, immune reaction, edema formation secondary to permeability changes of the intraneural capillaries, and impairment of the nutritional transport to the nerve root.

Compression of the nerve roots is dependent on the effective space available within the neural foramina, the osseous structures surrounding the neural foramina, and the tethering effects of the intraspinal and extraspinal ligaments. Posterolateral disc herniations can impinge on the lumbar dorsal root, which then initiates electrical discharges for as long as 25 minutes after the mechanical stimulus has been removed. Radiculopathy can be produced by either biochemical or mechanic stimulation of a swollen, stretched, or compressed nerve root. Approximately 3% to 12% of all lumbar disc herniations occur laterally and extend into or beyond the foraminal zone; in this setting, the patients will complain of sudden and severe radicular pain, often with dysesthesia. On the other hand, discogenic pain resulting from a central disc bulge or herniation stimulates several lumbar tissues such as the outer layer of the annulus fibrosus or PLL. Clinically, this is manifested as central low back pain without any radicular symptoms.

A.8. What is the anatomy of the spinal facets? How do the facet joints cause pain?

The facet, or zygapophysial, joints consist of two arthrodial joints superiorly and inferiorly, each lined with synovium, lubricated by synovial fluid, and contained within a joint capsule. These synovial joints enhance spinal stability and flexibility. In the upper part of the lumbar spine (L1–L3), the facet planes lie in a generally vertical sagittal plane and permit flexion and extension but prevent lateral flexion or bending in the lordotic curve. The lumbosacral facet joints at the level of L5–S1 depart the farthest from the sagittal plane, allowing some rotation of the lower part of the lumbar spine. With slight forward flexion, the facets of the other lumbar vertebrae separate and permit a modest degree of lateral movement and rotation. Facet loading, if of a repetitive nature, may play a role in the degeneration of the facet joint. After repeated wear and tear, these joints are susceptible to osteoarthritis and associated synovial cyst formation. Hypertrophic facet joints or cysts can encroach on the spinal canal or the intervertebral foramina and contribute to the development of central spinal, lateral recess, or foraminal stenosis.

A.9. What are the important findings through history and physical examination?

A problem-focused pain history should include onset, location, intensity (e.g., pain scale 0 to 10), characteristics (achy, spasmodic, stabbing, burning, shooting, etc.), and duration plus aggravating and alleviating factors. The essential purpose in the initial evaluation is to differentiate patients with serious underlying pathology from those with mild problems.

Patients with a disc problem will usually experience an exacerbation of their symptoms with spinal flexion, which increases intradisc pressure. By contrast, in the setting of spinal stenosis, standing or walking exacerbates back and leg pain, whereas some forward flexion may alleviate these symptoms. In moderate-to-severe spinal stenosis, extension of the spine may cause radicular pain.

Patients with compression fractures typically present with severe back pain, often intense with minimal lateral rotation or with flexion and relieved by rest. A history of bladder, bowel, or sexual dysfunction may indicate compression of the cauda equina or conus medullaris. Unlike sciatica, often with its unilateral nerve root involvement, patients with cauda equina syndrome usually have bilateral involvement. Although motor function may be normal and pain uncommon in those with conus lesions, patients often demonstrate abnormalities of sensation in a saddle distribution, feeling touch or dysesthesia, but neither pain nor temperature. Causes of these symptoms may be a fracture of L1 or L2, tumor, large central disc herniations, or

intramedullary cysts affecting the conus. These disorders are considered surgical emergencies and require aggressive evaluation and prompt surgical consultation.

The physical examination should include Lasègue sign (the straight leg raising test), Braggard (Bragard) test (dorsiflexion of the ankle with elevation of the leg), and the crossover test. These clinical tests are considered positive when sciatica is reproduced with elevation of the leg between 30 and 60 degrees. If testing the uninvolved leg produces contralateral symptoms, disc disease should be considered. A positive crossover sign occurs when straight leg raising of the patient's contralateral leg elicits pain on the affected side. It is usually a strong indication of nerve root irritation or compression. Extension of the knee while in a seated position, also known as *distracted straight leg raise*, can test sciatic nerve tension too. The patient with significant nerve root irritation tends to complain of increased pain or lean backward to reduce tension on the nerve. The differential diagnosis of spinal shock, upper motor neuron lesions, and lower neuron lesions is shown in **Table 50.1**. The nerve root signs are shown in **Table 50.2**.

TABLE 50.1 Differentiating Spinal Shock, Upper Motor Neuron Lesions, and Lower Motor Neuron Lesions

Disease State	Deep Tendon Reflex	Pathologic Reflex/Plantar Response	Superficial Reflex (Normal)
Spinal shock	Absent	Absent	Absent
Upper motor neuron disease	Increased; rarely may be decreased in the acute setting	Positive/extensor Babinski sign + Oppenheim sign +	Decreased or absent For example, cremasteric reflex −
Lower motor neuron disease	Decreased	Negative/flexor	Present (but L1–L2 lesion will have cremasteric reflex −)

+, positive; −, negative.

TABLE 50.2 Nerve Root Signs

Root Level	Reflex Decrease	Sensory Defect	Motor Weakness
L4	Knee jerk	Anterior thigh, knee, and shin	"Single squat and rise test"; quadriceps (mostly L4)
L5	No easily elicited reflex	Lateral leg and middle dorsal foot	"Heel walk test"; dorsiflexion of foot and toes (L5 and some L4); especially big toe, extensor hallucis longus (EHL)
S1	Ankle jerk	Posterior calf and sole	"Toe walk test"; gastrocnemius/soleus; "toe flexors"

A.10. What are the appropriate diagnostic studies for low back pain?

In the absence of signs of serious medical disease, there is no need for special studies because 90% of patients will recover spontaneously within 4 weeks of the onset of pain. Waiting 4 weeks before considering special tests allows these patients to recover spontaneously and avoid unneeded procedures. When pain persists beyond 4 to 6 weeks (or shorter if it is severe), plain radiographs (x-ray) of the spine should be considered. Pertinent findings include the height of the intervertebral spaces and vertebral bodies, and bony changes in the end plates. With oblique views, the facet joint space and any spondylolysis can be revealed. The lateral view can help estimate the severity of spondylolisthesis. If there is symptom of vague flank pain with or without hematuria, which renal colic pain often begins as, a kidney, ureter, and bladder (KUB x-ray, similar to abdomen x-ray) radiography can help to identify stones. A CT scan can show a herniated disc or fragment in the spinal canal. It can help to identify early epidural hematoma. With contrast, it can help

further differentiate tumors, abscesses, and granuloma in the central nervous system. MRI provides excellent anatomic definition of the disc and its hydration status; it can also show the anatomy of the surrounding soft tissues. MRI with intravenous gadolinium is indicated for distinguishing between a recurrent disc herniation and recent postoperative scar tissue. It is particularly useful when distinguishing intrinsic from extramedullary or epidural spinal cord lesions. When MRI is contraindicated, a myelogram may reveal a filling defect at the level of posterior bulging discs. The myelogram in conjunction with a CT scan enables axial imaging of the spinal cord and subarachnoid space. A bone scan is helpful in the diagnosis of bone or bony fractures that may not be visible by radiography or CT scan, or whenever metastatic disease is suspected.

A.11. What is the differential diagnosis of low back pain?

In general, there are numerous diagnostic labels used to describe low back pain, for example, lumbosacral sprain, lumbar discogenic syndrome, mechanical low back pain, spinal stenosis, spondylosis, spondylolisthesis, osteoarthritis/facet joint syndrome, myofascial pain syndrome, unstable low back, discitis, and failed back surgery syndrome (FBSS). Each of these labels suggests its own underlying pathology. It is also helpful to review causes of low back pain that are described at section A4.

Acute lumbosacral sprain, by far the most common cause of new-onset low back pain, is often only associated with the

presence of postural back pain. It frequently results from reflex muscle spasms secondary to local irritation of structures in the back. When muscle spasms occur, the normal anatomy may be disturbed and undue force applied to surrounding tissues and structures.

Clinically, the following five tests are not uncommonly requested by spinal surgeons for further differential diagnosis. Discography/discogram/discomanometry (discometry) is a specialized diagnostic test specifically indicated to help diagnose discogenic pain. The presence of pain fibers in the outer third of the annulus fibrosus may explain back pain in some individuals with an annulus tear or IDD. The test involves an intradiscal puncture and instillation of contrast into the disc nucleus. It provides direct confirmation of nuclear morphology and the integrity of the vertebral end plate and annulus. Selective nerve root block with local anesthetic is performed to determine if a specific spinal nerve is the source of pain. Either facet joint block (intra-articular injection) or medial branches block may help differentiate between axial discogenic pain and facet joint pain syndrome. Sacroiliac joint injection can help to rule out pain resulting from sacroiliac joint dysfunction. Electromyography (EMG) and nerve conduction studies (NCS) can help diagnose neuromuscular abnormalities/disorders. In every case, a careful history, physical examination, and the appropriate diagnostic studies will help elucidate the "pain generator."

A.12. What are the causes of persistent back pain after multiple spine surgeries?

Persistent back or leg pain after one or more spinal surgeries is called FBSS or *postlaminectomy syndrome*. The aforementioned implies persistent radicular symptoms or neuropathic complaints after previous surgery (most commonly in the lumbar spine). Usually, the cause is a combination of both nociceptive and neuropathic pain. Over time, a strong psychological component can develop with progressive disability as treatments fail. Approximately 37,500 patients are diagnosed with this syndrome annually in the United States.

When pain persists or recurs in a patient after spinal surgery, the most common causes are those of foraminal stenosis, discogenic disorder and recurrent disc herniation. Epidural fibrosis and scarring are less common. Patients with this condition often report constant dull, aching, poorly localized low back pain with intermittent sharp episodes. They may also report pain or abnormal sensations with neuropathic characteristics such as burning, shooting, throbbing, stabbing, or pulling. The exact source of these complaints is unclear, although the scar tissue or arachnoiditis is frequently implicated. When reoperation is performed for the purpose of neurolysis only, a transient improvement of sciatica may be seen, but it usually recurs within the first postoperative year. Success rates for reoperating on patients with FBSS have been highly variable, ranging from 25% to 80%. These patients are perhaps the most challenging of all. They deserve a comprehensive multidisciplinary evaluation, including orthopedic and neurosurgical consultations. Furthermore, surgical intervention should be avoided in the absence of a clear indication. Repeated imaging studies add to the health care expenses and

interventions that may not have a great therapeutic yield.

B. Management of Low Back Pain and Sciatica

B.1. What are the noninterventional treatments available?

The cornerstone of treatment for low back pain and mild sciatica caused by a herniated lumbar disc is conservative care, which includes bed rest, medications, and physical therapy. Patients whose symptoms fail to respond to conservative care may require more invasive treatment.

Evidence of both clinical and epidemiologic data suggests that the longer the back pain and work loss persist, the less likely there will be improvement of the pain. The chance for return to work is even lower. Improved early management and greater access to primary care services should greatly reduce the number of patients with a simple backache requiring a referral to a hospital. An early return to activity seems to be associated with a better outcome than does prolonged bed rest (greater than 4 days).

Treatment varies depending on the cause of pain. In December 1994, the Agency for Health Care Policy and Research announced the following guidelines for the care of acute low back problems:

- A brief period of rest
- Over-the-counter pain relievers

- Trunk-strengthening exercises
- A single spinal manipulation

In order to avoid reinjury, an incremental, gradually increasing regimen of aerobic exercise (up to 30 minutes daily) can usually be started within the first 2 weeks of symptom onset. Such activities have been found to stress the back no more than sitting on the side of the bed for an equal period of time. The combination of aerobics for general fitness with some specific training to improve the strength and endurance of the back muscles is often beneficial.

The role of medications in the treatment of low back pain is to control pain, facilitate rehabilitation, restore normal sleep patterns, and improve mood and motivation. Nonsteroidal anti-inflammatory drugs are an essential part of the treatment of patients with inflammatory back pain, such as that associated with spondylitis. Other medications that have been shown to be useful include tricyclic antidepressants and anticonvulsants. Muscle relaxants are often used to decrease muscle spasms and assist in promoting rest for patients with severe pain. These are usually indicated for short-term treatment and acute relief. Short-term therapy with opioid analgesics may be needed to promote rest as well as maintain activity in the acute phase of low back pain. Long-term use of these medications is generally discouraged. When recovery does not occur within 4 to 6 weeks and no additional pathology is detected, physical therapy is indicated. Patients should be encouraged to increase activities. Patients limited by back symptoms can minimize the stress of lifting by keeping any lifted object close to the body at the level of the navel. However, activities such as twisting, bending, and reaching while lifting, also increase stress on lumbar disc or back. Those are well-demonstrated by Dr. Alf Nachemson's studies, which are summarized by his classical drawings of different body positions over pressure (L3–L4 intradiscal

pressure) bar graphs. His pioneering disc pressure measurements are still quoted extensively in many textbooks.

Prolonged sitting may aggravate back symptoms in discogenic pain patients because of the progressive increase in pressure at specific points in the abnormal disc. Body weight optimization and a program that teaches good posture and body mechanics are very important. Neuromuscular reconditioning must be included to ensure a function-specific, task-oriented program. The exercise training is designed as a step-by-step program to improve a patient's function and optimize neutral spine posture. These programs include stabilization training to attain adequate dynamic control of their lumbar spine forces and eliminate repetitive injury. Soft tissue flexibility, joint mobility, abdominal muscle strengthening, and aerobic exercise are also important factors. Spinal manipulation is controversial and is neither recommended in patients with radiculopathy pain nor is it wise in those for whom a diagnosis has not been established.

Nachemson A. The load on lumbar disks in different positions of the body. *Clin Orthop Relat Res*. 1966;45:107–122.

B.2. What traditional interventional treatments are available and how should they be used?

Common traditional interventional treatment includes the following:

- Trigger point injection
- Traditional epidural steroid injection (interlaminar or caudal approach)
- Transforaminal epidural steroid injection (transforaminal approach)

- Facet joint intra-articular block or medial branch block
- Sacroiliac joint injection

Interventional techniques such as trigger point injections and local infiltration are used to provide pain relief of short duration, especially in acute phase, so that other activities and physical therapy that might otherwise be severely limited by pain may be pursued.

Corticosteroids play an important role against inflammation and reduction of edema. Steroids injected into the epidural space have been used for treating low back pain and radiculopathy for many decades. Despite widespread use, the results of epidural steroid injection are still in question because studies evaluating the response to this therapy have been small, poorly controlled, and lacking good long-term follow-up. Published studies of the effectiveness of epidural steroid injections have varied from 18% to 90%. Epidural steroid injections can be performed through the interlaminar route, the caudal canal, or the intervertebral foramina. The spread of solution in both caudal and interlaminar injection is less controllable because of inconsistent lateral flow into the ventral compartment. This renders the medication less effective as it is diverted away from the compartment, depending on the tightness of the lateral recess (e.g., lateral recess stenosis) and the size of the dural sac. In normal volunteers, the transforaminal method showed good ventral flow, whereas the interlaminar approach showed predominantly dorsal flow, which was far from the usual site of impingement.

Patients who suffer from lumbar facet arthropathy may have symptoms, including band-like low back pain and associated hip, groin, or thigh pain. Pain rarely radiates below the knee in this condition. Blockade of the medial branch of the dorsal ramus of the spinal nerve or intra-articular injections of the lumbar facets are effective in short-term alleviation of this type

of pain. Radiofrequency ablation (RFA) procedures use radiofrequency energy to disrupt nerve function. When it is applied to medial branch nerves, the transmission of pain signal from problematic facet joints can be limited or reduced for several months (greater than 6 months).

Among back pain patients, 15% to 30% were found to have pain arising from the sacroiliac joint. The joint is innervated by L5–S2 ventrally and L5–S4 dorsally. Liliang et al. demonstrated that 40% and Depalma et al. found that 43% of postlumbar fusion patients had pain that was derived from sacroiliac joint. In addition, Ha et al. reported that 75% of postlumbar fusion patients showed sacroiliac joint degenerative changes on CT scan at 5 years follow-up. The sacroiliac joint block serves as a diagnostic procedure to determine if the sacroiliac joint is the source of the patient's pain.

B.3. What are some of the recent safety improvements recommended for lumbar epidural steroid injection?

The working group (expert working group with facilitation from the U.S. Food and Drug Administration [FDA] Safe Use Initiative [SUI]) and the advising national organizations (representatives from leading specialty societies) unanimously agreed that epidural injections of steroid were rarely associated with serious complications due to injuries of the central nervous system. They agreed that transforaminal injections are associated with a risk of catastrophic neurovascular complications and that particulate steroids appear to be inordinately represented in case reports of these complications. Clinical considerations improving technical aspects of the procedures included use of appropriate image-guided views (**Figs. 50.1** and **50.2**), injection of contrast under the real-time fluoroscopy, review of prior imaging studies, use of face mask and sterile gloves, use of extension tubing, and avoidance of heavy sedation. Although digital subtraction imaging (DSI) may help to detect vascular uptake (**Fig. 50.3**), the sensitivity was demonstrated to be 60% in one study as compared to aspiration sensitivity of 20%.

B.4. What are some of other approaches in minimally invasive interventions?

There are different interventional techniques for the management of low back pain and sciatica that can be applied to

appropriately selected patients. These include the following:

- Epidural neuroplasty or epidural adhesiolysis
- Epiduroscopy (spinal canal endoscopy)
- Percutaneous radiofrequency denervation of medial branches for facet joint pain
- Automated percutaneous discectomy (APD) or percutaneous automated discectomy (PAD) or percutaneous automated nucleotomy (PAN)
- Percutaneous laser disc decompression (PLDD)
- Intradiscal electrothermal therapy (IDET)
- Percutaneous disc decompression using nucleoplasty
- Percutaneous lumbar discectomy using Dekompressor probe
- Minimally invasive lumbar decompression (MILD) procedure
- SCS/DRG stimulation
- Intrathecal drug delivery
- Percutaneous vertebroplasty (PV) and percutaneous kyphoplasty (PK)

Epidural neuroplasty or epidural adhesiolysis is done with hypertonic saline and hyaluronidase to lyse epidural adhesions. This technique involves placing a rigid catheter into the epidural space, with manipulation of the catheter to physically breakdown the adhesions and applying local anesthetic, steroid, hypertonic saline (10%), and hyaluronidase over several days.

Epiduroscopy (or spinal canal endoscopy) allows direct visualization of the epidural space using a flexible fiberoptic catheter. Adhesions are lysed with the catheter under direct vision; thereafter, better delivery of medications to the target area can be achieved.

Percutaneous radiofrequency denervation of the medial branches of the dorsal (or posterior) rami of segmental spinal nerves is achieved by applying heat to denature the nerves that innervate the painful facet joints. The success rate has been reported variably in the range of 17% to 90% for facet joint pain

of a few weeks' to several months' duration. With this technique, the pain may return several weeks to months after the axons regenerate; repeating the procedure is then indicated.

Percutaneous manual nucleotomy was first presented in 1975. It was proposed as a method of preventing perineural and epidural scar formation by avoidance of entry into the spinal canal. Thereafter, APD or PAD or PAN was designed as a procedure using a "nucleotome" (reciprocating suction-cutting probe) for intradiscal decompression in 1985. The cannula requires a sizable annular incision to reach the nucleus. Its success rate is approximately 70% to 80%.

PLDD is a technique, introduced in 1987, that uses neodymium:yttrium-aluminum-garnet (Nd:YAGq) laser to "vaporize" a small portion of the nucleus pulposus in an attempt to decompress the involved disc. It has been demonstrated that the inner pressure of the nucleus pulposus drops significantly after the disc ablation. Its success rate is approximately 78%. After 4 to 6 months from this treatment, it was demonstrated that one-third of repeat MRI scans showed a modest to moderate decrease in the size of disc herniation. There is concern, nevertheless, that the technique is potentially hazardous to bone and nerve tissue because of the significant rise in temperature resulting from thermal energy transfer.

IDET or annuloplasty, first reported by Saal and Saal in 2000, has been shown to be effective in managing discogenic pain. It is a minimally invasive procedure in which a catheter is inserted into the nucleus pulposus through which an electrode is passed so that a controlled level of heat at a temperature of 90°C (194°F) can be applied to a broad section of the affected disc's inner wall. This thermal therapy is postulated to alleviate discogenic pain by shrinking collagen at a target temperature of 65°C (149°F) to 75°C (167°F). Another proposed mechanism is denervation of exposed nociceptor endings in the outer disc

annulus starting at 45°C (113°F).

Percutaneous disc decompression with nucleoplasty is used for those patients whose symptoms are attributed to radiographically contained discs, that is, a disc with an intact outer annulus. Since 2000, by combining tissue removal with thermal treatment, disc decompression has been achieved. It applies a focused "coblation" technique, ablating while coagulating (by using bipolar radiofrequency) to reach the level of 40°C (104°F) to 70°C (158°F). At this temperature, molecular dissociation is achieved and thought to minimize the potential for surrounding tissue damage.

Percutaneous disc decompression using a Dekompressor probe is another option for those patients whose symptoms are attributed to radiographically contained discs. It provides objective evidence that disc was removed, the cellular character of that material, and provides a qualitative and quantitative measure.

MILD is a procedure that involves limited percutaneous laminotomy and thinning of the ligamentum flavum in order to increase the critical diameter of the stenosed spinal canal.

SCS is a technique in which electrodes are passed into the posterior epidural space. Electrical stimulation of the spinal cord has been shown to be effective in the management of certain neuropathic pain syndromes and postlaminectomy syndromes. The exact mechanism by which pain relief is achieved remains controversial. Frey et al. performed a systematic review of the literatures and found level II evidence for the use of SCS for FBSS on a long-term basis. Newer advances in spinal stimulation include high-frequency (10 kHz), burst, and DRG stimulation. High-frequency stimulation preferentially blocks larger diameter fibers and concomitantly recruits medium and small fibers. Burst stimulation involves delivering closely spaced, high-frequency stimuli to the spinal cord as opposed to

the usual low-frequency tonic stimulation, which is constant. Therefore, it may provide a benefit by breaking through the physiologic tolerance issue derived from tonic stimulation. The DRG contains the primary sensory neurons that transmit pain signals from the peripheral nerves to the brain. When stimulated, it can modulate or filter the transmission of peripheral painful signals to the brain. Recent study in 2018 by Kallewaard et al. demonstrated DRG stimulation induced pain relief in subjects with failed back pain syndrome. These reductions in pain were also associated with improvements in quality of life and disability.

Intrathecal drug delivery directly into the cerebrospinal fluid through an implanted catheter and pump can be used to treat intractable pain from a variety of causes, both nociceptive and neuropathic. A variety of medications and combinations thereof can be used depending on the type and location of symptoms. Among the experts, this is known as *intrathecal polyanalgesia*. This modality is indicated when increasing doses of opioid are required to achieve pain relief but at the expense of disabling side effects. The dose is effectively reduced to approximately 1/300, for example, when converting an oral dose of morphine to its equipotent equivalent delivered intrathecally.

PV and PK are both advanced techniques used in the treatment of painful compression fracture. In the United States, compression fractures occur in approximately 700,000 patients per year, and 80% of these fractures occur in women. The conventional management includes bed rest, analgesics, and bracing. PV was a technique developed in 1984 for the treatment of painful vertebral hemangiomas. It has since become popular for the treatment of osteoporotic vertebral body compression fracture. It involves the application of liquid cement (polymethylmethacrylate), tobramycin, and barium powder (as nonionic contrast) through a special metal needle inserted under

fluoroscopy. The cement provides vertebral solidification and buttresses the compressed bone within the vertebral body. The procedure usually takes 45 to 60 minutes, and the patient may be discharged several hours later. Some risks are involved with this procedure, such as leakage of cement into surrounding areas (i.e., disc, spinal cord, and nerve roots), infection, bleeding, worsened pain, embolism, and paralysis. Overall, more than 80% of treated patients had moderate to marked pain relief.

PK is a technique similar to PV, which involves the additional application of an inflatable balloon inside the collapsed vertebral body. The compressed fracture is thus expanded, the lost height of the vertebral body is restored, and an inner space or cavity is created for the cement. This procedure was approved by the FDA in 1998. A significant reconstitution of the curvature of the spine can be seen following kyphoplasty. According to Lieberman et al., in 70% of the collapsed vertebral bodies, the kyphoplasty restored 47% of lost height. This newer technique offers the additional advantage of realigning the spinal column and restoring height to the fractured vertebrae.

PV and PK are associated with pain relief in 67% to 100% of cases. Most patients experience significant pain relief within the first 1 to 2 days. There is also a report of 95% improvement in pain and significant improvement in function following treatment by either one of the two techniques.

B.5. What are the concerns about magnetic resonance imaging (MRI) safety in patients with a spinal cord stimulator (SCS)?

MRI safety recommendations vary between the models of SCS.

The most recent updates reveal that multiple models from different companies are more compatible with MRI full body scan (e.g., Prime Advanced SureScan, Restore Advanced SureScan, Restore Sensor SureScan and Intellis platform from Medtronic, Proclaim Elite SCS system from Abbott, Precision Montage from Boston Scientific, and Senza I from Nevro). Other models may only be compatible with a head only or "head and extremity" only MRI scan. In addition, each company's SCS has its certain parameters and limitations including MRI system type (1.5 T), radiofrequency Coil type, radiofrequency power specific absorption rate (SAR), gradient slew rate, spatial gradient, patient position, total active scan time limits (30 minutes on per 30 minutes off vs. 30 minutes on per 60 minutes off), and others.

Before an MRI is performed, it is imperative to ascertain that the system is intact, without any lead breaks or low impedances because these can result in heating of the SCS and injury to the patient. With an SCS, there is a risk of thermal injury to the patient at any point along the course of the device because of induction of current by the magnetic fields during the MRI.

During these scans, there is potential for heating or discomfort, and the patient must be advised to communicate with the technicians should this occur. The devices are also at risk for permanent malfunction after MRI, which would require surgical replacement. Magnetic pull could result in torque or rotation movement of the device with potential destruction of surrounding tissues. After the scan, the device must be interrogated for device damage/failure and turned back on. Ultimately, these devices have specific conditions under which MRI may be performed, and physicians must consult the manual for the specific implanted device before ordering MRI scans.

B.6. When should surgery be considered?

Several surgeries are indicated for low back pain and sciatica. These include laminotomy, laminectomy, microdiscectomy, foraminotomy, intervertebral body insertion, spinal fusion, and others.

According to Weber's study, the long-term results appear to be no different in the surgical versus nonsurgical group in the case of low back pain. If the following situations occur, surgery should be considered:

- Failure to respond to conservative management for at least 3 months
- A profound or progressing neurologic defect such as a complete foot drop
- Recurring episodes of intractable sciatica involving the same segment—mainly to avoid the cumulative disability of repeated events

Muscle weakness is a dubious indication for surgery if the paresis is of unknown duration. If the pressure on the nerve root can be relieved immediately after the appearance of the paresis, surgery has been regarded as the therapy of choice. Unfortunately, most patients are unaware of the subtle loss of motor function. The greatest concern and complaints are largely centered on pain, paresthesia, and immobility.

Within the first 3 months of acute low back symptoms, surgery is considered only when serious spinal pathology or nerve root dysfunction resulting from an obviously herniated

lumbar disc is detected. Nerve root decompression can be considered for a patient if all of the following criteria exist:

- Sciatica is both severe and disabling.
- Symptoms of sciatica persist without improvement for longer than 4 weeks or with extreme progression.
- There is strong physiologic evidence of dysfunction of a specific nerve root with intervertebral disc herniation confirmed ipsilaterally at the corresponding level by imaging.

Patients with acute low back pain alone, without findings of serious conditions or significant nerve root compression, rarely benefit from a surgical consultation. With or without surgery, more than 80% of patients with obvious surgical indications eventually recover.

B.7. What surgical options are available for the treatment of disc disease?

- Artificial disc replacement (ADR) or total disc replacement (TDR)
- Interspinous process decompression system (X-STOP in 2005)
- Decompression (laminotomy, laminectomy, and/or discectomy) or decompression with fusion

In the mid-1980s, German orthopedic surgeons developed a metal and plastic prosthesis that has been in clinical use since then. The prosthesis is known as the *SB CHARITÉ*. The prosthesis design is currently in its third generation. Other prosthetic discs are available (e.g., ProDisc, Maverick, FlexiCore, and Kineflex). In October 2004, the CHARITÉ artificial disc became the first to be approved for disc replacement in the United States. It is composed of two metallic end plates and a polyethylene core that moves between them (**Figs. 50.4** to **50.7**). Traditional spinal fusion does change the mechanics of the segment that is fused. Adjacent segment degeneration can develop at approximately 3% per year (or 16.5% at 5 years, 36.1% at 10 years). One major theoretical advantage of ADR over spine fusion is that it results in no change in the biomechanics of the lower spine, thereby allowing the spine to maintain its normal range of motion and reducing or eliminating the risk for degeneration in the adjacent segments of the spine. The potential disadvantage of ADR is a limited durability. Because disc injury is a common cause of back pain in younger adults, an artificial disc in such patients needs to last for decades. The demands on that disc will be very great, and it may not outlast the lifetime of the patient, who may need revision surgery later. Revision ADR can be very dangerous because of scar tissue from the original surgery in nearby vascular structures. In addition, there is a 1% to 3% incidence of the complication of retrograde ejaculation in men.

FIGURE 50.4. **CHARITÉ disc.**

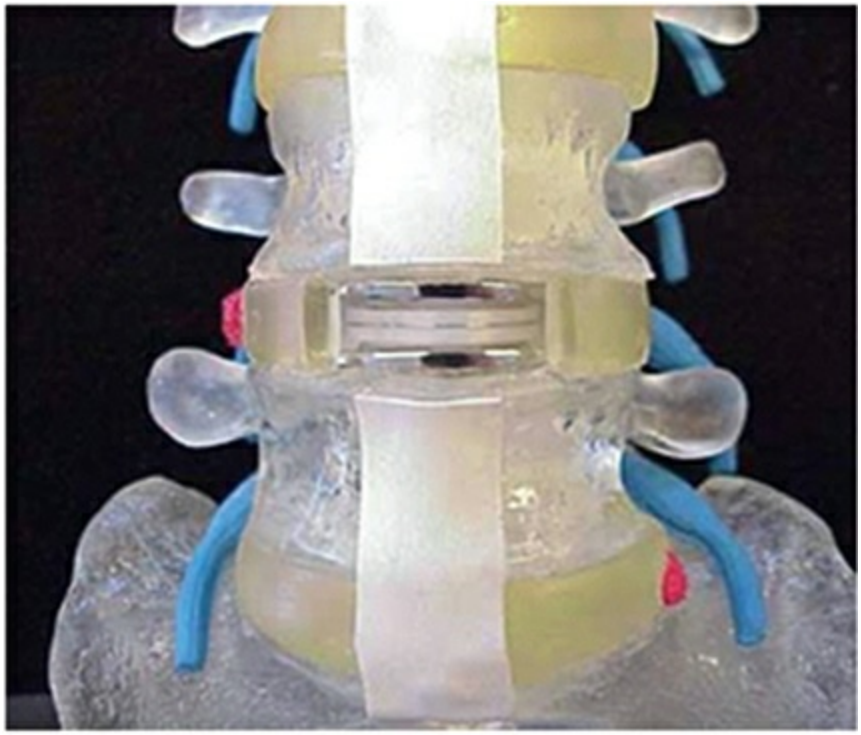

FIGURE 50.5. **CHARITÉ disc replacement at L4–L5.**

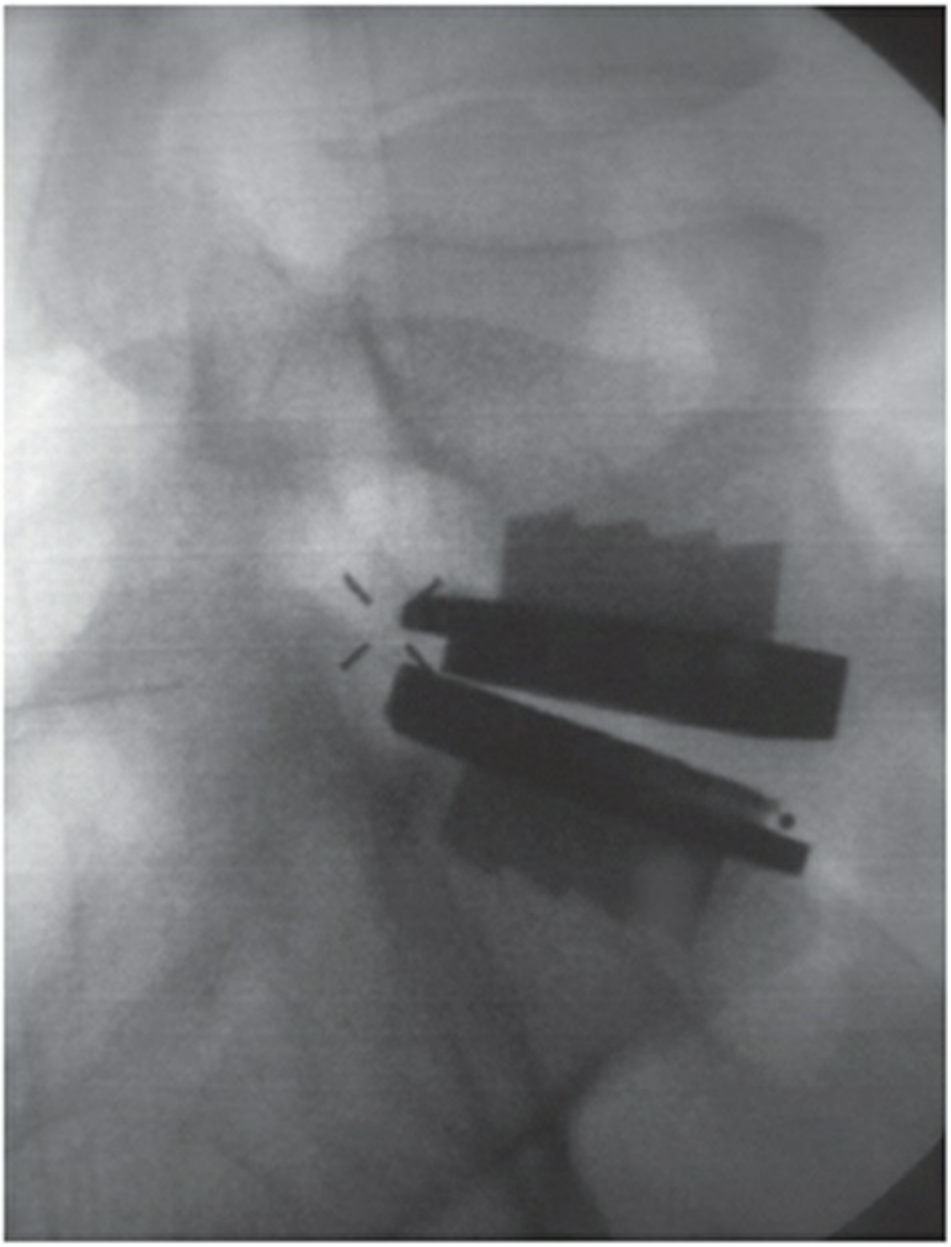

FIGURE 50.6. **L5–S1 ADR, lateral fluoroscopic view.**

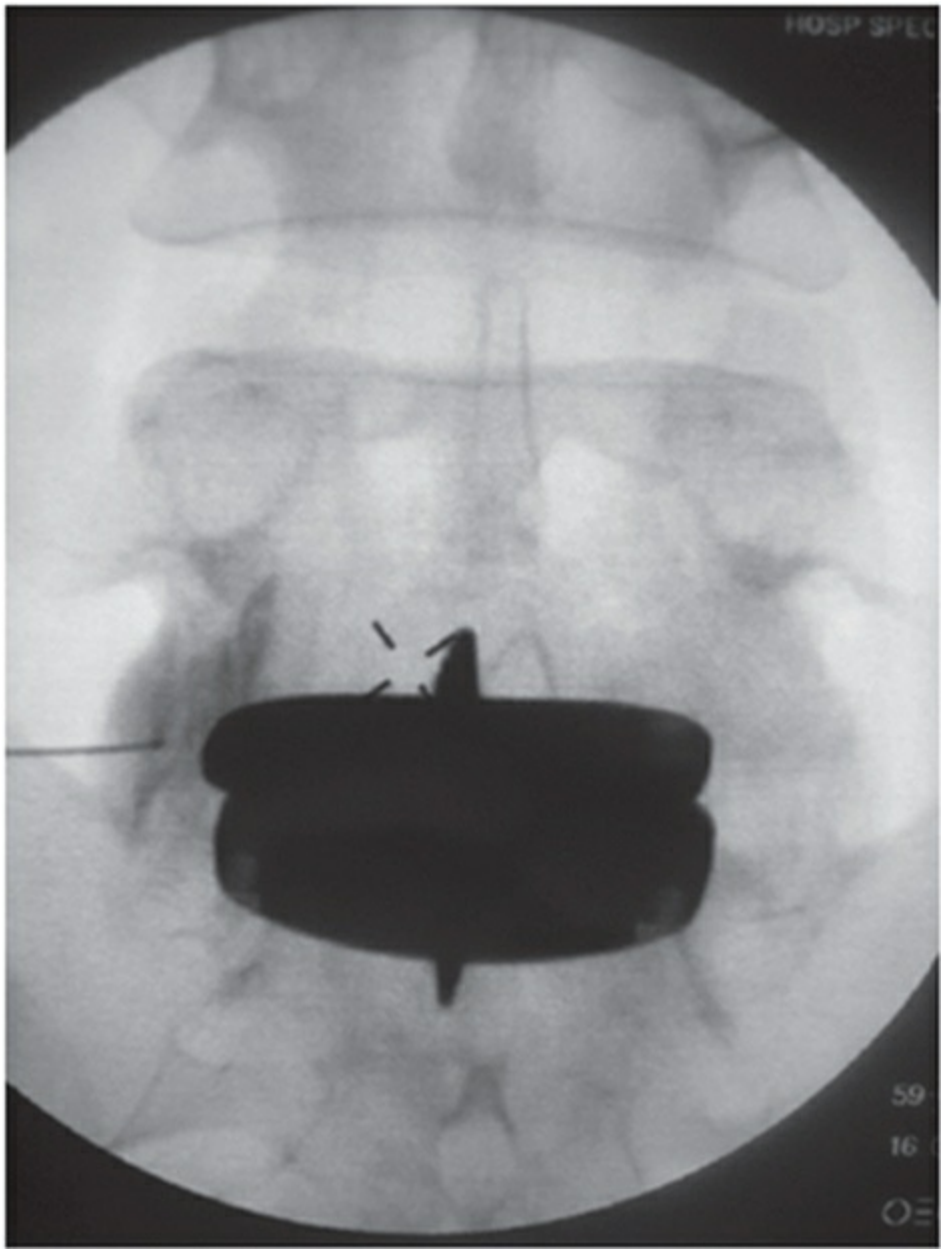

FIGURE 50.7. Anteroposterior fluoroscopic view of ARD.

Based on the systemic review of overlapping meta-analyses, the best available evidence indicated that TDR or ADR compared with fusion for lumbar degenerative disc disease (LDDD) had statistically, but not clinically, significant superiority regarding disability, pain relief, and quality of life in a selected group of patients in the short term. Therefore, considering that disadvantages may appear after years, spine

surgeons should be cautious about performing TDR on a large scale. Another similar meta-analysis result in 2019 suggests that TDR could be alternative treatment for LDDD because it yielded better clinical success and patient satisfaction, shorter hospital stays and operative time, less pain, and lower complication rates than did lumbar fusion.

In a recent retrospective study of ADR by Pettine et al., the overall clinical failure (one level operations performed at L4–L5 or L5–S1) occurred in 26% of patients at 2-year follow-up including Maverick (28%), Charité (39%) and Kinelfex (14%). It implied that overall clinical success may be improved most by patient selection and implant type.

The interspinous process decompression system (X-STOP) is a titanium metal implant made to fit between the lumbar spinous processes of the vertebrae (**Figs. 50.8** and **50.9**). It is designed to relieve narrowing of the spinal canal and neural foramen during extension, thereby reducing the symptoms of neurogenic intermittent claudication. The indications include spinal stenosis and degenerative lumbar spondylolisthesis. According to a Norwegian study in 2015, it revealed that the significantly higher cost of X-STOP is mainly due to implant cost and the significantly higher reoperation rate (33%) when compared to minimally invasive decompression surgery in patients with symptomatic lumbar spinal stenosis.

FIGURE 50.8. **Interspinous process decompression system (X STOP).**

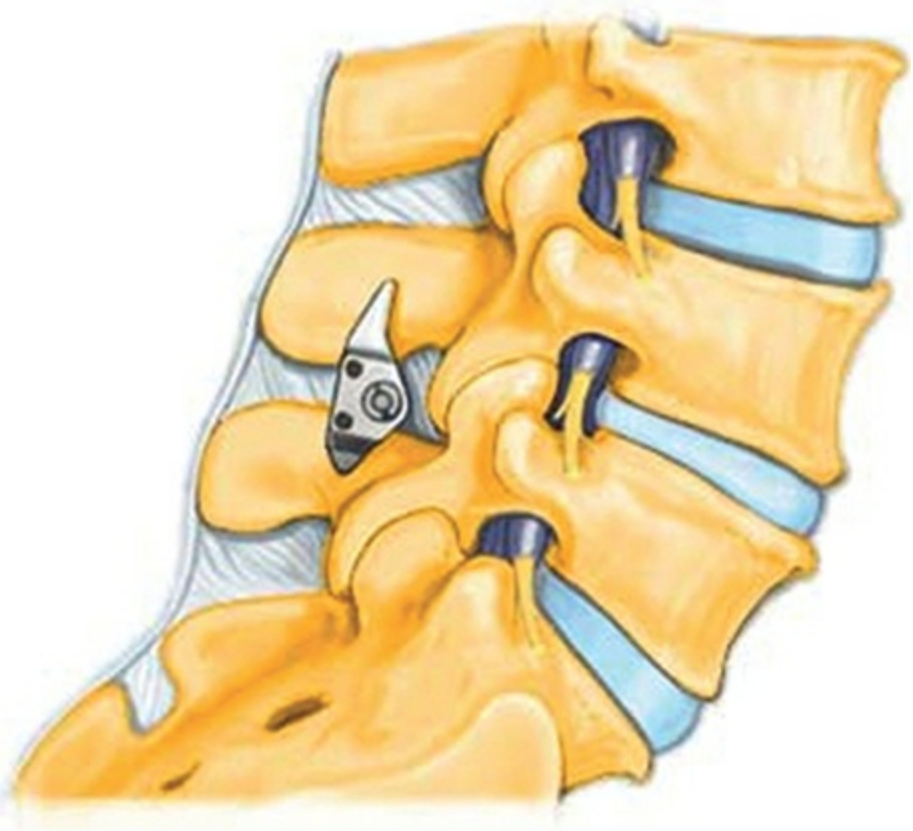

FIGURE 50.9. **Interspinous process decompression system (X STOP).**

Spinal surgery often involves direct decompression, where the pressure is reduced and/or removed from the nerve; it may include laminotomy, laminectomy, foraminotomy, and/or discectomy. These surgeries can be done by either a traditional

open approach or a minimally invasive technique/minimally invasive surgery (MIS). The latter can avoid separation of muscles and preserve stabilizing structures. It has many surgical advantages such as less muscle trauma, minimal postoperative back pain, shorter hospital stays, and faster recovery. The MIS decompression technique can be done by using a microscopic, tubular (using tubular retractors), or endoscopic decompression technique.

Degenerative spondylolisthesis in the lumbar spine occurs when the cephalad vertebral body slips relative to the caudal body. Symptoms may result from spinal stenosis and nerve root compression. Surgical management of this condition may entail decompression of the spinal canal followed by posterolateral fusion with or without an interbody fusion. The additional anterior stabilization of the vertebral column with an interbody fusion reduces the incidence of nonunion, degree of slippage, and recurrence of deformity in patients with degenerative spondylolisthesis. Additional anterior stabilization can be accomplished by using different approaches such as anterior lumbar interbody fusion (ALIF), posterior lumbar interbody fusion (PLIF), transforaminal lumbar interbody fusion (TLIF), or eXtreme lateral interbody fusion (XLIF).

51 Perioperative Pain Management

Anuj Malhotra and Vinod Malhotra

A 60-year-old man with a smoking history of a pack of cigarettes a day for approximately 40 years and chronic obstructive pulmonary disease is scheduled for thoracotomy for removal of carcinoma in his right middle lobe.

A. Perioperative Pain Management for Thoracotomy

1. What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?
2. How will you decide about the choice of anesthetic technique?
3. What is chronic postsurgical pain (CPSP)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?
4. What would be your perioperative analgesic strategy?
5. Does the choice of analgesic technique influence postoperative outcome?
6. Does it matter if the epidural catheter is at the thoracic or lumbar level?
7. Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?

8. What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?
9. If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?
10. What are the alternatives to TEA?
11. What is the usual clinical regimen for intravenous patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?
12. What are the side effects and complications of epidural technique?
13. What recommendations for placement and removal of epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?

A 70-year-old woman with metastatic breast cancer has been treated for the last 6 months with transdermal fentanyl (Duragesic patch) for her cancer pain. She is currently on a 100-μg per hour patch every 72 hours. She is now scheduled for surgery for hip fracture after a fall. The patient was very dissatisfied with postoperative pain management after her breast surgery 3 months earlier.

B. Chronic Opioid Therapy and Perioperative Pain Management

1. How does chronic opioid therapy influence postoperative pain management?
2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?
3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?
4. What issues need to be considered in the opioid-tolerant

patient who is scheduled for surgery?
5. What would be your strategy regarding preoperative information and choice of anesthesia technique?
6. What are the choices for perioperative pain management in opioid-tolerant patients?
7. What issues need to be considered before discharging an opioid-tolerant patient?

A 38-year-old woman scheduled for ambulatory laparoscopic cholecystectomy requests to see the anesthesiologist preoperatively to discuss her postoperative analgesia strategy. She experienced severe pain at home for several days after a previous ambulatory laparoscopic gynecologic procedure.

C. Perioperative Pain Management for Ambulatory Surgery

1. What would be your preoperative considerations and advice to the patient?
2. What are the consequences of inadequate pain management after ambulatory surgery?
3. What is the role of premedication or preoperative analgesic?
4. Does the choice of anesthetic technique influence postoperative pain?
5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?
6. What is the role of surgical technique in influencing postoperative pain after a laparoscopic cholecystectomy?
7. What would be your strategy for pain control after discharge home?

D. The Role of an Acute Pain Service (APS)

1. What is the extent of the problem, and which patients are at

greatest risk of undertreatment?
2. What are the consequences of inadequate postoperative pain relief?
3. What is the role of an APS in improving postoperative pain management?
4. Does an APS improve postoperative outcome?

A. Perioperative Pain Management for Thoracotomy

A.1. What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?

It is essential that patients undergoing thoracotomy be informed about what to expect after surgery because an understanding of the procedure as well as realistic expectations of pain and rehabilitation can promote recovery and return to normal activity. Patients undergoing thoracotomy may suffer from severe acute postoperative pain as well as CPSP if analgesia is not managed appropriately. Pulmonary function is impaired as a result of thoracic surgery and lung reduction and may be worsened by the effects of pain such as splinting promoting atelectasis, or oversedation from analgesics promoting respiratory depression. Therefore, during the early postoperative period, optimization and balancing pain control and maintenance of pulmonary function are the major goals.

For preoperative improvement of pulmonary function, patients should be advised to stop smoking and be instructed in deep breathing exercises such as incentive spirometry. Different techniques may be used to manage different levels of pain intraoperatively, immediately following surgery, within the first few postoperative days, and for discharge home, and each of these should be discussed. Pain management for these cases

often involves a step-down approach from neuraxial analgesia to intravenous opioids to oral medication. The following issues should be addressed:

- Information must be given on how pain will be assessed, for example, the use of visual analog scores.
- Patients require a realistic expectation of the intensity and duration of postoperative pain.
- Pain management techniques that require patient involvement (IV-PCA, patient-controlled epidural analgesia [PCEA]) need to be properly explained.
- Resources for chronic pain management should be discussed in case the pain goes beyond the expected duration.

A.2. How will you decide about the choice of anesthetic technique?

The decision about which anesthetic technique to use for an individual patient is based on a review of their overall medical condition and any medications that they are taking along with discussion with the surgeon. General anesthesia combined with epidural analgesia may be selected based on the patient's comorbidities and the planned procedure. Because lung volumes after thoracic surgery may be reduced by up to 50% through a combination of resection and splinting atelectasis, epidural analgesia can have benefit not only for pain relief but also for improving pulmonary function by improving respiratory mechanics and minimizing opioid-induced respiratory depression. Other factors such as surgeon preference,

anesthesiologist experience and practice, and institutional protocols for postoperative pain relief may also influence the choice of analgesic technique. If placement of an epidural catheter is included in the anesthetic plan, it may be used intraoperatively as an adjunct to general anesthesia or bolused at the end of the case prior to a postoperative infusion. Again, this decision is often based on patient and surgical considerations, such as potential blood loss, hypotension, need for fluid restriction, and invasiveness of surgery. Intraoperative epidural use prior to wake up has the benefit of ensuring epidural catheter function and can facilitate a more comfortable transition to the immediate postoperative period.

The use of TEA has become widespread for management of pain associated with thoracic and major abdominal surgery. Clinical studies have shown that TEA can have effects far beyond pain relief, including decreased opioid consumption, reduced risk of nausea and vomiting, increased lung volumes, reduced risk of pulmonary complications, improved bowel recovery, and a significant reduction in the incidence of myocardial infarction. There is also evidence that neuraxial block decreases the risk of recurrence after certain cancer resections, likely through an opioid-sparing effect.

between 1998 and 2006 (2nd revision): a database analysis of prospectively raised data. *Br J Anaesth*. 2008;101:832–840.

A.3. What is chronic postsurgical pain (CPSP)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?

CPSP is defined as pain that recurs or persists at least 2 months after surgery and is not related to ongoing tissue injury such as recurrence of tumor, wound dehiscence, or infection. Postthoracotomy pain syndrome (PTPS) is as subset of CPSP and is most commonly neuropathic in nature, with a reported incidence of 25% to 65%. Several studies suggest that severe perioperative pain is a predictor for development of CPSP, and thus aggressive management of early postoperative pain may be important to prevent this transition.

Although used with increasing frequency, thoracoscopic approaches have not had the favorable impact on pain that many had anticipated. Surprisingly, video-assisted thoracic surgery is associated with a prevalence of chronic pain comparable to that of open procedures, with rates of PTPS ranging from 22% to 63%, likely due to intercostal nerve and muscle damage from trocar insertion and chest tube placement.

A.4. What would be your perioperative analgesic strategy?

The analgesic plan should consider the entire perioperative period. A multimodal approach would be preferable to account for the multiple pathways by which nociceptive input is

conveyed to the central nervous system, the number of pharmacologically distinct mechanisms of modulating this input, the need for effective analgesia throughout the perioperative period and after discharge, and the importance of minimizing side effects, particularly respiratory depression.

TEA is the mainstay of recommended therapy for the reasons previously discussed. Contraindications to a thoracic epidural include patient refusal, coagulopathy, thrombocytopenia, therapeutic anticoagulation, previous thoracic spine surgery, and local infection over the entry site. When epidural catheters fail intraoperatively or have patchy coverage, intercostal nerve blocks (ICNBs) or paravertebral blocks may supplement epidural analgesia or serve as a bridge to the immediate postoperative period when an epidural catheter can be safely replaced.

NSAIDs are useful for treating shoulder pain secondary to referred diaphragmatic pain. This nociceptive input is carried by vagal and phrenic nerves and is often refractory to epidural analgesia. A concern with NSAIDs is platelet dysfunction; however, their efficacy and lack of respiratory side effects makes them an optimal choice for adjunct analgesia when possible. Cyclooxygenase-2 (COX-2) inhibitors have more limited effects on platelets aggregation and comparable efficacy to traditional NSAIDs and thus may be of use in this setting. Adverse cardiac side effects are unlikely with short-term perioperative dosing. Regular administration of paracetamol or acetaminophen (APAP) may also be useful for treating shoulder pain and can be used in addition to NSAIDs. Topical lidocaine patch or use of gabapentinoids may also have a role in select patients.

A.5. Does the choice of analgesic technique influence postoperative outcome?

Evidence from multiple studies strongly suggests that epidural analgesia is associated with lower rates of perioperative morbidity and, in particular, fewer pulmonary and cardiac complications. More recently, a meta-analysis of patients receiving TEA versus PCA after surgery requiring general anesthesia demonstrated decreased mortality in the thoracic epidural group. Compared with systemic opioids, epidural opioids decrease the incidence of postoperative atelectasis, hypoxemia, and pulmonary complications overall. Effective pain control with an epidural technique leads to improved pulmonary function, more effective coughing, earlier mobilization, and improved cooperation with respiratory physiotherapy.

Postoperative myocardial infarction rates are reduced when TEA is incorporated into anesthesia and extended at least 24 hours into the postoperative period. Supraventricular tachyarrhythmias, which are the most common form of cardiac morbidity after pulmonary resection and occur in up to 50% of cases, are reduced by TEA, even when compared with alternative analgesic regimens that confer equivalent pain control. The cardioprotective mechanism of TEA is believed to relate to its sympatholytic effects.

Epidural analgesia also provides superior postoperative analgesia compared with IV-PCA. As discussed earlier, better

postoperative pain relief may decrease the likelihood of developing CPSP, although it should be noted that this has not yet been demonstrated in longitudinal studies.

A.6. Does it matter if the epidural catheter is at the thoracic or lumbar level?

TEA is currently the standard for analgesia for thoracic surgery, and in the absence of contraindications, all patients undergoing major open thoracic surgical procedures should have a thoracic epidural catheter placed preoperatively. The tip of the catheter should ideally reside at the dermatome along which the incision will be made.

Thoracic (vs. lumbar) placement of the epidural catheter is dose saving and decreases side effects such as hypotension and bladder dysfunction at equianalgesic doses. Thoracic placement also reduces motor block of the lower extremities, which allows for improved postoperative ambulation. However, if thoracic epidural placement is contraindicated or cannot be achieved, lumbar epidural anesthesia can be utilized. Lumbar placement can be efficacious, particularly when used with hydrophilic opioids such as morphine; however, local anesthetic volume dosing is significantly higher and may be limited by toxicity or side effects such as hypotension or motor block.

A.7. Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?

Effective postoperative pain control may be achieved by delivering an opioid, local anesthetic, or a combination of both into the thoracic epidural space. Combinations are the standard because synergy between opioids and local anesthetic agents can enable an optimum balance between analgesia and minimizing blockade of motor function of the thorax and dynamic consequences of sympatholysis. Common components include opioids, such as morphine, fentanyl, or hydromorphone, and local anesthetic agents, such as bupivacaine, levobupivacaine, or ropivacaine. Systemic absorption effects (e.g., sedation) tend to be more common with the lipophilic opioids, such as fentanyl, presumably because of increased absorption into the epidural fat. Hydrophilic opioids, such as morphine, produce a wider dermatomal band of analgesia with less systemic absorption. Of the three commonly used local anesthetic agents, bupivacaine possesses the least favorable cardiac safety profile. In theory, ropivacaine offers the advantage of differential dose-dependent sensory and motor blockade; however, when used in dilute concentrations in combination with opioids, it is unlikely that any advantage of one agent over the other will be apparent. Addition of low-dose ketamine to epidural infusion or intravenously has not demonstrated beneficial effects in preventing postthoracotomy pain.

preventing chronic postthoracotomy pain: a prospective, double-blinded, randomized, clinical trial. *Clin J Pain*. 2011;27:304–308.

A.8. What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?

Before the initiation of PCEA, a test dose of 3 mL of 1.5% lidocaine with epinephrine 1:200,000 is usually employed with the patient awake to rule out intrathecal or intravascular placement of catheter. Once malposition is ruled out, the catheter is usually bolused (as allowed by hemodynamic status) prior to beginning continuous infusion.

Commonly employed combinations of epidural drugs vary. However, in the interest of patient safety, compliance, auditing, and quality assurance, standardization within the institution is recommended. Solutions and volumes can later be titrated to effect or to avoid side effects, for example, increasing or decreasing local anesthetic concentration to change block density, increasing or decreasing volume infused to increase spread, and adding or subtracting opioids to increase analgesia or decrease side effects such as itching, nausea, or sedation.

The following drugs and drug combinations are often used at a starting infusion rate of 4 to 6 mL per hour with each demand bolus of 2 to 3 mL as needed. This clinical dosing is consistent with fluoroscopic epidurography studies that have demonstrated vertebral spread of 7 to 8 levels with 2.5 to 5 mL bolus.

- Bupivacaine 0.0625% to 0.1% with fentanyl 5 μg per mL with a lockout period of 10 to 20 minutes between boluses
- Bupivacaine 0.0625% to 0.1% plain with a lockout of 20 minutes
- Fentanyl 5 to 10 μg per mL with a lockout period of 10 to 20 minutes
- Bupivacaine 0.0625% to 0.1% with Dilaudid 100 μg per mL

with a lockout period of 20 minutes (See sample order form, **Fig. 51.1**.)

A.9. If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?

If accidental dural puncture occurs during placement of epidural needle, the general practice is to remove the needle and place the epidural catheter at adjacent intervertebral spaces. The likelihood of intrathecal spread should be carefully assessed with the test dose. Epidural infusion may be started at the usual rate. Frequent monitoring for sensory and sympathetic block should continue in a controlled setting until the efficacy and safety of the epidural analgesia is established. In addition, the patient should be assessed for any symptoms of neuropathy relevant to the level attempted. The patient should be informed of the dural puncture and the potential for postdural puncture headache, although this is less frequent than with lumbar dural puncture.

A.10. What are the alternatives to TEA?

There are times when for technical, medical, or other reasons thoracic epidural catheter placement is unsuccessful, undesirable, or not possible. Alternatives to mid-TEA include lower thoracic and lumbar epidural catheter placement, ICNBs, paravertebral blocks, serratus anterior blocks, erector spinae blocks, intrathecal opioids, intrapleural catheters, local anesthetic infiltration, and systemic analgesia with one or more agents.

Lumbar epidural placement can be efficacious, particularly

when used with hydrophilic opioids such as morphine to increase dermatomal spread. Lumbar epidurals are most limited by the need for increased local anesthetic dosing and the higher incidence of side effects such as hypotension, motor block, and urinary retention versus thoracic epidurals.

If epidural placement is ruled out altogether for the reasons previously discussed, ICNBs can be performed percutaneously using anatomic or ultrasound-guided techniques or under direct vision intraoperatively, using single injections or placement of an intercostal catheter. Although often initially effective, unpredictable spread of local anesthetic and rapid local anesthetic absorption by surrounding vessels make this technique less effective than epidural analgesia. Furthermore, indwelling intercostal catheters cannot adequately control pain after posterolateral thoracotomy because posterior primary rami and sympathetic fibers are not blocked. Additionally, percutaneous positioning and securing of intercostal catheters may be technically problematic.

Paravertebral block results in ipsilateral somatic and sympathetic nerve blockade in multiple contiguous thoracic dermatomes above and below the site injection. Paravertebral analgesia has been found to produce good pain relief and preservation of pulmonary function after thoracotomy and is probably the best available alternative to epidural analgesia. Because the concomitant sympathetic blockade is unilateral, the incidence of adverse effects, such as hypotension and urinary retention, is lower. Paravertebral blocks can be performed as single injections or through a paravertebral catheter. Paravertebral catheters can be placed percutaneously via anatomic or ultrasound-guided approaches or intraoperatively under direct vision. In some studies, paravertebral blocks have been shown to be as effective as TEA with respect to acute pain control and preservation of pulmonary function after

thoracotomy.

A preoperative single bolus of spinal morphine as part of multianalgesic regimen can be considered in order to decrease the need for systemic opioids. Alternatively, pleural catheters may be placed intraoperatively to decrease pleural and visceral pain; however, they do not affect incisional pain and require high volumes of local anesthetic to be effective. Similarly, direct local anesthetic wound infiltration can be used but must be combined with longer acting strategies to provide adequate pain control throughout the perioperative period. Although systemic opioids have been well documented to reduce postthoracotomy pain, their adverse effects on the respiratory system after general anesthesia, even using patient-controlled delivery systems, and their inability to provide optimal dynamic pain relief favor regional anesthetic techniques, when possible, in thoracotomy patients. Systemic analgesics are best suited as adjuncts to these techniques and should become the mainstay of analgesic therapy only when invasive approaches are discontinued.

A.11. What is the usual clinical regimen for intravenous

patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?

Clinical regimens for IV-PCA vary among institutions, but the most commonly used opioids are fentanyl, morphine, and hydromorphone. Continuous delivery, or basal rate, of the drug is commonly avoided to decrease the likelihood of respiratory depression. For opioid-naive patients, boluses of fentanyl 10 to 15 μg, morphine sulfate 1 to 2 mg, or Dilaudid 0.2 to 0.3 mg are given per demand with a lockout period of 8 to 10 minutes. Incremental boluses may be given by the nurse if pain is not controlled. The dose may be decreased or the opioid may be discontinued if respiratory depression occurs. Close monitoring and rescue strategies must be in place to ensure patient safety, particularly for at-risk individuals, including central monitoring of oxygenation and ventilation (see sample order form, **Fig. 51.2**).

PATIENT CONTROLLED ANALGESIA (PCA) ADULT ORDER SHEET

IF NO PLATE, NAME, SEX AND MEDICAL RECORD NO.

DATE: / / TIME: am/pm	ORDERED POSTED	CHECKED BY RN
1) Analgesia by Patient Controlled Analgesia (PCA).		
2) The patient **MUST NOT** receive any supplemental narcotics, sedatives and/or antiemetics while receiving PCA unless approved the Pain Management Service or House Officer		
3) Narcotics (Specify drug, # of mgs, volume, and diluent)		
4) Initial Loading: Dose_____mg every 5 minutes until the patient is comfortable. Maximum total load_____mg.		
5) Initial Machine Settings: **PCA Mode** (circle one) Continuous / PCA / Both a) **Program in mg.** b) Continuous Rate_____mg per hour. c) PCA Dose_____mg per demand. d) PCA Lockout_____minutes. e) Limit_____mg per four hours.		
6) If pain is not controlled at the above settings (pain ≥ 6), the nurse may administer a PRN recue / loading dose_____every 5 minutes until the patient is comfortable. The maximum rescue / loading dose is_____mg. Increase pump settings to: a) PCA Dose_____mg per demand. b) Continuous Rate_____mg per hour. c) PCA Lockout_____minutes. d) Limit_____mg per four hours.		
7) For over sedation (sedation ≥ 4/R4) and respiratory rate < 14, decrease pump settings to: a) PCA Dose_____mg per demand. b) Continuous Rate_____mg per hour. c) PCA Lockout_____minutes. d) Limit_____mg per four hours. For respiratory rate of 10 or lower, stop the pump and call the Pain Management Service (X66700, beeper 16664) or House Officer.		
8) Upon initiation, and after every loading dose given, obtain respiratory rate, heart rate and blood pressure. Repeat qh X 2, q4h X 3, and then heart rate and blood pressure per unit routine or as otherwise ordered. Monitor respiratory rate, pain analog and sedation scale q4h.		
9) Note: For patients who receive intrathecal/Epidural Morphine intraoperatively and have PCA initiated within 12 hours, monitor blood pressure, pulse, respiratory rate, pain analog/sedation q30minutes X 2h, qh X2 and then q4 hours X3. Then, BP per unit routine, Monitor respiratory rate, pain analog/sedation of 4hr.		
10) If no maintenance IV is ordered, infuse D5 1/2NS at 40 ml/h via PCA Extension Set.		
11) For Nausea (Specify drug and dosing):		
12) For Sleep (Specify drug and dosing):		
13) For questions or problems, call the Pain Management Service at X62960 or page X66700, beeper 16664		
14) Please call the Unit Coordinator when the pump is discontinued.

FIGURE 51.2. PCA adult order sheet. BP, blood pressure; IV, intravenous. (*Source: NewYork-Presbyterian Hospital, NYC.*)

A workshop of the Anesthesia Patient Safety Foundation (APSF) looked at the issue of dangers of postoperative opioids. The observed incidence of respiratory depression in these cases

is 0.1% to 1.0% and increases to 3.2% in those older than 80 years. Patients with obstructive sleep apnea and the elderly are understandably at a higher risk for opioid-induced respiratory depression, but there is also a low and unpredictable incidence of life-threatening respiratory depression in young, healthy patients. The workshop highlighted the argument that in the United States, The Joint Commission's emphasis on pain as the "fifth vital sign" has had the unintended consequence of creating an expectation among patients that they will have little to no pain after surgery. As a result, more patients may be receiving inappropriate amounts of analgesics to meet this expectation. The conclusions of the APSF committee were that continuous monitoring of oxygenation and ventilation can prevent patient harm; any monitoring system should be centrally linked so that a health care professional can be summoned in a timely manner; programs should be instituted to educate providers and patients about the risks of opioid-associated life-threatening respiratory depression; governmental agencies and nongovernmental entities should provide increased support for scientific research in this area; and while treatment of postoperative, opioid-induced depression is an important consideration, prevention may be the more effective strategy.

A.12. What are the side effects and complications of epidural technique?

TEA interferes with sympathetic outflow and can produce hypotension through cardiodepressant action (blockade of cardiac accelerator fibers) and a reduction in systemic vascular

resistance (blockade of sympathetic chain). The use of dilute local anesthetic solutions has led to clinically insignificant motor blockade while maintaining adequate sensory block, although some small-muscle weakness may be observed. Opioid-related side effects include sedation, nausea and vomiting, pruritus, delayed gastrointestinal motility, urinary retention, and respiratory depression. The incidence of delayed respiratory depression after administration of epidural opioids is very low, and epidural opioid analgesia can be used safely on most hospital units. All patients who receive epidural analgesia should have standard orders for the treatment of breakthrough pain and side effects.

The overall catheter-related complication rate is low and includes such complications as dural puncture, paresthesia, pneumothorax, and neurologic injury. The most common documented complication is unsuccessful placement, reported at about 6%. Paraplegia associated with epidural analgesia may result from epidural hematoma, or less commonly epidural abscess. The potentially catastrophic complications of epidural or intrathecal hematoma are best prevented by realization that motor blockade should not occur with dilute local anesthetic solutions, and postoperative motor weakness should trigger immediate imaging evaluation (magnetic resonance imaging [MRI]) and neurosurgical consultation. Clearly, significant concerns about coagulopathy or local overlying infection should limit epidural catheter placement.

A.13. What recommendations for placement and removal

of epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?

On the basis of current practice and the fourth consensus statement for Regional Anesthesia in the Patient Receiving Antithrombotic or Thrombolytic Therapy developed by the American Society of Regional Anesthesia and Pain Medicine (ASRA), the following guidelines may be helpful.

Prophylactic Unfractionated Heparin

In the setting of twice or thrice daily subcutaneous prophylaxis with low-dose 5,000 U heparin, there is no contraindication to the use of neuraxial techniques. The clinician should keep in mind that subcutaneous heparin reaches peak effect 1 to 2 hours after administration and persists 4 to 6 hours after administration; therefore, the recommendation is that heparin be held 4 to 6 hours prior to neuraxial catheter placement or removal. Administration can resume at any time following.

Therapeutic Intravenous Unfractionated Heparin

- Neuraxial techniques combined with intraoperative IV anticoagulation (excluding the full anticoagulation of cardiac surgery) are acceptable with certain precautions. Neuraxial techniques should be avoided in patients with baseline coagulopathies (idiopathic or iatrogenic) in addition to heparinization. Placement or removal of catheters can occur 4 to 6 hours after last dosing and once normal coagulation status is verified. Dosing of heparin may resume 1 hour afterward. There is insufficient data to warrant canceling a case due to bloody or difficult block placement; however, discussion of risks and benefits with the surgeon regarding proceeding is warranted. Postoperative care should monitor for signs of hematoma such as motor blockade. Use of weak

local anesthetic solutions may facilitate detection.

Preoperative Low Molecular Weight Heparin (Enoxaparin)

Neuraxial blockade should not be performed if the patient is on other antiplatelet or oral anticoagulant medications in combination with low molecular weight heparin (LMWH). LMWH has its peak effect 2 to 4 hours after administration.

- *Prophylactic LMWH*. An example of a prophylactic dose is enoxaparin 40 mg every day or 30 mg every 12 hours. Block placement should occur no sooner than 12 hours after the last dose of LMWH, and a catheter should be maintained only if single-daily dosing is planned. If LMWH is administered within 2 hours of surgery (prophylactic dose), neuraxial blockade should be avoided.
- *Treatment dose LMWH*. An example of a treatment dose is enoxaparin 1.5 mg per kg every day or 1 mg per kg every 12 hours. Block placement should occur no sooner than 24 hours after the last dose of LMWH and only if treatment dosing is being discontinued.

Postoperative Low Molecular Weight Heparin

- *Prophylactic LMWH, twice-daily dosing*. This dosing regimen is associated with an increased risk of hematoma. The first dose of LMWH should be administered no sooner than 12 hours after needle or catheter placement. Epidural catheters should not be maintained in this situation and should be removed at least 4 hours before the first LMWH dose and no earlier than 12 hours after needle placement.
- *Prophylactic LMWH, single-daily dosing*. Epidural catheters may be maintained in this situation but only after a thorough risk/benefit analysis. The first dose of LMWH should be given greater than 12 hours postoperatively. The second dose should be given no sooner than 24 hours after the first dose.

The epidural catheter should be removed 12 hours after the last dose of LMWH, and the subsequent dose should be given no sooner than 4 hours after catheter removal.

- *Treatment dose LMWH*. Epidural catheters should not be maintained in this situation. The first dose of LMWH should be given 24 hours after needle placement or 4 hours after catheter removal, whichever is greater.

Oral Anticoagulants

- *Aspirin*. There is no contraindication to neuraxial anesthesia in patients taking aspirin alone (81 mg or 325 mg).
- *NSAIDs*. There is no contraindication to neuraxial anesthesia in patients taking NSAIDs alone.
- *Dipyridamole*. Discontinue 24 hours prior to neuraxial block and resume 6 hours after needle placement or catheter removal. Indwelling catheters are not recommended with continued use.
- *Preoperative Coumadin*

  Coumadin should be stopped 5 days before a neuraxial block, and the patient should not be on any additional antiplatelet or anticoagulant medications.

  The prothrombin time/international normalized ratio (PT/INR) should be measured before the block and should be normalized, which many clinicians define as less than 1.3. Of note, if warfarin is stopped for less than 4 days, INR (determined mainly by factors II and X) may not be reflective of coagulation status (determined mainly by factor VII).

  This differs from INR threshold for patients not taking warfarin chronically, as in this case, the INR is more reflective of overall coagulation factor status and an INR less than 1.5 is adequate.

  For patients receiving an initial preoperative Coumadin dose,

the PT/INR should be checked before neuraxial block if the first dose was given more than 24 hours earlier or if a second dose has been given.

- *Postoperative Coumadin*

  Epidural catheters may be maintained in patients on Coumadin up until the INR is less than 1.5. The PT/INR should be monitored daily and assessed before catheter removal.

  Epidural catheters should be removed while the INR is less than 1.5 and at 12 to 24 hours after initial warfarin dosing.

- *Preoperative clopidogrel (Plavix) and ticlopidine (Ticlid)*

  Clopidogrel must be held 5 to 7 days before neuraxial block placement and Ticlid must be held 10 days before neuraxial block placement. A loading dose may be administered 6 hours after needle placement or catheter removal. If no loading dose is given, therapy can resume immediately and catheters can be maintained 1 to 2 days.

- *Preoperative abciximab, eptifibatide, and tirofiban*

  GPIIb/IIIa inhibitors are profound inhibitors of platelet aggregation. Confirmation of normal platelet function is recommended prior to neuraxial block, particularly as patients are often on dual therapy with another agent. If resumption of therapy is planned, neither single shot nor catheter techniques are recommended.

  Abciximab must be held for a minimum of 24 to 48 hours prior to neuraxial blockade.

  Eptifibatide and tirofiban must be held 4 to 8 hours prior to block placement.

Newer Agents

Because many of these medications have not been available long, little postmarket surveillance data is available to determine complication rates. Accordingly, many of the following

recommendations are based on pharmacokinetics and the goal of allowing five half-lives to elapse to allow drug clearance prior to neuraxial blockade. All medications are recommended to be restarted greater than 6 hours after manipulation/catheter removal, and indwelling catheters with continued use is not recommended.

Apixaban should be held 3 days prior to neuraxial blockade.

Rivaroxaban should be held 3 days prior to neuraxial blockade.

Dabigatran should be held 5 days prior to block placement. May consider 3 to 5 days based on creatinine clearance (CrCl) if no additional risk factors.

Ticagrelor should be held 5 to 7 days prior to neuraxial block placement. May be resumed immediately after catheter removal if 24 hours after needle placement and if no loading dose, otherwise after 6 hours.

Prasugrel should be held 7 to 10 days prior to block placement. Similar recommendations for resuming as for aforementioned ticagrelor.

B. Chronic Opioid Therapy and Perioperative Pain Management

B.1. How does chronic opioid therapy influence postoperative pain management?

In recent years, a greater emphasis has been placed on pain as an important health problem, with The Joint Commission even labeling pain as the "fifth vital sign." Consequently, opioids now

play a greater role in the treatment of chronic pain of various causes. This has resulted in a rapid increase in the consumption of opioid analgesics. For example, between 1999 and 2003, the annual sales of outpatient opioid analgesics in the United States increased by approximately 130%. Because more patients are treated chronically with opioids, every anesthesiologist is likely to be confronted with acute pain management issues in these patients. Chronic opioid-consuming patients can experience significant postoperative pain given that health care professionals are not accustomed to their markedly increased opioid requirements.

Patients on long-term opioid therapy are more likely to require higher doses of opioids postoperatively. Although the prevalence of chronic opioid-consuming patients who present for surgery is not described, the growing use of opioids is likely to increase the number of such patients. Patients with chronic pain are more likely to have high levels of postoperative pain, and increased postoperative pain has been associated with an increased risk of CPSP. Therefore, the aggressive treatment of postoperative pain is important for patients with chronic pain because they may represent a population that is particularly vulnerable to develop CPSP.

Although available data are limited, the management of postoperative pain seems to be more difficult in chronic opioid-consuming patients even when they consume only a modest daily opioid dose. Tolerance to any one opioid preparation usually results in a clinically measurable increased tolerance to most others.

consuming patient. *Anesthesiol Clin North America*. 2005;23:37–48.

B.2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?

Chronic exposure to opioids may result in a need to increase the dose over time to maintain the desired analgesic effect. The need for escalating the dose is often attributed to the development of tolerance. However, dose escalation can be the result of other factors, such as progression of the underlying disease.

Recent evidence points to opioid-induced hyperalgesia as an alternative neuropharmacologic phenomenon to explain the need to escalate the opioid dose over time. Paradoxically, administration of opioids may induce an increased sensitivity to pain (hyperalgesia). Further complicating matters, the phenomena of tolerance and hyperalgesia can coexist.

Clinical surveys of long-term opioid use in patients with both cancer and non–malignancy-associated pain have not shown escalating drug dosage to be inevitable; however, some degree of dose increase over time is often observed, particularly in younger patients and with use of short-acting opioids.

B.3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?

Patients undergoing surgery may not admit that they are actively abusing or addicted to pain medications; however, several

differences may clue the practitioner to possible aberrant use. First, the daily dose of opioid consumed by opioid-abusing patients before surgery is typically larger and may differ from that prescribed, which can be confirmed by checking a State Prescription Monitoring Program. Second, opioid-abusing or opioid-addicted patients often have identifiable risk factors and may suffer from coexisting psychiatric diseases. For example, heroin addicts have an elevated prevalence of depression, anxiety, psychosis, and personality disorders. Depression and anxiety are also independent predictors of severe pain after surgery and may complicate the management of postoperative pain. Although it is useful to identify abuse or addiction, many of the perioperative management issues with respect to chronic pain opioid-consuming patients also apply to patients who abuse or are addicted to opioids. The attitude of health care providers toward the use of opioids for controlling pain may be influenced by the abuse history, which makes these patients particularly vulnerable to inadequate postoperative pain control.

B.4. What issues need to be considered in the opioid-tolerant patient who is scheduled for surgery?

Tolerance develops at different rates to desired (analgesia) and undesired effects (sedation, nausea, euphoria, respiratory depression, constipation). Long-term use of opioids results in tolerance to some opioid effects such as analgesia, nausea, sedation, and respiratory depression but not to miosis or constipation. Cross-tolerance with other opioids also occurs.

Opioid-tolerant patients report higher pain scores at rest and on movement and also remain longer under the care of APSs than do other patients. The incidence of opioid-induced nausea and vomiting, however, may be lower in opioid-tolerant patients.
