This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on health care professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Health care professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and health care professionals should consult a variety of sources. When prescribing medication, health care professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

SECTION 1 The Respiratory System

1 Asthma and Chronic Obstructive Pulmonary Disease

Jaroslav K. Usenko and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of dyspnea?
A.2. What is the prevalence of asthma and chronic obstructive pulmonary disease (COPD)?
A.3. What is the etiology of asthma?
A.4. Discuss the pathogenesis of asthma. How is asthma distinguished from COPD?
A.5. What are the triggers of bronchospasm?
A.6. What is the universal finding in ABGs during asthmatic attacks: hypoxemia or CO_2 retention?
A.7. Describe the abnormalities seen in spirometry, lung volumes, and lung capacities during an asthmatic attack.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient preoperatively? What preoperative workup would you order?
B.2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?

B.3. *Define normal lung volumes and lung capacities. Give normal values for an average adult male.*

B.4. *What are flow–volume loops? Draw flow–volume loops for a healthy subject and patients with COPD, restrictive lung disease, fixed obstruction of the upper airway, variable extrathoracic obstruction, and variable intrathoracic obstruction.*

B.5. *Define closing volume (CV) and closing capacity (CC). What is the normal value of CV?*

B.6. *Why is the functional residual capacity (FRC) important in oxygenation?*

B.7. *How are FRC and CC affected by age and posture? How are they affected by anesthesia?*

B.8. *Give the equations for shunt (Q_s/Q_t) and dead space/tidal volume (V_d/V_t). What are their normal values?*

B.9. *Interpret the following ABG: pH, 7.36; P_{CO_2}, 60 mmHg; P_{O_2}, 70 mmHg; and CO_2 content, 36 mEq per L.*

B.10. *What are the common physiologic causes of hypoxemia?*

Decreased pulmonary capillary oxygen tension
Increased shunting
Reduced venous oxygen content

B.11. *How would you prepare this asthmatic patient with COPD for surgery?*

B.12. *The patient comes to your perioperative clinic 2 weeks before surgery. He wants to know if his smoking puts him at increased risk during surgery. What do you tell him? Should he quit now?*

B.13. *You discover that the patient had a recent upper respiratory infection (URI), would you postpone surgery? For how long?*

B.14. *What medications would you expect the patient to have taken in the past or be taking at the present time?*

B.15. *The patient was on 20 mg of prednisone per day for 5 days as part of the treatment of an asthma exacerbation 3 months ago. He is currently not on steroids. Should the patient receive stress-dose steroids?*

B.16. *Should patients with reactive airway disease receive preoperative steroids?*

B.17. *What is the onset of action of intravenous steroid therapy in asthma?*

C. Intraoperative Management

C.1 *If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?*

C.2. *The patient did not have an asthmatic attack in the operating room and you proceed with induction. How would you induce anesthesia? Would you use a supraglottic airway instead of an endotracheal tube?*

C.3. *Would you use propofol for induction of anesthesia?*

C.4. *Would you use thiopental, methohexital, etomidate, or ketamine for induction?*

C.5. *Would you administer lidocaine for intubation?*

C.6. *If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?*

C.7. *Could a regional technique be used for this surgery? Discuss the advantages and disadvantages of neuraxial anesthesia in this patient for this surgery.*

C.8. *Would you choose an inhalational or an intravenous technique for maintenance of anesthesia?*

C.9. *What mechanisms produce bronchodilation from volatile anesthetics?*

C.10. *Which muscle relaxants would you use? Why?*

C.11. *How will you ventilate the patient? Will you use positive end-expiratory pressure (PEEP)? How can you detect the*

presence of auto-PEEP on your ventilator?

C.12. *What is the differential diagnosis of intraoperative bronchospasm?*

C.13. *In the middle of surgery, peak inspiratory pressures (PIPs) suddenly increase. How do you manage this?*

C.14. *How would you give β_2-agonists? What is their mechanism of action on asthma?*

C.15. *If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?*

C.16. *The asthmatic attack was relieved with your treatment, and the surgery was completed. Following emergence, the patient was found to be hypoventilating. What are the common causes of hypoventilation? What will be your approach to treat hypoventilation?*

C.17. *Would you consider a deep extubation in this patient?*

C.18. *If the patient cannot be extubated, what measures can you take to reduce the likelihood of bronchospasm with an endotracheal tube in place?*

D. Postoperative Management

D.1. *In patients with asthma and COPD, are there special considerations for the use of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) for postoperative pain control?*

D.2. *Would you consider using a regional technique for analgesia?*

D.3. *The patient was breathing well and was extubated. Would you place this patient on supplemental oxygen in the recovery room? How much?*

D.4. *The patient is hypoventilating in postanesthesia care unit (PACU). Would you initiate noninvasive ventilation (NIV)?*

2 Bronchoscopy, Mediastinoscopy, and Thoracoscopy

Alessia Pedoto, Paul M. Heerdt, and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis
   - *A.1. How is the diagnosis of lung cancer made? What is your prediction for the most likely type of malignancy?*
   - *A.2. What are the less common manifestations of bronchogenic carcinoma?*
   - *A.3. The patient has a long history of cigarette smoking. What is the significance of this finding?*

B. Preoperative Evaluation and Preparation
   - *B.1. How would you evaluate the patient prior to surgery?*
   - *B.2. What are the pulmonary function guidelines that indicate an increased risk for morbidity and mortality?*
   - *B.3. What are the preoperative concerns of induction immunotherapy?*

C. Intraoperative Management
   - *C.1. How would you premedicate, monitor, and anesthetize this patient?*
   - *C.2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?*
   - *C.3. What are the indications for cervical mediastinoscopy? Are there potential complications?*
   - *C.4. The decision was made to proceed with a robotic right middle lobectomy. How would this alter your management?*
   - *C.5. What are the indications for single-lung ventilation and how can it be accomplished?*
   - *C.6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?*
   - *C.7. Would you use a right- or left-sided DLT?*
   - *C.8. How do you know that the tube is in the correct position?*
   - *C.9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?*
   - *C.10. How will systemic oxygenation be monitored during single-lung ventilation? What is the mechanism of pulse oximetry?*

C.11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.
Respiratory Effects
C.12. What is hypoxic pulmonary vasoconstriction (HPV)?
C.13. What are the effects of anesthetic agents on HPV and their clinical implications?
C.14. Discuss pulmonary blood flow distribution, shunt flow, and partial pressure of oxygen in the arterial blood (Pa_{O_2}) (fractional inspired O_2 concentration [F_{IO_2}] = 1.0) during single-lung ventilation in the lateral position.
C.15. How could you improve oxygenation during single-lung ventilation?
Ventilated Lung
Collapsed Lung
C.16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?
D. Postoperative Management
D.1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?
D.2. Why is it important to control postoperative pain? How would you achieve this goal?
Epidural, Paravertebral, and Intrathecal Analgesia
Peripheral Nerve Blocks
Systemic Opioids and Adjuvants
Oral and Transdermal Agents
Intrapleural Regional Analgesia
Cryoanalgesia
Transcutaneous Electrical Nerve Stimulation
Shoulder Pain after Lung Resection
3 Aspiration and Postoperative Respiratory Failure
Kapil Rajwani, Edward J. Schenck, and David A. Berlin

A. Aspiration
   - *A.1. What are the risk factors for perioperative aspiration?*
   - *A.2. How does large volume aspiration affect the respiratory system?*
   - *A.3. How should you manage the patient after an aspiration event?*
   - *A.4. How would you prevent aspiration during emergency surgery?*

B. Postoperative Respiratory Failure
   - *B.1. How can you predict which patients will develop postoperative respiratory failure?*
   - *B.2. How can intraoperative anesthesia management prevent respiratory failure?*
   - *B.3. What is the pathogenesis of postoperative respiratory failure?*
   - *B.4. What is the diagnostic approach to postoperative respiratory failure?*

C. Indications for Ventilator Support
   - *C.1. What are the indications for noninvasive positive pressure ventilation (NIPPV)?*
   - *C.2. What are the indications for emergency endotracheal intubation?*

D. The Acute Respiratory Distress Syndrome
   - *D.1. What is the definition and etiology of the acute respiratory distress syndrome (ARDS)?*
   - *D.2. Explain the pathophysiology of ARDS.*
   - *D.3. What role does ventilator-induced lung injury (VILI) play in ARDS?*

E. Management of Mechanical Ventilation
   - *E.1. Which mode of mechanical ventilation will you choose? Describe the features of that mode.*
   - *E.2. How should you set the fraction of inspired oxygen (FIO_2)?*
   - *E.3. How should you set the positive end-expiratory pressure*

(PEEP)?
E.4. What tidal volume and inspiratory pressure target should you set?
F. Management of Refractory Respiratory Failure
F.1. What else can promote additional lung recruitment?
F.2. What rescue strategies can you use for refractory ARDS?
G. Adjunctive Management of Respiratory Failure
G.1. What is the cause and treatment of the hemodynamic instability associated with mechanical ventilation?
G.2. What is the adjunctive medical therapy for ARDS?
H. Liberation of the Patient from Mechanical Ventilation
H.1. Explain the importance of the decision to extubate the patient or continue mechanical ventilation.
H.2. How will you prepare the patient for liberation from the ventilator?
H.3. How will you recognize when the patient is ready for extubation?

4 Lung Transplantation
Choy Lewis, Ryan Hood, and Charles W. Hogue
A. Medical Disease and Differential Diagnosis
A.1. What are the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?
A.2. What other end-stage lung diseases can also be treated with transplantation?
A.3. How many lung transplantations have been performed?
A.4. What are the selection criteria for recipients?
A.5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?
A.6. How does a single-lung transplantation (SLT) differ technically from a bilateral-lung transplantation (BLT)?
B. Preoperative Evaluation and Preparation
B.1. What preoperative evaluation is desirable?

- *B.2. Would you premedicate this patient? If so, how?*
- *B.3. What vascular access is appropriate?*
- *B.4. Is preoperative epidural catheter placement advantageous?*

C. Intraoperative Management
- *C.1. What special equipment is necessary?*
- *C.2. How would you monitor this patient?*
- *C.3. How would you induce anesthesia in this patient?*
- *C.4. How would you ventilate this patient? What kind of endotracheal tube would you use?*
- *C.5. How does the physiology of single-lung ventilation influence the procedure?*
- *C.6. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?*
- *C.7. What problems are associated with the lateral position?*
- *C.8. Should volatile anesthetics be avoided during single-lung ventilation?*
- *C.9. At what specific points in the procedure are problems anticipated?*
- *C.10. How would you deal with problems related to clamping of the pulmonary artery (PA)?*
- *C.11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?*
- *C.12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?*
- *C.13. Should fluid administration be restricted, and are blood products commonly required?*
- *C.14. Would you extubate the patient upon conclusion of the procedure?*

D. Postoperative Management
- *D.1. What are the major complications after lung transplantation?*

D.2. *How is postoperative ventilation managed, and for how long is it required?*
D.3. *What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?*
D.4. *What are the long-term outcomes of lung transplantation?*
D.5. *Are there surgical alternatives to lung transplantation?*

SECTION 2 The Cardiovascular System

5 Ischemic Heart Disease and Coronary Artery Bypass Grafting
Yasdet Maldonado, Nikolaos J. Skubas, and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis
A.1. *What is triple-vessel CAD? Name the branches of the coronary arteries.*
A.2. *What are the indications for CABG?*
A.3. *What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.*
A.4. *What are the expected results of CABG?*

B. Preoperative Evaluation and Preparation
B.1. *Which preoperative tests would you order?*
B.2. *How would you evaluate the patient's left ventricular function?*
B.3. *Which factors determine myocardial oxygen supply?*
B.4. *What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?*
B.5. *Would you continue the β-blocker (metoprolol) on the day of surgery? Why/why not? What is its half-life? What is the role of β-adrenergic blockers in treating congestive heart failure (CHF)?*
B.6. *Would you continue the angiotensin-converting enzyme (ACE) inhibitor on the day of surgery? Why/why not?*
B.7. *If the patient who is on lisinopril develops hypotension intraoperatively, how would you manage it?*

C. Intraoperative Management

C.I. Before Cardiopulmonary Bypass

C.I-1. What is your plan to monitor the patient?

C.I-2. What is the Allen test?

C.I-3. How would you monitor electrocardiogram (ECG)? Why lead V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?

C.I-4. Should you monitor temperature from multiple sites?

C.I-5. Is it necessary to monitor pulmonary artery (PA) pressure for coronary artery operations?

Diagnostic

C.I-6. What are the possible complications of PA catheterization?

Similar to Central Venous Catheter Insertion

From Pulmonary Artery Catheter

C.I-7. What is normal pulmonary artery occlusion pressure (PAOP)?

C.I-8. What are the hemodynamic consequences of myocardial ischemia? How can you detect myocardial ischemia? Is PAOP a sensitive indicator of myocardial ischemia?

C.I-9. Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.

C.I-10. How would you induce anesthesia? Is there any advantage/disadvantage to using propofol versus etomidate as the main induction agent? What kind of neuromuscular blocker (NMB) would you use? Why?

C.I-11. How would you maintain anesthesia? Volatile anesthetics or total intravenous anesthesia (TIVA)?

C.I-12. What are the cardiovascular effects of volatile anesthetics, morphine, and fentanyl?

C.I-13. What should you do during sternotomy?

C.I-14. Would you use prophylactic nitroglycerin during CABG to

prevent intraoperative myocardial ischemia or perioperative MI?

C.I-15. *If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative MI?*

C.I-16. *Discuss autologous transfusion and blood conservation for cardiac surgery.*

C.I-17. *What antifibrinolytic will you use to reduce blood transfusions?*

C.I-18. *How do you know that the tip of the PA catheter is in the right ventricle (RV) or the PA?*

Pressure Contour

Ventricular Filling

C.II. *During Cardiopulmonary Bypass*

C.II-1. *What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?*

C.II-2. *What is the half-life of heparin? How is it eliminated?*

C.II-3. *How do you monitor heparin dosage? What is the activated coagulation time (ACT) test?*

C.II-4. *What is total CPB? What is partial bypass?*

C.II-5. *What kinds of pumps are used in CPB? Are they pulsatile or not?*

C.II-6. *What is the purpose of venting the LV? How can it be done?*

C.II-7. *How many types of oxygenators are there? What are the advantages of each type?*

Direct Gas Interface

Without Gas Interface

C.II-8. *What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?*

C.II-9. *What are the advantages and disadvantages of*

hemodilution?

Advantages of Hemodilution

Disadvantages of Hemodilution

C.II-10. *How do you monitor the patient during CPB?*

Clinical Monitoring

Laboratory Monitoring at Least Once Every Hour

C.II-11. *What should your target BP be during CPB?*

C.II-12. *How would you treat hypotension during CPB?*

C.II-13. *How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mmHg)?*

C.II-14. *How do you prepare an IV infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?*

C.II-15. *How much pump flow would you maintain during CPB? During hemodilution? During hypothermia?*

C.II-16. *How does blood viscosity change during hemodilution and hypothermia?*

C.II-17. *How is anesthesia provided during CPB?*

C.II-18. *Would you give muscle relaxants during CPB? How is the action of muscle relaxants affected during CPB?*

C.II-19. *How do you know the patient is well perfused during CPB?*

C.II-20. *How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?*

C.II-21. *What are the disadvantages of hypocapnia during CPB?*

C.II-22. *How would you preserve the myocardium during CPB?*

C.II-23. *What is cardioplegia? How much would you use?*

C.II-24. *The arterial blood gases and electrolytes during CPB are as follows: pH, 7.36; $Paco_2$, 42 mmHg; Pao_2, 449 mmHg; CO_2 content, 24 mEq per L; sodium (Na), 128 mEq per L; potassium (K), 5.8 mEq per L; glucose, 180 mg/dL; and hematocrit, 20%. The patient's temperature is 27°C (80.6°F). At what temperature are blood gases measured?*

How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37°C (98.6°F) or at patient's body temperature?

C.II-25. *How does the blood sugar level change during CPB? Why? What is optimal glucose control intraoperatively? Does hyperglycemia increase neurologic complications during CPB?*

C.II-26. *What are the effects of CPB on platelet and coagulation factors?*

C.II-27. *If the blood level of the venous reservoir is low, what would you replace it with? Blood or balanced salt solution?*

C.II-28. *How do you estimate the fluid balance during CPB?*

C.II-29. *For how long a period can the aorta be cross-clamped?*

C.II-30. *Why does the urine turn pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?*

C.II-31. *Why does it take longer to rewarm than to cool the patient via the pump oxygenator?*

C.II-32. *At what temperature can the patient be weaned from CPB?*

C.II-33. *How would you defibrillate the heart internally during CPB?*

C.II-34. *If the HR is 40 beats per minute, what should you do?*

C.II-35. *How would you prepare for termination of CPB?*

Laboratory Data
Anesthesia Machine
Monitors
Patient/Pump
Support

C.II-36. *How would you decide the need for inotropic support?*

C.III. *After Cardiopulmonary Bypass*

C.III-1. *How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize*

heparin?
C.III-2. What is the action mechanism of protamine?
C.III-3. What are the complications of too much protamine?
C.III-4. What is a protamine reaction? How can you prevent this condition? How do you treat it?
C.III-5. What are the indications for intra-aortic balloon pump (IABP)?
Ischemic Heart Disease
Cardiac Surgery
C.III-6. What are the principles of IABP?
C.III-7. What are the complications of IABP?
D. Postoperative Management
D.1. Would you reverse the muscle relaxants? Why?
D.2. When will you wean the patient from the ventilator?
D.3. What criteria would you use in deciding when to wean the patient from the ventilator?
D.4. What are potential postoperative complications?
Cardiovascular
Pulmonary
Renal
Hemorrhage
6 Mechanical Circulatory Support
Lisa Q. Rong, Mudit Kaushal, and Adam D. Lichtman
A. Medical Disease and Differential Diagnosis
A.1. What is an IABP?
A.2. How is an IABP placed and positioned?
A.3. Describe an IABP inflation and deflation timing.
A.4. How does the IABP help improve hemodynamics?
A.5. What are the indications for IABP placement?
A.6. What are the contraindications and potential complications of IABP placement?
A.7. What are the pitfalls of IABP timing?
A.8. What are the main advantages and disadvantages of IABP

support?

- *A.9. What is mechanical circulatory support?*
- *A.10. What is a ventricular assist device (VAD)?*
- *A.11. What are the types of percutaneous/temporary VADs?*
- *A.12. What are the types of permanent VADs?*
- *A.13. How does VAD work?*
- *A.14. When is circulatory support needed?*
- *A.15. What are the physiologic considerations in patients requiring a VAD?*
- *A.16. What are the reasons for suboptimal VAD support?*
- *A.17. What are common complications from VAD?*
- *A.18. How long can VADs remain in the patient?*

B. Preoperative Evaluation and Preparation

- *B.1. What is the focus of the preoperative assessment of an LVAD patient?*

C. Intraoperative Management

- *C.1. Detail the anesthetic management for a patient undergoing LVAD placement.*
- *C.2. How is a VAD patient monitored during a general anesthetic?*
- *C.3. Prescribe an anesthetic for a VAD patient.*
- *C.4. What is ECMO? What are the indications for ECMO? What are the different types of ECMO?*
- *C.5. What are the contraindications of ECMO?*
- *C.6. What are the main complications of ECMO?*
- *C.7. What are the necessary equipment and teams required to place ECMO? What are the pros and cons of different venoatrial ECMO (VA-ECMO) cannula placement?*
- *C.8. How are patients monitored and managed while on ECMO?*
- *C.9. What are the complications of ECMO?*
- *C.10. How frequently is VA-ECMO being used and how effective is it in cardiogenic shock?*

D. Postoperative Management

D.1. When and how is a patient weaned off IABP support?

D.2. How is weaning from ECMO accomplished?

7 Valvular Heart Disease

Meghann M. Fitzgerald and Natalia S. Ivascu

A. Medical Disease and Differential Diagnosis

A.1. What are the major etiologies of AS, AI, mitral stenosis (MS), and MR?

A.2. What are the major changes in the loading conditions of the LV that result from the four different lesions? Why do they occur? What changes result from them?

A.3. What are pressure–volume (P–V) loops? What do the different inflection points represent?

A.4. What are representative P–V loops for the four valvular lesions?

A.5. Draw the pressure/time curves for the LV, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.

Aortic Stenosis

Aortic Insufficiency

Mitral Stenosis

Mitral Regurgitation

A.6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?

A.7. What are the three TEE vantage points for the comprehensive imaging of the LV? How are pressure gradients measured by echocardiography? How do the pressure gradients derived from Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?

A.8. What is the role for three-dimensional (3D) echocardiography in the operating room?

A.9. *What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?*

Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation

B. Preoperative Evaluation and Preparation

B.1. *What are the presenting signs and symptoms of the four valvular lesions listed previously?*

Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation

B.2. *What is the New York Heart Association classification of heart failure?*

B.3. *Discuss the role of premedication for patients with the four different valvular lesions.*

B.4. *How would you premedicate the patient with severe AS and MR?*

C. Intraoperative Management

C.1. *Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and contractility?*

Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation

C.2. *What are the hemodynamic goals for this patient with the combination of severe AS and MR?*

C.3. *How would you monitor this patient with severe AS and MR?*

C.4. *Should the patient have a pulmonary artery catheter placed*

before induction?

C.5. *Is a pulmonary artery catheter with pacing capabilities indicated?*

C.6. *What anesthetic technique would you employ? Why?*

C.7. *What muscle relaxant would you use for this patient?*

C.8. *What are the usual TEE findings in a patient with AS or MR? How do you grade the severity of AS by TEE? How do you quantify the severity of MR? What is the impact of AS on the severity of MR?*

C.9. *What special considerations particular to cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.*

Aortic Stenosis
Aortic Insufficiency
Mitral Stenosis
Mitral Regurgitation

C.10. *The patient cannot be weaned from CPB following an AV replacement and MV replacement. What are the possible causes?*

C.11. *How would you diagnose right-sided heart failure and pulmonary hypertension? How would you treat it?*

C.12. *How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?*

C.13. *What role does the IABP have in this setting?*

C.14. *What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?*

C.15. *How would you properly time the IABP cycle?*

C.16. *What are the contraindications to the use of an IABP?*

C.17. *What is the role for ventricular assist devices?*

D. Postoperative Management

D.1. *In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could*

you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?
D.2. *Would you extubate this patient early in the ICU? Why?*
D.3. *What are the advantages and disadvantages of early extubation?*
E. Alternative Treatments
E.1. *What are the percutaneous options for MV repair?*
E.2. *How is percutaneous MV repair performed?*
E.3. *What are the percutaneous options for AV repair and replacement?*
E.4. *How is percutaneous AV replacement performed?*
E.5. *What anesthetic techniques and monitors are used?*
E.6. *What is minimally invasive cardiac valve surgery?*

8 Pacemakers, Implantable Cardioverter-Defibrillators, and Cardiac Resynchronization Therapy Devices
Alan Cheng and Fun-Sun F. Yao
A. Medical Disease and Differential Diagnosis
A.1. *What are the indications for PPMs?*
A.2. *What is sick sinus syndrome? What is chronotropic incompetence?*
A.3. *How would you diagnose first-, second-, and third-degree AV block; bifascicular block (right bundle branch block [RBBB] with left anterior fascicular hemiblock or left posterior fascicular hemiblock); and trifascicular block?*
A.4. *Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?*
A.5. *What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?*
A.6. *How many modes of pacing are available in modern PPMs?*

How do they work? What is the difference between DDD pacing and DDI pacing?

A.7. *The patient was mechanically hyperventilated during surgery, and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?*

A.8. *What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of right ventricular pacing only?*

A.9. *What are the indications for and complications associated with AV sequential PPMs?*

A.10. *How would you know if the patient's PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?*

A.11. *What is a biventricular PPM or CRT device? What are the indications for such a device?*

A.12. *What are the usual lifespans of PPMs and implantable cardioverter-defibrillators (ICDs)?*

A.13. *What is an ICD? How does it work? What is a subcutaneous ICD?*

A.14. *What are the indications for ICDs?*

A.15. *What is the NASPE and BPEG generic defibrillator (NBD) code?*

B. Preoperative Evaluation and Preparation

B.1. *How would you preoperatively evaluate the patient described earlier?*

B.2. *How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?*

B.3. *How do you determine whether the patient is dependent on the pacing from the CIED?*

B.4. *How do you know if the implanted PPM or ICD is working?*

B.5. *What information would you like to obtain from interrogating this device?*

B.6. *How do you preoperatively prepare the patient for surgery*

and anesthesia?

B.7. *Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?*

B.8. *The patient requires an abdominal magnetic resonance imaging (MRI) prior to the surgery. What considerations should you make regarding her CIED?*

C. Intraoperative Management

C.1. *How would you monitor this patient?*

C.2. *What drugs and equipment would you like to have on hand in the operating room?*

C.3. *How would you set up the transcutaneous external pacer and defibrillator?*

C.4. *Had this patient's ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?*

C.5. *Electromagnetic interference (EMI) from electrocautery results in significant noise on your cardiac monitor. You recall that EMI also can inhibit pacing function from the PPM. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the PPM is occurring?*

C.6. *What are the potential responses of pacemakers and ICDs to electrocautery?*

C.7. *How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?*

C.8. *What are the effects of a magnet on pacemakers and ICDs?*

C.9. *In the middle of surgery, the patient developed ventricular tachycardia. What would you do?*

C.10. *What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?*

C.11. *Is electroconvulsive therapy (ECT) contraindicated in*

patients with pacemakers or ICDs?

C.12. What precautions should be taken during radiofrequency ablation for a patient with a CIED?

C.13. During surgery, the patient developed frequent premature ventricular complexes and some of these resulted in rapid ventricular pacing (see Fig. 8.8). What is accounting for the pacemaker's behavior?

D. Postoperative Management

D.1. How would you monitor this patient in the postanesthesia care unit?

D.2. How would you confirm that the CIED is functioning properly after surgery?

9 Thoracic and Thoracoabdominal Aortic Aneurysms

Yong Zhan, Frederick C. Cobey, Sharon L. McCartney, Madhav Swaminathan, and Jamel Ortoleva

A. Pathophysiology and Differential Diagnosis

A.1. What is a thoracic aortic aneurysm (TAA) and TAAA, and how do they typically present?

A.2. How are TAAs and TAAAs classified?

A.3. What is the pathogenesis of aortic aneurysms and what genetic conditions predispose to their formation?

A.4. What are the risk factors for TAA rupture?

A.5. What is the natural history and medical management of thoracic aneurysms?

A.6. What is a thoracic aortic dissection, and how does it typically present?

A.7. How are thoracic aortic dissections classified?

DeBakey Classification

Stanford Classification

Penn Classification

B. Preoperative Evaluation and Preparation

B.1. What are the indications and timing of surgical intervention for TAAs?

- *B.2. Which patients are candidates for endovascular aortic repair, and what are the advantages to this approach?*
- *B.3. What are the preoperative considerations for the anesthesiologist before TAA repair?*
  - Cardiovascular
  - Respiratory
  - Renal
  - Neurologic
- *B.4. What is the preoperative management of a patient presenting with an acute aortic dissection (AAD)?*
- *B.5. What is the spinal cord blood supply?*

C. Intraoperative Management

- *C.1. What are the surgical approaches to thoracic aneurysm repair?*
  - Ascending and Arch Aortic Aneurysms
  - Thoracoabdominal Aneurysms
- *C.2. How is the open repair performed?*
  - Ascending and Arch Aortic Aneurysms
  - Thoracoabdominal Aneurysms
- *C.3. How are endovascular repairs of TAAAs performed?*
- *C.4. What are the surgical approaches to aortic dissections?*
  - Type A Aortic Dissection
  - Type B Aortic Dissection
- *C.5. What are the specific considerations for anesthetic management of the patient presenting for open TAAA repair?*
- *C.6. What are the specific considerations for anesthetic management of the patient presenting for endovascular TAAA repair?*
- *C.7. What hemodynamic monitors should be used for the patient undergoing thoracic aneurysm repair?*
- *C.8. What strategies are used for spinal cord protection during a TAAA repair?*

Left-Heart Bypass
Intraoperative Neuromonitoring
Cerebrospinal Drainage
Hypothermia
C.9. *What strategies are used for mesenteric and renal preservation?*
C.10. *What is the pathophysiology of aortic clamping and unclamping?*
Aortic Clamping
Aortic Unclamping
C.11. *Why does a coagulopathy ensue and how is it prevented/treated?*
D. Postoperative Anesthetic Management
D.1. *What are the postoperative complications after open TAAA repair?*
Respiratory Failure
Renal Failure
Spinal Cord Injury
D.2. *What are the postoperative complications after endovascular TAAA repair?*
Left Upper Extremity Ischemia
Stroke
Spinal Cord Ischemia
Renal Failure
Postimplantation Syndrome
Endograft Collapse
Endoleaks
10 Abdominal Aortic Aneurysm Repair
Fun-Sun F. Yao and Anup Pamnani
A. Medical Disease and Differential Diagnosis
A.1. *What risk factors are associated with an abdominal aortic aneurysm (AAA)?*
A.2. *What other diseases are commonly found in patients with*

aortic aneurysms?

A.3. *What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the natural history of the disease without surgical repair?*

A.4. *What should be done for smaller aortic aneurysms that are found in patients?*

A.5. *What is the risk of perioperative myocardial infarction (MI) in patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?*

A.6. *Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?*

B. Preoperative Evaluation and Preparation

B.1. *Which preoperative laboratory tests would you require for this patient?*

B.2. *What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what would they tell you?*

B.3. *Is it necessary to evaluate this patient's pulmonary status?*

B.4. *Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $Paco_2$, 47 mmHg; and Pao_2, 68 mmHg on room air. What is the significance of this result?*

B.5. *How would you measure creatinine clearance in this patient, and what is its value in this case?*

B.6. *Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?*

B.7. *How do you detect spinal cord ischemia?*

B.8. *What are the various surgical approaches to repair an AAA?*

B.9. *How does the choice of surgical technique affect the anesthetic management?*

B.10. *How would you premedicate this patient?*

C. Intraoperative Management

C.1. *Would you use an arterial line? What are the complications of arterial line placement?*

C.2. *What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?*

C.3. *What additional monitors would you employ?*

C.4. *Is there a role for somatosensory evoked potential (SSEP) monitoring during aortic clamping?*

C.5. *How would you anesthetize this patient for an open repair of the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.*

C.6. *This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?*

C.7. *What are your plans for fluid and blood replacement during surgery?*

C.8. *What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?*

C.9. *Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?*

C.10. *What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood*

pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?

D. Postoperative Management

D.1. What are the parameters used to extubate this patient?

D.2. What are the anticipated changes in postoperative pulmonary function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?

D.3. How would you control postoperative pain? What are the alternatives in the management of this patient's postoperative pain?

11 Hypertension

Christopher W. Tam and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis

A.1. Define hypertension and categorize its severity.

A.2. What is the prevalence of hypertension?

A.3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.

Etiology of Hypertension

A.4. What are the clinical patterns of hypertension encountered?

A.5. What is the pathophysiology of essential hypertension?

A.6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?

A.7. What are the end-organ damages caused by long-standing hypertension?

Cardiac Involvement

Eye Involvement

Renal Involvement

Cerebral Involvement

A.8. Are hypertensive patients at an increased risk for

perioperative cardiac morbidity?

A.9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?

A.10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?

A.11. What are the BP goals for patients with hypertension and when should antihypertensive drugs be initiated?

A.12. What is the mechanism of action of antihypertensive drugs?

Diuretics
Antiadrenergic Agents
Direct Vasodilators
Dopaminergic Agonists
Calcium Channel Blockers
Angiotensin-Converting Enzyme Inhibitors
Angiotensin II Receptor Blockers
Other Vasodilators

A.13. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?

A.14. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

B.2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?

B.3. Should all or any of the chronic medications be discontinued before the operation?

B.4. Should hypokalemia be treated before anesthesia? Why?

B.5. Should hypomagnesemia be treated before anesthesia? Why?

B.6. Does an asymptomatic carotid bruit increase the risk in these patients?

B.7. *The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mmHg and potassium 4.0 mEq per L. How would you premedicate this patient?*

B.8. *If the patient is an untreated hypertensive patient with BP 170/70 mmHg, would you treat the patient preoperatively with an antihypertensive agent?*

C. Intraoperative Management

C.1. *How would you monitor this patient?*

C.2. *What are the anesthetic goals for hypertensive patients?*

C.3. *How would you induce anesthesia for the hypertensive patient?*

C.4. *How does tracheal intubation produce hypertension?*

C.5. *What happens to the left ventricular ejection fraction during and immediately following intubation?*

C.6. *What other measures can prevent hypertension and tachycardia at the time of intubation?*

C.7. *After induction and intubation, the BP decreased to 70/40 mmHg. What would you do?*

C.8. *What is your choice of agents for maintenance of anesthesia? Why?*

C.9. *How would you manage fluid therapy for hypertensive patients?*

C.10. *During the surgery, BP increased to 220/120 mmHg. How would you treat the hypertension?*

C.11. *What could you do to prevent hypertension during extubation and emergence?*

C.12. *Would you consider regional anesthesia for this patient?*

D. Postoperative Management

D.1. *The patient developed hypertension, BP 210/110 mmHg, in the postanesthesia care unit. What would you do?*

12 Cardiac Tamponade

June M. Chan

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of low CO following cardiac surgery?

A.2. Describe the pathophysiology of cardiac tamponade.

A.3. What are the common etiologies of cardiac tamponade?

A.4. What is the difference between acute and delayed cardiac tamponade?

A.5. What is regional cardiac tamponade?

A.6. Describe the ventricular interaction in cardiac tamponade.

A.7. How is coronary blood flow affected in cardiac tamponade?

A.8. What is the Beck triad? Describe the typical signs and symptoms of cardiac tamponade.

A.9. Define pulsus paradoxus and describe its pathophysiology.

A.10. What is Kussmaul sign? Is this finding consistent with tamponade physiology?

A.11. Which medical conditions mimic cardiac tamponade?

B. Preoperative Evaluation and Preparation

B.1. Interpret and explain the pathophysiologic basis for this patient's hemodynamic findings.

B.2. How would you optimize this patient's cardiovascular status prior to definitive diagnosis and treatment?

B.3. What are the radiographic findings in tamponade?

B.4. A limited bedside transthoracic echocardiogram is performed, demonstrating a layer of clotted blood anterior to the right atrium (RA) and ventricle. What echocardiographic findings support the diagnosis of tamponade?

B.5. What additional information should be obtained from a limited echocardiographic study?

B.6. Describe the procedures for treating cardiac tamponade. What are the clinical indications for each approach?

B.7. *Having made the diagnosis of tamponade, what additional investigations are required prior to surgery?*

B.8. *Explain the technical and physiologic principles behind rotational thromboelastometry.*

B.9. *A rotational thromboelastometry was performed, and a 10-minute analysis reveals the following results (see Fig. 12.9 and Table 12.8). How do you interpret this information?*

B.10. *Given the ROTEM® findings and high clinical suspicion for occult postsurgical bleeding, what hemostatic products would you arrange to have in the operating room?*

B.11. *How would you organize and conduct the transport of this patient to the operating room?*

C. Intraoperative Management

C.1. *What are the cardiovascular effects of commonly used intravenous anesthetic and coinduction agents?*

Propofol
Etomidate
Ketamine
Thiopental
Fentanyl
Midazolam

C.2. *What is the effect of supine positioning and positive pressure ventilation on the hemodynamics of a patient with tamponade?*

C.3. *Describe the induction process for cardiac tamponade.*

C.4. *Following induction and intubation, the systemic blood pressure decreases to 55/30 mmHg. Describe your management.*

C.5. *What hemodynamic changes are frequently associated with opening the pericardial space?*

C.6. *Following the removal of approximately 500 mL of dark blood and clots from the mediastinum, the patient's CO remains low. What are your differential diagnoses?*

C.7. *What is pericardial decompression syndrome (PDS)?*

D. Postoperative Management

D.1. *A pericardial drain is placed following mediastinal decompression. How should this drainage tube be managed?*

D.2. *How would you manage hypertension in the intensive care unit?*

13 Heart Transplantation and Subsequent Noncardiac Surgery

Jeff T. Granton, Ranjana Bairagi, and Davy Cheng

A. Medical Disease and Differential Diagnosis

A.1. *What are the common diagnoses requiring adult heart transplantation?*

A.2. *What are the indications and relative contraindications for recipient selection?*

A.3. *What are the criteria for donor heart selection?*

A.4. *What is the role of donation after cardiac death (DCD) for heart transplantation?*

A.5. *What are the principles of perioperative donor management?*

A.6. *What are the risk factors associated with posttransplant mortality?*

A.7. *What is the difference between the biatrial and bicaval surgical techniques of heart transplant?*

A.8. *When is a combined heart/lung transplant indicated? What are the important differences?*

A.9. *What are the medical and surgical alternatives to cardiac transplantation?*

A.10. *What is the role of ventricular assist devices (VADs) in this type of patient?*

A.11. *What are the considerations in anesthetizing patients for LVAD insertion?*

B. Preoperative Management

B.1. *How would you assess this patient preoperatively?*

B.2. *How would you premedicate this patient? Why?*

C. Intraoperative Management
   - C.1. *What anesthetic equipment and monitors would you set up? Why?*
   - C.2. *What is the role of transesophageal echocardiography (TEE)?*
   - C.3. *Describe the induction and maintenance of anesthesia.*
   - C.4. *How would you manage this patient during cardiopulmonary bypass (CPB)?*

D. Postoperative Management
   - D.1. *What are the early postoperative complications?*
   - D.2. *What are the mechanisms of early right ventricular (RV) failure?*
   - D.3. *How would you treat RV failure following heart transplantation?*
   - D.4. *How does inhaled nitric oxide (NO) work as a selective pulmonary vasodilator?*
   - D.5. *What is the pathophysiology of the denervated heart?*
   - D.6. *What are the common cardiac dysrhythmias following heart transplant?*
   - D.7. *What are the causes of posttransplant bleeding?*
   - D.8. *How would you treat posttransplant bleeding?*
   - D.9. *What are the causes of early graft failure?*
   - D.10. *How would you manage this patient in the intensive care unit?*

E. Subsequent Noncardiac Surgery
   - E.1. *How would you monitor this patient?*
   - E.2. *What type of anesthetic is best for the heart-transplanted patient?*
   - E.3. *What anesthetic technique would you choose for this patient?*
   - E.4. *Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle relaxant in*

heart-transplanted patients?

E.5. *What are the anesthetic implications for heart-transplanted patients?*

E.6. *What is the significant implication of the denervated heart?*

E.7. *What is the significance of allograft rejection?*

E.8. *What is the significance of infection in these patients?*

E.9. *What are the significant implications of drug interactions?*

E.10. *What is cardiac allograft vasculopathy (CAV)? Why is this important?*

E.11. *What is the significant implication of posttransplant hypertension?*

E.12. *What is the significant implication of renal dysfunction?*

E.13. *What types of malignancy are found in recipients?*

E.14. *Is ambulatory surgery appropriate for heart transplant recipients?*

14 Ischemic Heart Disease and Noncardiac Surgery

Christopher Szabo and Manuel Fontes

A. Medical Disease and Differential Diagnosis

A.1. *What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?*

A.2. *What are the determinants of myocardial oxygen demand? How are they measured clinically?*

A.3. *What factors determine myocardial oxygen supply?*

A.4. *What is the mechanism of perioperative myocardial ischemia and MI?*

A.5. *What is the incidence of perioperative reinfarction for noncardiac surgery?*

A.6. *State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.*

β-Adrenergic Antagonists (Esmolol, Atenolol, Metoprolol, Bisoprolol)

α_2-Adrenergic Agonist (Clonidine)

Nitrovasodilators (Nitroglycerin, Isosorbide Dinitrate)

Calcium Channel Blockers (Verapamil, Diltiazem, Nifedipine, Nicardipine)
Aspirin
Statins

A.7. Based on his MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?

A.8. Would you recommend that this elective colectomy be postponed if the patient underwent placement of a right coronary artery, second-generation DES, and is taking aspirin and clopidogrel (Plavix)?

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?

B.2. Would you recommend further cardiac testing or coronary revascularization before surgery?

B.3. How would you classify the cardiac risk according to the type of surgery?

B.4. What is the role of exercise or pharmacologic stress test for this patient?

B.5. Would you discontinue any medication before surgery?

B.6. How would you premedicate this patient?

B.7. Is there a role for α_2-agonist in premedication?

C. Intraoperative Management

C.1. What are the intraoperative predictors for perioperative MACE?

Intraoperative Predictors

C.2. How would you monitor the patient in the operating room?

C.3. What electrocardiogram (ECG) leads would you monitor? Why lead V_5?

C.4. Would you use a pulmonary artery catheter (PAC)?

C.5. Would you use transesophageal echocardiography (TEE) as a monitor?

C.6. Is regional anesthesia better than general anesthesia for

patients with cardiac disease?
C.7. *How will you induce general anesthesia?*
C.8. *Would you induce anesthesia with etomidate? Why?*
C.9. *What is the best choice of anesthetic agents for maintenance of anesthesia? Why?*
C.10. *You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?*
C.11. *Would you give prophylactic intravenous NTG to prevent myocardial ischemia?*
C.12. *What is the significance of tight control of the heart rate intraoperatively?*
C.13. *When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?*

D. Postoperative Management
D.1. *What are the postoperative predictors of perioperative MACE?*
D.2. *How would you control postoperative pain?*
D.3. *Is postoperative anemia associated with adverse cardiac outcome?*
D.4. *Is postoperative hypothermia associated with postoperative myocardial ischemia?*
D.5. *How would you make a diagnosis of perioperative MI (PMI)?*
D.6. *How would you manage the patient with a suspected PMI?*

SECTION 3 The Gastrointestinal System

15 Intestinal Obstruction and Enhanced Recovery after Surgery
Leif Ericksen and Tong J Gan

A. Medical Disease and Differential Diagnosis
A.1. *What is the differential diagnosis of the acute abdomen?*
A.2. *What are the causes of intestinal obstruction of the small*

bowel and of the large bowel?

A.3. Differentiate between simple and strangulated bowel obstruction.

A.4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why? How might the distinction be made?

A.5. What are the causes and effects of bowel distention?

A.6. Describe the fluid shifts during small bowel intestinal obstruction.

A.7. Discuss the systemic derangements that occur with intestinal obstruction.

A.8. What is an ileus? Discuss its causes and pathophysiology.

B. Preoperative Evaluation and Preparation

B.1. What is Enhanced Recovery after Surgery (ERAS)? What are the core tenants of these programs?

B.2. Can ERAS be used in this case?

B.3. What components of ERAS are applied in the preoperative phase of the care of colorectal surgery (CRS) patients?

B.4. Is it important to decompress the abdomen before induction of anesthesia? Why?

B.5. Describe the respiratory implications.

B.6. What are the implications of the tense abdominal wall?

B.7. Outline the methods of abdominal decompression.

B.8. Discuss the goals of fluid management.

B.9. What would you use as a guide to fluid volume replacement?

C. Intraoperative Management

C.1. What dangers are present during induction? How are they planned for?

C.2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?

C.3. In what position would you intubate this patient?

C.4. What is the best muscle relaxant to use for the rapid

sequence induction?

C.5. Would you remove or leave the nasogastric tube (NGT) in place before inducing anesthesia?

C.6. Would you use nitrous oxide in this patient?

C.7. Are there any benefits to using a high concentration of inspired oxygen (FIO_2)?

C.8. What components of ERAS are applied in the intraoperative phase of the care of CRS patients?

C.9. What are the strengths, weaknesses, benefits, and challenges of ERAS?

Strengths

Weakness

Benefits

Challenges

C.10. What are the indications for ERAS?

D. Postoperative Management

D.1. What are the principles of postoperative care in this patient?

D.2. Are there any postoperative respiratory problems associated with factors other than aspiration?

D.3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?

D.4. What is gram-negative sepsis? Describe the clinical picture and treatment.

D.5. What components of ERAS are applied in the postoperative phase of the care of CRS patients?

16 Liver Transplantation

Christopher H. Choi and Vivek K. Moitra

A. Medical Disease and Differential Diagnosis

A.1. What are the potential graft options for liver transplantation?

A.2. What are the indications and contraindications for liver transplantation?

A.3. *What is acute liver failure (ALF)?*
A.4. *What is the MELD score, and how is it used in liver transplantation evaluation?*
A.5. *What is portal hypertension? What are the sequelae of portal hypertension?*
A.6. *Describe the cardiovascular system of patients with end-stage liver disease (ESLD).*
A.7. *What causes acute kidney injury (AKI) in patients with cirrhosis?*
A.8. *What causes hyponatremia in patients with cirrhosis?*
A.9. *Discuss the neurologic manifestations of acute and chronic liver disease.*
A.10. *Why do patients with ESLD have abnormalities of hemostasis?*
A.11. *What is the differential diagnosis for hypoxemia in patients with cirrhosis?*
A.12. *What are the risk factors and treatment guidelines for spontaneous bacterial peritonitis (SBP)?*

B. Preoperative Evaluation and Preparation
B.1. *What preoperative workup is desirable?*
B.2. *How is ascites managed preoperatively?*
B.3. *How is hyponatremia managed preoperatively?*
B.4. *What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?*
B.5. *How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?*
B.6. *Should this patient be transfused with fresh frozen plasma prior to surgery?*

C. Intraoperative Management
C.1. *What monitors would you use? Why?*
C.2. *What are the considerations for the induction of anesthesia?*
C.3. *How does liver disease affect intraoperative medication*

management?

C.4. *What happens during the first stage (preanhepatic phase) of the liver transplant operation?*

C.5. *What happens during the second stage (anhepatic phase) of the liver transplant operation?*

C.6. *What physiologic disturbances should be anticipated during the second stage (anhepatic phase) of the liver transplant operation?*

C.7. *What is venovenous bypass? What are the potential advantages and disadvantages of this procedure?*

C.8. *What surgical techniques anastomose the donor and recipient inferior vena cava (IVC)?*

C.9. *What are the potential advantages of the "piggyback" (vena cava preservation) technique?*

C.10. *What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome (PRS)?*

C.11. *How would you treat hyperkalemia?*

C.12. *Why should you anticipate hypocalcemia?*

C.13. *What happens during the third stage of the liver transplant operation?*

C.14. *What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What are thromboelastography (TEG) and rotational thromboelastography (ROTEM)?*

C.15. *What are the complications of massive transfusion?*

C.16. *How are the complications of massive transfusion prevented?*

C.17. *How is hyperfibrinolysis managed?*

C.18. *When is intraoperative renal replacement therapy indicated?*

C.19. *What intraoperative signs suggest that the hepatic graft is working?*

D. Postoperative Management

D.1. *What are the goals of immediate postoperative care of the liver transplant patient?*
D.2. *What postoperative findings suggest that the hepatic graft is functioning?*
D.3. *What coagulation disturbances should be anticipated in the postoperative period?*
D.4. *Can renal function change after liver transplantation?*
D.5. *What vascular and biliary complications occur after liver transplantation?*
D.6. *What immunosuppressive agents will be given after liver transplantation? What are the major side effects?*
Acknowledgment

SECTION 4 The Nervous System

17 Brain Tumor and Craniotomy
June M. Chan, Elena V. Christ, and Kane O. Pryor
A. Medical Disease and Differential Diagnosis
A.1. *What is the pathology of intracranial tumors?*
A.2. *What is intracranial pressure (ICP), and what are its determinants?*
A.3. *How does the presence of a mass alter the ICP in this patient, and what are the clinical manifestations of these alterations?*
A.4. *What is cerebral blood flow (CBF), and what are its determinants?*
A.5. *What are the cerebral steal syndromes?*
A.6. *Are there any issues specific to posterior cranial fossa pathology?*
A.7. *What is the role of preoperative embolization therapy?*
B. Preoperative Evaluation and Preparation
B.1. *What are the special considerations in preoperative evaluation of the patient scheduled for posterior fossa*

craniotomy?

- *B.2. In a patient who presents with intracranial hypertension, what management might have already been initiated preoperatively, and what are the implications for anesthetic management?*
- *B.3. What are the types of intraoperative neurophysiologic monitoring (IOM) that would likely be used for this procedure, and how will they affect the anesthetic management plan?*
- *B.4. What are the options for patient positioning during posterior fossa surgery?*
- *B.5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?*
- *B.6. How does the sitting position affect your preoperative assessment and planning?*
- *B.7. How should the patient position ultimately be determined?*
- *B.8. Should this patient receive premedication?*

C. Intraoperative Management

- *C.1. What are the anesthetic goals for craniotomy?*
- *C.2. What monitors should be used during craniotomy?*
- *C.3. Would you monitor for venous air embolism (VAE)? What are the monitoring options?*
- *C.4. What specific risks are associated with induction of anesthesia?*
- *C.5. How would you induce anesthesia?*
- *C.6. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRO_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?*
  - Volatile Anesthetics
  - Nitrous Oxide
  - Intravenous Anesthetics
  - Opioids
- *C.7. How would you manage ventilation and maintain arterial*

carbon dioxide (CO_2)?

C.8. How would you approach diuretic therapy?

C.9. How would you manage serum glucose?

C.10. How would you approach fluid management?

C.11. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still "tight." What would be your response?

C.12. If deliberate hypotension is indicated, how will you achieve it?

C.13. While the surgeon is resecting tumor from near the brainstem, the patient's heart rate suddenly drops to 20 beats per minute. What is your assessment and management?

C.14. Are there any measures you can take to prevent VAE?

C.15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($EtCO_2$) drops from 31 to 13 mmHg, and the systemic pressure from 121/63 to 64/32 mmHg. What is your assessment and management plan?

C.16. What is your approach to emergence? What if the patient does not regain consciousness?

D. Postoperative Management

D.1. What postoperative complications are of greatest concern? What level of monitoring is required?

D.2. What is your approach to postoperative pain control?

D.3. In the ICU, the patient's neurologic status deteriorates and ICP monitoring is instituted. What are the different methods of monitoring ICP, and what are their limitations?

18 Carotid Artery Disease

Priscilla Nelson and Hugh C. Hemmings Jr.

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting symptoms of carotid stenosis?

A.2. What is the prevalence of carotid artery disease?

A.3. *What is the natural course of carotid artery disease as it relates to stroke?*

A.4. *What in the patient's history puts them at higher risk for having carotid atherosclerosis?*

A.5. *Do we screen patients for asymptomatic carotid stenosis?*

A.6. *What is the risk of stroke and cardiovascular events in asymptomatic carotid atherosclerosis?*

A.7. *What are the current medical options that the patient has for treating carotid atherosclerosis?*

A.8. *What are the indications for CEA and carotid artery stenting (CAS) in asymptomatic carotid atherosclerotic disease?*

A.9. *What are the indications for performing a CEA in symptomatic carotid stenosis?*

A.10. *Is there any role for CAS in symptomatic patients?*

A.11. *Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.*

A.12. *Discuss cerebral blood flow (CBF) in the presence of carotid artery disease.*

A.13. *Discuss the different surgical approaches to carotid revascularization.*

A.14. *Discuss the endovascular approaches to carotid stenting.*

A.15. *What is normal CBF?*

A.16. *What is critically low CBF as measured by the electroencephalogram (EEG)?*

A.17. *What is cerebral autoregulation?*

A.18. *How does $PaCO_2$ affect CBF?*

A.19. *What are the principal determinants of CBF?*

A.20. *What is meant by the term luxury perfusion?*

A.21. *What is meant by the term intracerebral steal?*

B. Preoperative Evaluation and Preparation

B.1. *What will you look for in your preoperative evaluation of this patient?*

B.2. *Is this patient's blood pressure too high for elective surgery?*
B.3. *What laboratory data are required preoperatively?*
B.4. *Will you treat this patients' blood glucose?*
B.5. *Will you premedicate this patient?*

C. Intraoperative Management
C.1. *How will you monitor this patient?*
C.2. *How will you know that the patient's cerebral perfusion is adequate during surgery?*
C.3. *Discuss the differences and relative advantages and disadvantages of unprocessed EEG and processed EEG monitoring.*
C.4. *How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique?*
C.5. *Describe the use of stump pressure and its limitations.*
C.6. *Describe the use of transcranial Doppler (TCD) and its limitations.*
C.7. *Describe the use of jugular venous oxygen saturation ($SjvO_2$) and its limitations.*
C.8. *Describe the use of cerebral oximetry and its limitations.*
C.9. *Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during CEA.*
C.10. *What type of anesthesia will you choose for this patient if she chose to have an endarterectomy?*
C.11. *What type of anesthesia will you choose for this patient if she chose to have a carotid stent?*
C.12. *How will you induce and maintain general anesthesia in this patient for CEA?*
C.13. *How would you proceed if the patient were to receive regional anesthesia?*
C.14. *Discuss the effects of anesthetics on CBF.*
C.15. *Discuss the protective effects of anesthetic agents on cerebral function.*

C.16. *How will you manage this patient's ventilation under general anesthesia?*

C.17. *How will you manage this patient's blood pressure intraoperatively?*

C.18. *Discuss reperfusion injury following CEA and CAS.*

C.19. *What intravenous fluids will you give this patient intraoperatively?*

D. Postoperative Management

D.1. *The patient does not "wake up" from general anesthesia. Why?*

D.2. *Postoperatively, the patient's blood pressure is 170/96 mmHg. Will you treat this?*

D.3. *What immediate postoperative complications might you expect after a CEA?*

D.4. *What postoperative complications might you expect after a CAS?*

D.5. *Discuss postoperative neurocognitive dysfunction following uncomplicated carotid intervention.*

19 Awake Craniotomy for Mapping and Surgery in the Eloquent Cortex

Thomas A. Moore II and Kenneth G. Smithson

A. Medical Disease and Differential Diagnosis

A.1. *What is the eloquent cortex?*

A.2. *What is the underlying pathology?*

A.3. *What determines intracranial pressure (ICP)?*

A.4. *How does a space-occupying mass alter ICP?*

A.5. *What is autoregulation, and why is it important?*

A.6. *How is cerebral blood flow (CBF) regulated?*

A.7. *What drug therapies may be associated with this pathology?*

B. Preoperative Evaluation and Preparation

B.1. *Why is the craniotomy performed awake?*

B.2. *What neurologic symptoms of the patient are important?*

B.3. *What is the status of their other comorbid conditions?*

B.4. Are there anesthetic implications from current treatment drugs?
B.5. What laboratory data are required?
B.6. What radiology data should be reviewed?
B.7. How do you prepare the patient for an awake craniotomy?
B.8. Should this patient receive premedications?
B.9. What precautions should be made for airway management?
C. Intraoperative Management
C.1. How should this patient be monitored?
C.2. Does this patient require invasive monitoring?
C.3. Can current drug therapy alter eloquent cortex mapping?
C.4. Why use hypertonic fluids during a craniotomy?
C.5. What intravenous fluids (IVFs) are recommended?
C.6. Would a lumbar drain for cerebrospinal fluid (CSF) removal benefit this patient?
C.7. Venous air embolism (VAE): Is it a concern in this case?
C.8. How is the eloquent cortex mapped?
C.9. How are intraoperative seizures treated?
C.10. How will you conduct this anesthetic?
D. Postoperative Management
D.1. What are the major concerns following craniotomy?
Acknowledgments
20 Head Injury
Chris C. Lee, Susan A. Ironstone, and M. Angele Theard
A. Pathophysiology and Differential Diagnosis
A.1. What types of intracranial injuries are most likely to have occurred in this patient?
A.2. What is the difference between primary and secondary injury? What factors contribute to secondary injury?
A.3. What are the benefits and risks of administering mannitol?
Benefits
Risks
A.4. What is the effect of hyperglycemia on neurologic outcome

following head trauma?

A.5. *What alterations in sodium and potassium balance can occur in patients with head injury?*

A.6. *In addition to sodium and potassium, what other electrolyte abnormalities can be present after head trauma?*

A.7. *What are the neuroprotective effects of administering magnesium (Mg)?*

A.8. *What role do gender and female sex hormones have in the pathophysiology of traumatic brain injury (TBI)?*

A.9. *What is the role of decompressive craniectomy (DC) as a treatment option for ICP control after head injury?*

A.10. *Do genetic factors play a role in the outcome after head injury?*

B. Preoperative Evaluation and Preparation

B.1. *What is the GCS? What is the significance of a GCS of 7T in this patient?*

B.2. *In addition to the GCS, what other assessments can be done to evaluate neurologic function?*

B.3. *What is the role of CT scanning in the initial evaluation of the patient with head injury? What are the management options in patients whose neurologic condition is deteriorating before obtaining a CT scan?*

B.4. *What is the role of ICP monitoring in the management of head injury?*

B.5. *How can you clear this patient's cervical spine?*

B.6. *What are the advantages of early endotracheal intubation in this patient?*

B.7. *What is your plan for airway management in this patient? How would it change if the patient were combative? How would it change if the patient had facial fractures with significant swelling of the head and neck?*

B.8. *What are the effects of succinylcholine on ICP? What is the significance of the effect, if any?*

B.9. What coagulation abnormalities are present after TBI? What modalities can be used to provide hemostasis and reduce intracranial hematoma expansion?

C. Intraoperative Management

C.1. What is appropriate hemodynamic monitoring during CT scanning and during craniotomy for evacuation of a subdural hematoma?

C.2. Should hyperventilation be used in this patient?

C.3. What are the implications of arterial hypertension in patients with head injury? How should BP be managed?

C.4. What should be done about intravenous (IV) fluid replacement? Should corticosteroids be given empirically?

C.5. Should hypertonic saline (HTS) be administered to this patient? How is HTS administered?

C.6. The patient underwent a craniectomy for evacuation of a frontal intracerebral hematoma. Should some anesthetic agents be avoided in this situation? Which ones? What agents might be preferred in this situation?

C.7. Should hypothermia be employed in this patient?

D. Postoperative Neurointensive Care Management

D.1. What are the postoperative ventilation concerns in this patient?

D.2. What specific measure should be used to control the patient's ICP? What type of monitoring devices can be used to measure ICP?

D.3. What is neurogenic pulmonary edema? Would you avoid positive end-expiratory pressure (PEEP) in a patient with increased ICP?

D.4. What is the role of antiseizure prophylaxis in the perioperative management of head trauma?

D.5. How can cerebral oxygenation monitoring be used in the clinical management of TBI?

D.6. What methods can be used in the neurointensive care unit to

prevent hyperthermia?

21 Cerebral Aneurysm

Patricia Fogarty Mack

A. Medical Disease and Differential Diagnosis

- *A.1. What are the incidence, prevalence, and causes of subarachnoid hemorrhage (SAH), and what are the risk factors associated with rupture of intracranial aneurysms?*
- *A.2. What are common sizes and locations of intracranial aneurysms?*
- *A.3. What is the pathophysiology of aneurysmal rupture and SAH?*
- *A.4. What are symptoms and signs of SAH?*
- *A.5. How does one assess the severity of SAH?*
- *A.6. What are the cardiovascular effects of SAH?*
- *A.7. How is the diagnosis of SAH made?*
- *A.8. What is the risk for rebleeding for a patient with SAH?*

B. Preoperative Evaluation and Preparation

- *B.1. What are some concerns in going to the interventional neuroradiology suite in the midst of an angiogram to be followed immediately with coiling of an aneurysm?*
- *B.2. What type of anesthesia is required for coiling of an aneurysm?*
- *B.3. Should one proceed with induction of general anesthesia under these circumstances?*
- *B.4. What types of emergencies can occur during coiling of an aneurysm, and how should they be managed?*
- *B.5. What other modalities of endovascular therapy are available?*
- *B.6. A craniotomy is planned for the following day to clip the middle cerebral artery aneurysm. Should surgery be postponed because of the patient's elevated troponin and CPK-MB fractions?*
- *B.7. Would you premedicate this patient before craniotomy?*

C. Intraoperative Management

- *C.1. What are the goals of the induction and maintenance of anesthesia for this patient?*
- *C.2. Is placement of an arterial catheter necessary for induction of anesthesia in this patient in the interventional neuroradiology suite?*
- *C.3. How would you assess fluid status in this patient?*
- *C.4. Would monitoring central venous pressure (CVP) be useful for craniotomy and aneurysm clipping in this patient?*
- *C.5. What other forms of monitoring would you consider?*
- *C.6. What are your specific concerns during induction of anesthesia in this patient?*
- *C.7. How would you accomplish a smooth and safe induction and intubation in this patient?*
- *C.8. Would you perform a rapid sequence induction and tracheal intubation for this patient?*
- *C.9. What are the effects of hypoxemia and hypercapnia, such as would be seen with loss of the airway on induction, on cerebral blood flow (CBF)?*
- *C.10. What is optimal fluid management for aneurysm clipping? Would you use a dextrose-containing solution?*
- *C.11. After the bone plate was removed and as the dura was being opened, the surgeon complained that the brain was "tight." What could you do to achieve better brain relaxation and facilitate surgical exposure?*
- *C.12. How might transmural pressure be decreased to allow for aneurysm clip placement?*
- *C.13. What is the purpose of controlled hypotension, and how is it achieved?*
- *C.14. What are some of the drawbacks of controlled hypotension?*
- *C.15. What methods of cerebral protection might you use during this operation?*
- *C.16. Would you induce mild hypothermia as a means of cerebral*

protection?
C.17. What are the indications for deep hypothermic circulatory arrest?
C.18. What steps should be taken in the case of intraoperative rupture of an intracranial aneurysm?
C.19. How would you plan the emergence from an anesthetic for aneurysm clipping?
D. Postoperative Management
D.1. Would you extubate the patient postoperatively?
D.2. What would be the differential diagnosis if the patient did not return to her preoperative neurologic condition?
D.3. On postoperative day 2, the patient became disoriented and developed hemiplegia. A CT scan was obtained, which shows no new intracranial bleeding. What other diagnostic studies should be performed?
D.4. What is cerebral vasospasm, and what causes it?
D.5. What are pathophysiologic changes seen in cerebral vasospasm?
D.6. How is the diagnosis of cerebral vasospasm made?
D.7. What steps can be taken to prevent cerebral vasospasm?
D.8. What treatments can be undertaken once a diagnosis of cerebral vasospasm is made?
D.9. What are other neurologic complications following SAH and aneurysm clipping?
D.10. What other organ systems may manifest problems postoperatively in aneurysm clipping patients?

SECTION 5 The Endocrine System

22 Pheochromocytoma
Anup Pamnani and Vinod Malhotra
A. Medical Disease and Differential Diagnosis
A.1. What are some common differential diagnoses for arterial

hypertension?

- *A.2. What is a pheochromocytoma?*
- *A.3. Describe the anatomy of the adrenal gland.*
- *A.4. What substances does the adrenal medulla secrete?*
- *A.5. What are the mechanisms of action of epinephrine and norepinephrine?*
- *A.6. What is the pathway for synthesis and breakdown of catecholamines?*
- *A.7. What does the adrenal cortex secrete?*
- *A.8. What are the metabolic actions of the glucocorticoids and the mineralocorticoids?*
- *A.9. What are the clinical features associated with a pheochromocytoma?*
- *A.10. What is the prevalence of pheochromocytomas and paragangliomas?*

B. Preoperative Evaluation and Preparation

- *B.1. How can you diagnose and localize the tumor preoperatively?*
- *B.2. How do you pharmacologically prepare the patient with a pheochromocytoma for surgery?*
- *B.3. What other aspects of preoperative management are important?*

C. Intraoperative Management

- *C.1. What drugs should be avoided during the operation?*
- *C.2. How would you monitor this patient?*
- *C.3. Describe the anesthetic management of the patient with pheochromocytoma.*
- *C.4. What drugs are used to control the effects of catecholamine stimulation during surgery?*
- *C.5. What are some management concerns after the tumor is removed?*
- *C.6. What are some of the concerns with laparoscopic adrenalectomy?*

D. Postoperative Management

D.1. What is the significance of postoperative hypotension? How is it treated?

D.2. What other problems can arise in the postoperative period?

23 Diabetes Mellitus

Mark E. Nunnally and Vinod Malhotra

A. Medical Disease and Differential Diagnosis

A.1. What is the epidemiology of DM in the general population?

A.2. What are the factors in the etiology of the disease?

A.3. How is DM classified?

A.4. What are the complications of DM?

A.5. How are the different forms of this illness treated?

A.6. How is control of the disease adequately monitored?

A.7. What are some of the factors that alter insulin requirements?

A.8. What are the principles of management of diabetic ketoacidosis (DKA)?

A.9. What is a hyperglycemic hyperosmolar state?

B. Preoperative Evaluation and Preparation

B.1. How should this patient be evaluated?

B.2. How would the stiff joint syndrome affect her airway management?

B.3. What are the signs and implications of autonomic neuropathy in the diabetic patient?

B.4. How should this patient be prepared for anesthesia and surgery?

B.5. For elective surgery, how are insulin and glucose requirements managed on the day of surgery?

B.6. How should this patient be premedicated?

C. Intraoperative Management

C.1. What are the effects of anesthesia and surgery on insulin and glucose metabolism?

C.2. What anesthetic techniques should be considered?

C.3. *How should this patient be monitored?*
C.4. *How is hyperglycemia treated intraoperatively?*
C.5. *How is hypoglycemic shock recognized and treated intraoperatively?*

D. Postoperative Management
D.1. *How is diabetes controlled in this patient postoperatively?*
D.2. *Does diabetes increase perioperative risk?*
D.3. *What are the common postoperative complications to be expected in a diabetic patient?*
D.4. *Is it necessary to achieve tight perioperative control of glucose?*

SECTION 6 The Genitourinary System

24 Transurethral Resection of the Prostate and Geriatric Anesthesia
Anuj Malhotra, Vinod Malhotra, and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis
A.1. *What comorbidities are common in patients undergoing TURP?*
A.2. *What are the normal physiologic consequences of aging for the various organ systems?*
A.3. *How should drug dosages be adjusted for elderly patients? Should any particular medications be avoided?*
A.4. *Does a history of prior MI increase the patient's risk of perioperative reinfarction or stent thrombosis?*
A.5. *In patients with a history of recent MI, would you recommend that the surgery be postponed for a certain period?*

B. Preoperative Evaluation and Preparation
B.1. *How would you evaluate the patient's cardiac condition? Does he need additional testing?*
B.2. *Would you discontinue any antihypertensives or any*

medications for angina?

B.3. For a patient with a cardiac implantable electronic device (CIED), what information should you know? What precautions should be taken?

B.4. What types of coronary stents are available? What is their perioperative relevance?

B.5. What is the conventional recommendation for dual antiplatelet therapy (DAPT) in a patient with previous percutaneous coronary intervention (PCI) undergoing elective noncardiac surgery?

B.6. What risk is associated with continuing perioperative antiplatelet therapy? What risk is there with stopping it?

B.7. How should patients with coronary stents undergoing noncardiac surgery be managed?

C. Intraoperative Management

C.1. What monitors would you use for this patient?

C.2. Is there a preferred anesthetic technique for patients undergoing TURP, and why?

C.3. Does regional anesthesia result in a lower incidence of perioperative mortality than general anesthesia?

C.4. What intravenous fluid would you use during TURP?

C.5. Forty minutes after a sensory level of T10 was established with intrathecal anesthesia, and monopolar TURP (M-TURP) resection was initiated with the use of glycine as the bladder irrigating solution, the patient becomes agitated and complains of nausea. Further sedation along with an antiemetic is administered. However, shortly thereafter, the patient becomes very restless, blood pressure rises, and heart rate decreases. The patient becomes cyanotic and obtunded, blood pressure precipitously falls, and pupils are dilated and unresponsive to light. What is the most likely cause of these signs and symptoms, and would these occur during bipolar (B-TURP) or laser TURP (L-TURP)

resection?

C.6. *What are the important characteristics of irrigation solutions used during TURP?*

C.7. *What is the effect on body temperature of continuous bladder irrigation during TURP?*

C.8. *What is the definition of TURP syndrome? What are the signs and symptoms of the syndrome?*

Cardiopulmonary

Hematologic and Renal

Central Nervous System

C.9. *How does the patient absorb irrigation solution during TURP?*

C.10. *What factors increase the incidence of TURP syndrome?*

C.11. *What is the effect on cardiopulmonary, renal, and central nervous system (CNS) functions of excessive absorption of irrigation solution during TURP?*

C.12. *What causes CNS dysfunction in patients who have undergone M-TURP?*

C.13. *How does acute hyponatremia affect the cardiovascular system?*

C.14. *What prophylactic measures may reduce the incidence of TURP syndrome?*

C.15. *What therapeutic measures are recommended for patients with TURP syndrome?*

C.16. *Is hypertonic saline administration necessary to correct hyponatremia? Explain. What are the risks of rapidly correcting hyponatremia?*

C.17. *What are the toxic effects of glycine? Is there an antidote to glycine toxicity? What are the metabolic by-products of glycine?*

C.18. *What are the symptoms and clinical course of TURP-induced hyperammonemia?*

C.19. *What are the clinical characteristics, causes, and prognosis*

of TURP-related blindness?
C.20. What are the causes of excessive bleeding during TURP?
C.21. What are the causes, signs, symptoms, and treatment of bladder perforation during TURP?
C.22. What are the causes of hypotension during TURP?
D. Postoperative Management
D.1. What is the source of postoperative bacteremia in patients who have undergone TURP? What factors increase the incidence of bacteremia?
D.2. What are the signs of post-TURP septicemia? What preventive measures are generally recommended?
D.3. Is postoperative hypothermia a risk factor for myocardial ischemia?
D.4. What is postoperative cognitive dysfunction (POCD)? How does this differ from delirium, and what is the time course to resolution?
D.5. What are the mechanisms and risk factors for POCD? How would you mitigate the risk of POCD? Does anesthesia type influence development of POCD?
E. Comparing M-TURP, B-TURP, and L-TURP
E.1. What differentiates M-TURP from B-TURP?
E.2. Are decreased morbidity and mortality associated more closely with M-TURP or with B-TURP?
E.3. What differentiates the technologies for L-TURP?

25 Kidney Transplant
Christine Lennon and Fun-Sun F. Yao
A. Medical Disease and Differential Diagnosis
A.1. What are the causes of chronic renal disease that can progress to renal failure?
A.2. How is chronic kidney disease (CKD) diagnosed?
A.3. What are the indications for dialysis?
A.4. What are the common clinical manifestations of ESRD?
A.5. What electrolyte imbalances occur in patients with impaired

renal function, and how are they treated?

A.6. *How is metabolic acidosis managed in chronic renal failure?*

A.7. *Are patients with renal disease at increased risk of cardiovascular disease?*

A.8. *When is the best time to receive a kidney transplant?*

A.9. *How are immunosuppressive drugs managed in kidney transplant recipients?*

A.10. *How are kidneys allocated to recipients on the waiting list in the United States?*

A.11. *What is donation after cardiac death (DCD)?*

A.12. *What is a living donor transplant program?*

A.13. *What is a paired donor exchange transplant program?*

A.14. *What are some barriers to receiving a kidney transplant?*

A.15. *What surgical techniques are available for donor nephrectomy (DN)?*

A.16. *How is a donor kidney preserved?*

A.17. *Describe the operative procedure of kidney transplantation.*

B. Preoperative Evaluation and Preparation

B.1. *What preoperative workup would you order for a recipient?*

B.2. *How does the presence of obesity affect the outcome of a transplanted kidney?*

B.3. *How are routine medications and immunosuppressive medications managed in the perioperative period?*

C. Intraoperative Management

C.1. *Are a central venous pressure (CVP) monitoring line, an arterial line, and a pulmonary artery catheter required for the transplant procedure?*

C.2. *What type of intravenous fluid should be used during surgery?*

C.3. *How would you conduct the anesthesia induction?*

C.4. *Is succinylcholine contraindicated in renal failure patients?*

C.5. *How are the nondepolarizing muscle relaxants affected by*

renal failure?

C.6. How would you maintain anesthesia during the case?

C.7. What are the effects of inhalation anesthetics on renal blood flow (RBF), glomerular filtration (GFR), and urine output?

C.8. What are the potential nephrotoxic effects of inhalation anesthetics? What are the nephrotoxic metabolites of inhalation anesthetics?

C.9. How does renal failure affect the pharmacology of opioids?

D. Postoperative Management

D.1. How is the diagnosis of transplant rejection made?

D.2. What are immunosuppressive agents, and how do they affect anesthetic care?

26 Robotic-Assisted Laparoscopic Surgery

Judith Weingram

A. Medical Disease and Differential Diagnosis

A.1. What is the incidence of carcinoma of the prostate?

A.2. How is prostate cancer diagnosed?

A.3. How is prostate cancer treated?

A.4. Define laparoscopy.

A.5. Describe the development of robotic-assisted laparoscopy.

A.6. What are the advantages and disadvantages of minimally invasive surgery over open surgery?

A.7. What are the contraindications to laparoscopic or robotic-assisted laparoscopic surgery? Is pregnancy a contraindication to robotic surgery?

A.8. What other specialties commonly perform robotic surgery?

A.9. Why is carbon dioxide (CO_2) the gas of choice for robotic laparoscopy? What are its disadvantages?

A.10. How much endogenous CO_2 is produced at basal level and at maximal exercise?

A.11. How much CO_2 is stored in the body? Where is it stored? Of what significance is this to laparoscopy?

A.12. *Describe the diffusion and solubility properties of CO_2 and their significance in laparoscopy.*

A.13. *Is CO_2 soluble in water or plasma? Is it soluble in blood? Why?*

B. Preoperative Evaluation and Preparation

B.1. *What do you want to know about this patient's history and physical condition that may affect whether or not you clear him for robotic surgery?*

B.2. *What factors increase this patient's risk of pulmonary complications?*

B.3. *What laboratory tests should be performed preoperatively?*

B.4. *What specific information should the patient be given about robotic surgery before obtaining informed consent?*

B.5. *What additional procedures should be done before surgery?*

B.6. *What are the three major forces that uniquely alter the patient's physiology during robotic laparoscopy?*

C. Intraoperative Management

C.1. *What is the anesthetic technique of choice for robotic-assisted laparoscopy? Why?*

C.2. *Can a laryngeal mask airway (LMA) be used?*

C.3. *What anesthetic agents or adjuvant drugs are recommended for laparoscopy? Are any anesthetic agents contraindicated?*

C.4. *Should nitrous oxide (N_2O) be used during laparoscopy? What are the pros and cons? Does N_2O cause bowel distention during laparoscopy? Does N_2O cause nausea and vomiting after laparoscopy?*

C.5. *Can laparoscopy be performed under local or regional anesthesia?*

C.6. *What monitors and devices would you apply to the patient? Why?*

C.7. *How is the patient to be positioned? What special*

precautions are required for robotic laparoscopy?

C.8. *How will you ventilate the patient? What are the respiratory and circulatory effects of the Trendelenburg position during laparoscopy?*

Respiratory

Circulatory

C.9. *What techniques are available for initial access to the peritoneal cavity? What anesthetic problems can arise during insufflation?*

C.10. *What intravenous (IV) solution and how much fluid volume do you plan to infuse?*

C.11. *Under what circumstances should laparoscopy be converted to laparotomy?*

C.12. *What is the arterial to end-tidal CO_2 gradient ($PaCO_2$–$EtCO_2$) in the normal awake patient? What is the cause of the gradient? Does the gradient change during laparoscopy? Why?*

C.13. *Is an arterial line necessary? Why? Does end-tidal CO_2 tension accurately reflect arterial CO_2 tension? Under what circumstances may the $EtCO_2$ exceed the $PaCO_2$? Why?*

C.14. *What are the possible causes of hypercarbia?*

C.15. *What factors play a role in the unusually rapid and marked elevation of CO_2 that is sometimes seen in laparoscopy?*

C.16. *How rapidly does the $PaCO_2$ rise in the apneic patient (endogenous CO_2)? How rapidly does the $PaCO_2$ rise if 5% CO_2 gas is inhaled (exogenous)? How rapidly can the CO_2 rise during laparoscopy? What factors explain the differences?*

C.17. *What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the cardiovascular system?*

C.18. *What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the respiratory system?*

C.19. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the central nervous system?

C.20. What are the neuroendocrine changes that occur during laparoscopy?

C.21. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the renal system?

C.22. What is the net effect of pneumoperitoneum, hypercarbia, and steep Trendelenburg on the bowel and gastrointestinal system?

C.23. How would you recognize a CO_2 embolism during laparoscopy? How does this differ from an air embolism? Why should N_2O be discontinued during suspected embolization? Will N_2O increase the size of CO_2 emboli?

C.24. What is the mechanism of increase in shunting resulting from embolization?

C.25. How is a gas embolism (CO_2 or air) treated?

C.26. What are the causes of pneumothorax or pneumomediastinum during laparoscopy? How would you diagnose it? How would you treat it?

C.27. How would you decide when to extubate?

D. Postoperative Management

D.1. What are some of the unique complications of laparoscopy?

Injuries from Instruments
Complications of Pneumoperitoneum
Systemic Effects of CO_2 Absorption
Trendelenburg Position
Late Complications

D.2. In the postanesthesia care unit (PACU), our patient complains of numbness and weakness of the lower extremities after 6 hours of anesthesia for robotic prostatectomy. What tests will you order? When would you remove the Foley catheter and arterial line? Under what

circumstances would you order a chest x-ray film?

D.3. *What is the incidence of postoperative nausea and vomiting?*

SECTION 7 The Reproductive System

27 Placenta Previa/Placenta Accreta Spectrum

Jill Fong

A. Medical Disease and Differential Diagnosis

A.1. *What are the leading causes of maternal mortality, and what role does anesthesia play in this mortality?*

A.2. *What is the differential diagnosis for an antepartum hemorrhage?*

A.3. *How would you diagnose the etiology of antepartum bleeding after midpregnancy?*

A.4. *What is the incidence of placenta previa, and what are the associated conditions?*

A.5. *What are the different types of placenta previa?*

A.6. *What is the usual obstetric management for placenta previa?*

A.7. *What is vasa previa? How is it diagnosed and managed?*

A.8. *What are the risk factors for the development of a placental abruption?*

A.9. *How is placental abruption diagnosed and managed?*

A.10. *What complications are associated with placental abruption?*

A.11. *Who is at risk for uterine rupture, and how is uterine rupture diagnosed?*

A.12. *What is the treatment for uterine rupture?*

A.13. *Is this patient at risk for postpartum bleeding?*

A.14. *What is the placenta accreta spectrum (PAS)?*

A.15. *How is the PAS diagnosed?*

A.16. *How is the PAS managed obstetrically?*

A.17. *What tests and/or interventions can improve neonatal outcome of a preterm birth?*

B. Preoperative Evaluation and Preparation

B.1. *How does pregnancy change respiratory function, and what impact does this have on anesthetic care?*

B.2. *What are the maternal cardiovascular changes of pregnancy?*

B.3. *What are the maternal gastrointestinal changes of pregnancy?*

B.4. *What hematologic changes occur during pregnancy?*

B.5. *What laboratory data do you need before taking this patient to the operating room?*

B.6. *What preoperative medications would you administer to this patient?*

C. Intraoperative Management

C.1. *What monitors would you use for this patient?*

C.2. *What anesthetic could be used in this patient?*

C.3. *What are the absolute and relative contraindications for neuraxial anesthesia?*

C.4. *How is postpartum hemorrhage (PPH) defined, and what are the etiologies of this bleeding?*

C.5. *After delivery of the fetus, the placenta is removed with some difficulty in one small area and generalized oozing from the placental implantation site is noted. What is the most likely cause of this patient's bleeding?*

C.6. *After delivery of the placenta in a cesarean section, what maneuvers and drugs can enhance myometrial contractility and therefore decrease blood loss?*

C.7. *When should this patient receive tranexamic acid (TXA)?*

C.8. *If this patient had ongoing bleeding intraoperatively, what guidelines help determine when red blood cell (RBC) transfusions should be given?*

C.9. *What laboratory tests should be ordered during the*

resuscitation of this patient?

C.10. If this patient had a massive blood loss, what blood replacement therapy would be indicated?

C.11. What is the role of recombinant activated factor VII (rFVIIa) in the hemorrhaging obstetric patient?

C.12. What is the role of type O Rh-negative (universal donor) uncrossmatched blood in emergency transfusions, and how does this change your future management?

C.13. What complications can occur from the transfusion of blood products?

C.14. What is the role of autologous transfusion in obstetric patients?

C.15. Significant intraoperative blood loss required the transfusion of 8 units of type-specific, crossmatched packed RBCs (pRBCs). This patient had generalized oozing in the surgical field and hematuria. What is your differential diagnosis?

C.16. What is disseminated intravascular coagulation (DIC)?

C.17. Define amniotic fluid embolism (AFE) syndrome and discuss treatment.

D. Postoperative Management

D.1. If the patient received epidural anesthesia and subsequently developed DIC, when should the epidural catheter be removed?

D.2. You have successfully treated the patient's massive hemorrhage. Her laboratory values have returned to normal. The patient, however, is still hypotensive despite appropriate intravascular volume replacement and support with vasopressors. What is your concern in this case?

28 Hypertensive Disorders of Pregnancy

Sharon Abramovitz and Jennifer Wagner

A. Medical Disease and Differential Diagnosis

A.1. What is the classification of hypertension disorders in

pregnancy as defined by the American College of Obstetricians and Gynecologists?

A.2. What is preeclampsia?

A.3. What is preeclampsia with severe features?

A.4. What is eclampsia?

A.5. What is HELLP syndrome?

A.6. What are the risk factors for developing preeclampsia?

A.7. What is the mortality associated with preeclampsia?

A.8. Discuss the pathogenesis of preeclampsia.

- Immunologic Factors
- Genetic Factors
- Endothelial Factors
- Platelet Factors
- Calcium
- Coagulation Factors
- Fatty Acid Metabolism
- Markers of Angiogenesis

A.9. Discuss the pathologic alterations of preeclampsia.

- Cardiovascular Changes
- Hemodynamic Changes
- Hematologic Changes
- Renal Changes
- Endocrine Changes
- Respiratory Changes
- Hepatic Changes
- Neurologic Changes
- Uteroplacental Perfusion

A.10. What are some of the complications associated with preeclampsia?

B. Preoperative Evaluation and Preparation

B.1. What initial laboratory studies are recommended for patients with preeclampsia?

B.2. Discuss bleeding time and platelet count evaluation during

preoperative assessment of a patient with preeclampsia requesting epidural analgesia/anesthesia for labor and delivery.

- *B.3. What types of monitoring are important for patients with preeclampsia? When is a central venous pressure (CVP) monitor indicated?*
- *B.4. Discuss the obstetric management of preeclampsia with severe features.*
- *B.5. What are the antihypertensive agents of choice for preeclampsia?*
- *B.6. What drug therapy is the treatment of choice for seizure prophylaxis?*
- *B.7. Discuss the mechanism of action of magnesium sulfate.*
- *B.8. What are the fetal effects of magnesium sulfate therapy?*
- *B.9. Discuss the treatment of magnesium sulfate toxicity.*
- *B.10. What conditions mandate immediate delivery, regardless of the gestational age?*
- *B.11. Discuss the management of eclampsia.*

C. Intraoperative Management

- *C.1. What is your choice of labor analgesia for patients with preeclampsia?*
- *C.2. What is the advantage of prehydration prior to initiation of neuraxial analgesia?*
- *C.3. What sensory level of analgesia is required for labor and delivery?*
- *C.4. Discuss the commonly used local anesthetics for labor analgesia.*
- *C.5. Is the addition of epinephrine to local anesthetics advisable in preeclamptic patients?*
- *C.6. What is the treatment for the abnormal fetal heart rate pattern seen with maternal hypotension after neuraxial analgesia is instituted?*
- *C.7. What would you do after an accidental dural puncture?*

How do you treat postdural puncture headache?
C.8. *How would you manage total spinal anesthesia?*
C.9. *Should methylergonovine be given to preeclamptic patients?*
C.10. *When and how would you give spinal anesthesia?*
C.11. *Discuss a general anesthesia technique for the patient with preeclampsia presenting for cesarean delivery.*
C.12. *What agents can you use to prevent hypertension during the induction of general anesthesia for cesarean delivery?*

D. Postoperative Management
D.1. *Discuss the postpartum management of preeclamptic patients.*
D.2. *Can nonsteroidal anti-inflammatory drugs (NSAIDs) be used to treat postpartum pain in preeclamptic patients?*

29 Breech Presentation, Fetal Distress, and Mitral Stenosis
Jill Fong and Jaime Aaronson

A. Medical Disease and Differential Diagnosis
A.1. *How are fetal lie, presentation, and position defined and determined?*
A.2. *What is the approximate frequency of the various lies and presentations at or near term?*
A.3. *What are the different types of breech presentation, and what is their incidence?*
A.4. *What is the cause of breech presentation?*
A.5. *What are the delivery problems associated with breech presentation?*
A.6. *What is the usual obstetrical management for patients with breech presentation?*
A.7. *What is the incidence of heart disease in pregnancy and the mortality rate associated with maternal cardiac disease?*
A.8. *How is peripartum cardiomyopathy defined?*
A.9. *What classifications help predict an individual pregnant woman's cardiac risk?*
A.10. *What are the cardiovascular changes of pregnancy?*

A.11. *What changes normally occur in heart sounds during pregnancy?*
A.12. *What are the normal electrocardiographic and echocardiographic changes seen during pregnancy?*
A.13. *What causes rheumatic heart disease?*
A.14. *What are the physiologic consequences of mitral stenosis?*
A.15. *What are the auscultatory findings associated with mitral stenosis?*
A.16. *What may be seen on the electrocardiogram (ECG) in patients with mitral stenosis?*
A.17. *What are the echocardiographic findings associated with mitral stenosis?*
A.18. *What is the effect of the physiologic changes of pregnancy on patients with mitral stenosis?*
A.19. *If mitral stenosis is first recognized during pregnancy and symptoms develop, how would you treat the patient?*
A.20. *What are the determinants of fetal oxygenation?*
A.21. *What are the determinants of uterine blood flow?*

B. Preoperative Evaluation and Preparation

B.1. *How is fetal well-being assessed during labor?*
B.2. *How are FHR and maternal contractions monitored?*
B.3. *What is the normal FHR with beat-to-beat variability?*
B.4. *What are FHR decelerations?*
B.5. *How accurate is FHR monitoring in predicting fetal well-being?*
B.6. *In a fetus with minimal FHR variability, what other modalities can be used to assess fetal well-being?*
B.7. *What is the significance of meconium-stained amniotic fluid?*
B.8. *What is meconium aspiration syndrome?*
B.9. *What are the usual noninvasive tests used to evaluate the pregnant cardiac patient?*
B.10. *What preoperative medications, if any, would you give this*

patient?

C. Intraoperative Management

- *C.1. What monitors would you use in this functional New York Heart Association (NYHA) class II patient during her cesarean section?*
- *C.2. When would you use invasive monitoring in a pregnant patient with cardiac disease?*
- *C.3. What are the hemodynamic goals of intraoperative management of the pregnant patient with mitral stenosis?*
- *C.4. What anesthetic technique would you use for this emergency cesarean section?*
- *C.5. How would you manage local anesthetic systemic toxicity (LAST) in this patient?*
- *C.6. If cardiac arrest were to occur prior to delivery, how would you proceed?*
- *C.7. What technique could you use for general anesthesia in this patient?*
- *C.8. If you are unexpectedly unable to intubate this patient, how would you manage the airway?*
- *C.9. Would this patient benefit from the use of β-blockers?*
- *C.10. What is the effect of the inhalation agents on uterine contractility?*
- *C.11. What is the Apgar scoring system?*
- *C.12. What is the significance of Apgar scores?*
- *C.13. At birth, what should be done to minimize an infant's risk of meconium aspiration syndrome?*
- *C.14. If the Apgar score of the newborn is 3 at 1 minute, how would you treat the newborn?*
- *C.15. Blood gases are sent immediately after delivery. What are the normal values for umbilical vein and artery blood gases?*

D. Postoperative Management

- *D.1. Immediately after the baby is delivered, the mother's oxygen*

saturation decreases. What is the differential diagnosis?

D.2. *Additional bleeding occurs in the postanesthesia care unit, and the obstetrician diagnoses retained placenta. What, if any, antibiotics are indicated to prevent endometritis after manual extraction of retained placenta?*

30 Appendectomy for a Pregnant Patient 648

Robert S. White and Farida Gadalla

A. Medical Disease and Differential Diagnosis

A.1. *What is the differential diagnosis for acute abdomen in the pregnant patient?*

Medical Conditions

Obstetric Conditions

Gynecologic Conditions

Surgical Conditions

A.2. *How would you make the clinical diagnosis of acute appendicitis?*

A.3. *What is the incidence of surgery during pregnancy? What is the incidence of appendicitis during pregnancy?*

A.4. *What is the incidence of gangrenous appendix/peritonitis during pregnancy, and is this incidence higher in pregnant than in nonpregnant women?*

A.5. *What are the main concerns associated with nonobstetric surgery in the pregnant patient?*

A.6. *What are the factors influencing teratogenicity from anesthetic agents in humans?*

A.7. *Are there any specific concerns regarding neurotoxicity and cognitive development in the developing fetus?*

A.8. *What factors influence fetal oxygenation, and how would you prevent intrauterine fetal asphyxia?*

A.9. *What is the incidence of trauma during pregnancy, and what are the risks to the mother and the fetus secondary to trauma?*

A.10. *What are other common surgeries performed during*

pregnancy?

B. Preoperative Evaluation and Preparation

B.1. Preoperatively, what would you discuss with this patient? Are any additional medical consultations warranted?

B.2. Is there a difference in the goal of anesthesia for delivery and for nonobstetric surgery in a pregnant patient?

B.3. How would you premedicate this patient?

C. Intraoperative Management

C.1. What factors would alter your anesthetic technique from that used for a nonpregnant patient?

Cardiovascular System
Respiratory System
Gastrointestinal System
Central Nervous System
Airway, Skin, and Mucous Membranes

C.2. If you choose epidural anesthesia, describe your technique and dosage.

C.3. If the patient needs supplemental analgesia, what would be your choice?

C.4. What vasopressor would you choose to improve uteroplacental perfusion?

C.5. When this patient arrived in the operating room, she desired a general anesthetic. Describe your technique.

C.6. Does any controversy exist surrounding the use of nitrous oxide?

C.7. Does any controversy exist surrounding operating room personnel, anesthetic exposure, and pregnancy outcomes?

C.8. What is the impact of nonobstetric surgery on maternal mortality, birth defects, and fetal loss? What factors influence it?

C.9. Should intraoperative fetal heart rate (FHR) monitoring be used? What would you expect to see on the electronic fetal monitor during anesthesia?

C.10. *How would your anesthetic management differ if the patient were having upper extremity surgery?*

C.11. *The surgeon schedules the procedure to be performed laparoscopically. Does this pose any additional problems?*

D. Postoperative Management

D.1. *When would you extubate this patient?*

D.2. *Postoperatively, what monitors would you use?*

D.3. *What other postoperative precautions would you take? What is the incidence of preterm delivery following nonobstetric surgery during pregnancy?*

D.4. *The next day, the patient went into premature labor and now needs a cesarean section for prematurity and breech presentation. She requires another general anesthetic. In what way would your technique differ from your previous anesthetic technique?*

SECTION 8 The Hematologic System

31 Hemophilia and Disorders of Coagulation

Elizabeth M. Staley

A. Medical Disease and Differential Diagnosis

A.1. *Describe the various laboratory tests that evaluate the coagulation cascade and the specific components measured by each.*

A.2. *What is the difference between platelet adhesion, activation, and aggregation at sites of vascular injury?*

A.3. *Describe the physiologic events that occur following endothelial interruption in the blood vessel.*

A.4. *What factors prevent the extension of a clot beyond the site of injury?*

A.5. *Describe the factors involved in the extrinsic, intrinsic, and common coagulation cascade.*

A.6. *Describe the typical presentation history and*

pathophysiology associated with von Willebrand disease (vWD).

A.7. Explain the pathophysiology, frequency, and treatment of significant rare disorders of coagulation (factor VII [FVII], factor XII [FXII], and fibrinogen).

A.8. Differentiate between hemophilia A, B, and C.

A.9. What are the differences in factor replacement therapy between patients with hemophilia A and hemophilia B?

A.10. What is acquired hemophilia?

A.11. Which plasma protein is important in maintaining normal levels of factor VIII (FVIII)?

A.12. How are patients with severe hemophilia managed in the outpatient setting?

A.13. Describe the levels of FVIII necessary to maintain hemostasis in patients with spontaneous or surgical bleeding.

B. Preoperative Evaluation and Preparation

B.1. What steps would you take to normalize this patient's coagulation status before surgery?

B.2. What is meant by 1 unit of FVIII clotting activity, and how much does 1 unit of FVIII clotting activity per kilogram of body weight increase FVIII concentrations?

Approach 1

Approach 2

Plasma Volume Calculation

B.3. Would you administer FVIII using a bolus or infusion technique?

B.4. Can hemophiliac patients fail to mount an appropriate coagulation response following FVIII infusion?

B.5. If a patient with hemophilia does not respond to a bolus injection of FVIII, can an infusion technique be effective?

B.6. How much FVIII activity is present in plasma? What are the risks associated with plasma administration?

B.7. *What are the indications for the administration of plasma?*

B.8. *What is cryoprecipitate, and how is it prepared? How much FVIII activity is present in cryoprecipitate? When is cryoprecipitate indicated?*

B.9. *Describe the advantages and disadvantages of the products that are available for repletion of FVIII activity.*

B.10. *What is the role of desmopressin (D-amino D-arginine vasopressin [DDAVP]) for hemostatic management in this patient?*

B.11. *What is the role of antifibrinolytic therapy in the perioperative period for the patient with hemophilia? What are examples of antifibrinolytics used in the treatment of hemophilia?*

B.12. *What are the options for operative treatment of patients with acquired hemophilia? Describe the mechanism of action and dosing considerations for each of these therapies.*

C. Intraoperative Management

C.1. *Is it safe to administer an intramuscular injection to this patient before surgery?*

C.2. *Would an axillary block be appropriate for this patient?*

C.3. *If general anesthesia is used, would it be safe to intubate the patient's trachea?*

C.4. *Would you use any special precautions for this patient who is positive for HIV?*

C.5. *What special considerations should be taken in choosing anesthetic drugs for this patient?*

C.6. *During an operative procedure, if the surgeon indicates that significant blood loss is occurring, would you transfuse this patient with packed red blood cells (RBCs) or whole blood?*

C.7. *During the transfusion of the first unit of whole blood, the patient's temperature rose from 36.8°C to 37.9°C (98.2°F to 100.2°F). What immediate steps should be taken by the anesthesiologist at this time?*

C.8. *Does giving blood intraoperatively increase the potential for the development of FVIII inhibitors?*
C.9. *Can FVIII be safely administered to patients who have developed circulating inhibitors?*
C.10. *The surgeon has requested the use of a tourniquet to minimize surgical bleeding. What are the physiologic and hemodynamic responses to tourniquet use?*
C.11. *Is it appropriate to suction the endotracheal tube and oropharynx of this patient before extubation?*
D. Postoperative Management
D.1. *What special consideration should be given to postoperative pain management for this patient?*
D.2. *What steps should be taken to enhance the coagulation status of this patient in the postoperative period while at home?*
D.3. *Can this patient be treated with FVIII supplements using home infusion?*
Acknowledgment
32 Sickle Cell Disease
Chris R. Edmonds and Vinod Malhotra
A. Medical Disease and Differential Diagnosis
A.1. *What was the most likely underlying medical condition in this patient? How would you confirm the diagnosis of sickle cell anemia (SCA)?*
A.2. *What is sickle cell disease (SCD)?*
A.3. *What is sickle cell trait (SCT)?*
A.4. *What are some of the other common hemoglobinopathies and what are their clinical features?*
A.5. *What are the clinical features of SCD?*
A.6. *Describe the different types of sickle cell crises.*
A.7. *Discuss the pathophysiologic effects of SCD.*
A.8. *What is acute chest syndrome?*
B. Preoperative Evaluation and Preparation

B.1. What preoperative evaluation and testing would you perform on this patient prior to anesthesia? Would you ask for a hematology consult, and what question(s) would you ask?

B.2. What preoperative instructions would you give this patient prior to being admitted to the hospital? How would you prepare this patient for general anesthesia and regional anesthesia?

B.3. Discuss the indications for perioperative exchange transfusion in this patient.

B.4. What are the indications for blood transfusion in SCD?

Acute conditions

Chronic conditions

C. Intraoperative Management

C.1. Discuss the anesthetic management for this patient. Discuss both regional and general anesthesia considerations.

C.2. Discuss how the comorbidities associated with SCD can affect your anesthetic management.

C.3. What precautions should one take to prevent sickling in this patient?

C.4. Discuss what issues or concerns should be brought up by the team during the debrief at the conclusion of the case. What would you sign-out to the postanesthesia care unit (PACU) staff?

D. Postoperative Management

D.1. Discuss the postoperative management of this patient. What opioid sparing techniques can you use and discuss a multimodal analgesic plan?

D.2. What complications might occur in this patient in the immediate postoperative period?

D.3. What is the treatment of sickle cell crisis?

D.4. What is the role of hyperbaric oxygen therapy in treatment of sickle cell crisis?

SECTION 9 Eye, Ear, Nose, and Throat

33 Airway Trauma

Richard P. Dutton and LaRita Yvette Fouchè-Weber

A. Medical Disease and Differential Diagnosis

A.1. What variables mitigate injury from motorcycle collisions?

A.2. What other significant trauma may be present?

A.3. How is the initial assessment of a trauma patient organized?

A.4. How would you evaluate airway and breathing?

A.5. How would you evaluate the circulation?

A.6. How would you evaluate mental status and neurologic condition?

A.7. What diagnostic tests are indicated for this patient based on the mechanism of injury?

A.8. What are the zones of the neck, and what is their clinical significance?

A.9. What immediate treatment is necessary before diagnostic studies?

A.10. When and where should the impaling object be removed?

B. Preoperative Evaluation and Preparation

B.1. What laboratory tests would you want?

B.2. What x-ray studies are most important to the anesthesiologist?

B.3. Is an electrocardiogram (ECG) necessary?

B.4. Should this patient be intubated before going for computed tomography (CT) scanning?

B.5. When and where should this patient's airway be managed?

B.6. Are any prophylactic medications indicated?

C. Intraoperative Management

C.1. What monitors would you use? Is invasive monitoring necessary before definitive airway control?

C.2. What is the surgical approach to a zone I neck injury?

C.3. Is the patient likely to require tube thoracostomy? Should

this be placed before managing the airway?
C.4. *What are the options for managing this patient's airway?*
C.5. *What are the risks of rapid sequence induction in this patient?*
C.6. *What anesthetic agents would you use for a rapid sequence induction?*
C.7. *How can you minimize the risk of exacerbating cervical spine trauma?*
C.8. *How can you minimize the risks of aspiration?*
C.9. *How would you anesthetize the airway for an awake intubation?*
C.10. *What are the risks of awake fiberoptic intubation?*
C.11. *If the patient cannot be ventilated, what options are available?*
C.12. *Would a laryngeal mask airway (LMA) or other pharyngeal airway be of assistance?*
C.13. *What surgical airway options are available in this case?*
C.14. *What maintenance anesthetics are indicated or contraindicated in this patient?*
C.15. *What complications will the surgical plan introduce?*

D. Postoperative Management
D.1. *What are the criteria for extubation?*
D.2. *What techniques may be used during extubation?*
D.3. *How does alcohol abuse affect postoperative management?*
D.4. *What pain medication should be used?*

34 Open-Eye Injury and Cataract Surgery
Alaeldin A. Darwich

A. Medical Disease and Differential Diagnosis
A.1. *Why is this patient a particular challenge to the anesthesiologist?*
A.2. *What are the determinants of intraocular pressure (IOP) under normal circumstances? What is the normal range? What was the expected IOP in this patient's injured eye?*

A.3. *How is aqueous humor formed and eliminated?*

A.4. *How is IOP affected by arterial P_{CO_2}, systemic blood pressure, coughing and vomiting, deep inspiration, and hypoxemia?*

A.5. *What is the role of the central nervous system (CNS) on IOP?*

A.6. *What is glaucoma?*

A.7. *Is atropine contraindicated in patients with glaucoma?*

A.8. *How do carbonic anhydrase inhibitors work to decrease IOP? By what mechanism may osmotic agents decrease IOP?*

A.9. *Are carbonic anhydrase inhibitors or osmotic diuretics indicated in open-globe injuries?*

A.10. *Are topically applied ophthalmic medications absorbed systemically? How can this absorption be reduced? Which eyedrops may have effects that are of concern to the anesthesiologist?*

- Atropine
- Scopolamine
- Cyclopentolate (Cyclogyl)
- Tropicamide (Mydriacyl)
- Phenylephrine Hydrochloride (Neo-Synephrine)
- Epinephrine
- Timolol Maleate (Timoptic)
- Betaxolol Hydrochloride (Betoptic)
- Acetylcholine
- Echothiophate Iodide (Phospholine Iodide)
- Cocaine

B. Preoperative Evaluation and Preparation

B.1. *Is an open-globe injury always a surgical emergency?*

B.2. *What preoperative evaluation would you require?*

B.3. *The patient ate shortly before the accident. Would you attempt to pass a nasogastric tube or to administer emetics*

to empty the stomach?

B.4. Could this case be done with topical anesthesia or a retrobulbar block?

B.5. How would you premedicate this patient?

C. Intraoperative Management

C.1. What are some factors that may increase the risk of vitreous herniation during induction and maintenance of anesthesia?

C.2. Will you intubate this patient? Would you consider a laryngeal mask airway? How does intubation affect IOP? How can this effect be minimized?

C.3. Would you consider an awake intubation?

C.4. Is succinylcholine contraindicated in open-globe injuries? How does succinylcholine affect IOP?

C.5. Does pretreatment with nondepolarizing muscle relaxants prevent the succinylcholine-induced elevation in IOP?

C.6. How do nondepolarizing muscle relaxants affect IOP?

C.7. How will you perform a rapid sequence induction and intubation without using succinylcholine?

C.8. What are the effects of ketamine on the eye?

C.9. Would you consider the use of etomidate as an induction agent? What about propofol?

C.10. How do inhalation agents affect IOP and by what mechanism?

C.11. During the procedure, the patient's pulse suddenly dropped to 40 beats per minute. What do you think was happening? What is the oculocardiac reflex (OCR)?

C.12. What are the afferent and efferent pathways of the OCR?

C.13. What factors contribute to the incidence of the OCR?

C.14. How do you diagnose and treat the OCR?

C.15. Is atropine useful for the OCR?

C.16. Can a retrobulbar block prevent the OCR? Is it appropriate in this patient?

D. Postoperative Management

D.1. *Would you reverse the neuromuscular blockade in this patient?*
D.2. *Do reversal doses of atropine affect IOP?*
D.3. *What would you do before extubating this patient?*
D.4. *When would you extubate this patient?*
D.5. *The patient awakened in the recovery room and complained of pain and tearing in the opposite eye. The conjunctiva was inflamed. What was the likely cause?*
D.6. *Will taping the eyes shut or applying ointment prevent corneal abrasions? Are there any contributing factors?*
D.7. *What should you do when you suspect your patient might have a corneal abrasion?*
D.7. *A month after the surgical repair, the patient complained of impaired vision in the operative eye. He was examined and found to have a detached retina. As part of the surgical treatment, the ophthalmologist injected a gas bubble into the patient's posterior chamber. Why is this important to an anesthesiologist?*

E. Anesthesia for Cataract Surgery
E.1. *What is a cataract?*
E.2. *What are the causes and risk factors of cataract formation?*
E.3. *How would you conduct the preoperative medical evaluation for a patient having cataract surgery?*
E.4. *What is the cardiac risk for this patient? If this patient is on anticoagulation and/or antiplatelet medications, should he stop or continue these medications?*
E.5. *What are the anesthetic options for cataract surgery?*
E.6. *What is the postoperative course after cataract surgery?*

35 Laser Treatment for Laryngeal Lesions
Stephanie Marie Vecino and Hugh C. Hemmings Jr.

A. Medical Disease and Differential Diagnosis
A.1. *What is the cause of RRP?*
A.2. *What is the usual presentation of RRP?*

A.3. *How do you diagnose RRP?*
A.4. *What are the available treatment options for RRP?*
A.5. *What are common adverse effects of α-interferon therapy?*
A.6. *What is the differential diagnosis of hoarseness in this child?*

B. Preoperative Evaluation and Preparation

B.1. *What are the key points of the preanesthetic history and physical examination in this patient?*
B.2. *What preoperative laboratory tests are necessary?*
B.3. *How should this child be premedicated before coming to the operating room?*
B.4. *What are the special anesthetic considerations prior to inducing anesthesia in this patient?*

C. Intraoperative Management

C.1. *What is a laser, and how does it work?*
C.2. *What are the characteristics of laser radiation?*
C.3. *Discuss some advantages associated with the use of lasers for laryngeal surgery.*
C.4. *What are some disadvantages of lasers compared with microdebriders?*
C.5. *How would you protect the external surface of a conventional endotracheal tube (ETT) for use during laser microlaryngoscopy?*
C.6. *What special ETTs are available for laser surgery?*
C.7. *How would you manage an airway fire?*
C.8. *What is the Venturi effect?*
C.9. *What is Venturi jet ventilation?*
C.10. *How would you institute and maintain manual jet ventilation?*
C.11. *How is anesthesia maintained during jet ventilation?*
C.12. *What are the complications of jet ventilation?*
C.13. *Are there contraindications for the use of jet ventilation?*
C.14. *Discuss airway management options during laryngeal*

papilloma resection.
C.15. How would you plan to monitor this patient?
C.16. How would you induce anesthesia for an intermittent apnea technique?
D. Postoperative Management
D.1. What are the common postoperative complications?

SECTION 10 Pediatrics

36 Tracheoesophageal Fistula
Jacques H. Scharoun
A. Pathophysiology and Differential Diagnosis
A.1. What is the diagnosis? What are the clinical features of this disease?
A.2. What is the pathophysiology of this disease?
A.3. Describe the normal development of the trachea and esophagus.
A.4. How are tracheoesophageal fistula (TEF) and esophageal atresia (EA) inherited?
A.5. How are the different types of TEF/EA classified?
A.6. What other problems may this child have, and when should these be investigated?
A.7. What should the parents be told regarding perioperative risk? Risk of recurrence?
B. Preoperative Evaluation and Preparation
B.1. What laboratory workup should be obtained before surgery?
B.2. Describe management in the NICU before surgery.
B.3. How is severe lung disease managed before repair?
B.4. Should this patient be intubated preoperatively for airway protection?
C. Intraoperative Management
C.1. What invasive lines and monitoring are appropriate before induction? After induction?

C.2. *Discuss fluid and temperature management for this baby.*

C.3. *What are the options regarding induction and intubation?*

C.4. *What is the role of rigid and fiberoptic bronchoscopy in this patient prior to incision?*

C.5. *Describe the steps of an open repair of EA/TEF.*

C.6. *What are common intraoperative problems, and how can they be managed?*

C.7. *If the surgeon decides to proceed thoracoscopically, how will you perform your anesthetic? Is one-lung ventilation required? What are some complications unique to thoracoscopy in the newborn?*

D. Postoperative Management

D.1. *When should the baby be extubated?*

D.2. *What options are available for postoperative analgesia?*

D.3. *What are early and late complications of TEF repair?*

37 Congenital Diaphragmatic Hernia

Dana L. Gurvitch and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis

A.1. *What differential diagnoses are compatible with these signs and symptoms?*

A.2. *Describe the incidence and classification of congenital diaphragmatic hernia (CDH).*

A.3. *What are the causes of hypoxemia in patients with CDH?*

A.4. *How do you assess the severity of pulmonary hypoplasia?*

A.5. *How do you make a diagnosis of right-to-left shunting through the patent ductus arteriosus?*

A.6. *What other congenital anomalies are usually associated with CDH?*

B. Preoperative Evaluation and Preparation

B.1. *How would you interpret the following arterial blood gas analyses: pH, 7.20; $PaCO_2$, 55 mmHg; PaO_2, 35 mmHg; and CO_2 content, 19 mEq per L? How would you correct them?*

B.2. *What immediate treatment should be given to improve the newborn's respiratory status preoperatively?*

B.3. *Should CDH be repaired urgently once the diagnosis is made and confirmed?*

B.4. *What are the effects of nitric oxide (NO) on pulmonary and systemic circulation?*

B.5. *What is the current role of extracorporeal membrane oxygenation (ECMO) in the management of CDH?*

C. Intraoperative Management

C.1. *What monitors would you use for this neonate during surgery?*

- Respiratory
- Cardiovascular
- Thermoregulatory

C.2. *How would you induce and maintain anesthesia?*

C.3. *Would you use nitrous oxide for anesthesia? Why?*

C.4. *How would you ventilate the patient?*

C.5. *Is the infant with CDH more at risk from hypothermia?*

C.6. *The surgeon returned the intrathoracic stomach and intestine to the peritoneal cavity and the ipsilateral lung was found to be hypoplastic and collapsed. The resident anesthesiologist tried to expand the collapsed lung manually with positive airway pressure. Five minutes after the abdomen was closed, the blood pressure suddenly dropped from 70/40 to 30/20 mmHg, the heart rate from 150 to 80 beats per minute, and the pulse oximeter from 95% down to 60% saturation. What would you immediately do?*

C.7. *Discuss fluid therapy in this patient.*

C.8. *At the conclusion of surgery, would you extubate the patient in the operating room?*

D. Postoperative Management

D.1. *What is the mortality rate in patients with CDH? What postoperative problems would you expect in this patient?*

38 Tetralogy of Fallot

David Whiting and James A. DiNardo

A. Medical Disease and Differential Diagnosis

A.1. What is TOF?

Tetralogy of Fallot with Pulmonary Stenosis

Tetralogy of Fallot with Pulmonary Atresia

Tetralogy of Fallot with Absent Pulmonary Valve

A.2. What is the pathophysiology of TOF/PS?

A.3. What is shunting, and how is Q_P:Q_S calculated?

A.4. What is the pathophysiology of TOF with pulmonary atresia?

A.5. How is SaO_2 determined in single ventricle physiology?

A.6. What is a "pink Tet"?

A.7. What are hypercyanotic spells? How are they treated?

A.8. What palliative surgical procedures are available for treating patients with TOF/PS?

A.9. What palliative catheter-based procedures are available for patients with TOF?

A.10. What definitive surgical procedures are available for treating patients with TOF/PS?

A.11. What palliative and definitive surgical procedures are available for patients with TOF with pulmonary atresia?

A.12. What are the long-term outcomes of patients with TOF?

B. Preoperative Evaluation and Preparation

B.1. What preoperative history and physical examination information do you want?

B.2. Which other abnormalities need to be considered in this patient?

B.3. What premedication will you give to a child with congenital heart disease?

C. Intraoperative Management

C.1. How will you induce anesthesia in this patient if intravenous (IV) access cannot be obtained?

C.2. *Why would end-tidal carbon dioxide ($EtCO_2$) monitoring be of particular use in a patient with TOF/PS?*

C.3. *What is near-infrared spectroscopy (NIRS) and what does it measure?*

C.4. *What are the important management issues during creation of a palliative shunt?*

C.5. *What is the effect of inhalation anesthetics on airway reflexes, myocardial contractility, systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) in children?*

C.6. *What are the pre-cardiopulmonary bypass (pre-CPB) anesthetic goals for a patient undergoing definitive surgical correction of TOF/PS?*

C.7. *What interventions will reliably reduce PVR?*

C.8. *How does heparin administration and activated coagulation time (ACT) monitoring for CPB differ in children as compared with adults?*

C.9. *How is heparin reversed?*

C.10. *What is the incidence of protamine reactions in children?*

C.11. *What is the role of transesophageal echocardiography (TEE) in this patient?*

C.12. *What effect would a residual ventricular septal defect (VSD) have in this patient following separation from CPB?*

D. Postoperative Management

D.1. *How should postoperative ventilation be managed in this patient following placement of a transannular patch for TOF/PS?*

D.2. *Following complete repair of TOF/PS in an infant, what SaO_2 is acceptable?*

D.3. *Following placement of a modified Blalock-Taussig shunt (MBTS) for TOF/PS in an infant, what SaO_2 is acceptable?*

D.4. *What is junctional ectopic tachycardia (JET)?*

39 Transposition of the Great Arteries

David Whiting and James A. DiNardo

A. Medical Disease and Differential Diagnosis

A.1. What defines the cardiac situs?

A.2. What is transposition of the great arteries (D-TGA)?

A.3. What additional cardiac lesions are associated with D-TGA?

A.4. What is the natural history of D-TGA?

A.5. What is the pathophysiology of D-TGA?

A.6. What determines the oxygen saturation in patients with D-TGA?

A.7. Why did this infant have reverse differential cyanosis?

A.8. What are the preoperative issues pertaining to the coronary arteries in D-TGA?

A.9. What are the clinical subsets of D-TGA?

A.10. What is the differential diagnosis of D-TGA and how is the diagnosis made?

A.11. What preoperative interventions can help stabilize a patient with D-TGA?

Intact Ventricular Septum

Ventricular Septal Defect

Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction

Pulmonary Artery Hypertension

A.12. What are the surgical options for repair? Why is one chosen over the others?

Arterial Anatomic Repair: Arterial Switch (Jatene) Operation

Intra-atrial Physiologic Repairs: Mustard and Senning Procedures

Rastelli, LeCompte, and Nikaidoh Procedures

B. Preoperative Evaluation and Preparation

B.1. What information is important to prepare for this case?

- *B.2. What are the anesthetic goals before cardiopulmonary bypass (CPB)?*
- *B.3. What is the plan for glucose management in this patient?*

C. Intraoperative Management
- *C.1. How would you monitor this infant?*
- *C.2. What would be the best method of induction for this patient?*
- *C.3. Is CPB in infants and children different from adults?*
- *C.4. What is modified ultrafiltration (MUF)?*
- *C.5. Briefly describe the surgical techniques of the Mustard/Senning, ASO, and Rastelli procedures.*
  - Intra-atrial Physiologic Repairs: Mustard and Senning Procedures
  - Arterial Anatomic Repair: Arterial Switch (Jatene) Operation
  - Rastelli Procedure
- *C.6. What is hypothermia, and how is it classified? What is low-flow cardiopulmonary bypass (LFCPB)? What is deep hypothermic circulatory arrest (DHCA)?*
- *C.7. Why is hypothermia beneficial to the brain during LFCPB and DHCA?*
- *C.8. Explain the difference between α-stat and pH-stat blood gas management.*
- *C.9. What are the immediate post-CPB issues following ASO?*

D. Postoperative Management
- *D.1. How is myocardial ischemia addressed in the intensive care unit (ICU) following the ASO?*
- *D.2. What immediate postoperative problems would be anticipated following the Rastelli procedure?*
- *D.3. What intermediate and long-term surgical problems are seen after ASO?*
- *D.4. What are the long-term outcomes after ASO?*
- *D.5. What are the long-term outcomes after Rastelli repair for patients with D-TGA with left ventricular outflow tract*

(LVOT) obstruction?
D.6. What is long-term neurologic outcome like after ASO?

40 Pyloric Stenosis
Aarti Sharma and Vinod Malhotra

A. Medical Disease and Differential Diagnosis
A.1. What is the diagnosis in this patient?
A.2. What is the differential diagnosis of pyloric stenosis?
A.3. What are the metabolic problems in this newborn secondary to his disease?
A.4. What are the adverse effects of metabolic alkalosis?
A.5. How would you treat this infant?
Supportive Therapy
Fluids
Electrolytes
Prevention of Aspiration
Diagnostic Tests
Surgery
A.6. How would you determine fluid replacement in a newborn, and what fluids would you use?
Maintenance Fluids
Electrolytes
Correction of Deficits
Replacement of Losses
A.7. How would you correct the metabolic alkalosis in this patient?
A.8. What causes a cardiac murmur?
B. Preoperative Evaluation and Preparation
B.1. How would you evaluate this patient preoperatively?
History
Physical Examination
Laboratory Findings
B.2. How would you evaluate a heart murmur?
B.3. How would you differentiate between functional versus

organic murmur?
B.4. What are the types of VSD? What type of shunt do they cause?
B.5. What are the risks of surgery and anesthesia in a patient with VSD?
B.6. How would you prepare this patient rapidly for emergency surgery? Is surgical intervention an acute emergency in this case?
B.7. How would you prepare this patient for anesthesia?
C. Intraoperative Management
C.1. What induction–intubation sequence would you use?
C.2. What are the anatomic characteristics of the airway in the newborn and how do they differ from those in the adult?
C.3. How do you determine the size of an endotracheal tube in a pediatric patient?
C.4. What anesthesia system would you use and why?
C.5. What are the advantages and the disadvantages of commonly employed nonrebreathing systems?
C.6. How would you monitor this patient intraoperatively?
C.7. How does the pulse oximeter function?
C.8. What factors affect the measurement of oxygen saturation by the pulse oximeter?
D. Postoperative Management
D.1. What are the complications that can occur in the postanesthesia recovery period?
D.2. How would you treat postextubation "croup" in this infant?

41 Inflammatory Airway Disease in Childhood: Laryngotracheobronchitis
Miles Dinner and Anthony Longhini

A. Medical Disease and Differential Diagnosis
A.1. What portion of the airway is affected in the croup syndrome and why?
A.2. What is stridor?

A.3. *How does stridor correlate with anatomic location?*
A.4. *Define croup. What is the clinical presentation of laryngotracheitis?*
A.5. *What is the differential diagnosis of acute upper airway obstruction in children?*
A.6. *What is bacterial tracheitis?*
A.7. *What congenital problems can mimic features of croup?*
A.8. *How is the severity of croup assessed?*
A.9. *What is the medical management of croup? Does this have implications for the anesthesiologist?*
A.10. *What is epiglottitis? What are its common causes? What is the incidence?*
A.11. *What are the clinical manifestations of epiglottitis?*
A.12. *How is the diagnosis of epiglottitis made?*
A.13. *What is postextubation croup? How is it managed?*
A.14. *What are the nonacute causes of partial airway obstruction in children?*

Extrinsic Pathologies
Intrinsic Pathologies

B. Preoperative Evaluation and Preparation
B.1. *Is intubation always required in children with epiglottitis?*
B.2. *Why is general anesthesia administered to a child with epiglottitis?*
B.3. *How would you prepare the patient for anesthesia?*

C. Intraoperative Management
C.1. *How is the airway of the child with epiglottitis best secured?*
C.2. *How would you induce anesthesia?*
C.3. *Should a child with epiglottitis undergo a rapid sequence induction?*
C.4. *Is awake intubation a practical alternative to secure the patient's airway?*
C.5. *What would you do if the airway cannot be secured with intubation?*

C.6. *Should this patient have a nasotracheal or orotracheal tube placed?*

C.7. *Shortly after intubation, frothy secretions were obtained on suctioning the endotracheal tube. What is the reason for this? How can this be treated?*

D. Postoperative Management

D.1. *How long should this patient remain intubated? What criteria determine extubation time?*

D.2. *How would you make this patient comfortable during the course of intubation?*

D.3. *What outcome can one expect for the child with acute epiglottitis?*

42 Cleft Palate

Aarti Sharma

A. Medical Disease and Differential Diagnosis

A.1. *Describe the anatomic concept of a cleft palate and a cleft lip.*

A.2. *What is the cause of a cleft lip or a cleft palate?*

A.3. *What is the incidence of a cleft lip and a cleft palate?*

A.4. *Discuss the pathophysiology of a cleft lip and palate in the neonate and the older child (e.g., age >5 years).*

A.5. *What other conditions are associated with a cleft lip and a cleft palate?*

A.6. *What is Pierre Robin syndrome?*

A.7. *What is Treacher Collins syndrome?*

A.8. *What kind of specialized team care would these patients need?*

A.9. *Discuss indications and timing of closure of cleft lip and palate.*

A.10. *What is velopharyngeal incompetence, and how can it be diagnosed?*

A.11. *What is the relation of tonsillectomy and adenoidectomy to velopharyngeal incompetence?*

B. Preoperative Evaluation and Preparation
B.1. What information do you need before closure of a cleft lip and palate?
B.2. What preoperative orders are needed?
C. Intraoperative Management
C.1. What monitors will you need for cheiloplasty and palatoplasty?
C.2. Discuss the induction and the anesthetic management for cleft lip and palate.
C.3. What positioning is recommended for cleft palate repair surgery?
C.4. What are the reported complications of this type of surgery and anesthesia?
C.5. Briefly describe the surgical techniques used to repair cleft defects.
C.6. How does a pharyngeal flap affect anesthetic management or any subsequent anesthetic administered to this patient?
C.7. What is an Abbe flap? What are its anesthetic implications?
C.8. What is the crucial problem of anesthesia for cleft palate? What are the unique considerations of this surgical repair?
C.9. What is laryngospasm? How would you make a diagnosis of laryngospasm?
C.10. How would you manage the patient with laryngospasm?
D. Postoperative Management
D.1. What complications of cleft lip and cleft palate surgery may be seen in the recovery room?
D.2. How do you protect the airway postoperatively?
D.3. How would you control postoperative pain in patients following a cleft lip and cleft palate repair?

43 Congenital Heart Disease with a Cervical Mass in Infancy
Miles Dinner and Elizabeth Q. Starker

A. Medical Disease and Differential Diagnosis
A.1. What is 22q11 deletion syndrome?

A.2. *What are the associated cardiovascular defects in 22q11 deletion syndrome?*
A.3. *What are the metabolic and endocrine abnormalities in patients with 22q11 deletion syndrome and the attendant manifestations?*
A.4. *What are the immunologic findings in 22q11 deletion syndrome?*
A.5. *What is the differential diagnosis of cervical masses in infancy?*
A.6. *What is a cystic hygroma? What are the complications? What is the treatment?*
A.7. *What is the IAA anomaly?*
A.8. *What is the pathophysiology of the IAA syndrome?*
A.9. *How is ductal patency maintained?*
A.10. *What are the side effects of prostaglandin infusion?*
A.11. *What is the hyperoxia test?*

B. Preoperative Evaluation and Preparation

B.1. *What preoperative studies should be obtained to evaluate the neck mass?*
B.2. *How would you categorize the difficult airway in children?*
B.3. *What features of the difficult airway can be noted on physical examination?*
B.4. *How would you preoperatively optimize the ability to secure the airway in the operating room?*
B.5. *What laboratory studies are necessary before surgery?*
B.6. *What are the causes of heart failure (HF) in the infant? How would you assess this infant in your preoperative evaluation for signs of HF?*
B.7. *How would you optimize the preoperative treatment of HF?*
B.8. *How would you premedicate this infant?*
B.9. *When is premedication useful in infants and children?*
B.10. *Before the planned surgery, the infant is scheduled for a magnetic resonance imaging (MRI) scan. You are asked to*

ensure that the baby remains immobile for 20 minutes to perform the scan adequately. How would you accomplish this?

C. Intraoperative Management

C.1. What anesthesia equipment, circuit, and monitors would you use?

C.2. Describe techniques other than direct laryngoscopy that would be useful for securing the airway in this baby.

Infant Video Laryngoscope
Intubation through a Laryngeal Mask Airway
Retrograde Cricothyroid Wire
Blind Nasal Intubation
Nasal Intubation with Laryngoscope and Magill Forceps
Fiberoptic Intubation

C.3. How would you monitor blood loss in this patient?

C.4. What anesthetic technique should be used in a patient who may experience severe loss of blood intraoperatively?

C.5. How would you induce and maintain anesthesia in this neonate?

C.6. Intraoperatively, the surgeon must dissect the tumor in the anterior mediastinum and needs to have a quiet surgical field. How would you accomplish this in the infant?

D. Postoperative Management

D.1. How would you manage this patient postoperatively?

44 Patent Ductus Arteriosus and Prematurity

Albert C. Yeung and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis

A.1. How would you classify prematurity? What are the common problems associated with prematurity?

A.2. What are the survival rates of preterm infants?

A.3. What are the incidence and survival rates of respiratory distress syndrome (RDS)? Discuss its pathophysiology.

A.4. What is bronchopulmonary dysplasia (BPD)? How would

you treat it?

A.5. *What are apnea spells? What are the possible causes of apneic spells?*

A.6. *Discuss the incidence and pathophysiology of PDA in preterm infants.*

A.7. *How would you make a diagnosis of PDA? Describe its treatment.*

A.8. *Would you give digitalis to treat congestive heart failure in preterm infants? Why?*

A.9. *How does indomethacin close the ductus? What are the adverse effects of indomethacin?*

A.10. *When is surgical closure indicated? What are the complications associated with surgical ligation?*

A.11. *What is retinopathy of prematurity (ROP) (retrolental fibroplasia [RLF])? Discuss its etiology, pathophysiology, prognosis, prevention, and treatment.*

A.12. *Define neutral and critical temperatures. What are these values in the preterm neonate, in the term neonate, and in the adult? Discuss temperature regulation in the neonate.*

B. Preoperative Evaluation and Preparation

B.1. *How would you evaluate this patient preoperatively?*

B.2. *What are the normal values of arterial blood gases and pH in neonates and infants?*

B.3. *Interpret the arterial blood gases: pH, 7.30; $Paco_2$, 60 mmHg; Pao_2, 49 mmHg; HCO_3^-, 20 mEq per L on 50% oxygen; and 6 cm H_2O of positive end-expiratory pressure (PEEP). How would you improve them?*

B.4. *What are the normal values of arterial blood pressure, heart rate, and respiratory rate for preterm infants?*

B.5. *What are the normal values of WBC, red blood cells (RBCs), hemoglobin, glucose, electrolytes, calcium, blood urea nitrogen, and creatinine for preterm infants?*

B.6. *Would you transfuse blood to this patient preoperatively?*

B.7. *How would you interpret the urinalysis: specific gravity, 1.005; sugar, 1+; and protein, 1+?*

B.8. *Would you correct a serum calcium level of 6.0 mg per dL? What other information would you like to have? Which contains more calcium, 10 mL of 10% calcium chloride or 10 mL of 10% calcium gluconate? Could you hyperventilate this child safely?*

B.9. *How would you premedicate this patient?*

C. Intraoperative Management

C.1. *Where should the procedure take place? In the neonatal intensive care unit (NICU) or the operating room?*

C.2. *What monitors would you use for this child during surgery?*

C.3. *How does the oxygen analyzer work?*

C.4. *What is the Doppler effect? How does the Doppler transducer measure blood pressure?*

C.5. *What is the mechanism of pulse oximetry? Why is it important to monitor arterial oxygen saturation? What levels of arterial oxygen saturation would you like to keep during surgery?*

C.6. *How would you maintain the patient's body temperature?*

C.7. *How do the anesthetic requirements of the preterm infant differ from those of the adult?*

C.8. *What size endotracheal tube would you have used if the patient had not been intubated?*

C.9. *How would you have induced anesthesia if the patient had not been intubated?*

C.10. *How would you maintain anesthesia?*

C.11. *How would you ventilate the patient? What tidal volume, respiratory rates, and F_{IO_2} would you set for the infant?*

C.12. *Discuss blood and fluid therapy in this preterm infant.*

C.13. *During dissection of the ductus arteriosus, the arterial oxygen saturation dropped from 92% to 80% and the heart*

rate decreased from 140 beats per minute to 80 beats per minute. What were the causes? How would you correct this situation?

D. Postoperative Management

D.1. Would you reverse the muscle relaxants and extubate the patient at the end of surgery?

D.2. How can one minimize the risk of transporting the patient to the NICU after surgery?

D.3. The patient's condition deteriorated postoperatively in the intensive care unit (ICU). Physical examination revealed persistent cardiac murmur. What was the possible diagnosis?

45 Post-tonsillectomy Hemorrhage

Dana L. Gurvitch, Jessica A. Latzman, and Hugh C. Hemmings Jr.

A. Medical Disease and Differential Diagnosis

A.1. Approximately how many pediatric tonsillectomies are performed in the United States each year? What are the indications for tonsillectomy?

A.2. What is the differential diagnosis for this patient?

A.3. What is the treatment for a patient with von Willebrand disease?

A.4. Describe the vascular anatomy of the tonsils. What is the incidence of post-tonsillectomy hemorrhage?

A.5. What are the risk factors for post-tonsillectomy hemorrhage? Does age matter?

A.6. Describe the morbidity and mortality of post-tonsillectomy hemorrhage.

B. Preoperative Evaluation and Preparation

B.1. What is your approach to assessing this patient?

B.2. What will you set up in the operating room for this patient? How will your preparation be different from a routine general anesthetic set up?

B.3. Should you plan to use vasopressors?

B.4. *The patient seems anxious. Will you administer a sedative to calm the patient down?*

B.5. *How do you plan on interpreting this patient's laboratory results?*

B.6. *What are your expectations of the surgeon, specifically as it relates to induction of anesthesia?*

C. Intraoperative Management

C.1. *What is your plan for induction of anesthesia? During the initial procedure, this patient underwent an uneventful inhalational induction, with postinduction intravenous (IV) placement. Would you perform an inhalational induction again? Why or why not?*

C.2. *What is your plan for management of blood in the oropharynx?*

C.3. *What is your plan for airway management?*

C.4. *Laryngoscopy and intubation prove challenging due to blood in the airway. What options do you have now?*

C.5. *What is your plan for maintenance of the anesthetic? What other medications might you want to give?*

C.6. *Assuming the surgical intervention is successful, what is your plan for emergence and extubation?*

D. Postoperative Management

D.1. *Is postoperative management in the pediatric intensive care unit (PICU) indicated?*

D.2. *What would you require for safe transport from the operating room to the PICU?*

D.3. *Discuss potential postoperative complications for this patient.*

D.4. *What discharge instructions should be given post-tonsillectomy?*

SECTION 11 Pain Management and Neuraxial

Blocks

46 Brachial Plexus Block

Tiffany Tedore and William Urmey

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting problems in this patient?

A.2. What additional medical history would you want to obtain?

A.3. What implications does the use of atenolol have on the patient's coexisting medical condition?

A.4. Why is immobilization of the arm important following humeral fracture?

A.5. What nerve is at particular risk for injury from humeral fracture?

B. Preoperative Evaluation and Preparation

B.1. What testing would be helpful to elucidate the cause of this patient's fainting spells?

B.2. What premedication would you order?

B.3. What are the respiratory effects of benzodiazepines?

C. Intraoperative Management

C.1. What anesthetic technique would you use?

C.2. Describe the relevant anatomy of the brachial plexus.

C.3. What relevant anatomic structures in the neck and below the neck can be injured or injected accidentally during brachial plexus block?

C.4. What regional technique would you choose to block the brachial plexus in this patient?

C.5. What are the advantages and disadvantages of the following blocks?

Interscalene Block

Supraclavicular Block

Infraclavicular Block

Axillary Block

C.6. Describe the landmarks and procedures for nerve stimulator

and ultrasound-guided interscalene block.

C.7. *Describe the landmarks and procedures for supraclavicular block.*

C.8. *Describe the landmarks and procedures for infraclavicular block.*

C.9. *Describe the landmarks and procedures for axillary block.*

C.10. *The patient requests to have the brachial plexus block performed after you administer general anesthesia. Would you agree to this request?*

C.11. *What relevant respiratory complications or side effects are you concerned about in this patient?*

C.12. *What is the incidence of hemidiaphragmatic paresis following interscalene brachial plexus block? Can this complication be avoided by decreasing the volume or concentration of local anesthetic injected or by using ultrasound-guided supraclavicular block?*

C.13. *Describe the pulmonary function changes that occur after interscalene brachial plexus block.*

C.14. *What would you do if the patient complained of dyspnea after you performed an interscalene or supraclavicular block?*

C.15. *The surgeon prefers to perform the surgical procedure in the sitting position. What are the advantages and disadvantages of this position compared to the lateral position in this patient?*

C.16. *Which nerves are most commonly missed with axillary brachial plexus block? With interscalene block? With all brachial plexus blocks?*

C.17. *What is the expected duration of brachial plexus block with 30 mL of 1.5% mepivacaine with 5 μg per mL epinephrine?*

C.18. *What is the maximum safe dose of local anesthetic for brachial plexus block?*

D. Postoperative Management

D.1. What regimen would you suggest for postoperative pain management?

D.2. In the postanesthesia care unit, the patient complains of dyspnea. How would you evaluate and manage this?

D.3. On the third postoperative day after removal of the brachial plexus catheter, the patient complains of persistent numbness and paresthesia in the ulnar nerve distribution. What would you tell the patient? How would you manage neurologic dysfunction after brachial plexus block that persists for 1 week?

47 Nerve Blocks of the Lower Extremity

Roniel Weinberg, Melvin La, and Danielle M. Gluck

A. Preoperative Evaluation

A.1. What is the Glasgow Coma Scale and its significance in this patient?

A.2. Should surgery be allowed to proceed in this patient who has a subdural bleed?

A.3. Does the patient's atrial fibrillation need to be addressed prior to surgery, and if so, how?

B. Preoperative Preparation

B.1. What is dabigatran (Pradaxa)? How is its effect measured? How far in advance of elective surgery should it be stopped? Can its effect be reversed?

B.2. What concerns do you have regarding neuraxial anesthesia in this patient who has a subdural hematoma?

B.3. What concerns do you have regarding neuraxial anesthesia in this patient who has prior back surgery?

B.4. The surgeon is willing to wait a few days prior to surgery while the swelling around the injury decreases. When would you feel comfortable proceeding with surgery in this patient?

C. Intraoperative Management

C.1. What two nerve plexuses need to be blocked in this case?

What nerve roots contribute to each plexus? Name the major nerves that come from each plexus.

C.2. *What is the innervation to the medial and lateral aspects of the ankle? What nerves need to be blocked for his surgery?*

C.3. *What nerves are blocked with an ankle block? Would you do an ankle block in this case?*

C.4. *Explain the posterior landmark technique to blocking the lumbar plexus. What motor response would be elicited with a nerve stimulator? At what stimulation level would you feel safe injecting the patient? Why not at a lower level of stimulation? Can ultrasound guidance be utilized for this injection?*

C.5. *What is a fascia iliaca block (three-in-one block)?*

C.6. *Describe the different ultrasound approaches to blocking the saphenous nerve above the knee.*

C.7. *What benefits might a saphenous nerve block above the knee provide compared to a femoral nerve block?*

C.8. *How would pain from a midthigh tourniquet dictate which peripheral nerve blocks to use in this patient? Describe the landmark technique of sciatic nerve block in the gluteal region. What is seen while performing an ultrasound technique to block the sciatic nerve?*

C.9. *Why does a popliteal nerve block have a high failure rate if performed too proximate to the popliteal fossa when using a landmark/nerve stimulator technique? Describe how this can be avoided when using ultrasound-based popliteal block.*

C.10. *What is the IPACK block? In what situations would this block be useful?*

D. Postoperative Pain Management

D.1. *Describe compartment syndrome and how that risk would influence your postoperative plan for peripheral regional analgesia.*

D.2. How would the addition of dexamethasone to your local anesthetic influence the duration of the blocks placed in the OR?

D.3. What is liposomal bupivacaine?

D.4. What benefit would a peripheral nerve catheter provide over a long-acting local anesthetic? Are there any downsides?

D.5. You were able to perform a continuous spinal epidural (CSE) at L3–L4 and used 0.125% bupivacaine via epidural route for postoperative pain control. The patient reports that he is comfortable regarding both his back pain and his ankle pain. What benefit would continuing the patient's methadone confer in this case?

D.6. How can regional analgesia aid in fast-track postoperative care?

48 Complex Regional Pain Syndromes

Mohammad M. Piracha, Neel D. Mehta, Sudhir A. Diwan, and Vinod Malhotra

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of pain in this patient?

A.2. What is complex regional pain syndrome (CRPS)?

A.3. What are the two types of CRPS?

A.4. What are the diagnostic criteria for CRPS? What is the incidence of this disease?

A.5. Define allodynia, hyperalgesia, hyperesthesia, and dysesthesia.

A.6. What are the stages of CRPS?

Stage I

Stage II

Stage III

A.7. What are the possible etiologies of CRPS?

A.8. Explain the pathophysiology of the development of CRPS.

A.9. Define sympathetically maintained pain (SMP) and sympathetically independent pain (SIP).

A.10. *How does CRPS differ from neuralgia?*
A.11. *What is central pain? How will you differentiate central pain from CRPS?*
A.12. *Is the social history of this patient relevant to the development of chronic pain syndrome?*

B. Pain Management

B.1. *How will you work up CRPS types I and II?*
B.2. *Describe the sympathetic nerve supply to the arm?*
B.3. *Where is the stellate ganglion located?*
B.4. *What are the anatomic landmarks used in the stellate ganglion block?*
B.5. *What are the clinical signs of stellate ganglion block?*
B.6. *What is Horner syndrome?*
B.7. *After a stellate ganglion block, this patient reports no significant change in the degree of pain despite developing Horner syndrome. Is the pain psychogenic in this patient?*
B.8. *What types of nerve fibers are interrupted in stellate ganglion block?*
B.9. *What is a differential block?*
B.10. *What are the two major classes of local anesthetics? Describe the major differences in their clinical pharmacology.*
B.11. *What factors determine the onset, potency, and duration of a local anesthetic block?*
B.12. *How does the addition of epinephrine to commercially available premixed solutions affect the efficacy of local anesthetics?*
B.13. *How will you treat this patient?*
B.14. *What is the pharmacologic management of CRPS?*
B.15. *What is the role of intravenous regional block (Bier method) in diagnosis and treatment of CRPS?*
B.16. *Compare and contrast the mechanism of actions of ketamine and methadone.*

B.17. What roles does ketamine infusion play in the treatment of CRPS? Is there a guideline for ketamine infusion in treating CRPS?
B.18. What is neuromodulation? What is the role of spinal cord stimulation (SCS) in treating CRPS?
B.19. What is the role of surgical sympathectomy?
B.20. What role does intrathecal (IT) therapy play in managing CRPS?
B.21. If opioids are prescribed as treatment for CRPS patients, what is the Centers for Disease Control and Prevention (CDC) guideline of chronic opioid therapy?

C. Complications

C.1 What are the complications of stellate ganglion block?
C.2 What is the systemic toxicity of local anesthetics?
Central Nervous System Effects
Cardiovascular Effects
C.3 How do you treat the systemic toxicity of local anesthetic drugs?
C.4 What are the possible complications of SCS?
C.5. What are the possible complications of IT therapy?

49 Cancer Pain
Shakil Ahmed and Sudhir A. Diwan

A. Medical Disease and Differential Diagnosis

A.1. What is the definition of pain?
A.2. How significant is the problem of pain in patients with cancer?
A.3. What are the components of cancer pain?
A.4. How does the pain contribute to the suffering of patients with cancer?
A.5. How do psychological factors affect pain in patients with cancer?
A.6. What are the causes of pain in patients with cancer?
A.7. How do you classify pin in patients with cancer?

A.8. *What are the characteristics of pancreatic cancer pain?*
A.9. *How do you assess pain in patients with cancer?*
A.10. *What is the differential diagnosis of abdominal pain?*

B. Pharmacologic Treatment of Pain
B.1. *What is the World Health Organization stepladder approach for cancer pain management?*
B.2. *What class of drugs does morphine sulfate belongs to?*
B.3. *What is the difference between morphine and synthetic opioids?*
B.4. *How does mixed opioid agonist/antagonist differ from opioid agonist?*
B.5. *Describe the role of methadone in the management of cancer pain.*
B.6. *What are the advantages and disadvantages of methadone?*
B.7. *What is the mechanism of action of opioids?*
B.8. *What are the side effects of opioid therapy?*
B.9. *Define tolerance and physical dependence.*
B.10. *How would you treat the side effects of opioid therapy?*
B.11. *What is tramadol? Is it an opioid?*
B.12. *When would you consider adjuvant analgesics as part of the treatment plan?*
B.13. *The patient and his family are worried about addiction. How would you approach this problem?*
B.14. *Describe different routes of opioid administration.*
B.15. *Describe advantages and complications of patient-controlled analgesia (PCA). What is minimum effective analgesic concentration (MEAC)?*
B.16. *What is meperidine? How is it different from other opioids?*
B.17. *What is rotation of opioids? When would you consider rotation of opioids?*

C. Invasive Therapy
C.1. *Describe the role of peripheral nerve blocks in cancer pain management.*

C.2. *Describe the role of celiac plexus block in cancer pain management.*

C.3. *What are the complications of celiac plexus block?*

C.4. *Would you consider neuraxial opioid infusion in this patient? Discuss complications of this procedure.*

C.5. *Which medications can be used intrathecally? What is ziconotide?*

C.6. *What is a Personal Therapy Manager (PTM), and what role does it play in neuraxial pain relief?*

C.7. *Would you consider neuraxial neurolysis in this patient to manage his pain? Discuss advantages and disadvantages of these blocks.*

C.8. *Which neuroablative procedures can be considered in the terminal stage of pancreatic cancer?*

C.9. *Describe the role of radiation therapy in cancer pain.*

D. Nonpharmacologic Management

D.1. *What are the various nonpharmacologic techniques of cancer pain management?*

D.2. *What physical modalities have been successfully tried in cancer pain management?*

D.3. *Describe the role of neuromodulation in cancer pain management.*

D.4. *What psychological techniques have been promoted for comfort care and pain relief?*

D.5. *What are distraction and reframing techniques? What is the role of hypnosis in cancer pain?*

50 Low Back Pain and Sciatica

David Y. Wang

A. Medical Disease and Differential Diagnosis

A.1. *How great an issue is low back pain in the general population?*

A.2. *What is the prevalence of low back pain?*

A.3. *What is the societal cost of low back pain?*

A.4. *What causes low back pain?*
A.5. *What are the risk factors for low back pain?*
A.6. *What are the potential sources of pain in the spine?*
A.7. *What is the anatomy of the intervertebral discs? What is the mechanism of pain from herniated discs?*
A.8. *What is the anatomy of the spinal facets? How do the facet joints cause pain?*
A.9. *What are the important findings through history and physical examination?*
A.10. *What are the appropriate diagnostic studies for low back pain?*
A.11. *What is the differential diagnosis of low back pain?*
A.12. *What are the causes of persistent back pain after multiple spine surgeries?*

B. Management of Low Back Pain and Sciatica
B.1. *What are the noninterventional treatments available?*
B.2. *What traditional interventional treatments are available and how should they be used?*
B.3. *What are some of the recent safety improvements recommended for lumbar epidural steroid injection?*
B.4. *What are some of other approaches in minimally invasive interventions?*
B.5. *What are the concerns about magnetic resonance imaging (MRI) safety in patients with a spinal cord stimulator (SCS)?*
B.6. *When should surgery be considered?*
B.7. *What surgical options are available for the treatment of disc disease?*

51 Perioperative Pain Management
Anuj Malhotra and Vinod Malhotra

A. Perioperative Pain Management for Thoracotomy
A.1. *What would be your advice to the patient about the planned thoracotomy and postoperative pain relief?*

A.2. *How will you decide about the choice of anesthetic technique?*

A.3. *What is chronic postsurgical pain (CPSP)? Does video-assisted thoracic surgery reduce the risk of chronic pain after thoracotomy?*

A.4. *What would be your perioperative analgesic strategy?*

A.5. *Does the choice of analgesic technique influence postoperative outcome?*

A.6. *Does it matter if the epidural catheter is at the thoracic or lumbar level?*

A.7. *Does the choice of drugs influence the efficacy or safety of thoracic epidural analgesia (TEA)?*

A.8. *What are the usual doses and concentrations of the anesthetic combinations commonly employed in epidural analgesia?*

A.9. *If accidental dural puncture occurs during placement of the epidural needle, what steps should be taken?*

A.10. *What are the alternatives to TEA?*

A.11. *What is the usual clinical regimen for intravenous patient-controlled analgesia (IV-PCA) and is special patient monitoring required during its use?*

A.12. *What are the side effects and complications of epidural technique?*

A.13. *What recommendations for placement and removal of epidural catheter will you make if this patient is on antiplatelet or anticoagulant therapy or thromboprophylaxis is planned?*

Prophylactic Unfractionated Heparin
Therapeutic Intravenous Unfractionated Heparin
Preoperative Low Molecular Weight Heparin (Enoxaparin)
Postoperative Low Molecular Weight Heparin
Oral Anticoagulants

Newer Agents

B. Chronic Opioid Therapy and Perioperative Pain Management
   - *B.1. How does chronic opioid therapy influence postoperative pain management?*
   - *B.2. What are the causes for increased postoperative pain and opioid consumption in patients chronically using opioids?*
   - *B.3. What are the main differences between a chronic opioid-consuming patient and a patient who abuses or is addicted to opioids?*
   - *B.4. What issues need to be considered in the opioid-tolerant patient who is scheduled for surgery?*
   - *B.5. What would be your strategy regarding preoperative information and choice of anesthesia technique?*
   - *B.6. What are the choices for perioperative pain management in opioid-tolerant patients?*
   - *B.7. What issues need to be considered before discharging an opioid-tolerant patient?*

C. Perioperative Pain Management for Ambulatory Surgery
   - *C.1. What would be your preoperative considerations and advice to the patient?*
   - *C.2. What are the consequences of inadequate pain management after ambulatory surgery?*
   - *C.3. What is the role of premedication or preoperative analgesic?*
   - *C.4. Does the choice of anesthetic technique influence postoperative pain?*
   - *C.5. Are nonsteroidal anti-inflammatory drugs (NSAIDs) effective? If so, does the choice of drug matter?*
   - *C.6. What is the role of surgical technique in influencing postoperative pain after a laparoscopic cholecystectomy?*
   - *C.7. What would be your strategy for pain control after discharge home?*

D. The Role of an Acute Pain Service (APS)

D.1. What is the extent of the problem, and which patients are at greatest risk of undertreatment?
D.2. What are the consequences of inadequate postoperative pain relief?
D.3. What is the role of an APS in improving postoperative pain management?
D.4. Does an APS improve postoperative outcome?

52 Acupuncture
Yuan-Chi Lin

A. Acupuncture as a Complementary Medical Therapy
A.1. What is acupuncture?
A.2. How is acupuncture practiced? (Video 52.1)
A.3. What are the mechanisms of acupuncture analgesia?
A.4. What were the conclusions of the National Institutes of Health Consensus Conference about acupuncture?
A.5. Can acupuncture be a novel nonopioid alternative pain therapy?

B. Acupuncture for the Treatment of Chronic Conditions
B.1. What are the rationales in integrating acupuncture for the treatment of postoperative nausea and vomiting?
B.2. Can acupuncture be used for the treatment of chemotherapy-induced nausea and vomiting?
B.3. How effective is acupuncture for the management of chronic headache?
B.4. Can acupuncture be used for the treatment of chronic neck and back pain?
B.5. Can acupuncture be used for the treatment of osteoarthritis?
B.6. What role can acupuncture play in the care of patients with cancer?
B.7. Can acupuncture/acupressure be used to decrease anxiety?
B.8. What is ear acupuncture/acupressure? Can it be useful for alleviating anxiety and pain? (Video 52.2)

C. Complications

C.1. *What are the possible complications of acupuncture treatment?*

SECTION 12 Miscellaneous

53 Myasthenia Gravis
James B. Eisenkraft and Bryan S. Carter

A. Medical Disease and Differential Diagnosis
- A.1. *What is MG?*
- A.2. *What is the etiology and pathophysiology of MG?*
- A.3. *Describe the clinical classification of MG.*
- A.4. *How is the diagnosis of MG made?*
- A.5. *What should be considered in the differential diagnosis?*
- A.6. *How does myasthenic syndrome (Lambert-Eaton syndrome) differ from MG?*
- A.7. *What treatments are available for a patient with MG?*
  - Medical Therapy
  - Surgical Therapy

B. Preoperative Evaluation and Preparation
- B.1. *Describe the preoperative evaluation of this patient.*
- B.2. *What preoperative laboratory data are required?*
- B.3. *How should the patient's medications be managed preoperatively?*

C. Intraoperative Management
- C.1. *What are your considerations in the choice of anesthetic technique?*
- C.2. *How should this patient be monitored intraoperatively?*
- C.3. *What anesthetic regimen would you choose for this patient?*
- C.4. *Can neuromuscular blocking drugs be used safely in a patient with MG?*
- C.5. *Should the MG patient who is in remission (i.e., symptom free without treatment) be managed differently?*

D. Postoperative Management

D.1. What factors will help you predict this patient's need for continued intubation or other postoperative ventilatory support?
D.2. How will you determine if this patient's trachea can be safely extubated?
D.3. How will you manage postoperative analgesia?
D.4. How will you define and manage postextubation ventilatory failure in this patient?

54 Malignant Hyperthermia
Henry Rosenberg, Harvey K. Rosenbaum, and Vinod Malhotra

A. Medical Disease and Differential Diagnosis
A.1. What was the problem of concern in this case?
A.2. What is malignant hyperthermia (MH)?
A.3. What are the clinical features of a susceptible patient?
A.4. Does the history of previous uneventful sevoflurane anesthesia reasonably exclude the patient's susceptibility to MH?
A.5. What are the clinical features of the syndrome?
Hyperkalemic Cardiac Arrest
A.6. What are the laboratory findings during an acute crisis of MH?
A.7. What is the incidence of this syndrome?
A.8. What is the mode of inheritance of the disease? Does MH "skip" generations?
A.9. What genetic disorder results in MH susceptibility?
A.10. What is the pathophysiology of the syndrome?
A.11. What laboratory tests can further substantiate the susceptibility of the patient to MH?
Molecular Genetic Testing for MH Susceptibility
A.12. What is neuroleptic malignant syndrome (NMS)?

B. Preoperative Evaluation and Preparation
B.1. How would you prepare this patient for anesthesia and surgery?

B.2. *Is dantrolene prophylaxis indicated?*
B.3. *What laboratory tests would you obtain before surgery?*
B.4. *Is outpatient surgery appropriate for this patient?*
B.5. *In anticipation of general anesthesia, what preparations would you make?*

C. Intraoperative Management
C.1. *What anesthetic techniques and agents would you employ?*
C.2. *Should body (core) temperature be monitored during general anesthesia lasting more than a short time?*
C.3. *What anesthetic agents are contraindicated?*
C.4. *If the surgeon wants to use local anesthesia for a procedure, what agents will you recommend?*
C.5. *What is the significance of masseter muscle spasm occurring after succinylcholine administration?*
C.6. *Twenty minutes into the procedure with sevoflurane anesthesia, the patient developed increasing tachycardia with ventricular premature beats and mottled skin. What emergency measures would you take?*
C.7. *What modalities would you monitor closely during management of the crisis?*
C.8. *What steps should be taken to avoid major morbidity from MH?*
C.9. *How does the new formulation of dantrolene (Ryanodex) compare with the existing formulation of dantrolene (Dantrium or Revonto)?*

D. Postoperative Management
D.1. *What complications may follow this syndrome?*
D.2. *What would be your follow-up in this case?*
D.3. *What would you advise the patient and the family?*
D.4. *What precautions should an MH-susceptible patient take outside of the operating room (OR)?*

55 Postoperative Residual Neuromuscular Weakness and

Prolonged Apnea

Mary So, Danielle McCullough, and David J. Kopman

A. Medical Diseases and Differential Diagnosis

- *A.1. What is the differential diagnosis for postoperative hypoventilation?*
- *A.2. How is residual neuromuscular blockade (NMB) diagnosed?*
- *A.3. What is the order of recovery of voluntary muscle groups from nondepolarizing muscle relaxants?*
- *A.4. What is the mechanism of action of succinylcholine, and how is it metabolized? What are the side effects of succinylcholine?*
- *A.5. If succinylcholine were the only muscle relaxant used during the case and the patient did not exhibit a response to train-of-four (TOF) stimulation, what is the likely diagnosis? How would you confirm it?*
- *A.6. What are acetylcholinesterase and serum cholinesterase? What is the clinical significance of heterozygosity for atypical pseudocholinesterase (PChE)?*
- *A.7. What is the incidence of atypical cholinesterase activity?*
- *A.8. What are some factors that can lower PChE levels?*

B. Intraoperative Management

- *B.1. How is the choice among muscle relaxants made?*
- *B.2. What factors can alter sensitivity to nondepolarizing neuromuscular blockers?*
- *B.3. What are the characteristics of nondepolarizing block?*
- *B.4. What is a TOF stimulus?*
- *B.5. Why is the TOF ratio of clinical importance?*
- *B.6. How do we define adequate recovery of neuromuscular function?*
- *B.7. Are there useful and/or trustworthy clinical tests of neuromuscular recovery?*
- *B.8. How accurate are subjective estimates of the TOF ratio, and what purpose do peripheral nerve stimulator (PNS)*

monitors serve?
B.9. *What is double burst stimulation (DBS)?*
B.10. *What is the posttetanic count (PTC)?*
B.11. *How can the TOF ratio be measured quantitatively?*
B.12. *What are the limitations of acetylcholinesterase antagonists?*
B.13. *Is there anything wrong with administering neostigmine when the TOFC is less than 3?*
B.14. *Is reversal of blockade always necessary?*
B.15. *Is there any way to rapidly antagonize a profound nondepolarizing block?*
C. Postoperative Management
C.1. *What is the incidence of residual NMB in the PACU?*
C.2. *Does undetected postoperative residual neuromuscular block (PORB) have clinical consequences?*
56 Burns
Shreyajit R. Kumar and Anup Pamnani
A. Medical Disease and Differential Diagnosis
A.1. *How do you classify the burn injury?*
A.2. *How do you express the extent of the burn injury?*
A.3. *Should the "rule of nines" be used in children?*
A.4. *What functions does the skin perform?*
A.5. *What pathophysiologic changes accompany major thermal injury?*
A.6. *What is the prognosis for this patient? What major factors affect his prognosis?*
A.7. *What are the common causes of death in burn patients?*
A.8. *Does this patient have a smoke inhalation burn? How do you make the diagnosis?*
A.9. *What is carbon monoxide poisoning? How do you diagnose and treat carbon monoxide poisoning?*
A.10. *What resuscitative measure would you institute immediately in this patient with 40% burns?*

A.11. *What fluid formula would you use?*

Parkland Formula

A.12. *What cardiovascular changes typify the burn injury?*

A.13. *What changes occur in hepatic function? What are the anesthetic implications of such changes?*

A.14. *What are Curling ulcers? How can they be prevented?*

A.15. *What complications are associated with electrical burns?*

B. Preoperative Evaluation and Preparation

B.1. *What preoperative preparations would you order? What are particular concerns in this patient?*

B.2. *What are the various operative and management options available for severely burned patients?*

B.3. *What are the advantages and disadvantages of early tangential excision split-thickness skin grafting (TE/STSG)?*

B.4. *What is this patient's mean arterial blood pressure? How do you calculate it?*

B.5. *Are you concerned about this patient's blood pressure? What treatment would you institute?*

B.6. *This patient was ventilated with respirator settings of tidal volume, 800 mL; respiratory rate, 20 breaths per minute; fraction of inspired oxygen (F_{IO_2}), 60%; and positive end-expiratory pressure, 10 cm H_2O. Arterial blood gas analyses showed the following: pH, 7.24; P_{O_2}, 56 mmHg; P_{CO_2}, 60 mmHg; and oxygen saturation, 80%. How would you interpret these arterial blood gas analysis results? What are the possible causes of high P_{CO_2} and low P_{O_2}?*

B.7. *How do you calculate oxygen content and oxygen delivery? What factors govern the oxygen delivery to the tissues?*

C. Intraoperative Management

C.1. *What monitors would you use in the operating room?*

C.2. *What information can be obtained from an arterial line and a pulmonary artery catheter? How are these calculations*

performed?

C.3. *If the patient had not been intubated, how would you proceed with the anesthetic induction?*

C.4. *Why is awake intubation considered the safest?*

C.5. *What anesthetic agents would you use? Discuss inhalation versus intravenous agents.*

C.6. *Why are you concerned about the patient's body temperature? What is normothermia for a burned patient?*

C.7. *How is temperature best maintained?*

C.8. *What derangements occur with hypothermia?*

C.9. *What muscle relaxant would you use?*

C.10. *Why is succinylcholine contraindicated in burned patients? For how long should it be avoided?*

C.11. *What other adverse effects are associated with succinylcholine?*

C.12. *How are the doses of nondepolarizing muscle relaxants affected by burn injury?*

C.13. *How are the muscle relaxants such as succinylcholine, atracurium, cisatracurium, vecuronium, pancuronium, rocuronium, and curare metabolized and eliminated? Which of them has significant histamine release?*

D. Postoperative Management

D.1. *How would you monitor this patient during transport?*

D.2. *What is meant by diffusion hypoxia? How do you prevent it?*

D.3. *Why do patients often shiver in the recovery room on emergence from anesthesia?*

D.4. *Discuss the causes of oliguria in the recovery room.*

57 Trauma

Rohan K. Panchamia, Jaideep K. Malhotra, and Ralph L. Slepian

A. Medical Disease and Differential Diagnosis

A.1. *How is trauma classified?*

A.2. *What are the injuries associated with thoracic trauma?*

A.3. *What are the injuries associated with cardiac trauma?*

A.4. *What is the pathophysiology of acute pericardial tamponade?*
A.5. *What are the anesthetic implications for treating cardiac tamponade?*
A.6. *How is the initial assessment and management of the trauma patient performed?*
A.7. *What constitutes a primary survey, and what is its objective?*
A.8. *What constitutes a secondary survey, and what is its objective?*
A.9. *What is the definition of massive hemothorax? What are the signs and symptoms of a hemothorax?*
A.10. *What are the indications for a thoracotomy to treat a hemothorax?*
A.11. *How are pneumothoraces categorized?*
A.12. *What is an occult pneumothorax?*
A.13. *If the patient has a widened mediastinum on chest radiograph, what are your concerns?*
A.14. *What are the most commonly injured organs in blunt abdominal trauma?*
A.15. *What is a focused abdominal sonography for trauma (FAST) examination?*
A.16. *What is diagnostic peritoneal lavage (DPL)?*
A.17. *Why was DPL not performed for this patient?*
A.18. *Define shock.*
A.19. *What are the four types of shock?*
A.20. *List the signs and symptoms of shock.*
A.21. *What is the pathophysiology of hypovolemic shock?*
Cardiovascular Derangement
Acid–Base Disturbance
A.22. *How would you classify hemorrhage?*
A.23. *What is the initial treatment of hemorrhagic shock?*
A.24. *Would you choose crystalloid, colloid, or blood products to treat hemorrhagic shock?*

A.25. *Is there a place for dextran or hetastarch (Hespan) in treating hypovolemic shock?*

B. Preoperative Evaluation and Preparation

B.1. *What premedication would you order?*

B.2. *What preoperative testing would you order?*

C. Intraoperative Management

C.1. *How would you monitor this patient?*

C.2. *How would you induce anesthesia?*

C.3. *What technique could you use if single-lung ventilation was indicated?*

C.4. *What agents would you choose to maintain anesthesia?*

C.5. *What muscle relaxant would you choose?*

C.6. *What can be done to decrease the incidence of intraoperative awareness?*

C.7. *Five minutes after intubation, the peak airway pressure increased from 20 to 40 cm H_2O. What are the possible causes?*

C.8. *How would you make a diagnosis of tension pneumothorax?*

C.9. *What is the treatment of tension pneumothorax?*

C.10. *The patient's blood loss was continuing, and the hematocrit was 18%. What type of blood would you give if the type and crossmatch are not completed?*

C.11. *What precautions should be taken if more than 2 units of low titer type O uncrossmatched whole blood are given?*

C.12. *What are the complications associated with any blood transfusion?*

Transfusion Reactions

Transmission of Disease

Microembolization

What is considered a massive transfusion (MT)? What is the Assessment of Blood Consumption (ABC) score?

C.14. *What are the complications associated with an MT?*

C.15. *Can the shift of the oxygen–hemoglobin dissociation curve*

be quantified?

C.16. *How is hypothermia defined?*

C.17. *What are the adverse effects of hypothermia?*

C.18. *What is the treatment of hypothermia?*

C.19. *What are the effects of blood transfusion on the immune system?*

C.20. *What are the guidelines for transfusion of blood products?*

Red Blood Cell Transfusion Criteria
Platelet Transfusion Criteria
Fresh Frozen Plasma Transfusion Criteria
Cryoprecipitate Transfusion Criteria
What are the guidelines for the ratio of plasma/platelet transfusion to packed red blood cells in an MT?

C.22. *If a patient were a member of the Jehovah's Witness religious sect, would you give a blood transfusion?*

C.23. *If a child is a Jehovah's Witness and suffered from hemorrhagic shock, what would you do?*

C.24. *What are the concentrated factors and hemostatic agents available for bleeding patients?*

Recombinant Activated Factor VII (rFVIIa, NovoSeven)
Four-Factor Prothrombin Complex Concentrate
Fibrinogen Concentrates
Tranexamic Acid
What is thromboelastography (TEG) and thromboelastometry? How can they guide transfusion?
Rotation Thromboelastometry
Thromboelastography

D. Postoperative Management

D.1. *What is acute respiratory distress syndrome (ARDS)? What is acute lung injury?*

D.2. *How is ARDS treated?*

D.3. *In the recovery room, you are called to see this patient because of oliguria. How would you evaluate and treat this*

patient?

Prerenal

Renal

Postrenal

D.4. *If this patient had a crush injury and low urine output, what other concerns might you have? What if the patient has dark or "tea-colored" urine?*

58 Scoliosis

Jordan M. Ruby and Victor M. Zayas

A. Medical Disease and Differential Diagnosis

A.1. *What is scoliosis?*

A.2. *What is the most common type of scoliosis?*

A.3. *What are the other types of scoliosis?*

Idiopathic

Neuromuscular

Myopathic

Congenital

Neurofibromatosis

Mesenchymal Disorders

Trauma

A.4. *How is the severity of scoliosis assessed, and why is the severity important?*

A.5. *What are the nonoperative treatment options of scoliosis?*

A.6. *What abnormalities in pulmonary function tests (PFTs) are most commonly seen in scoliosis? What is the cause of these abnormalities?*

A.7. *What is the most common arterial blood gas abnormality seen in scoliosis? What are possible causes for this abnormality?*

A.8. *What abnormalities of ventilatory drive may be associated with scoliosis?*

A.9. *How may the cardiovascular system be affected in patients with scoliosis?*

A.10. *What is the relationship between scoliosis and malignant hyperthermia?*

B. Preoperative Evaluation and Preparation

B.1. *What should the anesthesiologist know about the nature of the spinal curve?*

B.2. *What aspects of the history are most important?*

B.3. *What aspects of the physical examination are most important?*

B.4. *Why is a preoperative neurologic assessment important?*

B.5. *What tests would you order preoperatively?*

B.6. *What is an enhanced recovery after surgery (ERAS) pathway? How has it been applied to the recovery for pediatric patients undergoing posterior spinal instrumentation and fusion?*

B.7. *How will the surgical procedure influence the anesthetic management?*

C. Intraoperative Management

C.1. *What monitoring would you use?*

C.2. *What is the incidence of neurologic complications in scoliosis surgery, and which patients are at highest risk?*

C.3. *What monitoring techniques are used to minimize neurologic complication?*

C.4. *What are somatosensory evoked potentials (SSEPs), and how are they used?*

C.5. *How reliable are SSEPs for predicting spinal injury?*

C.6. *What are motor evoked potentials (MEPs), and how are they used?*

C.7. *How is spinal cord monitoring affected by anesthetic agents? What other factors affect spinal cord monitoring?*

C.8. *What is the optimal anesthetic technique for scoliosis surgery?*

C.9. *What should be done if the SSEPs or MEPs become abnormal during surgery?*

C.10. *How is the "wake-up" test performed? What complications can occur during this test?*

C.11. *Four hours into the surgical procedure, the surgeon reports some bubbling in the thoracic portion of the wound. Shortly thereafter, end-tidal carbon dioxide decreases abruptly from 35 to 18 mmHg, heart rate increases from 80 to 120 beats per minute, blood pressure begins to fall, and arterial saturation decreases to 90%. On auscultation through esophageal stethoscope, you hear a loud gurgling murmur. What is your diagnosis?*

C.12. *How common is significant air embolism during scoliosis surgery?*

C.13. *What should be done if an air embolus is suspected?*

C.14. *What complications occur related to positioning the patient?*

C.15. *What is transfusion-related acute lung injury (TRALI)? How do you distinguish it from transfusion-associated circulatory overload (TACO)?*

C.16. *What techniques can be used to minimize transfusion requirements?*

D. Postoperative Management

D.1. *When would you extubate the patient?*

D.2. *What should be done to optimize pulmonary status?*

D.3. *What laboratory tests should be ordered postoperatively?*

D.4. *What fluid therapy would you use postoperatively?*

D.5. *What complications may occur following scoliosis surgery?*

D.6. *Upon arrival to the recovery room, you notice that the urine appears to be tea colored. What is your diagnosis, and how should this be managed?*

D.7. *How would you manage this patient's pain, nausea, and vomiting postoperatively?*

59 Hypoxia and Equipment Failure

James B. Eisenkraft and Garrett W. Burnett

A. Medical Disease and Differential Diagnosis

A.1. What is hypoxia, and what is hypoxemia?

A.2. Is the partial pressure of oxygen in arterial blood (Pa_{O_2}) related to age?

A.3. Was this patient hypoxemic?

A.4. What is a pulse oximeter, and what is a hemoximeter?

A.5. How does a pulse oximeter work?

A.6. How is a two-wavelength pulse oximeter calibrated by the manufacturer?

A.7. What may affect the accuracy of a two-wavelength pulse oximeter?

A.8. How do the dyshemoglobins, methemoglobin (metHb), and carboxyhemoglobin (Hb_{CO}) affect Sp_{O_2} readings?

A.9. What is a capnometer, and what is capnography? Of what value are they in patient monitoring?

A.10. What is meant by the term end-tidal carbon dioxide (Et_{CO_2})?

A.11. What is the appearance of a normal capnogram, and what is its significance?

A.12. What are mainstream and sidestream capnometers?

A.13. Show some common capnograms and provide a differential diagnosis of each event.

A.14. What is the arterial–alveolar difference in carbon dioxide (CO_2)?

A.15. What are some of the important safety features of the contemporary anesthesia workstation?

Features Intended to Prevent Human Error

Features to Correct for Use Error

Monitoring Systems

Alarm Systems

A.16. What are the common sites for gas leakage?

A.17. How is the anesthesia machine checked for leaks?

B. Preoperative Evaluation and Preparation

B.1. *What should be included in the equipment checkout in preparation for anesthesia?*

- *Emergency ventilation equipment*
- *High-pressure system*
- *Low-pressure systems*
- *Scavenging system*
- *Breathing system*
- *Manual and automatic ventilation systems*
- *Monitors*
- *Final position*

B.2. *What emergency equipment should be easily available to the anesthesiologist?*

B.3. *How should this patient be premedicated?*

C. Intraoperative Management

C.1. *How should this patient be monitored?*

- *Oxygenation*
- *Ventilation*
- *Circulation*
- *Body temperature*

C.2. *Following uncomplicated induction of anesthesia and endotracheal intubation, the procedure begins. Upon insufflation of the abdomen with CO_2, the SpO_2 decreases to 78%. What acute diagnostic and therapeutic interventions would you perform?*

C.3. *The endotracheal tube was withdrawn 2 cm. Squeezing the reservoir bag in the circle breathing system failed to generate positive pressure in the circuit. What are the common sites for gas leaks in the circle breathing system?*

C.4. *The patient was taken out of Trendelenburg position. Direct laryngoscopy revealed the endotracheal tube to be supraglottic. Additionally, green secretions were noted to be pooled in the posterior pharynx. What should be done next?*

D. Postoperative Management

D.1. *What criteria would you use for tracheal extubation?*

D.2. *What are the causes of postoperative hypoxemia?*

D.3. *What is the difference between shunt, ventilation/perfusion mismatch, and dead space?*

D.4. *Postoperatively, the patient developed hypoxia and pulmonary edema. What is the differential diagnosis of pulmonary edema? What is the most likely cause of pulmonary edema in this patient?*

D.5. *How should the ventilator be set if mechanical ventilation is required postoperatively?*

D.6. *If this patient had acute respiratory distress syndrome (ARDS) secondary to aspiration, besides low-tidal volume ventilation, what other changes in routine therapy should be considered?*

D.7. *What therapies routinely administered by the anesthesiologist may cause acute lung injury?*

D.8. *What methods of oxygen administration may be used postoperatively?*

60 Electroconvulsive Therapy

Patricia Fogarty Mack

A. Medical Disease and Differential Diagnosis

A.1. *What are the indications for ECT?*

A.2. *Are there any contraindications to ECT?*

A.3. *What is the mechanism of action of ECT?*

B. Preoperative Evaluation and Preparation

B.1. *How would you assess the cardiac status of this patient?*

B.2. *How should his anticoagulation be managed during ECT?*

B.3. *What implications do his history of sleep apnea have on management of ECT?*

B.4. *How does his history of TIA and carotid endarterectomy impact your preoperative evaluation?*

B.5. *Is ECT contraindicated in a patient with a permanent pacemaker or implantable cardioverter-defibrillator?*

B.6. *Are there any psychiatric medications he is taking that would impact your anesthetic care?*

C. Intraoperative Management

C.1. *Describe the hemodynamic and cardiac response to ECT in a typical patient.*

C.2. *Is an arterial line warranted in this patient?*

C.3. *By what means would you attempt to maximize hemodynamic stability?*

C.4. *Describe the cerebral hemodynamic effects of ECT.*

C.5. *How would you proceed with an anesthetic induction for this procedure?*

C.6. *How do you intend to manage his airway during each treatment?*

D. Postoperative Management

D.1. *The patient is extremely agitated upon emergence. Discuss the risk factors for postictal agitation (PIA) as well as the therapeutic options.*

D.2. *After three consecutive uneventful inpatient treatments, the psychiatrist asks if the patient may undergo ECT as an outpatient. Would you agree to this plan?*

61 Ambulatory Surgery

Melinda Randall and Hugh C. Hemmings Jr.

A. Medical Disease and Differential Diagnosis

A.1. *Is this patient morbidly obese?*

A.2. *What medical conditions may be associated with obesity and morbid obesity?*

A.3. *Is there a link to a decline in memory and thinking with anesthesia and surgery?*

B. Preoperative Evaluation and Preparation

B.1. *What advantages does outpatient surgery offer?*

B.2. *What are the goals of the preoperative evaluation of the surgical outpatient?*

B.3. *In order to thoroughly screen for disease, should one put all*

outpatients through a full battery of laboratory testing?

- *B.4. What preoperative laboratory testing is necessary for surgical outpatients?*
- *B.5. Which outpatients should receive a preoperative chest roentgenogram?*
- *B.6. In which patients is an electrocardiogram (ECG) necessary before outpatient anesthesia and surgery?*
- *B.7. Would age or physical status influence the decision to perform outpatient surgery?*
- *B.8. What patients are considered inappropriate for ambulatory surgery?*
- *B.9. What questions are critically important to ask this patient when obtaining her history?*
- *B.10. What instructions should the patient be given with regard to continuing or discontinuing lisinopril in the perioperative period?*
- *B.11. What is an enhanced recovery after surgery (ERAS) protocol, and how would you apply it in the outpatient setting?*
- *B.12. How would you premedicate this patient?*
- *B.13. Should every outpatient receive prophylaxis against aspiration pneumonitis?*
- *B.14. Is an overnight fast justified for all outpatients?*

C. Intraoperative Management

- *C.1. What are the important considerations in choosing an anesthetic technique for outpatient surgery?*
- *C.2. How would you monitor this patient?*
- *C.3. What is the bispectral index (BIS) monitor, and what information does it convey?*
- *C.4. What benefits might be derived from using a BIS monitor?*
- *C.5. Is BIS monitoring applicable to children?*
- *C.6. What are the major limitations of BIS monitoring?*
- *C.7. What does a BIS reading of 56 mean?*

C.8. *What anesthetic agents would you use to induce and maintain general anesthesia in this patient?*
C.9. *Under what circumstances might spinal anesthesia be appropriate for outpatient surgery?*

D. Postoperative Management
D.1. *What are the common causes of nausea and vomiting in outpatients?*
D.2. *How would you pharmacologically prevent PONV in the susceptible ambulatory patient?*
D.3. *How is postoperative pain treated?*
D.4. *What criteria would you use to establish that a patient can be safely discharged after ambulatory surgery?*
D.5. *How would you decide when to discharge a patient after regional anesthesia?*
D.6. *What instructions should be given to an ambulatory surgical patients upon discharge?*

62 Magnetic Resonance Imaging
Jayanth Swathirajan, Dana L. Gurvitch, and Hugh C. Hemmings Jr.

A. Medical Disease and Differential Diagnosis
A.1. *What is MRI, and how does it work?*
A.2. *What are some advantages of MRI?*
A.3. *What are some disadvantages associated with MRI? What are some safety concerns?*
A.4. *How do you manage patients with implanted devices?*
A.5. *What are the biologic effects of clinical MRI?*
A.6. *What are the anesthetic considerations for this procedure?*
A.7. *What is intraoperative MRI (iMRI)? What is real-time MRI, and in what setting can this be used?*

B. Preoperative Evaluation and Preparation
B.1. *What type of patients may require sedation or general anesthesia for MRI?*
B.2. *Do all children require sedation for MRI?*
B.3. *What preoperative laboratory testing would you require for*

this patient?

B.4. How would you premedicate this patient? What are some options that can be used to premedicate other patients for MRI?

C. Intraoperative Management

C.1. What are some of the anesthetic options for this patient?

C.2. How is an MRI conducted?

C.3. How would you monitor this patient?

C.4. What special considerations apply to monitoring equipment used during MRI?

C.5. How would you induce and maintain general anesthesia in this patient?

C.6. What are ways to maintain the airway during an MRI scan?

C.7. During the scan, you notice loss of end-tidal carbon dioxide. You immediately go into the scanner, remove the patient from the MRI scanner and initiate bag ventilation. However, you are still unable to ventilate the patient, and asystole follows. What do you do next?

C.8. What is the risk to the patient of gadolinium administration in the presence of acute renal insufficiency?

D. Postoperative Management

D.1. How will you recover the patient from anesthesia?

63 Morbid Obesity, Obstructive Sleep Apnea, and Bariatric Anesthesia

Jon D. Samuels and Fun-Sun F. Yao

A. Medical Disease and Differential Diagnosis

A.1. What problems exist with this patient? The patient asks you if he is high risk. What is the evidence? Is surgical therapy a safe and viable alternative for this patient?

A.2. Define the terms overweight, obesity, MO, super obesity (SO), super-SO (SSO), normal weight, ideal body weight (IBW), and lean body weight (LBW). What is the impact of obesity on society?

A.3. *What is OSA? What are the risk factors for OSA?*

A.4. *How is OSA diagnosed? What is a sleep study, or PSG? How are results obtained from a PSG used to grade the severity of OSA? What are the subtypes of OSA? Are there genetic disorders with a predisposition to OSA? What is the role of OSA screening tests in the preoperative setting?*

A.5. *How does OSA differ in the pediatric population in clinical presentation and pathogenesis?*

A.6. *What is the Pickwickian syndrome (PS)? What is obesity hypoventilation syndrome (OHS)? Describe the pathogenesis of severe OSA.*

A.7. *What is the association between obesity and OSA? What is the etiology of OSA in severe obesity?*

A.8. *What are the anesthetic implications of OSA?*

A.9. *What type of metabolic problems would you expect to find in morbidly obese patients? What are the roles of leptin and ghrelin in obesity?*

A.10. *Describe the changes that occur in the following respiratory parameters in morbidly obese patients:*

A.11. *What changes occur in Pa_{O_2} and Pa_{CO_2} in morbidly obese patients?*

A.12. *What changes occur in intrapulmonary shunt (Q_S/Q_T) and dead space (V_D/V_T) in MO? Describe the Shunt equation and the physiologic dead space, or Bohr equation.*

A.13. *What changes occur in the cardiovascular system of the obese patient? Discuss cardiac output, blood volume, blood pressure, and pulmonary arterial pressure.*

A.14. *Are there any other disease entities commonly associated with obesity? What is their relationship?*

A.15. *What anatomic changes that affect the airway are associated with MO and OSA?*

A.16. *What derangements of the gastrointestinal system are*

associated with MO?

B. Preoperative Evaluation and Preparation

- *B.1. How would this patient be optimized for surgery preoperatively? Would you use preoperative screening questionnaires to diagnose OSA? Summarize the workup for this patient.*
- *B.2. One of the recent developments in bariatric surgery is that many patients are receiving prebariatric screening procedures performed in the endoscopy suite. Describe the anesthetic considerations.*
- *B.3. Summarize the evidence-based workup, risk, chance of various adverse outcome, and expected length of stay for this patient.*
- *B.4. What is the role of enhanced recovery after surgery (ERAS) in bariatric surgery? How does the public find a quality bariatric surgery team and surgical facility? What is the role of robotics in bariatric surgery?*
- *B.5. Would you premedicate the patient?*
- *B.6. Describe the mechanism of action of each premedication in the ENERGY protocol.*
- *B.7. How would you adjust doses of anesthetics in the morbidly obese?*

C. Intraoperative Management

- *C.1. How would you monitor this patient?*
- *C.2. The American Society of Anesthesiologists' (ASA) Difficult Airway Algorithm (DAA) provides a guideline for management of the difficult airway. How do the comorbidities of MO and OSA modify implementation of the algorithm?*
- *C.3. Why is it important to preoxygenate the obese patient? How would you do it? Compare the effectiveness of the four-maximum-breath and 3-minute techniques. What is the importance of continuous positive airway pressure (CPAP)*

during the induction of general anesthesia? Describe use of the nasal CPAP mask in the induction of general anesthesia.

- *C.4. There are many new airway devices on the marketplace. Which of these devices have been particularly successful on the morbidly obese or OSA patient?*
- *C.5. How would you induce anesthesia? Describe the intubation technique.*
- *C.6. How would you maintain general anesthesia? What agents would you choose? How would you prepare for emergence?*
- *C.7. Which muscle relaxants would you use?*
- *C.8. Is postoperative pain severe after bariatric surgery? What are the pain generators? What is the role of regional anesthesia to decrease opioid requirements for bariatric surgery? What are the advantages and disadvantages of regional anesthesia? What are some of the newer techniques available?*
- *C.9. What is the pathophysiology of pneumoperitoneum (PNP)? What is the effect on the cardiopulmonary system? How does it change perioperative care? What are the optimal ventilator strategies for morbidly obese patients undergoing bariatric surgery?*
- *C.10. What are the devices that anesthesiologists place in the upper gastrointestinal canal during laparoscopic bariatric surgery? Are there risks associated with placement and management of these devices?*
- *C.11. When will you extubate this patient? Describe weight-based extubation criteria.*
- *C.12. What is apneic oxygenation?*
- *C.13. What is diffusion hypoxia (DH)? How do you prevent it?*

D. Postoperative Management

- *D.1. What are the early postoperative complications of bariatric surgical procedures?*
- *D.2. What are the late complications of bariatric surgical*

procedures?
D.3. What is the effect of position on respiratory function in the obese patient?
D.4. How would you prevent postoperative atelectasis?
D.5. How long would you prescribe supplementary oxygen postoperatively?
D.6. How would you control postoperative pain?

Preface

Important advances in surgical procedures and in the clinical practice of anesthesiology have prompted the production of a new edition of this text. The book has been published in five languages: English, German, Japanese, Chinese, and Portuguese. The remarkable popularity of the first eight editions in the anesthesiology community both in the United States and abroad encouraged us to update and expand its subject matter. The ninth edition is written to further improve anesthesia management for sophisticated modern surgery.

As with our previous editions, *Yao & Artusio's Anesthesiology: Problem-Oriented Patient Management* was written to present a group of important clinical entities covering the most critical anesthetic problems. It is intended to provide logical and scientific fundamentals for individualized patient management.

In this ninth edition, *Yao & Artusio's Anesthesiology: Problem-Oriented Patient Management* is organized by organ systems into 12 sections consisting of 63 chapters. Each chapter begins with a brief case presentation, followed by essential problems of each disease covering four areas: (1) pathophysiology and differential diagnosis, (2) preoperative evaluation and preparation, (3) intraoperative management, and (4) postoperative anesthetic management. Using a question-and-answer format, the book is designed to stress anesthetic problems and to give the anesthesiologist the opportunity to organize his or her own ideas of patient care. A reasonable answer, with updated references, follows each question.

To maintain the fresh quality of the textbook, the ninth edition has been

updated with significant newer content and contributions by new authors. The text originally reflected the clinical experience of the Department of Anesthesiology at Weill Cornell Medicine—NewYork-Presbyterian Hospital. In this edition, experts from other prestigious institutions have shared their evidence-based invaluable experience and practice to make this book more universally acceptable and applicable. The material in the book is prepared for the education of the trainee as well as the practicing anesthesiologist; it also serves as a review source for continuing education. The question-and-answer format, combined with current references, enhances its educational value.

We welcome comments, criticisms, and suggestions for future editions.

Acknowledgments

I wish to express my personal gratitude to the individual contributors. This book would not have been possible without their hard work and dedication. I am grateful to the associate editors: Jill Fong, MD; Vinod Malhotra, MD; and Hugh C. Hemmings Jr., MD, PhD, FRCA, for their invaluable assistance. I would like to thank Colleen Distefano for her extraordinary secretarial help. I also like to show my special thanks to our editors at Wolters Kluwer: Keith Donnellan, Ashley Pfeiffer, and Ashley Fischer, for their commitment to excellence. In addition, I am indebted to Hugh C. Hemmings Jr., MD, PhD, FRCA, for his advice and support. Above all, my deepest appreciation goes to my family, Tong-Yi, Ning-Yen, Jean-Kuan, and especially to my dear compassionate wife, Baw-Chyr Peggy Yao. Her understanding, patience, and encouragement made this book possible.

Fun-Sun F. Yao, MD

SECTION 1 The Respiratory System

1 Asthma and Chronic Obstructive Pulmonary Disease

Jaroslav K. Usenko and Fun-Sun F. Yao

A 55-year-old man with cholelithiasis is scheduled for laparoscopic cholecystectomy. He has a long history of asthma, has smoked two packs of cigarettes a day for the past 30 years, and reports dyspnea with moderate exertion (walking uphill). He sleeps on two pillows. There is no peripheral edema. Arterial blood gas (ABG) on room air shows the following: pH, 7.36; P_{CO_2}, 60 mmHg; P_{O_2}, 70 mmHg; and CO_2 content, 36 mEq per L.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of dyspnea?
2. What is the prevalence of asthma and chronic obstructive pulmonary disease (COPD)?

3. What is the etiology of asthma?
4. Discuss the pathogenesis of asthma. How is asthma distinguished from COPD?
5. What are the triggers of bronchospasm?
6. What is the universal finding in ABGs during asthmatic attacks: hypoxemia or CO_2 retention?
7. Describe the abnormalities seen in spirometry, lung volumes, and lung capacities during an asthmatic attack.

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient preoperatively? What preoperative workup would you order?
2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?
3. Define normal lung volumes and lung capacities. Give normal values for an average adult male.
4. What are flow–volume loops? Draw flow–volume loops for a healthy subject and patients with COPD, restrictive lung disease, fixed obstruction of the upper airway, variable extrathoracic obstruction, and variable intrathoracic obstruction.
5. Define closing volume (CV) and closing capacity (CC). What is the normal value of CV?
6. Why is the functional residual capacity (FRC) important in oxygenation?
7. How are FRC and CC affected by age and posture? How are they affected by anesthesia?
8. Give the equations for shunt ($\dot{Q}_S/\dot{Q}_T$) and dead space/tidal volume (V_D/V_T). What are their normal values?
9. Interpret the following ABG: pH, 7.36; P_{CO_2}, 60 mmHg; P_{O_2}, 70 mmHg; and CO_2 content, 36 mEq per L.
10. What are the common physiologic causes of hypoxemia?
11. How would you prepare this asthmatic patient with COPD for

surgery?

12. The patient comes to your perioperative clinic 2 weeks before surgery. He wants to know if his smoking puts him at increased risk during surgery. What do you tell him? Should he quit now?
13. You discover that the patient had a recent upper respiratory infection (URI), would you postpone surgery? For how long?
14. What medications would you expect the patient to have taken in the past or be taking at the present time?
15. The patient was on 20 mg of prednisone per day for 5 days as part of the treatment of an asthma exacerbation 3 months ago. He is currently not on steroids. Should the patient receive stress-dose steroids?
16. Should patients with reactive airway disease receive preoperative steroids?
17. What is the onset of action of intravenous steroid therapy in asthma?

C. Intraoperative Management

1. If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?
2. The patient did not have an asthmatic attack in the operating room and you proceed with induction. How would you induce anesthesia? Would you use a supraglottic airway instead of an endotracheal tube?
3. Would you use propofol for induction of anesthesia?
4. Would you use thiopental, methohexital, etomidate, or ketamine for induction?
5. Would you administer lidocaine for intubation?
6. If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?
7. Could a regional technique be used for this surgery? Discuss

the advantages and disadvantages of neuraxial anesthesia in this patient for this surgery.

8. Would you choose an inhalational or an intravenous technique for maintenance of anesthesia?
9. What mechanisms produce bronchodilation from volatile anesthetics?
10. Which muscle relaxants would you use? Why?
11. How will you ventilate the patient? Will you use positive end-expiratory pressure (PEEP)? How can you detect the presence of auto-PEEP on your ventilator?
12. What is the differential diagnosis of intraoperative bronchospasm?
13. In the middle of surgery, peak inspiratory pressures (PIPs) suddenly increase. How do you manage this?
14. How would you give β_2-agonists? What is their mechanism of action on asthma?
15. If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?
16. The asthmatic attack was relieved with your treatment, and the surgery was completed. Following emergence, the patient was found to be hypoventilating. What are the common causes of hypoventilation? What will be your approach to treat hypoventilation?
17. Would you consider a deep extubation in this patient?
18. If the patient cannot be extubated, what measures can you take to reduce the likelihood of bronchospasm with an endotracheal tube in place?

D. Postoperative Management

1. In patients with asthma and COPD, are there special considerations for the use of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) for postoperative pain control?
2. Would you consider using a regional technique for analgesia?

3. The patient was breathing well and was extubated. Would you place this patient on supplemental oxygen in the recovery room? How much?
4. The patient is hypoventilating in postanesthesia care unit (PACU). Would you initiate noninvasive ventilation (NIV)?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of dyspnea?

Dyspnea is a symptom of a broad array of underlying conditions. Although the differential diagnosis is extensive, pulmonary and cardiac conditions account for as many as 85% of the underlying causes of dyspnea. Pulmonary causes include asthma, COPD, interstitial lung disease, and chest wall disease (kyphoscoliosis). Cardiac causes include left heart failure, sometimes called cardiac asthma, and pericardial disease (restrictive pericarditis, cardiac tamponade). Dyspnea can also be due to anemia, deconditioning, and psychological causes.

In this patient, with known asthma, the most likely causes of dyspnea are pulmonary. In patients such as this one with a considerable smoking history, concomitant COPD and asthma is common, and airway obstruction with both reversible and irreversible components is frequently seen.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:226–229, 1957–1969, 1990–1998.

A.2. What is the prevalence of asthma and chronic obstructive pulmonary disease (COPD)?

Asthma is one of the most common chronic diseases globally and currently affects up to 334 million people. The global incidence of asthma has been increasing for the past three decades. The prevalence of asthma in the United States is 8.2%

of the adult population and 9.5% of children. It occurs at all ages, with a peak in children aged 5 to 9 years. In childhood, there is a 10:7 male/female preponderance, which is reversed in adulthood (6.5:10 male/female).

The greatest modifiable risk factor for asthma is smoking. Nonmodifiable risk factors include income (inversely proportional), ethnicity (Whites and Hispanics have a reduced risk, increased prevalence in African Americans), and environmental exposure.

In the United States, deaths from asthma are rare, with an age-adjusted rate of 11 per million in 2010. However, the annual rate of death from asthma is approximately 15-fold higher in adults older than 65 years than in children (37.2 vs. 2.6 per million).

COPD affects more than 200 million people in the world. In the United States, 14.1% of smokers carry a diagnosis of COPD, 7.1% of former smokers, and 2.9% of never smokers. The majority (71.2%) of COPD patients carry the diagnosis of at least one comorbidity and have a significantly higher rate of hyperlipidemia, hypertension, coronary artery disease, diabetes, cancer, stroke, and chronic kidney disease than patients without COPD.

A.3. What is the etiology of asthma?

Asthma is a heterogeneous disease with complex, multifactorial etiologies. The common denominator that underlies the asthmatic diathesis is a nonspecific hyperirritability of the tracheobronchial tree. Although asthma can be subdivided according to several clinical, physiologic, and pathologic variables, traditionally asthma is classified into two groups: atopic (allergic, extrinsic) and nonatopic (nonallergic, intrinsic). Atopic asthma is usually associated with a personal or family history of allergic diseases, positive skin reactions to extracts of airborne antigens, and increased levels of immunoglobulin E (IgE) in the serum. Most patients with asthma have the atopic type. Patients with nonatopic asthma have negative skin tests to common inhalant allergens and normal serum concentrations of IgE. The patients with nonatopic asthma usually show later onset of disease, and may be aspirin-sensitive.

A.4. Discuss the pathogenesis of asthma. How is asthma distinguished from COPD?

Asthma is a chronic disease characterized by reversible expiratory airflow obstruction resulting from narrowing of the airways in response to various stimuli and a nonspecific hyperirritability of the tracheobronchial tree.

COPD is characterized by persistent respiratory symptoms and airflow limitation that is not fully reversible.

In asthma, exposure to an initiating stimulus triggers inflammatory cells (mast cells, eosinophils, T lymphocytes, macrophages, basophils, neutrophils, and platelets) and

structural cells (epithelial cells, fibroblasts, and airway smooth muscle cells) to release various mediators that lead to bronchospasm, vascular congestion, increased capillary permeability (edema of bronchial mucosa), and thick tenacious secretions.

The net result is a reduction in airway diameter, an increase in airway resistance, decreased forced expiratory volumes and flow rates, hyperinflation of the lungs and thorax, increased work of breathing, alterations in respiratory tract muscle function, mismatched ventilation/perfusion, and altered blood gases.

In COPD, goblet cell hypertrophy, activation of inflammatory cells (lymphocytes, neutrophils, and macrophages), and alteration in function of structural cells lead to increased mucus production, airway fibrosis, loss of alveolar attachments, and pulmonary vascular remodeling. The net result is hypersecretion of mucus, emphysema with peripheral airway collapse, impaired gas exchange, pulmonary hypertension, and right ventricular dysfunction. The minority of COPD cases are a result of a genetic deficiency in antitrypsin levels, leading to an imbalance between antiproteinases and increased lung parenchymal destruction.

Although asthma and COPD are distinct syndromes, some patients, such as this patient with extensive smoking history, have features of COPD, such as irreversible airflow limitation. Additionally, although airway hyperresponsiveness to a variety of exogenous stimuli is one of the defining features of asthma, many patients with COPD also have airway hyperresponsiveness.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:1957–1969, 1990–1998.

A.5. What are the triggers of bronchospasm?

- *Allergens*. Inhaled allergens activate mast cells with bound IgE directly leading to the immediate release of bronchoconstrictor mediators. This early response is reversed by bronchodilators. Common allergens are house dust mites (*Dermatophagoides* species), pet dander, grass pollen, ragweed, and tree pollen.
- *Infections*. Respiratory tract infections are among the most common triggers of acute severe asthma exacerbations.
- *Pharmacologic agents*. Drugs that can trigger bronchospasm include β-adrenergic antagonists, aspirin and other NSAIDs, and sulfiting agents (food preservatives). All nonspecific β-blockers should be avoided in asthmatics because their use can lead to severe bronchospasm. The ultra–short-acting β_1 selective antagonists landiolol and esmolol can be safely used perioperatively in patients with airway hyperreactivity. Aspirin-sensitive asthma is a well-defined phenotype of asthma that affects a small proportion of asthmatics. Because asthma can be triggered by cyclooxygenase (COX)-1 inhibitors, all nonselective COX inhibitors (aspirin, ibuprofen, ketorolac) should be avoided, but selective COX-2 inhibitors (celecoxib) are safe to use. Theoretically, reversal of neuromuscular blockade with anticholinesterase drugs could precipitate bronchospasm due to stimulation of postganglionic cholinergic receptors in airway smooth muscle. Adequate dosing of a concomitant anticholinergic is necessary to avoid this complication. Alternatively, sugammadex may be used for reversal of rocuronium-induced neuromuscular blockade.
- *Environment and air pollution*. Increased levels of sulfur dioxide, ozone, diesel particulates, and nitrogen oxides are associated with increased asthma symptoms. Dry, cold air can also trigger bronchospasm in susceptible individuals.
- *Occupational factors*. Various compounds used in industry

can cause asthma in susceptible individuals. Various names have been applied to this condition, such as meat wrapper's asthma, baker's asthma, and woodworker's asthma.

- *Exercise*. Asthma can be induced or made worse by physical exertion. The mechanism is linked to hyperventilation, which results in increased osmolality in airway lining fluid and triggers mast cell mediator release, resulting in bronchoconstriction.
- *Emotional stress*. Psychological factors can induce bronchoconstriction through the cholinergic reflex pathway.

A.6. What is the universal finding in ABGs during asthmatic attacks: hypoxemia or CO_2 retention?

Hypoxemia is a universal finding during asthmatic attacks. Frank ventilatory failure with CO_2 retention is relatively uncommon because CO_2 has a diffusion capacity that is 20 times higher than that of oxygen. During acute asthmatic attacks, most patients try to overcome airway obstruction and hypoxia by hyperventilation. This results in hypocarbia and respiratory alkalosis. CO_2 retention is a late finding and indicates severe and prolonged airway obstruction, as in status asthmaticus.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:15–32.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:1957–1969.

A.7. Describe the abnormalities seen in spirometry, lung volumes, and lung capacities during an asthmatic attack.

There is a substantial reduction in forced expiratory volume in 1 second (FEV_1) but less reduction in forced vital capacity (FVC), giving a decreased FEV_1/FVC ratio. Forced expiratory flow at 25% to 75% ($FEF_{25\%–75\%}$) is sharply reduced as well. $FEF_{25\%–75\%}$ (also referred to as the maximum midexpiratory flow rate or MMEFR) is the forced expiratory flow rate during 25% to 75% of the vital capacity (VC). Unlike the FEV_1, the $FEF_{25\%–75\%}$ is independent of patient effort. Other classic spirometry findings include a decreased expiratory reserve volume (ERV), whereas the residual volume (RV), FRC, and total lung capacity (TLC) are increased.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient preoperatively? What preoperative workup would you order?

Preoperative evaluation of patients with asthma and COPD focuses on the assessment of disease severity, the effectiveness of current medical management, and the potential need for additional therapy before surgery. The history should include assessment of exercise tolerance, recent or current respiratory

infections, sputum quantity and quality, known triggers of attacks, most recent exacerbations, current medications and time of last use, smoking history, and prior surgical and anesthetic history.

A focused cardiopulmonary exam should occur, which should focus on detecting signs of acute bronchospasm, active lung infection, and right heart failure. Note the patient's general appearance and observe the patient's breathing. Look for use of accessory muscles, pursed-lip exhalation, or cyanosis. Auscultation of the lungs can reveal wheezing, adventitious lung sounds, and hyperinflation. Auscultation of the heart may reveal a split second heart sound typical of cor pulmonale or the murmur of tricuspid or pulmonary regurgitation present in some patients with long-standing pulmonary hypertension. Additionally, jugular venous distension, peripheral edema, and hepatic enlargement may be present. Cachexia may also be seen.

Laboratory testing is guided by the history and physical examination. For major surgery, it is reasonable to obtain a complete blood count, serum electrolytes, electrocardiogram, and chest radiograph. Additionally, these patients should have a room air Spo_2. It is not recommended to routinely perform pulmonary function tests. However, if the worsening of disease severity is elicited from the history and physical examination, additional diagnostic tests may include a computed tomography scan of the chest, echocardiogram, detailed lung volume testing, and a room air ABG.

B.2. How would you distinguish obstructive lung disease from restrictive lung disease by spirometry?

Table 1.1 summarizes the distinctions between the two types of lung diseases. In restrictive lung disease (e.g., pulmonary fibrosis and ankylosing spondylitis), the FVC is low because of limited expansion of the lungs or chest wall, although the FEV_1 is often not reduced proportionately, because airway resistance is normal. Therefore, the FEV_1/FVC percentage is normal or high.

TABLE 1.1 Differences between Obstructive and Restrictive Lung Diseases

	Obstructive	Restrictive
Vital capacity	N or ↓	↓
Total lung capacity	N or ↓	↓
Residual volume	↑	↓
FEV_1/FVC	↓	N or ↑
Maximum midexpiratory flow rate	↓	N
Maximum breathing capacity	↓	N

↓, decreased; ↑, increased; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; N, normal.

In obstructive lung disease, the FEV_1/FVC is grossly reduced because the airway resistance is high. Normally, FEV_1 is more than 80% of FVC, and VC should be more than 80% of predicted value. The predicted values depend on body size, age, and sex. The FEV_1/FVC is less than 0.70 in COPD. The severity of airflow limitation in COPD is determined by the FEV_1. Patients with an FEV_1 less than predicted but greater than or equal to 80% of predicted are considered to have mild COPD (Global Initiative for Chronic Obstructive Lung Disease [GOLD] 1). Those with FEV_1 greater than or equal to 50% but less than 80% of predicted are classified as having moderate

COPD (GOLD 2). Severe cases of COPD have an FEV_1 that is greater than or equal to 30% but less than 50% of predicted (GOLD 3). Finally, patient with an FEV_1 that is less than 30% of predicted have very severe COPD (GOLD 4).

The TLC is increased in obstructive lung disease and decreased in restrictive lung disease. However, TLC cannot be obtained by routine screening spirometry.

B.3. Define normal lung volumes and lung capacities. Give normal values for an average adult male.

There are four basic "volumes" and four derived "capacities" that are combinations of these volumes (**Fig. 1.1**).

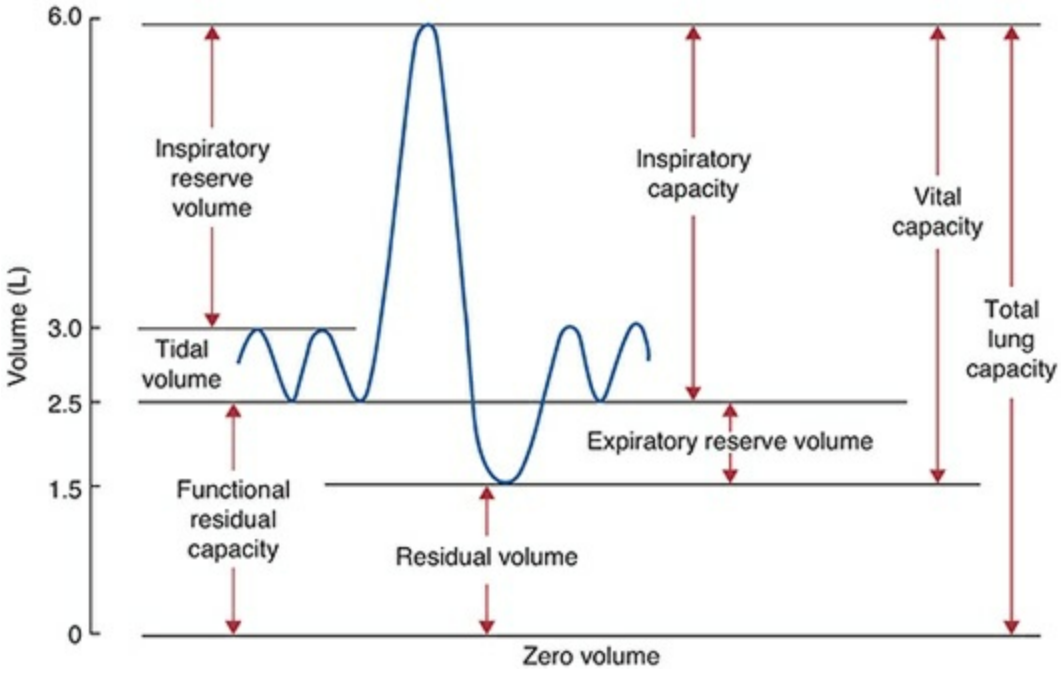

FIGURE 1.1. Lung volumes and lung capacities.

V_T is the volume of air inhaled or exhaled during normal breathing. Normal V_T is 500 mL or approximately 6 to 8 mL per kg.

Inspiratory reserve volume (IRV) is the maximum volume of gas that can be inhaled following a normal inspiration while at rest. Normal IRV is 2,500 to 3,500 mL.

ERV is the maximum volume of gas that can be exhaled after a normal expiration. Normal ERV is 1,200 mL.

RV is the volume of gas remaining in the lungs after a forced exhalation. Normal RV is 1,200 mL.

VC is the maximum amount of gas that can be exhaled after a maximum inhalation. VC is the sum of V_T, ERV, and IRV. Normal VC is 4,500 mL or approximately 60 to 70 mL per kg.

Inspiratory capacity (IC) is the maximum amount of gas that can be inhaled from the resting expiratory position after a normal exhalation. It is the sum of V_T and IRV. Normal IC is 3,500 mL.

FRC is the remaining lung volume at the end of a normal quiet expiration. It is the sum of RV and ERV. Normal FRC is 2,500 mL or 30 to 40 mL per kg.

TLC is the lung volume at the end of a maximum inspiration. It is the sum of VC and RV. Normal TLC is 5,000 to 6,000 mL for an adult man and 4,000 to 5,000 mL for an adult woman.

B.4. What are flow–volume loops? Draw flow–volume

loops for a healthy subject and patients with COPD, restrictive lung disease, fixed obstruction of the upper airway, variable extrathoracic obstruction, and variable intrathoracic obstruction.

Flow–volume loops provide a graphic analysis of flow at various lung volumes. To perform the test, subjects are asked to inhale maximally (to TLC) and then exhale as forcefully and maximally as possible (to RV). This cycle is repeated. The flow (liters per second) is plotted on the y-axis and volume (liters) on the x-axis (**Fig. 1.2A**). The test requires a compliant patient for accurate results—the majority of the test is effort dependent, including the entire inspiratory curve and both ends of the expiratory curve (near TLC and RV). The forced expiratory flow during 25% to 75% of VC ($FEF_{25\%–75\%}$) is reflective of the small- to medium-sized airways and is considered a relatively effort-independent value.

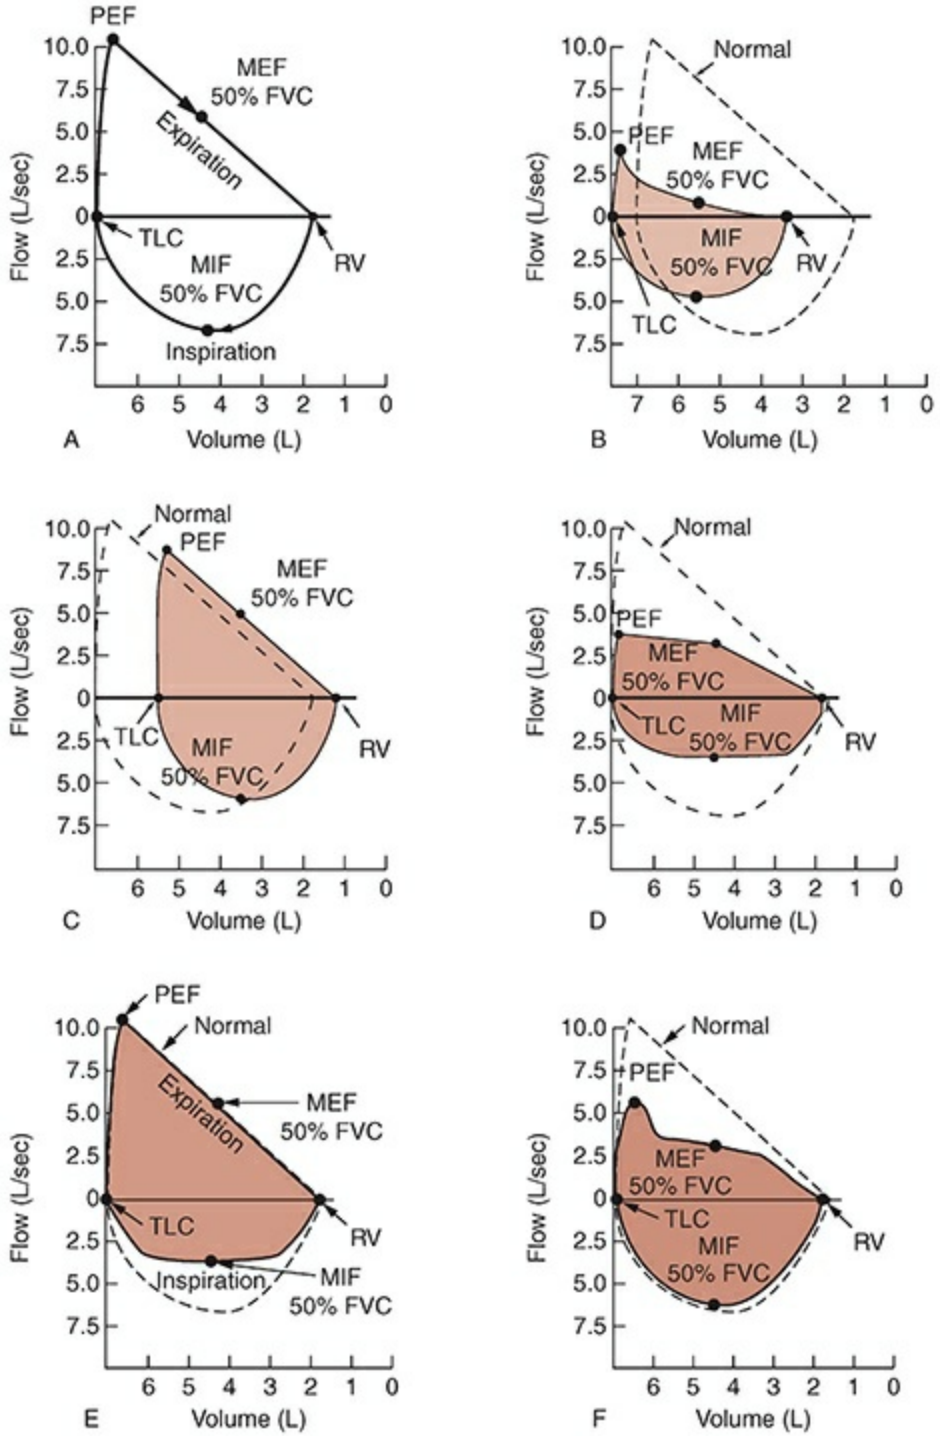

FIGURE 1.2. Flow–volume loops in a healthy person (A), a patient with obstructive lung disease (B), a patient with restrictive lung disease (C), a patient with a fixed obstruction (D), a patient with a variable extrathoracic obstruction (E), and a patient with a variable intrathoracic obstruction (F). FVC, forced vital capacity; MEF, maximal expiratory flow; MIF, maximal inspiratory flow; PEF, peak expiratory flow; RV, residual volume; TLC, total lung capacity. (*From the Merck Manual Professional Version [known as the Merck Manual in the United States and Canada and the MSD Manual in the rest of the world], edited by Robert Porter. Copyright 2019 by Merck Sharp &*

Dohme Corp., a subsidiary of Merck & Co, Inc, Kenilworth, NJ. Available at http://www.msdmanuals.com/professional. *Accessed November 11, 2014.*)

Normal flow–volume loop (**Fig. 1.2A**). Inspiratory limb of loop is symmetric and convex. Expiratory limb is linear. Airflow at the midpoint of IC and airflow at the midpoint of expiratory capacity are often measured and compared. Maximal inspiratory flow (MIF) at 50% FVC is greater than maximal expiratory flow (MEF) at 50% FVC because dynamic compression of the airways occurs during exhalation.

Obstructive disorder (e.g., emphysema, asthma) (**Fig. 1.2B**). Although all airflow is diminished, expiratory prolongation predominates, and MEF < MIF. Peak expiratory flow (PEF) is sometimes used to estimate degree of airway obstruction but depends on patient effort.

Restrictive disorder (e.g., interstitial lung disease, kyphoscoliosis) (**Fig. 1.2C**). The loop is narrowed because of diminished lung volumes. Airflow is greater than normal at comparable lung volumes because the increased elastic recoil of lungs holds the airways open.

Fixed obstruction of the upper airway (e.g., tracheal stenosis, goiter) (**Fig. 1.2D**). The top and bottom of the loops are flattened so that the configuration approaches that of a rectangle. Fixed obstruction limits flow equally during inspiration and expiration, and MEF = MIF.

Variable extrathoracic obstruction (e.g., unilateral vocal cord paralysis, vocal cord dysfunction) (**Fig. 1.2E**). When a single vocal cord is paralyzed, it moves passively with pressure gradients across the glottis. During forced inspiration, it is drawn inward, resulting in a plateau of decreased inspiratory flow. During forced expiration, it is passively blown aside, and expiratory flow is unimpaired. Therefore, MIF 50% FVC < MEF 50% FVC.

Variable intrathoracic obstruction (e.g., tracheomalacia) (**Fig.**

1.2F). During a forced inspiration, negative pleural pressure holds the floppy trachea open. With forced expiration, loss of structural support results in tracheal narrowing and a plateau of diminished flow. Airflow is maintained briefly before airway compression occurs.

B.5. Define closing volume (CV) and closing capacity (CC). What is the normal value of CV?

CC is the lung volume at which the small airways in the dependent parts of the lung begin to close. CC is the sum of CV and RV. CV is the volume above the RV at which small airways begin to close during expiration. It can be measured during the single-breath nitrogen test (Fig. 1.3) or with an inert tracer gas such as helium, xenon, or argon.

In healthy young people, CV is approximately 10% of the VC, or 400 to 500 mL. CV and CC increase with age. CV is increased in patients with small airway disease and in chronic smokers.

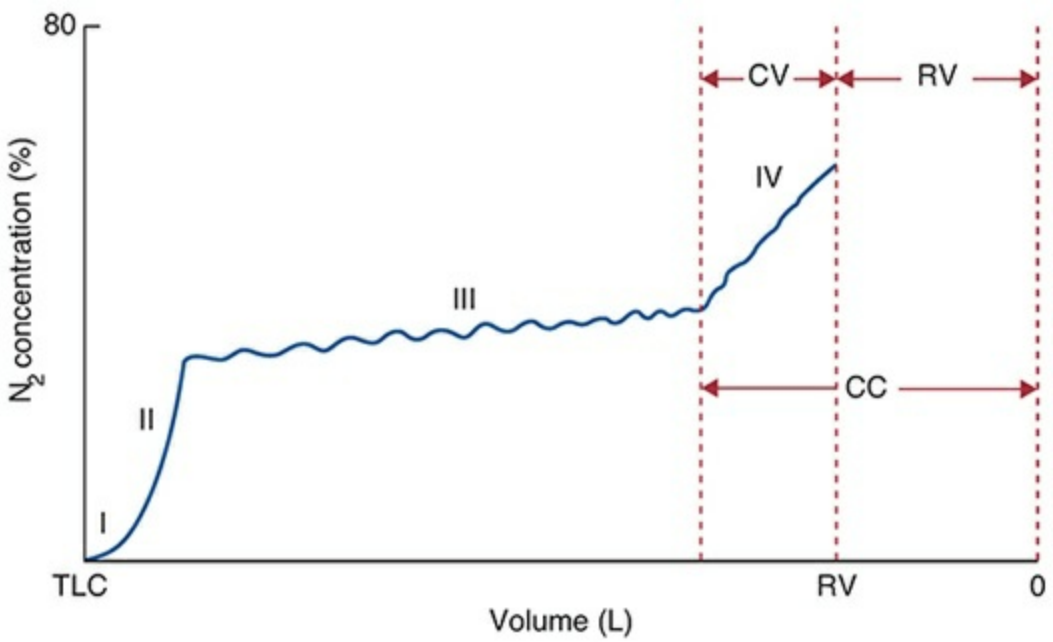

FIGURE 1.3. Closing volume (CV) measurement by single-breath nitrogen test. CC, closing capacity; RV, residual volume; TLC, total lung capacity.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:26–29.

B.6. Why is the functional residual capacity (FRC) important in oxygenation?

In a healthy young adult, FRC is above CC (FRC > CV + RV). Increases in CC and/or decreases in FRC can result in CC exceeding FRC and subsequent closure of the small airways during certain periods of normal tidal ventilation. Airway closure produces shunting, with perfusion of unventilated alveoli. Therefore, shunt ($\dot{Q}_S/\dot{Q}_T$) is increased and arterial oxygenation is decreased.

Perfusion to the lung occurs in both inspiratory and expiratory phases of respiration. The FRC, or lung volume remaining at end expiration, provides surface area for gas exchange during this phase of respiration. The greater the FRC, the more oxygenation occurs. Patients in the supine position, under

general anesthesia, or with acute respiratory distress syndrome all have decreased FRC to varying degrees. PEEP increases FRC, improving oxygenation in the expiratory phase and reducing small airway collapse.

FRC can be measured by helium dilution, nitrogen washout, or body plethysmography.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:37–38.

B.7. How are FRC and CC affected by age and posture? How are they affected by anesthesia?

Posture has a dramatic effect on FRC. When a patient goes from upright to the supine position, FRC decreases approximately 30%. Body position does not affect CC.

Conversely, age has a greater effect on CC than on FRC. CC increases with age, whereas FRC does not change or increases only slightly. Therefore, CC will exceed FRC in healthy adults over the age of 44 years when in the supine position and in healthy adults over the age of 70 years in the upright position.

During general anesthesia, FRC is reduced approximately 20%, whether breathing is controlled or spontaneous. The anatomic basis of the FRC reduction under anesthesia is not well understood. Traditionally, it was thought to be due to the cephalad shift of the diaphragm, induced by anesthesia and muscle paralysis. Although the role of the anatomic position of the diaphragm remains debatable, the current understanding is that FRC is reduced due to loss of respiratory muscle tone.

CC was previously reported to be unchanged during anesthesia, but later studies concluded that CC reduced in parallel to FRC during anesthesia.

B.8. Give the equations for shunt (Qs/Qt) and dead space/tidal volume (Vd/Vt). What are their normal values?

$$\text{QS/QT} = \frac{\text{CcO}_2 - \text{CaO}_2}{\text{CcO}_2 - \text{C}\bar{\text{v}}\text{O}_2} \qquad \text{VD/VT} = \frac{\text{PaCO}_2 - \text{P}\bar{\text{E}}\text{CO}_2}{\text{PaCO}_2}$$

where CcO_2, CaO_2, and $C\bar{v}O_2$ are oxygen contents in pulmonary capillary, arterial, and mixed venous blood, respectively; QT is cardiac output; QS is shunt blood; and $PaCO_2$ and $P\bar{E}CO_2$ are partial pressures of CO_2 in arterial blood and the mixed expired gases, respectively.

Normal QS/QT is 4% to 5%, and VD/VT is approximately 0.3.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:122–124.

B.9. Interpret the following ABG: pH, 7.36; PCO_2, 60 mmHg; PO_2, 70 mmHg; and CO_2 content, 36 mEq per L.

The fraction of inspired oxygen (FIO_2) is essential to evaluate PaO_2. Assume the blood sample is obtained while the patient is

breathing room air. The blood gases show mild hypoxemia and respiratory acidosis, compensated by metabolic alkalosis. The blood gases are compatible with COPD.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:1990–1998.

B.10. What are the common physiologic causes of hypoxemia?

From the shunt equation, arterial oxygen content is related to the change in pulmonary capillary oxygen content, venous oxygen content, and venous admixture. It is easier to classify hypoxemia into the following three categories.

Decreased pulmonary capillary oxygen tension

- Hypoventilation
- Low F_{IO_2}
- Ventilation/perfusion mismatch from pulmonary parenchymal change
- Diffusion abnormality (rare)

Increased shunting

- Either intrapulmonary or cardiac

Reduced venous oxygen content

- Congestive heart failure—low cardiac output
- Increased metabolism—fever, hyperthyroidism, shivering
- Decreased arterial oxygen content—anemia

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:354–383, 2592–2593.

Jameson JL, Fauci AS, Kasper DL, et al, eds. *Harrison's Principles of Internal Medicine*. 20th ed. New York: McGraw-Hill; 2018:234–236.

B.11. How would you prepare this asthmatic patient with COPD for surgery?

The goal of preoperative preparation is to optimize the patient for surgery and to decrease the risk of postoperative pulmonary complications (PPCs). This patient's risk factors for PPCs include preexisting pulmonary disease, cigarette smoking, abdominal surgery, and general anesthesia.

Preoperative strategies that have proven to reduce PPC rates include smoking cessation (see section B.12), optimizing airflow limitation in patients with obstructive lung disease (such as this patient), and treating respiratory tract infections, if present.

The severity of airflow limitations is assessed during preoperative evaluation and laboratory and diagnostic studies (see section B.1). Airflow limitation can be optimized by continuation of anti-inflammatory and bronchodilator therapy up to the time of surgery. Additional therapy, such as systemic corticosteroids may need to be initiated in patients with poorly controlled symptoms.

Elective surgery should not be performed in the presence of active respiratory infection and symptoms should be actively treated until the patient is back to baseline status.

Additionally, preoperative lung expansion maneuvers, such as deep breathing exercises, incentive spirometry, and chest physiotherapy are of proven benefit in reducing PPC rates.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:15–32.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

B.12. The patient comes to your perioperative clinic 2 weeks before surgery. He wants to know if his smoking puts him at increased risk during surgery. What do you tell him? Should he quit now?

Smoking results in increased levels of carboxyhemoglobin, lower oxygen content, and decreased delivery of oxygen by hemoglobin to the tissues. These effects are dramatically improved with as little as 12 hours of smoking cessation.

Smoking also increases the risk of PPCs, which include respiratory failure, unplanned intensive care unit (ICU) admission, pneumonia, airway events during anesthesia, and increased need for postoperative respiratory support. Smokers have an increased rate of wound-related complications and decreased bone healing after surgery. Although a cessation period of at least 8 weeks prior to surgery is optimal and results in improved mucociliary clearance, decreased sputum production, and a relative risk reduction in PPCs, it is highly recommended for patients to stop smoking at any time prior to surgery.

A persistent misconception in our specialty is that short-term smoking cessation (<4 weeks) is detrimental to the patient. Some have argued that a patient smoking 2 weeks before surgery should continue smoking to avoid *increased* risks associated with cessation. There is now a preponderance of evidence that debunks this myth. Short-term smoking cessation is *not* a risk factor for long-term perioperative complications. In contrast, the long-term detrimental effects of continued smoking are well known. Anesthesiologists should be aware that admission for surgery can be a powerful motivator for patients to quit smoking, providing a "teachable moment" for smoking cessation and frequently resulting in successful, long-term cessation. Therefore, this patient should be counseled to quit smoking as soon as possible.

B.13. You discover that the patient had a recent upper respiratory infection (URI), would you postpone surgery? For how long?

Respiratory tract infections are the most common stimuli that trigger acute exacerbations of asthma. Even healthy subjects have transiently increased airway responsiveness to nonspecific stimuli following a viral infection. It is unclear how long surgery should be delayed following a URI because airway hyperreactivity can last 2 to 8 weeks after the infection in both healthy subjects and patients with asthma. Cohen and Cameron reported that a child with a URI having endotracheal anesthesia has an 11-fold increased risk of respiratory complications. In addition, Tait and Knight found that laryngospasm and bronchospasm were significantly increased in healthy children 2 weeks after a URI. However, the data are controversial. A frequently cited retrospective study by Warner et al. found no increase in intraoperative bronchospasm in patients with well-controlled asthma and a recent URI.

In this patient presenting for elective surgery with multiple risk factors for PPCs, postponing surgery at least 2 weeks after clinical recovery from the URI is reasonable.

B.14. What medications would you expect the patient to have taken in the past or be taking at the present time?

The main drugs for asthma and COPD can be divided into rescue medications (bronchodilators) and controllers (for maintenance).

Patients with infrequent asthma symptoms are placed solely on a short-acting β_2-agonist (SABA). Alternatively, anticholinergic inhalers such as ipratropium may be given, although their slower onset of action makes them less preferred.

Patients with increased risk for exacerbations (including smokers) and/or those with frequent symptoms should be placed on controller therapy with a low-dose inhaled corticosteroid (ICS). In patients with severe symptoms, a long-acting β_2-agonist or a high-dose ICS are added. Acute exacerbations are treated with a short course of oral corticosteroids.

Theophylline was a widely prescribed oral controller medication for asthma but has fallen out of favor secondary to its narrow therapeutic index, multiple drug interactions, and side effect profile. It may be prescribed in patients with COPD. Patients taking theophylline require routine level testing. They should continue theophylline in the perioperative period to avoid an asthma or COPD exacerbation secondary to withdrawal.

Other oral medications targeting the inflammatory component of asthma include the mast cell stabilizer cromolyn, the anti-IgE antibody omalizumab, and leukotriene receptor antagonists such as zafirlukast and montelukast. The phosphodiesterase-4 inhibitor roflumilast may be added to the treatment regimens of patients with severe COPD.

B.15. The patient was on 20 mg of prednisone per day for 5 days as part of the treatment of an asthma exacerbation 3 months ago. He is currently not on steroids. Should the patient receive stress-dose steroids?

Patients on chronic steroid therapy may experience hypothalamic-pituitary-adrenal (HPA) axis suppression that can result in decreased cortisol (hydrocortisone) production, a process known as secondary adrenal insufficiency. The concern is that inadequate cortisol production in response to the stress of surgery can manifest as full-blown adrenal crisis in the perioperative period. The anesthesiologist must decide whether to administer stress-dose steroids to mitigate this rare but potentially life-threatening complication of chronic steroid use. However, the decision is not always clear-cut because even the recommendations found in most textbooks are inconsistent and lacking in class A and B evidence. Additionally, there is no universally agreed on dose or duration of exogenous steroids required to cause HPA axis dysfunction, although prednisone 20 mg per day for 2 weeks within the previous 6 months has been cited.

Given this patient's short duration of prednisone treatment, he should not require administration of stress-dose steroids. However, 100 mg of hydrocortisone intravenous (typical stress-dose for this type of surgery) should be available in the

operating room in case hypotension attributable to adrenal insufficiency occurs during surgery.

Another consideration is whether the patient will receive prophylaxis for postoperative nausea/vomiting (PONV) with dexamethasone. Dexamethasone has 30 times glucocorticoid potency of hydrocortisone, so even a modest PONV dose of 4 mg of dexamethasone is equivalent to the usual stress dose of hydrocortisone. Because there is no mineralocorticoid deficiency in secondary adrenal insufficiency, dexamethasone's absence of mineralocorticoid activity is not an issue.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

B.16. Should patients with reactive airway disease receive preoperative steroids?

The increasing understanding of the inflammatory component of reactive airway disease has led to greater appreciation of the importance of steroids in preventing and treating exacerbations. In wheezing patients, oral methylprednisolone 40 mg daily for 5 days before surgery has been shown to decrease postintubation bronchospasm. The oft-cited concern that steroids increase the rate of wound complications is not well founded. A study of patients with asthma treated with steroids preoperatively found no increase in the incidence of wound infections or wound-healing problems.

Patients with poorly controlled asthma presenting for surgery with high risk of PPCs (open aortic aneurysm repair, thoracic, upper abdominal) that will require endotracheal intubation must be treated with utmost caution, and may benefit from

preoperative optimization of pulmonary function with a short course of systemic steroids. On the other hand, patients with mild, well-controlled disease should not require such treatment.

B.17. What is the onset of action of intravenous steroid therapy in asthma?

Parenteral steroids remain a mainstay of the treatment of acute asthma. Although the bronchial effects of intravenous steroids are not immediate and are typically seen 4 to 6 hours after initial administration, their administration is nonetheless indicated with severe bronchospasm that has not resolved despite intense optimal bronchodilator therapy.

C. Intraoperative Management

C.1 If the patient had a severe asthmatic attack in the operating room before the induction of anesthesia, would you proceed with the anesthetic or postpone the surgery?

First, medical treatment should be given to relieve the asthmatic

attack. Elective surgery should be postponed, the patient reevaluated carefully, and his asthma better optimized. In the case of emergency surgery, such as acute appendicitis, the surgery can be performed after the asthmatic attack is successfully treated. Regional anesthesia, if feasible, should be considered. During surgery, the medical treatment should be continued.

Dewachter P, Mouton-Faivre C, Emala CW, et al. Case scenario: bronchospasm during anesthetic induction. *Anesthesiology*. 2011;114:1200–1210.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

C.2. The patient did not have an asthmatic attack in the operating room and you proceed with induction. How would you induce anesthesia? Would you use a supraglottic airway instead of an endotracheal tube?

The principles of anesthetic management for the asthmatic patient are threefold: to block airway reflexes before laryngoscopy and intubation, to relax airway smooth muscle, and to prevent release of biochemical mediators.

Before induction of general anesthesia, the patient should take two or three puffs of albuterol from a metered-dose inhaler (MDI). Propofol is often used for induction of hemodynamically stable asthmatic patient. Ketamine may be chosen in a hemodynamically unstable patient with asthma (see sections C.3 and C.4). Then, oxygen and a potent inhalation agent, such as sevoflurane, are administered by mask to achieve an adequate depth of anesthesia that suppresses hyperreactive airway reflexes sufficiently to permit tracheal intubation without triggering bronchospasm. The lesser pungency of sevoflurane (compared with desflurane and isoflurane) may decrease the likelihood of coughing, which can induce bronchospasm.

Muscle relaxants that do not release histamine, such as cisatracurium and rocuronium, can be used to facilitate endotracheal intubation. Prior to intubation, lidocaine may be administered (see section C.5).

Avoidance of intubation altogether is another approach. A supraglottic airway provides a unique opportunity for the clinician to control the airway without having to introduce a foreign body into the trachea. Kim and Bishop demonstrated a reversible increase in airway resistance in intubated patients under isoflurane anesthesia and showed that this increase was not present with supraglottic airway use. Therefore, it may be an ideal airway tool in the patient with asthma not at risk for reflux and aspiration.

Laparoscopic surgeries using a supraglottic airway have been reported by multiple centers for both gynecologic surgeries and cholecystectomies. Insufflation of the abdomen and manipulation of the bowel places these patients at increased aspiration risk. However, the use of a specialized supraglottic airway such as LMA ProSeal can mitigate these effects by allowing for placement of an orogastric tube for drainage of the stomach and a larger cuff size that reduces both the risk for gastric inflation and aspiration of refluxed gastric contents.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

C.3. Would you use propofol for induction of anesthesia?

Propofol may be the induction agent of choice for the hemodynamically stable patient with reactive airways. In comparison to induction with thiopental, thiamylal, or methohexital, 2.5 mg per kg propofol induction resulted in a significantly lower incidence of wheezing after tracheal intubation in asthmatic patients. The incidence of wheezing was 0%, 45%, and 26% in patients who received propofol, a thiobarbiturate, and oxybarbiturate, respectively. Another study in unselected patients found a significantly lower respiratory resistance after tracheal intubation following induction with propofol than with thiopental or etomidate. Nevertheless, propofol-induced bronchospasm has been reported in patients with allergic rhinitis and should be used with caution in patients with a high allergic component.

Eames WO, Rooke GA, Wu RS, et al. Comparison of the effects of etomidate, propofol, and thiopental on respiratory resistance after tracheal intubation. *Anesthesiology*. 1996;84:1307–1311.

Pizov R, Brown RH, Weiss YS, et al. Wheezing during induction of general anesthesia in patients with and without asthma. A randomized, blinded trial. *Anesthesiology*. 1995;82:1111–1116.

C.4. Would you use thiopental, methohexital, etomidate, or ketamine for induction?

Thiopental and thiamylal are thiobarbiturates that have been demonstrated to release histamine. Methohexital and pentobarbital are oxybarbiturates that have not been shown to release histamine. This suggests that the sulfur atom is important in barbiturate-induced histamine release. Moreover, thiobarbiturates, but not oxybarbiturates, have been shown to lead to a thromboxane-mediated tracheal constriction in guinea pigs. For these reasons, methohexital may be preferred as the

induction agent in patients with extreme sensitivity to histamine (asthmatics) or increased histamine releasability (atopics).

Because it provides only a light plane of anesthesia, airway instrumentation under thiopental anesthesia alone may trigger bronchospasm. However, it may be used cautiously in asthmatics provided that an adequate depth of anesthesia is achieved before airway stimulation.

Etomidate has not been shown to release histamine, does not depress myocardial function, and provides hemodynamic stability in critically ill patients. Both etomidate and thiopental afford no protection against wheezing after intubation and are therefore inferior to propofol in this regard.

Ketamine produces bronchodilation both through neural mechanisms and through release of catecholamines. In an actively wheezing patient, ketamine is the induction agent of choice, particularly with unstable hemodynamics.

C.5. Would you administer lidocaine for intubation?

The administration of intravenous lidocaine 1 to 1.5 mg per kg several minutes prior to intubation to prevent reflex-induced bronchospasm is a long-standing practice. However, some caution is required, as paradoxical bronchospasm has been demonstrated in patients with asthma. It appears that while intravenous lidocaine reduces airway responsiveness to drugs and stimuli that cause bronchospasm, lidocaine on its own does not reduce baseline airway tone, and may actually increase it.

Therefore, intravenous lidocaine should be administered with care in these patients.

Alternatively, topical endotracheal spray of lidocaine can be used. However, inhalation of lidocaine is itself irritating and can *provoke* bronchospasm in a patient with asthma. If lidocaine spray is used to tropicalize the airway, an adequate depth of anesthesia should be achieved before lidocaine is administered.

C.6. If this is an emergency surgery and rapid sequence induction is indicated, how would you induce anesthesia in this patient?

All the precautions to prevent aspiration of gastric contents and asthmatic attack must be considered simultaneously. Rapid sequence induction and tracheal intubation is necessary to prevent aspiration. However, light anesthesia may precipitate severe bronchospasm.

Prior to induction, inhalation of β_2-agonists such as albuterol should be administered. The patient should then be adequately denitrogenated with 100% oxygen administered by mask. Preoxygenation is particularly important because mask ventilation is usually not performed in rapid sequence induction.

Preoxygenation is administered for three minutes of normal V_T breathing, or for eight deep breaths over 1 minute.

Propofol is the induction agent of choice in a hemodynamically stable patient with asthma. Ketamine and etomidate are alternatives to propofol in a patient at risk of hemodynamic instability. It is important to note that in a patient with depleted sympathetic reserve, ketamine administration may result in hypotension.

Intravenous lidocaine is a useful adjunct drug to prevent reflex bronchospasm, particularly in emergency situations when deep anesthesia cannot be achieved before intubation (see section C.5).

Traditionally, opioids were not used as part of rapid sequence induction. However, opioids reduce cardiovascular effects associated with laryngoscopy and suppress cough reflex. They also reduce the dose of induction agent required to achieve adequate depth of anesthesia. Therefore, administration of opioids that do not release histamine, such as fentanyl and remifentanil, should be considered.

Muscle relaxant is administered after the induction agent to achieve optimal intubating conditions. Unless contraindicated, succinylcholine should be used because it provides excellent intubating conditions within 30 to 60 seconds of administration. Rocuronium 1.2 mg per kg is an alternative to succinylcholine but results in much longer neuromuscular block.

In a patient with asthma, efforts to achieve adequate depth of anesthesia necessary to minimize bronchospasm may result in hypotension. Therefore, medications to treat hypotension, such as phenylephrine, should be immediately available.

C.7. Could a regional technique be used for this surgery? Discuss the advantages and disadvantages of neuraxial anesthesia in this patient for this surgery.

For laparoscopic surgery, regional anesthesia can be used. Typically, this is performed with epidural or combined spinal–epidural anesthesia, which allows for repeated dosing to obtain an adequate level and duration of anesthesia. Laparoscopic surgery requires a T4 to T5 dermatomal level. Even with adequate analgesia to this dermatome, patients will often complain of shoulder pain, which can be treated with intravenous narcotic administration. The advantages of regional anesthesia include the avoidance of instrumenting the airway, a decrease in the resultant risk of bronchospasm, and the ability to maintain the epidural postoperatively to reduce or even eliminate the need for postoperative narcotics.

However, the high level required for laparoscopic surgery has multiple effects on the respiratory system. First, patients with a high blockade lose sensory input from chest wall movement, and patients feel dyspneic, even in the presence of normal respiratory function. This feeling of dyspnea can be anxiety producing and in a patient with asthma can lead to bronchospasm.

More important, however, high levels of neuraxial anesthesia should be avoided in patients with severe respiratory disease who require accessory muscle contribution in order to maintain adequate ventilation. These patients will have reduced

expiratory flow and minute ventilation under high neuraxial blockade and can become hypoxic and hypercarbic.

Newer surgical techniques, including the natural orifice transluminal endoscopic surgery (NOTES), are being developed for minimally invasive cholecystectomy. These procedures may be done with a lower dermatomal level.

C.8. Would you choose an inhalational or an intravenous technique for maintenance of anesthesia?

For maintenance of anesthesia, inhalation agents such as sevoflurane and isoflurane can be used. These agents are thought to be superior to desflurane because of its pungent odor that may cause airway irritation and trigger bronchospasm. At lower doses (<1.0 minimum alveolar concentration), the inhaled anesthetics inhibit chemically induced tracheal contractions in the order: *enflurane* ≥ *isoflurane* > *sevoflurane*. More recent clinical observations in humans indicate that sevoflurane at 1.1 minimum alveolar concentration may be the most effective agent, particularly in the presence of airway instrumentation. In addition, sevoflurane may have a more rapid onset of bronchodilation than isoflurane.

Desflurane has been shown to cause elevations in airway resistance and tissue mechanical parameters, with markedly enhanced airway narrowing in children with asthma or a recent URI. Therefore, desflurane should be avoided in children with susceptible airways.

Nitrous oxide can also be used, provided that the patient does not have pulmonary hypertension, a condition commonly

present in patients with COPD.

For scenarios that require avoidance of inhaled anesthetics, such as patients with history of malignant hyperthermia or cases that require monitoring of motor and somatosensory evoked potentials, intravenous anesthetics can be used for maintenance. Bronchodilating properties of propofol make it a choice intravenous anesthetic for patients with obstructive lung disease. Opioids without histamine-releasing effects and ketamine can be used as adjuncts to the intravenous technique.

C.9. What mechanisms produce bronchodilation from volatile anesthetics?

The volatile anesthetics relax airway smooth muscle primarily by directly reducing smooth muscle contractility and indirectly by inhibiting the reflex neural pathways. Direct effects of the volatile anesthetics partially depend on intact bronchial epithelium, suggesting that epithelial damage or inflammation secondary to asthma or a respiratory infection may lessen their bronchodilating effect.

The mechanisms responsible for the direct relaxation effects involve decreases in intracellular calcium, an important regulator of smooth muscle reactivity. Several intracellular mediators responsible for mobilization of calcium ions are potential sites for the action of volatile anesthetics, but the

predominant mechanism appears to be inhibition of cell membrane–associated voltage-dependent calcium channels, an action that decreases entry of calcium ions into the cytosol. Volatile anesthetic–induced increases in cyclic 3′,5′ adenosine monophosphate (cAMP) cause decreases in free intracellular calcium by stimulating efflux of calcium and increasing uptake of calcium into the sarcoplasmic reticulum. This action contributes to airway smooth muscle relaxation. In addition, volatile anesthetics reduce calcium sensitivity as a result of inhibition of protein kinase C activity and inhibition of G protein function.

C.10. Which muscle relaxants would you use? Why?

Any muscle relaxants that do not release histamine, such as cisatracurium, vecuronium, rocuronium, and pancuronium may be used. Atracurium causes histamine release, especially in high doses, and should be avoided. Succinylcholine can cause slight histamine release, but there is no evidence that succinylcholine is associated with increased airway resistance in patients with asthma.

It may be advantageous to avoid the long-acting pancuronium and instead to use muscle relaxants of intermediate duration of action because the earlier recovery from neuromuscular blockade may allow avoidance of reversal with an anticholinesterase, which, theoretically, could precipitate bronchospasm due to stimulation of postganglionic cholinergic receptors in airway smooth muscle. However, avoidance of anticholinesterase antagonism requires monitoring with a quantitative peripheral nerve stimulator to ensure adequate

spontaneous recovery, defined as a train-of-four (TOF) ratio greater than 0.90. If anticholinesterase is used, adequate dosing of a concomitant anticholinergic is necessary. Alternatively, sugammadex may be used for reversal of rocuronium-induced neuromuscular blockade.

C.11. How will you ventilate the patient? Will you use positive end-expiratory pressure (PEEP)? How can you detect the presence of auto-PEEP on your ventilator?

There are competing interests involved in managing the ventilation of this patient with COPD undergoing laparoscopic surgery. PIPs should be kept at a minimum, end-expiratory time needs to be adequate to overcome air trapping, and hypercarbia from insufflation with CO_2 must be compensated for.

A pressure control ventilation mode would be preferable to volume control because it results in lower PIPs at similar VTs. However, the laparoscopic technique leads to increasing airway resistance and increasing PIPs, so the VTs must be watched closely because they will decrease with insufflation of the abdomen and PIP set on the ventilator will need to be increased as the case proceeds.

High PIP should be avoided, especially in patients with emphysema and blebs, because a pneumothorax can result from

barotrauma. PIP should never be greater than 50 cm H_2O, and plateau pressures should be kept below 30 cm H_2O to minimize barotrauma.

The inspiratory-to-expiratory time ratio (I:E ratio) can be increased in order to reduce PIP. However, in this patient, the I:E ratio will likely need to be *reduced* in order to allow for complete expiration in the setting of expiratory obstruction and avoid air trapping. Allowing for an adequate expiratory time is a key component in the ventilatory management of patients with obstructive pulmonary disease.

Adequate minute ventilation will need to be maintained and should be increased, as the case proceeds and insufflated CO_2 is absorbed into the bloodstream and exhaled through the alveoli. Minute ventilation may need to increase as much as 60% in order to maintain normocarbia. Absorbed CO_2 can result in hypercapnia that lingers well into the postoperative period.

Achieving adequate minute ventilation with sufficient expiratory time and reasonable PIP can be a difficult task. In patients with severe pulmonary disease, it may be impossible. In this scenario, alternatives to traditional laparoscopy should be discussed with the surgeon. Gasless laparoscopic techniques that do not require insufflation of the abdomen are preferable, when feasible. These techniques utilize abdominal wall lifting to avoid necessitating a pneumoperitoneum.

The application of PEEP during positive pressure ventilation is a controversial issue. This type of PEEP is also referred to as extrinsic PEEP and must be differentiated from intrinsic or auto-PEEP. Intrinsic PEEP occurs in patients with COPD or asthma because outflow obstruction leads to air trapping. In ventilators equipped with an expiratory hold control, intrinsic PEEP can be measured during positive pressure ventilation. PEEP applied by the ventilator should be subtracted from the airway pressure

measured during the expiratory hold time in order to obtain intrinsic PEEP. When extrinsic PEEP is lower than intrinsic PEEP, it can improve ventilation, especially in the spontaneously ventilating patient. Extrinsic PEEP reduces the amount of negative pressure required to generate a breath and therefore reduces the work of breathing.

However, extrinsic PEEP that exceeds intrinsic PEEP can worsen air trapping and hyperinflation. Excessive PEEP also results in decreased venous return, decreased left ventricular compliance, and increased pulmonary capillary resistance. All of these changes lead to hypotension.

C.12. What is the differential diagnosis of intraoperative bronchospasm?

The causes of intraoperative wheezing and increased airway pressure include the following:

- Mechanical obstruction of endotracheal tube
  - Kinking
  - Secretions or blood
  - Overinflation of tracheal tube cuff
- Inadequate depth of anesthesia
  - Active expiratory efforts
- Pulmonary edema
- Pneumothorax (especially consider in a patient with emphysema and blebs)

- Aspiration pneumonitis
- Pulmonary embolism
- Endobronchial intubation
- Acute asthmatic attack
- Anaphylaxis

Anaphylaxis is a rare event but should be considered in all patients with intraoperative bronchospasm. The most common causes of intraoperative allergies include neuromuscular blocking drugs (NMBDs), latex, and antibiotics. Cardiovascular (hypotension) and cutaneous (flushing, urticaria) manifestations along with bronchospasm are the most common presenting signs of anaphylaxis during anesthesia. In the setting of bronchospasm with hypotension, even without cutaneous signs, anaphylaxis is high on the differential. Administration of likely inciting agents should cease; epinephrine 5 to 10 μg, diphenhydramine, and steroids should be given. An infusion of epinephrine may be necessary. A tryptase level should be sent to confirm the diagnosis, and the patient should be notified in writing of the potential reaction so that follow-up allergy testing can be obtained.

C.13. In the middle of surgery, peak inspiratory pressures (PIPs) suddenly increase. How do you manage this?

Elevation of PIPs is one of the signs of intraoperative bronchospasm. One of the most common causes of bronchospasm during surgery is inadequate depth of anesthesia. The patient with asthma has an extremely sensitive

tracheobronchial tree. When the level of anesthesia is too light, the patient may develop straining or coughing as a result of the foreign body (endotracheal tube) in the trachea and then bronchospasm. Therefore, during surgery, the initial treatment of bronchospasm is to increase F_{IO_2} and deepen anesthesia while investigating other potential causes of bronchospasm (see section C.12).

First, increase the F_{IO_2} and bag ventilate in order to manually assess pulmonary compliance. Check the anesthesia circuit and the endotracheal tube for kinking and any other visible obstruction. Auscultate the lungs to assess for wheezing. Bilaterally diminished or absent breath sounds can be an ominous sign suggesting critically low airflow, which can occur during severe bronchospasm or a mechanical obstruction of the tube. Unilaterally decreased breath sounds may indicate a main-stemmed endotracheal tube or, rarely, a pneumothorax. Once bronchospasm is confirmed, prior to deepening anesthesia, take a blood pressure. If normal or high, deepen anesthesia by increasing the concentration of inhalation agents, such as sevoflurane or isoflurane, which are direct bronchodilators, or administer an incremental dose of propofol. This has the advantage of deepening anesthesia without relying on alveolar ventilation (which is decreased during bronchospasm) for administration. Likewise, in a patient with a low to normal blood pressure, an incremental dose of ketamine both deepens anesthesia and bronchodilates.

Second, relieve mechanical stimulation. Pass a catheter through the endotracheal tube to suction secretions and determine whether there is an obstruction or kinking of the tube. Occasionally, the endotracheal tube slips down and stimulates the carina of the trachea, causing severe bronchospasm during light anesthesia. The cuff of the endotracheal tube can be deflated, the tube moved back 1 to 2 cm, and the cuff reinflated.

Surgical stimulation, such as traction on the mesentery, intestine, or stomach, should be stopped temporarily because it stimulates a vagal reflex and can cause bronchospasm.

Third, start medical intervention if the previously mentioned treatment does not break the bronchospasm or anesthesia cannot be deepened secondary to hypotension. The cornerstone of the treatment of intraoperative bronchospasm is inhalation of β_2-agonists such as albuterol, which induce further bronchodilation even in the presence of adequate inhalational anesthesia. Because of rain-out in the endotracheal tube, a large dose (8 to 10 puffs) should be given to achieve adequate therapeutic levels. If bronchospasm continues despite optimal bronchodilation therapy, high-dose intravenous corticosteroids are indicated (see sections B.16 and B.17). Epinephrine 5 to 10 μg can be given intravenously, but caution should be taken as it can exacerbate tachycardia and tachyarrhythmias. Alternatively, a continuous infusion of epinephrine 0.5 to 2 μg per minute in adults can provide maintenance bronchodilation with fewer adverse effects.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:22.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

C.14. How would you give β_2-agonists? What is their mechanism of action on asthma?

Historically, it was fashionable to treat episodes of severe asthma with intravenous sympathomimetics such as isoproterenol. This approach no longer appears justifiable. Isoproterenol infusions can induce ventricular arrhythmias during halothane anesthesia and is clearly associated with myocardial damage. Even the intravenous administration of β_2-selective agents such as terbutaline and albuterol offers no advantage over the inhaled route.

β_2-Agonists such as albuterol, levalbuterol, and terbutaline may be administered through MDI adapters or small-volume jet nebulizers to the anesthetic circuit. Because MDI adapters are not very efficient in the intubated patient due to rain-out in the endotracheal tube, 8 to 10 puffs are needed to break acute bronchospasms.

Adrenergic stimulants produce bronchodilation through action on β-adrenergic receptors. β-Agonists increase intracellular cAMP by activating adenyl cyclase, which produces cAMP from adenosine triphosphate. Increased cAMP promotes bronchial relaxation and inhibits the release of mediators from mast cells (**Fig. 1.4**).

FIGURE 1.4. C.15. If the patient does not respond to the aforementioned treatment and becomes cyanotic, what would you do?

The ABG values should be determined immediately. In a severe, prolonged asthmatic attack, there will be combined respiratory and metabolic acidosis resulting from CO_2 retention and lactic acidosis from tissue hypoxia. Hypercarbia, hypoxemia, and acidemia promote arrhythmias and impair the response to bronchodilator therapy. Sodium bicarbonate ($NaHCO_3$) should be given to correct the acidosis because β-agonists are not effective in severe acidosis. At the same time, bronchodilator therapy should be continued or increased.

A patient with severe, refractory bronchospasm may require ventilation with a ventilator equipped to generate very high inspiratory pressures. An ICU ventilator can generate inspiratory pressures as high as 120 cm H_2O. Most anesthesia machines cannot deliver adequate alveolar ventilation because the circuit has too much compressible volume (tubing compliance) and the ventilator does not have sufficient driving power. The major disadvantage of an ICU ventilator is its inability to use inhalational anesthetics. Some newer anesthesia machines incorporate an ICU-type ventilator with vaporizers and oxygen mixers. They may be ideal for this situation.

Heliox is a helium/oxygen mixture that, secondary to its lower density to air, can permit higher flow rates at lower pressures, theoretically improving delivery of oxygen during bronchospasm. A major limitation is that heliox mixtures can

only provide 21% to 30% oxygen. Also, although heliox facilitates ventilation, it does not reverse the underlying bronchospasm. Reports on the perioperative use of heliox remain limited.

Finally, although not available at all centers, venovenous extracorporeal membrane oxygenation (VV-ECMO) may be established in order to adequately oxygenate the blood when all other measures have failed. ECMO is expensive, requires specially trained personnel, and is an invasive treatment modality associated with a number of potential complications. However, it is a potentially lifesaving measure that should be considered in select cases of severe, refractory hypoxemia secondary to respiratory disease.

C.16. The asthmatic attack was relieved with your treatment, and the surgery was completed. Following emergence, the patient was found to be hypoventilating. What are the common causes of hypoventilation? What will be your approach to treat hypoventilation?

The following are common causes of apnea or hypoventilation at the end of surgery:

- Respiratory center depression by inhalational anesthetics,

opioids, or mechanical hyperventilation (low P_{CO_2})

- Peripheral blockade by muscle relaxants
- Hypothermia

This list of the common causes of postoperative hypoventilation can be used to guide the systematic approach for the diagnosis and management. Measuring the temperature can easily diagnose hypothermia, and residual neuromuscular blockade can be assessed by a response to peripheral nerve stimulator. If hypothermia and residual neuromuscular blockade are ruled out, then hypoventilation is likely due to residual anesthetics and opioids. This can be managed by waiting longer or by pharmacologic reversal (if deemed appropriate) of opioid or benzodiazepine effect.

Management of residual neuromuscular blockade requires extra care in patients with reactive airway disease. In a patient with severe asthma, avoiding the use of an anticholinesterase, such as neostigmine, to reverse a nondepolarizing relaxant may be beneficial because neostigmine may trigger bronchospasm by cholinergic and prosecretory effects. However, any hypoventilating patient without adequate recovery (defined as TOF ratio greater than 0.90 when measured with a peripheral nerve stimulator) should be reversed.

If reversal is required, larger than customary doses of glycopyrrolate or atropine should be administered to minimize the possibility of bronchospasm. Although atropine or glycopyrrolate given simultaneously with neostigmine may prevent bronchospasm, the duration of action of neostigmine can outlast that of a vagolytic agent, especially in the presence of renal insufficiency, and lead to delayed bronchospasm. Intraoperatively, it is advisable to use inhalation agents to potentiate relaxants and to use smaller amounts of intermediate-acting relaxants for surgery. Alternatively, sugammadex may be safely used for reversal of rocuronium-induced neuromuscular

blockade (see section C.10).

Finally, if the patient does not appear to have any of the aforementioned causes of hypoventilation but is still inadequately ventilating, extubation should be delayed.

C.17. Would you consider a deep extubation in this patient?

To avoid bronchospasm triggered by coughing and straining caused by laryngeal and pharyngeal reflexes during emergence and extubation, patients may be extubated at surgical (deep) levels of anesthesia. However, the risks of aspiration, airway obstruction, and hypoventilation should be weighed against the benefits. With a history of severe COPD, chronic hypoxemia, and CO_2 retention, the patient is not a good candidate for extubation while deeply anesthetized. A systematic approach for emergence and extubation is illustrated in **Figure 1.5**. However, the guidelines do not include all possible patient-surgical-anesthetic conditions. Certainly, the practitioner's clinical judgment is of utmost importance regarding the decision to extubate.

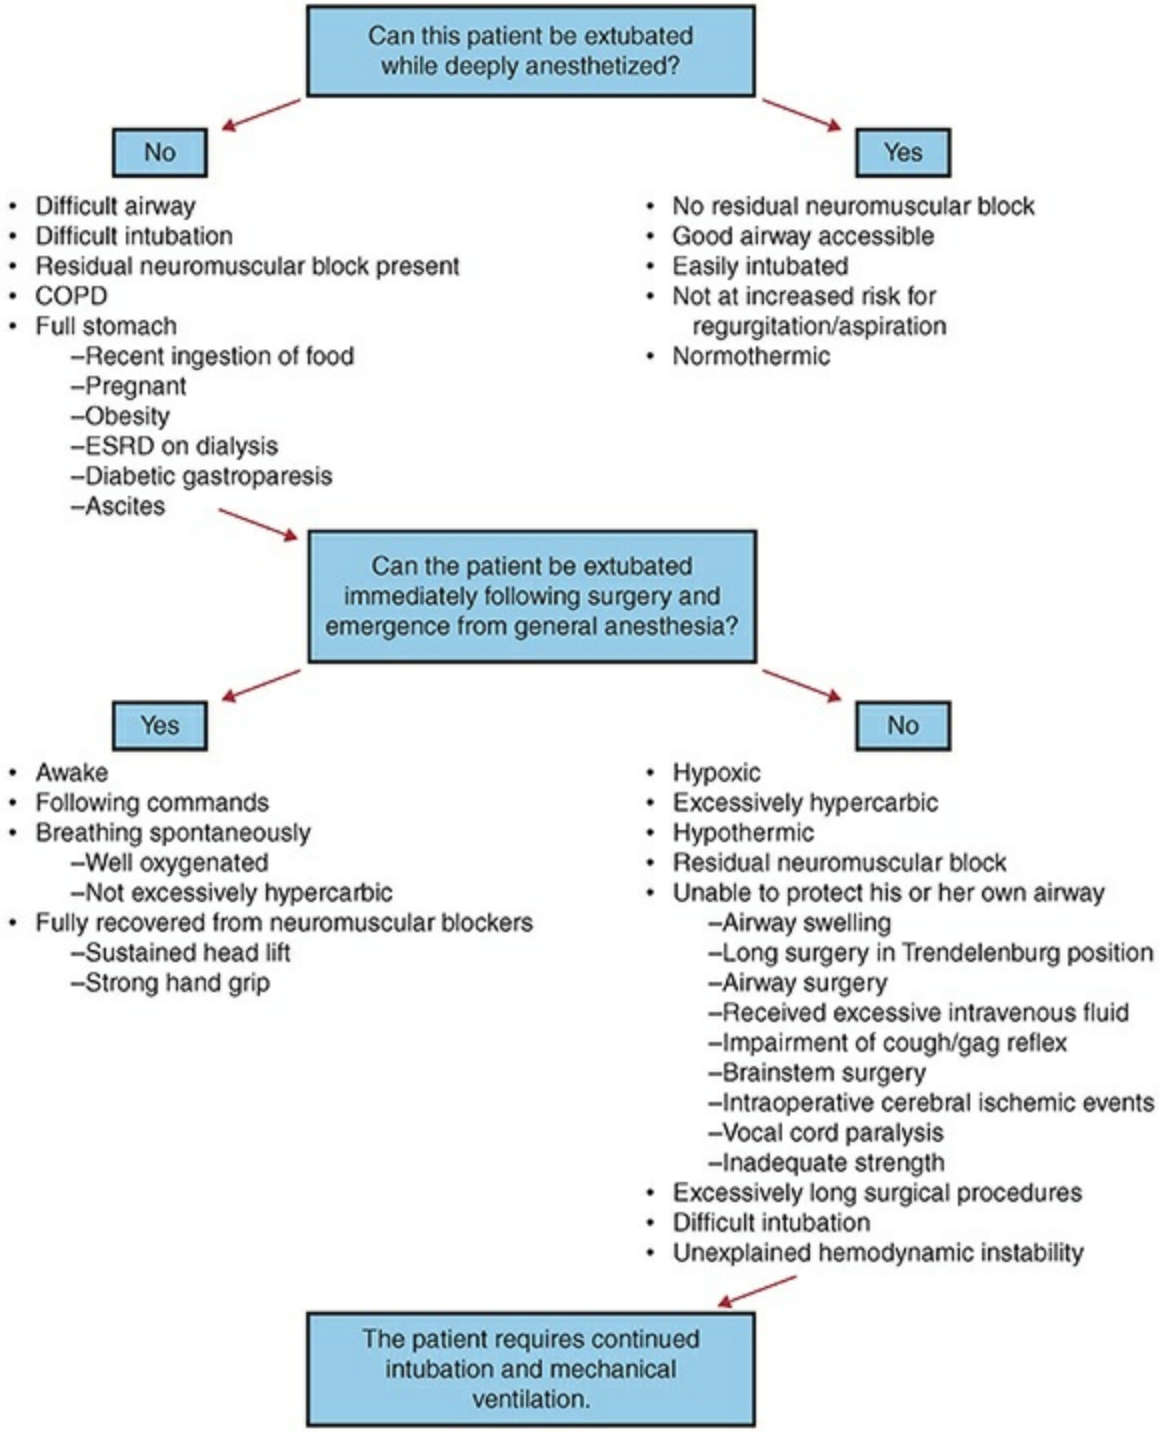

FIGURE 1.5. A systematic approach to emergence and extubation. COPD, chronic obstructive pulmonary disease; ESRD, end-stage renal disease.

Woods BD, Sladen RN. Perioperative considerations for the patient with asthma and bronchospasm. *Br J Anaesth*. 2009;103(suppl 1):i57–i65.

C.18. If the patient cannot be extubated, what measures can you take to reduce the likelihood of bronchospasm with an endotracheal tube in place?

Loading doses of lidocaine, followed by continuous infusion, as described in section C.5, may be administered intravenously to prevent bronchoconstriction induced by stimulation of the trachea by the endotracheal tube. β_2-Agonists such as albuterol may be administered through MDI adapter to prevent bronchospasm. Dexmedetomidine, which has a favorable profile, including anxiolysis, sympatholysis, and drying of secretions without respiratory depression, can be used to sedate an agitated patient with asthma who does not meet extubation criteria. Alternatively, if there are no contraindications, a supraglottic airway may be used to replace the endotracheal tube for control of ventilation and to avoid tracheal stimulation.

D. Postoperative Management

D.1. In patients with asthma and COPD, are there special considerations for the use of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) for postoperative pain control?

Morphine is avoided because of possible histamine release and increased central vagal tone, which may cause bronchospasm. Meperidine causes histamine release more frequently than do

most other opioids and should be avoided as well. Fentanyl, on the other hand, is an appropriate choice for patients with asthma or other bronchospastic diseases because of its antimuscarinic, antihistaminergic, and antiserotoninergic actions. Effective analgesia is especially important in patients with respiratory disease because poor pain control may compromise respiration further due to splinting of the thoracic cage and decreased ability to cough. However, narcotics should be titrated very carefully to avoid dose-dependent respiratory depression.

An estimated 4% to 11% of asthmatics have a sensitivity toward NSAIDs, known as aspirin-sensitive respiratory disease (ASRD). NSAIDs block the cyclooxygenase-mediated conversion of arachidonic acid to prostaglandins, thereby shunting arachidonic acid toward the formation of bronchoconstricting leukotrienes. Patients with ASRD are more likely to have an irreversible component to their obstructive airway disease, more likely to have frequent exacerbations, and more likely to have had a history of severe attacks and oral steroid use. Persistent rhinorrhea, nasal polyps, and nasal congestion are common symptoms. Most patients with ASRD are unaware of the diagnosis. If a focused preoperative history reveals any of the aforementioned symptoms, NSAIDs should be avoided.

D.2. Would you consider using a regional technique for analgesia?

Were this surgery to be accomplished laparoscopically, a

regional technique for analgesia is typically not necessary. However, in a patient with severe respiratory disease, the complete avoidance of systemic narcotics may be desired in order to reduce the risk of PPCs. In this case, epidural analgesia is preferred. The epidural may be placed before surgery and may be used as an adjunct or alternative to general anesthesia (see section C.7). The complete analgesia that can be obtained with epidural anesthesia allows for patients to avoid "splinting" secondary to abdominal pain and improves postoperative respiratory recovery.

Contraindications to epidural anesthesia include patient refusal and anticoagulation. In patients unable to receive neuraxial anesthesia, an alternative is the transversus abdominis plane (TAP) block. A study of 43 patients undergoing laparoscopic cholecystectomy showed decreased postoperative opiate use and mean discharge time from PACU in patients receiving a TAP block as compared to those with conventional port site infiltration. A TAP block consists of two to four injections of local anesthetic (typically bupivacaine, ropivacaine, or liposomal bupivacaine) providing 12 to 36 hours of pain relief. Unlike an epidural, once the block is performed and following a period of adequate postblock monitoring, no special equipment is necessary and patients can be discharged home. However, a TAP block only covers surgical incision pain and does not affect internal surgical pain. Therefore, a multimodal pain regimen will still be required.

D.3. The patient was breathing well and was extubated.

Would you place this patient on supplemental oxygen in the recovery room? How much?

Administration of oxygen to patients with severe COPD can lead to hypercapnia. This was traditionally attributed to the impairment of hypoxic respiratory drive and subsequent hypoventilation. Although there is a transient reduction in minute ventilation when high-flow oxygen is administered to patients with COPD, this does not appear to play a major role in oxygen-induced hypercapnia.

The primary mechanism responsible for hypercapnia with oxygen administration in patients with COPD appears to be ventilation/perfusion mismatch. Under normal conditions, hypoxic pulmonary vasoconstriction helps minimize ventilation/perfusion mismatch. Oxygen therapy may abolish hypoxic pulmonary vasoconstriction in poorly ventilated areas, increasing blood flow to these areas, and decreasing blood flow to other lung regions with normal or high ventilation:perfusion ratios. These areas will then contribute further to alveolar dead space causing an increase in P_{CO_2}.

Although uncontrolled oxygen therapy in patients with COPD is potentially harmful, hypoxemic patients should receive oxygen. A carefully titrated oxygen therapy to achieve saturations of 88% to 92% is recommended.

Lumb AB. *Nunn's Applied Respiratory Physiology*. 8th ed. Philadelphia, PA: Elsevier; 2017:399–400.

D.4. The patient is hypoventilating in postanesthesia care unit (PACU). Would you initiate noninvasive ventilation (NIV)?

NIV refers to delivery of ventilatory support via the patient's upper airway using a mask or a similar device. NIV respiratory support ranges from continuous positive airway pressure (CPAP) to bilevel positive airway pressure (BIPAP). NIV has been shown to be safe and effective in patients with COPD and should be readily available in PACU to treat postoperative respiratory distress. Judicious use of NIV may reduce reintubation rates after surgery.

2 Bronchoscopy, Mediastinoscopy, and Thoracoscopy

Alessia Pedoto, Paul M. Heerdt, and Fun-Sun F. Yao

A 60-year-old man has suffered from cough, intermittent hemoptysis, and weight loss for 2 months. He has smoked one pack of cigarettes per day for 40 years. A chest radiograph 1 month ago revealed a right middle lobe infiltrate that was treated with antibiotics without clinical improvement. Subsequent evaluation revealed a mass. He is now scheduled for fiberoptic bronchoscopy, possible mediastinoscopy, and possible video-assisted thoracoscopic (VATS) lobectomy.

A. Medical Disease and Differential Diagnosis

1. How is the diagnosis of lung cancer made? What is your prediction for the most likely type of malignancy?
2. What are the less common manifestations of bronchogenic carcinoma?
3. The patient has a long history of cigarette smoking. What is the significance of this finding?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient prior to surgery?

2. What are the pulmonary function guidelines that indicate an increased risk for morbidity and mortality?
3. What are the preoperative concerns of induction immunotherapy?

C. Intraoperative Management

1. How would you premedicate, monitor, and anesthetize this patient?
2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?
3. What are the indications for cervical mediastinoscopy? Are there potential complications?
4. The decision was made to proceed with a robotic right middle lobectomy. How would this alter your management?
5. What are the indications for single-lung ventilation and how can it be accomplished?
6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?
7. Would you use a right- or left-sided DLT?
8. How do you know that the tube is in the correct position?
9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?
10. How will systemic oxygenation be monitored during single-lung ventilation? What is the mechanism of pulse oximetry?
11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.
12. What is hypoxic pulmonary vasoconstriction (HPV)?
13. What are the effects of anesthetic agents on HPV and their clinical implications?
14. Discuss pulmonary blood flow distribution, shunt flow, and partial pressure of oxygen in the arterial blood (Pa_{O_2}) (fractional inspired O_2 concentration [F_{IO_2}] = 1.0) during

single-lung ventilation in the lateral position.

15. How could you improve oxygenation during single-lung ventilation?
16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?

D. Postoperative Management

1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?
2. Why is it important to control postoperative pain? How would you achieve this goal?

A. Medical Disease and Differential Diagnosis

A.1. How is the diagnosis of lung cancer made? What is your prediction for the most likely type of malignancy?

The initial presenting symptoms in patients with lung cancer are constitutional and nonspecific, mainly related to metastatic disease. Nonproductive cough, dyspnea, hemoptysis, and chest pain, along with an unresolved lung infiltrate on chest radiography, should suggest carcinoma. In the attempt to make an early diagnosis, the American Cancer Society has issued preliminary guidelines for screening high-risk patients using low-dose computed tomography (LDCT) imaging. Recommended candidates include subjects aged between 55 and 77 years with a smoking history of at least 30 packs per year, who are current smokers or quit within the past 15 years. The main limitation of this test is the 23.3% incidence of false-positive results, which may lead to further testing including surgical biopsy. Biomarkers from large airway epithelial cells or buccal mucosal biopsies are being investigated and may represent early diagnostic options in the future. Currently, the

initial diagnosis and staging are done in the operating room and include flexible bronchoscopy with airway washings and brush biopsy, possibly followed by ultrasound-guided transbronchial biopsy (endobronchial ultrasound [EBUS]) for mediastinal lymph node biopsy. Additional areas for biopsy include palpable lymph nodes in the neck or axilla, needle aspiration biopsy, cervical mediastinoscopy, and possibly exploratory thoracoscopy or thoracotomy. An extensive evaluation must be performed to exclude metastases that would contraindicate major surgery.

Cancers of the lung account for 12% of all malignancies and nearly 18% of cancer-related deaths worldwide. Bronchogenic carcinomas are the most common tumors requiring surgical resection and can be classified into four major types: small cell, large cell, squamous cell, and adenocarcinoma. For surgical purposes, lung tumors are classified as non–small cell or small cell. The former is amenable to surgical resection, whereas the latter tends to be nonresectable and is medically treated.

Further subclassification of lung tumors involves the TNM classification in which *T* designates tumor site, size, and local extent; *N* the presence and location of regional lymph node involvement; and *M* the presence of distal metastases beyond the ipsilateral hemithorax. This system is used for staging bronchogenic carcinomas and helps predict the response to therapy. In general, small cell carcinomas that have spread beyond possible resection by the time of presentation are primarily managed with chemotherapy, with or without radiation, and are associated with a 5-year survival of approximately 20%. In contrast, non–small cell cancers found to be localized at the time of presentation should be considered for primary resection. The 5-year survival can be as high as 85% for small tumors without regional lymph node involvement or metastases (stage I). Approximately 45% of patients present

with circumscribed extrapulmonary disease or lymphatic spread to the ipsilateral mediastinal or subcarinal lymph nodes (stage IIIa). Their 5-year postresection survival is less than 20%.

A.2. What are the less common manifestations of bronchogenic carcinoma?

Other manifestations of lung tumors are primarily related to mass effects or altered metabolism. In addition to bronchial obstruction (evident in this patient) occasionally leading to postobstructive pneumonia, mass effects include invasion into the chest wall and pleura, compression of great vessels (e.g., superior vena cava syndrome) and heart, tracheobronchial displacement, and/or paresis of the recurrent laryngeal or phrenic nerves and the sympathetic chain. *Pancoast syndrome* can present with pain and upper extremity weakness secondary to invasion of the brachial plexus as well as the first and second thoracic and eighth cervical nerve roots. Recognized *metabolic manifestations* of small cell lung tumors include symptoms

resembling those of Cushing syndrome (from ectopic adrenocorticotropic hormone production), carcinoid syndrome, hypercalcemia and hypophosphatemia (resulting from ectopic parathyroid hormone or parathyroid hormone–related peptides), hypokalemia (caused by ectopic adrenocorticotropic hormone secretion), and hyponatremia (from inappropriate secretion of antidiuretic hormone and possibly atrial natriuretic factor). *Neurologic paraneoplastic syndromes* include Eaton-Lambert myasthenic syndrome, peripheral motor and sensory neuritis, cerebellar degeneration, retinopathy, limbic encephalopathy, and autonomic neuropathy. An autoimmune process has been suggested for these findings, and it seems to be more common in patients with limited disease.

Extrathoracic spread of the tumor can affect the bones, liver, adrenal glands, intra-abdominal and subcutaneous lymph nodes, brain, and spinal cord, contributing to the nonspecific presentation of the cancer.

Ettinger DS, Wood DE, Aisner DL, et al. Non–small cell lung cancer, version 5.2017, NCCN Clinical Practice Guidelines in Oncology. *J Natl Compr Canc Netw*. 2017;15:504–535.

A.3. The patient has a long history of cigarette smoking. What is the significance of this finding?

Cigarette smoking remains the leading cause of lung cancer in the United States. Tobacco exposure is linked to chronic obstructive pulmonary disease (COPD), which includes chronic bronchitis and emphysema, and is strongly associated with an increased incidence of stroke, myocardial infarction, and cancer (lung, oral cavity, larynx, and esophagus). Pulmonary hypertension from chronic hypoxemia and subsequent cor pulmonale may also occur.

Eight percent to 17% of patients with lung cancer who are scheduled for surgical resection are still smoking at the time of surgery. Current tobacco use increases the risk of postoperative respiratory failure, pneumonia, aspiration, air leak, and atelectasis as well as 1-year mortality. Preoperative smoking cessation is strongly recommended, but it is unclear how long is needed before surgery to see a significant reduction in postoperative complications. Carboxyhemoglobin concentrations decline substantially within 12 hours of smoking cessation. Four weeks of abstinence decrease the incidence of postoperative respiratory complications, probably because of an improved mucociliary function. However, because continuous local tumor growth and metastatic spread may preclude resectability, a prolonged period of preoperative abstinence may not be practical. Nonetheless, smoking cessation at any time prior to surgery is still strongly recommended. A combined approach including counseling and polypharmacology has been shown to increase the success rate and decrease relapses after hospital discharge.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient prior to surgery?

The main goal of preoperative evaluation is to identify in advance those at risk for major postoperative complications and optimize their functional status. The first step should include a complete history, physical examination, and laboratory tests

(e.g., complete blood count, basic metabolic profile, coagulation study, electrocardiogram, chest radiography, and computed tomographic imaging). A positive smoking history, especially if current, and in the presence of cough, sputum production, orthopnea, and dyspnea, requires further investigation. An abnormal exercise tolerance, such as the inability to climb at least three flights of stairs or walk for 6 minutes, may indicate a compromised cardiorespiratory function and the inability to tolerate the stress of anesthesia and surgery. In this subgroup of patients, further cardiopulmonary function testing may be indicated to define cardiac disease or customize a prehabilitation program. A brief review of symptoms, physical limitations, interval changes, and airway anatomy is usually performed before entering the operating room.

In addition to routine preoperative testing, patients scheduled for lung resection usually undergo pulmonary function testing to help define the relative risks of the planned resection. *Respiratory function* can be assessed by the following:

- **Respiratory mechanics** is evaluated via forced vital capacity (FVC), forced expiratory volume in the first second (FEV_1), and the ratio between residual volume and total lung capacity (RV/TLC). Flow–volume loops may be helpful to document the location of the obstruction (small vs. large airway) and its severity. Post-bronchodilator FEV_1 and FEV_1/FVC paired with clinical symptoms are used to determine the severity of COPD.
- **Cardiopulmonary reserve** evaluation includes maximal oxygen uptake ($\dot{V}O_{2max}$), stair climbing, 6-minute walk, and shuttle walk. In case of poor performance in these tests, cardiopulmonary exercise tolerance testing (CPET) can be added to identify patients who are not surgical candidates. $\dot{V}O_{2max}$ is the gold standard for aerobic capacity and

cardiorespiratory fitness. Patients with $\dot{V}O_{2max}$ value less than 10 mL/kg/min are at increased risk for postoperative morbidity and mortality.

- **Lung parenchymal function** include diffusing lung capacity for carbon monoxide (DLCO), Pa_{O_2}, and partial pressure of arterial carbon dioxide (Pa_{CO_2}). Predicted postoperative DLCO and FEV_1 less than 40% to 44% are significant independent predictors for increased postoperative morbidity and mortality.

B.2. What are the pulmonary function guidelines that indicate an increased risk for morbidity and mortality?

The reported mortality from lung resection is between 2% and 4%, mainly as a result of pneumonia, respiratory failure, bronchopleural fistula, empyema, and pulmonary embolism. Respiratory insufficiency occurs in approximately 5% of patients following lung resection and is associated with a 50% mortality rate. Advanced age and the associated increased

incidence of concomitant nonpulmonary disease seem to contribute to this outcome. An increased risk of postoperative complications can be predicted by the following:

- **Spirometry:** Spirometric parameters, such as FEV_1/FVC ratio and FEV_1 (reflective of the degree of airway obstruction), as well as static volumes (such as inspiratory and TLC), are used to define the severity of COPD. Several studies have indicated a strong correlation between predicted postoperative FEV_1 and DLCO and a respective increase in morbidity and mortality, especially for open procedures and extensive dissection. Concerning values are summarized in **Table 2.1**.

TABLE 2.1 Minimal Pulmonary Function Test Criteria for Various-Sized Pulmonary Resections

Test	Unit	Normal	Pneumonectomy	Lobectomy	Biopsy or Segmental
MBC	Liters per minute	>100	>50	>40	>25

FEV_1, forced expiratory volume in first second; $FEV_{25\%–75\%}$, forced expiratory volume from 25% to 75% of forced vital capacity; FVC, forced vital capacity; MBC, maximum breathing capacity.

- **Arterial blood gases:** Historically, hypercapnia ($PaCO_2$ greater than 45 mmHg) was considered an exclusion criterion for lung resection. However, no independent correlation has been found with an increased mortality. Patients who are hypercapnic often have a low predicted postoperative FEV_1 and an abnormal exercise capacity, which may preclude

surgery. Preoperative hypoxemia (Pa_{O_2} less than 50 mmHg and percentage of available hemoglobin saturated with oxygen [Sa_{O_2}] less than 90%) has been associated with an increased risk of postoperative complications. However, baseline hypoxemia can be the result of ventilatory mismatch caused by obstructive tumors that once resected may theoretically improve gas exchange.

Other factors influencing outcome include patient comorbidities and functional status, the extent and location of the proposed surgical resection, and whether the patient has undergone preoperative induction chemotherapy. Improvements in both surgical and anesthesia techniques have broadened the criteria for surgical respectability. As evident from lung volume reduction studies, patients with severely impaired pulmonary function (e.g., FEV_1 less than 1 L) can still undergo surgical resection with general anesthesia without prohibitive risk for postoperative complications. Moreover, the development of minimally invasive surgical techniques has raised the question of whether standard selection criteria should always be adopted.

Although preoperative pulmonary function tests are valid indices of physiologic performance, the actual predictive utility of a range of values for a single parameter is poorly defined. Overall, emphasis has been directed toward integrating multiple aspects of the preoperative evaluation (e.g., spirometry, ventilation-perfusion scanning, extent of planned resection, patient functional status) into the estimate of postoperative function. “Enhanced Recovery After Surgery” (ERAS) protocols have contributed to improve outcomes. Multimodal analgesia, early ambulation, and thromboprophylaxis are among the recommendation for the perioperative period that have affected outcome after major lung resection in patients at high risk.

B.3. What are the preoperative concerns of induction immunotherapy?

Chemotherapy and high-dose stereotactic radiation have been used in the preoperative period after diagnosis and staging of lung cancer with an increase in survival when started in the early stages (IB-IIIA). In the past decade, the approach to chemotherapy has changed with an increased use of immunomodulators that affect the autoimmune response in favor of the organism. Lung cancer cells abound of programed death (PD)-1 and programmed death-ligand 1 (PD-L1) receptors, which upon activation, decrease the function of the killer T cells. Drugs that inhibit these receptors (also known as check point inhibitors, such as pembrolizumab, nivolumab, cemiplimab, atezolizumab, avelumab, and durvalumab) can increase the T-cell immune response toward cancer cells. This treatment modality has shown a very good oncologic response and outcome. However, a new toxic profile has emerged secondary to the overwhelming inflammation and autoimmune process, ranging from mild reaction to life-threatening conditions. Concerning **side effects** include skin reactions (diffuse rash), enteritis and diarrhea, hypothyroidism, hypophysitis, and adrenal insufficiency as well as hepatic insufficiency. *Endocrine and hepatic* side effects may be so severe to warrant delaying surgery to allow optimization. *Grade 3 to 4 toxicity* usually requires prednisone 1 to 2 mg/kg/day, gradually tapered to

symptoms improvement and discontinuation of the immunotherapy. Anti-tumor necrosis factor-α (TNF-α) inhibitors are added in case of suboptimal response to steroids. *Interstitial pneumonitis* has been reported in patients receiving phosphoinositol 3-kinase inhibitors. When severe, it warrants intensive care unit admission and high-dose corticosteroids (1 to 2 mg/kg/day) with further immunosuppression in refractory cases. *Cytokine release syndrome* (CRS) can present with encephalopathy, mental status changes, and cerebellar disease. In this subpopulation, surgery should be delayed. CRS is a major concern in recipients of chimeric antigen receptor–modified T-cell lymphocytes and checkpoint inhibitors. Altered cerebellar function, mental status, and seizures have been described after its use.

C. Intraoperative Management

C.1. How would you premedicate, monitor, and anesthetize this patient?

Patients usually arrive at the hospital on the day of surgery, making traditional oral or parenteral premedication before transport to the operating room largely obsolete. Bronchoscopy and mediastinoscopy are generally ambulatory procedures, necessitating a relatively rapid hospital discharge.

EBUS-guided lymph node biopsy has become more popular

in the past decade as a minimally invasive, highly accurate alternative to cervical mediastinoscopy for staging of lung cancer. It is usually performed either under sedation or general anesthesia. When combined with esophageal ultrasound-guided biopsies, it allows staging of the entire mediastinal lymphatic chain (from station 1 through 11, including 8 and 9, accessible via esophageal approach). On-site cytologic exam is usually performed during the procedure. Mediastinal, hilar, lobar, and interlobar lymph nodes are accessible with this technique with a complication rate of 1.4%. Coughing (if the airway is not adequately topicalized) and bronchospasm are common perioperative complications. The incidence of pneumothorax is rare and depends on the location of the lymph node to biopsy or the presence of bullous disease rather than the type of anesthesia and the ventilation modality. Bleeding is also a rare instance, therefore not requiring aggressive reversal of preoperative anticoagulation as generally required for a mediastinoscopy.

Cervical mediastinoscopy is now reserved for small lymph nodes not readily accessible via EBUS or in the presence of inconclusive results. During mediastinoscopy, intermittent compression or occlusion of the innominate artery can occur. Therefore, the blood pressure cuff should be placed on the left arm and the pulse oximeter on the right hand. In the case of innominate artery compression, a dampening of the pulse oximetry trace will be evident, whereas blood pressure measurements will remain accurate. Although rare, injury to vascular structures (such as the azygos veins and innominate artery) can occur, potentially necessitating a median sternotomy. Patient positioning and placement of electrocardiography leads should be considered accordingly. Arterial access is not routinely used for this procedure unless the patient has clinical indications for continuous hemodynamic monitoring. In this case, the catheter should be placed in the left radial artery as

well to avoid falsely low readings related to innominate artery compression. Noninvasive continuous blood pressure monitoring can be used as an alternative. Artifacts related to compression of the reading site, especially if the arms are tucked, will affect the accuracy and precision of the monitoring, making it the main limitation to its use. Body temperature should be monitored and a warming blanket applied. Despite the potential of being a short procedure, hypothermia can occur, especially in elderly patients. Induction, maintenance of anesthesia, and muscle relaxation can be achieved with relatively short-acting agents. Propofol is frequently used for induction of general anesthesia followed by rocuronium, vecuronium, or cisatracurium to facilitate tracheal intubation via a single-lumen endotracheal tube (ETT). Anesthesia can be maintained with a potent inhalational agent in oxygen or air if adequate oxygen saturation can be maintained. Two to 3 μg per kg of fentanyl often provides sufficient analgesia for the procedure. Local anesthetic can be infiltrated in the wound by the surgeon at the beginning or at the end of the procedure. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be used as adjuvant agents, in addition to intravenous acetaminophen, if not contraindicated. Finally, many clinicians choose to avoid the use of nitrous oxide because of the potential for the mediastinoscope to enter the pleural space and create a pneumothorax. The advent of sugammadex has allowed to prolong patient paralysis until the end of the procedure. Recommended reversal doses are based on the train of four (2 milligram per kilogram for two or more twitches, 4 milligram per kilogram in case of no twitches). Hypersensitivity reactions as well as anaphylaxis have been reported with the use of sugammadex and should be considered when the medication is administered.

C.2. How many types of bronchoscopes are available and what are the intraoperative considerations of each one?

Four types of bronchoscopes are currently in use: flexible fiberoptic, EBUS bronchoscope, rigid ventilating, and rigid Venturi.

The *flexible fiberoptic bronchoscope* can be used either in sedated patients under local anesthesia (allowing examination of vocal cords movements) or under general anesthesia with a supraglottic airway device or an ETT. For the awake or sedated examination, viscous lidocaine can be gargled to anesthetize the upper airway and a 2% or 4% lidocaine solution inhaled via nebulizer mask to reach the lower airway. Bilateral superior

laryngeal nerve blocks and transtracheal block can be added; however, they are not as popular as in the past due to potential complications. Intravenous sedation can be achieved with 0.5-mg increments of midazolam, 10 μg of remifentanil boluses or propofol infusion. Alternatively, dexmedetomidine (as a bolus of 0.5 to 1 μg per kg over 10 minutes followed by a continuous infusion of 0.2 to 1.5 μg/kg/hr) can also be used, with the main advantage of causing amnesia without impaired ventilation. When compared to propofol, the main disadvantage of dexmedetomidine seems to be the prolonged recovery time, limiting its use in the ambulatory setting. If the oropharynx is adequately anesthetized, a supraglottic airway device can be inserted without discomfort in sedated patients and used to assist ventilation at higher F_{IO_2} concentrations.

EBUS can be done with either sedation or general anesthesia, depending on the number and locations of the lymph nodes to biopsy. Good topical anesthesia is paramount to prevent coughing and bronchospasm. The EBUS bronchoscope is a 6.9-mm outer diameter flexible bronchoscope with a latex balloon tip, coupled with a 7.5-MHz convex ultrasound probe. When the balloon is inflated with normal saline, it allows a tight adhesion to the airway wall facilitating ultrasound identification of the lymph nodes. A 21-gauge needle is used through a dedicated channel in the bronchoscope for real-time biopsy. Color Doppler is available to differentiate the lymph nodes from vascular structures. In the sedated patient, or in the presence of a supraglottic airway device, attention should be used to avoid vocal cord trauma, due to the positioning of the optical view at a 30-degree angle. Intravenous steroids may be used to prevent inflammation and edema. In nonintubated patients, local anesthetic toxicity may result from larger doses necessary to tolerate the longer procedure and abolish the cough reflex. If an ETT is used, an 8.5 is recommended to accommodate the

bronchoscope and ventilate. In the presence of precarinal lymphadenopathy, the ETT may require placement high in the trachea, potentially leaving the balloon between vocal cords. Trauma may occur with prolonged procedures or in the absence of paralysis. Other rare complications associated with the technique include pneumo- and hemomediastinum, pneumothorax, mediastinitis, and bacteremia.

Rigid bronchoscopy usually necessitates general anesthesia. Although spontaneous ventilation has been used, the risk of tracheal trauma is high with coughing. Therefore, muscle relaxation is commonly used unless contraindicated. The rigid ventilating bronchoscope has a side-port adapter that can be attached either to the anesthesia circuit or the jet ventilator, allowing the delivery of a high flow rate. A variable air leak usually exists around the bronchoscope, so high flow rates of inspired gases or packing of the oropharynx are needed. Significant loss of volatile anesthetic into the operating room environment needs to be considered; thus, the use of total intravenous technique is a good alternative.

The *rigid Venturi-effect bronchoscope* relies on an intermittent high flow (20 to 60 L per minute), high pressure (50 psi) oxygen jet to entrain air and insufflate the lungs. The jet is delivered through a reducing valve (25 psi) into a 16- or 18-gauge needle inside and roughly parallel to the lumen of the bronchoscope. Major disadvantages of this technique are the lack of control of the inspired oxygen concentration and the inability to administer inhaled anesthetics. Accordingly, anesthesia should be maintained by intravenous techniques. Inadequate ventilation (with resultant hypercapnia) can also occur.

Rigid bronchoscopic procedures can be relatively short. If sugammadex is available, patients can be fully paralyzed and reversed at the end of the case. Otherwise, continuous

succinylcholine infusion is an alternative even though rarely used nowadays. When followed by another procedure (such as the mediastinoscopy scheduled for this patient), an intermediate-duration nondepolarizing muscle relaxant is often desirable.

C.3. What are the indications for cervical mediastinoscopy? Are there potential complications?

For many years, cervical mediastinoscopy was the gold standard for evaluating disease in the mediastinum and the staging of lung cancer. However, with the introduction of EBUS, cervical mediastinoscopy has become less common. Independent of the technique used, if lymph nodes are positive for malignancy by frozen section, the patient is probably not a candidate for surgical resection at the time of biopsy.

Conventional cervical mediastinoscopy involves a small incision at the sternal notch for the insertion of the mediastinoscope and sampling of lymph nodes. The pleural space is generally not entered intentionally, and, therefore, a chest tube is not indicated. Occult pneumothorax can occur as a complication, so a chest radiograph is usually obtained before discharge. Complications during mediastinoscopy are relatively rare (1% to 2%) and generally result from trauma to adjacent structures (pleura, trachea, esophagus, superior vena cava, azygos vein, innominate artery, pulmonary artery, and aorta) or nerve injury (recurrent laryngeal or phrenic nerve). Should a major vascular structure be perforated, blood loss can be rapid and profound, necessitating emergent sternotomy. Because packing or vascular clamps may be applied to the superior vena cava, clinicians should always have a plan for establishing

venous access in the lower extremity.

C.4. The decision was made to proceed with a robotic right middle lobectomy. How would this alter your management?

Robotic thoracic procedures present some unique challenges when compared to VATS despite both being minimally invasive.

In both cases, patients are **positioned** in the lateral decubitus and the bed may be flexed. However, for robotic cases, the bed may also be rotated 90 to 180 degrees from the original position to allow docking of the robot and hence far away from the anesthesiologist. Extensions for the intravenous tubing and the breathing circuit may be necessary. Special care is required for the upper arm, which is suspended and sometimes abducted to facilitate the robotic arms motion. Unnatural positioning with stretching of the brachial plexus can lead to potentially permanent damage. Direct injury can also result from the robotic arms resting on the patient's arm or head.

Optimal **lung isolation** and **collapse** are needed to enhance lung visualization during the case and allow full motion of the instruments in the chest cavity. Because this space remains partially closed, lung collapse is slower than for the open approach. Carbon dioxide (CO_2) insufflation may be used to expedite the process. Left DLTs are commonly used due to less chance of displacement and the ability to quickly collapse the lung. Once the patient is positioned and the robot docked, it may be difficult to gain access to the airway. Bronchial blockers may be an alternative, but they may require repositioning during the

case.

Intravenous access should be placed before final positioning and draping because patient access will be limited. Although not uniformly regarded as necessary for lung resection via thoracotomy, an **arterial catheter**, generally in the dependent radial artery, may be beneficial in patients undergoing robotic procedures for hemodynamic monitoring especially if the chest will be insufflated with CO_2. This "iatrogenic tension pneumothorax" can be associated with a transient increase in peak airway pressures and a decrease in venous return with significant hypotension and decreased lung compliance. In most cases, this is transient and effectively treated with pressors and/or temporary decrease of the insufflation pressures. Suggested insufflation pressure should be less than 10 to 15 mmHg, whereas peak inspiratory pressures should be less than 30 cm H_2O. Minute ventilation should be adjusted to maintain normocapnia while complying with protective lung ventilation guidelines.

Hemodynamic compromise can also be caused by unexpected bleeding, arrhythmias, or, in rare cases, contralateral pneumothorax (more common during robotic esophagectomy). Bleeding can be more difficult to control in robotic cases than VATS because the robotic arms limit the access to the chest, causing delays in making an incision or performing CPR. Helpful maneuvers to decrease bleeding involve increasing the CO_2 insufflation pressure (potentially worsening systemic hypotension) and allowing periods of apnea to decrease mediastinal movement and facilitate compression/clipping of the source of bleeding.

Robotic resections tend to take longer than open procedures or VATS, with duration influenced by experience of the surgical team and the need for added equipment. As a consequence,

exposure to anesthesia and lung collapse may be prolonged, and intraoperative costs are increased.

C.5. What are the indications for single-lung ventilation and how can it be accomplished?

Absolute and relative indications for lung separation are listed in **Table 2.2**. Several techniques can be used to provide single-lung ventilation, including DLTs, bronchial blocking catheters passed inside or outside an ETT, bronchial blocking catheters incorporated within an ETT (Univent® ETT, Teleflex, Triangle Park, NC), or conventional ETTs placed endobronchially. Newer DLTs include the VivaSight®, ET (ETView Medical Ltd, Misgav, Israel), a left DLT with a high-resolution built-in video camera at the tip of the tracheal lumen that provides a continuous view of the airway; the Silbroncho® (Teleflex, Triangle Park, NC) left DLT constructed of silicone with a wire reinforced tip; and the Cliny® (Create Medic Co, Ltd, Yokohama, Japan) right DLT, a device with an oblong cuff and two ventilation slots for the right upper lobe. Currently, DLTs remain the most common method for achieving lung isolation. Although DLTs of variable design and material have been used in the past (e.g., Robertshaw, Carlens, and White), the models

most commonly used today are disposable and made of polyvinylchloride. Such a tube was chosen for this procedure. Several manufacturers produce right and left DLTs that are available in six sizes: 28, 32 (only one manufacturer), 35, 37, 39, and 41 French (size in French = 3.14 × external diameter in millimeters or 4 × the internal diameter + 2). Although the general rule is that average-sized Caucasian men usually accommodate a 39 French and average-sized women a 37 French.

TABLE 2.2 Indications for Single-Lung Ventilation

Absolute	
1. To isolate from spillage or contamination	• Infection: bronchiectasis and lung abscess • Massive hemorrhage
2. To control the distribution of ventilation	• Bronchopleural fistula • Bronchopleural cutaneous fistula • Giant unilateral lung cyst or bulla • Tracheobronchial tree disruption or trauma • Surgical procedures on major conducting airway (i.e., pneumonectomy or sleeve resection) • Life-threatening hypoxemia resulting from unilateral lung disease • Unilateral bronchopulmonary lavage (pulmonary alveolar proteinosis)
3. To facilitate surgical exposure	• Video- and robotic-assisted thoracoscopic surgery
Relative	
1. Facilitation of surgical exposure—high priority	• Thoracic aortic aneurysm • Pneumonectomy • Upper lobectomy • Mediastinal exposure • Pulmonary resection via median sternotomy
2. Facilitation of surgical exposure—low priority	• Esophageal resection • Middle and lower lobectomies and segmental resection • Procedures on the thoracic spine
3. Severe hypoxemia resulting from unilateral lung disease	

A variety of techniques have been described based on measurements of airway size derived from radiographic or computed tomographic imaging, but these have been questioned across gender and ethnicity. A properly sized DLT should pass atraumatically through the glottis, advance easily into the trachea and bronchus, and exhibit an air leak when the bronchial cuff is deflated.

Bronchial blockers (see section C.9) are a good option for lung isolation in patients who have difficult airways, when postoperative mechanical ventilation is needed, in case of a fresh tracheostomy, or in the pediatric population. Lobar blockade can also be accomplished by using a blocker, especially after pneumonectomy or in case one-lung ventilation (OLV) is not tolerated. Disadvantages of blockers include slow lung collapse, especially in patients with severe COPD, dislodgment of the catheter tip during surgical manipulation of the hilum or being stapled in the bronchial stump.

Independent of the technique chosen, single-lung ventilation is associated with certain disadvantages and complications. The most notable is the large and variable alveolar-to-arterial oxygen tension difference ($P_{[A-a]}O_2$) that occurs because of continued perfusion to the nondependent nonventilated lung. The incidence of severe hypoxemia and hypercarbia is relatively small and often the result of DLT malposition resulting from overinflation of the endobronchial cuff, surgical manipulation of the bronchus, or head extension/flexion during positioning in the lateral decubitus. Traumatic laryngitis and tracheobronchial rupture secondary to bronchial cuff overinflation, forceful placement, or airway pathology have also been reported as potential complication of DLT placement.

Pedoto A. How to choose the double-lumen tube size and side: the eternal debate. *Anesthesiol Clin*. 2012;4:671–681.

C.6. What are the contraindications to the use of double-lumen endotracheal tubes (DLTs)?

Placement of a DLT should be carefully considered in the following situations:

- Patients whose upper airway anatomy may preclude safe insertion such as recessed jaw, prominent teeth, bull neck, anterior larynx, mandibular surgery, and neck radiation
- Patients with lesions along the pathway of the tube that could be traumatized, such as airway stricture or endoluminal tumors
- Small patients for whom a 35 or 32 French tube is too large to fit comfortably through the larynx and a 28 French tube is considered too small
- Critically ill patients already intubated who cannot tolerate cessation of mechanical ventilation and positive end-expiratory pressure (PEEP) for a short time.

Under these circumstances, single-lung ventilation can be achieved via an endobronchial blocker. Endobronchial placement of a single-lumen tube for lung isolation is an alternative but suboptimal option. The tip of the ETT can cause direct distal airway trauma, whereas significant airway compression with potential mucosal ischemia may occur if the cuff bulges at carina. When placed on the right side, the right upper lobe will be occluded by the cuff of the tube, preventing the ability to ventilate.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1663–1700.

Licker M, Le Guen M, Diaper J, et al. Isolation of the lung: double-lumen tubes and endobronchial blockers. *Trends Anaesth Crit Care*. 2014;4:47–54.

C.7. Would you use a right- or left-sided DLT?

A left-sided DLT is preferred for most procedures. The left mainstem bronchus is much longer than the right (approximately 5.0 to 5.5 cm vs. 1.5 to 2.0 cm), allowing small movements of the tube without obstructing a bronchial division. The variable origin of the right upper lobe (1.5 to 2.0 cm below carina) may complicate maintaining a good placement of a right-sided tube. Nevertheless, in an institution where the use of right-sided DLTs is routine, no difference was found in the incidence of hypoxemia, hypercarbia, or high airway pressures between patients managed with left or right DLTs, even when infrequent users were studied. A right-sided DLT is specifically indicated in the case of pathology involving the left mainstem bronchus, such as large exophytic lesions, significant bronchial stenosis, tracheobronchial disruption, endobronchial stent, and distortion by an adjacent tumor or a thoracoabdominal aneurysm. Other indications include left pneumonectomy, sleeve resection, or lung transplantation to avoid the presence of a foreign body in the surgical field that could be included in the staple line or prevent suturing of the lung. At the end of a pneumonectomy, the stump can be protected from positive pressure ventilation by leaving the tracheal side clamped until the patient returns to spontaneous ventilation; for a left lung transplant or a sleeve resection, the right lung can be ventilated when the bronchus is open during the reconstruction phase. The only absolute contraindication for right-sided DLTs use is the presence of an anomalous takeoff of the right upper bronchus above the

tracheal carina, commonly referred to as a "pig bronchus." The presence of any right mainstem lesion may also preclude the use of this lung isolation device.

Pedoto A. How to choose the double lumen-tube size and side: the eternal debate. *Anesthesiol Clin*. 2012;4:671–681.

C.8. How do you know that the tube is in the correct position?

Recommended insertion techniques for a DLT include direct laryngoscopy followed by fiberoptic guidance in the appropriate mainstem. Blind insertion may cause the potential of airway injury. Auscultation alone is unreliable to confirm the position of a DLT especially in the presence of a baseline decrease in breath sounds, such as in case of COPD. The position of the device should be reconfirmed once the patient is in the lateral decubitus prior to lung collapse.

During bronchoscopy, the tracheal cartilaginous rings are anterior and the tracheal membrane is posterior. Therefore, right versus left can be discerned by the relationship of the mainstem bronchi to the anterior cartilaginous rings and the posterior membrane (**Fig. 2.1A**). In addition, the right upper lobe takeoff (which usually arises from the lateral aspect of the right mainstem bronchus, just below the tracheal carina) is a useful landmark when the airway anatomy has been obscured by bleeding, edema, or radiation-induced changes or has been distorted by extrinsic compression. Left DLT position and depth

are confirmed by inserting the fiberoptic bronchoscope in the tracheal lumen. The entire right mainstem bronchus should be visible, and the tracheal lumen orifice of the DLT should be 1 to 2 cm above the tracheal carina. When properly positioned, the upper part of the blue endobronchial cuff is visualized just below the tracheal carina in the left mainstem bronchus (**Fig. 2.1B**). If a right DLT is used, correct positioning is confirmed by visualization of the bronchial cuff in the right mainstem bronchus (**Fig. 2.1C**) and visualization of the right upper lobe orifice through a slot on the lateral surface of the DLT (**Fig. 2.1D**). For both left- and right-sided tubes, the bronchoscope should also be inserted in the bronchial lumen to evaluate the distance between the tip of the tube and the distal bifurcation of the bronchus. DLT position should be reconfirmed after the patient is positioned laterally, before inflating the blue cuff and isolating the lung.

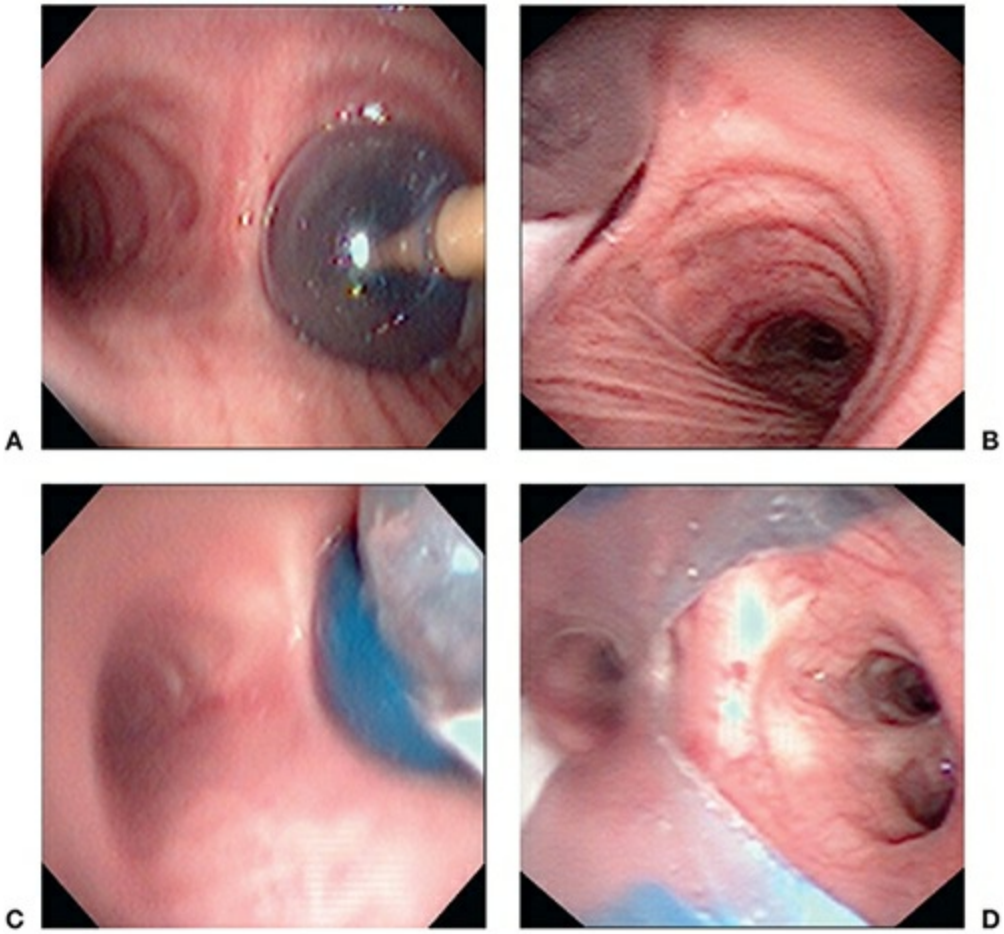

FIGURE 2.1. Representative bronchoscopic images of a bronchial blocker and DLT placement. **A.** Normal tracheal anatomy with cartilaginous rings anteriorly and membranous trachea posteriorly; this helps define left versus right. A bronchial blocking catheter is seen in the right mainstem bronchus. **B.** Placement of a left-sided DLT; the upper portion of the endobronchial cuff is evident as well as the orifice of the right upper lobe just below tracheal carina. **C.** Placement of a right-sided DLT; the upper portion of the endobronchial cuff is evident in the right mainstem bronchus. **D.** The orifice of the right upper lobe visualized through the slot on the lateral aspect of the bronchial side of a right-sided DLT.

When the **VivaSight**® (Ambu Inc, Columbia, MD) tube is used, placement and repositioning can be facilitated by the high-resolution built-in camera. The main advantage for its use is during robotic cases because of the difficult access to the patient being potentially far away from the anesthesiologist and the robotic arms very close to the patient head, making any adjustments to the DLT position a challenge. The main disadvantage is the fogging of the camera by secretions, especially during right-sided procedures, and the bigger outer

diameter, which may cause airway injury during the placement. The lack of a camera on the bronchial side still requires the use of a fiberoptic bronchoscope to assess secondary carina.

C.9. How many types of bronchial blockers are available? What are the advantages and disadvantages of bronchial blockers?

Several blockers are available, leaving ample preference of choice to the operator and the institution. Advantages and disadvantages of blockers are listed in **Table 2.3**.

TABLE 2.3 Advantages and Disadvantages of Bronchial Blockers

Advantages	Disadvantages
• Able to use in adults and children too small to fit a double-lumen tube • Difficult airway • If double-lumen tube contraindicated • Placed inside the ETT • No need to change ETT in the case of postoperative mechanical ventilation • Lobar isolation	• Unable to suction efficiently • Need to be positioned via fiberoptic bronchoscopy • Difficult for right mainstem position and RUL isolation, when the takeoff is too close to the carina • Tracheal occlusion if proximal dislodgment • Cross ventilation if the cuff is not completely inflated • Possible stapling in the stump if not retracted at the appropriate time

ETT, endotracheal tube; RUL, right upper lobe.

- **Fogarty embolectomy catheters** (Edwards Lifesciences, Irvine, CA) can be used to isolate the lung, although not specifically made for this purpose. No. 7 French (7F) Fogarty

catheters come with either a 12- or 20-mL high-pressure, low-volume balloon in both latex and nonlatex models. They have a metallic stylet that can be bent to facilitate endobronchial placement. In the case of dislodgment, the stylet can be reinserted and the blocker repositioned. Fogarty catheters have no communicating central channel; therefore, continuous positive airway pressure (CPAP) or suction cannot be applied intraoperatively. Lung collapse occurs by absorption of oxygen. Therefore, prior to inflating the balloon, it is recommended to both discontinue ventilation and depressurize the circuit of the ventilator if the patient tolerates it. The catheters are usually placed outside a single-lumen ETT and positioned via fiberoptic bronchoscopy (**Fig. 2.1A**). If placed inside the ETT, a connector such as a two-swivel adaptor is needed to facilitate insertion of both the catheter and a bronchoscope.

- **Arndt blockers** (Cook Medical Inc, Bloomington, IN) (wire-guided endobronchial blocker) are available in no. 5, 7, and 9 French with elliptical or spherical cuffs (low pressure, high volume), the latter particularly advantageous to isolate the right lung. They are usually inserted through the ETT via a three-way connector (catheter, bronchoscope, ventilation circuit). Their positioning is facilitated via Seldinger technique by an inner wire with a loop at the distal tip, where the flexible bronchoscope is placed. The wire is then removed once the blocker is in position, leaving an inner lumen that allows for suctioning or CPAP. Once the wire loop has been removed, it can be reinserted, allowing repositioning of the blocker in case of dislodgment.
- **Cohen blockers** (Cook Medical Inc, Bloomington, IN) are similar in shape to the Arndt blockers, but they use a positioning wheel to facilitate placement. By turning the wheel in a clockwise fashion, the distal portion of the blocker

deflects to the left. The main advantage of this blocker is its placement in the left mainstem because of its steep angle. Disadvantages include the cost, the fragility of the wheel, and the availability of only one size (no. 9 French).

- **EZ-blockers** (Teleflex Life Science Ltd, Morrisville, NC) are blockers with a Y-shaped bifurcation at the end fitted with two inflatable cuffs and a hollow channel in the center. The cuffs are high-pressure, low-volume, and color-coded. The blocker is placed inside the ETT, with the end on a horizontal plane to facilitate the placement of the Y across carina. Final position needs be confirmed via fiberoptic visualization because both cuffs may go in the right mainstem. The main advantage of this blocker is its stability, making it useful in cases where patient access is limited. The presence of the two cuffs makes sequential lung isolation feasible.
- **Univent tubes** (Teleflex, Triangle Park, NC) consist of an ETT with a built-in silicone bronchial blocking catheter. The main advantage is the ability of leaving the device in place in case of postoperative mechanical ventilation. However, this device is not commonly used in the United States because of its bulkiness. The outer diameter ranges from 9.7 to 13.7 mm (for a 6.0 to 8.0 inner diameter tube), with the potential to cause subglottic edema and stenosis in case of long-term use. The inner diameter is quite narrow, making suctioning or fiberoptic bronchoscopy difficult. The silicone blocker in the Univent is available as an isolated item (**Fuji blocker**). It is a high-volume, low-pressure system with a preformed “hockey stick” bend at the tip and a double stylet. It has a spherical cuff (ideally more suited to isolate the right mainstem bronchus) and two different sizes (no. 5 and 9 French). The **Coopdech** blocker (Daiken Medical Co Ltd, Izumi, Japan) is similar in shape to the Fuji blocker but offers the extra option of an auto-inflate balloon via an auto-inflate button, allowing

the use of one hand while maneuvering the fiberoptic bronchoscope.

Blockers can be used to rescue nonworking DLT, by placing the device inside the lumen of the nondependent lung. This may be needed in case of rupture of the bronchial cuff in a patient already positioned, or for lobar collapse in case of DLT dislodgment and inability to appropriately reposition in the mainstem bronchus. The DLT may be left in the original place or withdrawn and used as a single-lumen tube.

C.10. How will systemic oxygenation be monitored during single-lung ventilation? What is the mechanism of pulse oximetry?

Pulse oximetry is still the hallmark for monitoring arterial oxygenation during lung resection, decreasing the need for repeated measurements of arterial blood gases. This technique uses spectrophotoelectric oximetric principles to determine oxygen saturation. Pulse oximeters are multiple-wavelength plethysmographs. The amplitude of the pulse is a function of arterial distention, hemoglobin oxygen saturation of the arterial blood inflow, and light wavelength. Hemoglobin saturation in the arterial blood is the result of the ratio between the pulse amplitude of red (660 nm = deoxyhemoglobin) and infrared (940 nm = oxyhemoglobin) light. Pulsatile waveform is a

characteristic of arterial blood flow, so there is no interference from surrounding venous blood, skin, connective tissue, or bone. Arterial pulsations cause changes in light absorption, which are used to calculate oxygen saturation. Adequate finger pulsation generally is lost with hypothermia of a few degrees, hypotension (mean blood pressure less than 50 mmHg), and infusion of vasoconstrictive drugs. Accuracy of the measurement is also lost for values below 70% and can be affected by dyshemoglobinemias (such as carboxyhemoglobin, methemoglobin, and sulfhemoglobin) as well as intravenous dye injection. The use of arterial oxygen saturation to monitor organ perfusion has been recently questioned by data of cerebral desaturation in the absence of arterial desaturation.

Cerebral oximetry has recently become a popular monitor of brain perfusion during thoracic and cardiac anesthesia. The technique uses near-infrared spectroscopy (NIRS) to integrate venous and arterial hemoglobin oxygen saturation signals in a ratio of 3:1. The presence of autoregulatory mechanisms guarantee that the brain is perfused and oxygenated at the expenses of other organs. Therefore, when significant cerebral desaturation occurs (<65%), it is likely that other organs have already been exposed to the same insult, with a higher risk for damage. Specifically, brain hypoperfusion seems to correlate with renal ischemia and subsequent acute renal failure (ARF). The magnitude and the duration of mean arterial pressure values below autoregulation limits appear to correlate with the incidence of postoperative ARF after cardiac surgery. ARF is also a known complication after anatomical lung resection. At the present time, there are no studies correlating its incidence with cerebral desaturation. Postoperative changes in mental status have been reported for prolonged periods of cerebral desaturation after thoracic procedures. Proposed physiologic mechanisms include hypoxemia during single-lung ventilation

and mediastinal shift with reduced cardiac output related to the lateral decubitus position.

C.11. The patient was placed in the lateral decubitus position. Describe the effects of lateral positioning on pulmonary blood flow and respiration.

In both upright and supine positions, the right lung receives approximately 55% of the total blood flow, whereas the left lung receives the remaining 45%. In the lateral decubitus position, gravity causes a vertical gradient in blood flow distribution. Therefore, perfusion of the dependent lung is significantly greater than the nondependent counterpart. When the right lung is nondependent, it receives 45% of the total blood flow, whereas 55% perfuses the dependent left lung. When the left lung is nondependent, it receives 35% of the total blood flow, whereas right lung receives 65%. Therefore, the average blood flow of the nondependent lung is approximately 40% of the total blood flow with the dependent lung being perfused with the remaining 60% (**Fig. 2.2**).

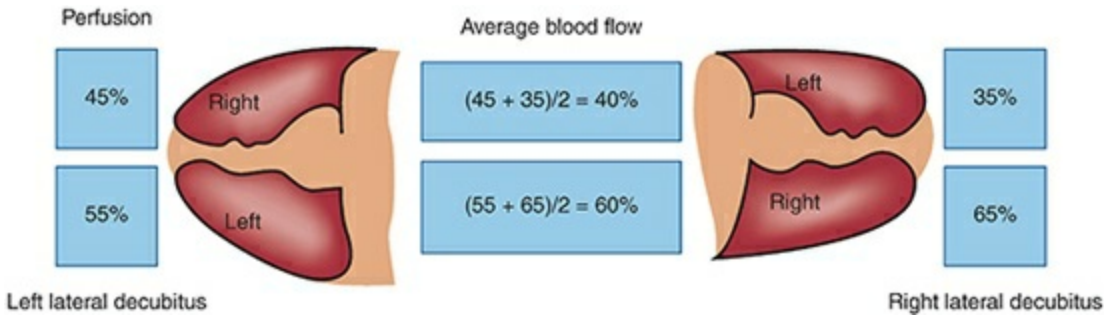

FIGURE 2.2. Changes in blood perfusion with the lateral decubitus position.

Respiratory Effects

The lateral decubitus position causes both mechanical interference with chest wall motion and a decrease in lung expansion. Specifically, the dependent chest wall is constricted by the operating room table, the lateral movements are limited by the bolsters or the "beanbag" used to hold the patient in position, whereas the upper expansion is reduced by the weight of the mediastinum. The flexion at the hips causes a theoretical improvement of the diaphragmatic motion, especially in morbidly obese patients. However, the caudad displacement of the abdominal organs is counteracted by the negative effects of general anesthesia and muscle relaxation. The final result is a gravity-induced mismatch of ventilation and perfusion while in the lateral position, with redistribution of blood flow toward the dependent lung, which is compressed by the mediastinal contents, resulting in an increase in atelectasis and hypoventilation. In the awake, spontaneously breathing subject, the lower (dependent) diaphragm is still able to contract more efficiently, maintaining ventilation in the dependent lung and matching the increased perfusion. In contrast, when the patient is anesthetized, with or without paralysis, most of the ventilation is preferentially switched to the more compliant upper lung, whereas perfusion increases in the lower lung. The result is an increased degree of ventilation/perfusion mismatch.

C.12. What is hypoxic pulmonary vasoconstriction (HPV)?

HPV is an autoregulatory mechanism to prevent ventilation/perfusion mismatch and improve arterial oxygenation. Proposed mechanisms include an increase in reactive oxygen species in the pulmonary arterial smooth muscle, activation of redox-based oxygen sensors, and an increase in intracellular calcium. HPV is triggered by a decrease in Pa_{O_2} within the lung from low F_{IO_2}, hypoventilation, or atelectasis. The selective increase of vascular resistance in the hypoxic parenchyma diverts blood away to the better ventilated normoxic lung, decreasing the amount of shunt flow. This is a biphasic response that starts within 15 to 30 minutes from lung collapse, culminates at 120 minutes, and takes hours to reverse after normoxia is restored.

Increasing evidence indicates that significant systemic oxidative stress can be elicited by hyperoxic reperfusion of a lung in which HPV has been sustained for an extended period of time. Although the exact ramifications of this insult remain to be clarified, clinical data suggest an association between the magnitude of the oxidative stress and postoperative cardiopulmonary complications. Recommendations to decrease reexpansion injury include reinflating the collapsed lung with less than 100% F_{IO_2} as well as using protective lung strategies. The lowest F_{IO_2} possible is also recommended.

C.13. What are the effects of anesthetic agents on HPV and their clinical implications?

Any medication that causes vasodilation may inhibit hypoxic vasoconstriction. Several clinical studies have failed to demonstrate a decrease in HPV during single-lung ventilation and total intravenous anesthesia. Intravenous anesthetics, such as thiopental, ketamine, morphine, and fentanyl, have no direct effect on HPV. In contrast, inhalational anesthetics have been shown to inhibit HPV in a dose-related fashion but usually at concentrations much higher than clinically used. Other nonanesthetic drugs such as β-agonists and antagonists, calcium channel blockers, nitrovasodilators, and theophylline may influence the effects of inhalation anesthetics on shunting and arterial oxygenation during single-lung ventilation. There is no good evidence that neuraxial blockade affects HPV, unless causing a decrease in cardiac output or systemic vasodilation.

- The result of an increased shunt on Pa_{O_2} depends on the absolute level of the initial shunt and the inspired oxygen concentration used. Even when shunt is increased, Pa_{O_2} usually remains well above 100 mmHg, with minimal changes in oxygen saturation and content.
- Inhalational agents inhibit HPV, but they also decrease

cardiac output, oxygen consumption, and may cause a decrease in mixed oxygen venous tension (PvO_2). If cardiac output decreases and oxygen consumption does not change, there will be a decrease in PvO_2, which is a potent stimulus for HPV. A low cardiac output will result in a decreased perfusion of the collapsed lung (where there is an increase in pulmonary vascular resistance as a result of HPV). Nevertheless, the presence of chronic and irreversible vascular disease in the nondependent lung may impair HPV response.

- The presence of disease in the dependent lung will decrease the ability of accepting blood flow redistribution, thereby decreasing the local HPV effect.
- Direct surgical manipulation may cause the release of vasoactive substances, such as thromboxane and prostacyclin (PGI_2), promoting local vasodilatation and blunting HPV, with a subsequent increase in shunt.
- Metabolic or respiratory acidosis and hypothermia are also associated with an impairment in HPV.

Lumb AB, Slinger P. Hypoxic pulmonary vasoconstriction: physiology and anesthetic implications. *Anesthesiology*. 2015;122:932–946.

C.14. Discuss pulmonary blood flow distribution, shunt flow, and partial pressure of oxygen in the arterial blood (PaO_2) (fractional inspired O_2 concentration [FIO_2] = 1.0) during single-lung ventilation in the lateral position.

When the nondependent lung is collapsed, HPV will ultimately increase pulmonary vascular resistance and decrease lung blood flow in this area. If no complicating factors exist, HPV should decrease blood flow to that lung by approximately 50%, causing a total reduction from 40% to 20%. The resulting

nondependent/dependent lung blood flow ratio during OLV should be 20%:80%.

Once atelectatic, all the blood flowing into the nonventilated lung is shunt flow. Therefore, OLV creates an obligatory right-to-left transpulmonary shunt that was not present during double-lung ventilation. During single-lung ventilation, an ideal total shunt flow of 20% would be expected, if no shunt existed during double-lung ventilation (ignoring the normal 1% to 3% physiologic amount from the bronchial, pleural, and thebesian circulation). Pa_{O_2} with an F_{IO_2} equal to 1 should be approximately 280 mmHg if hemodynamic and metabolic states are normal. Clinically, Pa_{O_2} ($F_{IO_2} = 1$) ranges from 150 to 250 mmHg.

Marshall BE, Marshall C. Continuity of response to hypoxic pulmonary vasoconstriction. *J Appl Physiol Respir Environ Exerc Physiol*. 1980;59:189–196.

C.15. How could you improve oxygenation during single-lung ventilation?

When hypoxia occurs during single-lung ventilation, the goal is to optimize the match between ventilation and perfusion on the dependent lung or increase the amount of oxygen in the shunted blood of the collapsed lung.

Ventilated Lung

a. *Optimize ventilation.*

- Use 100% oxygen.
- Check the position of the DLT with a fiberoptic bronchoscope.
- Ventilate manually to determine whether higher or lower tidal volumes or inspiratory pressures are beneficial.

- Set minute ventilation to maintain $Paco_2$ at 40 mmHg (hypocapnia may inhibit HPV in the nondependent lung, whereas hyperventilation may increase airway pressure and promote blood flow to the nonventilated lung).
- Apply 5 cm H_2O of PEEP. It may be beneficial if larger tidal volumes delivered manually improved arterial saturation (i.e., recruitable alveoli). Alternatively, if tidal volumes are too large, adding PEEP may overdistend alveoli that are already open and compress blood vessels, diverting blood to the nonventilated lung and worsening the shunt.
- Use two-lung ventilation intermittently.

b. *Increase perfusion.*

- Selective vasodilators (inhaled nitric oxide, inhaled PGI_2)

Collapsed Lung

a. *Oxygenate shunt blood:* A variety of approaches have been described but must be carefully considered for minimally invasive procedures because most involve some degree of lung reexpansion and therefore may affect surgical visualization.

- Insufflate oxygen continuously: A flow of about 3 L per minute allowed to freely circulate will often increase arterial oxygen saturation 3% to 4%.
- Intermittent single breath with oxygen
- Partially reexpand the nonventilated lung and then keep the lumen side closed.
- Apply continuous CPAP.
- Differential CPAP to the collapsed lung and PEEP to the ventilated lung has been described but is rarely necessary and generally impractical for minimally invasive procedures.
- High-frequency ventilation to the nonventilated lung

b. *Decrease the shunt.*

- Use medications to augment HPV (phenylephrine, norepinephrine, almitrine).
- Temporary clamp lobar vessels or the pulmonary artery of the nonventilated lung (rarely necessary).

Possible hypoventilation, in compliance with protective lung strategy and the ERAS guidelines will increase the need for the aforementioned maneuvers to maintain the saturation and the $Paco_2$ within acceptable ranges.

Batchelor TJP, Rasburn NJ, Abdelnour-Bertchtold E, et al. Guidelines for enhanced recovery after lung surgery: recommendations of the Enhanced Recovery after Surgery (ERAS®) Society and the European Society of Thoracic Surgeons (ESTS). *Eur J Cardiothoracic Surg*. 2019;1(55):91–115.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1663–1700.

C.16. A right middle lobectomy was performed. Would you extubate the trachea at the end of the procedure?

After routine lung resection, the trachea can be extubated if the patient meets criteria and has adequate analgesia. If the patient cannot maintain adequate oxygenation and ventilation, postoperative mechanical support is indicated. If so, the DLT needs to be exchanged to a single lumen tube or a supraglottic device. Spontaneous ventilation avoids the potential hazards of positive pressure on the suture lines of the new bronchial stump or parenchymal air leaks. The combination of modest CPAP and pressure support ventilation is usually preferable to controlled intermittent mandatory ventilation.

Slinger PD, ed. *Principle and Practice of Anesthesia for Thoracic Surgery*. Cham, Switzerland: Springer; 2019:885–923.

D. Postoperative Management

D.1. What are the immediate life-threatening complications that follow lobectomy or pneumonectomy?

Serious complications after lobectomy include lobar collapse, massive hemorrhage caused by loosening of pulmonary vessels ligatures, bronchopleural fistula from disruption of a bronchial stump, and pulmonary torsion and infarction resulting from increased mobility of the remaining lobe. Mediastinal shift, pleural effusion, hemothorax, chylothorax, empyema, and pulmonary edema can also occur. Deep venous thrombosis can lead to pulmonary embolism.

Pneumonectomy can be complicated by supraventricular arrhythmias, acute respiratory insufficiency, nerve injuries (phrenic, vagus, or recurrent laryngeal) during radical hilar dissection or excision of mediastinal tumors, cardiac herniation (in the case of intrapericardial approach), acute right heart failure, and right-to-left shunting across a patent foramen ovale as a result of increased pulmonary vascular resistance and increased right ventricular pressure. *Postpneumonectomy syndrome* is a rare complication characterized by mediastinal shift ipsilateral to the side of surgery with herniation of the hyperinflated lung in the same direction.

Slinger PD, ed. *Principle and Practice of Anesthesia for Thoracic Surgery*. Cham, Switzerland: Springer; 2019:885–923.

D.2. Why is it important to control postoperative pain? How would you achieve this goal?

Adequate postoperative analgesia is important not only for patient comfort but also to minimize pulmonary complications, allowing the patient to breathe deeply, cough effectively, and ambulate. Several options are available, depending on the institution and surgical preferences.

Enhanced recovery pathways have been developed to decrease postoperative complications and expedite discharge. A multimodal analgesic approach is paramount for any surgical technique.

Epidural, Paravertebral, and Intrathecal Analgesia

Since the introduction of regional analgesia, there has been a trend towards reduced morbidity and mortality after open lung resection. **Thoracic epidural** analgesia is commonly achieved with a continuous infusion of a local anesthetic alone or in combination with an opiate. In order to reduce the volume required to produce an effect and lessen the chance of hypotension and motor weakness, the catheter is usually placed as close as possible to the dermatomes to be covered. A low concentration of local anesthetic such as 0.1% or 0.05% bupivacaine hydrochloride combined with an opiate (e.g., fentanyl 5 to 10 μg per mL, hydromorphone 8 μg per mL, or sufentanil 0.1 μg per mL) produces synergistic effects with a reduction of the sympathetic blockade associated with the use of a more concentrated local anesthetic alone. In addition, the presence of local anesthetics seems to increase the affinity of the narcotic for the opioid receptors. Potential complications of thoracic epidural technique can be related to the placement (inadvertent dural puncture, trauma to the spinal cord, hematoma) or drug administration (intravascular injection of local anesthetics with resultant cardiovascular and central nervous system toxicity). Long-acting antiplatelet medications discontinuation should follow the American Society of Regional Anesthesia and Pain Medicine guidelines to prevent neuraxial hematomas.

Paravertebral blocks and **catheters** can be used preoperatively or postoperatively, in combination with parenteral opiates and NSAIDs, as an alternative to thoracic

epidural analgesia. To be effective, multiple levels need to be blocked unless a catheter is placed. The failure rate for the blind technique is relatively high (6% to 10%) and can be decreased by locating the space via ultrasound guidance or under direct vision by the surgeon before closing the chest. Pneumothorax (especially if bilateral blocks are attempted), hypotension, local anesthetic toxicity due to the high vascularity of the area, and inadvertent total spinal are all potential risks. Advantages compared with epidural analgesia include less hypotension, less nausea or vomiting, and the ability to block just the surgical side.

Intrathecal injection of opiates can be used pre- or intraoperatively for an 18- to 24-hour postoperative pain relief. However, when compared to epidural injection, intrathecal opiates (i.e., morphine) are associated with an increased incidence of late respiratory depression (4% to 7% compared to less than 1% for epidural administration), pruritus, nausea and vomiting, which could increase length of stay (LOS) in the postoperative period.

The advantages of neuraxial techniques compared to systemic opiates include selective blockade of spinal pain receptors with minimal sympathetic blockade, no loss of motor function, and greater predictability of pain relief. Epidural opiates in combination with local anesthetics block the presynaptic and postsynaptic neuron cells of the substantia gelatinosa of the spinal cord by passive diffusion across the dura into the cerebrospinal fluid. The lipophilic narcotics, such as fentanyl 0.1 mg, methadone 5 mg, and meperidine 30 to 100 mg, have a relatively short onset of action (less than 12 minutes). They provide significant pain relief in 20 to 30 minutes, which can last for 6 to 7 hours. In contrast, a hydrophilic opiate such as morphine (5-mg dose) has a relatively slow onset of action (15 to 30 minutes), provides maximal pain relief in 40 to 60 minutes

with a duration of action of more than 12 hours. Other side effects include urinary retention, pruritus, nausea, and vomiting. The narcotic antagonist naloxone can reverse all the aforementioned side effects but will also reverse the analgesia, so it must be used cautiously. Overall, unlike epidural local anesthetic, epidural opioids have not been shown to decrease the incidence of postoperative respiratory complications.

Peripheral Nerve Blocks

Peripheral nerve blocks with long-acting local anesthetics can be used to control pain after thoracoscopy or thoracotomy. The duration of single injections is relatively short (6 to 8 hours when bupivacaine hydrochloride is used). Catheters can be left in place and dosed postoperatively. *Intercostal nerve blocks* can be done under direct vision by the surgeon before closing the chest cavity or percutaneously before awakening the patient. The intercostal nerves to be blocked are at the level of the incision and two or three interspaces above and below. Of the three main sensory divisions of the intercostal nerve (posterior, lateral, and anterior cutaneous nerve), the posterior branch cannot be blocked with this approach, limiting its usefulness in the case of a posterolateral incision. There is controversy on the quality of analgesia with this technique alone when compared with the epidural route. Intercostal catheters are indicated as part of a multimodality treatment when neuraxial blocks are contraindicated (e.g., patients on anticoagulation or tumor involvement of the epidural space) or for minimally invasive procedures. Recently, *serratus plane* and *erector spinae* block and catheters have been described as good analgesic options for minimally invasive lung resections. Ultrasound guidance makes these blocks relatively easy and with low risks of complications.

The use of extended-release formulation of liposomal bupivacaine (Exparel, Pacira Pharmaceuticals, Inc, Parsippany,

NJ) may increase the duration of the block, improving the quality of analgesia, especially when paired with other adjuvants. Because of the relatively high rate of systemic absorption of the local anesthetic from the intercostal space, there is an increased risk of systemic toxicity. Liposomal bupivacaine has been used off label for intercostal nerve blockade and other peripheral nerve blocks. The few case reports where the medication was used did not show permanent nerve damage or toxicity, whereas the degree of analgesia was reported comparable to thoracic epidural. Due to the concern of systemic toxicity, the use of liposomal bupivacaine in a peripheral nerve block precludes the use of local anesthetic via neuraxial blockade.

Systemic Opioids and Adjuvants

Systemic administration of **opioids** was the main analgesic modality in the past, alone or as part of a multimodal approach, especially for minimally invasive surgical procedures. With the advent of Enhanced Recovery after Thoracic Surgery (ERATS) protocols and the current opioid epidemic affecting the United States, there has been a shift in the analgesic paradigm in favor of a multimodal approach based on regional techniques and nonopioid medications, leaving opioids as a rescue. Sedation, potential respiratory depression, hypoventilation, inhibition of cough, and reduced sighing are the main side effects that can prolong LOS.

NSAIDs such as ketorolac, diclofenac, ketoprofen, and indomethacin can be used as adjuvants to parenteral opiates, particularly for the treatment of shoulder pain associated with chest tube placement. Potential side effects for NSAIDs include gastric bleeding, platelet dysfunction, and renal insufficiency in patients who are severely fluid restricted, especially the elderly. Intravenous acetaminophen is used in the US can be added to

potentiate analgesia if not contraindicated.

Low-dose intravenous **ketamine** infusion (0.25 mg/kg/hr) has been used as an adjuvant in the perioperative period, especially in patients with chronic pain. Psychomimetic side effects are a possibility but are rare at this dosage. Intravenous **dexmedetomidine** can be used intraoperatively to potentiate analgesia. The recommended dose is a continuous infusion of 0.2 to 0.7 (to a maximum of 1.5) μg/kg/hr without loading. Its central α_2-agonism potentiates analgesia, allowing a decrease in the dose of intravenous narcotics and decrease the minimal alveolar concentration (MAC) of general anesthesia. Hypotension and bradycardia are potential side effects as well as sedation. **Lidocaine infusion** (1.0 to 1.5 mg/kg/hr) can also be used as an adjuvant. Despite the concern of systemic toxicity, there has been no reports of such complication. Intravenous lidocaine infusion should be considered as an alternative when neuraxial blockade is contraindicated or for minimally invasive procedures.

Oral and Transdermal Agents

Gabapentin and **pregabalin** are analogues of γ-aminobutyric acid, usually used for neuropathic pain and given in the preoperative period as part of a multimodal analgesic approach. Sedation and dizziness are the main side effects, limiting their use in the elderly population. Their maximal plasma concentration occurs at 2 to 3 hours from ingestion. Pregabalin has a faster onset of action when compared with gabapentin, reaching faster peak of action. For both medications, it seems there is a better effect on analgesia if the drug is started days prior to surgery rather than one dose preoperatively. **Glucocorticoids** decrease postoperative pain, opioid requirements, and postoperative nausea and vomiting (PONV). Glucocorticoids mixed with local anesthetic prolong the

duration of the block more than when given intravenously in adjunct to the block. **Beta blockers** have antinociceptive properties. Esmolol infusion has been associated with a small decrease in intra- and postoperative pain scores in abdominal surgery, with a decrease in morphine equivalents and rescue doses. **Capsaicin** applied directly in the wound prior to closure deactivates C-fiber conduction due to depletion of substance P. Capsaicin has a long duration of action without any motor and autonomic activity, facilitating early rehabilitation in the postoperative period. Due to an intense burning on injection, the medication should be delivered during anesthesia. **Lidocaine patch** (5% concentration) has been used with some success as an adjuvant in chronic pain patients. Its efficacy is limited in the postoperative period, possibly because of an insufficient concentration in the wound and the inability of properly placing the patch on top of the incision, therefore with minimal absorption.

Intrapleural Regional Analgesia

Intrapleural analgesia utilizes the percutaneous introduction of a catheter between the parietal and visceral pleura for the injection of local anesthetic. Analgesia is thought to occur because of (1) diffusion of local anesthetic through the parietal pleura and the innermost intercostal muscle to the intercostal nerves (where the block occurs), (2) block of the intrathoracic sympathetic chain, and (3) direct action of local anesthetic on nerve endings within the pleura. Nevertheless, the quality of analgesia is extremely variable and unfavorable compared to that of other modalities. The local anesthetic can be lost through the thoracotomy drainage, it can be diluted by extravasated blood and tissue fluid in the pleural space, or it can be sequestered and channeled because of the decreased movements of the operated lung. Moreover, in the sitting position, the local anesthetic pools in the

costophrenic angle, limiting the quality of analgesia. The use of multiple or fenestrated catheters may achieve a more even distribution over the pleura and improve the quality of analgesia. However, this technique is rarely used today.

Cryoanalgesia

Long-lasting (3 to 4 weeks up to 6 months) intercostal nerve block can be obtained by cryoablation. Two 30- to 60-second freeze cycles (−60°C), separated by a 5-second thaw period, are applied to each of the nerves selected. Although cryoanalgesia was initially shown to effectively relieve pain and improve postoperative pulmonary function, more detailed studies have revealed a significant incidence of paresthesia and post thoracotomy pain syndrome.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) relies on the application of brief pulses of current via electrodes to the affected area. The advantages of TENS include low cost, ease of application, and lack of undesirable side effects. Nevertheless, TENS has a weak analgesic effect. It is generally reserved for adjunctive use to relieve mild-to-moderate postthoracotomy pain. It is ineffective if the pain is severe and is contraindicated in patients with pacemakers, defibrillators, and infusion pumps because the current could produce interference.

Shoulder Pain after Lung Resection

Independently from the analgesic technique used and the surgical approach, approximately 80% of patients who have undergone lung resection complain of ipsilateral shoulder pain that is unresponsive to epidural block or systemic opioid. Possible causes for shoulder pain include referred pain from diaphragmatic irritation, chest tube placement (too far at the apex of the hemithorax), the posterior end of a large

posterolateral incision, or surgical positioning in patients with arthritis. Shoulder pain usually responds to anti-inflammatory agents and often resolves on the second postoperative day. Phrenic nerve infiltration and brachial plexus block have been used but have the potential of causing diaphragmatic dysfunction.

3 Aspiration and Postoperative Respiratory Failure

Kapil Rajwani, Edward J. Schenck, and David A. Berlin

A 62-year-old woman presents to the emergency department with a small bowel obstruction. She is vomiting and hypotensive and appears to aspirate. She is emergently intubated, fluid resuscitated, and brought to the operating room for emergency laparotomy.

A. Aspiration

1. What are the risk factors for perioperative aspiration?
2. How does large volume aspiration affect the respiratory system?
3. How should you manage the patient after an aspiration event?
4. How would you prevent aspiration during emergency surgery?

B. Postoperative Respiratory Failure

After successful lysis of abdominal adhesions, the patient recovers well and is extubated at the completion of surgery. Subsequently, she develops progressive hypoxemic respiratory failure while in the postanesthesia care unit.

1. How can you predict which patients will develop postoperative

respiratory failure?

2. How can intraoperative anesthesia management prevent respiratory failure?
3. What is the pathogenesis of postoperative respiratory failure?
4. What is the diagnostic approach to postoperative respiratory failure?

C. Indications for Ventilator Support

The patient has worsening hypoxemia and tachypnea despite treatment with high-flow supplemental oxygen.

1. What are the indications for noninvasive positive pressure ventilation (NIPPV)?
2. What are the indications for emergency endotracheal intubation?

D. The Acute Respiratory Distress Syndrome

The patient is intubated for respiratory failure. She has bilateral pulmonary infiltrates on chest x-ray and is severely hypoxemic.

1. What is the definition and etiology of the acute respiratory distress syndrome (ARDS)?
2. Explain the pathophysiology of ARDS.
3. What role does ventilator-induced lung injury (VILI) play in ARDS?

E. Management of Mechanical Ventilation

1. Which mode of mechanical ventilation will you choose? Describe the features of that mode.
2. How should you set the fraction of inspired oxygen (F_{IO_2})?
3. How should you set the positive end-expiratory pressure (PEEP)?
4. What tidal volume and inspiratory pressure target should you set?

F. Management of Refractory Respiratory Failure

The patient remains hypoxemic on F_{IO_2} of 0.8.

1. What else can promote additional lung recruitment?
2. What rescue strategies can you use for refractory ARDS?

G. Adjunctive Management of Respiratory Failure

Since intubation, the patient has become hypotensive.

1. What is the cause and treatment of the hemodynamic instability associated with mechanical ventilation?
2. What is the adjunctive medical therapy for ARDS?

H. Liberation of the Patient from Mechanical Ventilation

The patient slowly recovers over the next 3 days.

1. Explain the importance of the decision to extubate the patient or continue mechanical ventilation.
2. How will you prepare the patient for liberation from the ventilator?
3. How will you recognize when the patient is ready for extubation?

A. Aspiration

A.1. What are the risk factors for perioperative aspiration?

Clinically significant aspiration is a relatively rare complication of anesthesia. The reported incidence is 1 to 5 per 10,000 patients, although it is more common in certain situations, such as traumatic brain injury. About half of the cases of perioperative aspiration occur during induction of anesthesia. Although an emergency indication for surgery is a major risk factor for aspiration, the majority of cases occur during elective procedures. Increased gastric pressure, decreased lower esophageal sphincter tone, and blunted protective airway reflexes promote aspiration. Therefore, risk factors for aspiration

include full stomach, pregnancy, bowel obstruction, gastroesophageal reflux, obesity, gastrointestinal motility disorders, and neurologic conditions. Airway manipulation in an unfasted patient or an inadequate depth of anesthesia may increase the risk of aspiration. Many anesthetics reduce lower and upper esophageal sphincter tone and diminish protective airway reflexes. The appropriate use of laryngeal mask airways does not increase the risk of aspiration, although it may induce gastroesophageal reflux. Certain surgical procedures such as laparoscopic insufflation of the abdomen and bowel manipulation are associated with increased rates of aspiration.

A.2. How does large volume aspiration affect the respiratory system?

Aspiration of gastric and oropharyngeal contents causes three overlapping syndromes. First, aspiration of large particulate matter may obstruct the airways and lead to atelectasis. Acute aspiration pneumonitis is more common and is a result of chemical burning of the tracheobronchial tree and pulmonary parenchyma by gastric and oral fluids. Finally, aspiration of bacteria from the oropharynx or a superinfection of the chemical pneumonitis may result in aspiration pneumonia.

Mendelson originally described aspiration pneumonitis in 66

obstetrical patients who aspirated gastric contents during anesthesia. Respiratory distress and cyanosis developed within 2 hours after the aspiration event. All of the patients (except two who had airway obstruction from solid food particles) recovered within 24 to 36 hours without antibiotics and had radiographic resolution. Signs and symptoms of aspiration pneumonitis include coughing, wheezing, dyspnea, hypoxia, fever, tachypnea, and crackles on lung auscultation. Radiography usually demonstrates diffuse bilateral infiltrates.

Aspiration pneumonitis may be mild and elude clinical detection. Rarely, aspiration is fulminant and rapidly fatal. Most patients rapidly improve after aspiration and have clearing of radiographic lung infiltrates. Occasionally, patients initially improve but then develop progressive lung infiltrates on chest radiograph. These infiltrates probably represent a secondary bacterial infection or ARDS. The volume and pH of the aspirated fluid are important factors affecting the degree of lung injury. In adults, approximately 25 mL of gastric acid with a pH <2.5 is considered a clinically relevant threat. Smaller volumes may produce a milder syndrome. Bile may elicit a potent inflammatory response and has been identified in patients' endotracheal tubes. Atelectasis, peribronchial hemorrhage, pulmonary edema, and degeneration of bronchial epithelial cells all develop within minutes of aspiration. By 4 hours, the alveoli fill with polymorphonuclear leukocytes and fibrin, and hyaline membranes form. The lung becomes grossly edematous and hemorrhagic with alveolar consolidation.

Aspiration pneumonia may result from a superimposed infection of the chemical injury or inhalation of microorganisms from the oropharynx. Poor dentition is a risk factor for aspiration pneumonia. Common bacteria include *Haemophilus influenzae*, streptococci, and other anaerobes. The oral flora changes in chronically ill patients and those in health care

settings for greater than 48 to 72 hours. In these patients, gram-negative bacteria and resistant *Staphylococcus* may colonize the oropharynx and cause pneumonia.

A.3. How should you manage the patient after an aspiration event?

Awake patients capable of airway protection should be placed in the upright or recovery position and encouraged to cough. However, clinicians may need to suction or rescue the airway if the patient has impaired protective airway reflexes. Supplemental oxygen should be administered for hypoxemia. Clinicians should avoid noninvasive ventilation because of the risk of gastric insufflation unless there is no further risk of additional vomiting. There is no evidence supporting lavage with saline or sodium bicarbonate. Gastric acid is rapidly neutralized by the physiologic response. When possible, the stomach should be emptied with a nasogastric tube. A chest radiograph should be ordered. In select circumstances, a bronchoscopy may be necessary for airway clearance and evaluation especially if airway obstruction is suspected. Bronchoscopy can provide quantitative lower respiratory tract

cultures from bronchoalveolar lavage or protected brushings. These techniques can distinguish aspiration pneumonitis from pneumonia.

Although some animal studies support the use of corticosteroids in aspiration pneumonitis, there is no evidence of benefit in human studies. Moreover, the literature does not support the routine use of antibiotics immediately after aspiration. A retrospective cohort study reviewing 200 patients divided into groups that received supportive care versus antimicrobials did not show any clinical benefit when looking at mortality or need for transfer to an intensive care unit. Patients, however, should be followed closely to identify the development of a secondary infection. If the clinicians diagnose aspiration pneumonia, they should choose antibiotics that provide coverage against oral flora including gram-negative coverage for patients with nosocomial colonization. This may include extended spectrum β lactamases inhibitors such as piperacillin-tazobactam.

A.4. How would you prevent aspiration during emergency surgery?

Certain measures may help reduce the risk of perioperative aspiration. These include adequate fasting, prophylactic antiemetics, rapid sequence intubation (RSI), limited tidal volumes if bag ventilation is used, and extubation when the patient's laryngeal reflexes have returned. Anti-acid medications can increase gastric pH; however, their use is only supported by expert opinion.

RSI involves preoxygenation followed by intubation using an induction agent and neuromuscular blockade without face-mask ventilation. There are no prospective randomized controlled trials that show whether RSI reduces the incidence of aspiration. However, RSI has been shown to decrease the time to achieve successful intubation, which may be beneficial when the risk of aspiration is high. The value of cricoid pressure during intubation remains controversial. A recent randomized trial did not demonstrate a reduction in aspiration with cricoid pressure but did note an increased intubation time when cricoid pressure was applied.

B. Postoperative Respiratory Failure

After successful lysis of abdominal adhesions, the patient recovers well and is extubated at the completion of surgery. Subsequently, she develops progressive hypoxemic respiratory failure while in the postanesthesia care unit.

B.1. How can you predict which patients will develop postoperative respiratory failure?

Respiratory failure commonly complicates the postoperative period and is strongly associated with an increased mortality. A number of clinical prediction rules exist to predict the risk of postoperative pulmonary complications. Predisposing factors include a high American Society of Anesthesiologists (ASA) Physical Status Classification, poor functional status, and hypoalbuminemia. Lung diseases such as obstructive airways dysfunction, extrapulmonary diseases such as liver cirrhosis, congestive heart failure, renal failure, and current or former smoking status also predispose patients to respiratory failure. Additional risk factors include emergency indications for surgery, prolonged procedural time, and the requirement for large volume fluid and blood product resuscitation. Because of their effects on respiratory mechanics, thoracoabdominal surgeries, especially aortic aneurysm repair, are particularly high-risk procedures.

B.2. How can intraoperative anesthesia management prevent respiratory failure?

An extensive literature has evaluated the role of limiting tidal volumes to prevent VILI. Ventilation with tidal volumes greater than 8 mL per kg ideal body weight (IBW) is a risk factor for postoperative pulmonary complications in thoracic and abdominal surgery. Moreover, a randomized controlled trial in major abdominal surgery demonstrated that restricting tidal volumes from 6 to 8 mL per kg IBW decreased the incidence of postoperative respiratory failure. This intervention was part of a lung-protective strategy, which combined restricted tidal volumes with PEEP as compared to large tidal volumes without PEEP. Because the intervention also included PEEP, we cannot ascribe the full benefit to tidal volume restriction. A recent meta-analysis that included 19 studies comparing patients receiving tidal volumes of 6 to 8 mL per kg of IBW to those greater than 10 mL per kg of IBW showed a reduction in postoperative pneumonia and need for postoperative ventilatory support. In sum, the current data support targeting tidal volumes to less than 8 mL per kg IBW. However, there may be situations where these tidal volumes are inadequate. The optimum dose of intraoperative PEEP is less clear. A meta-analysis revealed that a no-PEEP approach was a risk factor for postoperative pulmonary complications in thoracic and abdominal surgery.

However, randomized trials during high-risk abdominal surgery did not demonstrate a benefit from high PEEP and recruitment maneuvers. Another observational study compared the effect of PEEP ≥5 cm H_2O on patients undergoing abdominal surgery and craniotomies. The beneficial effect of PEEP in reducing postoperative respiratory complications was observed in the abdominal surgery group but not in those undergoing craniotomies. As a whole, the current evidence supports the use of moderate PEEP (approximately 5 cm H_2O) during surgery in patients at risk of atelectasis, and higher PEEP and recruitment maneuvers when the patient's physiology suggests derecruitment.

Driving pressure is calculated as the plateau pressure minus the PEEP. The driving pressure is a factor of both the tidal volume and the set PEEP. A high driving pressure (>15 cm H_2O) is associated with an increased risk of postoperative pulmonary complications. Observing the effect of ventilator settings on driving pressure may be a useful strategy. However, this approach has not yet been fully evaluated in prospective studies.

B.3. What is the pathogenesis of postoperative respiratory failure?

Numerous mechanisms contribute to the pathogenesis of postoperative respiratory failure (**Fig. 3.1**). A combination of postoperative pain, recumbent position, anesthetics, and impaired secretion clearance leads to collapse of dependent lung regions. Atelectasis increases shunt fraction, diminishes respiratory system compliance, and commonly contributes to postoperative respiratory failure.

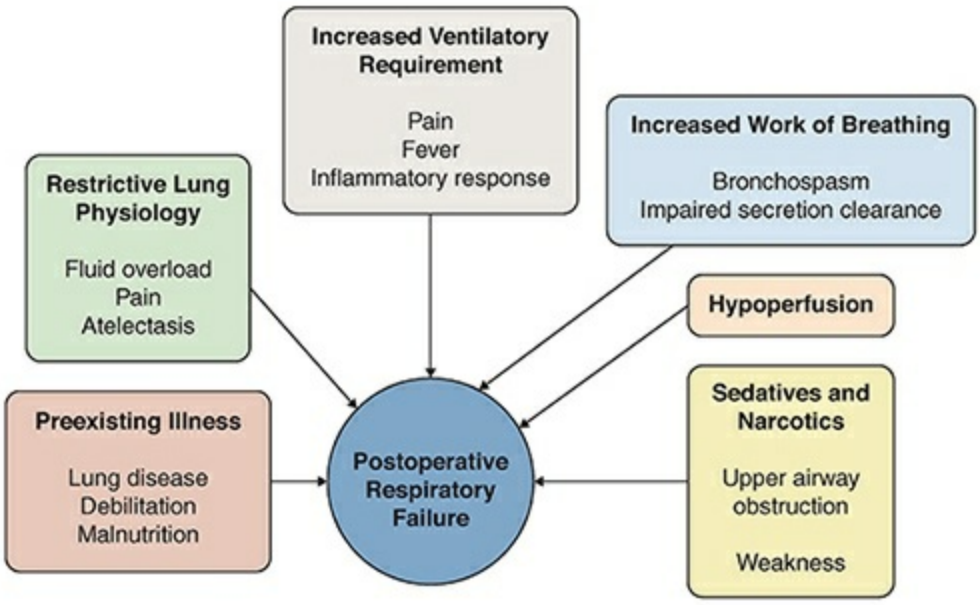

FIGURE 3.1. Pathogenesis of postoperative respiratory failure.

Treating postoperative patients with high concentrations of inspired oxygen can lead to absorption atelectasis. Normally, the consumption of oxygen by peripheral tissues creates a small gradient between the gas tensions in the alveoli and pulmonary capillary blood. The gradient is normally small compared to the total gas tensions because nitrogen is the most abundant gas in both compartments. Nitrogen acts as a pneumatic splint in the lung by limiting the magnitude of the gas tension gradient between the alveoli and pulmonary capillary. Breathing high F_{IO_2} denitrogenates the body and increases the partial pressure of oxygen in alveolar gas much more than in mixed venous blood. Without nitrogen, venous blood becomes very hypobaric relative to alveolar gas. Therefore, high F_{IO_2} increases the gas tension gradient, which drives gas from the alveoli to the pulmonary capillary blood. This promotes the collapse of poorly ventilated alveoli (**Fig. 3.2**).

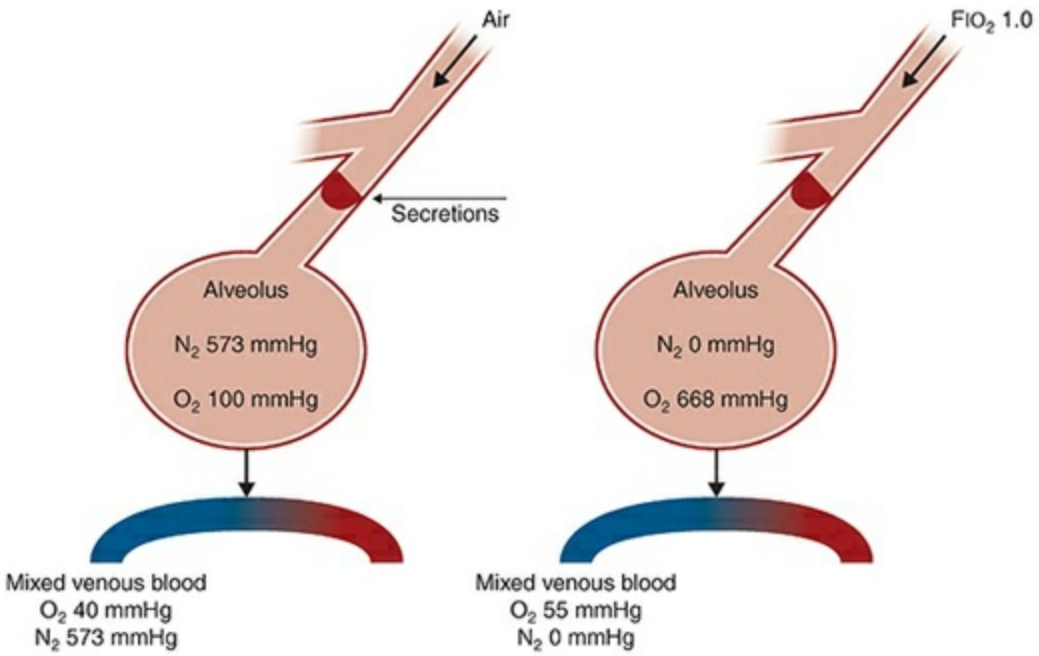

FIGURE 3.2. Nitrogen (N_2) content of inspired air prevents alveolar collapse. On the left, secretions obstruct the airway while the patient was breathing room air. There is a small oxygen (O_2) gradient between the alveolus and mixed venous blood. On the right, secretions obstruct the airway after denitrogenation. As a result, the mixed venous blood is very hypobaric compared with the alveolus. The alveolus will tend to collapse as O_2 rapidly flows down its pressure gradient. CO_2 and H_2O have been omitted for simplicity. (*Adapted with permission from West JB.* Respiratory Physiology. *4th ed. Baltimore, MD: Williams & Wilkins; 1990.*)

In the postoperative period, bronchospasm and impaired mucociliary clearance can decrease the rate of expiratory airflow and increase the work of breathing. Residual sedation and neuromuscular blockade may weaken respiratory muscles and diminish protective muscle tone in the upper airway. Shock causes acidosis and hypoperfusion of respiratory muscles leading to respiratory failure. In particular, clinicians should consider the diagnosis of occult hemorrhage in any postoperative patient who develops respiratory failure. However, the clinician must also consider the opposite problem of fluid overload. Fluid accumulation in the lungs, chest wall, pleura, and peritoneum is a common problem and may decrease respiratory compliance and worsen gas exchange.

The systemic inflammatory response to major surgery or an acute illness will increase rates of tissue oxygen consumption and carbon dioxide (CO_2) production. The increased ventilatory requirement may impose an unsustainable burden on a respiratory system impaired by the aforementioned factors. This is especially true in the setting of debility, malnutrition, and chronic lung disease.

West JB. *Respiratory Physiology—The Essentials*. 9th ed. Baltimore: Lippincott Williams & Wilkins; 2012.

B.4. What is the diagnostic approach to postoperative respiratory failure?

The history of the patient's illness provides key evidence for determining the cause of respiratory failure. The clinician should review the past medical history, anesthesia record, operative reports, and perform a careful physical examination. The integration of these data should generate a short list of diagnostic possibilities (**Table 3.1**). Laboratory testing can help exclude or confirm diagnoses.

TABLE 3.1 Differential Diagnosis of Postoperative Respiratory Failure

Aspiration pneumonitis Exacerbation of obstructive sleep apnea	Atelectasis Wound infections Abdominal compartment syndrome	Pneumonia Upper airway obstruction Diaphragmatic palsy from scalene nerve block	Bleeding and shock Neuromuscular weakness	Pleural effusions Exacerbation of underlying lung disorder Acute respiratory distress syndrome	Pulmonary embolism Pulmonary edema

Arterial blood gas analysis can help triage disease severity

and identify alveolar hypoventilation, increased alveolar–arterial oxygen gradient, and acid–base status. Additional labs including complete blood count, metabolic profile, and coagulation parameters are an important part of the early evaluation. Chest x-rays are an essential part of the diagnostic approach to respiratory failure. However, their interobserver variability is high and their diagnostic accuracy is limited in acute respiratory failure.

Point-of-care diagnostic ultrasound can aid the diagnosis of acute respiratory failure (**Table 3.2**). In critically ill patients, pulmonary ultrasound is superior to chest x-ray in identifying pneumothorax, consolidation, pleural effusion, and lung edema. The use of basic echocardiography to identify right or left heart dysfunction can improve diagnostic accuracy. This approach can help distinguish cardiogenic from noncardiogenic causes of pulmonary edema and raise the suspicion for pulmonary embolism. Ultrasonography, like all clinical skills, requires expert training.

TABLE 3.2 Pulmonary Ultrasound Findings

Sliding lung (rules out pneumothorax)	Consolidation	A lines (normal finding)
Lung point (rules in pneumothorax)	B lines (interstitial edema)	Pleural effusion
Diaphragm movement (rules out diaphragmatic palsy)		

Pulmonary emboli (PE) are common in the postoperative period. PE cause tachycardia, tachypnea, and mild hypoxemia. Large PE may cause shock. An abrupt increase in arterial to end-tidal P_{CO_2} gradient can be a sign of increased alveolar dead space from PE. If a clinician suspects PE, a computed tomography (CT) angiography is the best test. Ventilation-perfusion scintigraphy is an alternative if CT angiography cannot be performed. Given the high case fatality rate of untreated PE, therapeutic anticoagulation is indicated when PE is strongly suspected or confirmed. Clinicians must carefully

consider the risk of bleeding from surgery or neuraxial anesthesia sites.

Pneumonia is the most important postoperative infection. Surgery, hospitalization, and illness alter the host's bacterial flora and lead to pneumonia with antibiotic-resistant organisms. A chest x-ray, arterial blood gas, and blood cultures should be obtained in all patients suspected of having health care–associated pneumonia. In the case of ventilator-associated pneumonia, clinical diagnosis may be inaccurate. Quantitative cultures of the lower respiratory tract obtained from bronchoalveolar lavage or protected brushings can assist the diagnosis.

C. Indications for Ventilator Support

The patient has worsening hypoxemia and tachypnea despite treatment with high-flow supplemental oxygen.

C.1. What are the indications for noninvasive positive pressure ventilation (NIPPV)?

NIPPV may be an alternative to endotracheal intubation in some situations. NIPPV can deliver high flow rates of oxygen, maintain PEEP, stent open the upper airway, and unload the work of breathing. Careful patient selection and recognition of contraindications to its use are essential. In this patient, the vomiting due to bowel obstruction is likely a contraindication to a trial of noninvasive ventilation (**Table 3.3**). Generally, the etiology of the respiratory failure and the type of mask interface are more important determinants of treatment success than the mode of NIPPV. The clinical indications with the best supporting evidence for NIPPV are acute cardiogenic pulmonary edema, obstructive sleep apnea, and exacerbations of chronic obstructive pulmonary disease (COPD). In cardiogenic pulmonary edema, the application of positive pressure can markedly reduce left ventricular preload and afterload. Bilevel and continuous positive airway pressure (CPAP) modes are both effective in cardiogenic pulmonary edema. Although there is little data from randomized controlled trials, there is a compelling physiologic rationale for the use of noninvasive ventilation for respiratory failure due to neuromuscular weakness and obesity–hypoventilation syndrome.

TABLE 3.3 Use of Noninvasive Positive Pressure Ventilation in Acute Respiratory Failure

Possible Indications	Contraindications
Increased dyspnea	Respiratory arrest
Tachypnea	Unable to fit/wear mask

Excessive work of breathing	Progressive shock
Hypoventilation	Multiorgan dysfunction
Obstructive sleep apnea	Poor airway protection
Hypercapnia	Recent upper airway or gastrointestinal surgery
Hypoxia	No patient cooperation
	Progressive and severe clinical instability
	Vomiting/hematemesis

Adapted from Nava S, Hill N. Non-invasive ventilation in acute respiratory failure. *Lancet*. 2009;374(9685):250–259. Copyright © 2009 Elsevier. With permission.

The clinical trial data for NIPPV in other causes of postoperative respiratory failure are mixed. A randomized trial compared the use of NIPPV to standard oxygen therapy in patients with hypoxemic respiratory failure within 7 days of abdominal surgery. The use of NIPPV reduced the need for tracheal intubation. However, clinicians must exercise caution when using NIPPV for acute hypoxemic respiratory failure. Although it can help avoid intubation in some situations, about half of the patients treated with NIPPV for ARDS or pneumonia ultimately require intubation. Patients with multiorgan dysfunction are more likely to require intubation. Unfortunately, the largest randomized trial of NIPPV for acute hypoxemic respiratory found no benefit. This trial used CPAP mode, which improved gas exchange. However, there was a markedly increased mortality rate among patients who failed NIPPV. There was also an alarmingly high rate of cardiac arrest during rescue intubation in this setting. This risk is likely due to the sudden derecruitment and loss ventilation during the intubation process.

Delivery of high flow rates of warmed and humidified O_2 via nasal cannulae (HFNC) is increasingly used for acute hypoxemic respiratory failure. The high flow rates limit entrainment of room air and therefore provide more consistent F_{IO_2} than traditional low flow oxygen systems. HFNC can theoretically help wash out the anatomic dead space and provide

a small amount of CPAP, which may decrease work of breathing and improve gas exchange. The exact role of HFNC in acute hypoxemic respiratory failure remains unclear. HFNC has similar contraindications to NIPPV, and there are concerns that its use may delay needed endotracheal intubation.

C.2. What are the indications for emergency endotracheal intubation?

Endotracheal intubation is performed for impending or actual respiratory failure. The possible indications for emergency endotracheal intubation are shown in **Figure 3.3**. Often, a combination of problems drives the decision to intubate. In borderline situations, a need to transport the patient or a worsening trajectory of acute illness may tip the balance in favor of intubation.

D. The Acute Respiratory Distress Syndrome

The patient is intubated for respiratory failure. She has bilateral pulmonary infiltrates on chest x-ray and is severely hypoxemic.

D.1. What is the definition and etiology of the acute respiratory distress syndrome (ARDS)?

ARDS is a clinical syndrome of rapidly progressive respiratory failure characterized by severe hypoxemia and bilateral pulmonary infiltrates. ARDS occurs after or during an insult to the lungs or other organs and is not due to hydrostatic (cardiogenic) edema. The characteristic pathologic finding is diffuse alveolar damage (DAD).

The research definition of ARDS has evolved over time. A previous classification distinguished ARDS from acute lung injury (ALI) based on the severity of hypoxemia. The current consensus is called the Berlin (Germany) definition of ARDS (**Fig. 3.4**). This definition removed the distinction of ALI. This case definition encompasses a number of distinct disease

processes. A significant proportion of patients meeting the diagnostic criteria for ARDS do not have DAD on biopsy or autopsy.

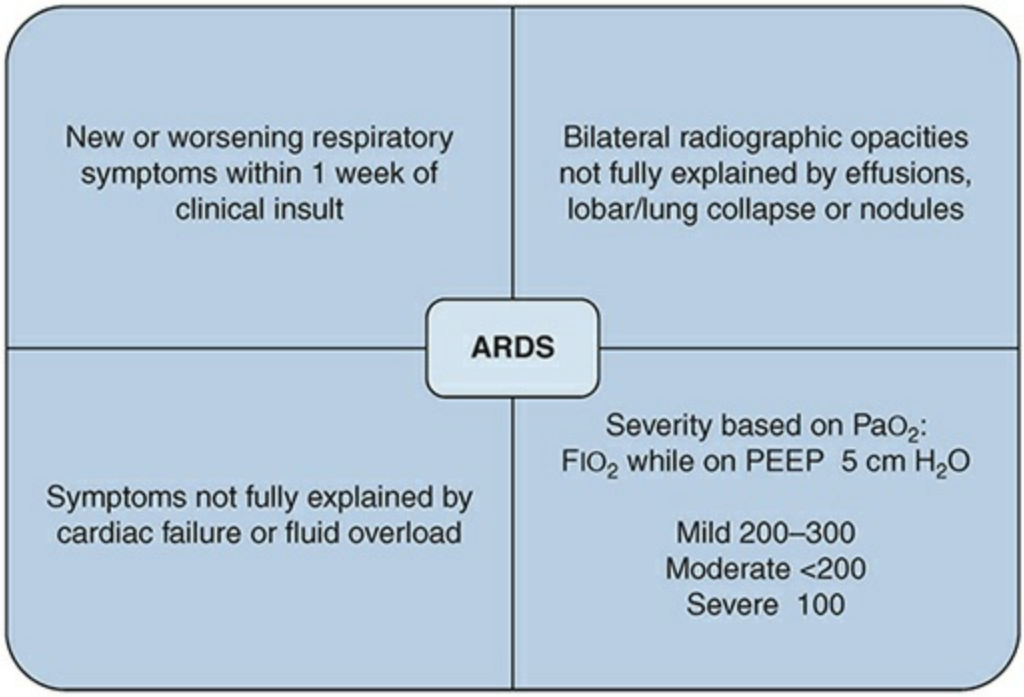

FIGURE 3.4. Definition of the acute respiratory distress syndrome (ARDS). FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen; PEEP, positive end-expiratory pressure. (*Adapted from Ranieri VM, Rubenfeld GD, Thompson BT, et al. Acute respiratory distress syndrome: the Berlin definition.* JAMA. *2012;307[23]:2526–2533.*)

There are approximately 175,000 cases of ARDS each year in the United States, although the incidence has been decreasing. Worse outcomes are associated with severe hypoxemia, increased dead space, and the presence of concomitant organ failure. The case fatality rate of ARDS has decreased from approximately 40% in the late 1990s to approximately 25% in the mid-2000s; however, unadjusted mortality of those patients with severe ARDS may approach 50%. The most common etiologies of ARDS include pulmonary and nonpulmonary infections, large volume aspiration of gastric contents, trauma, acute pancreatitis, drug reactions, and transfusions of blood

products.

D.2. Explain the pathophysiology of ARDS.

In ARDS, the alveoli are flooded with a neutrophilic protein-rich edema fluid (**Fig. 3.5**). Dysfunction of the alveolar epithelium and pulmonary capillary endothelium lead to noncardiogenic pulmonary edema. A depletion of functioning surfactant leads to alveolar collapse. The pathophysiologic cascade is incited at the molecular level. Pathogen microbial products (PAMPs) or endogenous damage-associated molecular pattern molecules (DAMPs) activate pattern recognition receptors such as the Toll-like receptors. This activation of innate immunity recruits inflammatory cells to the lung. The regulation of pulmonary inflammation plays a crucial role in both the control of pathogens and lung injury.

ARDS progresses through distinct clinical, pathologic, and radiologic phases. The acute exudative phase of ARDS is characterized by severe hypoxemia that is refractory to supplemental oxygenation and often requires invasive mechanical ventilation. Hypoxemia in this early phase is due to

increased shunt fraction. Acute right-sided heart failure is common due to a marked elevation in pulmonary vascular resistance. Hypoxic and hypercapnic pulmonary vasoconstriction, regional atelectasis, and hyperinflation due to mechanical ventilation all contribute to the rise in pulmonary resistance. Radiologically, there are bilateral alveolar infiltrates. CT imaging demonstrates bilateral patchy opacities and dependent consolidation. Pleural effusions are common. ARDS caused by direct lung injury maybe more responsive to higher PEEP strategies. ARDS caused by systemic inflammatory states is associated with more pronounced shock and multisystem organ dysfunction.

The acute exudative phase of ARDS may progress to fibrosing alveolitis, which can appear as linear opacities on chest x-ray. The fibrosis reduces pulmonary compliance and increases dead space. Patients who recover from ARDS may have normal lung function or chronic fibrotic lung disease.

D.3. What role does ventilator-induced lung injury (VILI) play in ARDS?

Mechanical ventilation injures the lungs through complex pathophysiologic processes. A variety of illnesses, particularly

ARDS, increase the lung's susceptibility. Rarely, VILI leads to air leaks from the lung into the pleura or mediastinum. However, microscopic injury is a more common problem. The complications of VILI extend beyond the lungs. Excessive alveolar stretch in ARDS increases circulating inflammatory cytokines and injures small bowel and renal epithelial cells. These processes have been linked to progressive multisystem organ failure, which is the most common cause of death in ARDS.

VILI is due to excessive distention of some lung regions and repetitive collapse with shearing of others. "Volutrauma" is the name for the damage caused by excessive lung stretch with large amount of air. Despite its importance, it is difficult to measure the amount of air distending the lungs on mechanical ventilation. This is because ventilators only display the tidal volume—the amount of air delivered or exhaled. Ventilators do not measure the volume of air remaining in the lungs at end expiration (the functional residual capacity). The total lung volume that distends the lungs is the tidal volume plus the functional residual capacity. Because it is not possible to measure this volume, clinicians use the airway pressure at end inspiration as a surrogate marker for the lung's maximum distention by the ventilator. To measure this pressure, the clinician must pause the ventilator cycle momentarily at the end of inspiration to minimize the effect of resistance to airflow. This pause also allows time for the ventilator circuit to better equilibrate with the lungs. The plateau pressure is the pressure in the ventilator circuit during this pause.

The plateau pressure is an imperfect surrogate for the distending pressure of the lung. It is a composite of the force in the airway that distends the lung and the forces adjacent to the lung that may distend or oppose lung inflation. For example, a patient's inspiratory effort distends the lungs yet tends to lower

plateau pressure on volume-controlled ventilation. Conversely, positive pleural pressure from intra-abdominal hypertension and gravitational effects from obesity tend to raise plateau pressure without increasing lung distention. In sum, clinicians should consider both tidal volume and plateau pressure to evaluate the risk of overdistention.

Driving pressure is another way to evaluate the risk of VILI. Driving pressure reflects the relationship between the delivered tidal volume and lung compliance, and high driving pressure suggests a risk of overdistention. In an analysis of randomized trials in ARDS, higher driving pressure had a stronger correlation with mortality than tidal volume. Ventilator techniques that optimize lung compliance and driving pressure may offer some benefit, but this concept requires confirmation.

E. Management of Mechanical Ventilation

E.1. Which mode of mechanical ventilation will you choose? Describe the features of that mode.

There is no proof that any mode of ventilation is superior in any clinical situation. Aside from avoiding purely assisted modes for passive patients, the choice of mode is largely dictated by physician preference. Choosing appropriate settings for a given mode of mechanical ventilation is more important than the choice of the mode. Therefore, it is essential for clinicians to have a detailed understanding of the settings for the mode they are using.

With traditional controlled mechanical ventilation, the patient had no control over any aspect of the respiratory cycle. Modern controlled ventilation modes can “assist” patients’ respiratory efforts. In assisted modes, the ventilator recognizes the patient’s inspiratory effort by a negative pressure deflection in the ventilator circuit. The ventilator then cycles to inspiration and forces gas into the circuit’s inspiratory limb. Gas is delivered until it reaches a set target of either pressure or volume.

Assist/control with volume targeting is the most commonly used mode in intensive care units worldwide. Inspiration begins when the ventilator recognizes the patient’s inspiratory effort or at a minimum frequency set by a clinician. The ventilator compresses the air sufficiently to deliver a set tidal volume. In general, assist/control volume targeting allows the best assessment of respiratory mechanics. The mode also guarantees the delivery of a minimum minute volume. It also limits tidal volume, which can help avoid alveolar overdistention. However, assist/control with volume targeting may provide insufficient support for a patient with a strong respiratory drive. The tidal volume, duration of inspiration, and inspiratory flow rate are all set by the clinician. The ventilator cannot meet the patient’s demand for an increased tidal volume or faster inspiratory gas flow. Patients with a strong respiratory drive may develop severe dyssynchrony and perform substantial work of breathing on this mode. Dyssynchrony is common with assist/control

volume targeting and is usually due to double or ineffective triggering of inspiration.

With assist/control pressure targeting, the ventilator delivers gas until the pressure reaches a specified target. The volume and rate of gas delivered varies with patient effort and respiratory mechanics. Clinicians must set some criteria of timing of the inspiratory and expiratory cycles (either the inspiratory time or the ratio of the duration of inspiration and exhalation). The usual time of inspiration to prevent dyssynchrony is 0.8 to 1.2 seconds. A virtue of assist/control pressure targeting is that the inspiratory pressure will not exceed the upper limit. Moreover, the patient with high ventilator demand can increase the volume and rate of gas delivery by making stronger inspiratory efforts. However, the ventilator does not guarantee a minimum tidal volume.

Assisted ventilation with pressure targeting is called pressure support. Patients have the most control with this mode because the rate and duration of inspiratory airflow depend on patient effort. This mode is inappropriate for passive apneic patients. Like all pressure-targeted modes, it provides increasing support to match increased patient inspiratory demand. In fact, oversupport is a common cause of dyssynchrony with this mode. In this situation, the patient's strong inspiratory drive causes the ventilator to deliver excessive airflow. This can lead to dynamic hyperinflation if the patient has insufficient time to exhale. Dynamic hyperinflation can lead to ineffective triggering and wasted ventilator effort. In this situation, dyssynchrony may improve with decreasing the inspiratory pressure target. Unlike assist/control pressure targeting, pressure support lacks a set ventilator rate. It also has different criteria for cycling from inspiration to exhalation. The inspiratory flow rate decreases as the patient's effort wanes during inspiration. The ventilator cycles to exhalation when inspiratory flow decreases below a set

threshold.

Synchronized intermittent mandatory ventilation (SIMV) is another popular mode. SIMV is a mixed mode; therefore, it shares the virtues and problems with its constituent modes. It is a combination of assist/control with spontaneous breaths. If the patient does make sufficient respiratory effort, the ventilator delivers controlled ventilation (either volume or pressure targeted). If the ventilator recognizes patient effort, it allows spontaneous ventilation. Spontaneous ventilation may provide improved distribution of gas flow compared with more supported breaths. Moreover, spontaneous breathing mitigates the hemodynamic effects of positive pressure. If there is PEEP, the breaths are CPAP. However, it is difficult for the patient to respond to alternating levels of support by modulating their effort on a breath-to-breath basis. Therefore, patient effort increases on controlled breaths. Many clinicians add pressure support to the spontaneous breaths. This will diminish the effects of spontaneous ventilation on SIMV.

A number of alternative modes are available. Many have refinements so that the ventilator adjusts flow during a breath or on subsequent breaths. Adaptive support ventilation, pressure-regulated volume control, and volume support are some of the options. Neurally adjusted ventilation assist (NAVA) uses a novel strategy; a tube placed from the nose/mouth into the esophagus provides electromyographic analysis of diaphragmatic effort. The ventilator synchronizes respiratory cycling and the magnitude of pressure support to the patient's diaphragmatic contraction. NAVA can improve ventilator patient synchrony because air leaks and dynamic hyperinflation do not obscure the patient's inspiratory efforts. High-frequency oscillating ventilation (HFOV) is an alternative mode that requires a special ventilator. The principle of HFOV is the maintenance of a high mean airway pressure with extremely

brief cycling above and below the mean. The ventilator targets pressure alternating between 70 and 0 cm H_2O at frequency around 4 to 12 Hz. Because the duration of the respiratory cycle is so brief, there is insufficient time for the lungs to equilibrate with the ventilator airway pressure. This results in 1 to 2 mL per kg breaths at a rate of 4 to 12 times per second. These breaths are smaller than the airway's dead space; therefore, HFOV exchanges gas via alternative mechanisms. The increased hemodynamic instability found in the HFOV trial is likely due to the continuously elevated airway pressure. In particular, right ventricular failure commonly complicates HFOV for ARDS. A well-designed randomized controlled trial found that HFOV increased mortality compared with a lung protective ventilation strategy when used as a treatment for adults with ARDS. It is possible that a different HFOV protocol (such as one that targets a lower mean airway pressure) would have a benefit.

There is increasing interest in airway pressure release ventilation (APRV) as a method to improve lung recruitment. This mode provides CPAP at a high level (called "PEEP high) coupled with very brief periods of exhalation. These brief releases incompletely empty the lung and lead to dynamic hyperinflation which raises mean airway pressures leading to lung recruitment. Importantly, APRV allows spontaneous pressure supported breaths during CPAP as well during the releases (called "PEEP low"). The freedom to initiate spontaneous breaths during all phases of the respiratory cycle may improve ventilator–patient synchrony.

At present, there is no proven benefit for any of these alternative modes. In general, pressure-targeted modes create less dyssynchrony than volume-targeted modes when the respiratory drive is strong. However, the settings on the mode affect dyssynchrony more than the choice of mode. For the patient in ARDS, unconventional modes are acceptable as long

as they are employed as part of a lung protective strategy described in the following text.

E.2. How should you set the fraction of inspired oxygen (FIO_2)?

The FIO_2 is set to maintain sufficient arterial oxygenation. Given the poor solubility of oxygen, the oxygen saturation of hemoglobin rather than the PaO_2 is the more important determinant of arterial oxygen content. For example, a patient without anemia and hemoglobin that is 97% saturated with oxygen will carry 200 mL oxygen in every liter of blood (in

hemoglobin). The same patient will have a Pa_{O_2} 90 mmHg and just 2.7 mL oxygen dissolved in every liter of blood (in the plasma). In ARDS, it is acceptable to target an oxygen saturation of hemoglobin >88%. The F_{IO_2} should be limited as low as possible to avoid oxygen toxicity. The oxygen saturation target should be higher in situations such as intracranial hypertension, right ventricular failure, and systemic vasodilation.

Brower RG, Matthay MA, Morris A, et al. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med*. 2000;342(18):1301–1308.

E.3. How should you set the positive end-expiratory pressure (PEEP)?

PEEP can recruit atelectatic alveoli, prevent cyclical alveolar closure, and decrease shunt fraction (**Fig. 3.6**). There is a theoretical benefit of higher levels of PEEP in severe ARDS. However, high levels of PEEP can decrease venous return and cardiac output. Excessive PEEP also overdistends alveoli leading to VILI and increased pulmonary vascular resistance. The ideal dose of PEEP would maximize respiratory system compliance, gas exchange, patient comfort, and hemodynamics. Unfortunately, the best method to select PEEP for individual patients remains controversial. The trial that established the current standard of care for ventilation in ARDS used a table to determine PEEP based on F_{IO_2} requirement. Multiple trials have failed to demonstrate a better method of PEEP determination than this table. Some clinicians use decremental PEEP trials by serially reducing PEEP after a recruitment maneuver. Other protocols set PEEP according to pressure–volume curves or measurement of transpulmonary gradients by esophageal probes. However, there is currently no evidence that physiologic methods effectively determine the PEEP that recruits lungs in

ARDS. Some protocols emphasize hemodynamic effects such as limiting PEEP based on Doppler analysis of pulmonary artery flow. The average PEEP used for ARDS in clinical settings is around 8 cm H_2O. It is unclear whether or not this is the ideal practice. A recent analysis of studies comparing high versus low PEEP settings showed no significant difference.

E.4. What tidal volume and inspiratory pressure target should you set?

The approach of limiting tidal volume and plateau pressure has been validated in a landmark randomized controlled trial in patients with ARDS. This technique, called low tidal volume ventilation, significantly reduced organ failure and mortality. Recent data has also looked at the driving pressure (plateau pressure—PEEP) and has demonstrated reduced mortality with decreases in driving pressure. Although low tidal volume ventilation initially worsens gas exchange, it ultimately limits lung and extrapulmonary injury. Therefore, the initial tidal volume or inspiratory pressure should be set to keep the tidal volume <8 mL/kg/IBW and the plateau pressure <30 cm H_2O. Tidal volume and pressure should be incrementally lowered to target 6 mL/kg/IBW and a plateau pressure <30 cm H_2O while monitoring the patient for dyssynchrony and worsening gas exchange (**Table 3.4**). Low tidal volume ventilation may reduce alveolar ventilation and worsen hypercapnia. Increasing

respiratory rate is often insufficient to maintain alveolar ventilation. In fact, the low tidal volume approach may necessitate permitting hypercapnia. Although it may be well tolerated, hypercapnia can constrict pulmonary arterioles and dilate systemic and cerebral arterioles. Tidal volume restriction and hypercapnia can worsen ventilator patient dyssynchrony and double triggering of the ventilator. In this setting, the delivered tidal volumes are much larger than the clinician sets on the ventilator. Moreover, a patient's strong inspiratory effort can overdistend the lungs. On pressure-controlled ventilation, the tidal volumes may be excessive, whereas on volume-controlled ventilation, the plateau pressure may underestimate the distending pressure.

TABLE 3.4 Low-Stretch Lung Protective Ventilator Strategy for Acute Respiratory Distress Syndrome

	Allowable Combinations of PEEP and F_{IO_2}			
	F_{IO_2}	PEEP cm H_2O	F_{IO_2}	PEEP cm H_2O
Ventilator mode: assist/control volume	0.3	5	0.7	14
Initial tidal volume 6 mL/kg predicted body weight	0.4	5	0.8	14
Plateau pressure ≤30 cm H_2O	0.4	8	0.9	14
Respiratory rate 6–35 breaths/min set to achieve pH 7.3–7.45	0.5	8	0.9	16
Ratio of inspiration to expiration 1:1–1:1.3	0.5	10	0.9	18
Oxygenation goal Pa_{O_2} 55–80 mmHg or Sp_{O_2} 88%–95%	0.6	10	1.0	18
	0.7	10	1.0	20
	0.7	12	1.0	22
	0.7	14	1.0	24

F_{IO_2}, fraction of inspired oxygen; Pa_{O_2}, partial pressure of oxygen; PEEP, positive end-expiratory pressure; Sp_{O_2}, peripheral capillary oxygen saturation.

F. Management of Refractory Respiratory Failure

The patient remains hypoxemic on F_{IO_2} of 0.8.

F.1. What else can promote additional lung recruitment?

Recruitment maneuvers rely on the principle that it requires more pressure to inflate an atelectatic lung to a given volume than it does to maintain that volume after exhaling from maximum inflation. To perform a recruitment maneuver, the clinician sets a high level of CPAP for a short time interval (e.g., 40 cm H_2O for 40 seconds). Alternatively, for passively ventilated patients, the extrinsic PEEP can be increased on the ventilator for a short duration. Recruitment maneuvers may prevent or treat derecruitment related to disconnection of the ventilator circuit for suctioning.

Ideally, lung recruitment will reduce the amount of atelectatic lung and decrease shunt fraction. The hallmark of success is an improvement in the ratio of Pa_{O_2} to F_{IO_2}. Recruitment maneuvers share the deleterious effects of all treatments that raise airway pressure. The high level of airway pressure may be sufficient to obstruct venous return and reduce cardiac output as well as cause barotrauma. The benefit of recruitment maneuvers for patients depends on the inherent recruitability of their lungs.

Recruitment maneuvers have been examined in various trials with conflicting results. This may be a result of the heterogeneity of the underlying disease processes as well as differing recruitment protocols. Given the physiologic rationale and benefits on gas exchange, clinicians may consider using recruitment maneuvers on a case-by-case basis especially in a setting of refractory hypoxemia.

Pronation is a recruitment strategy that avoids the deleterious effects of increased positive airway pressure. There are a number of mechanisms by which pronation may exert its benefit. Prone ventilation decreases the volume of lung that is compressed by the heart in the supine position. Pronation also displaces the diaphragm caudally and homogenizes the distribution of the pleural pressure. In ARDS, these mechanisms may recruit lung and decrease alveolar hyperinflation. Pronation may also have multiple effects on hemodynamics. By reducing the airway pressures clinicians set on mechanical ventilation, pronation may improve venous return and lower pulmonary vascular resistance. A large randomized trial demonstrated a survival advantage from prone positioning in severe ARDS. The patients had Pa_{O_2}:F_{IO_2} ratios <150 mmHg and were treated early in their illness for at least 16 hours per day. Other meta-analyses have also demonstrated a survival advantage in severe ARDS.

Providing mechanical ventilation to patients while they sit in a chair or walk is the ideal therapy to recruit lung. Exercise improves cardiac output, lowers pulmonary vascular resistance, and avoids sedation. Similarly, avoidance of deep sedation and neuromuscular blockade can improve recruitment.

F.2. What rescue strategies can you use for refractory ARDS?

Inhaled nitric oxide (NO) can improve ventilation/perfusion matching in the heterogeneous lungs of ARDS. Inhaled NO distributes to better ventilated lung units where it relieves reflexive hypoxic and hypercapnic vasoconstriction. This effect can improve hypoxia and reduce pulmonary vascular resistance. NO has multiple other effects that may explain the absence of a demonstrable mortality benefit in ARDS. Therefore, the role of inhaled NO, if any, in ARDS should be restricted to refractory

hypoxemia. Similarly, inhaled prostacyclins have also been shown to improve oxygenation but evidence for any improvement in patient outcomes in lacking.

A number of ventilator strategies have been employed to rescue patients with refractory hypoxemia. A common feature is their use of high mean airway pressure to recruit lung. HFOV, APRV, and inverse ratio ventilation all employ a brief expiratory phase. This prevents exhalation and maintains high intrathoracic pressure throughout the respiratory cycle. With HFOV and APRV, the goal is to create auto-PEEP. It is unclear if any of these ventilator strategies offer any advantage over setting a high level of extrinsic PEEP on a conventional mode of ventilation. Recruitment maneuvers may also improve oxygenation. These are brief intervals (30 to 40 seconds) of high PEEP or CPAP (30 to 40 cm H_2O). Any of the strategies using high inflation pressures for lung recruitment may cause hemodynamic instability and barotrauma.

Extracorporeal gas exchange is also being evaluated as a rescue strategy for refractory ARDS. One approach is extracorporeal CO_2 removal, which requires relatively low blood flow rates. CO_2 removal can theoretically increase the gas tension available for oxygen in the alveoli and allow a reduction in tidal volume. A more aggressive strategy is venovenous extracorporeal membrane oxygenation (VV ECMO). It requires high blood flow rates and can reduce the CO_2 content and raise the oxygen content of mixed venous blood. VV ECMO can improve hemodynamics in ARDS by reducing hypoxic/hypercapnic pulmonary vasoconstriction and the magnitude of positive airway pressure required from mechanical ventilation. A randomized trial done at multiple centers in England demonstrated a survival advantage for patients with severe ARDS who were transferred to an ECMO center. There

was also better than expected survival for patients with severe ARDS due to influenza when treated with ECMO. Bleeding and vascular complications are its main side effects. A recent trial showed no statistically significant difference in mortality in patients with severe ARDS receiving ECMO versus conventional ventilation. However, there was a trend toward lower 60-day mortality in the ECMO group and the study was stopped early because of this benefit that in later analysis was not statistically significant. Patients receiving early ECMO had a higher survival as opposed to late (i.e., rescue) use of ECMO.

G. Adjunctive Management of Respiratory Failure

Since intubation, the patient has become hypotensive.

G.1. What is the cause and treatment of the hemodynamic

instability associated with mechanical ventilation?

Hemodynamic instability is a common complication of emergency airway management and the institution of mechanical ventilation. Positive pressure ventilation can decrease the pressure gradient for venous return to the heart, thereby reducing cardiac output. Normally, circulatory reflexes will constrict the veins to restore venous return. However, sedatives and narcotics used to facilitate endotracheal intubation can blunt the autonomic response. Even low levels of positive pressure ventilation can reduce cardiac output in anesthetized postoperative patients, particularly if they have normal or reduced circulating blood volume. Fluid resuscitation and catecholamine vasopressors can raise the venous pressure and restore the pressure gradient for venous return and cardiac output. Many patients with ARDS require a positive fluid balance during the first 48 hours of mechanical ventilation to counteract the hemodynamic effects of PEEP and sedatives/narcotics.

Although diminished venous return is the most likely cause of hemodynamic instability, it is essential to consider acute cor pulmonale as an alternative explanation. The hypoxia, hypercarbia, and regional atelectasis associated with ARDS all raise pulmonary vascular resistance. Mechanical ventilation in ARDS may lead to areas of hyperinflation of the more normal lung regions. Hyperinflation raises pulmonary vascular resistance by compression of the capillaries in the alveolar septa. The severe rise of pulmonary vascular resistance can lead to right ventricular failure, particularly if the patient has had significant intravascular fluid resuscitation. The pressure rises in the right ventricle because it is unable to efficiently pump blood through the pulmonary vasculature. The incidence of acute cor pulmonale is as high as 50% in patients on mechanical ventilation for ARDS. The use of low-stretch ventilation and

limitation of PEEP can lower this risk. The presence of markedly elevated central venous pressure as well as echocardiographic evidence of dilated right ventricular size with flattening of the interventricular septum suggests the diagnosis of acute cor pulmonale. Respirophasic variation in pulse pressure or inferior vena cava diameter does not predict an increase in cardiac output with fluid resuscitation when right-sided heart failure is present. In acute cor pulmonale, vasopressors can raise the systemic blood pressure to maintain the coronary perfusion to the right ventricular myocardium. Diuresis can help optimize right ventricular preload. The ventilator should be adjusted to prevent extremes of lung hyperinflation and provide sufficient PEEP to recruit poorly ventilated lung regions. Pulmonary vasodilators may be needed.

G.2. What is the adjunctive medical therapy for ARDS?

After the initial resuscitation phase, many patients with ARDS require a different approach to fluid balance. The Fluids and Catheters Treatment Trial (FACTT) evaluated two fluid strategies instituted after the first 48 hours. With the “restrictive fluid” approach, patients received diuretics if they had oliguria and adequate perfusion. The “restricted fluid” approach group had better gas exchange and a shorter duration of mechanical ventilation than the “liberal fluid” group. There was no increase in hemodynamic instability or renal failure with a restrictive fluid approach. FACTT had a two-by-two factorial design and simultaneously demonstrated that routine use of pulmonary artery catheterization did not improve outcomes in ARDS. Therefore, clinicians should target even or slightly negative net fluid balance once patients have achieved hemodynamic stability and to avoid routine use of pulmonary artery catheters.

Severe anemia can diminish oxygen delivery. However, red blood cell transfusions are linked to a wide range of complications including nosocomial pneumonia. Moreover, red blood cell transfusions have a limited capacity to improve oxygen consumption in critically ill patients. Although there is no specific randomized trial data in ARDS, it is reasonable to limit red blood cell transfusions in adequately perfused patients with isovolemic anemia unless the hemoglobin concentration is less than 7 g per dL.

Numerous trials have evaluated the ability of medications to modulate the natural history of ARDS. The support for systemic corticosteroids has waxed and waned for decades. The largest and highest quality randomized controlled trial found that corticosteroids offered no benefit and increased mortality if started after the first 2 weeks of ARDS. However, other analyses have shown improvement in mortality or time to resolution of ARDS. Currently, the evidence does not support the routine use of corticosteroids for ARDS. However, the Society of Critical Care Medicine (SCCM) and European Society of Intensive Care Medicine (ESICM) 2017 guideline does suggest the use of intravenous methylprednisolone 1 mg/kg/day in patients with early moderate-to-severe ARDS (Pa_{O_2}/F_{IO_2} <200 and within 14 days of onset).

A number of other disease-modifying agents have been studied in ARDS. Rosuvastatin, a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor (statin), had no benefit in a much anticipated trial. Recombinant activated protein C and ω-3 fatty acids also had no benefit. Theoretically, inhaled β-agonists would decrease lung edema and lung inflammation. However, no randomized trial has shown a benefit. Their use should be restricted to treating bronchospasm. Mesenchymal stem cell therapy is currently the most promising therapy entering clinical trials.

Patients with severe respiratory failure often have a strong respiratory drive due to increased metabolic rates and dead space. This high demand for minute ventilation can lead to intolerance of low stretch ventilation. In these situations, deep sedation and neuromuscular blocking agents can blunt excessive respiratory effort and enforce low stretch ventilation. Moreover, neuromuscular blockade can reduce metabolic demand which may be helpful when oxygen delivery and carbon dioxide clearance are inadequate. However, neuromuscular blockade and

deep sedation may worsen delirium and muscular weakness. Surprisingly, a meta-analysis of three trials of neuromuscular blockade for ARDS did not find an increase in neuromuscular weakness. To help define the role of neuromuscular blockade, two high-quality randomized controlled trials of patients with early ARDS and severe hypoxemia have been performed. Both trials randomized patients to either cisatracurium besylate or placebo. Cisatracurium is useful in critical illness because it is cleared by a plasma esterase. The control group of the initial study received deep sedation, whereas the control group in the second was treated with lighter sedation targets. Rescue use of neuromuscular blockade was allowed in both studies to treat double triggering and overt ventilator dyssynchrony. The first study demonstrated that cisatracurium improved gas exchange, barotrauma, and mortality compared with placebo. The second study did not confirm this benefit. As a result, the exact role for neuromuscular blockade in ARDS remains unclear. One approach is to avoid the routine use of cisatracurium for ARDS and reserve it for patients with severe respiratory failure as well as strong respiratory efforts and dyssynchrony with mechanical ventilation.

A growing body of evidence supports limiting sedative use in patients on mechanical ventilation. In the absence of a compelling need for sedatives (e.g., status epilepticus), clinicians should interrupt continuous sedatives and neuromuscular blocking agents at least daily. This approach is associated with a marked reduction in duration of mechanical ventilation. Reassuringly, this approach is also associated with improved long-term neuropsychiatric function among survivors of respiratory failure. Another strategy uses a detailed sedation protocol to avoid oversedation. Sedatives can contribute to delirium and disuse muscle atrophy. Moreover, clinicians may fail to recognize that their deeply sedated patients may be able to

breathe without ventilator support. Sedation is not restorative sleep. Narcotics are still necessary for pain and dyspnea, and neuroleptics can be used for agitated delirium. Deeper sedation could be reserved for situations when severe agitation occurs or pronation is required. Treatment plans that limit sedative use require clinicians to provide calming, reassurance, repositioning, and ventilator adjustment to assure patient comfort. The study that validated the avoidance of routine sedatives for patients on mechanical ventilation used one-to-one bedside nursing and continuous presence of an intensivist in the intensive care unit.

Limiting sedation allows physical therapy. Patients may perform full physical therapy including walking while breathing through an endotracheal tube and a portable ventilator. The theoretical benefit of this approach is to decrease muscular atrophy, sedative requirements, and delirium.

The evolving treatment paradigm is to use deep sedation, narcotics, and neuromuscular blockade early in the course of severe ARDS in patients with excessive ventilator demands and ventilator dyssynchrony. Patients may require pronation during this phase. Clinicians should switch to the opposite approach of limited sedation as soon as there is stabilization. This includes limited or no sedation (aside from opiates for relief of pain or dyspnea) and physical therapy. This approach should also be used when the ARDS is less severe.

H. Liberation of the Patient from Mechanical Ventilation

The patient slowly recovers over the next 3 days.

H.1. Explain the importance of the decision to extubate the patient or continue mechanical ventilation.

Unnecessarily, prolonged mechanical ventilation can lead to pneumonia, delirium, and neuromuscular weakness. Unfortunately, clinicians may not recognize that a substantial number of their mechanically ventilated patients are capable of breathing without ventilator support. Conversely, the mortality rate associated with reintubation is extremely high. Intensive care unit patients fail extubation at rates of 15% to 20%. The risk is substantially higher in patients with chronic illnesses. Patients who suffer extubation failure are 7 times more likely to die, and the survivors are much more likely to require long-term care. Reintubation is associated with nosocomial pneumonia, although it is unknown whether the pneumonia is the cause or effect of reintubation. Therefore, the decision of whether or not to extubate a patient is one of the most important challenges facing anesthesiologists. There is extensive literature and great

controversy surrounding the topic, and the strategies employed to liberate patients from mechanical ventilation vary widely.

H.2. How will you prepare the patient for liberation from the ventilator?

The most important aspect of liberation from mechanical ventilation is the general care of the patient and the reversal of the cause of the patient's respiratory failure. Early in the course of an acute illness, the patient must be resuscitated out of shock. Generally in later stages, volume overload and hypertension must be avoided. This is especially important during the switch to negative pressure ventilation, which increases cardiac preload and left ventricular wall tension. Adequate protection against the development of coronary ischemia should be ensured in patients with significant coronary artery disease. The neurologic status should be optimized with the goal of maintaining airway protection and patency as well as adequate respiratory drive and strength. Sedation should be limited and reversed at least daily. Delirium should be avoided and treated.

Clinicians should aggressively reduce the F_{IO_2} and PEEP to the minimum acceptable level. Derecruitment happens quickly after reducing PEEP, so lengthy weaning may be unnecessary.

Chiumello D, Coppola S, Froio S, et al. Time to reach a new steady state after changes of positive end expiratory pressure. *Intensive Care Med*. 2013;39(8):1377–1385.

H.3. How will you recognize when the patient is ready for

extubation?

Traditionally, once FIO_2 and PEEP were at minimal settings, clinicians would assess patients for their ability to undergo a weaning trial. Tests of weaning readiness were used to identify patients in whom it was safe to reduce ventilator support. These tests included objective measures such as the negative inspiratory force, vital capacity, and the rapid shallow breathing index (RSBI). The research literature makes a clear distinction between these tests of weaning readiness and tests of extubation readiness (such as a prolonged T-tube trial as discussed in the following text). The best validated test to predict readiness for weaning is the RSBI. This test was performed by switching patients from assist control ventilation to a T-tube. A spirometer attached to the end of the endotracheal tube measured the tidal volume, and the respiratory rate was counted. Patients with ratios of <105 could safely go on to a test of extubation readiness with a T-tube trial lasting up to 2 hours. However, there is no clear advantage to performing a test of weaning readiness (such as the RSBI calculation) prior to initiating a test of extubation readiness. Instead, clinicians can perform daily clinical screening of patients on mechanical ventilation to assess them for extubation readiness (**Table 3.5**).

TABLE 3.5 Clinical Screening Criteria for Extubation Readiness

Adequate level of alertness	Cause of respiratory failure improving
PaO_2/FIO_2 ≥150 or SpO_2 ≥90% on FIO_2 ≤0.4	Able to initiate an inspiratory effort
PEEP ≤5 cm H_2O	Hemodynamic stability
	Absence of refractory acidemia

FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen; PEEP, positive end-expiratory pressure; SpO_2, peripheral capillary oxygen saturation.

The purpose of clinical screening is to determine a pretest probability of extubation success. The pretest probability of success will be extremely low in the presence of clinical signs

that clearly predict extubation failure. These signs include shock, severe intracranial hypertension, requirement of high F_{IO_2} or PEEP, and the absence of protective airway reflexes or spontaneous inspiratory efforts. If the pretest probability of extubation success is extremely low, there is no additional test that would be able to raise the posttest probability of success sufficiently to allow extubation. In these situations, the clinician should continue mechanical ventilation, treat the cause of the respiratory failure, and repeat the screening at least daily. Similarly, clinicians also should not perform tests of extubation readiness in situations where the pretest probability of extubation success is very high. These situations include patients who had been intubated for a brief and uncomplicated procedure as well as those intubated for a sedative overdose that has resolved. When clinicians calculate a very high pretest probability of extubation success, they can proceed directly to extubation without testing.

When there is an intermediate pretest probability for extubation success, clinicians should consider performing tests of extubation readiness. These tests simulate the conditions of spontaneous breathing after extubation. The most common tests are T-tube, CPAP, pressure support ventilation, and flow-by ventilation. The appearance of tachypnea, hemodynamic instability, diaphoresis, anxiety, or agitation signifies failure of the test. If the patient tolerates it, the trial continues for 30 to 120 minutes. Clinicians should consider extubation if the patient passes the trial. It is unclear there is a single best approach to test for extubation readiness. A recent trial fund that pressure support ventilation for 30 minutes was superior to 120 minutes of unassisted breathing via T-tube. Importantly, the vast majority of critically ill patients who undergo these tests are able to sustain spontaneous breathing after extubation. There are, however, important physiologic differences between the

methods. Given the varied causes of extubation failure, the utility of the different tests may vary in different situations. For example, in patients with significant heart disease, it is important to predict the consequences of switching from positive to negative pressure ventilation that occurs with extubation. Because positive pressure ventilation decreases cardiac preload and left ventricular afterload, extubation readiness testing performed with CPAP or minimal pressure support may not be predictive of success. Tests using T-tube or "flow-by" ventilation (with pressure support and PEEP set to 0 cm H_2O) better simulate the hemodynamic stressors of breathing after extubation (**Fig. 3.7**). There are concerns about T-tubes imposing an unfair resistive load due to its narrow diameter. In one series, T-tube trials failed to identify a number of patients capable of successfully breathing after extubation. However, T-piece trials using size 7 to 8.5 endotracheal tubes accurately predict the work of breathing after extubation in critically ill patients. T-tube trials add the expense of the humidification and tubing attachments to the oxygen source. Moreover, the T-piece trials do not benefit from ventilator alarms.

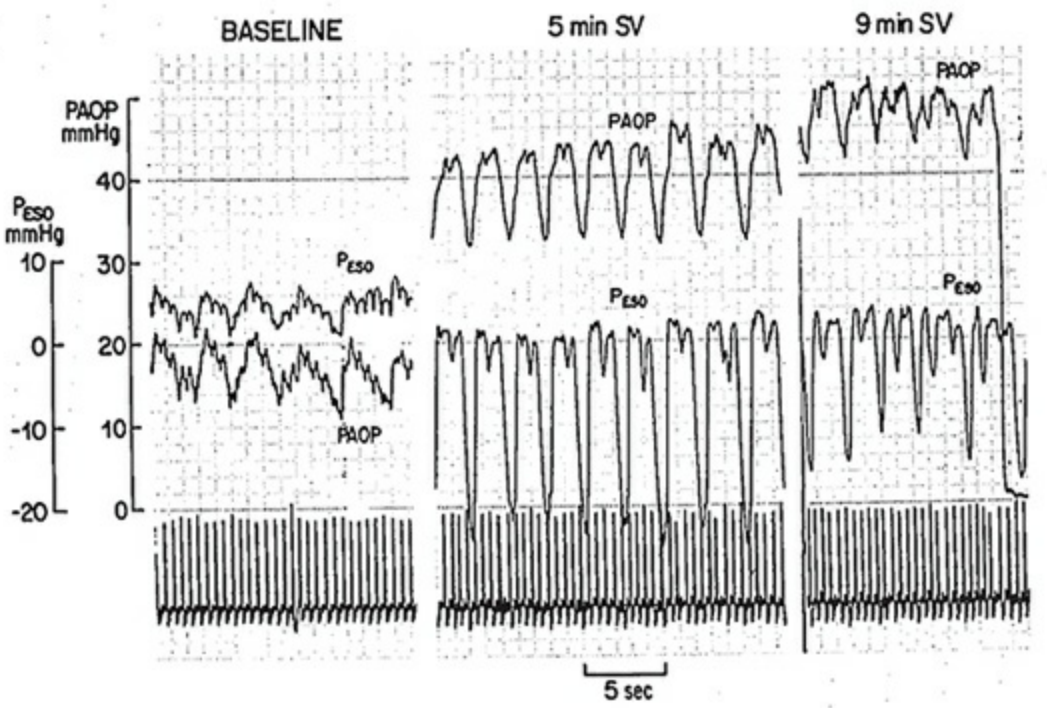

FIGURE 3.7. Ventricular failure and pulmonary edema precipitated by spontaneous ventilation. At baseline **(left)**, the patient is on positive pressure ventilation. During spontaneous ventilation (SV), the esophageal pressure (P_{ESO}) is negative during inspiration and the pulmonary artery occlusion pressure (PAOP) rises. By 9 minutes, the PAOP is catastrophically elevated and respiratory muscle fatigue decreases the amplitude of P_{ESO}. (*Reprinted with permission from Lemaire F, Teboul JL, Cinotti L, et al. Acute left ventricular dysfunction during unsuccessful weaning from mechanical ventilation.* Anesthesiology. *1988;69[2]:171–179.*)

Trials with pressure support theoretically overcome the resistance imposed by the ventilator circuit. However, the amount of pressure support required is unclear. These trials may underestimate the work of breathing after extubation. The opposite phenomenon is also important. Pressure support may create dyssynchrony on mechanical ventilation. In particular, oversupport may induce tachypnea. Clinicians may misinterpret tachypnea to mean that the patient cannot be extubated. This may lead to needlessly prolonged mechanical ventilation. Automatic tube compensation software is designed to improve the application of minimal pressure support during tests of extubation readiness. However, at present, there is no proof of advantage for this approach in clinical trials.

In place of tests of readiness for extubation, some clinicians prefer to gradually wean ventilator support. Pressure support can be incrementally reduced or the number of controlled breaths reduced on SIMV. However, there is no proof that any ventilator strategy or weaning process trains and strengthens respiratory muscles. Moreover, in clinical trials, these methods prolong the time to extubation. The importance of liberation as opposed to weaning from mechanical ventilation is illustrated by a clinical trial, which showed that pairing a once daily awakening from sedatives with a trial of spontaneous ventilation reduces mortality.

A final step prior to extubation is to consider the risk of postextubation stridor. The cuff leak test is an imperfect predictor. Clinicians should only consider using it when there are risk factors for laryngeal edema such as prolonged intubation, large endotracheal tube, asthma, traumatic intubation, and ventilator patient dyssynchrony.

In situations such as COPD or congestive heart failure, extubation directly to prophylactic NIPPV may reduce the need for reintubation. However, these patients must be carefully reevaluated to make sure they are not dependent on NIPPV for excessive periods of time, preventing effective nutrition and physical therapy.

4 Lung Transplantation

Choy Lewis, Ryan Hood, and Charles W. Hogue

A 63-year-old woman with progressively worsening dyspnea on exertion and limited functional capacity despite maximal treatment with medication, pulmonary rehabilitation, and supplemental oxygen therapy is scheduled for bilateral sequential lung transplantation. Laboratory, radiographic, and spirometric data are consistent with severe obstructive pulmonary disease. Other significant medical findings include a 30 pack-year history of smoking (although none for 10 years), mild hypertension (145/86 mmHg), mild pulmonary hypertension (mean pulmonary arterial pressure, 32 mmHg), normal left and right ventricular function, and osteoarthritis.

A. Medical Disease and Differential Diagnosis

1. What are the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?
2. What other end-stage lung diseases can also be treated with transplantation?
3. How many lung transplantations have been performed?
4. What are the selection criteria for recipients?
5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?

6. How does a single-lung transplantation (SLT) differ technically from a bilateral-lung transplantation (BLT)?

B. Preoperative Evaluation and Preparation

1. What preoperative evaluation is desirable?
2. Would you premedicate this patient? If so, how?
3. What vascular access is appropriate?
4. Is preoperative epidural catheter placement advantageous?

C. Intraoperative Management

1. What special equipment is necessary?
2. How would you monitor this patient?
3. How would you induce anesthesia in this patient?
4. How would you ventilate this patient? What kind of endotracheal tube would you use?
5. How does the physiology of single-lung ventilation influence the procedure?
6. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?
7. What problems are associated with the lateral position?
8. Should volatile anesthetics be avoided during single-lung ventilation?
9. At what specific points in the procedure are problems anticipated?
10. How would you deal with problems related to clamping of the pulmonary artery (PA)?
11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?
12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?
13. Should fluid administration be restricted, and are blood products commonly required?
14. Would you extubate the patient upon conclusion of the

procedure?

D. Postoperative Management

1. What are the major complications after lung transplantation?
2. How is postoperative ventilation managed, and for how long is it required?
3. What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?
4. What are the long-term outcomes of lung transplantation?
5. Are there surgical alternatives to lung transplantation?

A. Medical Disease and Differential Diagnosis

A.1. What are the expected manifestations of severe obstructive pulmonary disease in this patient, and why is she a transplant candidate?

Severe obstructive pulmonary disease results in increased airway resistance, reduced expiratory flow rates, and high residual lung volumes. There is a point at which the expiratory airway obstruction and lung hyperinflation become so severe that the chest wall cannot physically expand to accommodate a normal tidal volume, resulting in restrictive physiology superimposed on obstructive disease. This condition is usually refractory to medical management and substantially limits daily activity. This patient's age, the severity and progression of her disease despite maximal therapy, and the lack of contraindications support referral for lung transplant candidacy.

The International Society of Heart and Lung Transplantation (ISHLT) guidelines state that chronic obstructive pulmonary disease (COPD) patients can be recommended for lung transplantation if they demonstrate disease progression despite maximal medical therapy; hypoxemia (Pa_{O_2} <60 mmHg) or

hypercapnia ($PaCO_2$ >50 mmHg); forced expiratory volume in 1 second (FEV_1) <25% predicted; and body mass index, obstruction dyspnea, and exercise capacity (BODE) score 5 to 6 and are not candidates for lung volume reduction surgery (LVRS); simultaneous evaluation for lung transplant and LVRS is appropriate. The BODE index is a multivariate assessment that combines body mass index, FEV_1, the Modified Medical Research Council Dyspnea scale, and 6-minute walk test (6MWT) into a weighted 10-point score that is correlated to mortality in COPD. To be listed for transplant COPD, patients must meet one of more of the following criteria: (1) BODE index ≥7, (2) FEV_1 <15% predicted, (3) three or more severe exacerbations during the preceding year, (4) acute hypercapnic respiratory failure, or (5) concomitant moderate to severe pulmonary hypertension.

Historically, SLT has been used for patients with COPD and interstitial lung disease (ILD). There has been a progressive decline in the use of SLT for COPD due to concerns for the development of significant ventilation/perfusion mismatch from hyperinflation of the native lung and mediastinal displacement. In addition, there is a body of evidence showing a survival benefit and improved functional outcomes with double-lung transplantation (DLT) for COPD patients when compared to SLT in this patient population. Conversely, numerous studies have shown no difference in outcomes in COPD patients who had a single-lung transplanted versus those who had DLT or BLT. Clinical experience has also demonstrated that many patients with COPD can be successfully treated with SLT. With a severe shortage in organs for transplant, single-lung transplant has been advocated as a way to increase the number of recipients. The decision for SLT or BLT remains controversial and is based on the individual situation taking into account

regional organ allocation policies, individual center experience, and organ availability. Lung transplantation, when successful, significantly improves quality of life and survival for patients with severe COPD.

A.2. What other end-stage lung diseases can also be treated with transplantation?

The first successful (i.e., the patient left the hospital) SLTs were performed in 1983 for idiopathic pulmonary fibrosis. Since that time, the procedure has been applied to patients suffering from various end-stage pulmonary diseases (**Table 4.1**). In general, the underlying disease processes that produce lung dysfunction can be broadly characterized as obstructive, restrictive, infectious (e.g., cystic fibrosis and bronchiectasis), or vascular. As of 2008, most SLTs have been performed for obstructive lung disease, followed by idiopathic pulmonary fibrosis. The most common indications for BLT are cystic fibrosis and obstructive lung disease.

TABLE 4.1 Lung Transplants Categorized by Disease

End-Stage Lung Disease	Single-Lung Transplant (% of Total)	Bilateral-/Double-Lung Transplant (% of Total)
Cystic fibrosis	1.5	24.9

Retransplant	3.4	2.3
Idiopathic pulmonary arterial hypertension	0.6	4.4
α_1-Antitrypsin deficiency	5.0	5.9
Sarcoidosis	1.8	2.9
Interstitial lung disease	34.9	18.2
Emphysema/chronic obstructive pulmonary disease	43.0	26.6
Miscellaneous	4.5	5.9

Reflecting a loss of lung parenchymal elasticity and compliance, *end-stage restrictive disease* is characterized by profoundly reduced lung volumes and diffusing capacity but relative preservation of ventilatory flow rates. Comparisons of flow–volume loops representing obstructive and restrictive diseases are shown in **Figure 4.1**. The underlying disease process also tends to obliterate pulmonary microvasculature, thereby chronically increasing vascular resistance, producing pulmonary hypertension, and predisposing to cor pulmonale. Most patients with restrictive disease are good candidates for an SLT because the stiff, vasoconstricted native lung will receive relatively little ventilation and perfusion and can therefore usually be left without compromising the transplanted lung.

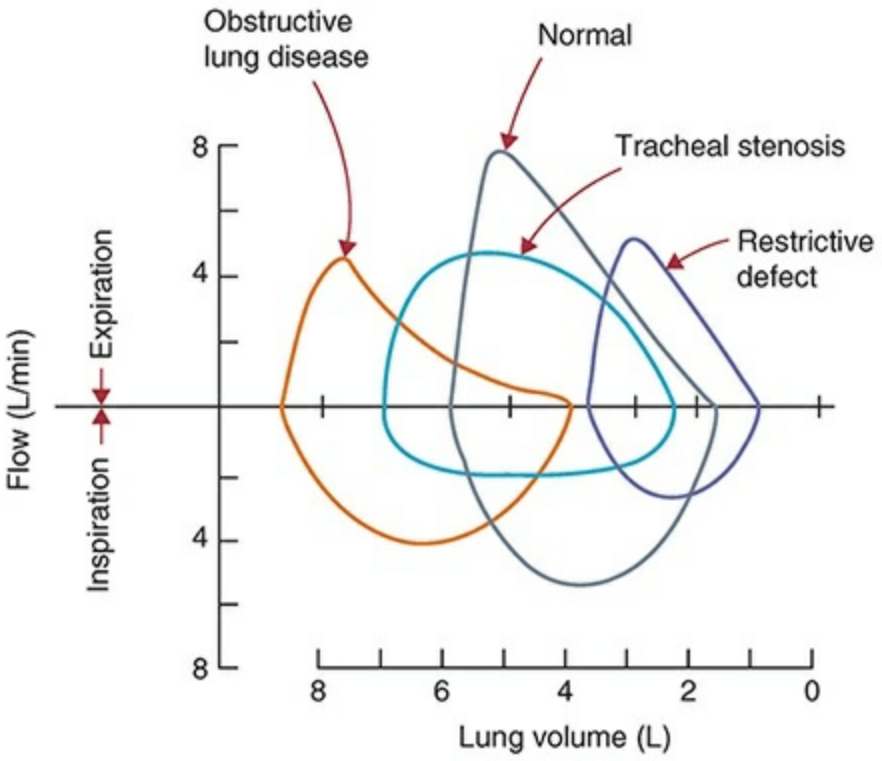

FIGURE 4.1. Representative tracings of flow–volume loops from a healthy individual, a patient with parenchymal obstructive disease, a patient with tracheal stenosis, and a patient with restrictive disease from parenchymal fibrosis. (*Modified with permission of McGraw-Hill Education, from Goudsouzian N, Karamanian A.* Physiology for the Anesthesiologist. *2nd ed. Norwalk, CT: Appleton-Century-Crofts; 1984:213; permission conveyed through Copyright Clearance Center, Inc.*)

Infectious lung disease, such as cystic fibrosis, is the most frequent indication for lung transplantation in patients younger than 18 years old. Characterized by chronic infection and the production of copious purulent secretions, patients with cystic fibrosis primarily exhibit obstructive functional abnormalities with increased airway reactivity. Under most circumstances, residual lung volumes and functional residual capacity are increased and bronchodilators have little effect on expiratory flow rates. Because of potential infectious cross-contamination of the transplanted lung, chronic infectious disease represents a contraindication to SLT. However, SLT with contralateral pneumonectomy has been performed as an alternative solution.

Pulmonary vascular disease with severe pulmonary hypertension and right ventricular dysfunction has also emerged

as an indication for transplantation. Pathologically, severe PA hypertension can result from idiopathic proximal vascular processes such as persistent pulmonary hypertension (PPH) or secondary to chronically increased pulmonary blood flow (e.g., left-to-right intracardiac shunt, leading to Eisenmenger's syndrome) or pulmonary venous hypertension from left-sided heart diseases. Pulmonary hypertension may precipitate chronic hypoxemia via an intracardiac defect that allows for development of a right-to-left shunt. Improved medical therapy for PPH, particularly with continuous long-term intravenous prostacyclin infusions or sildenafil, has affected the numbers of patients undergoing lung transplantation for this disease. Controversy exists with respect to choice of SLT versus BLT for patients with idiopathic pulmonary arterial hypertension (IPAH). Because a native lung can usually be left intact without compromising a transplanted lung (which will receive most of blood flow), some patients with pulmonary arterial vascular disease may be reasonable candidates for SLT, *with concurrent repair of any cardiac anomalies*. Early reports indicated poorer functional recovery and higher mortality after SLT versus BLT for PPH. Some reports suggest the earlier manifestation of bronchiolitis obliterans syndrome (BOS) in patients after SLT versus BLT, and although survival curves diverge 3 years after transplantation, controversy remains whether or not procedure type is the main cause. Some centers have adopted BLT as the mainstay of treatment for patients presenting with IPAH.

A.3. How many lung transplantations have been performed?

Although the first human lung allograft was performed in 1963, transplantation of one or both lungs did not emerge as a viable therapeutic option for patients with end-stage lung disease until the 1980s. The ultimate emergence of this procedure can be largely attributed to advances in surgical technique, anesthetic management, organ harvest and preservation, infection prevention, and immunosuppressive therapy. Since initiation of the International Thoracic Organ Transplant registry in the mid-1980s, the number of procedures reported yearly has continue to rise. This is in part due to the use of extended criteria donors and ex-vivo lung perfusion systems. As of the end of June 2017, the registry contains data for 64,803 adult lung and 4,054 adult heart-lung transplants. There were 2,449 lung transplants and 29 heart-lung transplants done in the United States in 2017, based on Organ Procurement and Transplantation Network (OPTN) data as of January 9, 2019. These numbers do not include pediatric patients or patients who received both a lung and a liver or a lung and a kidney transplant. Despite this volume, the number of patients awaiting lung transplantation continues to exceed the limited donor supply.

A.4. What are the selection criteria for recipients?

In general, patients with severe end-stage lung disease are considered candidates for transplantation when their life expectancy is less than 2 to 3 years. They have minimal disease of other organ systems, and they are mentally and psychologically capable of following strict regimens for rehabilitation and immunosuppressive therapy. These criteria contribute to a high (>80%) likelihood of surviving the lung transplantation for at least 90 days and 5-year posttransplant survival from a general medical standpoint. Specific criteria, including age, are dependent on the type of lung disease and whether the planned procedure is SLT or BLT. Recent data reveal that the age of lung transplant recipients is increasing with approximately 35% now 60 years of age and older compared to 15% in 1998. The average age of the recipient is 35.5 years. In contrast to inclusion criteria formulated when lung transplantation was in its infancy, concomitant steroid therapy, previous intrathoracic surgery, mechanical ventilation, and right ventricular failure are no longer considered absolute contraindications.

A.5. How is the decision made to transplant one or both lungs, and does this influence preoperative management?

Although BLTs are increasingly being performed for all etiologies of end-stage lung disease, bronchiectasis including cystic fibrosis and other infectious pathologies are the only *absolute* indication for BLT. The concern is that leaving an infective native lung can increase the risk of infection and decrease the long-term viability of the transplanted lung particularly in the setting of immunosuppression. However, SLT and BLT can be performed for all other etiologies of end-stage lung disease, including COPD, ILD, and primary pulmonary hypertension. With a perceived long-term mortality benefit with BLT, SLT is less frequently performed and BLT is more common for all etiologies of end-stage lung disease. In addition to greater distribution of limited donor organs and decreased wait times for recipients, SLT is technically less challenging with the potential for reduced cumulative periprocedural mortality. The data regarding short-term outcomes for SLT versus BLT is equivocal at best; there are some studies showing better outcomes with SLT. With BLT, there is increased functional lung parenchyma and greater reserve if there is a complication. With the exception of infectious etiologies, the decision to proceed with SLT versus DLT remains controversial. Patient (age, size, lung allocation scoring [LAS], etc.) as well as donor (age, size, comorbidities, state of the donor organ, etc.) specific factors must be taken into consideration and the benefits

must be weighed against the risk for both. Although SLT is technically easier and advocated for more difficult recipients, such as those with prior thoracic surgery or coexisting illnesses, functional improvements are often better with BLT. In addition, the status of the donor lungs further influences the decision of whether to perform a single or bilateral procedure. Finally, transplantation of two lobes from two living related donors for patients with inflammatory disease who are unlikely to survive the wait for a cadaver donor is gaining acceptance. The decision to proceed with SLT versus BLT may impact preoperative management of these patients. Although it is important to screen all patients for aspiration risk and to administer the appropriate premedications where necessary, it is especially important for potential SLT recipients. Aspiration can further damage the native lung and significantly impact outcome. Some people advocate that all SLT recipients should be treated as high aspiration risk and the appropriate premedications to safeguard against this should be administered. Also, with a lower chance for extracorporeal support and anticoagulation, SLT recipients are more likely to receive an epidural preoperatively than BLT recipients.

A.6. How does a single-lung transplantation (SLT) differ

technically from a bilateral-lung transplantation (BLT)?

It is extremely important that anesthesiologists be broadly familiar with the surgical methods because manipulation of the heart and lungs at specific points during the transplantation can produce marked cardiopulmonary disturbances. Ideally, the anesthesiologist should anticipate these changes and adapt the anesthetic management accordingly.

SLT is usually performed in the lateral decubitus position through a thoracotomy incision, often with the upper leg and pelvis angled to allow groin exposure for potential femoral cannulation and CPB. In contrast, bilateral sequential lung transplantation is usually performed with the patient supine through a "clamshell" incision (bilateral anterior thoracotomies with or without transverse sternotomy). For both SLT and BLT, intermittent single-lung ventilation is required during dissection of the native lung to be removed and implantation of the graft. Once stable single-lung ventilation is established, dissection of the lung to be transplanted is initiated with isolation of the PA. To assess the cardiopulmonary response to diverting the entire cardiac output through one lung, progressive temporary occlusion of the vessel is first performed manually; if well tolerated, the vessel is then clamped and stapled. After ligation of the PA, the pneumonectomy is completed. Implantation of the graft begins with anastomosis of the airway. In the past, the bronchial anastomosis was wrapped with an omental pedicle, mobilized through a small abdominal incision in an effort to improve blood supply to the airway and promote healing. However, the use of a "telescoping" bronchial anastomosis has now largely obviated the need for omental wrapping. The PA branch is then attached to the graft, followed by anastomosis of a cuff of the left atrium containing the pulmonary veins. The implanted lung is then partially inflated, the left atrial cuff and

pulmonary veins de-aired, and circulation to the organ restored. If the attempt to establish adequate hemodynamics and oxygenation after reperfusion of the transplanted lung is unsuccessful, this is the time to consider using extracorporeal membrane oxygenation (ECMO) or CPB. In a sequential BLT, the point in the case where the decision may be made to place the patient on extracorporeal support is prior to attempting to transplant the second lung. The use of extracorporeal support for BLT often varies by institutional and patient factors. If an en bloc technique for BLT is used, CPB is required. Additional surgical technique for BLT is described in the following text.

Patients presenting for SLT with chronic PPH of primary or secondary etiology often exhibit severe compromise of the right ventricular function. To avoid additional right ventricular compromise, many institutions choose to institute partial normothermic CPB during SLT for PPH or in patients with severe pulmonary hypertension and right ventricular dysfunction secondary to restrictive or obstructive disease. Cannulation is typically through the femoral artery and the right atrium unless simultaneous correction of an intracardiac defect is planned. In such patients, conventional aortic and single- or double-stage atrial cannulation are performed. Implantation of the lung is otherwise performed in the same manner as described earlier.

BLT was first described by the Toronto Lung Transplant Group in the mid-1980s as en bloc implantation of both lungs simultaneously. The procedure is performed through a median sternotomy using hypothermic CPB, cardioplegic cardiac arrest, and single tracheal (or double bronchial) anastomosis of the trachea and main PA. Although the procedure initially produced encouraging results, considerable limitations related to technical complexity, morbidity, mortality, and application to many patients with end-stage lung disease soon became apparent. Not surprisingly, use of the procedure declined sharply and has now

been largely replaced by the bilateral sequential implantation technique, which does not uniformly require hypothermic CPB. Introduced in 1990, bilateral sequential (or bilateral single) lung transplantation has become the surgical procedure of choice when replacement of both lungs is necessary. According to the 2014 international registry, approximately 75% of the transplants performed in 2012 were BLTs. As noted earlier, in contrast to SLT, bilateral sequential lung transplantation procedures are performed in the supine position. In general, the procedure can be regarded as having two phases. First, the most severely compromised lung (as determined by preoperative ventilation-perfusion lung scanning) is removed during ventilation of the "good" contralateral lung. Implantation is achieved through a bronchial anastomosis as with an SLT. The second lung is then removed and transplanted during ventilation of the new lung alone. As noted earlier, if there is hemodynamic or ventilatory instability during ventilation of the new lung alone, extracorporeal support may be instituted prior to implanting the second lung.

B. Preoperative Evaluation and Preparation

B.1. What preoperative evaluation is desirable?

At most centers, an extensive physical examination, psychological evaluation, and numerous tests of cardiopulmonary function are performed before acceptance into the transplant program. This facilitates the preanesthetic evaluation that ideally is performed when the patient is first accepted into the transplant program. Familiarity with pulmonary function tests, ventilation-perfusion lung scan results, heart catheterization, echocardiographic data (including evidence of intracardiac shunts), exercise tolerance, oxygen use, and dependence on continuous pulmonary vasodilator infusion (i.e., prostacyclin) are beneficial for formulating an anesthetic plan. Although many of these parameters are regularly reassessed, the interval between evaluation and transplantation necessitates that a careful history and physical examination be repeated before the procedure, focusing on signs of pulmonary hypertension and cardiac dysfunction.

B.2. Would you premedicate this patient? If so, how?

As with all critically ill patients, considerations regarding preoperative sedation are governed primarily by the functional limitations imposed by the underlying disease and the potential consequences of hypercarbia and hypoxemia as a result of the

sedation. Special consideration must also be given to the possibility that the donor lungs will be deemed unacceptable at final inspection, and therefore, the procedure is canceled. When indicated, parenteral sedation is usually chosen because of insufficient time to effectively administer oral anxiolytics. Midazolam alone or with diphenhydramine (potentially protecting the lung against drug-induced histamine release) is often sufficient. Clinically, most patients with end-stage restrictive, obstructive, or infectious lung disease are tachypneic while breathing room air and cannot tolerate aggressive sedation. Also, patients with pulmonary hypertension and significant right-to-left intracardiac shunting (i.e., Eisenmenger's physiology) are often cyanotic despite oxygen supplementation and may not tolerate sedation well. In contrast, patients with PPH and no intracardiac defect often appear reasonably normal and will benefit from sedation because of the potential for stress-related increases in pulmonary vascular resistance. In addition to sedative premedication, consideration needs to be given to immunosuppression protocols and in appropriate patients to supplemental bronchodilator therapy.

Slinger P, Blank RS, Campos J, et al, eds. *Principles and Practice of Anesthesia for Thoracic Surgery*. 2nd ed. Basel, Switzerland: Springer; 2019:773–790.

B.3. What vascular access is appropriate?

Typically, a large-bore intravenous catheter and central venous access for PA catheter placement are secured before surgery. In many centers, additional central venous cannulation is performed with a multiple-lumen catheter to provide intraoperative and postoperative venous access. For patients with chronic infectious lung disease or a history of previous

intrathoracic procedures, a second large-bore intravenous catheter is often obtained because of the potential for brisk blood loss during dissection of pleural adhesions. Meticulous removal of air from venous infusion lines should be performed, particularly in patents with known or suspected right-to-left shunts. At many institutions, cannulation of a femoral artery, instead of the radial artery, is performed under local anesthesia in the operating room because radial arterial pressures may become damped during the procedure secondary to vasoactive medication infusion or positioning of the arms.

Hartigan PM, Pedoto A. Anesthetic considerations for lung volume reduction surgery and lung transplantation. *Thorac Surg Clin*. 2005;15(1):143–157.

B.4. Is preoperative epidural catheter placement advantageous?

Pain control after lung transplantation can be critical in facilitating tracheal extubation and rehabilitation. Both lumbar and thoracic epidural catheters have been used for postoperative pain management. Epidural catheters may be placed immediately before the procedure or postoperatively prior to extubation. If placed before the procedure, there must be consideration that there is the possibility of anticoagulation and CPB during the transplantation procedure. The practice of placing preoperative epidurals is supported by data indicating no adverse sequelae to preoperatively placed epidural catheters, including those patients who required emergent heparinization and CPB. Obvious exceptions to this approach are patients who are anticoagulated preoperatively or those in whom CPB is planned. Delaying placement of the epidural catheter until the postoperative period may also be a possibility.

C. Intraoperative Management

C.1. What special equipment is necessary?

Necessary items for lung transplantation include an anesthesia ventilator with options for several ventilatory modes and with good efficacy at higher airway pressures. In addition, the ventilator should be capable of delivering a wide range of inspiratory-to-expiratory ratios (I:E ratios) and varying inspired oxygen concentrations. A fiberoptic bronchoscope is necessary for airway assessment, guided airway suctioning, inspection of the bronchial anastomoses, and for confirmation of appropriate placement of the double-lumen endotracheal tube or bronchial blocker. An apparatus to deliver continuous positive airway pressure (CPAP) and a system for delivery of pulmonary arterial vasodilators, such as nitric oxide should be readily available. Transesophageal echocardiography (TEE) should be used. Lastly, a CPB machine and/or extracorporeal circuit should always be immediately accessible. Because multiple vasopressors and inotropes are often needed, infusion pumps that allow for the simultaneous administration of numerous drugs should be utilized.

C.2. How would you monitor this patient?

Intraoperatively, hemodynamic and respiratory changes are often acute and profound, so extensive monitoring is imperative. In addition to the electrocardiogram, arterial blood pressure, and peripheral arterial oxygen saturation, PA catheter placement is routine for lung transplantation at most institutions because of the profound changes in pulmonary and systemic hemodynamics that often occur. During SLT, PA catheters often migrate to the

operative side after the patient has been laterally positioned even when radiographically confirmed to be in the nonoperative lung. Therefore, the surgeon should be reminded to palpate the PA and withdraw the catheter if necessary before cross-clamping the vessel. PA catheters capable of measuring mixed venous oxygen saturation have become widely used. TEE is often employed during lung transplantation to evaluate vascular anastomoses and right ventricular function, particularly during clamping of the PA as well as to assess for intracardiac shunts and adequacy of de-airing maneuvers.

C.3. How would you induce anesthesia in this patient?

As with induction of anesthesia in any critically ill patient, multiple techniques have been safely used for patients undergoing lung transplantation. Effective alveolar ventilation and nitrogen washout are poor in the patient with severe obstructive lung disease and high residual volumes; therefore, prolonged (i.e., 15 to 20 minutes) preoxygenation is worthwhile. A slow, controlled induction is generally preferred; abrupt withdrawal of sympathetic tone in these patients with high sympathetic activity can lead to marked cardiovascular compromise, especially as you transition from spontaneous to mechanical ventilation. Rapid sequence induction should

therefore be reserved for patients deemed to be a high aspiration risk because large boluses of medication may cause profound hemodynamic instability. A rapid-acting induction agent to shorten the excitement stage, expedite airway management, and prevent opiate-induced truncal rigidity should be used. Propofol, etomidate, ketamine, and midazolam have all been used safely; the specific properties of each drug in the setting of the patient's underlying disease should be considered. For example, the sympathomimetic properties of ketamine may preclude use in the presence of pulmonary hypertension, whereas its bronchodilating effects may be beneficial in the setting of bronchospasm. Lidocaine, sufentanil or fentanyl, and succinylcholine or a nondepolarizing muscle relaxant are generally used to complete induction.

Because of the greater potential for hemodynamic and respiratory instability in this patient population, the surgeon and perfusionist must be present during induction to initiate ECMO or CPB if needed. In patients requiring high noninvasive respiratory support or with severe pulmonary hypertension, ECMO may be instituted prior to induction. Alternatively, the groin vessels may be accessed prior to induction to facilitate initiation of ECMO of CPB after induction.

Optimization of right ventricular preload, right ventricular support, and efforts to prevent increases in right ventricular afterload are keys to a safe anesthesia induction. Dysrhythmias, which may lead to decreased perfusion and ischemia of the right ventricle, should be avoided. Especially with positive pressure ventilation, suppression of the sympathetic system, myocardial depression, and vasodilation may lead to cardiovascular collapse. Conversely, acute increases in pulmonary arterial pressures and right heart failure may result from sympathetic stimulation (e.g., with intubation, acidemia, hypoxemia, hypercapnia) and should be avoided.

C.4. How would you ventilate this patient? What kind of endotracheal tube would you use?

After induction, the trachea is usually intubated with a left endobronchial double-lumen tube for both SLT and BLT. Use of a single-lumen endotracheal tube with either an external or an internal bronchial blocking catheter has been described but does not appear to be clearly superior to the left double-lumen tube for most procedures. Furthermore, an endobronchial double-lumen tube allows for differential lung ventilation if required postoperatively. One exception to this approach has been in patients with cystic fibrosis who exhibit thick tenacious secretions that are difficult to suction through the small-lumen suction catheters necessary for double-lumen tubes. In these patients, it is often helpful to first place a large single-lumen tube and perform extensive bronchoscopic-directed bronchial lavage and suctioning before placement of the double-lumen tube.

The transition from spontaneous to mechanical ventilation invariably produces hemodynamic alterations resulting from acute changes in intrathoracic pressure and chest wall compliance. With obstructive lung disease, mechanical ventilation magnifies air trapping, leading to “pulmonary tamponade.” Varying degrees of this phenomenon should be expected during anesthesia induction. The treatment consists of intermittent apnea with an open ventilator circuit, adjustment of the ventilatory pattern to an I:E ratio of 1:5 or less with

moderate tidal volumes, and administration of bronchodilating drugs. Prompt restoration of blood pressure usually ensues. If hypotension persists, other causes of circulatory compromise must be excluded including pneumothorax. With restrictive disease, higher inflation pressures and positive end-expiratory pressure (PEEP) are often required. In both obstructive and restrictive disease, optimal balance of ventilation with hemodynamic stability often necessitates tolerating a degree of hypercapnia. In pulmonary hypertensive patients, mechanical ventilation usually produces less cardiovascular disturbance if caution is exercised to not increase pulmonary vascular resistance (e.g., from hypoxia, hypercarbia, or lung hyperinflation).

Youngberg JA, Lake CL, Roizen MF, et al, eds. *Cardiac, Vascular, and Thoracic Anesthesia*. New York: Churchill Livingstone; 2000:703.

C.5. How does the physiology of single-lung ventilation influence the procedure?

In laterally positioned patients, gravity helps redistribute blood away from the nonventilated lung during single-lung ventilation and lessen the intrapulmonary shunt. In patients who are supine, this benefit is lost and single-lung ventilation may not be well tolerated. If appropriately preoxygenated prior to induction and ventilated prior to one-lung ventilation (OLV), patients with higher residual volumes, such as patients with severe obstructive pulmonary disease, may tolerate OLV better than patients with lower residual volumes. These patients have a higher reserve and may maintain oxygenation for the first 10 to 15 minutes of single-lung ventilation. Rapid arterial desaturation may then occur once a substantial portion of the residual volume is absorbed. Conversely, patients with restrictive lung disease and

a low functional residual capacity may become hypoxemic and hypercarbic rather rapidly if not ventilated. Multiple steps can be taken to improve oxygenation including insufflation of oxygen or CPAP to the nonventilated lung, bronchoscopic-guided suctioning of the ventilated lung, careful manipulation of the ventilatory pattern, and adding PEEP to the ventilated lung. Differential PEEP/CPAP should be done cautiously; however, because increased airway pressure in the ventilated lung can divert blood toward the nonventilated lung, thereby increasing the shunt and leading to a further decrease in Pa_{O_2}. Likewise, sustained hyperinflation of the ventilated lung may lead to an increase in right ventricular afterload and preload and have severe hemodynamic consequences. In some patients, intermittent ventilation of the operative lung may be necessary for appropriate oxygenation. In general, oxygenation improves after the clamping of the PA supplying the nonventilated lung. For desaturation not responding to the usual maneuvers, tourniquets can be placed around the PA by the surgeon as a temporizing step until dissection permits proper stapling of this vessel. Inhaled pulmonary arterial vasodilators may improve ventilation/perfusion matching by selective vasodilation of only the PAs that are being ventilated. ECMO or CPB should be initiated if the Pa_{O_2} continues to decrease, the Pa_{CO_2} continues to increase, and the patient is severely acidemic, despite all the previously stated interventions.

C.6. How does single-lung ventilation affect cardiopulmonary function? What are the problems of single-lung ventilation in this patient? How would you treat them?

Isolated ventilation of the dependent lung is often accompanied by a marked acute increase in peak inspiratory pressure and a subsequent gradual progressive rise in PA pressure. As noted earlier, because of the beneficial effect of gravity on redistributing blood away from the nondependent nonventilated lung, single-lung ventilation is often tolerated better from a respiratory standpoint by patients undergoing SLT in the lateral position than those undergoing BLT in the supine position. Close monitoring of right ventricular performance during conversion to single-lung ventilation is extremely important because of the increase in afterload produced by hypoxic vasoconstriction and redistribution of blood flow. Although unusual, if the right ventricle becomes hypokinetic and distended (TEE imaging) or the central venous pressure (CVP) increases disproportionally to the raise in PA pressure and if the left ventricular ejection fraction decreases, ventilation may have to be altered to minimize the increase in PA pressure.

Triantafillou AN, Pasque MK, Huddleston CB, et al. Predictors, frequency, and indications for cardiopulmonary bypass during lung transplantation in adults. *Ann Thorac Surg*. 1994;57:1248–1251.

C.7. What problems are associated with the lateral position?

SLT is usually performed in the lateral decubitus position, often with the upper leg and pelvis angled to allow groin exposure for potential femoral cannulation and CPB. Not surprisingly, position-related changes in venous return, coupled with compression of the dependent lung by the mediastinum and diaphragm, may promote systemic hypotension and

ventilation/perfusion mismatch. Furthermore, PA pressure usually tends to rise after lateral positioning; this is likely secondary to gravity-induced shifts in pulmonary blood flow distribution, vascular congestion, and increased vascular resistance.

Youngberg JA, Lake CL, Roizen MF, et al, eds. *Cardiac, Vascular, and Thoracic Anesthesia*. New York: Churchill Livingstone; 2000:703.

C.8. Should volatile anesthetics be avoided during single-lung ventilation?

Because of experimental evidence demonstrating inhibition of hypoxic pulmonary vasoconstriction (HPV) by the volatile anesthetic agents, some authors have suggested that these drugs be avoided in the anesthetic management of patients with end-stage lung disease requiring single-lung ventilation. However, true clinical significance of these experimental observations remains somewhat controversial. From a clinical standpoint, commonly used doses of isoflurane (e.g., end-tidal concentrations of 1.0% or less) have not been empirically associated with worsening of intrapulmonary shunt and hypoxia. Therefore, isoflurane remains widely used in these patients and may actually benefit some lung recipients because of its bronchodilating properties (also see Chapter 2, section C.13).

C.9. At what specific points in the procedure are problems anticipated?

Challenges encountered during surgeries for lung transplantation

are usually related to the underlying disease process, anesthesia, the complexity of the surgery, physiologic changes associated with the different stages of the procedure, patient positioning, and immediate complications such as primary graft dysfunction (PGD). The procedure can be especially challenging at these particular points:

- Anesthesia induction
- Lateral positioning
- Single-lung ventilation
- Clamping of the PA
- Graft implantation
- Graft reperfusion

C.10. How would you deal with problems related to clamping of the pulmonary artery (PA)?

To assess the cardiopulmonary response to diverting the entire cardiac output through one lung, progressive occlusion of the vessel is first performed manually (**Fig. 4.2**). Careful assessment of right ventricular function is performed with the TEE looking for evidence of right ventricular distension or hypokinesis. If well tolerated, the vessel is then clamped and stapled. If occlusion is poorly tolerated, the vessel is unclamped and a pulmonary vasodilator, such as prostaglandin E_1 or inhaled nitric oxide (iNO), and/or a positive inotropic infusion are begun. If severe respiratory or cardiovascular derangement persists after reclamping of the vessel despite pharmacologic intervention, heparin is administered and CPB instituted to avoid profound hypoxia or right ventricular failure. However, for most patients undergoing SLT, hypoxemia during single-lung ventilation and after PA clamping is rarely a problem, and right ventricular performance is adequately maintained.

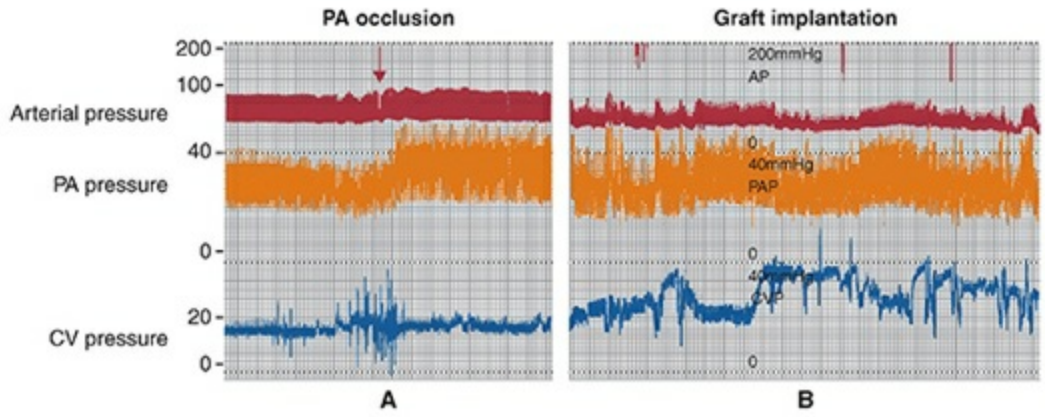

FIGURE 4.2. Tracings of femoral arterial blood pressure, along with pulmonary artery (PA) and central venous (CV) pressures, before and after occlusion of the left PA (A) and during implantation of a left lung graft (B). All pressures are in millimeters of mercury. AP, arterial pressure; CVP, central venous pressure; PAP, pulmonary artery pressure.

Youngberg JA, Lake CL, Roizen MF, et al, eds. *Cardiac, Vascular, and Thoracic Anesthesia*. New York: Churchill Livingstone; 2000:703.

C.11. What hemodynamic alterations would you expect during graft implantation and reperfusion? How would you correct them?

During the process of performing the vascular and bronchial anastomoses, major disturbances on cardiac filling and rhythm can be produced. Although often transient, systemic hypotension and pulmonary hypertension can ensue. Temporization with vasopressors, inotropes, or an inhaled pulmonary arterial vasodilator may be necessary. Electrical therapy should be used for sustained dysrhythmia causing hemodynamic instability. The final stages of graft implantation include attaching the pulmonary veins, via a left atrial cuff, to the left atrium. Bleeding of the pulmonary veins, prior to doing this, facilitates de-airing and removal of graft preservatives. Transient hypotension may follow the introduction of the preservative solution into the systemic circulation. Incomplete de-airing of the pulmonary veins can cause a coronary artery air embolism and lead to transient myocardial ischemia. The latter is manifested by ST-segment elevation and regional wall motion

abnormalities on TEE. These echocardiographic and electrocardiogram changes can be reversed by maintaining adequate perfusion pressure, with vasopressors. Rapid intravascular volume replacement may also be necessary during this time. After reperfusion and subsequent ventilation of the new lung, PA pressures and arterial blood gases should be closely followed. PA pressure usually falls after reperfusion of the transplanted allograft. If a substantial decrease is not observed, potential causes include anastomotic problems with the atrial cuff (pulmonary veins) or the PA. Such obstruction may lead to hemodynamic instability. Echocardiography is very useful in assessing for potential obstruction of the pulmonary vessels. Turbulent high-velocity flow and/or a diameter less than 75% of the proximal PA in the left or right PA are suggestive of obstruction. When pulmonary anastomotic problems are suspected, the surgeon should palpate to assess whether the PA catheter is located proximal or distal to the anastomosis. If a proximal location is confirmed, the PA pressure distal to the anastomosis should be directly measured by inserting a needle and connecting it to a pressure tubing handed off the operative field. A large difference in the two measurements is suggestive of obstruction to flow. Pulmonary vein obstruction from a thrombus or suture is possible and careful assessment must be done to assess for patency of these vessels. Pulmonary vein diameter greater than 0.5 cm and a velocity greater than 1 m per second are suggestive of obstruction. If significant obstruction of the pulmonary vasculature is detected, surgical revision/correction may be necessary because this may lead to early or late hemodynamic compromise. Anticoagulation may be necessary for obstruction secondary to thrombus. Ischemic metabolites may lead to severe vasodilation and hypotension with reperfusion. Vasopressors, inotropes, calcium chloride, and sodium bicarbonate may be needed. Other sources of

hypotension include pneumoplegia and leaks at the vascular anastomoses. Vasopressors, inotropes, and rapid intravascular replacement may be helpful in these situations.

Early graft dysfunction can manifest shortly after reperfusion of the first lung and may be the consequence of various insults. This may result in severe hypoxemia with hemodynamic compromise. Supportive measures with a lung protective ventilator strategy, iNO, and, if necessary, vasopressors/inotropes should be employed. ECMO should be considered for patients with refractory hypoxemia and/or hypotension despite these measures.

C.12. When is cardiopulmonary bypass (CPB) necessary for lung transplantation?

CPB may be used electively for patients with severe PA hypertension, in whom double-lumen endobronchial tubes cannot be placed or when visualization of hilar structures is poor. However, in the absence of intraoperative complications, CPB is not always used because it may increase bleeding and blood product usage. It has also been suggested that CPB may aggravate postoperative lung dysfunction, although this has not been evident in cases where lung transplant was performed in conjunction with cardiac surgery. Nonetheless, the use of CPB has been associated with longer duration of mechanical ventilation and hospitalization, although it is difficult to differentiate whether the latter results directly from CPB or is the result of a complicated procedure that resulted in the need

for CPB. Indications for CPB include right ventricular dysfunction not responding to medical therapy, early graft dysfunction occurring during or prior to implantation of the second lung during bilateral procedures, and surgical misadventures. Unplanned CPB is reported to occur in 12% to 46% of lung transplantation procedures, but predicting which patients may require this intervention is extremely difficult. Some report that CPB is more likely to be necessary for restrictive lung diseases than obstructive diseases. Based on a 2010 review of published lung transplant articles regarding patient outcomes and the use of CPB, there was weak evidence to support using CPB electively. As noted in an earlier section, the use of CPB may vary based on institution and patient factors. In attempt to derive the benefits of CPB while reducing complications, some centers advocate the use of heparin-bound ECMO systems. This approach allows for pulmonary support both during and after the procedure with minimal systemic anticoagulation.

C.13. Should fluid administration be restricted, and are

blood products commonly required?

The amount of crystalloid that can be safely administered intraoperatively without adversely affecting the graft appears to be widely variable. Although efforts should be made to minimize fluid infusion intraoperatively, many patients undergoing lung transplantation require large amounts to maintain hemodynamic stability. The transplanted lung is at risk for pulmonary edema due to lack of lymphatic drainage and inflammatory insults, direct pulmonary trauma, and inflammatory cytokine release associated with reperfusion and organ harvest.

PGD occurs in 10% to 30% of patients after lung transplantation and is thought to be in part due to decreased alveolar fluid clearance. Severe (grade 3) PGD is a risk factor for early mortality following lung transplantation and the development of BOS. With increasing evidence that large volume fluid administration is a modifiable risk factor for PGD, many providers advocate fluid restriction for lung transplantation. In a retrospective cohort study of 500 patients, Geube et al. showed that grade 3 PGD (PGD3) occurs in 25% of patients and that every liter of fluid increased the odds for grade 3 PGD by 22%. The patients who developed grade 3 PGD were transfused with more red blood cell concentrate than patients who did not develop grade 3 PGD. Interestingly, there was no association between the use of crystalloid or colloid (nonblood) and grade 3 PGD. Likewise, the Lung Transplant Outcomes Group published data showing that transfusing 1 L of red blood cell concentrate was associated with a twofold increase in the incidence of PGD.

Before the development of the BLT procedure without CPB, patients with a history of surgery involving the lung or pleura or chronic infectious lung diseases were not deemed acceptable candidates for lung transplantation because of the anticipated

excessive bleeding associated with dissecting a scarred lung after anticoagulation for CPB. Without the uniform requirement for heparinization (ECMO, bilateral sequential LT, etc.), such patients are now generally regarded as operative candidates. Even without the need for full heparinization, these patients are still at increased risk for excessive bleeding, albeit a lower risk. Other variables reported to increase the need for blood product usage include double-lung procedures (DLT/BLT) and patients with cystic fibrosis. The need for CPB is a confounding factor, however. Historically, BLT patients were more likely to get planned or rescue CPB. With the advent of ECMO, new circuit, new cannulas, and cannulation strategies, excessive bleeding occurs less frequently in all categories of patients. Strategies for blood conservation should be adopted. For example, some groups have found a reduction in intraoperative bleeding in patients with a history of cystic fibrosis or previous intrathoracic surgery when antifibrinolytics are given continuously. ECMO, especially with heparin-bonded circuits, is a reasonable alternative to CPB because full anticoagulation is not needed. In addition, use of ECMO for hemodynamic support also helps with reducing the amount of crystalloid and blood products being administered. Transfusion therapy should remain a team decision and warrants a discussion between members of the anesthesiology and surgical staff. If blood products are to be administered, the anesthesiologist must know whether the patient has antibodies to cytomegalovirus (CMV) and must closely check blood products to confirm they coincide with the patient's status.

C.14. Would you extubate the patient upon conclusion of the procedure?

A few studies have shown with proper selection of patients after SLT or BLT that early or immediate tracheal extubation is possible and can be successful. However, because of the frequent use of CPB, the resulting insult often associated with the procedure, the large postoperative volume shifts, hypothermia, and the frequent need for postoperative bronchoscopy, the trachea of lung transplant recipients is not generally extubated immediately after the procedure. Accordingly, unless intraoperative events (e.g., hyperinflation of the remaining intact lung, functional issues such as profound oropharyngeal edema, or difficult intubation are present) suggest that postoperative differential lung ventilation will be required, the double-lumen endotracheal tube is exchanged for a single-lumen tube. In many patients, the endotracheal tube change can be facilitated by use of an exchange catheter. However, great care should be taken to not advance the catheter too far and damage the graft. It is often beneficial to perform fiberoptic bronchoscopy to examine bronchial anastomoses and aggressively suction secretions or blood after replacement of the double-lumen tube with a single-lumen endotracheal tube. As with many procedures, careful inspection of the upper airway for edema should be performed by laryngoscopy before the endotracheal tube is exchanged.

D. Postoperative Management

D.1. What are the major complications after lung transplantation?

Complications from lung transplantation can occur in the immediate (<24 hours), early (24 hours to 1 week), intermediate (8 days to 2 months), or late (>2 months) postoperative period. Major immediate complications include hyperacute rejection, abnormalities due to malpositioning of tubes and lines (e.g., pneumothorax, hemothorax, and hemomediastinum), and issues related to size mismatch between the donor and recipient lung. Reperfusion injury and pleural complications (e.g., hemothorax, pneumothorax, and empyema) are the major early complications. Acute rejection, bronchial dehiscence, and *Candida pneumonia* are intermediate complications. Late complications include chronic rejection, infection (CMV, aspergillus, mycobacterium), and bronchial stenosis. Infection and graft failure are the leading causes of death in the first posttransplant year. In later years, BOS predominates, and there are fewer cases caused by graft failure, infection, and malignancy. BOS is perhaps the most important complication in the burden of subsequent mortality; it occurs in 10% of patients each year; the incidence is highest at 5 years posttransplant. Retransplant patients are at the highest risk for BOS, whereas patients with cystic fibrosis and those with multiorgan transplants seem to be protected.

Early graft dysfunction varies in severity from mild shunting and chest radiograph infiltrates to gross pulmonary edema with

reduced lung compliance and intrapulmonary shunting. Management includes fluid restriction, diuretics, PEEP, iNO, and ECMO for severe cases. Immunosuppression is usually initiated before surgery, and the induction phase of therapy is continued for 5 to 10 days. The exact regimen varies between institutions but typically includes azathioprine, steroids, cyclosporine, and polyclonal antilymphocyte/antithymocyte globulins or interleukin-2 receptor antagonists. Acute rejection episodes are usually treated with *intense* steroid therapy and optimization of other immunosuppressant dosages. A challenge arises in differentiating acute rejection from infection as a source of shunting and chest radiograph infiltrates. Transbronchial biopsy is often necessary to make the distinction from histologic specimens. Bacterial pneumonia is the most frequent infection in the first 2 weeks. Although unusual in the first 2 weeks after transplantation, CMV is the second most common source of infectious pneumonitis. Broad-spectrum antibiotics are given perioperatively, and the regimen is adjusted based on the results of donor and recipient cultures. Antibiotic therapy for patients with cystic fibrosis is challenging, and the drug chosen is dictated by the patient's cultures and prior history of the organisms colonizing his or her lungs. Prophylactic acyclovir appears to be effective in reducing infections caused by herpes simplex, and trimethoprim-sulfamethoxazole is given to prevent infections from *Pneumocystis carinii*.

Radiographics. 2007;27(4):957–974.

D.2. How is postoperative ventilation managed, and for how long is it required?

After most procedures, the fraction of inspired oxygen (FIO_2) can be rapidly reduced, and weaning from the ventilator can be initiated as soon as the patient is warm and stable. An exception to this approach is the patient who has undergone SLT for pulmonary hypertension. Because of a propensity for episodes of cardiopulmonary instability during the first 24 to 48 hours postoperatively, it is advantageous to keep these patients mechanically ventilated during this period, although increasing experience is revealing the positive effects of rapid weaning protocols in those patients that tolerate it.

Lung protective strategies should be employed; patients should be ventilated with 4 to 5 mL per kg for single-lung ventilation and 6 to 7 mL per kg for double-lung ventilation with PEEP as well to protect against lung injury. When possible, a low FIO_2 (<40%) should be used for the same reason. Plateau pressures >30 cm H_2O should be avoided. The ventilator settings should be adjusted according to the patient's needs to achieve adequate ventilation with the lowest plateau pressure and optimal ventilation/perfusion matching.

Postoperatively, ventilation/perfusion mismatch and intrapulmonary shunt are often more pronounced after SLT than BLT. Not surprisingly, patients with restrictive disease usually display the best pulmonary function after SLT because the graft receives the majority of both ventilation and perfusion. After SLT in emphysemic patients, the remaining native lung often receives a substantial portion of the tidal volume. The opposite is true in patients with pulmonary hypertension; the native lung continues to be ventilated but with limited blood flow. On rare occasions where there is a high difference in compliance

between the graft and recipient lung, lung isolation and differential ventilation of the transplanted and native lung is needed after SLT for obstructive lung disease (e.g., emphysematous lung disease). In these situations, the double-lumen endobronchial tube is left in place and two ventilators are employed. The native lung is ventilated with a low tidal volume (2 to 3 mL per kg) and rate, or even just connected to CPAP without intermittent mandatory ventilation. Nonetheless, the condition usually resolves rapidly with the return of spontaneous ventilation. Postural changes in arterial oxygen saturation are often prominent in SLT recipients. In general, patients who received a single lung for pulmonary hypertension or emphysema display better postoperative pulmonary function with the "transplant side up," whereas the opposite may be true in certain patients with restrictive lung disease. The precise etiology of this response is unclear but probably reflects positional variation in ventilation/perfusion matching.

D.3. What special precautions should be taken when a lung transplant recipient requires general anesthesia for subsequent nonpulmonary surgery?

Both the utilization of "extended criteria" donors and ex vivo lung perfusion systems have allowed for an increase in the number of recovered donor organs. Despite transplanting more complex patients and a greater acceptance of donor organs, survival has not changed over the past 5 years. The increased

number of transplants along with stable survival resulted in more lung transplant recipients being alive than ever before. After lung transplantation, patients may present to the operating room for surgeries not related to their pulmonary disease. With careful consideration and vigilance of the implications of lung transplantation, successful anesthetics can be carried out with minimal issues. Aspiration precautions should be implemented, and patients should be assessed for gastritis, peptic ulcer disease, or a history of gastrointestinal bleed especially in situations where anticoagulation is necessary. They should be evaluated for renal dysfunction, which may be caused by immunosuppressive therapy as well as hepatobiliary and/or pancreatic dysfunction. In addition to perioperative antibiotics, stress dose steroids, and bronchodilators, such as β_2-agonists, should be considered; lung transplant patients usually take steroids long term and are more apt to bronchoconstriction.

Not surprisingly, differences in the compliance and expiratory flow rates of a native and transplanted lung after SLT for emphysema can result in alterations in intraoperative capnography. This phenomenon has been described as producing a biphasic pattern of carbon dioxide exhalation, with the first peak reflecting exhalation from the transplanted lung and the second peak exhalation from the native lung. In addition, the transplanted lung is denervated so the cough reflex is present only in the proximal native airway and mucociliary function is impaired. In contrast, HPV is intact after lung transplantation and central respiratory control is unaffected. However, a blunted response to carbon dioxide may persist for patients with preoperative hypercapnia. The major factor limiting long-term survival from lung transplantation is BOS. This progressive condition characterized by progressive narrowing of small airways must be considered in patients with prior lung transplantation presenting for surgery and anesthesia after the

initial recovery phase. Other perioperative considerations for the patient with a prior lung transplant undergoing subsequent surgery are based on whether the patient was the recipient of one versus two lungs. In the former case, ventilation and perfusion of the remaining "diseased" native lung is influenced by the functional status of the transplanted lung. For patients with obstructive lung disease, overinflation of the native lung and resultant mediastinal shift with associated ventilation and hemodynamic consequences, although rare, must be considered when employing positive pressure ventilation.

Feltracco P, Falasco G, Barbieri S. Anesthetic considerations for nontransplant procedures in lung transplant patients. *J Clin Anesth*. 2011;23(6):508–516.

D.4. What are the long-term outcomes of lung transplantation?

Increased experience, improved techniques, and an increase in the number of donor organs facilitated by extended criteria donor and ex vivo perfusion systems have made lung transplantation a realistic option for many patients. The LAS system was introduced in 2005 to shift the method of distributing organs from a time-based seniority system to one where severity of disease is prioritized. Since then, more complex patients have been receiving lung transplantation. The procedure, however, is not without substantial risk, and a favorable outcome is by no means ensured. Although survival has not changed over the last 5 years (84.6% 1-year, 67.8% 3-year, and 55.5% 5-year survival), the absolute number of patients living after lung transplantation has increased because more procedures are being done. From June 2009 to 2016, the median survival was 6.5 years after primary lung

transplantation. For adult recipients who survived for 1-year posttransplantation, the median survival is 8.7 years. Graft failure is the leading cause of death in the first posttransplant year and BOS predominates in later years, with lower rates of death due to graft failure, infection, and malignancies. Gender, underlying cause for lung transplantation, and type of procedure (SLT vs. BLT) are a few of the factors influencing outcomes for these patients. SLT recipients seem to do better in the first year posttransplantation, whereas BLT recipients have a survival benefit starting the first year after transplantation. Likewise, patients with cystic fibrosis have better survival than patients with all other indications for lung transplantation. Female gender also confers a survival benefit.

A history of hypertension for donors is independently associated with higher 1-year survival while donor smoking, CMV mismatch, nonidentical blood type, history of diabetes, and other donor comorbidities as well as poor functional status for the donor are independently associated with lower survival at 1 year. Other factors associated with 1-year mortality include recipient age, donor age, recipient serum creatinine and bilirubin, recipient lung functional vital capacity (percent predicted), allograft ischemic time, and transplant center volume. Risk factors that are independently associated with 5-year mortality are similar to those of 1-year mortality with a few differences. Patients with lymphangioleiomyomatosis have better survival than those with an increasing number of human leukocyte antigen mismatches who have lower 5-year survival. Likewise, extremes of recipient age, older donor age, lower transplant center volume, and higher panel reactive antibody percentage are associated with higher mortality.

D.5. Are there surgical alternatives to lung transplantation?

Some patients with severe emphysema who are not deemed transplant candidates may benefit from LVRS or "reduction pneumoplasty." Performed either through a median sternotomy, through a bilateral thoracoscopy, or via bronchoscopy, LVRS is thought to be most beneficial in patients with upper lobe emphysematous disease with the goal being to remover up to 30% of the patient's most severely compromised lung tissue. Postoperatively, this allows the previously hyperexpanded chest and depressed diaphragm to resume a more normal shape, improving chest wall mechanics, and eventually pulmonary function. There is a body of data demonstrating improved functional capacity in patients after LVRS. However, the beneficial effects of the procedure are not immediately evident and usually require 1 to 2 months to appear. Furthermore, whether the improvement in pulmonary function is sufficient to warrant the risk of the procedure remains controversial. Bronchoscopic LVRS techniques are relatively new and may be beneficial in this regard because they are less invasive. The data for endoscopic lung volume reduction is limited to small case series and case reports; more extensive studies are warranted. The evidence suggests that for carefully selected patients, LVRS represents a viable alternative to transplantation. In addition, LVRS may be used as a bridge to transplant. There are concerns that prior LVRS increases the risk during lung transplantation because of tissue scarring. Several studies have addressed this

and found no difference between outcomes in patients with end-stage COPD who had and those who did not have LVRS prior to transplantation. For patients with hyperinflation of the native lung after SLT for COPD/emphysema, LVRS of the native lung can be considered instead of a second SLT.

SECTION 2 The Cardiovascular System

5 Ischemic Heart Disease and Coronary Artery Bypass Grafting

Yasdet Maldonado, Nikolaos J. Skubas, and Fun-Sun F. Yao

A 57-year-old man with triple-vessel coronary artery disease (CAD), hypertension, and type-II diabetes is scheduled for coronary artery bypass grafting (CABG). He had a myocardial infarction (MI) 7 months ago. He is taking metoprolol, metformin, and lisinopril. His blood pressure (BP) is 130/80 mmHg, and his heart rate (HR) is 55 beats per minute.

A. Medical Disease and Differential Diagnosis

1. What is triple-vessel CAD? Name the branches of the coronary arteries.
2. What are the indications for CABG?

3. What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.
4. What are the expected results of CABG?

B. Preoperative Evaluation and Preparation

1. Which preoperative tests would you order?
2. How would you evaluate the patient's left ventricular function?
3. Which factors determine myocardial oxygen supply?
4. What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?
5. Would you continue the β-blocker (metoprolol) on the day of surgery? Why/why not? What is its half-life? What is the role of β-adrenergic blockers in treating congestive heart failure (CHF)?
6. Would you continue the angiotensin-converting enzyme (ACE) inhibitor on the day of surgery? Why/why not?
7. If the patient who is on lisinopril develops hypotension intraoperatively, how would you manage it?

C. Intraoperative Management

C.I. *Before Cardiopulmonary Bypass*

1. What is your plan to monitor the patient?
2. What is the Allen test?
3. How would you monitor electrocardiogram (ECG)? Why lead V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?
4. Should you monitor temperature from multiple sites?
5. Is it necessary to monitor pulmonary artery (PA) pressure for coronary artery operations?
6. What are the possible complications of PA catheterization?
7. What is normal pulmonary artery occlusion pressure (PAOP)?
8. What are the hemodynamic consequences of myocardial

ischemia? How can you detect myocardial ischemia? Is PAOP a sensitive indicator of myocardial ischemia?

9. Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.
10. How would you induce anesthesia? Is there any advantage/disadvantage to using propofol versus etomidate as the main induction agent? What kind of neuromuscular blocker (NMB) would you use? Why?
11. How would you maintain anesthesia? Volatile anesthetics or total intravenous anesthesia (TIVA)?
12. What are the cardiovascular effects of volatile anesthetics, morphine, and fentanyl?
13. What should you do during sternotomy?
14. Would you use prophylactic nitroglycerin during CABG to prevent intraoperative myocardial ischemia or perioperative MI?
15. If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative MI?
16. Discuss autologous transfusion and blood conservation for cardiac surgery.
17. What antifibrinolytic will you use to reduce blood transfusions?
18. How do you know that the tip of the PA catheter is in the right ventricle (RV) or the PA?

C.II. *During Cardiopulmonary Bypass*

1. What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?
2. What is the half-life of heparin? How is it eliminated?
3. How do you monitor heparin dosage? What is the activated

coagulation time (ACT) test?
4. What is total CPB? What is partial bypass?
5. What kinds of pumps are used in CPB? Are they pulsatile or not?
6. What is the purpose of venting the LV? How can it be done?
7. How many types of oxygenators are there? What are the advantages of each type?
8. What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?
9. What are the advantages and disadvantages of hemodilution?
10. How do you monitor the patient during CPB?
11. What should your target BP be during CPB?
12. How would you treat hypotension during CPB?
13. How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mmHg)?
14. How do you prepare an IV infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?
15. How much pump flow would you maintain during CPB? During hemodilution? During hypothermia?
16. How does blood viscosity change during hemodilution and hypothermia?
17. How is anesthesia provided during CPB?
18. Would you give muscle relaxants during CPB? How is the action of muscle relaxants affected during CPB?
19. How do you know the patient is well perfused during CPB?
20. How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?
21. What are the disadvantages of hypocapnia during CPB?
22. How would you preserve the myocardium during CPB?
23. What is cardioplegia? How much would you use?
24. The arterial blood gases and electrolytes during CPB are as

follows: pH, 7.36; $Paco_2$, 42 mmHg; Pao_2, 449 mmHg; CO_2 content, 24 mEq per L; sodium (Na), 128 mEq per L; potassium (K), 5.8 mEq per L; glucose, 180 mg/dL; and hematocrit, 20%. The patient's temperature is 27°C (80.6°F). At what temperature are blood gases measured? How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37°C (98.6°F) or at patient's body temperature?

25. How does the blood sugar level change during CPB? Why? What is optimal glucose control intraoperatively? Does hyperglycemia increase neurologic complications during CPB?
26. What are the effects of CPB on platelet and coagulation factors?
27. If the blood level of the venous reservoir is low, what would you replace it with? Blood or balanced salt solution?
28. How do you estimate the fluid balance during CPB?
29. For how long a period can the aorta be cross-clamped?
30. Why does the urine turn pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?
31. Why does it take longer to rewarm than to cool the patient via the pump oxygenator?
32. At what temperature can the patient be weaned from CPB?
33. How would you defibrillate the heart internally during CPB?
34. If the HR is 40 beats per minute, what should you do?
35. How would you prepare for termination of CPB?
36. How would you decide the need for inotropic support?

C.III. *After Cardiopulmonary Bypass*

1. How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize heparin?
2. What is the action mechanism of protamine?
3. What are the complications of too much protamine?
4. What is a protamine reaction? How can you prevent this

condition? How do you treat it?

5. What are the indications for intra-aortic balloon pump (IABP)?
6. What are the principles of IABP?
7. What are the complications of IABP?

D. Postoperative Management

1. Would you reverse the muscle relaxants? Why?
2. When will you wean the patient from the ventilator?
3. What criteria would you use in deciding when to wean the patient from the ventilator?
4. What are potential postoperative complications?

A. Medical Disease and Differential Diagnosis

A.1. What is triple-vessel CAD? Name the branches of the coronary arteries.

Triple-vessel CAD involves progressive atherosclerosis of the major branches of the coronary arteries with eventual luminal obstruction and myocardial injury. The intimal disease is typically segmental but can be diffuse in severe cases. The coronary arteries are the following:

- The right coronary artery (RCA)
- The left anterior descending (LAD) branch of the left main coronary artery (LMCA)
- The left circumflex (CX) branch of the LMCA

The branches of coronary arteries are shown in **Figure 5.1**. The LAD and CX arise from the LMCA. The sinus node is supplied by the RCA in approximately 50% to 60% of people and by the CX artery in the remaining 40% to 50%. Cardiac dominance is determined by which coronary artery branch supplies the posterior descending artery (PDA). It could be the RCA (right dominant circulation, 70% to 80%), left CX artery (left dominant), or both (codominant). Small branches from the

PDA perfuse the atrioventricular (AV) node.

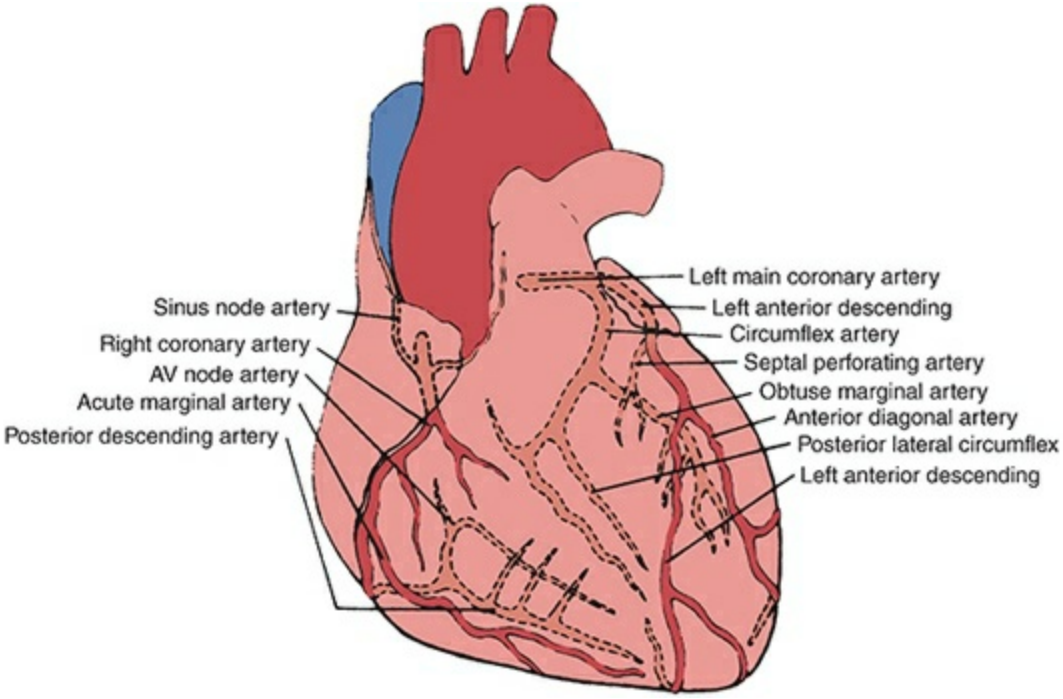

FIGURE 5.1. Branches of the coronary arteries. AV, atrioventricular.

The most common "targets" for coronary bypass grafting are the LAD, obtuse marginal (branch of CX), and posterior descending (branch of RCA) arteries. A suitable distal target site, beyond the level of the proximal stenosis, is determined by the surgeon after review of angiographic images and direct external inspection and palpation.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:1301.

A.2. What are the indications for CABG?

Patients whose angina is not controlled by medical treatment or who have unacceptable side effects with such management should be considered for coronary revascularization. The indications for CABG are as follows:

- Acute MI if a nonsurgical intervention failed or there is ischemia at rest or hemodynamic instability/cardiogenic shock or complications, such as ventricular septal defect or ruptured papillary muscle and mitral regurgitation
- Life-threatening ventricular arrhythmia in the presence of significant left main (>50%) or coronary artery (>70%) obstruction
- At the same time with other cardiac surgical procedures

The SYNTAX (Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery) trial provided a good comparison of PCI versus CABG. A SYNTAX score is a derivative of this trial, with a score >22 being associated with favorable outcomes after CABG. The score reflects factors that increase complexity of PCI.

Patel MR, Calhoon JH, Dhemer GJ, et al. ACC/AATS/AHA/ASE/ASNC/SCAI/SCCT/STS 2017 appropriate use for coronary revascularization in patients with stable ischemic heart disease: a report of the American College of Cardiology Appropriate Use Criteria Task Force, American Association for Thoracic Surgery, American Heart Association, American Society of Echocardiography, American Society of Nuclear Cardiology, Society for Cardiovascular Angiography and Interventions, Society of Cardiovascular Computed Tomography, and Society of Thoracic Surgeons. *J Am Coll Cardiol*. 2017;69(17):2212–2241.

A.3. What is percutaneous coronary intervention (PCI)? Discuss its indications, contraindications, and results.

PCI has developed rapidly since its introduction in 1977. It is now an acceptable method of treating selected patients who have angina pectoris. This technique involves the passage of a small (3 French) catheter into the involved coronary artery and

through the stenosis. With the balloon portion of the catheter straddling the stenosis, inflations are performed that result in enlargement of the stenotic lumen and a controlled injury involving, to a varying degree, plaque compression, intimal fissures, and medial stretching. Following the dilation, coronary stents are introduced to maintain long-term patency. The stents are either bare-metal (cobalt–chromium alloy) or drug-eluting stents (DES).

PCI has redefined who is candidate for elective surgical myocardial revascularization. With the current available technology, PCI is considered a therapeutic option in any individual with disabling ischemic symptoms despite good medical therapy and focal obstructive coronary disease regardless of cause. The indications for PCI are as follows:

- Isolated discrete proximal single- or double-vessel disease
- Post-CABG with new stenotic lesions or stenosis at distal anastomosis
- Restenosis following PCI
- Contraindications to CABG
- Coronary stenosis following cardiac transplantation
- Occluded vessels within the last 6 months and less than 15 mm in length
- Post-streptokinase therapy for revascularization

PCI is contraindicated in the following:

- Left main CAD in which the distal coronary vessels are not protected by at least one completely patent large collateral vessel
- Multivessel severe diffuse disease
- Absence of a discrete obstructing lesion

The primary success rate of PCI is approximately 90%, but restenosis occurs at a rate of approximately 30%, 6 months postprocedure. Dilatation can be repeated with a 90% success rate. The artery tends to remain patent after the second

angioplasty. With the introduction of coronary stents, which act as a metal scaffold, the restenosis rate after PCI has been decreasing, and fewer patients require subsequent revascularization: 10% to 15% after stenting versus 25% to 35% after PCI alone. The decrease in luminal diameter following stent placement is evident within the first 6 to 9 months after stent placement and is the result of proliferative neointimal tissue growth in response to the associated injury and inflammation. The stent scaffold is coupled with polymers that elute or slowly release pharmacologic agents (sirolimus, an immunosuppressant, and paclitaxel, an antineoplastic), which inhibit the neointimal growth. The DES have reduced the need for repeat revascularization to an even lower rate, 4% to 6%.

However, PCI is a different therapeutic approach other than CABG. PCI is targeting the area of lesion only, whereas CABG bypasses these lesion areas. This may be the reason that, at least in the intermediate term, CABG is considered to be superior for patients with multivessel disease.

Diegeler et al. showed that, for isolated high-grade lesions of the LAD, CABG through a left anterior thoracotomy is as effective as PCI with stent placement. Although stenting provided excellent short-term results with fewer periprocedural adverse events, CABG was superior with regard to the need for repeated intervention in the target vessel and freedom from angina at 6 months of follow-up. Further, Serruys et al. compared outcomes between PCI with stent and CABG surgery and found that at 5 years, there was no difference in mortality between stenting and surgery for multivessel disease. Importantly, the incidence of stroke or MI was not significantly different between the two groups. However, the rate of major adverse cardiac and cerebrovascular events was higher in the stent group, driven by the increased need for repeat revascularization. A recent report on 10-year outcomes also

showed that for the treatment of unprotected LMCA disease, PCI with stent implantation showed similar long-term mortality and rates of death, Q-wave MI, or stroke. However, stenting, even with DES, was associated with higher rates of repeat revascularization than was CABG. Lastly, a recent comparison between stenting and CABG in patients with previously untreated three-vessel disease or LMCA disease concluded that CABG remains the standard of care for patients with three-vessel or LMCA disease because the use of CABG, as compared with PCI, resulted in lower rates of the combined end point of major adverse cardiac or cerebrovascular events at 1 year.

A.4. What are the expected results of CABG?

CABG has been demonstrated to provide a survival benefit over medical therapy alone in the following three randomized, controlled trials from the 1970s and 1980s: the Veterans

Administration Cooperative Study, the European Coronary Surgery Study, and the Coronary Artery Surgery Study. A 1994 meta-analysis confirmed that CABG resulted in lower mortality when compared to medical management at 5 years (10% vs. 16%, $P < .01$) and 10 years (26% vs. 31%, $P = .03$). Survival is greatest for those with extensive disease and/or left ventricular dysfunction. Patients in the SYNTAX trial with triple-vessel disease also had a survival benefit with CABG when compared to PCI (mortality, 9.2% vs. 14.6%; $P = .006$).

Bypass conduits can be either arterial or venous, with arterial grafts considered superior conduits over venous grafts. The success of CABG depends on the long-term patency of the graft. The internal thoracic (mammary) artery (ITA) is the most commonly used bypass graft. Use of the ITA graft is considered a quality indicator by the Society of Thoracic Surgeons (STS). The saphenous vein is the most commonly used venous graft. Failure rates of venous grafts are related to variable size and quality.

B. Preoperative Evaluation and Preparation

B.1. Which preoperative tests would you order?

In addition to the routine systemic examinations of all organ systems, special attention should be paid to the cardiovascular status.

- Renal function—urinalysis, blood urea nitrogen, creatinine
- The routine evaluation of hepatic function is not standard. Patients who should have testing to evaluate hepatic function include those with a previous history of hepatitis, jaundice, or a history of drug abuse.
- Pulmonary function—chest x-ray film, baseline arterial blood gases, and spirometry if indicated
- Hematologic function—complete blood count, prothrombin time, partial thromboplastin time, platelets (platelet function if available and/or indicated; namely, for those patients previously receiving antiplatelet therapy)
- Metabolism—electrolytes and blood sugar
- Cardiovascular function—computed tomography (CT) scan absolutely indicated in redo sternotomy to investigate the proximity of the sternum to the anterior surface of the heart, resting and exercise ECG (if a stress test was performed preoperatively), cardiac catheterization and coronary angiography, location and severity of coronary occlusion, echocardiography, and left ventricular function (from catheterization, magnetic resonance imaging, enhanced multidetector CT, and/or echocardiography)

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA:

Elsevier; 2017:3–19.

B.2. How would you evaluate the patient's left ventricular function?

- Medical history: history of MI and presence or absence of angina
- Symptoms and clinical signs of left ventricular failure (dyspnea at rest or exercise, nocturnal orthopnea) and/or right heart failure (ascites, pitting edema, jugular vein distention)
- Cardiac catheterization, angiography, and echocardiography
- Ejection fraction (normally approximately 65%)
- Left ventricular end-diastolic pressure (LVEDP) or PAOP: normal 6 to 15 mmHg
- Left ventricular wall motion (by echocardiography)—normal (wall thickening of >30%), hypokinesis (wall thickening of 10% to 30%), akinesia (wall thickening of <10%), or dyskinesia (outward motion during systole) (**Fig. 5.2**)

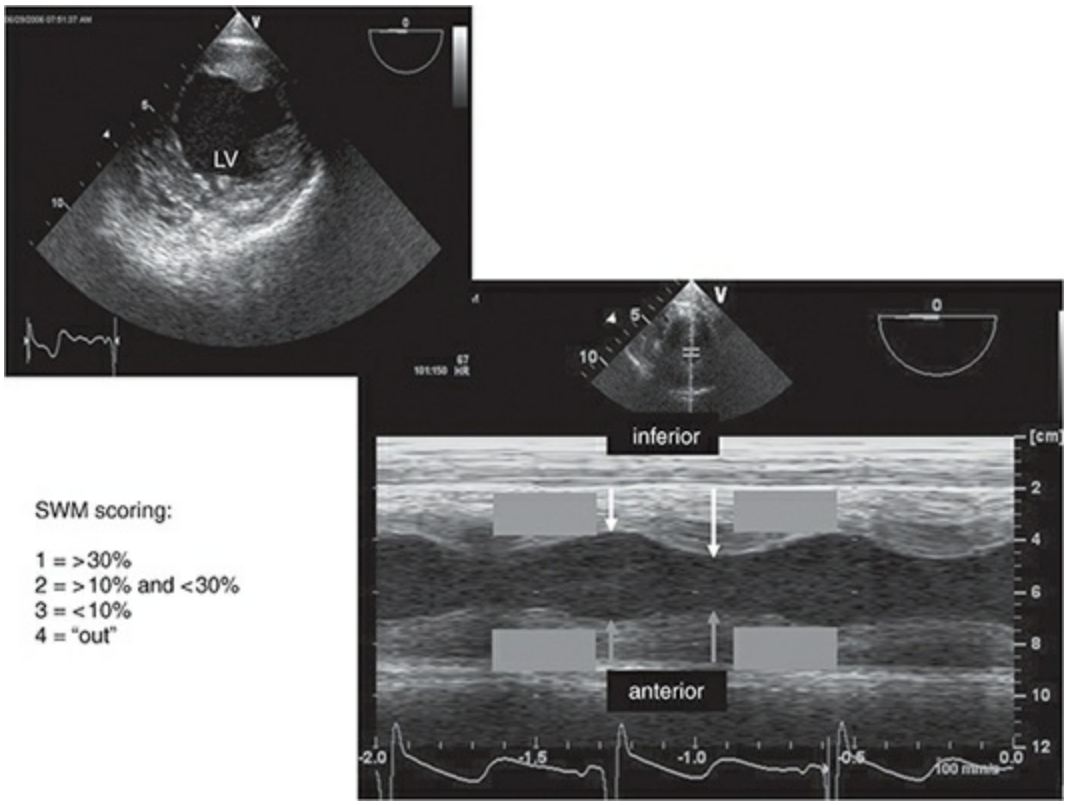

FIGURE 5.2. Echocardiographic evaluation of the left ventricle (LV). The transgastric midpapillary

short-axis view of the LV is shown in left. By placing a cursor line across the middle of the inferior **(top of the image)** and anterior **(bottom of the image)** segments of the left ventricular myocardium, the motion of the segments over time is shown in the right image. The percentage of wall thickening can be either visually estimated or measured between diastole and systole. SWM, segmental wall motion.

- Cardiac index (normal >2.2 L/min/m^2)
- Myocardial viability studies (contrast echocardiography or positron emission tomography study)

Segmental wall motion abnormality (SWMA) is the result of CAD. The interruption of perfusion results in abnormal motion in the related myocardial segments. There is a gradation of wall motion abnormality that consists progressively of hypokinesis, akinesis, and, subsequently, dyskinesis in which a wall moves away from the center of the ventricle. Wall thickening and endocardial motion are intrinsically tied, and all SWMAs are expected initially to be associated with abnormalities of thickening as well as endocardial motion.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:179–205, 390–426.

B.3. Which factors determine myocardial oxygen supply?

Myocardial oxygen (O_2) supply = coronary blood flow × arterial O_2 content

The coronary blood flow depends on the following:

- Diastolic aortic pressure (DAP)
- LVEDP
- Patency of coronary arteries
- Coronary vascular tone

And it can be determined by the formula:

Coronary blood flow = coronary perfusion pressure ÷ myocardial vascular resistance, or, Coronary blood flow = (DAP − LVEDP) ÷ myocardial vascular resistance

The arterial O_2 content (CaO_2) is determined by the following equation:

$$CaO_2 = 1.34\ (mL/g) \times \text{hemoglobin concentration}\ (g/dL) \times O_2\ \text{saturation}\ (\%) + (0.0031 \times PaO_2)$$

O'Brien ERM, Nathan HJ. Coronary physiology and atherosclerosis. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2011:132–156.

B.4. What are the three major determinants of myocardial oxygen consumption? How are they measured clinically?

The three major determinants of myocardial oxygen consumption are myocardial wall tension, contractility, and HR.

Myocardial wall tension of the LV is estimated by the following:

- The Laplace equation states that the myocardial wall tension (T) is analogous to the diameter of the ventricle (R, radius) and the intracavitary pressure (P) and inversely proportional to the myocardial wall thickness (Th): $T = P \times R \div 2Th$
- Diastolic wall tension is related to the diastolic radius (R) of the ventricle, which is considered a surrogate of preload or left ventricular end-diastolic volume (LVEDV); the latter is estimated by the PAOP (because neither LVEDP nor left atrial pressure can be directly measured).
- Afterload is approximated via the systolic BP, which equals systolic ventricular pressure if there is no aortic stenosis.

Contractility is evaluated by:

- *Invasive techniques*. Maximal velocity of contraction (Vmax), dP/dt (pressure time indices of ventricle: how fast [dt] the

intraventricular pressure [dP] rises), or left ventricular end-systolic pressure/volume ratio

- *Noninvasive technique*. Pre-ejection period/left ventricular ejection time, and global and regional ventricular wall motion by echocardiography (**Fig. 5.3**)

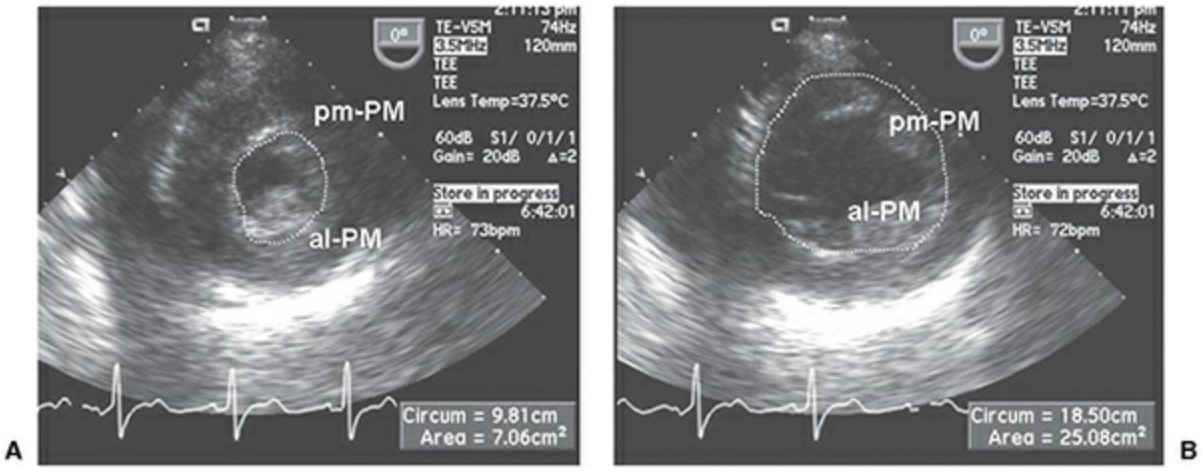

FIGURE 5.3. Echocardiographic evaluation of the systolic function of the LV. The transgastric midpapillary short-axis view of the LV is shown in systole **(A)** and diastole **(B)**. The endocardial border is traced (without including the endocardium of the two papillary muscles), and the end-systolic area (ESA) and end-diastolic area (EDA) are calculated. The percentage area change (fractional area change [FAC]) is calculated as: FAC = (EDA − ESA) / EDA. The FAC correlates with but does not substitute the percentage ejection fraction. al-PM, anterolateral papillary muscle; pm-PM, posteromedial papillary muscle.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:179–205.

B.5. Would you continue the β-blocker (metoprolol) on the day of surgery? Why/why not? What is its half-life? What is the role of β-adrenergic blockers in treating congestive heart failure (CHF)?

The β-blocker (metoprolol) should be continued not only up until surgery but also throughout the perioperative period. In patients with unstable angina, sudden withdrawal of β-blocker may produce an exacerbation of symptoms and may precipitate an acute MI. The dose of β-blocker does not need to be reduced

before surgery for fear of bradycardia, hypotension, or difficulty in weaning from CPB. The half-life of oral metoprolol is 3 hours. It is metabolized in the liver.

Reductions in HR with a β-blocker occur at lower serum levels than depression of myocardial contractility. Accordingly, as drug levels decrease after discontinuation of therapy, reductions in chronotropic response last longer than reductions in inotropy. This is an important concept in treating tachycardias in patients with significant ventricular dysfunction and CHF—a small dose is appropriate and indicated, whereas a large dose may suppress even further the inotropic state.

Numerous studies have confirmed improvements in cardiac function, exercise capacity, and long-term survival in patients with heart failure resulting from MI, hypertrophic cardiomyopathy, or idiopathic dilated cardiomyopathy with β-blockers. β-Blockers may also be of benefit in patients with diastolic dysfunction, secondary to hypertension.

Potential benefits of β-adrenergic blockade in heart failure include decreased HR and normalization of β-receptor function. A slower HR improves diastolic function by increasing the diastolic filling time and myocardial perfusion and by decreasing the myocardial oxygen consumption. β-Adrenergic receptors are downregulated in heart failure, but their response is normalized by long-term β-blockade.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:292–356.

B.6. Would you continue the angiotensin-converting enzyme (ACE) inhibitor on the day of surgery?

Why/why not?

Major medical societies such as the American College of Cardiology and American Heart Association recommend continuation of ACE inhibitors in the perioperative period. There is no difference in the amount of vasopressor or inotrope requirements during cardiac surgery in those patients who continue ACE inhibitors preoperatively. In fact, ACE inhibitors may help control post-CPB hypertension. Diabetic patients may specifically benefit from receiving ACE inhibitors preoperatively. Patients at risk for vasoplegia or impaired left ventricular function may, however, suffer from intraoperative hypotension.

B.7. If the patient who is on lisinopril develops hypotension intraoperatively, how would you manage it?

The more common causes of intraoperative hypotension, such as hypovolemia, deep anesthesia, and surgical manipulation, should be corrected first. Vasoplegic syndrome is most commonly observed in cardiac surgery. It is characterized by severe refractory hypotension in the absence of other identifiable causes of hypotension. Persistent hypotension increases

perioperative mortality.

BP is maintained by three systems: the sympathetic system, the renin–angiotensin system (RAS), and the vasopressinergic system. Most anesthetic medications reduced the influence of the sympathetic system, and, as a result, the body relies more on the RAS and vasopressinergic systems. ACE inhibitors and angiotensin receptor blockers are RAS antagonists. ACE inhibitors specifically prevent the conversion of angiotensin I to angiotensin II. This results in a lower arterial resistance and increased vascular capacitance.

There is no specific antagonist for ACE-inhibitors. Treatment may be challenging. Conventional therapies such as volume expansion and vasopressors may be tried. When these conventional therapies are not effective, exogenous vasopressin may improve hypotension. Refractory hypotension may be treated with methylene blue, which interferes with the nitric oxide-cyclic guanylate monophosphate (cGMP) pathway. Methylene blue is contraindicated in patients with renal impairment because it is primarily eliminated by the kidneys.

C. Intraoperative Management

C.I. Before Cardiopulmonary Bypass

C.I-1. *What is your plan to monitor the patient?*

- Standard American Society of Anesthesiologists (ASA) monitors
- ECG—simultaneous leads V_5 and II, multiple-lead ST-segment analysis
- Arterial line for BP and arterial blood gases. The site of arterial line placement will vary per institution. Brachial artery catheters provide a good balance of estimating aortic pressures and rarely cause complications. Arterial cannulation is performed on the upper extremity not intended to be used for harvesting of an arterial conduit.
- PA catheter—pulmonary and central venous pressures (CVPs), hemodynamic parameters (cardiac output, stroke volume, systemic and pulmonary vascular resistance)
- CVP line only—if the patient has good left ventricular function and no problems are expected
- Urine output
- Temperature—esophageal (or PA) and bladder (or rectal, tympanic, or nasopharyngeal)
- Laboratory—arterial blood gases, electrolytes, hematocrit, ACT, and oxygen saturation of the mixed venous blood (SVO_2)
- Transesophageal echocardiography (TEE) if not contraindicated. Absolute contraindications are esophagectomy or esophagogastrectomy, active upper gastroesophageal bleeding, or recent surgery, oropharyngeal trauma, and presence of esophageal pathology (tracheoesophageal fistula, stricture, trauma, tumor, scleroderma, Mallory-Weiss tear, and diverticulum). The anticipated benefits should be weighed, however, against potential risks in every patient prior to

deciding whether to insert a TEE probe.

- Cerebral oximetry, especially for patients with high risk of postoperative neurologic outcomes, such as those undergoing hypothermic circulatory arrest
- Bispectral index to ensure adequate level of unconsciousness and eliminate the risk of intraoperative awareness

---

Singh A, Bahadorani B, Wakefield B, et al. Brachial artery pressure monitoring during cardiac surgery rarely causes complications. *Anesthesiology*. 2017;126(6):1065–1076.

C.I-2. *What is the Allen test?*

The Allen test is used to detect the presence of adequate collateral ulnar arterial circulation. The radial and ulnar arteries are occluded by the examiner's fingers, and the patient is then asked to make a tight fist repeatedly until the palmar skin is blanched (to empty the blood from the hand). If the patient is under anesthesia, the blood in the hand may be drained by a third person squeezing the hand. The hand is held above the heart level to help venous drainage. Then, the fist is opened slowly and put down to the heart level. Only the ulnar compression is released, and the flush of the palmar skin is watched. The Allen test is:

- Normal—if the flush appears in less than 7 seconds (presence of adequate collateral connections between the superficial [ulnar] and deep [radial] palmar arches)
- Borderline—7 to 15 seconds
- Abnormal—greater than 15 seconds

A modified Allen test may be done with a Doppler detector or a pulse oximeter. The results of Allen test are abnormal in approximately 3% of young healthy individuals. However, Slogoff et al. studied the complications following radial artery cannulation in 1,699 cardiovascular surgical

patients. They concluded that in the absence of peripheral vascular disease, Allen test is not a predictor of ischemia of the hand during or after radial artery cannulation, and that radial artery cannulation is a low-risk, high-benefit monitoring technique that deserves wide clinical use. However, in the current litigious setting and in the face of some evidence to the contrary, it is probably prudent to continue to perform Allen test and document the results. Some authorities still consider the use of Allen test as the standard of care.

C.I-3. *How would you monitor electrocardiogram (ECG)? Why lead V_5? If you do not have precordial leads in your ECG machine, how can you monitor the left ventricle (LV)?*

Multiple-lead ECG monitoring provides the best clinically available method of detecting perioperative ischemia. Based primarily on results obtained from exercise treadmill testing, 96% of ischemic events can be detected by combining ECG

leads II and V_5; therefore, leads II and V_5 are the optimal leads for intraoperative myocardial ischemia. However, London et al. found that the standard combination of leads II and V_5 was only 80% sensitive, whereas combining leads V_4 and V_5 increased sensitivity to 90% in patients with known or suspected CAD undergoing noncardiac surgery with general anesthesia. The sensitivity increased to 96% by combining leads II, V_4, and V_5. If only one lead can be displayed, lead V_5 should be used because it has the greatest sensitivity: 75% intraoperatively and 89% during exercise treadmill testing (see also Chapter 14, section C.3).

London MJ, Hollenberg M, Wong MG, et al. Intraoperative myocardial ischemia: localization by continuous 12-lead electrocardiography. *Anesthesiology*. 1988;69:232–241.

C.I-4. *Should you monitor temperature from multiple sites?*

In many cardiac surgery centers, temperature may be measured from two or more sites in order to estimate the accurate core temperature and achieve even distribution of body heat during cooling and rewarming by extracorporeal circulation (ECC). Esophageal, nasopharyngeal, bladder, or tympanic sites measure core temperature; the axillary and rectal sites measure peripheral temperature. Urinary bladder temperature monitoring through a urinary catheter is quite convenient and popular and reflects a body temperature between core and periphery. During cooling and rewarming by ECC, the core temperature changes rapidly, whereas the peripheral temperature changes slowly. The opposite changes are witnessed during surface cooling or warming. Nowadays, single-site core temperature monitoring is the prevailing practice when ECC is conducted at near normal body temperature.

Temperatures are measured during cooling on ECC to ensure that the organs most susceptible to potential hypoperfusion, such as the brain, actually receive the protective effect of the desired hypothermia. In this regard, nasopharyngeal or tympanic membrane temperatures are the monitoring sites, although they, at times, overestimate or underestimate the actual brain temperature. During rewarming, cerebral hyperthermia should be avoided (by maintaining a gradient of 5°C between the arterial blood and brain, with the brain having the lower temperature) and should be corrected immediately because hyperthermia increases the cerebral oxygen consumption and may exacerbate postoperative neuropsychological dysfunction.

C.I-5. *Is it necessary to monitor pulmonary artery (PA) pressure for coronary artery operations?*

The indication to monitor PA pressure includes the following:

Diagnostic

- Diagnosis of shock states
- Differentiation of high- versus low-pressure pulmonary edema
- Diagnosis of primary pulmonary hypertension
- Diagnosis of valvular disease, intracardiac shunts, cardiac tamponade, and pulmonary embolus

- Monitoring and management of complicated acute MI
- Assessing hemodynamic response to therapies
- Management of multiorgan system failure and/or severe burns
- Management of hemodynamic instability after cardiac surgery
- Assessment of response to treatment in patients with primary pulmonary hypertension

Therapeutic: Aspiration of Air Emboli

The indication to monitor PA pressure depends on the ventricular function. For patients who have good left ventricular function (ejection fraction >50% and normal ventricular wall motion), the CVP is considered to correlate well with the PAOP; therefore, PA pressure monitoring may not be necessary for this group of patients. On the other hand, for patients with poor left ventricular function (ejection fractions <40% or prominent wall motion abnormalities), PA pressure monitoring is indicated. Other indications for monitoring PA pressure include the presence of pulmonary hypertension, combined coronary stenosis and valvular disease, and complex cardiac lesions.

However, results of several studies in recent past involving critically ill patients have consistently demonstrated that use of PA catheter was either associated with increased mortality and morbidity or no difference in fatal and nonfatal outcomes as compared to use of CVP alone or other noninvasive monitoring. Much debate exists regarding this topic, and it is unlikely that there ever will be a resolution. Nevertheless, there has been substantive reduction in the use of the PA catheter both in surgical and medical settings.

C.I-6. *What are the possible complications of PA catheterization?*

Similar to Central Venous Catheter Insertion

Common Complications

- Infection—sepsis
- Hematoma
- Air embolism
- Thrombosis
- Catheter shearing and embolization

Subclavian Approach

- Pneumothorax
- Hemothorax
- Hydrothorax

Internal Jugular Approach

- Pneumothorax
- Neck hematoma from puncture of carotid artery
- Possible vagus nerve injury and brachial plexus injury
- Thoracic duct perforation from left-side approach

The basilar or cephalic vein approach has fewer

complications, but the failure rate is higher.

From Pulmonary Artery Catheter

- Arrhythmias 1.5% to 11%
- Complete heart block
- Thromboembolism
- Pulmonary infarction from continuous wedging
- Massive hemorrhage from perforation of PA or right atrium (RA)
- Failure to wedge
- Hemoptysis
- Intracardiac knotting
- Balloon rupture
- Endocardial thrombi
- Tricuspid valve injury

The incidence of PA catheter complications is more related to operator experience.

C.I-7. *What is normal pulmonary artery occlusion pressure (PAOP)?*

- Normal—4 to 12 mmHg
- Borderline—13 to 17 mmHg
- Heart failure—over 18 mmHg

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:390–426.

C.I-8. *What are the hemodynamic consequences of myocardial ischemia? How can you detect*

myocardial ischemia? Is PAOP a sensitive indicator of myocardial ischemia?

Acute myocardial ischemia affects systolic and diastolic cardiac function. Diastolic dysfunction usually manifests before alterations in systolic function. The immediate impact on ventricular compliance is related to the etiology of the ischemic event. Decreased myocardial oxygen supply is initially accompanied by an increase in compliance. In contrast, increased myocardial oxygen demand is associated with an immediate loss of ventricular compliance (e.g., the ventricle becomes stiffer). Therefore, the ventricle requires a higher filling pressure (end-diastolic pressure) to maintain a given stroke volume. A cascade of events occurs, which may include SWMA, dysrhythmias, and conduction blocks. An 80% reduction of coronary blood flow causes akinesis (<10% of radial systolic thickening), whereas a 95% decrease causes dyskinesis (thinning, instead of thickening, during systole). If the ischemia becomes severe, the continuously elevated LVEDP will lead to pulmonary edema (**Fig. 5.4**).

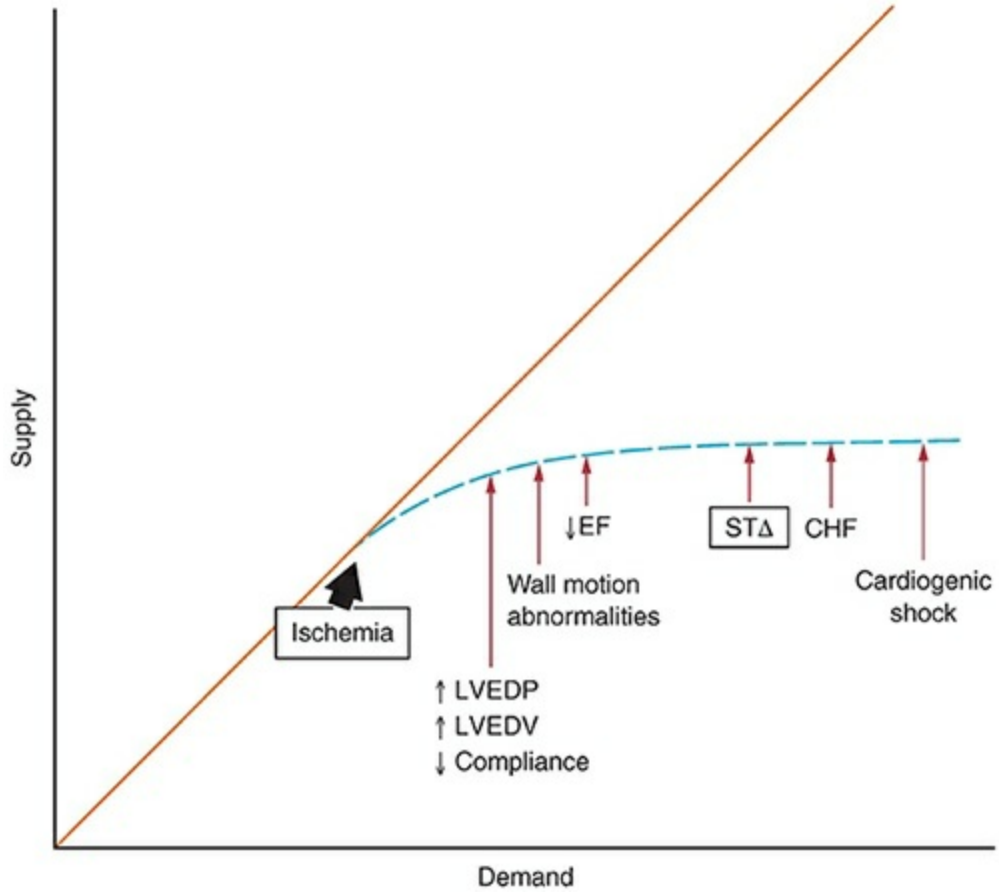

FIGURE 5.4. Hemodynamic consequences of myocardial ischemia. Ischemia occurs when demand exceeds supply. CHF, congestive heart failure; EF, ejection fraction; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; STΔ, ST-segment changes. (*Reprinted with permission from Barash PG. Monitoring myocardial oxygen balance: physiologic basis and clinical application.* ASA Refresher Courses in Anesthesiology. *1985;13:24.*)

The most popularly recognized sign of ischemia is ECG ST-segment changes. The ECG criteria for ischemia are horizontal or down-sloping ST-segment depression at least 0.1 mV at 0.06 second from the J-point, up-sloping ST-segment depression at least 0.2 mV at 0.08 second from the J-point, and ST-segment elevation at least 0.15 mV (1 mV = 10 mm). Other ECG signs of ischemia include inverted T waves and a new onset of arrhythmias or conduction abnormalities.

SWMA, detected with two-dimensional echocardiography, have been shown to be the earliest and most sensitive sign of

myocardial ischemia. SWMA appear with just 25% decrease in coronary blood flow in the absence of ECG changes, whereas ECG signs of ischemia are apparent with a 50% decrease in coronary blood flow. SWMA is 4 times more sensitive than ECG ST-segment change in detecting intraoperative ischemia. Moreover, ST-segment changes cannot be analyzed if the patient has conduction disturbances, such as bundle branch block or ventricular-paced rhythms. Worsening wall motion after CABG surgery should be considered a prognostic indicator of adverse cardiovascular outcome.

Measurement of PAOP has been suggested as an early and sensitive indicator of ischemia to be used when the ECG is not diagnostic. Although acute increases in PAOP or development of V waves may reflect ischemia, the absence of a change in PAOP does not ensure the absence of ischemia. Häggmark et al. reported that the sensitivity, specificity, and predictive value (positive and negative) of PAOP abnormalities for ischemia ranged between 40% and 60%. Leung et al. found that 61% of TEE wall motion abnormalities in CABG patients occurred without significant changes in HR, systolic arterial pressure, or PA pressure. Only 10% of episodes were accompanied by 5 mmHg or greater changes in PA pressure. These studies question the value of PA catheterization and monitoring for detection of intraoperative ischemia.

C.I-9. *Discuss the principles and clinical applications of intraoperative transesophageal two-dimensional echocardiography.*

TEE is a well-established technique to visualize cardiac anatomy and function. Echocardiography is based on fundamental ultrasonic principles. Ultrasound is defined as sound above the upper threshold of human hearing (20,000 Hz). The ultrasound waves (1 to 7 MHz) are created by applying an alternating electric current of 500 to 1,500 pulses per second on a piezoelectric crystal. A short burst (pulse) of high-frequency, low-intensity sound is then emitted and directed through the human body to detect boundaries between structures of different acoustic impedance. The ultrasound wave is partially reflected at the boundary of media with different acoustic impedance, a property that is primarily determined by the slight difference in density between different tissues. The transmission of ultrasound through the heart, with detection of the returning echoes detailing the position and movement of cardiac structures, is termed *cardiac ultrasound* or *echocardiography*. Two-dimensional ultrasound reconstructs cardiac anatomy in shades of gray, from the time delay and decreased intensity of the reflected ultrasound. The ultrasound beam sweeps in an arc to give a panoramic view of the heart that results in cross-sectional images that are anatomically recognizable (see also Chapter 7, section A.6).

Doppler echocardiography blood flow is measured by

applying Doppler frequency shift analysis to echoes reflected by a moving target (red blood cells or cardiac tissue). According to the Doppler principle, the frequency of the reflected ultrasound is different from the frequency of the emitted ultrasound. This change in frequency is proportional to the speed of the moving target. Color-coded Doppler flow imaging (color flow Doppler) simultaneously presents real-time images of intracardiac blood flow and moving cardiac structures in two dimensions. Color flow Doppler permits the evaluation of valvular function and intracardiac shunts.

The clinical applications of intraoperative echocardiography are as follows:

- Monitoring ventricular volume and function. When left ventricular short-axis cross section is monitored at the level of the midpapillary muscles, TEE provides the anesthesiologist with a direct, semiquantitative method to assess left ventricular preload (left ventricular cross-sectional area at end-diastole) and ejection (difference of left ventricular cross-sectional area between end-diastole and end-systole) in real time and guide the administration of fluids, inotropes, or pressors.
- *Monitoring diastolic filling patterns*. Both Doppler assessment of transmitral and transpulmonary vein flow patterns can provide important information about diastolic dysfunction that may be prevalent in as many as 50% of patients presenting for open heart surgery, namely, those with history of hypertension, aortic stenosis, and hypertrophic cardiomyopathy. It is important to note that in patients with valvular disease, a component of left ventricular dysfunction arises from abnormal diastolic function.
- *Ischemic heart disease*. SWMAs, such as hypokinesia, akinesia, and dyskinesia, are the earliest signs of

myocardial ischemia (**Figs. 5.2** and **5.3**), as discussed in section C.I-9. Measurements of systolic wall thickening, a sensitive sign of myocardial ischemia, are not reproducible because of a difficulty in delineating the epicardial border accurately in two-dimensional echocardiography. The impairment of the diastolic function can be qualitatively estimated, and the filling pressures can be estimated using a combination of spectral Doppler measurements of the blood flow through the transmitral and transpulmonary vein flows.

- *Air embolism*. In the left atrium, LV, and aorta, air embolism can be detected by TEE during open heart surgery. Therefore, TEE can be used to help the surgeon evacuate air bubbles from the left heart before the heart ejects blood and air into the systemic circulation. This is more important when cardiac cavities are opened during surgery (aortic or valve surgery, etc.).
- *Valvular regurgitation*. Valvular regurgitation can be determined intraoperatively by color Doppler echocardiography before and immediately after conservative valve repair (annuloplasty, commissurotomy) or valve replacement. The degree of valvular incompetency can be accurately measured using a combination of two-dimensional and Doppler techniques (**Figs. 5.5** and **5.6**), and the function of the repaired or replaced valve can be quantitatively evaluated.

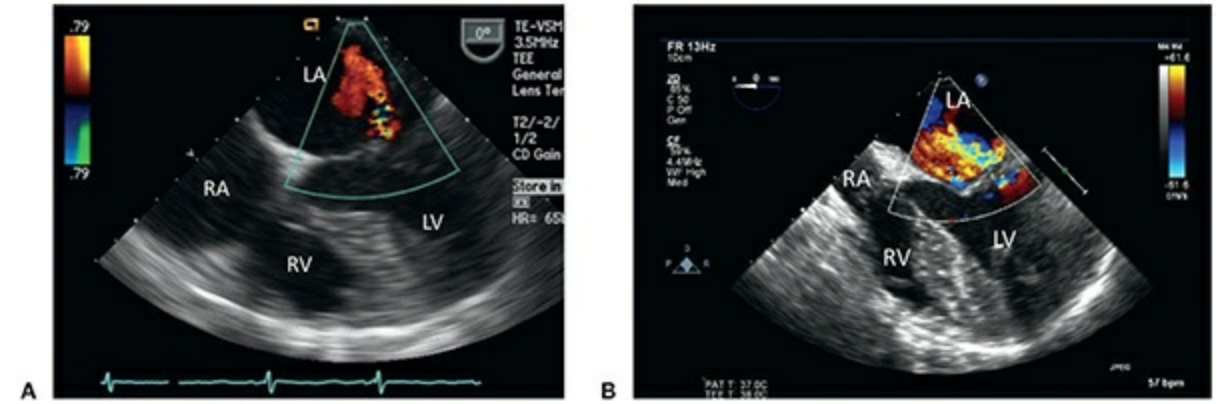

FIGURE 5.5. Color Doppler echocardiography. A. Superimposed on a two-dimensional image (here, the midesophageal view), the relative velocities of the red blood cells from a selected area *(triangle)* are visualized. Timed to the ECG (on the bottom of the sector image), normal or abnormal blood flows can be viewed as they cross orifices. In this case, a small regurgitant jet originating from the mitral valve during systole is seen. The color of the jet displays velocity and direction, according to the scale, on the left side of the figure. The mitral regurgitation jet is moving upward toward the left atrium (LA) and is colored red. **B.** In this midesophageal four-chamber view of the left ventricle (LV), a systolic mitral regurgitant jet is directed inside the LA. RA, right atrium; RV, right ventricle.

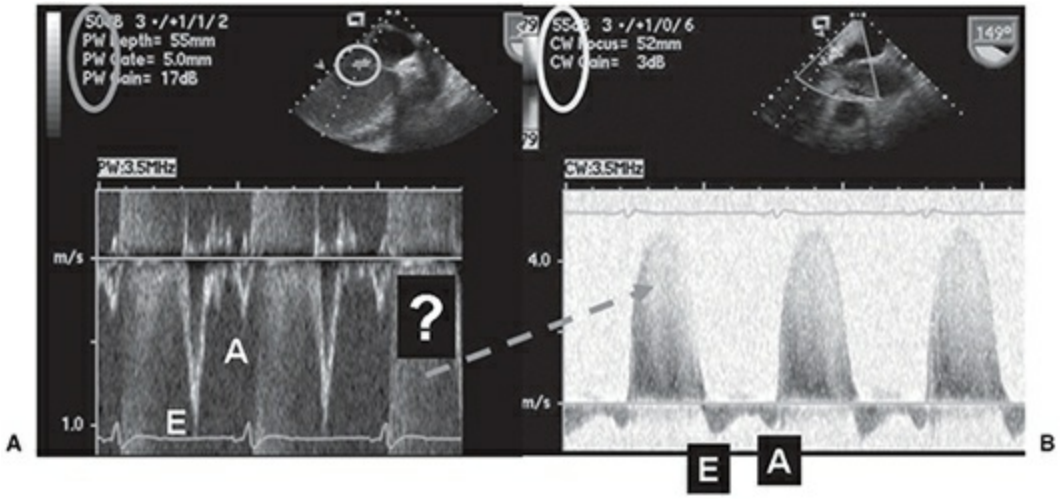

FIGURE 5.6. Doppler mode. A. A typical pulsed-wave (PW) Doppler velocity consists of a spectral recording of varying intensity, depending on the acoustic density of the reflected interface (the mass of blood cells). The most dense (or brightest) portion of the spectral tracing represents the velocity of most blood cells. The velocity is recorded from a specific site *(white circle)*, and the maximum velocity recorded is limited (usually <1.5 m per second). In this PW Doppler spectrum, *E* represents the diastolic early filling, and *A* the diastolic late (due to atrial contraction) velocity. During systole, there is a broad signal *(question mark)* representing systolic flow through the mitral valve (probably mitral regurgitation). However, neither the direction nor the peak velocity can be visualized. **B.** In contrast, continuous-wave (CW) Doppler records the velocities of all the red blood cells moving along the path of the sound beam. A CW Doppler recording always consists of a full spectral envelope with the outer border corresponding to the fastest moving blood cells. The site of origin of a high-velocity jet is inferred from the particular lesion that is being examined. The maximum velocity that can be recorded

can be as high as 8 m per second. Here, the direction (from bottom to top or from the LV toward the left atrium) as well as the maximum systolic velocity (approximately 5 m per second) can be visualized, detailing the mitral regurgitation jet.

- *Valvular stenosis*. Spectral Doppler echocardiography can be used intraoperatively to measure the pressure gradient across a valvular stenosis and calculate the area of the diseased valve.
- *Congenital heart disease*. TEE techniques facilitate complex cardiac reconstructions because the surgeon has the ability to visualize the heart and evaluate adequacy of the surgical repair immediately after the operative procedure.
- *Thoracic aorta*. TEE can accurately diagnose thoracic aortic aneurysm, dissection, disruption, and atheroma. Epiaortic echocardiography is performed to examine the ascending aorta and arch if severe atheroma is found in the descending aorta or arch by TEE. Severe atheroma of the thoracic aorta is an independent predictor of postoperative neurologic outcome. Atheromas are graded as follows: grade I, normal to mild intimal thickening; grade II, severe intimal thickening; grade III, atheroma protruding less than 5 mm into the lumen; grade IV, atheroma protruding greater than 5 mm; and grade V, atheroma with a mobile component (**Fig. 5.7**).

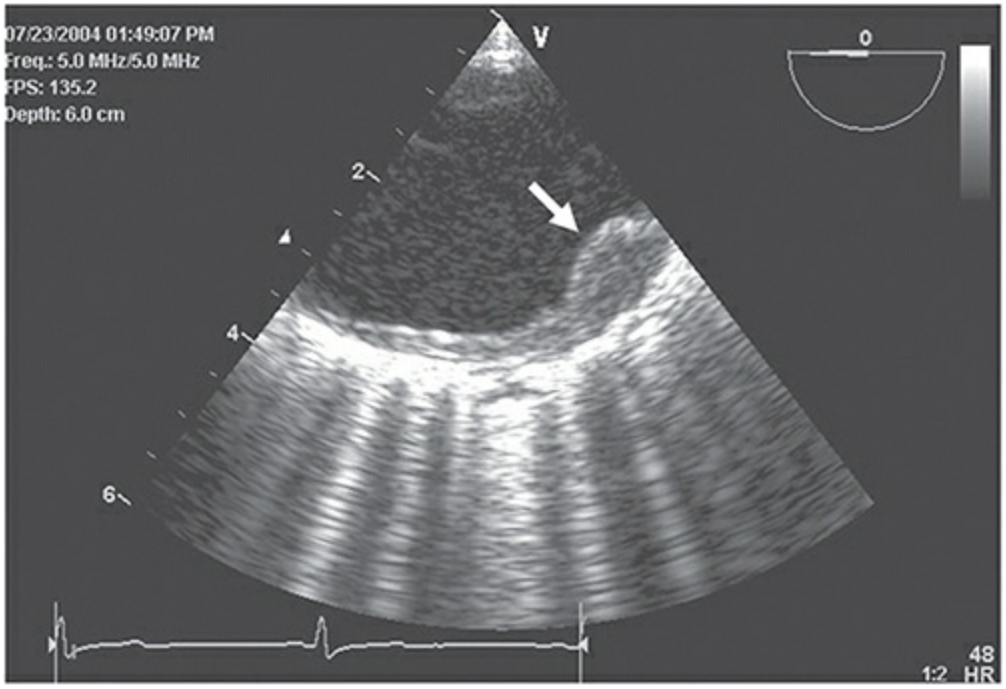

FIGURE 5.7. Atheromatous aortic disease. An echocardiographic picture of the short-axis view of the descending thoracic aorta is shown. The anterior aortic wall is irregularly thickened, and a large atheroma (8 mm) is present at 5 o'clock *(arrow)*. This is a grade IV atheroma.

- *Cardiac tumors*. Atrial myxoma can be easily diagnosed by TEE. Preoperative and postoperative TEE with contrast can assess the presence and severity of mitral regurgitation secondary to valve damage from a ball valve effect of the myxoma.
- *Other cardiac pathology*. Hypertrophic obstructive cardiomyopathy (HOCM) (idiopathic hypertrophic subaortic stenosis) can be identified by the combination of systolic anterior motion of the mitral valve and left ventricular outflow obstruction. Cardiac tamponade caused by a pericardial effusion or hematoma can be detected.
- *Neurosurgery*. TEE was found to be the most sensitive monitor to detect venous air embolism during neurosurgical operations in the sitting position. Patent foramen ovale and paradoxical air embolism can be detected by TEE.

- *Monitoring for noncardiac surgery*. Recent guidelines by Porter et al. suggest the utility of TEE in healthy patients who are acutely hemodynamically unstable during surgery, critically ill patients with significant respiratory and cardiac diseases undergoing noncardiac surgery, and patients undergoing high-risk noncardiac procedures, such as orthopedic surgery and kidney and liver transplants. TEE would be used as a hemodynamic diagnostic and monitoring tool to guide and evaluate effectiveness of therapeutic interventions.

C.I-10. *How would you induce anesthesia? Is there any advantage/disadvantage to using propofol versus etomidate as the main induction agent? What kind of neuromuscular blocker (NMB) would you use? Why?*

Midazolam 1 to 2 mg is given as soon as the standard

monitors are applied and prior to the arterial line is inserted (under local anesthesia). This is important in alleviating anxiety, which can exacerbate myocardial ischemia. In lieu of the increasing incidence of delirium in the elderly postoperatively, benzodiazepines should be avoided in patients older than 70 years.

A smooth induction is essential to prevent hypotension, hypertension, and tachycardia. Different techniques may be used to achieve a smooth induction. For patients with good left ventricular function, anesthesia is induced with fentanyl, 2 to 5 μg per kg, and propofol, 1 to 2 mg per kg. Propofol may cause a reduction in MAP; however, this is less likely if it is administered at 10 mg per 40 seconds, as recommended in the package insert. Alternatively, etomidate 0.2 mg per kg may be administered for induction. Etomidate causes a transient adrenal insufficiency; however, this does not translate into increased vasopressor requirements or inferior early outcomes. A randomized controlled trial by Hannam et al. comparing the two induction agents in the cardiac surgery population confirmed that propofol has a less favorable hemodynamic profile, although the proportion of patients receiving vasopressors was not significantly different.

After administration of a nondepolarizing muscle relaxant (vecuronium, rocuronium), the trachea is intubated. The choice of nondepolarizing muscle relaxant varies from center to center and among practitioners. Succinylcholine is used less frequently in cardiac surgery.

For patients with poor left ventricular function, all anesthetics, including potent inhalation agents such as isoflurane, sevoflurane, and desflurane, should be used cautiously during induction of anesthesia because of their dose-dependent reduction in myocardial contractility and systemic arterial resistance. There is also the risk of

occupational exposure of inhalational agents due to poor mask design and seal.

See also Chapter 11, section C.6, for other measures to prevent tachycardia and hypertension at the time of intubation.

C.I-11. *How would you maintain anesthesia? Volatile anesthetics or total intravenous anesthesia (TIVA)?*

Hemodynamic stability is essential to achieve a balance between myocardial oxygen demand and supply. Different agents and techniques may be used to accomplish the same goal. A combination of fentanyl (or another synthetic opioid) and isoflurane, sevoflurane, or desflurane (or propofol) is a popular choice (balanced technique). Volatile anesthetics have cardioprotective effects through various mechanisms. A study by Landoni et al. evaluating volatile anesthetics versus TIVA for CABG demonstrated, however, that volatile anesthetics do not improve mortality in this patient population. After the patient is intubated, a mixture of 60% air and 40% oxygen is administered to lessen the possibility of oxygen toxicity. Clearly, this ratio is subject to underlying pulmonary disease and ongoing intraoperative clinical

conditions.

The depth of anesthesia must be titrated to meet the requirements of the varying intensities of surgical stimulation. Skin incision and sternal splitting are very painful. However, the strongest stimulation is usually from sternal retraction with the self-retaining retractor. Fentanyl, around 5 μg (0.1 mL) per kg (or equivalent doses of other opioids), is given right before the skin incision, before sternotomy, and intermittently throughout surgery as needed to maintain adequate analgesia. Very high doses of fentanyl or sufentanil have been successfully used for cardiac anesthesia. There have been significant changes in practice over the past decade, whereby much lower doses of narcotic are administered to facilitate early extubation. Nowadays, maintenance of anesthetic is based on administration of volatile agents and smaller opioid dosages. Longer acting opioids, such as methadone, can be used to reduce the quantity of opioids administered both intraoperatively and postoperatively. A study by Murphy et al. demonstrated that methadone administration during cardiac surgery reduces postoperative opioid requirements and improves pain scores. Vasoactive agents are also used to regulate the hemodynamics (HR, systemic arterial pressure, and filling pressures).

C.I-12. *What are the cardiovascular effects of volatile anesthetics, morphine, and fentanyl?*

Isoflurane, desflurane, and sevoflurane all produce a dose-related depression in ventricular function and vascular tone due to altered Ca_2+ entry and sarcoplasmic reticulum function in myocytes. Out of all the volatile anesthetics, isoflurane causes the most reduction in vascular tone and coronary vasodilation, suggesting the possibility of steal syndrome in patients with CAD. However, there is not conclusive evidence that isoflurane is more harmful than other anesthetics, assuming that coronary perfusion pressure is maintained. Compared to the other volatile anesthetics, desflurane causes the most increase in HR. Isoflurane and desflurane may cause tachycardia if the inspiratory concentration is increased rapidly. This mechanism is due to increased sympathetic system outflow.

All of the potent drugs decrease arterial pressure in a dose-related manner. The mechanism of BP decrease includes vasodilation, myocardial depression and decreased cardiac output, and decreased sympathetic nervous system tone.

Narcotics such as morphine and fentanyl at their clinical dose have minimal cardiovascular effects. Both may cause bradycardia. Neither sensitizes the heart to catecholamines or depresses myocardial function. The cardiovascular effects of morphine depend on the dose used. Large doses of morphine sulfate have reportedly caused myocardial lactate production and reduction in coronary blood flow in animals. Sethna et al. found that morphine sulfate, 0.25 mg per kg IV, did not produce a global myocardial ischemia in patients with CAD. High doses of morphine, 1 mg per kg, produce a significant

decrease in arterial BP and systemic vascular resistance accompanied by an average 750% increase in plasma histamine. On the other hand, high doses of fentanyl, 50 μg per kg, do not produce any significant changes in BP, vascular resistance, or plasma histamine levels.

C.I-13. *What should you do during sternotomy?*

It is recommended that ventilation be held to protect the lungs from injury by the electric saw for first-time sternotomy.

C.I-14. *Would you use prophylactic nitroglycerin during CABG to prevent intraoperative myocardial ischemia or perioperative MI?*

No. It has been reported that prophylactic administration of nitroglycerin, 0.5 or 1.0 μg/kg/min, during fentanyl anesthesia in patients undergoing CABG did not prevent myocardial ischemia or reduce the incidence of perioperative MI.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:292–356.

C.I-15. *If ST-segment depression is seen during surgery, how would you treat it? What is the relation between perioperative myocardial ischemia and postoperative*

MI?

An ST-segment depression is indicative of ischemia and should be treated by:

- *Increasing coronary oxygen supply*: correct hypotension, hypoxemia, anemia
- *Increasing coronary perfusion pressure*: most often with small boluses of short-acting vasopressor, such as phenylephrine
- *Decreasing coronary oxygen demand*: correct hypertension, tachycardia, and increased PAOP or CVP by deepening anesthesia with a volatile agent or by using vasodilators or β-blockers. All the major determinants of decreased oxygen demand have to be considered and corrected to their normal levels.

If there are no obvious changes in BP, HR, and pulmonary wedge pressure, nitroglycerin is indicated if coronary spasm is suspected. Nitroglycerin may be given by IV drip. IV nicardipine may also be given to relieve coronary spasm.

Slogoff and Keats reported that perioperative myocardial ischemia occurred in 37% of all patients undergoing CABG. They demonstrated that perioperative MI was almost 3 times as frequent in patients with ischemia (6.9%) compared with patients without ischemia (2.5%). Intraoperative tachycardia was associated with a higher incidence of myocardial ischemia and infarction. However, Knight et al. demonstrated that 42% of CABG patients had preoperative episodes of myocardial ischemia, 87% of which were clinically silent. They further found that anesthesia and surgery did not worsen the preoperative ischemic pattern. Furthermore, Slogoff and Keats in another study postulated that approximately 90% of new myocardial ischemia observed during anesthesia was the manifestation of silent ischemia observed in the patient before the operation, and only 10%

was related to anesthetic management. Therefore, the relationship between intraoperative ischemia and postoperative outcome is still unsolved.

It is important to note that ST-segment changes suggestive of myocardial ischemia may be observed with alteration of the patients' position, particularly during retraction of the sternum for internal mammary harvesting. In addition to being attentive to the ECG, addressing presence of ischemia by PA catheter and echocardiography is advised. Segmental wall motion abnormalities may be detected earlier than changes in ECG.

C.I-16. *Discuss autologous transfusion and blood conservation for cardiac surgery.*

Autologous transfusion is the collection and reinfusion of the patient's own blood or blood components. The realization that homologous blood is responsible for transmission of AIDS, hepatitis, transfusion reaction, and autosensitization has led to increased interest in autologous transfusion and blood conservation. Most often, the easiest, safest, and most cost-effective approach for blood conservation is intraoperative normovolemic hemodilution, pharmacologic

treatment, and perioperative blood salvage, whereas options such as preoperative autologous blood donation, preoperative use of erythropoietin, and intraoperative plasmapheresis are rarely used nowadays.

Intraoperative normovolemic hemodilution is the removal of blood through an arterial or venous catheter immediately after induction of anesthesia, before CPB, or the administration of heparin. Depending on the patient's size and hematocrit, 500 to 1,000 mL of blood is collected into blood bags containing citrate phosphate dextrose adenine (CPDA-1) anticoagulant and is kept at room temperature. This blood is spared the rigors of CPB, including hemolysis, platelet destruction, and clotting factor degradation. The autologous blood is transfused after reversal of the heparin with protamine. It has been demonstrated that the effect of 1 unit of fresh whole blood on platelet aggregation after CPB is at least equal, if not superior, to the effect of 8 to 10 stored platelet units. Normovolemic hemodilution is not recommended, however, if the patient's hematocrit is below 33% or the hemoglobin is below 11 g per dL because further decreasing the oxygen-carrying capacity may worsen myocardial ischemia. In addition, hemodilution during CPB will further decrease hematocrit to levels that require homologous blood transfusion. Normovolemic hemodilution should be performed cautiously in patients with critical left main coronary stenosis, aortic stenosis, and HOCM because sudden cardiac arrest has been observed during the procedure.

Perioperative blood salvage is the collection and reinfusion of blood lost during and immediately after surgery. The posttransfusion survival of perioperatively salvaged red blood cells has been shown to be comparable to that of allogeneic red blood cells. At the conclusion of CPB,

all blood remaining in the oxygenator and bypass circuits should be salvaged and, if needed, infused. Blood salvaged intraoperatively may be transfused directly (unwashed) or processed (washed) before infusion. Commercially available equipment exists for each option. Blood collected by intraoperative salvage represents an excellent source of red blood cells. Salvaged blood is, however, deficient in coagulation factors and platelets.

Postoperative blood salvage is another technique of autologous blood transfusion utilizing blood lost following surgery. Blood salvaged following cardiac surgery generally is collected from mediastinal and chest drains and transfused without washing. It does not require anticoagulation before transfusion. Although dilute, the blood is sterile and contains viable red blood cells.

C.I-17. *What antifibrinolytic will you use to reduce blood transfusions?*

Antifibrinolytic agents include lysine analogues epsilon

aminocaproic acid (EACA) and tranexamic acid (TXA). Lysine analogues block plasminogen's conversion to plasmin, in turn inhibiting fibrinolysis. These agents reduce bleeding and the amount of blood transfusions. The Society of Thoracic Surgeons/Society of Cardiovascular Anesthesiologists 2011 guidelines on blood conservation strongly recommend antifibrinolytics to be part of a blood conservation strategy.

Extensive dosing variability is reported for TXA. A low-dose strategy consists of a 10-mg per kg loading dose, 1 to 2 mg per kg into the CPB prime, and a 1-mg/kg/hr infusion. On the other hand, a high-dose strategy consists of a 30-mg per kg loading dose, 2 mg per kg into the CPB prime, and a 16-mg/kg/hr infusion. Up to 50% of cardiac surgical patients have renal dysfunction, and TXA is eliminated renally. High doses of TXA may also cause seizures. The mechanism of TXA-associated seizures is not fully understood, although dosage has been demonstrated to be an important variable. A lower dosing strategy should be used in those patients who have renal dysfunction and/or are at risk for seizures. Jerath et al. recommend a dosing strategy of a single 50 mg per kg bolus for patients with chronic renal dysfunction.

Pharmacokinetic data is also sparse for EACA. The loading dose is typically 100 mg per kg with a 5-g or 10-g bolus into the CPB prime and a 1 g per hour or 30-mg/kg/hr infusion. There is risk of renal dysfunction after the administration of EACA.

The 2008 BART trial (Blood conservation using Antifibrinolytics: Randomized trial) compared the 3 available antifibrinolytic agents available at the time: aprotinin, EACA, and TXA. The trial was terminated early due to a higher rate of death in the aprotinin group. Aprotinin was subsequently withdrawn from the market by the

manufacturer.

C.I-18. *How do you know that the tip of the PA catheter is in the right ventricle (RV) or the PA?*

There are three main differences in the pressure tracings, as shown in **Figure 5.8**.

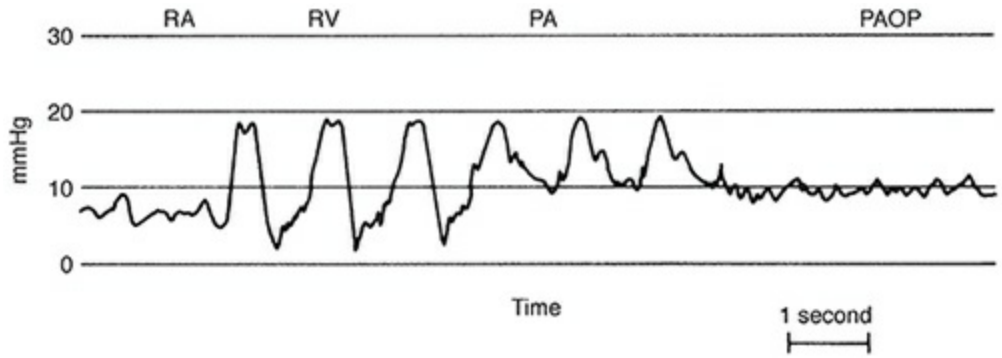

FIGURE 5.8. Pressure tracings of right atrium (RA), right ventricle (RV), pulmonary artery (PA), and pulmonary artery occlusion pressure (PAOP).

Diastolic pressure is higher in PA than in RV because the closed pulmonary valve maintains a diastolic gradient between the PA and the RV.

- PA pressure: 20 to 25/5 to 10 mmHg
- Right ventricular pressure: 20 to 25/0 to 5 mmHg

Pressure Contour

- PA pressure tracing has a dicrotic notch, which is created by the closure of pulmonary valve, and the diastolic part is descending (decreasing).
- Right ventricular pressure tracing has a sharp drop and a plateau in early diastole, and the diastolic part is ascending (increasing).

Ventricular Filling

In the late diastolic phase, PA pressure is decreasing because of diastolic runoff in the pulmonary circulation, whereas the right ventricular pressure is increasing because of ventricular filling.

C.II. During Cardiopulmonary Bypass

C.II-1. *What anticoagulant would you give before cardiopulmonary bypass (CPB)? How much would you give? What is its mechanism?*

Heparin has been used conventionally in doses of 300 (200 to 400) units per kg of body weight, assuming an initial concentration of at least 2 to 4 units per mL of whole blood. Empirically, after 2 hours of the initial dose, subsequent doses of 100 units per kg are given for each additional hour of bypass. Because there is marked individual variation, heparin doses are best monitored by the celite-ACT test.

Heparin acts indirectly by means of a plasma cofactor. The heparin cofactor, or antithrombin III (AT III), is an α_2-globulin and a protease inhibitor that neutralizes several activated clotting factors: XIIa, kallikrein, XIa, IXa, Xa, IIa, and XIIIa. AT III forms irreversible complexes with thrombin (IIa) and, as a result, both proteins are inactivated.

Inhibition of thrombin and factor Xa accounts for most of the anticoagulant effect of heparin. Heparin increases the rates of the thrombin–antithrombin reaction at least 1,000-fold by serving as a catalytic template to which both the inhibitor and the protease bind. Heparin also binds to cofactor II, a glycoprotein that inactivates thrombin independently of AT III. This reaction occurs more slowly and requires higher heparin concentrates than does thrombin inhibition through the heparin–AT III complex.

Spiess BD, Horrow JC, Kaplan JA. Transfusion medicine and coagulation disorders. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia, PA: Elsevier Saunders; 2011:949–991.

C.II-2. *What is the half-life of heparin? How is it eliminated?*

The biologic half-life of heparin varies with dosages and temperature. It has a remarkable individual variation. The average half-life is approximately 100 minutes in a normothermic man for the initial doses of 300 units per kg, increasing with higher doses and decreasing temperature. When 100, 400, or 800 units per kg of heparin are given intravenously, the approximate half-life is 1, 2.5, and 5 hours, respectively. Heparin concentrations decline progressively at all temperatures, but the rate of decline is delayed in proportion to the hypothermia.

The primary mechanism for heparin elimination remains uncertain. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system. A small amount of heparin also appears in the urine.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1248–1290.

C.II-3. *How do you monitor heparin dosage? What is the activated coagulation time (ACT) test?*

Heparin therapy can be assessed by the partial thromboplastin time, heparin assay, heparin–protamine titration, and the ACT test. The most convenient and practical method used to monitor heparin therapy in the operating room is the celite-ACT test. There is a very good correlation among the ACT, plasma heparin units, and thrombin time. After central venous injection of a heparin bolus, the onset of maximal ACT prolongation occurs within 1 minute.

Two milliliters of blood are put into a test tube containing celite to activate coagulation. Then, the tube is kept at 37°C (98.6°F) and clot formation is watched for ACT. The normal control value of ACT is 105 to 167 seconds. A baseline value is determined before the administration of heparin, and the test is repeated 3 to 5 minutes after heparin is given and at intervals of 30 to 60 minutes thereafter. With the dose of heparin in milligrams per kilogram on the vertical axis and ACT in seconds on the horizontal axis, a dose-response curve can be plotted. ACT values are maintained at approximately twice the control value and should never decrease less than 300 seconds during normothermia.

Precise determination of plasma heparin concentration can also be used. The patient's plasma is incubated with factor Xa in the presence of its inhibitor, Xai. Heparin accelerates factor Xa inhibition, and residual factor Xa remaining after 2 minutes is measured and converted to a heparin concentration, expressed in units per milliliter. This method has been shown to decrease the amount of heparin used compared to heparin-ACT dose-response curves. The major disadvantage of this technique is the time delay before results are available.

C.II-4. *What is total CPB? What is partial bypass?*

Total bypass indicates that all the venous return from superior and inferior venae cavae and the coronary sinus is drained to the oxygenator. No blood is pumped by the RV to the lungs. The PA and systemic pressure tracings become nonpulsatile. Partial bypass means that some of the blood return is still pumped by both RV and LV. This venous blood is drained to the oxygenator and pumped back to the arterial side. Femoral–femoral bypass is one example of partial CPB.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:665.

C.II-5. *What kinds of pumps are used in CPB? Are they pulsatile or not?*

There are three types of pumps available for modern CPB machines: the double-headed non-occlusive roller pump, the centrifugal blood pump, and the ventricular-type pneumatic or hydraulic pump. Only the first two types are in common use.

The roller pump is the most commonly used pump. It is driven by an afterload-independent motor. Once the pump speed is set, it will continue the forward displacement of the same blood volume (or air volume) even if the resistance is increased by kinking or clamping the arterial line. This will result in the rupture of connections between sections of tubing. Some centers use pressure gauges on the arterial

inflow line to avoid this type of disaster.

The centrifugal pump is a kinetic pump that operates on the constrained vortex principle. Blood is driven through the pump by centrifugal forces generated by a vortex in the pump. The advantages of centrifugal pumps are as follows:

- Less trauma to blood components than the roller pump
- Less risk of increasing arterial line pressure because blood flow decreases when line resistance is increased
- Inflow responsiveness—if a large quantity of air is introduced into the pump, cohesive forces will no longer exist between layers of blood and pumping will stop
- Less risk of micro-air embolism because small, low-density air bubbles are trapped in the center of the vortex

Ventricular-type pumps, although potentially more powerful, are rather cumbersome and have not been well accepted. This type of pump is mainly used for pulsatile bypass.

C.II-6. *What is the purpose of venting the LV? How can it be done?*

Although all the venous return is bypassed from the RV, 2% to 5% of cardiac output is draining to the LV. This represents the physiologic shunt from the bronchial, thebesian, and pleural veins. Other sources of blood flow to the left heart during CPB include aortic regurgitation from aortic insufficiency and extracardiac left-to-right shunts such as

patent ductus arteriosus and Blalock-Taussig, Waterston, and Potts shunts. The left ventricular sump drain (left ventricular "vent") prevents overdistention of the LV, which may cause post-ECC heart failure. A suction needle inserted proximal to the aortic cross-clamp may serve the same purpose.

Venting of the LV can be accomplished by inserting a catheter to the following sites:

- Aortic root such as cardioplegia cannula for CABG
- Junction of the right superior pulmonary vein and the left atrium and advancing through the left atrium and mitral valve into the LV
- Apex of the LV
- PA or the left atrium only

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:667–668.

C.II-7. *How many types of oxygenators are there? What are the advantages of each type?*

There are two basic types of oxygenators in terms of their interface with blood.

Direct Gas Interface

- Disk
- Vertical screen
- Bubble

Without Gas Interface

- Membrane—solid or microporous
- Fluid—using fluorocarbon liquid

The disk and screen oxygenators are not disposable and have proven to be somewhat difficult to clean, prepare, and resterilize. The bubble oxygenator has the advantages of simplicity, disposability, and relatively low cost.

The disadvantages of gas interface oxygenators include the following:

- Protein denaturation
- Increased fragility of cells
- Susceptibility to hemolysis
- Denaturation of platelet membrane materials resulting in platelet aggregation, clumping
- Formation of air embolism
- Large priming volume
- Variable reservoir level resulting in potential shifts of blood volume between intracorporeal and extracorporeal circuit

Direct gas interface oxygenators are not used anymore. The membrane oxygenator has become more popular, economical, efficient, and less traumatic to blood. Its advantages include the following:

- Less trauma to blood components
- No defoaming
- Decreased complement activation
- Independent control of oxygen and CO_2 exchange
- Use of air–oxygen mixture without the risk of gaseous microemboli

The advantage of a membrane oxygenator for a short bypass (<2 hours) is unclear, however, although lower plasma hemoglobin levels are present using membrane oxygenators.

The disadvantages of membrane oxygenators include the following:

- Expense
- Potential difficulty in eliminating all bubbles during priming
- Moderately large priming volume

The major differences in changes of clotting factors

between the bubble and membrane oxygenators become apparent after 4 to 6 hours of ECC.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:95–106.

C.II-8. *What kind of priming solution would you use? How much priming solution would you use? When would you prime with blood? Why?*

The usual priming solution includes a balanced salt solution, albumin, and mannitol. The priming volumes vary with the size of the oxygenators used and the tubing volume. Most oxygenators for adults have priming volumes of 500 to 1,000 mL. In general, blood is added to the oxygenator if the patient is markedly anemic (prepump hematocrit below 30%) or if the priming volume is large in relation to the patient's blood volume, such as in pediatric patients. In order to maintain oxygen-carrying capacity, the hematocrit is kept at levels above 18% to 20%. Mannitol has long been used as an osmotic diuretic in situations where hemolysis or diminished renal function is expected. Mannitol has been found to decrease the incidence of renal failure during hypotension by promoting osmotic diuresis and increasing renal blood flow by decreasing renal vascular resistance. Heparin, 3,000 to 10,000 units, is added to the prime depending on the size of the prime volume. This allows heparin to be distributed over the thrombogenic surfaces of the CPB circuit.

Del Nido solution is an extracellular cardioplegia based on Plasma-Lyte A. It has a 1:4 blood-to-crystalloid composition. Similar outcomes having been reported in the CABG population when using del Nido compared to traditional

solutions.

C.II-9. *What are the advantages and disadvantages of hemodilution?*

Advantages of Hemodilution

- An increase in microcirculation due to a reduction of blood viscosity
- Improved oxygen delivery to tissues
- Decreased metabolic acidosis
- Reduced risk of hypertension
- Reduced blood demands
- Reduced incidence of hepatitis, AIDS, or reactions from blood transfusions
- Reduced postoperative blood loss
- Improved blood flow at lower perfusion pressure, especially during hypothermic perfusion

Disadvantages of Hemodilution

- Decreased oxygen-carrying capacity
- Postoperative extracellular fluid overload
- Possible pulmonary edema
- Increased risk of postoperative renal dysfunction
- Hypotension from decreased viscosity and peripheral resistance

- Decreased concentration of calcium, magnesium, phosphate, and zinc

C.II-10. *How do you monitor the patient during CPB?*

Clinical Monitoring

- ECG
- MAP should be kept between 50 and 100 mmHg to maintain tissue perfusion. In hypertensive patients and in older patients, a higher MAP is frequently utilized. There is very little support for this in the literature.
- Bladder and esophageal temperatures are recorded (tympanic also may be used).
- CVP should be low or zero to make sure there is no obstruction to venous return from the head (when monitored from a site proximal to the RA) or there is adequate drainage of blood to the CPB circuit (when

monitored from inside the RA).

- PA pressure should be low or zero to prevent over distention of the LV.
- Urine output should be maintained above 1 mL/kg/hr by adequate perfusion.
- TEE may be used to detect aortic and cerebral embolism.
- Cerebral oximetry can be used to help monitor for adequate brain oxygen saturation (<20% change from baseline).
- Pump-flow rate should be adequate for tissue perfusion and oxygenation.

Laboratory Monitoring at Least Once Every Hour

- Arterial blood gases are kept at normal range.
- Venous P_{O_2} should be 40 to 45 mmHg.
- Hematocrit maintained between 20% and 24%
- Electrolytes Na^+, K^+, ionized Ca^{2+}
- ACT measured each hour and maintained above 400 to 480 seconds
- Glucose should be kept below 250 mg per dL.

C.II-11. *What should your target BP be during CPB?*

Controversy continues over what constitutes adequate pressures while the patient is on bypass. The MAP is usually maintained at approximately 50 to 100 mmHg to ensure adequate tissue perfusion. BP depends on cardiac output (pump flow) and total peripheral resistance (TPR). Adequate cardiac output (pump flow) is more important for tissue perfusion than BP.

During hypothermic cardioplegia, higher systemic pressures (mean BP >70 mmHg) are often avoided because of increased noncoronary collateral blood flow into the heart through the pericardium and pulmonary venous drainage. Such collateral flow of relatively warm blood tends to wash the colder cardioplegic solution out of the heart and decreases the hypothermic protection against myocardial ischemia.

Gold et al. studied 248 patients randomized to either low MAP (50 to 70 mmHg) or high MAP (80 to 100 mmHg) during CPB and found a trend toward improvement in cardiac and neurologic outcome with higher MAP. However, MAP had no significant effect on neurologic outcome in those patients at low risk for cerebral embolization (normal to mild aortic atherosclerosis by TEE). Patients at high risk for adverse neurologic outcome (severe aortic atherosclerosis by TEE) had a significantly lower risk of worse neurologic outcome when randomized to higher MAP.

However, keeping the MAP high during CPB, above the limit of cerebral autoregulation, is associated with a risk of delirium. The range of cerebrovascular autoregulation during hypothermia is controversial. Although pooled data from clinical studies indicate a lower autoregulatory threshold of

20 to 30 mmHg in patients without cerebrovascular disease or preexisting hypertension, other studies suggest a pressure-dependent cerebral circulation when MAP is less than 50 mmHg. Until prospective studies clearly define the autoregulatory threshold under various clinical conditions, a BP of less than 50 mmHg should be regarded as a potential physiologic trespass, which may compromise cerebral circulation. Higher perfusion pressure is recommended in patients with cerebrovascular disease and/or hypertension. Real-time monitoring of autoregulation with transcranial Doppler allows for tailoring of the target MAP for the patient during CPB. This may improve patient outcomes.

With the recent introduction of noninvasive cerebral oximetry, the frontal cortex oxygen saturation can be monitored by near-infrared spectroscopy. The technique measures the oxygen saturation of the mixed arterial and venous blood in the brain cortex. Because the volume of blood is predominantly venous, it reflects the balance between oxygen supply and demand in the brain. Yao et al. showed good correlation between brain oxygen saturations and neurologic and cognitive outcomes. The MAP should be kept at levels enough to maintain adequate cerebral oxygen saturations (at least within 20% change of baseline values). Murkin et al. demonstrated in a randomized controlled trial that profound cerebral desaturation was avoided in patients undergoing CABG in whom cerebral regional oxygen saturation was monitored. This resulted in significantly fewer incidences of major organ dysfunction and death.

C.II-12. *How would you treat hypotension during CPB?*

Mean arterial pressure (MAP) = cardiac output (CO) × total peripheral resistance (TPR)

Hypotension may be caused by low cardiac output or low peripheral resistance. Cardiac output should first be corrected by increasing the pump-flow rate. If the cardiac output is adequate, then peripheral resistance can be raised by giving primarily an α-adrenergic vasopressor, typically phenylephrine in increments of 0.1 mg to raise the MAP to 50 mmHg. In cases of more profound vasoplegia, agents such as norepinephrine and vasopressin may be required. According to Poiseuille law, low systemic vascular resistance usually is due to decreased viscosity or increased vascular diameter (vasodilation). Total viscosity is reduced by hemodilution during CPB using blood-free priming solutions, although plasma viscosity is increased by hypothermia. A short period of hypotension with a MAP of approximately 30 to 40 mmHg is usually observed in the first 5 to 10 minutes of bypass. It is due to the following causes:

- Inadequate pump flow at the beginning of bypass
- Hypoxic vasodilation from initial perfusion with blood-free priming
- Vasodilation from vasoactive materials released because of the initial reaction of the serum proteins, blood cells, and platelets with the foreign surfaces of the heart–lung machine
- Decreased plasma levels of catecholamines by hemodilution

Balasaraswathi K, Glisson SN, El-Etr AA, et al. Effect of priming volume on serum catecholamine during cardiopulmonary bypass. *Can Anaesth Soc J*. 1980;27:135–139.

C.II-13. *How would you treat hypertension (a mean arterial pressure [MAP] of over 100 mmHg)?*

Hypertension during bypass is usually the result of inadequate depth of anesthesia, which causes increased catecholamine output and increased vascular resistance. Pump-flow rate should not be reduced to lower the pressure. Low pump flow may cause tissue hypoxia even though BP is high. The most effective treatment involves administering an inhalational agent through the vaporizer in the heart-lung machine. IV agents such as propofol, midazolam, and narcotics may be used, but they are frequently not as effective and have to be supplemented with vasodilator drugs. Previously, nitroprusside and nitroglycerin were commonly used, but more recently, the IV calcium channel blockers (nicardipine and clevidipine) are frequently used.

Aronson S, Dyke CM, Stierer KA, et al. The ECLIPSE trials: comparative studies of clevidipine to nitroglycerin, sodium nitroprusside, and nicardipine for acute hypertension treatment in cardiac surgery patients. *Anesth Analg*. 2008;107:1110–1121.

C.II-14. *How do you prepare an IV infusion of sodium nitroprusside, nicardipine, and nitroglycerin? What are the usual doses? Which do you prefer to use?*

IV solutions may be prepared by adding to 250 mL of 5% dextrose in water 50 mg of nitroglycerin or sodium nitroprusside, or 25 mg of nicardipine, to make a

concentration of 200 μg per mL (nitroglycerin or nitroprusside) or 100 μg per mL nicardipine. The usual doses are nitroglycerin or nitroprusside 0.5 to 10 μg/kg/min, or 0.05 μg/kg/min nicardipine, determined by careful titration (**Table 5.1**).

TABLE 5.1 Cardiac Anesthesia Intravenous Medications[a]

Drug	Amount to Add	Total Volume with D_5W	Concentration	Dosage Range
Amicar (EACA)	15 g	150 mL	1 mL = 100 mg 10 mL = 1 g	Load: 10 g over 1/2 hr Maintenance: 1 g/hr × 5 hr
Amiodarone	450 mg	250 mL	1 mL = 1.8 mg	Initial: 150 mg over 10 min Followed by: 1 mg/min × 6 hr (360 mg) Then: 0.5 mg/min × 18 hr
Dexmedetomidine			1 mL = 4 μg	Load: 1.0 μg/kg over 10 min Maintenance: 0.2–0.7 μg/kg/hr
Diltiazem	25 mg	100 mL	1 mL = 0.25 mg	Load: 0.1−0.15 mg/kg Maintenance: 0.5−0.25 μg/kg/min
Dobutamine	500 mg	250 mL	1 gt = 33.3 μg 1 mL = 2 mg	5–20 μg/kg/min
Dopamine	400 mg	250 mL (premixed)	1 gt = 26.6 μg 1 mL = 1.6 mg	Renal: 1−5 μg/kg/min β: 10 μg/kg/min α: 10−15 μg/kg/min
Epinephrine	2 mg	250 mL	8 gtt = 1 μg	2–8 μg/min
Esmolol	5 g	250 mL	1 gt = 333 μg 1 mL = 20 mg	50−300 μg/kg/min
Levophed	8 mg	250 mL	2 gtt = 1 μg	4–32 μg/min
Lidocaine	2 g	500 mL (premixed)	15 gtt = 1 mg 1 mL = 4 mg	1−4 mg/min
Milrinone	20 mg	100 mL	3 gtt = 1 μg 1 mL = 200 μg	0.375−1 μg/kg/min
Nicardipine	25 mg	250 mL	1 gt = 1.66 μg	Load: 5 mg/hr Maintenance: Increase by 2.5 mg/hr every 15 min Maximum amount: 15 mg/hr
Nitroprusside	50 mg	250 mL (premixed)	1 gt = 3.33 μg	1−10 μg/kg/min

Nitroglycerin	50 mg	250 mL (premixed)	1 gt = 3.33 μg	10−80 μg/min
Phenylephrine	20 mg	250 mL	19 gtt = 25 μg	25−125 μg/min
Procainamide	2 g	500 mL (premixed)	15 gtt = 1 mg 1 mL = 4 mg	Load: 500−1,000 mg (20 mg/min) Dosage: 1−4 mg/min
Sodium bicarbonate	100 mEq	100 mL undiluted	1 mL = 1 mEq	1−3 mEq/kg/hr (titrate to pH)
Tranexamic acid			1 mL = 100 mg	Load: 10 mg/kg Maintenance: 1 mg/kg/hr
Vasopressin	100 units	100 mL	1 mL = 1 unit	Initial dose: 0.04 U/min, 2.4 U/hr Titrate: 0.005–0.01 U/min (0.3−0.6 mL/hr) every 10 min to max of 0.1 U/min or 6 U/hr

[a]There are 60 gtt/mL; therefore, gtt/min = mL/hr.
D_5W, dextrose 5% in water; EACA, ε-aminocaproic acid.

Nitroglycerin or nicardipine infusion is preferred. Sodium nitroprusside dilates both arterial and venous smooth muscle. It is very effective in reducing both preload and afterload. At high doses and prolonged duration, it may cause cyanide and thiocyanate toxicity. Because nitroprusside dilates the intramyocardial arterioles, intracoronary steal may occur. The solution has to be covered with aluminum foil to prevent decomposition from exposure to light. Nitroglycerin primarily causes venodilation, resulting in reduction of preload and myocardial oxygen consumption. At larger doses and by the IV route, it has mild arteriolar dilation and reduces afterload. It has no known toxicity and does not produce intracoronary steal because it dilates epicardial arteries. It may redistribute blood flow to the subendocardium and increase collateral circulation through the myocardium. Nicardipine is a systemic and coronary arterial dilator. The afterload is decreased, whereas the preload is not affected. It may cause a slight increase in HR (reflex tachycardia).

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:247–356.

C.II-15. *How much pump flow would you maintain during CPB? During hemodilution? During hypothermia?*

The pump blood flow is equivalent to cardiac output and to supply tissue oxygenation. The normal average cardiac output for adults is 70 mL/kg/min or 3.1 L/min/m^2. Seventy percent of normal cardiac output is usually enough to maintain tissue oxygenation. When body surface is used, both pediatric and adult patients require about the same pump flow—2.2 to 3.1 L/min/m^2. In summary, at normothermia and normal hemoglobin levels, the pump flow is as follows:

Adults 50 to 70 mL/kg/min	or 2.2 to 3.1 L/min/m^2
Children 100 to 150 mL/kg/min	or 2.2 to 3.1 L/min/m^2

Some perfusion teams, however, use low-flow (40 mL/kg/min), low-pressure (approximately 40 mmHg) bypass quite successfully. This technique has the advantages of less bleeding through intracardiac collaterals, less trauma to blood cells and platelets, and lower fluid requirement. It also, however, may lead to inadequate organ perfusion. Although there have been studies demonstrating good clinical results with low-flow and low-pressure techniques used in conjunction with hypothermia and hemodilution, the minimal safe flow rate during CPB has not been established.

$$\text{Oxygen delivery} = \text{cardiac output} \times \text{arterial oxygen content}$$

$$\text{Arterial oxygen content} = 1.34 \times \text{hemoglobin} \times O_2 \text{ saturation} + (0.003 \times Pa_{O_2})$$

Hemodilution reduces hemoglobin concentration and

hence decreases oxygen content. In order to deliver the same amount of oxygen, the pump flow has to be increased accordingly during hemodilution. For example, if the hematocrit is diluted from 40% to 20% during CPB, the pump flow has to be doubled (increased by a factor of 40 / 20 = 2). Clinically, both hypothermia and hemodilution are applied simultaneously so that the adjustment has to be done at the same time. For example, the pump flow for adults at a temperature of 30°C (86°F) and a hematocrit of 25% will be as follows:

50 to 70 mL/kg/min × 50% × 40/25 = 40 to 56 mL/kg/min

Hypothermia decreases oxygen consumption. Therefore, the pump flow may be decreased proportionally if the blood oxygen content does not change. The oxygen consumption at different body temperatures is listed in the following text:

Temperature (°C)	37	32	30	28	25	20	10
O_2 consumption (%)	100	60	50	40	25–30	20	10

Because the O_2 consumption at 30°C (86°F) is half of that at 37°C (98.6°F), the required pump flow at 30°C (86°F) is 50% of the flow at 37°C (98.6°F) (50 to 70 mL/kg/min). Therefore, a pump flow of 25 to 35 mL/kg/min is adequate for adults at 30°C (86°F) if there is no hemodilution. During profound hypothermia (10°C to 20°C [50°F to 68°F]), patients can usually tolerate total circulatory arrest without pump support for approximately 60 to 90 minutes. The decrease in metabolism during hypothermia is not a linear process. From 37°C to 30°C (98.6°F to 86°F), the metabolism decreases approximately 7% by each degree

centigrade. Below 30°C (86°F), the rate of metabolism decrease slows down. Usually, every 7°C to 8°C (44.4°F to 46.4°F) decrease in temperature reduces oxygen consumption by 50%. Clinically, it has been demonstrated that pump flows as low as 30 mL/kg/min or 1.2 L/min/m^2 will not compromise whole-body oxygen delivery when moderate systemic hypothermia is employed.

C.II-16. *How does blood viscosity change during hemodilution and hypothermia?*

Blood viscosity varies inversely with temperature; a 2% increase occurs for every 1°C (1.8°F) decrease in temperature. At a hematocrit of 40%, a decrease in temperature from 37°C to 27°C (98.6°F to 80.6°F) increases viscosity by approximately 25%. Hemodilution with balanced salt solution will decrease blood viscosity. Decreasing the hematocrit from 40% to 20% at 27°C (80.6°F) decreases viscosity by approximately 40%. It has been recommended that the hematocrit be adjusted to the same numerical value as the core body temperature in degree centigrade if blood viscosity is to be kept approximately constant. For example, normal viscosity at 37°C (98.6°F) with hematocrit of 40% approximates that seen at 25°C

(77°F) with hematocrit of 25%.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:395.

C.II-17. *How is anesthesia provided during CPB?*

Anesthesia is maintained with intermittent administration of IV propofol, benzodiazepines, narcotic, and/or inhalation agents through the pump oxygenator to achieve unconsciousness and analgesia, to control BP, and to prevent shivering. IV agents are diluted by the priming solution during CPB. Meanwhile, hypothermia itself produces anesthesia and prolongs the action of duration of IV agents by decreasing hepatic metabolism and urinary excretion.

Cardiac surgery patients are at increased risk for intraoperative awareness. Processed EEG monitors may reduce the incidence of awareness. However, these monitors have important limitations, such as unresponsiveness to certain hypnotic agents, interference artifacts, indices that are relatively unvarying, and cost-effectiveness. A large multicenter randomized trial by Avidan et al. demonstrated that the superiority of a processed EEG monitor such as the bispectral index is not established. Vigilance is required at all stages of anesthesia to prevent intraoperative awareness, especially in CPB during the rewarming phase.

Serfontein L. Awareness in cardiac anesthesia. *Curr Opin Anaesthesiol*. 2010;23(1):103–108.

C.II-18. *Would you give muscle relaxants during CPB? How is the action of muscle relaxants affected during CPB?*

Yes. Muscle relaxants are given to prevent diaphragmatic movement that interferes with surgery and to prevent shivering during hypothermia. Shivering may increase oxygen consumption to as high as 486% of normal. The effect of a muscle relaxant is altered by both hypothermia and hemodilution. The plasma concentration of muscle relaxants is diluted by the priming solution. Therefore, more relaxant is required to maintain the same degree of relaxation. Hypothermia does prolong the onset of paralysis. Moreover, hypothermic CPB per se facilitates neuromuscular transmission at the electrochemical level yet compromises mechanical contractility. The duration of action of rocuronium is prolonged by hypothermic CPB. Modifications of partial neuromuscular blockade by hypothermic bypass are the result of muscle relaxation enhancing or interfering with the impact of hypothermia on normal neuromuscular transmission. The best way to monitor muscle relaxation is by using a peripheral nerve stimulator.

C.II-19. *How do you know the patient is well perfused during CPB?*

If the perfusion pressure is maintained between 50 and 100 mmHg, and the pump-flow rate is adequately maintained according to the degree of hypothermia and hemodilution, there should be adequate urine output, greater than 1

mL/kg/hr, no metabolic acidosis, and normal mixed venous oxygen tension of 40 to 45 mmHg. However, cerebral perfusion is not routinely monitored, and the autoregulation range of BP may be higher than the normal range in the elder and high-risk patients. Cerebral oximetry should be used for patients with increased risk for neurologic and cognitive outcomes. It is recommended to keep cerebral oxygen saturation over 40%.

C.II-20. *How much gas flow would you use for the oxygenator? What kind of gas would you use? Why?*

Normal alveolar ventilation is 4 L per minute, and pulmonary circulation is 5 L per minute. That ratio is 0.8. The oxygenator is not as efficient as human lungs. Usually, 2 L of gas are used for each liter of pump-flow rate and then the gas flow rate is adjusted according to blood $Paco_2$ and Pao_2. The gas flow may be decreased if the $Paco_2$ is low and the Pao_2 is too high. The ratio may be increased if the $Paco_2$ is over 40 mmHg or the Pao_2 is under 100 mmHg. Meanwhile, air–

oxygen mixtures allow for better control of oxygen tension during CPB. It is not necessary to add CO_2 to the ventilating gas during hypothermia to elevate $PaCO_2$ and decrease the pH because α-stat regulation is used for acid–base management.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:97, 101.

C.II-21. *What are the disadvantages of hypocapnia during CPB?*

- Cerebral blood flow decreases approximately 2% to 4% for each mmHg decrease in $PaCO_2$ when $PaCO_2$ is in the range of 20 to 60 mmHg due to cerebral vasoconstriction. Cerebral O_2 saturation decreases approximately 1% for each mmHg decrease in $PaCO_2$.
- Respiratory alkalosis shifts the oxygen dissociation curve to the left, which increases the O_2 affinity to hemoglobin and decreases the release of O_2 to the tissues.
- Hypokalemia occurs because alkalosis shifts the potassium intracellular.
- Alkalosis decreases ionized calcium.

C.II-22. *How would you preserve the myocardium during CPB?*

The most popular and effective method of protecting the myocardium is to reduce myocardial oxygen demand by

hypothermia and cardioplegia. Hypothermia is induced by a combination of the following: (1) systemic blood cooling by heat exchangers in the oxygenator; (2) local application of cold saline solution or iced slush to the external surface and chambers of the heart (if the heart is open); (3) infusion of cold cardioplegic solution through the aortic root, venous grafts, retrograde coronary sinus, and/or coronary ostium to the coronary arterial tree. The myocardial temperature may be decreased to 10°C to 15°C (50°F to 59°F).

In addition to inducing hypothermia and cardioplegia, one may take the following measures before aortic cross-clamping:

- Avoid tachycardia or increased contractility by discontinuing pacing at rapid rate and discontinuing inotropes if they were utilized.
- Initiate rapid arrest (asystole).
- Utilize proper venting methods and ensure adequate venous drainage to the pump to avoid ventricular distention, which decreases subendocardial blood supply.
- Prevent and treat ventricular fibrillation, which increases oxygen demand in normothermic myocardium.
- Maintain adequate coronary perfusion pressure of at least 50 mmHg and greater than 70 mmHg in the presence of severe coronary disease or left ventricular hypertrophy.

C.II-23. *What is cardioplegia? How much would you use?*

Cardioplegic solution usually contains high concentrations of potassium (10 to 30 mEq per L) or magnesium (160 mEq per L) to arrest the heart. Cardioplegia reduces myocardial oxygen consumption and provides optimal conditions for surgery. Bicarbonate or tris(hydroxymethyl)-aminomethane (THAM) is usually added to raise the pH to levels between 7.40 and 7.80 to increase the intracellular shift of potassium and to decrease the metabolic acidosis from ischemia. Steroids, calcium, and procaine may be added to stabilize lysosomal and cell membranes. Glucose and insulin are added to provide energy and improve the intracellular shift of potassium. Nitroglycerin is added to dilate coronary vessels, resulting in better perfusion to the myocardium, including ischemic areas.

When blood cardioplegia is used, four parts of bypass blood are mixed with one part of cardioplegic solution. Blood cardioplegia seems to have several advantages over crystalloid cardioplegia. The heart is arrested while being oxygenated, so that adenosine triphosphate (ATP) is not depleted before asystole. Repeated infusions provide a source of oxygen and glucose for continued metabolism and ATP repletion. Although little oxygen is released from hemoglobin during hypothermia, enough is probably dissolved in the plasma to sustain metabolism when reinfusion is performed every 30 minutes. Buffering capacity is improved because of the presence of the histidine buffering system present in red blood cells. Myocardial edema is reduced because of the osmolarity of blood. The risk of calcium paradox following ischemia is reduced and functional recovery is improved because of the physiologic calcium concentration provided by blood. The presence of red blood cell enzyme catalase may scavenge free radicals

produced by ischemia. Capillary perfusion is improved and more homogeneous because of the presence of red blood cells. However, results of clinical studies in which blood cardioplegia was compared with crystalloid cardioplegia either detected no significant difference or showed that blood cardioplegia improved contractility late in the postoperative course. Multiple-dose cardioplegia is required for satisfactory results, whereas single-dose blood cardioplegia results in poor ventricular function.

Intermittent, continuous, or single infusions of cardioplegic solution have been used. Usually 300 to 600 mL of cold cardioplegic solution is needed to paralyze the myocardium and cool the myocardium to 10°C to 20°C (50°F to 68°F).

In the case of severe obstructive coronary lesions, antegrade infusion into the aortic root may cause poor distribution of the cardioplegia. Therefore, retrograde infusion through the coronary sinus into the coronary veins may be additionally employed to ensure homogeneous distribution of cardioplegia.

C.II-24. *The arterial blood gases and electrolytes during CPB are as follows: pH, 7.36; $PaCO_2$, 42 mmHg; PaO_2, 449 mmHg; CO_2 content, 24 mEq per L; sodium (Na), 128 mEq per L; potassium (K), 5.8 mEq per L; glucose, 180 mg/dL; and hematocrit, 20%. The patient's temperature is 27°C (80.6°F). At*

what temperature are blood gases measured? How would you correct the blood gases according to patient's body temperature? Would you treat the arterial blood gases at 37°C (98.6°F) or at patient's body temperature?

Blood gases are measured at a constant temperature of 37°C (98.6°F). They may be corrected according to body temperature. Each degree centigrade below 37°C (98.6°F) increases blood pH by 0.015. If pH is 7.40 at 37°C (98.6°F) in vitro, in vivo pH will be 7.55 at 27°C (80.6°F) body temperature ($7.40 + 0.015 \times [37 - 27] = 7.55$). The pH increases at lower temperatures because of increased pKa and decreased CO_2 tension from increased CO_2 blood solubility during hypothermia. In vivo Pa_{O_2} is decreased because of increased oxygen solubility during hypothermia. Nowadays, blood gases are measured at 37°C (98.6°F) and interpreted at 37°C (98.6°F) without correcting them to body temperature. The normal values of blood gases at 37°C (98.6°F) are as follows: pH, 7.40 ± 0.05; Pa_{CO_2}, 40 ± 5; and Pa_{O_2}, 95 ± 5. During hypothermia, the normal values of blood gases are not the same as those at 37°C (98.6°F). The same blood specimen has different P_{O_2} values when measured at different temperatures. Yet, the oxygen content remains unchanged. It is easier to calculate the oxygen content at 37°C (98.6°F) than at other temperatures where oxygen dissociation curves are shifted.

Optimal management of pH and Pa_{CO_2} for patients undergoing hypothermic CPB remains controversial. The two strategies for interpreting blood gases are the pH-stat (temperature-corrected) method and the α-stat (temperature-uncorrected) method. The pH-stat strategy aims at keeping

constant arterial pH at 7.40 and $PaCO_2$ at 40 mmHg at any given temperature. A $PaCO_2$ of 60 mmHg analyzed at 37°C (98.6°F) would be equivalent to a $PaCO_2$ of 40 mmHg if "corrected" for a body temperature of 27°C (80.6°F). The *α*-stat strategy aims at keeping a constant ratio of $[OH^-]:[H^+]$ at approximately 16:1. This is based on the premise that the pH of blood is regulated to keep the state of dissociation of the imidazole moiety (i.e., the alpha of imidazole) constant. Histidine, which contains the imidazole moiety, is an integral part of the active site of many enzyme systems. The function of enzyme systems has been shown to be optimal when the ratio of $[OH^-]:[H^+]$ is approximately 16:1. This ratio represents different pH values at different temperatures.

The differences between pH-stat and *α*-stat strategies are listed in **Table 5.2**. With the pH-stat strategy, the blood gas values are corrected to the patient's temperature; the patient is treated as a hibernating animal. With the *α*-stat strategy, the blood gas values are not corrected regardless of the patient's actual temperature; the patient is treated as a poikilotherm. Studies indicate that myocardial function is better preserved when the *α*-stat strategy is employed. Moreover, maintenance of cerebral blood flow autoregulation appears to remain intact with *α*-stat management, whereas flow becomes pressure dependent with pH-stat management. *α*-Stat blood gas management preserves cerebral blood flow-metabolism coupling such that hypothermic-induced decreases in metabolic rate are accompanied by proportionate decreases in cerebral blood flow. As a result, most medical centers use *α*-stat management of blood gases during hypothermic CPB. However, Bashein et al. found no difference in neuropsychological outcome between patients randomized to

α-stat versus pH-stat management.

TABLE 5.2 Different Hypothermic Acid–Base Regulatory Strategies

Strategy	Aim	Total CO_2 Content	pH and $PaCO_2$ Maintenance	Intracellular State	α-Imidazole and Buffering	Enzyme Structure and Function	C F C
pH-stat	Constant pH	Increases	Normal corrected values	Acidotic (excess H^+)	Excess (+) charge Buffering decreased	Altered and activity decreased	F n ? m u
α-Stat	Constant OH^-/H^+	Constant	Normal uncorrected values	Neutral (H^- = OH^-)	Constant net charge Buffering constant	Normal and activity maximal	F d (? m c

?, questionable.

Other studies have shown less decline in cognitive performance when α-stat management is used, especially in cases with prolonged CPB times. These data may support an embolic threshold above which recognizable neurologic injury occurs.

During deep hypothermic circulatory arrest, both animal and clinical studies have shown that pH-stat is associated with better neurologic outcome likely because of increased cerebral blood flow, leading to better brain cooling and greater cellular oxygen availability. In summary, most recent outcome studies support the utilization of α-stat for adult CPB and pH-stat for children under deep hypothermic circulatory arrest.

C.II-25. *How does the blood sugar level change during CPB? Why? What is optimal glucose control intraoperatively? Does hyperglycemia increase neurologic complications during CPB?*

Blood sugar levels are elevated during the perioperative period in patients undergoing cardiac surgery with the use of CPB. Hyperglycemia is most profound during hypothermic CPB, with approximately 100% of patients (diabetic and nondiabetic) achieving plasma glucose levels greater than 200 mg per dL. There are several reasons for this: First, the practice of making patients nothing by mouth (NPO) overnight induces a state of starvation, marked by peripheral resistance to insulin at the level of muscle and fatty tissues, therefore allowing glucose uptake by the brain. Second, sympathoadrenal activation, in response to surgical stress, also tends to induce a diabetogenic state. Third, active

cooling the body during bypass causes a profound reduction in insulin production, induces peripheral insulin resistance, and is associated with renal tubular impairment in glucose regulation. And lastly, use of dextrose-containing cardioplegia is a major contributor to intraoperative hyperglycemia. Of interest, postoperative hyperglycemia continues despite insulin administration and has been shown to remain above normal up to several weeks postoperatively. At the cellular level, the alterations in insulin receptor/resistance are very similar to that of type 2 diabetes. It is controversial whether hyperglycemia increases neurologic complications during CPB. Under conditions of limited cerebral oxygen delivery, anaerobic glucose oxidation becomes the primary method of ATP production, resulting in intracellular lactic acidosis. Hyperglycemia, by providing more glucose for anaerobic oxidation, increases the degree of intracellular acidosis, which, in numerous animal studies, correlates with the severity of subsequent injury.

Given the tendency of hyperglycemia during cardiac surgery, there have been several large-scale studies evaluating the question of how much of glycemic control is optimal during CPB. The first by Ouattara et al., an observational study of 200 consecutive diabetic patients undergoing cardiac surgery, demonstrated that poor intraoperative control of blood glucose concentrations was associated with an increased incidence of in-hospital morbidity, including neurologic, cardiovascular, infectious, respiratory, and/or renal complications. Based on these findings, “tight” glucose control had been recommended for all patients undergoing CPB. More recently, tight intraoperative glycemic control for all patients has come under scrutiny due to equivocal results in nondiabetic

patients, finding that tight glucose control intraoperatively either did not make a difference or was related to increased morbidity and mortality.

Butterworth et al. studied the effects of tight glucose control in 381 patients without diabetes undergoing isolated CABG surgery with one group receiving an insulin infusion for glucose levels above 100 mg per dL and the other group receiving no insulin. Although glucose levels were lower in the patients who received insulin infusions, there was no difference between the incidences of neurologic complications, mortality, need for inotropic support, or length of hospital stay between the groups.

Gandhi et al. studied the effects of strict glucose control in 400 CABG patients (20% diabetic) randomized to a continuous insulin group (glucose levels maintained between 80 and 100 mg per dL) and a conventional group (glucose <200 mg per dL) using boluses of insulin. They found no difference in number of deaths, hospital length of stay, sternal wound infections, prolonged ventilation, cardiac arrhythmias, strokes, or renal failure within 30 days of surgery. There was a tendency for more deaths and strokes in the intensive insulin group.

As a result of these studies, the STS revised guidelines in 2009 state that glycemic control is best achieved with the use of an insulin drip (Level A) and diabetic patients should receive insulin infusions intraoperatively (Level B). However, insulin infusions are not necessary intraoperatively for patients without diabetes for glucose levels <180. These patients can be treated initially with an IV insulin bolus. However, an insulin infusion should be instituted (Level B) in those patients with persistently elevated serum glucose levels (>180 mg per dL) after CPB.

Most recently, the focus has shifted to evaluating glucose

variability, with increased variability being linked to conditions such as postoperative atrial fibrillation, acute kidney injury, and intensive care unit (ICU) length of stay.

C.II-26. *What are the effects of CPB on platelet and coagulation factors?*

Platelet dysfunction and thrombocytopenia occur during and after CPB. The level of coagulation factors decreases at the beginning of bypass due to hemodilution; surface absorption by the plastic, glass, and metal; and protein denaturation induced by the blood–gas interface. Transient defects in platelet plug formation and aggregation are seen in all patients placed on CPB. It is important to rule out bleeding due to insufficient heparin reversal and/or surgical bleeding; however, after those causes have been excluded, platelet dysfunction is the most common cause of bleeding issues after CPB. Platelet function generally returns to near-normal

status 2 to 4 hours following CPB. The dysfunction is exacerbated and prolonged by medications such as aspirin and platelet glycoprotein GPIIb/IIIa inhibitors (clopidogrel, tirofiban).

Platelet counts fall more with the bubble-type oxygenator than with the membrane-type oxygenator but rarely below the levels clinically required for hemostasis. Thrombocytopenia is mainly caused by hemodilution, aggregation, adhesion, and the adenosine diphosphate–release reaction induced by the foreign surfaces and the blood–gas interface. Membrane oxygenators cause few changes in clotting factors.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:433–445.

C.II-27. *If the blood level of the venous reservoir is low, what would you replace it with? Blood or balanced salt solution?*

The hematocrit should be maintained around 18% to 20% during hemodilution. If the hematocrit decreases below 18%, blood is added to the CPB circuit. If the hematocrit is above 20%, a balanced salt solution is added to the oxygenator. Hematocrit values in the range of 15% to 18% appear to be well tolerated clinically. When cerebral oxygen saturation (rSO_2) decreases to more than 20% baseline, packed red blood cells are used to improve oxygen-carrying capacity. When rSO_2 is within 20%, the patient has acceptable cerebral oxygenation, even if the hematocrit is below 18%.

C.II-28. *How do you estimate the fluid balance during CPB?*

All IV lines are turned off during CPB. The input consists of the decreased blood level in the oxygenator and the cardioplegic solution, fluid or blood added to the oxygenator during CPB. The output consists of the increased blood level in the oxygenator and urine.

C.II-29. *For how long a period can the aorta be cross-clamped?*

The limits of "safe" ischemic time during aortic cross-clamping are between 15 and 45 minutes. This can be increased to as much as 240 minutes in animal models with normal ventricular function when cardioprotective strategies are employed, such as intermittent hypothermic blood cardioplegia, initiation of rapid arrest, and left ventricular venting. However, many patients have preoperative ventricular dysfunction and the protection from hypothermic cardioplegia may not be optimal due to coronary artery obstruction. Clinically, the aorta may be safely cross-clamped for 60 to 120 minutes without perfusion. The myocardial function will be better the shorter the cross-clamping time.

Nissinen et al. evaluated the impact of prolonged CBP and aortic cross-clamp times (XCT) in 3,280 patients undergoing adult cardiac surgery, with myocardial protection provided

by continuous anterograde and retrograde cardioplegia. They found that XCT greater than 150 minutes and bypass times greater than 240 minutes were both associated with higher 30-day mortality (1.8% vs. 12.2% for increased XCT and 1.9% vs. 31.5% for CPB). Both increased XCT and CBP times also correlated significantly to increased transfusion of blood products, hospital length of stay, time to extubation, and postoperative morbidity such as stroke.

Salis S, Mazzanti VV, Merli G, et al. Cardiopulmonary bypass duration is an independent predictor of morbidity and mortality after cardiac surgery. *J Cardiothorac Vasc Anesth*. 2008;22(6):814–822.

C.II-30. *Why does the urine turn pink in some cases of CPB? What is the renal threshold for plasma hemoglobin?*

Pink urine is a sign of massive hemolysis. Hemolysis is mainly associated with the negative pressures generated by the suction apparatus and is associated to a lesser degree with the action of the pumps and/or with the gas–blood interface effects in the oxygenator. The renal threshold for hemoglobin is 100 to 150 mg per 100 mL. It is advisable to maintain a high output of alkaline urine to prevent possible tubular damage from acid hematin crystals, which are converted from hemoglobin.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:104, 548.

C.II-31. *Why does it take longer to rewarm than to cool the patient via the pump oxygenator?*

It usually takes 5 to 10 minutes to cool the patient from 37°C to 25°C (98.6°F to 77°F) of average body temperature,

whereas it takes 20 to 40 minutes to rewarm the patient from 28°C to 35°C (82.4°F to 95°F). The speed of heat exchange by the bloodstream depends on the temperature gradient between venous blood and water in the heat exchanger, the pump blood-flow rate, and the water-flow rate of the heat exchanger. The initial venous blood temperature is 37°C (98.6°F), and the water temperature of the heat exchanger is 0°C to 4°C (32°F to 39.2°F) during cooling, creating a temperature gradient of 34°C to 37°C (93.2°F to 98.6°F). During rewarming, the water temperature is limited to 42°C (107.6°F) or less to prevent denaturation and destruction of blood proteins. The temperature gradient is limited to 10°C (18°F) or less to prevent gas embolism from a decrease of gas solubility in the blood associated with a sharp increase in temperature. The heat exchanger water flow does not differ much during cooling and rewarming. However, the pump blood flow is usually maintained to a very high level during the initial cooling because of low BP in the beginning of cooling. During rewarming, the pump blood flow is frequently maintained at a low level because the BP is usually high and the body temperature is still low. Rewarming may be accelerated by administering inhalation anesthetics, or employing vasodilators, to decrease vascular resistance and thereby increase pump flow to maintain the same BP. Because the increased vascular resistance is usually due to inadequate anesthesia during rewarming, inhalation anesthetics are preferred over vasodilators in patients with good ventricular function. In cases of poor ventricular function, inhalation agents are avoided because of the potential cardiac depression after CPB.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:547–548.

C.II-32. *At what temperature can the patient be weaned from CPB?*

An esophageal or nasopharyngeal temperature of 37°C (98.6°F) and a rectal or bladder temperature at least 35°C (95°F) must be reached before the patient can come off the pump. After discontinuation of the pump, surface warming should be continued in pediatric patients to prevent hypothermia owing to redistribution of heat in the body. However, in adults, the use of warming blankets and warmed humidified airway gases has not been found beneficial in preventing the expected temperature "after drop." Esophageal or nasopharyngeal temperature usually will decrease and rectal or bladder temperature will increase during heat redistribution.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:603.

C.II-33. *How would you defibrillate the heart internally during CPB?*

The heart is defibrillated internally by a direct current (DC) defibrillator, with 5 to 10 watt-seconds (joules). If the heart remains in ventricular fibrillation, blood gases, electrolytes, and temperature are rechecked and lidocaine, 1 to 2 mg per kg, is administered before repeated DC defibrillation attempts. MAP is usually increased to 80 mmHg. Amiodarone is occasionally added to treat intractable ventricular fibrillation.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1291–1312.

C.II-34. *If the HR is 40 beats per minute, what should you*

do?

A temporary AV block is often found at the end of bypass because of potassium cardioplegia and the ischemic insult that occurs during aortic cross-clamping. Although atropine may be theoretically administered to treat sinus or nodal bradycardia, a temporary epicardial pacemaker is usually employed. Atrial pacing is preferred because of improved cardiac output when the atrial kick is preserved. Ventricular pacing is necessary if there is complete AV block. AV sequential pacing is indicated when ventricular pacing does not provide adequate cardiac output.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1291–1312.

C.II-35. *How would you prepare for termination of CPB?*

Before termination of CPB, cardiac and pulmonary function must be optimized. To ensure that all important steps are not inadvertently omitted, the patient and all monitors should be carefully checked. The mnemonic LAMPS for Laboratory data, Anesthesia machine, Monitors, Patient (Pump), and Support is one useful approach.

Laboratory Data

- Arterial pH, P_{CO_2}, P_{O_2} within normal limits
- Hematocrit—20% to 25%
- K^+—4.0 to 5.5 mEq per L
- Ionized calcium 1.1 to 1.2 mmol per L
- Pump mixed venous O_2 saturation greater than 70%

Anesthesia Machine

- Anesthesia machine functional
- Adequate depth of anesthesia

Monitors

- ECG—stable rate and rhythm (use pacing if necessary)
- Systemic BP restored to normothermic levels
- PA catheter functional
- Transducers zeroed and calibrated
- TEE out of freeze mode
- Nasopharyngeal/PA catheter temperature 36°C to 37°C (96.8°F to 98.6°F)
- Bladder/rectal temperature greater than 35°C (95°F)

Patient/Pump

- The heart—contractility, size, rhythm, and air removed
- The lungs—atelectasis minimized, fluid in thoracic cavities drained, ventilation reinstituted

Support

- Inotropes/vasopressors/vasodilators
- IABP if needed

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:603–620.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1291–1312.

C.II-36. *How would you decide the need for inotropic support?*

The need for inotropic support after CPB is usually assessed by the following (**Fig. 5.9**):

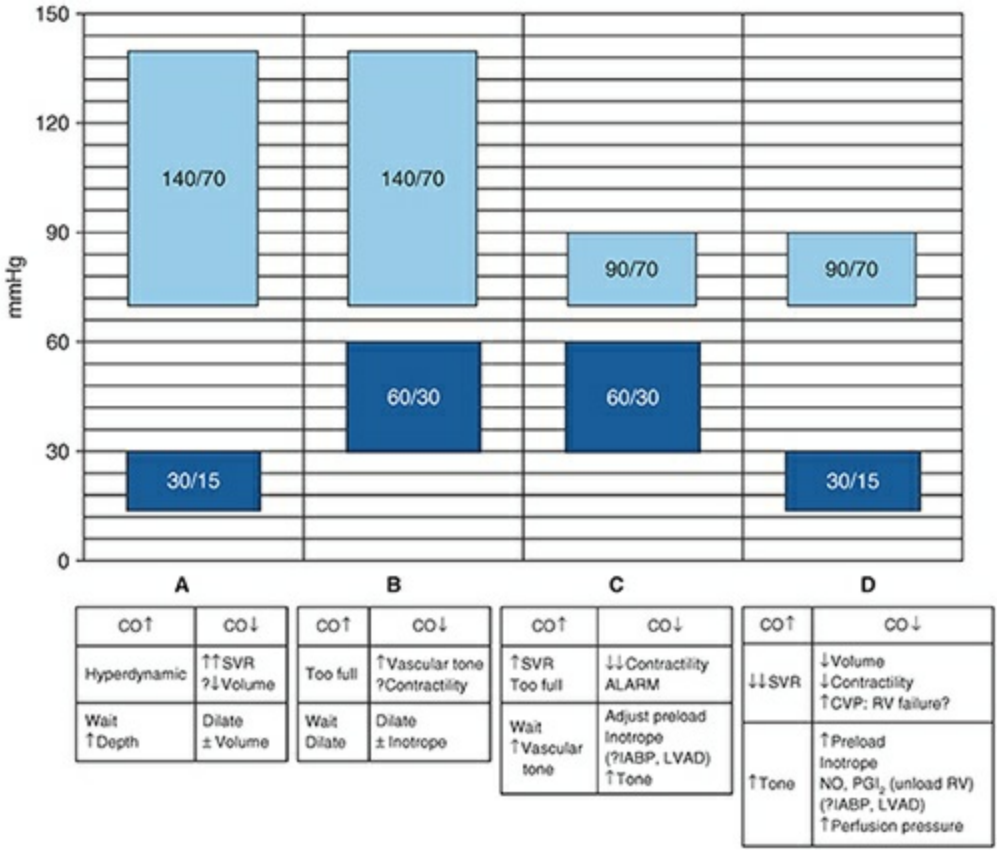

FIGURE 5.9. Hemodynamic management during weaning from CPB. The hemodynamic evaluation is performed by combining information from the systemic *(light shade boxes)* and pulmonary *(dark shade boxes)* arterial pressures. **A.** A combination of elevated systemic arterial and low pulmonary arterial pressure suggests either a hyperdynamic cardiac function (if cardiac output is high) or a vasoconstrictive state (if the peripheral vascular resistance is high). **B.** If systemic hypertension is accompanied by pulmonary hypertension, then either the volume status is elevated (if cardiac output is high) or there is generalized vasoconstriction (if cardiac output is decreased). **C.** In case of systemic hypotension and pulmonary hypertension, the cardiac output may be high (systemic vasodilation) or low (depressed contractility, requiring immediate intervention). **D.** When both systemic and pulmonary pressures are decreased, there is either vasodilation (if the cardiac output is high) or hypovolemia or depressed contractility or right-sided failure is suspected (if cardiac output is decreased). The relative treatment for each hemodynamic derangement is shown in the table. CO, cardiac output; CVP, central venous pressure; IABP, intra-aortic balloon pump; LVAD, left ventricular assist device; NO, nitric oxide; PGI_2, prostacyclin; RV, right ventricle; SVR, systemic vascular resistance; ↑, increase; ↑↑, marked increase; ?, questionable.

- Preoperative ventricular function (ejection fraction)
- Effectiveness of intraoperative myocardial protection
- Adequacy of surgical repair
- Duration of aortic cross-clamping and CPB
- Patient's age

If left ventricular ejection fraction is predicted to be 25% to 35%, milrinone infusion may be added. Norepinephrine infusion is usually needed during milrinone therapy. Generally, IABP is also employed when left ventricular ejection fraction is predicted to be below 25%. The choice of vasoactive and cardioactive agents used is frequently center- and/or physician-specific and is initiated either pre-bypass or while coming off bypass.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1291–1312.

C.III. After Cardiopulmonary Bypass

C.III-1. *How would you reverse heparin? How much protamine would you use? What are the other drugs used to neutralize heparin?*

It has been recommended that 1 mg of protamine sulfate is needed to reverse each 100 units of remaining heparin calculated by ACT dose-response curve or protamine titration test. Protamine, 1 mg, is given to reverse each 100 units or 1 mg of heparin initially administered. Only the initial dose of heparin is counted. Subsequently added doses of heparin, to keep the ACT level above 480 seconds, are not considered due to heparin's metabolism and elimination. The ACT test is repeated 10 minutes after the administration of protamine. ACT usually returns to its control level. If the ACT is still prolonged, additional protamine is given according to the ACT dose-response curve. The ACT is affected, however, by dilution and by hypothermia. Dose-response curves utilizing data obtained during hypothermia may be misleading. In addition, severe thrombocytopenia

also prolongs the ACT because clot formation using the ACT depends on platelet phospholipid surface. Of note, Bolliger and colleagues suggest that an increase in bleeding may occur paradoxically from "extra" protamine administration.

Other drugs that have been used to neutralize heparin include platelet factor 4 (PF4), heparinase, protamine variants, hexadimethrine bromide (Polybrene), and toluidine blue. Human or recombinant PF4 has been used in animals and humans to reverse heparin and does not cause systemic arterial hypotension, or pulmonary hypertension, or changes in white blood cell count, platelet count, or complement levels. Heparinase neutralizes heparin by enzymatic cleavage of α-glycoside linkages at AT III binding site. Heparinase is an effective antagonist of heparin and has minimal effects on platelets, whereas protamine markedly inhibits platelet responsiveness. It appears to be a potential alternative to protamine.

Lastly, reversal for low molecular weight heparin compounds does not exist, but a recombinant antithrombin variant was shown to be a potent antidote to fondaparinux and other heparin derivatives.

Bolliger D, Szlam F, Azran M, et al. The anticoagulant effect of protamine sulfate is attenuated in the presence of platelets or elevated factor VIII concentrations. *Anesth Analg*. 2010;111(3):601–608.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:498–500.

Nielsen VG, Malayaman SN. Protamine sulfate: crouching clot or hidden hemorrhage? *Anesth Analg*. 2010;111(3):593–594.

C.III-2. *What is the action mechanism of protamine?*

Heparin is a strong organic acid (polyanion). Protamine is a

strong organic base (polycation). They combine ionically to form a stable salt and lose their own anticoagulant activity. Protamine contains two active sites: one that neutralizes heparin and another that exerts a mild anticoagulant effect independent of heparin.

Gravlee GP, Davis RF, Hammon J, et al, eds. *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2016:497–498.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1248–1290.

C.III-3. *What are the complications of too much protamine?*

Protamine itself is an anticoagulant. Protamine administered intravenously in the absence of heparin interacts with platelets and with clotting proteins. It induces transient thrombocytopenia in humans. Platelet aggregation is impaired by the protamine–heparin complex, although protamine alone has no deleterious effects on platelet aggregation. Protamine may bind to thrombin and inhibit thrombin's ability to convert fibrinogen to fibrin.

Bolliger D, Szlam F, Azran M, et al. The anticoagulant effect of protamine sulfate is attenuated in the presence of platelets or elevated factor VIII concentrations. *Anesth Analg*. 2010;111(3):601–608.

Nielsen VG, Malayaman SN. Protamine sulfate: crouching clot or hidden hemorrhage? *Anesth Analg*. 2010;111(3):593–594.

C.III-4. *What is a protamine reaction? How can you prevent this condition? How do you treat it?*

Three different types of circulatory reactions to protamine reversal of heparin have been proposed by Horrow:
Type I: Systemic Hypotension from Rapid Injection: A

Predictable Pharmacologic Reaction

Type II: Anaphylactic or Anaphylactoid Reaction

- Antibody-mediated
- Immediate anaphylactoid response without antibody involvement
- Delayed anaphylactoid response (noncardiac pulmonary edema)

Type III: Catastrophic Pulmonary Vasoconstriction with Systemic Hypotension

Etiologically, however, there are only two types of reaction: (1) pharmacologic side-effect reactions and (2) idiosyncratic reactions. Therefore, an alternative classification was proposed by Lowenstein as follows:

- Pharmacologic histamine release
- True anaphylaxis (immunoglobulin E–mediated)
- Anaphylactoid reactions
  - Pulmonary vasoconstriction
  - Noncardiogenic pulmonary edema

Mild-to-moderate systemic hypotension from pharmacologic side effects is almost always the reaction seen when protamine is given rapidly or is given to patients who are relatively hypovolemic and vasoconstricted. Because it can be elicited in most patients, it is classified as a pharmacologic side effect, not an idiosyncratic reaction. This side effect is possibly mediated by histamine and is characterized by venodilation, reduced cardiac filling pressures, and decreased vascular resistance. Mild cardiac depression by protamine is suggested but probably does not occur. This type of hypotension can be corrected by rapid volume administration from the CPB pump while the arterial cannula is in place and by administration of phenylephrine in 0.1-mg increments. There have been many attempts to modify the hypotensive response (e.g., intra-aortic or left

atrial administration, protamine pretreatment), with little evidence of predictable success. Only slower rates of IV infusion over 5 to 10 minutes and simultaneous maintenance of an adequate blood volume have been shown to decrease the incidence of hypotension.

Anaphylactic or anaphylactoid reaction is uncommon and rarely seen in infants and children. The reaction varies from mild skin flushing and urticaria to severe vascular collapse. Systemic hypotension is usually accompanied by low pulmonary arterial pressure and low right-sided and left-sided filling pressures. This type of hypotension may be treated and prevented with rapid volume infusion and administration of vasoconstrictors. The use of antihistamines and steroids is commonly employed by many cardiovascular anesthesiologists with few, if any, existing data supporting this practice. There are several unanswered questions such as: When should these agents be given? What dose to give? Which agent?

Diabetic patients taking neutral protamine Hagedorn (NPH) insulin may develop antibodies to protamine and would appear to be at increased risk. However, clinical reactions do not predictably occur in these patients. Suspected cross-sensitivity in cases of fish allergy or autosensitization in men after vasectomies does not seem to put most patients at increased risk.

Catastrophic pulmonary hypertension occurs in approximately 0.2% to 4.0% of patients. Several-fold increases in PA pressure leads to right ventricular failure, elevated CVP, low flow across the pulmonary circuit, and low left atrial pressure. Elevated plasma levels of C5a anaphylatoxins and thromboxane are responsible for pulmonary vasoconstriction and accompanied bronchoconstriction. Epinephrine in 0.1-mg increments has

been successfully used. If severe hypotension persists, the patient should be heparinized again and return to bypass to maintain circulation. Slowing the rate of protamine infusion results in a proportional attenuation of the response (**Figs. 5.10** and **5.11**).

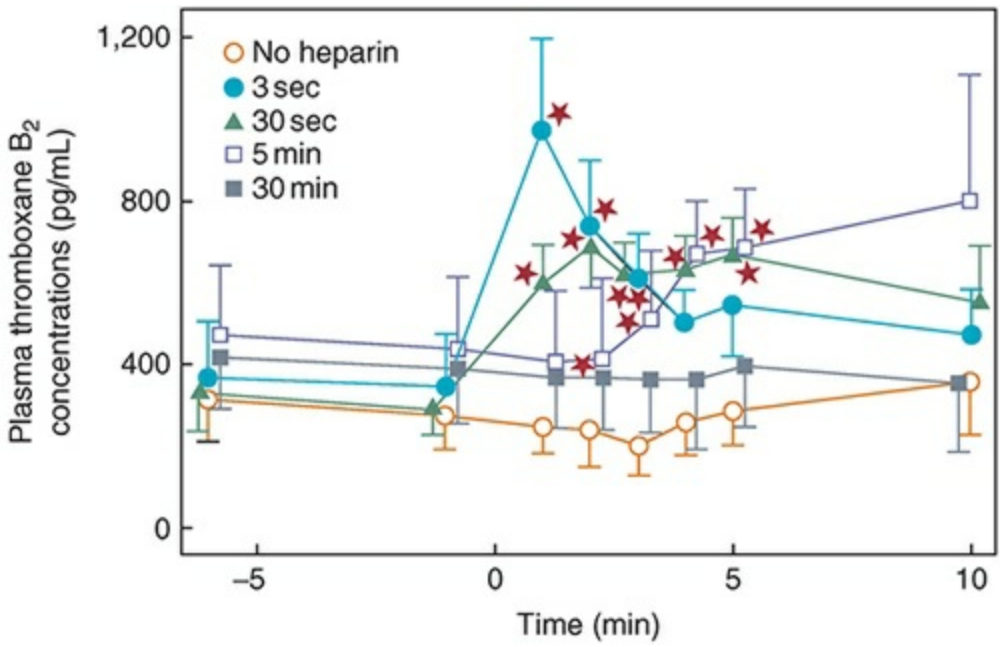

FIGURE 5.10. Plasma thromboxane B_2 concentrations before and after administration of protamine infused over 3 seconds, 30 seconds, 300 seconds, and 30 minutes. Heparin is injected at 5 minutes; protamine infusion is started at 0 minute. Data points represent mean ± *SE* values; n = 6 in each group ($P < .05$ from unheparinized group). (*Reprinted with permission from Morel DR, Costabella PM, Pittet JF. Adverse cardiopulmonary effects and increased plasma thromboxane concentrations following the neutralization of heparin with protamine in awake sheep are infusion rate-dependent.* Anesthesiology. *1990;73:415–424.*)

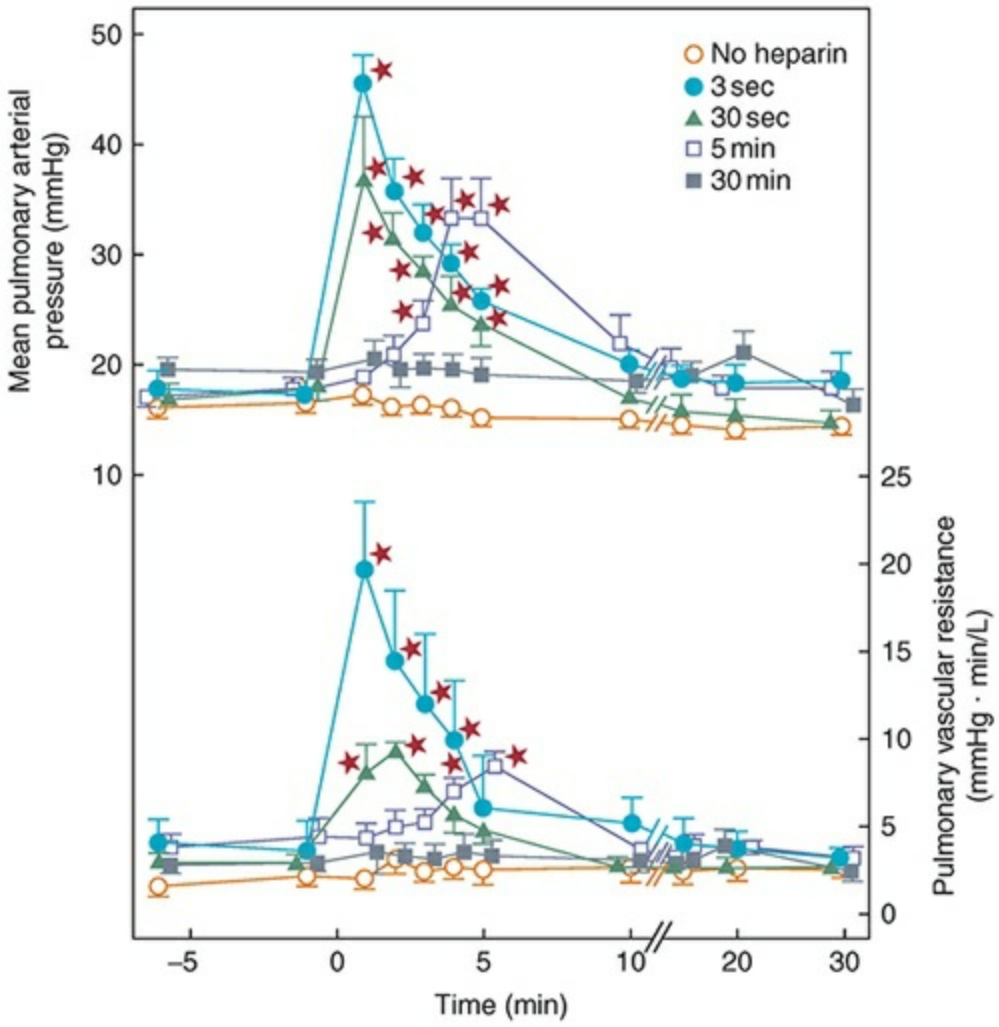

FIGURE 5.11. Pulmonary hemodynamics before and after administration of protamine infused over 3 seconds, 30 seconds, 300 seconds, and 30 minutes. Heparin is injected at 5 minutes; protamine infusion is started at 0 minute. Data points represent mean ± *SE* values; n = 6 in each group (*red star*, $P < .05$ from unheparinized group). (*Reprinted with permission from Morel DR, Costabella PM, Pittet JF. Adverse cardiopulmonary effects and increased plasma thromboxane concentrations following the neutralization of heparin with protamine in awake sheep are infusion rate-dependent.* Anesthesiology. *1990;73:415–424.*)

In conclusion, the treatment of hypotension after protamine administration depends on pulmonary arterial pressure. Hypotension with low pulmonary arterial pressure may be corrected with rapid volume infusion and vasoconstrictors, whereas hypotension with high pulmonary arterial pressure should be treated with inotropes that have a vasodilatory effect. The only effective prevention is a slow

infusion of diluted protamine solution.

C.III-5. *What are the indications for intra-aortic balloon pump (IABP)?*

IABP is primarily used for pump failure and myocardial ischemia not responsive to maximal pharmacologic support. The indications include the following:

Ischemic Heart Disease

- Cardiogenic shock
- Acute MI
- Mechanical defects: ventricular or septal rupture, acute mitral insufficiency, or ventricular aneurysm
- Continued ischemic pain and extension of infarction
- Refractory ventricular arrhythmias
- During cardiac catheterization
- Failed PCI and awaiting CABG
- Acute mitral insufficiency with CHF

Cardiac Surgery

- Before CPB and postoperatively
- After CPB: low output syndrome

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed.

Philadelphia, PA: Elsevier; 2017:1042–1063, 1291–1312.

C.III-6. *What are the principles of IABP?*

IABP counterpulsation is designed to increase the myocardial oxygen supply during diastole and to decrease myocardial oxygen demand during systole (Fig. 5.12). The balloon is inflated during diastole to increase the DAP, resulting in increased coronary blood flow. The balloon should be inflated immediately following the closure of the aortic valve at the dicrotic notch of arterial tracing. The balloon is deflated just before the next systole to decrease the intra-aortic pressure and afterload, resulting in decreased myocardial oxygen consumption. The cardiac output is increased because of increased coronary perfusion (diastolic augmentation) and decreased resistance (systolic unloading).

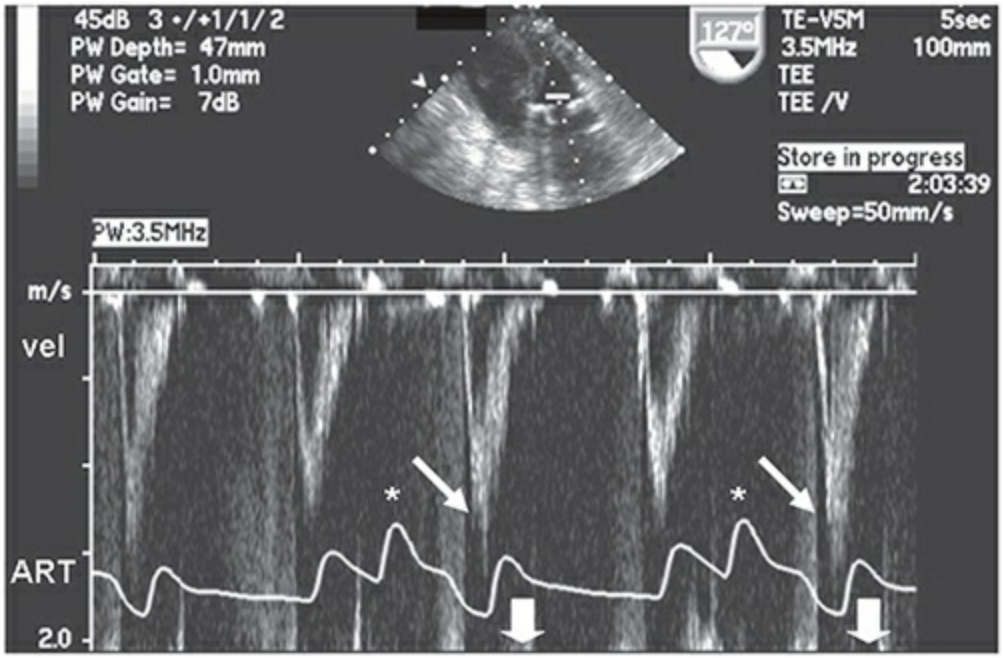

FIGURE 5.12. The function of the intra-aortic balloon pump (IABP). In this patient with an IABP in place, the velocity (vel) of the blood flow, as it exits the left ventricle (LV), is recorded. The arterial waveform is shown in the following text. The IABP is set on a 1:2 ratio; that is, it inflates every other beat, in diastole *(asterisks)*. The velocity (and the amount) of blood exiting the LV is increased *(diagonal arrows)* after the diastolic inflation of the IABP because the LV is ejecting against lower systemic resistance. This is the reason that the systolic arterial pressure following IABP inflation is lower *(down arrows)*.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1042–1063, 1291–1312.

C.III-7. *What are the complications of IABP?*

- Lower extremity ischemia
- Aortic dissection
- Thrombus formation and embolization
- Renal artery occlusion
- Splenic, mesenteric, and spinal cord infarction
- Internal mammary occlusion
- Thrombocytopenia
- Infection
- Gas embolization
- Retroperitoneal bleeding
- Arterial–venous fistula

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1042–1063, 1291–1312.

D. Postoperative Management

D.1. Would you reverse the muscle relaxants? Why?

It depends. If fast-track extubation is planned, reversal agent can be given to ensure that the patient does not experience paralysis while awake. It may be advisable to continue a short-acting sedative/hypnotic agent such as propofol or dexmedetomidine during transport to the ICU and for the immediate period required to establish criteria for extubation. Muscle relaxants should remain in patients who are hemodynamically unstable, with profound hypoxemia (acute respiratory distress syndrome) and/or "open" chest until the clinical state has improved. However, it is important to recognize that prolonged paralysis can lead to marked skeletal myopathy.

Djaiani G, Silverton N, Fedorko L, et al. Dexmedetomidine versus propofol sedation reduces delirium after cardiac surgery: a randomized controlled trial. *Anesthesiology*. 2016;124(2):362–368.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1313–1326.

D.2. When will you wean the patient from the ventilator?

Ventilator management, weaning strategy, and extubation time vary significantly among centers practicing cardiac surgery. Historically, patients were weaned from the respirator the following morning after surgery. More recently, if the operative course is smooth and if the patient is hemodynamically stable, weaning and extubation can be performed early (usually 2 to 6 hours after surgery).

Early tracheal extubation (fast-track) after CABG surgery may have cost benefits and improvement in resource utilization when compared with delayed tracheal extubation. In one report by Cheng et al., early tracheal extubation 1 to 6 hours after surgery reduced total cost per CABG surgery by 25% without increasing the rate or costs of complications in patients younger than 75 years.

Cheng DC, Karski J, Peniston C, et al. Early tracheal extubation after coronary artery bypass graft surgery reduces costs and improves resource use. A prospective, randomized, controlled trial. *Anesthesiology*. 1996;85:1300–1310.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1358–1373.

D.3. What criteria would you use in deciding when to wean the patient from the ventilator?

- Consciousness—awake and alert
- Stable vital signs
- Acceptable arterial blood gases—pH, 7.35 to 7.45; Pa_{O_2}, over 80 mmHg with F_{IO_2}, 0.4; Pa_{CO_2}, 35 to 45 mmHg

- Acceptable respiratory mechanics
- Vital capacity greater than 10 to 15 mL per kg
- Maximal inspiratory force—greater than 20 to 25 cm H_2O
- Hemostasis—less than 100 mL per hour of chest tube drainage
- Stable metabolic state—normal temperature and electrolytes

The patient should tolerate being on continuous positive airway pressure of 5 cm H_2O and pressure support of 5 cm H_2O with 40% oxygen. If the patient tolerates the continuous positive airway pressure well for 30 minutes and arterial blood gases are acceptable, the patient may be extubated.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1358–1373.

D.4. What are potential postoperative complications?

Cardiovascular

CHF, arrhythmias, low output syndrome, myocardial ischemia or infarction due to surgical manipulation, prolonged CPB and aortic cross-clamp (coronary ischemia), use of cardioplegic solution, and occlusion or kinking of grafts.

Pulmonary

Acute lung injury or adult respiratory distress syndrome due to the following:

- Decreased blood flow to the lung during total CPB
- Collapsed alveoli during CPB, resulting in decreased surfactant and decreased distensibility
- Fluid overload
- Hyperoxia during CPB
- Left ventricular failure
- Microemboli
- Reperfusion injury

- Inflammatory response
- Infections
- Transfusion-related lung dysfunction

Renal

- Polyuria from hemodilution and diuretics
- Oliguria from hypoperfusion
- Acute kidney injury
  - Hypoperfusion
  - Ischemia
  - Inflammatory response
  - Nephrotoxins (preoperative contrast dyes, antibiotics)
- Acute tubular necrosis
- Acute or chronic renal insufficiency

Hemorrhage

- Too much or too little protamine to reverse heparin
- Thrombocytopenia and decreased coagulation factors
- Qualitative and quantitative platelet defect
- Disseminated intravascular coagulopathy
- Fibrinolysis with low levels of fibrinogen
- Poor surgical hemostasis

Embolism: due to air, destroyed or aggregated formed blood elements, fat, endogenous and exogenous debris

Neurologic: stroke and neurocognitive dysfunction marked by functional changes in behavior, personality, or other brain functions; cerebral embolism; and seizures

Hyperglycemia: hypothermia, dextrose-containing cardioplegia, increased catecholamine levels, and diabetogenic state associated with surgery and CPB

Hypokalemia: due to hemodilution, alkalosis, and diuretics

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia for Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:1327–1357.

6 Mechanical Circulatory Support

Lisa Q. Rong, Mudit Kaushal, and Adam D. Lichtman

A 58-year-old man is scheduled to undergo an upper gastrointestinal (GI) endoscopy under monitored anesthesia care (MAC). The patient underwent aortic and mitral valve replacement for aortic stenosis and mitral regurgitation 4 weeks earlier, and the procedure was complicated by postcardiotomy cardiogenic shock. He was unable to separate from cardiopulmonary bypass (CPB) after maximum vasopressor support and emergent placement of an intra-aortic balloon pump (IABP). He was finally able to separate from bypass after initiation of extracorporeal membrane oxygenation (ECMO) support. Over the next several days, the patient's cardiac function did not recover, and he was brought back to the operating room for placement of a left ventricular assist device (LVAD).

A. Medical Disease and Differential Diagnosis

A.1. What is an IABP?

An IABP is a device used to improve the function of a failing heart. It is an 8.5 to 9.5 French dual-lumen catheter with a 40- to 60-mL helium-filled balloon attached at its tip. The IABP provides counterpulsation, whereby the systolic afterload to cardiac ejection is reduced and the perfusion of the coronaries and proximal aortic arteries is augmented.

Kapur NK, Esposito M. Hemodynamic support with percutaneous devices in patients with heart failure. *Heart Fail Clin*. 2015;11:215–230.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24:335–341.

A.2. How is an IABP placed and positioned?

The IABP is placed either percutaneously or under surgical exposure into a large peripheral artery (most commonly femoral) and directed retrograde into the thoracic aorta over a wire. The volume of the balloon used is dictated by the height of the patient (50-mL balloons being most common). The optimal position is with the tip of the balloon positioned just distal to the origin of left subclavian artery and the proximal end of the balloon before the orifice of the renal arteries. IABP positioning is performed either blindly, with subsequent verification of its location with fluoroscopy/x-ray or under the guidance of transesophageal echocardiography (TEE). Incorrect placement

may cause obstruction of the cerebral or visceral vessels, which may result in possible cerebral or visceral organ ischemia and an ineffective counterpulsation. During IABP support, the patient is usually anticoagulated.

Klopman MA, Chen EP, Sniecinski RM. Positioning an intraaortic balloon pump using intraoperative transesophageal echocardiogram guidance. *Anesth Analg*. 2011;113:40–43.

A.3. Describe an IABP inflation and deflation timing.

The balloon is connected to a control console that regulates the inflation and deflation of the balloon at the tip of the IABP. The IABP balloon is inflated in diastole and deflated in systole. The triggers for balloon inflation are (1) the electrocardiogram (ECG) T wave; (2) the dicrotic notch on the arterial waveform, which is recorded from the tip of the IABP; and (3) an internal, predetermined ratio. The balloon deflation is timed to occur prior to the ECG Q wave or the upstroke of the arterial line waveform (**Fig. 6.1**). Improper IABP timing reduces its effectiveness and will increase myocardial oxygen consumption. Examples of this include the following:

- Early inflation: inflation of the IABP before aortic valve closure (**Fig. 6.2A**)
- Late inflation: inflation of the IABP after the closure of the aortic valve (**Fig. 6.2B**)
- Early deflation: premature deflation of the IABP during the diastolic phase (**Fig. 6.2C**)
- Late deflation: deflation of the IABP after the onset of systole (**Fig. 6.2D**)

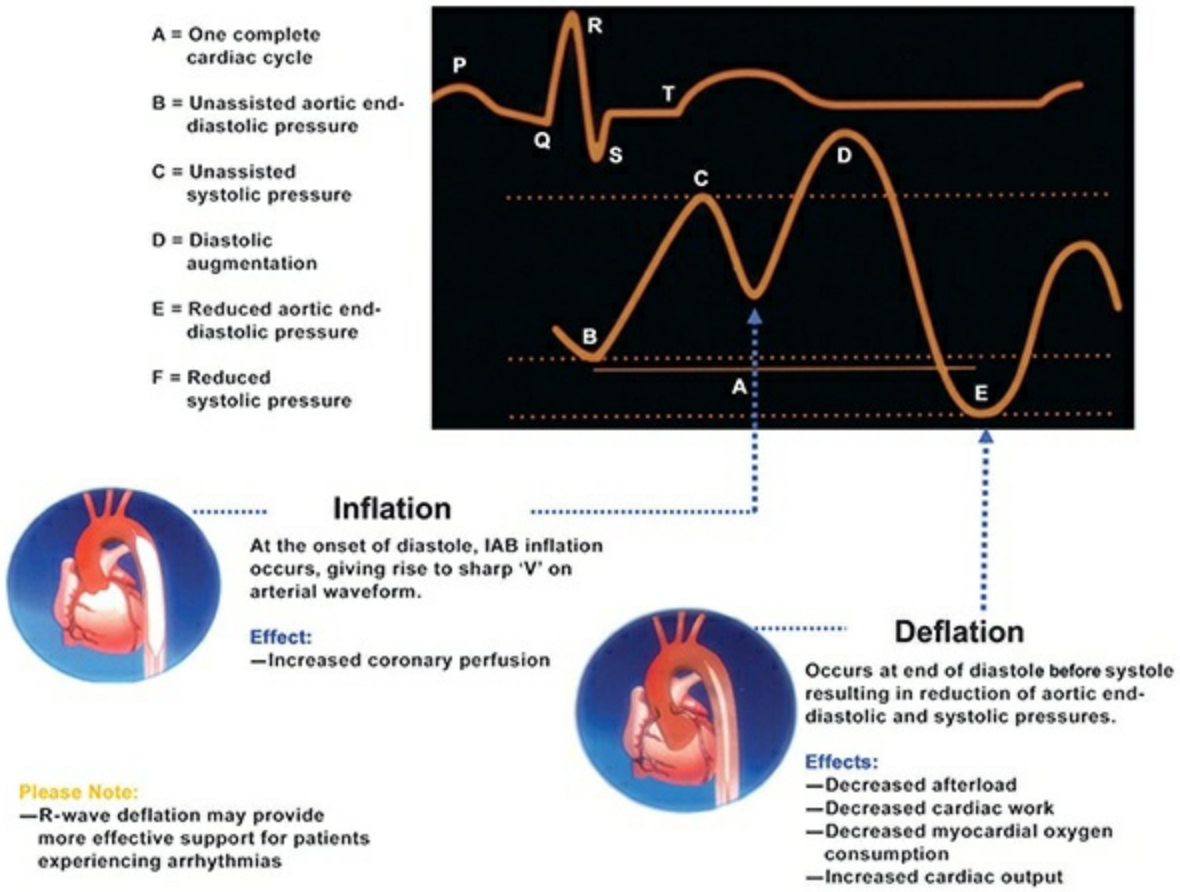

FIGURE 6.1. One complete cardiac cycle and the corresponding waveform of the IABP during the inflation and deflation. *(Reproduced with permission from Datascope®.)*

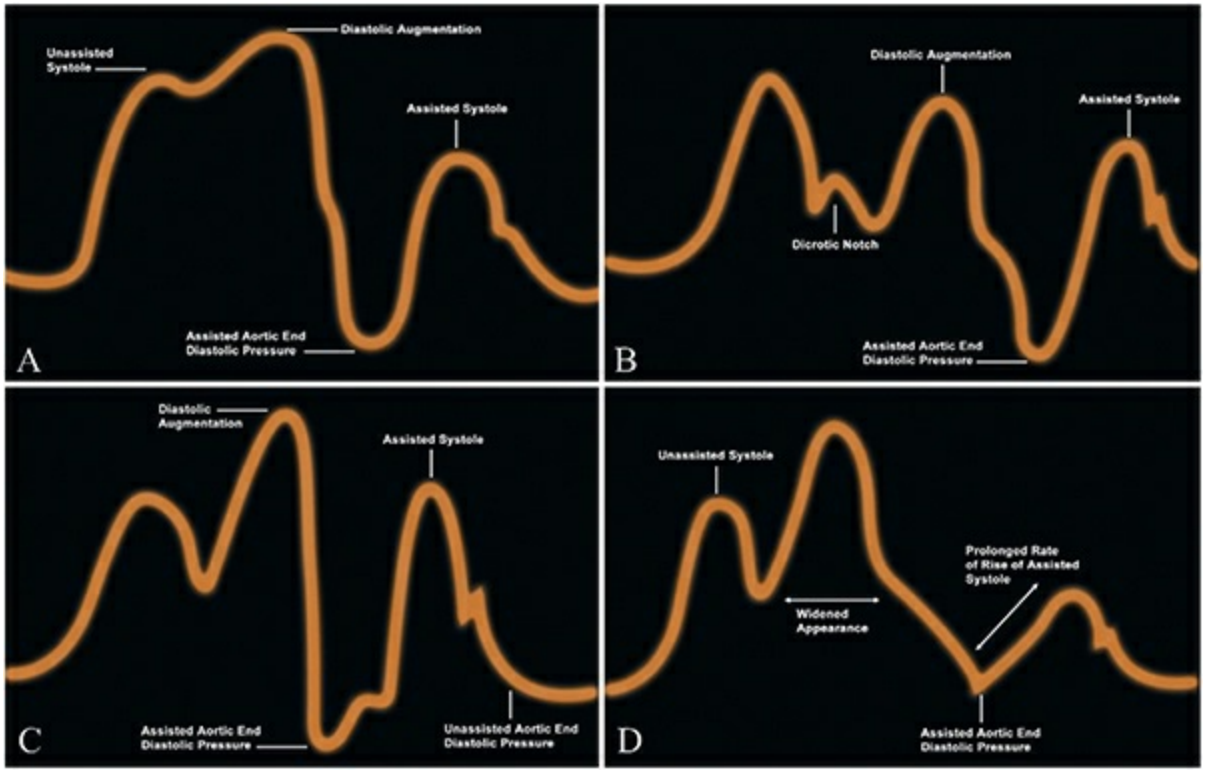

FIGURE 6.2. **A.** *Waveform characteristics:* inflation of IABP before dicrotic notch; diastolic augmentation encroaches onto systole, may be unable to distinguish. *Physiological effects:* potential premature closure of the aortic valve; potential increase in left ventricular end diastolic volume (LVEDV) and left ventricular end diastolic pressure (LVEDP) or pulmonary catheter wedge pressure (PCWP); increased LV wall stress or afterload; aortic regurgitation; increased myocardial oxygen (MVO_2) demand. **B.** *Waveform characteristics:* inflation of IABP after the dicrotic notch; absence of sharp 'V'. *Physiological effects:* suboptimal coronary artery perfusion. **C.** *Waveform characteristics:* deflation of IABP is seen as a sharp decrease after diastolic augmentation; suboptimal diastolic augmentation; assisted aortic end-diastolic pressure may be equal to or less than the unassisted aortic end-diastolic pressure; assisted systolic pressure may increase. *Physiological effects:* suboptimal coronary perfusion; potential for retrograde coronary and carotid blood flow; suboptimal afterload reduction; increased MVO_2 demand. **D.** *Waveform characteristics:* assisted aortic end-diastolic pressure may be equal to the unassisted aortic end-diastolic pressure; rate of increase of assisted systole is prolonged; diastolic augmentation may appear widened. *Physiological effects:* afterload reduction is essentially absent; increased MVO_2 consumption because of the left ventricle ejecting against a greater resistance and a prolonged isovolumetric contraction phase; IABP may impede LV ejection and increase the afterload. (*Reproduced with permission from Datascope®.*)

A.4. How does the IABP help improve hemodynamics?

The balloon is timed to inflate in diastole causing an augmented diastolic pressure with resultant increase in blood flow to the coronary arteries, great vessels, and visceral organs. The balloon deflates in systole (just prior to the opening of the aortic valve) causing a "void" or "potential" space in the aorta that reduces left ventricular (LV) afterload, which in turn facilitates ventricular systolic ejection and an increase in stroke volume. The decreased systolic afterload reduces the LV wall tension, decreases the myocardial oxygen demand, and ameliorates the effects of coronary ischemia. IABP counterpulsation intervals can be regulated by the operator, from a 1:1 ratio to a 1:3 ratio (each beat, to every third beat, respectively). In a properly functioning IABP, the operator looks for (1) the counterpulsation to create a diastolic pressure wave, which is usually higher than the preceding systolic wave, that is, the "assisted" diastolic aortic pressure, with a diastolic pressure value lower than the unassisted diastolic pressure; and (2) for the following systolic pressure wave that is lower than the unassisted systolic pressure.

The degree to which the diastolic pressure is augmented depends on a number of variables: (1) balloon position—IABPs placed closer to the aortic valve will produce a greater augmentation of diastolic pressures than those placed further away; (2) balloon volume—maximal augmentation is seen when the balloon volume is equal to the stroke volume; (3) balloon diameter and aortic occlusivity—greatest augmentation is seen with complete aortic occlusion; (4) effective balloon configuration, driving gas, and timing; (5) stroke volume—if the SV is less than 25 mL, minimal augmentation of diastolic pressures is seen. Therefore, the IABP may be less effective in patients in severe cardiogenic shock.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24:335–341.

A.5. What are the indications for IABP placement?

- Cardiogenic shock secondary to acute coronary syndromes (ACS): The most common indication for IABP placement is often after ACS, such as unstable angina refractory to medical therapies and ST-elevation myocardial infarction (MI) with or without acute mitral regurgitation, and ventricular septal defect.
- Postcardiotomy cardiogenic shock: postcardiac surgery where a patient is unable to separate from CPB
- Elective high-risk percutaneous coronary interventions (PCIs) in patients with LV dysfunction and extensive coronary artery disease (CAD) to maintain coronary perfusion and cardiac output during intervention
- Symptomatic severe CAD (i.e., high-grade left main CAD) to increase coronary perfusion before intervention
- Less common indications include bridge to cardiac transplantation and patients with “high-risk” cardiac disease presenting for urgent noncardiac surgical procedures.

In many cases, a patient is on maximal vasoactive support without significant improvement in hemodynamics, peripheral tissue, or organ perfusion measured by cardiac out/mixed venous oxygen saturation, or has a rising lactate and/or decreasing urine output.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24:335–341.

A.6. What are the contraindications and potential complications of IABP placement?

The contraindications to IABP placement include the following:

- Significant aortic insufficiency (the IABP-induced increased diastolic pressure will worsen the severity of the aortic valvular incompetence and increase the LV diastolic pressure)
- Major aortic pathology (aneurysm, dissection, severe atherosclerotic plaque), which may cause complications during the retrograde advancement of the IABP device retrograde inside the aortic lumen
- Sepsis, with the risk of colonization of the IABP catheter
- Uncontrolled coagulopathy
- Cancer with metastasis

The potential complications include the following:

- Vascular injury at the placement site is the most common complication of IABP placement. This is especially true in patients with severe peripheral vascular disease (reported as 8% to 18% with major limb ischemia reported at 1%). Bleeding at the insertion site is another major complication.
- Thrombocytopenia has been reported in 57.9% of patients receiving IABP but has not been associated with major bleeding events or mortality.
- A rare complication is rupture of IABP causing gas embolism.

Parissis H, Graham V, Lampridis S, et al. IABP: history-evolution-pathophysiology-indications: what we need to know. *J Cardiothorac Surg*. 2016;11(1):122.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24:335–341.

A.7. What are the pitfalls of IABP timing?

Correct diastolic inflation and systolic deflation are critical to optimizing the benefits of IABP counterpulsation. Early diastolic inflation of the IABP balloon (inflation is initiated during late systole) will result in increased LV afterload and increased myocardial oxygen consumption. Late diastolic inflation will result in suboptimal coronary perfusion and diastolic augmentation. Early deflation of the IABP will cause suboptimal diastolic augmentation. In late deflation, there may be a prolonged isovolumetric contraction phase with increased LV afterload and increased myocardial oxygen consumption.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24:335–341.

A.8. What are the main advantages and disadvantages of IABP support?

The main advantages of IABP are its multiple indications and relative ease of use. IABPs are widely used for cardiogenic shock and are easier and quicker to insert (smaller cannula and less complicated procedure) compared to other VADs. An IABP also has relatively low incidence of complications and is easy to manage postoperatively. However, the main disadvantage is it provides limited hemodynamic support at 0.5 to 1.0 L per minute. Despite the fact that there are several indications for the use of IABP in cardiogenic shock including cardiac surgery, there is little evidence of proven benefit. Recently, a large randomized controlled trial, the IABP-SHOCK II trial, did not show improvement in 30-day survival after implantation of IABP after acute MI-related cardiogenic shock.

Werdan K, Gielen S, Ebelt H, et al. Mechanical circulatory support in cardiogenic shock. *Eur Heart J*. 2014;35:156–167.

A.9. What is mechanical circulatory support?

Mechanical circulatory support is a broad term that encompasses the use of devices that provide support ("assist") or replace the function of the failing heart, lungs, or both. The failure of pharmacologic therapy or ventilation techniques to maintain adequate perfusion, oxygenation, and ventilation in order to prevent irreversible end-organ failure has led to the use of mechanical circulatory devices.

The cardiac support systems ("ventricular assist devices" or VAD) can be used as a short-term "bridge" until recovery occurs or as permanent cardiac replacement ("destination" therapy) in the case of end-stage heart failure. The mechanical circulatory support devices include IABPs, VAD (for a single or both ventricles, "biventricular"), extracorporeal membrane oxygenators, and total artificial hearts.

Ferrari M, Kruzliak P, Spiliopoulos K. An insight into short- and long-term mechanical circulatory support systems. *Clin Res Cardiol*. 2015;104:95–111.

A.10. What is a ventricular assist device (VAD)?

A VAD is a device inserted to support one or both ventricles of a failing heart. The cardiac chamber that is supported is used to classify them: An LVAD provides support for a failing left ventricle, a right VAD (RVAD) supports a failing right ventricle, and a biventricular VAD (BiVAD) provides support of both ventricles.

VADs may be fully implantable, with only the electrical or venting components exiting the skin, or may be paracorporeal, with cannulas that direct blood from the patient to an external device. Externally driven VADs are most likely seen following cardiac surgery and as a temporary bridge to recovery or definitive therapy.

Ferrari M, Kruzliak P, Spiliopoulos K. An insight into short- and long-term mechanical circulatory support systems. *Clin Res Cardiol*. 2015;104:95–111.

Slininger KA, Haddadin AS, Mangi AA. Perioperative management of patients with left ventricular assist devices undergoing noncardiac surgery. *J Cardiothorac Vasc Anesth*. 2013;27(4):752–759.

A.11. What are the types of percutaneous/temporary VADs?

The Impella® system (Abiomed, Danvers, MA) is an axial flow pump which provides support by propelling blood from the left ventricle into the ascending aorta. It is positioned retrograde across the aortic valve. There are two versions: the Impella® 2.5 can provide up to 2.5 L per minute of flow and can be inserted percutaneously in the catheterization laboratory, whereas the Impella® 5.0 can deliver up to 5.0 L per minute of flow but requires surgical cutdown of the femoral or axillary artery. When the Impella® 2.5 was compared to the IABP in the ISAR-SHOCK randomized trial on cardiogenic shock patients, the cardiac index and blood pressure were significantly improved in the Impella® group compared to the control group while having no difference in complications. Similarly, the Impella® 5.0 device has been found superior to the IABP in postcardiotomy low-output syndrome patients (cardiac output of 1 L per minute).

The TandemHeart® (CardiacAssist, Pittsburgh, PA) is percutaneously inserted through a transseptal puncture and transfers oxygenated blood from the left atrium and pumps up to 4 L per minute of blood through a continuous-flow centrifugal pump into the lower abdominal aorta or iliac arteries through a femoral cannula. Hemodynamically, the TandemHeart® provides a greater increase in cardiac output and blood pressure compared to IABP and decreases right and LV filling pressures and work. However, both the complexity of the placement of the device and high complication rate (vascular injury, bleeding leading to transfusion, sepsis/systemic inflammatory response syndrome [SIRS], stroke, GI bleeding) have limited its use and

popularity.

Percutaneous biventricular support is possible by using a combination of the TandemHeart® with modified position of the inflow cannula placed in the right atrium and an outflow cannula in the pulmonary artery to support the right ventricle combined with placement of an IABP or Impella® to support the left ventricle.

Lampert BC. Perioperative management of the right and left ventricles. *Cardiol Clin*. 2018;36(4):495–506.

Werdan K, Gielen S, Ebelt H, et al. Mechanical circulatory support in cardiogenic shock. *Eur Heart J*. 2014;35:156–167.

A.12. What are the types of permanent VADs?

Permanent VADs provide pulsatile or continuous flow. Early permanent VADs used pulsatile flow primarily in an effort to mimic the native circulatory pattern but were prone to mechanical failure and infection. The newer VADs rely on the principle of continuous, nonpulsatile flow. Continuous-flow devices can be classified further as either axial (HeartMate® 2 or 3 Left Ventricular Assist System; Thoratec Corp, Pleasanton, CA) or centrifugal flow devices (Heartware Ventricular Assist Device®; Heartware International, Framingham, MA). Both pumps are powered by electric currents that impart motion to a central rotor which displaces blood. In the more common centrifugal pumps, the rotor is levitated by permanent magnets, controlled by the electric currents that cause blood acceleration circumferentially. Blood is removed from the left ventricle through the inflow cannula into the device, propelled around an impeller, and returned into the outflow cannula in the aorta. The pulsatility of the systemic blood pressure is proportional to the amount of intrinsic LV function of the patient. Continuous-flow devices are now the mainstay of VADs because they have been found to have a higher incidence of survival and quality of life

and decreased number of adverse events when compared to first generation pulsatile devices.

Of the implantable continuous-flow LVAD options, the HeartMate® 3 LVAD (St. Jude Medical Inc., St. Paul, MN) has recently emerged as a popular option due to decreased hemolysis, platelet activation, and cleaving of von Willebrand factor as well as a decreased incidence of pump thrombosis.

The Total Artificial Heart (TAH, SynCardia Systems, Tucson, AZ) is a biventricular pulsatile flow pump with all chambers of the native heart mimicked in a single device implanted into the pericardial sac. Anastomoses are made from the caval circulation, pulmonary arterial and venous circulation, and the ascending aorta. Large series studies have shown that when used as a bridge to transplantation, posttransplantation survival is 60% at 5 years after transplantation. Complications include strokes in 8% of the patients and clinically significant hemorrhage in over half of the patients.

Carpentier A, Latrémouille C, Cholley B, et al. First clinical use of a bioprosthetic total artificial heart: report of two cases. *Lancet*. 2015;386(10003):1556–1563.

Lampert BC. Perioperative management of the right and left ventricles. *Cardiol Clin*. 2018;36(4):495–506.

Werdan K, Gielen S, Ebelt H, et al. Mechanical circulatory support in cardiogenic shock. *Eur Heart J*. 2014;35:156–167.

A.13. How does VAD work?

In the case of LV support, blood is drained from either the left atrium or LV apex and routed to the VAD and returned to the systemic circulation via a cannula in the ascending aorta. In the

case of right ventricular (RV) support, blood is drained from the right atrium or right ventricle and is directed to the VAD, from which it is returned to the pulmonary circulation via a cannula in the main pulmonary artery.

Ferrari M, Kruzliak P, Spiliopoulos K. An insight into short- and long-term mechanical circulatory support systems. *Clin Res Cardiol*. 2015;104:95–111.

A.14. When is circulatory support needed?

Circulatory support is indicated for temporary, long-term, and destination therapy. Temporary support is indicated in patients undergoing high-risk interventions, such as PCIs; in patients with severely impaired LV function; or in other complicated percutaneous or surgical interventions. Additional indications for circulatory support include the prevention of the sequelae of cardiogenic shock (i.e., multisystem organ failure) following MI, cardiac surgery, or decompensated heart failure. Due to the severe shortage of donor hearts, long-term circulatory support (usually LVAD or RVAD) is used as a bridge to cardiac transplantation, bridge to candidacy for transplant, or destination therapy in patients not eligible for cardiac transplantation. The goal when using long- or short-term circulatory support in patients who require hemodynamic support is to avoid the "bridge to nowhere" scenario, when circulatory support is initiated with no clear therapeutic end point.

Ferrari M, Kruzliak P, Spiliopoulos K. An insight into short- and long-term mechanical circulatory support systems. *Clin Res Cardiol*. 2015;104:95–111.

A.15. What are the physiologic considerations in patients requiring a VAD?

The left ventricle is the most commonly supported ventricle. The LVAD will replace some or all of the LV function in supplying systemic perfusion. This will leave the right ventricle unassisted and susceptible to failure from the increased preload (the effect

of LVAD). At the same time, pulmonary hypertension from any cause will increase RV afterload which may cause RV ischemia and will further decrease RV performance. In a similar fashion, an RVAD may increase the preload of the left ventricle and precipitate LV failure. The most common scenario is for a patient with cardiogenic shock or acute decompensated heart failure to be supported with an LVAD or ECMO.

Dalia AA, Cronin B, Stone ME, et al. Anesthetic management of patients with continuous-flow left ventricular assist devices undergoing noncardiac surgery: an update for anesthesiologists. *J Cardiothorac Vasc Anesth*. 2018;32(2):1001–1012.

A.16. What are the reasons for suboptimal VAD support?

The performance of a VAD (its systemic output) may decrease from hypovolemia, bleeding, RV failure, cardiac tamponade, and increased left-sided afterload. Relative or absolute hypovolemia reduces VAD output by causing a "suction event" where the interventricular septum gets "sucked into" the outflow cannula causing decreased VAD filling and device "stroke volume." Increased afterload increases the resistance to pump outflow and will likewise decrease cardiac output from the VAD. Additionally, a long-term complication causing decreased VAD function is VAD thrombosis, described in the following text.

Nicolosi AC, Pagel PS. Perioperative considerations in the patient with a left ventricular assist device. *Anesthesiology*. 2003;98:565–570.

Sen A, Larson JS, Kashani KB, et al. Mechanical circulatory assist devices: a primer for critical care and emergency physicians. *Crit Care*. 2016;20(1):153.

A.17. What are common complications from VAD?

VAD thrombosis, reported in 2% to 4% of patients, is defined as clot formation in the VAD. It is often ascribed to noncompliance, inadequate response to anticoagulation therapy, an inherited hypercoagulable state, atrial fibrillation, and

infection. Inflow cannula malposition and low pump flow have also been associated with VAD thrombosis. Clinically, VAD thrombosis manifests as occult cardiogenic shock, hemolysis with increasing lactate dehydrogenase levels (LDH) above 500 IU per L and increasing LVAD pump power. A “ramp study” can be performed to further support the diagnosis of VAD thrombosis. In this study, increasing pump speed should normally produce an increasingly empty left ventricle, a decrease in LV end-diastolic diameter, and a loss of aortic valve opening. When the left ventricle does not decompress (measured by end-diastolic diameter), VAD thrombosis is increasingly suspected.

Surgical treatment (i.e., pump exchange or heart transplantation) of the thrombosed VAD is considered far more effective than medical treatment in HeartMate® II devices. The mortality rate with medical treatment is reported as 48.2%, and the mortality after surgical treatment at 6 months is similar to those patients who did not experience VAD thrombosis. Medical treatment focuses on anticoagulation and antiplatelet therapies.

Right heart failure occurs in 20% to 50% of patients who receive LVAD support. Those patients who have significant right heart dysfunction should be carefully evaluated before LVAD placement.

Bleeding accounts for 9% of the mortality observed in LVAD patients. It is thought to be due to an acquired von Willebrand syndrome secondary to polymer degradation by the VAD impeller.

Sepsis and systemic infections affect nearly 1 in 3 patients with an LVAD and may necessitate evaluation for endocarditis and device removal.

Birati E, Rame E. Left ventricular assist device management and complications. *Crit Care Clin*. 2014;30(3):607–627.

Oleyar M, Stone M, Neustein SM. Perioperative management of a patient with a nonpulsatile left ventricular-assist device presenting for noncardiac surgery. *J Cardiothorac Vasc Anesth*. 2010;24(5):820–823.

A.18. How long can VADs remain in the patient?

VADs can remain in patients until there are complications that necessitate exchange or removal. Myocardial recovery is also an indication for VAD explanation. Current survival for continuous-flow LVADs is 81% at 1 year and 59% at 3 years.

Sladen RN. New innovations in circulatory support with ventricular assist device and extracorporeal membrane oxygenation therapy. *Anesth Analg*. 2017;124(4):1071–1086.

B. Preoperative Evaluation and Preparation

B.1. What is the focus of the preoperative assessment of an LVAD patient?

The number of patients with LVADs are increasing mainly due to their success as a destination therapy in advanced heart failure. Therefore, these patients are increasingly encountered for noncardiac surgical procedures. Commonly encountered procedures include upper and lower GI procedures for bleeding due to arteriovenous malformation or larger and more extensive surgical procedures.

The preoperative evaluation should include a standard evaluation assessing the patient's current state of health and changes in exercise tolerance to screen for symptoms of acute heart failure. Careful physical examination should be performed to determine fluid status, right heart function, and signs of worsening heart failure. Medications, recent cardiology notes,

and laboratory results should be reviewed.

The medications list should be examined for diuretics, inotropes, anticoagulants, and anti-arrhythmic therapies. Laboratory results should be reviewed for baseline renal function, coagulation panel (as all of these patients should be on anticoagulation), and hepatic function (which may indicate worsening right heart function). VAD patients often have renal impairment and renal precautions should be taken during surgery.

Coagulation status should be carefully assessed. The risk of bleeding versus VAD thrombosis should be assessed for each individual procedure to determine whether or not to stop or bridge anticoagulation perioperatively.

The most recent cardiology note should be reviewed for the type of VAD, indication for device placement, VAD settings (including flow rate, device alarms, power elevations, and backup battery life), and any other device interrogations (i.e., pacemakers and implantable cardioverter-defibrillators [ICDs]). Many VAD patients have implanted defibrillators. Depending on the procedure, the tachyarrhythmia therapies may need to be disabled, and the pacemaker function may need to be switched to asynchronous mode if electrocautery interference is anticipated.

The most recent echocardiogram should be reviewed for inflow cannula position, outflow graft patency, and, most importantly, RV function and tricuspid regurgitation. The most common valvular pathologies present in patients with an LVAD are aortic stenosis and insufficiency as well as tricuspid insufficiency.

Patients with VADs should ideally be cared for at a facility that has a support team dedicated to caring for these patients perioperatively. Members of this team should include a cardiologist, a VAD coordinator, cardiac surgeons, cardiac

anesthesiologists, and perfusionists. The team should be notified in advance, if possible, that the patient with a VAD will be presenting for surgery.

VAD patients require extensive support services, and there is frequently 24-hour coverage by a specialized nurse or physician assistant, specifically assigned to the hospital VAD program. These specialists often accompany VAD patients to the operating room and are very facile in the intricacies of individual VADs. In addition, device manufacturers have 24-hour support services and are a source of useful clinical information.

Dalia AA, Cronin B, Stone ME, et al. Anesthetic management of patients with continuous-flow left ventricular assist devices undergoing noncardiac surgery: an update for anesthesiologists. *J Cardiothorac Vasc Anesth*. 2018;32(2):1001–1012.

Nicolosi AC, Pagel PS. Perioperative considerations in the patient with a left ventricular assist device. *Anesthesiology*. 2003;98:565–570.

C. Intraoperative Management

C.1. Detail the anesthetic management for a patient undergoing LVAD placement.

The management of patients requiring LVAD placement can be divided into the preoperative, intraoperative, and post-CPB periods.

Preoperatively, a patient requiring an LVAD will, by definition, have severely reduced LV function. They may require mechanical ventilation, multiple inotropes, vasopressors, and/or an IABP. Due to chronic heart failure and its treatment, such a patient may have profoundly abnormal electrolytes, liver, renal, and coagulation function tests. Preoperative echocardiography demonstrating the presence of pulmonary hypertension, impaired RV function, or tricuspid regurgitation is

particularly important because these findings indicate the possible need for RV support or even placement of an RVAD as well. Severe irreversible pulmonary hypertension, severe tricuspid regurgitation, and severe RV dysfunction may be a contraindication for an LVAD or indicate the need for a BiVAD.

An arterial line is placed prior to the induction of anesthesia. No matter what the anesthetic induction is, myocardial depression or rapid changes in systemic vascular resistance must be avoided. Given the patient's slow circulation time, the preemptive administration of vasopressors is prudent to offset the unwanted side effects of induction agents. To avoid possible acute RV dysfunction due to hypoxia and hypercarbia, ventilation and intubation should be accomplished as expeditiously as possible. Early administration of muscle relaxants and controlled lung ventilation with low inspiratory airway pressure is suggested to avoid increases in intrathoracic pressure that may have deleterious effect on the right heart. Once the patient is successfully induced, ICDs must be deactivated and the pacing mode changed to allow the use of intraoperative electrocautery. Large-bore peripheral and central intravenous access and a pulmonary artery catheter should be placed. Large-bore venous access is especially important in the case of patients who have had prior cardiac surgery because the risk of adhesions and massive hemorrhage is a major concern. Blood and blood products should be available in case of major bleeding.

Intraoperatively, the anesthetic goals are to avoid deterioration of the existing cardiac function, to avoid hypovolemia and anemia, and to optimize the cardiovascular status while the LVAD is implanted under CPB. Because the primary concern in a patient undergoing an LVAD is RV failure, real-time monitoring of central venous pressure (and its association with pulmonary pressures) is crucial. TEE is

invaluable in patients undergoing LVAD placement, and a complete echocardiographic assessment should be performed on every patient. The focus of the transesophageal echocardiographic examination is the presence of (1) atrial septal defects, which may predispose to hypoxemia due to right-to-left shunting post-VAD placement as left atrial pressures are decreased; (2) aortic regurgitation, which will cause a "recycling" of the blood from the aorta back to the left ventricle; (3) tricuspid regurgitation, which may cause or exacerbate RV failure; (4) mitral stenosis, which may decrease filling of the left ventricle and therefore the "preload" to the LVAD; (5) an intracardiac LV thrombus; and (6) preexisting RV dysfunction.

Following the LVAD implantation, the focus is on maintaining euvolemia, treating coagulation abnormalities, and supporting the RV function as needed. A variety of vasoactive medications and inotropes are infused, and frequently inhaled nitric oxide (NO) or prostacyclin is administered to ameliorate any pulmonary hypertension. Those patients treated with pulmonary vasodilators early after LVAD had a decreased incidence of RV failure in observational studies, notably. The VAD patients require long-term anticoagulation.

C.2. How is a VAD patient monitored during a general anesthetic?

Standard American Society of Anesthesiologists (ASA) monitoring is used at a minimum. Due to the continuous flow of the newer VADs, noninvasive blood pressure cuffs and pulse oximeters may not function reliably in all patients. Nevertheless, the mean arterial blood pressure should be monitored with noninvasive or direct measurements, and oxygenation may be determined by arterial blood gas measurement and continuously by cerebral oxygenation monitors. When arterial line placement is necessary, ultrasound may prove useful to locate the vessel as the systemic pulse may be weak or nonpalpable. The monitoring of central venous pressure or placement of pulmonary artery catheters must be individualized based on the procedure and the patient's underlying RV function. In patients with impaired RV function or for procedures involving large fluid shifts, intraoperative TEE is recommended if available.

No consensus guidelines currently exist to recommend whether these patients should be cared for by a cardiac or general anesthesiologist in the setting of noncardiac surgery. It is generally agreed on that the anesthesiologist should be familiar with LVAD settings and specific alarms. Increasingly, these patients are being cared for safely by general anesthesiologists.

Invasive arterial blood pressure monitoring is recommended for major surgery given its accuracy, reliability, and the ability to obtain blood gasses. Mean arterial pressure (MAP) should generally be kept less than 85 mmHg given concern for reduced LVAD flows, pump stasis, and an association with stroke at higher MAPs.

Common VAD settings: *Pulsatility index* (*PI*) is a dimensionless measure of LV pulsatility, ranging from 1 to 10 with an average of 5 for the HeartMate® LVADs. It is increased in the setting of adequate LV preload and suggests LV systolic

augmentation, and a low PI represents low preload or contractility. Increasing pump speed, by decompressing the left ventricle, will typically decrease PI and vice versa. Once a normal PI range is determined for a patient, it should not vary significantly. *Pump speed* is determined to allow adequate LV preload for intermittent LV ejection and avoid suction events. A low speed may cause pump stasis and thrombosis, and a high speed may cause hemolysis, excessive LV decompression, and suction events as well as RV dysfunction. *Pump power*, which typically correlates directly with pump speed, may be reduced secondary to inflow cannula obstruction or reduced LV preload. An increase in pump power without increased pump flow should raise suspicion for pump thrombosis.

In the event of periprocedural cardiac arrest, standard advanced cardiac life support (ACLS) should be employed with the exception of external chest compressions. Chest compressions are contraindicated because they may disrupt or dislodge VAD cannulas.

C.3. Prescribe an anesthetic for a VAD patient.

No specific type of anesthetic is recommended for patients with mechanical circulatory support. The presence of chronic anticoagulation and the acute decrease in systemic vascular resistance following neuraxial anesthesia make spinal or

epidural anesthesia undesirable. Patients with fully implantable VADs should be considered as having a "full stomach" and be treated accordingly. Decreased rates of gastric emptying and deaths from aspiration of gastric contents have been reported in patients with VADs.

Regardless of the anesthetic technique chosen, physiologic derangements that increase pulmonary and systemic vascular resistance must be avoided because they negatively impact RV function and VAD performance. Hypoxemia, acidosis, and hypercarbia all contribute to RV failure and must be avoided at all costs. Adequate preload must be maintained to promote adequate VAD flows. Rapid changes in venous capacitance due to vasodilating medications (propofol) and patient positioning (i.e., reverse Trendelenburg) are poorly tolerated because decreased venous return will reduce LVAD flow. Intravascular volume must be administered carefully to avoid a rapid increase in central venous pressure and possible RV failure in those patients with impaired RV function.

Many, if not all, VAD patients have an implanted defibrillator/pacemaker, and the anesthesiologist should be aware of potential interference from the electrical cautery. Standard of care should be followed with these devices; if the patient is pacemaker dependent, the device should be programmed to an asynchronous mode because a magnet will likely only turn off the tachyarrhythmia therapy. The electrophysiology team should also be consulted to turn off tachyarrhythmia therapy if necessary and external defibrillator pads should be placed after it is switched off. After the surgery, the tachyarrhythmia therapy should be reinstated.

C.4. What is ECMO? What are the indications for ECMO? What are the different types of ECMO?

ECMO is the mechanical support of the heart, lungs, or both using a modified heart–lung bypass machine. It usually consists of a centrifugal pump, a heat exchanger, and a membrane oxygenator. Venous blood is aspirated from the right atrium into a centrifugal pump through a long cannula inserted into the right atrium via the femoral vein or jugular vein, sent to the membrane oxygenator, and returned to the circulation via an outflow cannula into the descending aorta from the femoral artery.

Although ECMO can provide up to 4.0 L per minute of support and reduce LV preload, it also increases LV afterload and may increase myocardial oxygen demand.

Although originally used for short-term therapy (days), the development of improved oxygenators and circuits have allowed patients to be supported on ECMO for weeks, as in the case of patients with respiratory failure due to novel influenza type A (H1N1). There are two basic types of ECMO: VA-ECMO and venovenous (VV-ECMO). The terms illustrate the location of the cannulas. In each case, a modified CPB circuit is used that is composed of (1) the cannulas and tubing to drain and return the blood, (2) oxygenator/heat exchanger, and (3) pump.

VV-ECMO is primarily used for severe acute respiratory distress syndrome (ARDS) or as a bridge to lung transplantation but may also be used during surgical procedures on the lungs or airway. In VV-ECMO, an oxygenator is placed in series

between an *outflow* cannula (usually internal jugular vein) and a venous *inflow* cannula (usually femoral vein). However, using a dual-lumen cannula eliminates the need for separate in/outflow cannulae. There is no pump, and the patient's native cardiac output supplies the driving pressure that creates flow across the oxygenator, where gas exchange occurs. Once deoxygenated venous blood has passed through the oxygenator, it is returned to the patient where it mixes with systemic venous blood and is returned via the pulmonary circulation to the left side of the heart and to systemic circulation. As such, there is no cardiac support provided by VV-ECMO. This allows patients on VV-ECMO the opportunity to ambulate or perform physical therapy as well as making the VV-ECMO circuit simpler. TEE is especially useful in directing placement of caval cannulas and diagnosing cannula malposition, obstructed flow, and LV dilatation.

VV-ECMO is often instituted by upper body venovenous cannulation, which uses a bicaval dual-lumen cannula to drain venous return from the superior and inferior vena cava and return oxygenated blood into the right atrium.

VA-ECMO is akin to conventional CPB, in which blood is drained via a cannula placed in the vena cava, routed to a blood pump and an oxygenator/heat exchanger, and returned via the aorta or a large artery. As a result, both cardiac and pulmonary support is achieved. The indications for VA-ECMO include (1) reversible postcardiotomy shock/failure to wean from CPB, (2) bridge to transplantation, and (3) recently as an adjunct to advanced life support for cardiac arrest (i.e., extracorporeal cardiopulmonary bypass [ECPB]). There has been a steep increase in the number of patients placed on ECMO. Although ECMO can provide up to 4.0 L per minute of support and reduce LV preload, it also increases LV afterload and may increase myocardial oxygen demand.

The main advantages of ECMO are quick and easy percutaneous insertion of inflow and outflow cannulas, full circulatory support with up to 4.0 L per minute, and the ability to rapidly improve tissue oxygenation in situations of cardiogenic shock combined with severe pulmonary edema. Due to these reasons, ECMO use is increasing popular and has potential for wider clinical use. The main disadvantage is that it does not reduce LV afterload.

C.5. What are the contraindications of ECMO?

The most universally agreed on contraindications to ECMO support are the absence of a reversible etiology, perceived short life expectancy due to malignancy or other terminal disease, and ongoing bleeding. Other increasingly debated contraindications include advancing age, obesity, sepsis, end-stage renal disease, end-stage hepatic disease, and coagulopathy.

C.6. What are the main complications of ECMO?

Similar to other types of percutaneous VAD support, the most common complications of ECMO are systemic inflammation, renal failure, limb ischemia, and bleeding.

C.7. What are the necessary equipment and teams required to place ECMO? What are the pros and cons of different venoatrial ECMO (VA-ECMO) cannula placement?

The basic ECMO circuit includes a blood pump, oxygenator,

heat exchanger, and the venous and arterial cannulae. A manual pump is also necessary in the event of power outage. Typically, a cardiothoracic surgeon, an intensive care team, and perfusion teams are needed to initiate and manage ECMO support.

Peripheral VA-ECMO cannulation most often uses femoral venous and femoral arterial sites for venous and arterial cannulation. As a result, retrograde flow from the arterial cannula up the aorta can compete with the native antegrade flow through the aorta. To demonstrate oxygenation from native pulsatile flow of the heart that is perfusing the right upper extremity and the right common carotid artery, it is imperative to perform arterial blood gas sampling from the right upper extremity. Peripheral cannulation is associated with an increased risk of limb ischemia.

Central VA-ECMO cannulation (most often after failure to wean from CPB) is associated with an increased risk of infection, less risk of right upper extremity and right cerebral ischemia, and less risk of limb ischemia. It may "rest" the heart better than peripheral cannulation because of improved LV emptying and decreased afterload.

C.8. How are patients monitored and managed while on ECMO?

All patients on ECMO require anticoagulation due to the thrombotic nature of the circuit and oxygenator. Heparin is administered with a goal activated clotting time (ACT) of 1.5 to 2.0 times normal. In VA-ECMO, the circuit flow is titrated to mean arterial pressure and the oxygen saturation of blood in the drainage cannula (S_{DO_2}). On VV-ECMO, flow is titrated to Sa_{O_2} and S_{DO_2}. Because VV-ECMO is primarily used in respiratory failure, once adequate oxygen saturation is achieved, mechanical ventilation is reduced and the lungs are "rested." This is achieved by the use of protective lung ventilation strategies,

including low respiratory rate, low tidal volumes, limited peak inflation pressures, and the use of positive end-expiratory pressure.

Lafç G, Budak AB, Yener AÜ, et al. Use of extracorporeal membrane oxygenation in adults. *Heart Lung Circ*. 2014;23:10–23.

C.9. What are the complications of ECMO?

Complications of ECMO can be either patient or circuit related. Blood clots are the most feared circuit-related complications and may develop in any part of the ECMO circuit, including the pump, oxygenator, or tubing. Signs of clot formation include rising plasma-free hemoglobin or D-dimers, an increasing pressure gradient across the oxygenator, and a fall in post-oxygenator Sa_{O_2}.

Patient-related complications include cannula site and coagulopathic bleeding, hemodynamic instability, sepsis, and intracerebral hemorrhage. In VA-ECMO, hypotension, as evidenced by low mean arterial pressure in the presence of adequate ECMO flow, indicates reduced vascular tone. This can be treated with vasopressors such as norepinephrine or vasopressin. In a patient supported by VA-ECMO, low pump output and "line chatter" (visible oscillations of the circuit tubing) are signs of hypovolemia. Because VV-ECMO has no effect on cardiac function, hypotension in a patient supported by VV-ECMO may be caused by hypovolemia, reduced vascular tone, or myocardial dysfunction. In each case, the treatment must be tailored to the specific cause or causes. This includes the administration of volume and the use of inotropes/vasopressors.

Lafç G, Budak AB, Yener AÜ, et al. Use of extracorporeal membrane oxygenation in adults. *Heart Lung Circ*. 2014;23:10–23.

C.10. How frequently is VA-ECMO being used and how

effective is it in cardiogenic shock?

Due to technologic advances and improvements in ECMO circuit components, ECMO use has increased by over fourfold from 2006 to 2011. As per a January 2018 extracorporeal life support organization (ELSO) report, there were 15,201 adult patients with cardiogenic shock treated with VA-ECMO in 2017 and survival to hospital discharge was 41%. Those patients on VA-ECMO for myocarditis and post–heart transplantation graft failure have a survival of greater than 70%.

D. Postoperative Management

D.1. When and how is a patient weaned off IABP support?

Weaning from IABP support is initiated once the patient's requirement for inotropic support is reduced. IABP weaning is done in conjunction with vasoactive support; so, if cardiac output or overall hemodynamics worsen, inotropic support may be increased. Weaning is gradually undertaken over the course of 6 to 12 hours while the ratio of augmented to nonaugmented beats is decreased gradually from 1:1 to 1:2 to 1:3 if the patient maintains hemodynamic stability. If there are any hemodynamic derangements, the weaning process is halted and vasoactive medications are titrated to achieve an adequate cardiac output (or mixed venous oxygen saturation). Following a successful weaning period, the IABP device is removed.

Klopman MA, Chen EP, Sniecinski RM. Positioning an intraaortic balloon pump using intraoperative transesophageal echocardiogram guidance. *Anesth Analg*. 2011;113(1):40–43.

D.2. How is weaning from ECMO accomplished?

Weaning from VA-ECMO follows a similar sequence of actions as weaning from CPB. It is important that the underlying cause requiring ECMO placement has resolved or improved. The patient should be optimized both from a hemodynamic standpoint (titrating vasopressors and inotropes) and from a volume perspective (have low filling pressures). Respiratory status should be optimized as hypercarbia and hypoxia will impair RV function. Inotropic support is usually increased several hours before the planned weaning. Using echocardiography (transthoracic or transesophageal) and a pulmonary artery catheter to guide therapy, ECMO circuit flows are slowly reduced over the course of several hours. With a combination of inotropes for contractility, vasopressors for tone, volume/red blood cells for preload and optimal tissue oxygen delivery, and blood products to treat coagulopathy, the patient is weaned to minimal circuit flows. If the patient remains stable, the circuit is clamped and the cannulas are removed. The presence of pulsatility on the arterial waveform at full ECMO flows indicates myocardial recovery and is a promising sign for a successful wean. If there are declining hemodynamics and/or evidence of poor tissue perfusion (decreasing mixed venous saturation/low cardiac output/low MAPs), then the ECMO flows are increased and the weaning is postponed.
Echocardiographically, it is important that the interventricular septum remains midline; shifting of the septum to the left and dilation of the right ventricle, as well as the presence of increased tricuspid regurgitation indicates impending right heart failure, and weaning should be discontinued. Increased dilation of the left ventricle and presence of increasing functional mitral regurgitation similarly indicates impending LV failure. There is some evidence that TEE-measured systolic velocities on tissue Doppler imaging at the lateral mitral annulus and aortic valve velocity time integrals at minimal ECMO support may correlate

with successful weaning from ECMO.

Weaning from VV-ECMO requires recovery of adequate lung function and may take weeks or longer to occur. Signs that a patient can be weaned include improvements in chest radiograph, improved lung compliance, as well as an increasing Sa_{O_2} for a given circuit flow.

7 Valvular Heart Disease

Meghann M. Fitzgerald and
Natalia S. Ivascu

A 78-year-old man was admitted with increasing shortness of breath. He had chest pain in the past but was able to continue with normal activities. In the past year, he experienced two episodes of syncope. On physical examination, a loud systolic murmur could be heard at the left sternal border radiating to the neck. His vital signs were blood pressure 150/90 mmHg and heart rate 88 beats per minute and irregular. The electrocardiogram (ECG) showed sinus rhythm with atrial premature contractions and left ventricular hypertrophy (LVH) with strain. A transthoracic echocardiogram (TTE) showed a hypertrophied left ventricle (LV), and Doppler examination demonstrated severe aortic stenosis (AS) with a pressure gradient of 64 mmHg, mild aortic insufficiency (AI), and moderate mitral regurgitation (MR). He was scheduled for an aortic valve (AV) replacement and a possible mitral valve (MV) repair or replacement.

A. Medical Disease and Differential Diagnosis

1. What are the major etiologies of AS, AI, mitral stenosis (MS), and MR?
2. What are the major changes in the loading conditions of the LV that result from the four different lesions? Why do they occur? What changes result from them?

3. What are pressure–volume (P–V) loops? What do the different inflection points represent?
4. What are representative P–V loops for the four valvular lesions?
5. Draw the pressure/time curves for the LV, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.
6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?
7. What are the three TEE vantage points for the comprehensive imaging of the LV? How are pressure gradients measured by echocardiography? How do the pressure gradients derived from Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?
8. What is the role for three-dimensional (3D) echocardiography in the operating room?
9. What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?

B. Preoperative Evaluation and Preparation

1. What are the presenting signs and symptoms of the four valvular lesions listed previously?
2. What is the New York Heart Association classification of heart failure?
3. Discuss the role of premedication for patients with the four different valvular lesions.
4. How would you premedicate the patient with severe AS and MR?

C. Intraoperative Management

1. Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and

contractility?

2. What are the hemodynamic goals for this patient with the combination of severe AS and MR?
3. How would you monitor this patient with severe AS and MR?
4. Should the patient have a pulmonary artery catheter placed before induction?
5. Is a pulmonary artery catheter with pacing capabilities indicated?
6. What anesthetic technique would you employ? Why?
7. What muscle relaxant would you use for this patient?
8. What are the usual TEE findings in a patient with AS or MR? How do you grade the severity of AS by TEE? How do you quantify the severity of MR? What is the impact of AS on the severity of MR?
9. What special considerations particular to cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.
10. The patient cannot be weaned from CPB following an AV replacement and MV replacement. What are the possible causes?
11. How would you diagnose right-sided heart failure and pulmonary hypertension? How would you treat it?
12. How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?
13. What role does the IABP have in this setting?
14. What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?
15. How would you properly time the IABP cycle?
16. What are the contraindications to the use of an IABP?
17. What is the role for ventricular assist devices?

D. Postoperative Management

1. In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?
2. Would you extubate this patient early in the ICU? Why?
3. What are the advantages and disadvantages of early extubation?

E. Alternative Treatments

1. What are the percutaneous options for MV repair?
2. How is percutaneous MV repair performed?
3. What are the percutaneous options for AV repair and replacement?
4. How is percutaneous AV replacement performed?
5. What anesthetic techniques and monitors are used?
6. What is minimally invasive cardiac valve surgery?

A. Medical Disease and Differential Diagnosis

A.1. What are the major etiologies of AS, AI, mitral stenosis (MS), and MR?

AS occurs as a congenital lesion but more commonly as an acquired disease. Stenosis may develop on a previously normal AV following rheumatic fever or from progressive calcification. Congenitally bicuspid AVs are also prone to calcification with eventual stenosis. Calcification of the AV leaflets can result in incomplete closure of the valve with associated insufficiency.

AI is usually an acquired disease. The most common causes include bacterial endocarditis and rheumatic heart disease. Annular dilation with resultant AI may result from diseases, such as cystic medial necrosis and collagen disorders, or following aortic dissection.

MS is almost always caused by rheumatic fever, although

only half of patients will have a history of an acute febrile illness. The inflammatory process of rheumatic fever results in thickening of the leaflets and fusion of the commissures. Other rare causes include congenital stenosis and other systemic diseases, such as systemic lupus erythematosus and carcinoid. Pathophysiology similar to that seen with valvular MS can occur with obstructing left atrial tumors and cor triatriatum. MS commonly occurs in conjunction with other valvular heart disease; only 25% of patients present with isolated MS, and approximately 40% have combined MS and MR.

MR can result from defects in the leaflets, the annular ring, or the supporting chords or papillary muscles or any combination of these. Primary leaflet dysfunction occurs with rheumatic fever but can also follow bacterial endocarditis, connective tissue disorders, and congenital malformations. Annular dilation can follow left ventricular dysfunction and dilation. MV prolapse and rupture of papillary muscles result in incomplete leaflet closure or coaptation with resultant MR. Left ventricular ischemia can affect papillary muscle contraction and is the cause of functional MR.

A.2. What are the major changes in the loading conditions of the LV that result from the four different lesions? Why do they occur? What changes result from them?

AS represents a chronic systolic pressure load on the LV. This

increases the wall tension (stress) in accordance with Laplace's law:

$$\text{Wall tension} = \frac{(\text{Pressure} \times \text{Radius})}{(2 \times \text{Wall thickness})}$$

The LV undergoes parallel duplication of muscle fibers in an attempt to compensate, and this results in increased wall thickness or concentric hypertrophy and some decrease in radius, thereby normalizing wall stress. If the MV remains competent, little change occurs in the other cardiac chambers.

AI causes left ventricular diastolic volume overload due to the additional volume flowing retrograde into the LV across the incompetent AV during diastole. This results in eccentric hypertrophy and left ventricular dilation (increased muscle mass and chamber radius). However, AI decreases the aortic diastolic pressure, which is the pressure that must be exceeded by the contracting LV to open the AV and result in left ventricular systolic ejection. Therefore, left ventricular work is performed against a lower outflow impedance (aortic diastolic pressure). Stroke volume and ejection fraction may be preserved until late in the disease process. As with AS, the presence of a competent MV confines the changes to the LV. However, the left ventricular dilation that follows chronic AI may result in mitral annular dilation or alteration in the papillary muscle orientations with resultant MR. Left atrial enlargement secondary to MR, or left atrial pressure overload as left ventricular end-diastolic pressure (LVEDP) rises in the course of AI, can occur.

MS results in a chronically underfilled LV because of progressive obstruction to left atrial emptying. This chronic underloading condition can result in diminished contractile function (a "disuse atrophy" of sort). In addition, if the cause of the MS is rheumatic, myofibril damage may also occur.

Contrary to the left ventricular pressure and volume *under*loading, the left atrium is both pressure and volume *over*loaded in order to maintain flow across the progressively narrowing mitral orifice. According to Gorlin's equation for pressure gradient:

$$\text{Pressure gradient (mmHg)} = \left\{ \frac{\text{Valve flow rate (mL/s)}}{[\text{K} \times \text{valve area (cm}^2)]} \right\}^2$$

It would predict that the pressure gradient increases by the square of any increase in flow rate or decrease in valve area. The elevated left atrial pressure leads to hypertrophy and eventually dilation that predisposes to premature atrial contractions and subsequent atrial fibrillation. The loss of atrial contraction will further diminish the flow across the stenotic MV. At the same time, the elevated left atrial pressure hinders pulmonary venous flow with consequent pulmonary vascular engorgement. This will lead to intimal hypertrophy that induces irreversible elevations in pulmonary vascular resistance. As a consequence of pulmonary hypertension, the right ventricular (RV) systolic pressure increases and right ventricle dilates, and these may lead to RV failure and tricuspid regurgitation.

MR results in volume overload of the LV. In MR, the LV ejects into both systemic circulation (across the AV; high afterload and low compliance) and retrograde to the left atrium (low afterload and high compliance) across the incompetent MV. This "back and forth" of the regurgitant volume results in left ventricular volume overload. However, this work is performed at a low pressure; therefore, left ventricular wall tension is minimally increased initially. As with AI, the volume overload results in marked left ventricular dilation and eccentric hypertrophy. At the same time, the left atrium is also volume overloaded and undergoes dilation. When the volume overload

occurs slowly, the pulmonary pressures increase minimally despite large regurgitant volumes. In contrast, acute MR, for example, following an acute myocardial infarction with papillary muscle rupture, presents a sudden volume overload to the left atrium. Without the time to dilate, the left atrial pressure rapidly rises, limiting pulmonary drainage with resultant pulmonary engorgement and acute increase in pulmonary pressures.

A.3. What are pressure–volume (P–V) loops? What do the different inflection points represent?

The P–V loop analysis (**Fig. 7.1**) depicts the relation between left ventricular volume and pressure during a single cardiac cycle. Opening and closing of the MV and AV are represented by the inflection points A, B, C, and D, respectively (**Fig. 7.1**). Moving from points A to D, AB depicts left ventricular filling, BC depicts isovolumetric contraction, CD shows left ventricular ejection, and DA shows isovolumetric relaxation. Point A coincides with opening of the MV and represents left ventricular end-systolic volume and early diastolic pressure. Point B is closure of the MV and the relationship of end-diastolic pressure (LVEDP) and volume (left ventricular end-diastolic volume [LVEDV]). Point C represents the opening of the AV and coincides with systemic, aortic diastolic pressure. Finally, point D is the closure of the AV and represents left ventricular end-systolic pressure (LVESP) and volume (LVESV), coinciding

with the dicrotic notch in the aortic pressure tracing (**Fig. 7.1**). Left ventricular compliance is the relation between pressure and volume and is defined by the slope of the filling phase (segment AB). Preload is the P–V relation before the onset of contraction (LVEDP). Contractility may be illustrated by the slope of a line termed the *end-systolic pressure–volume relation* (ESPVR). The ESPVR slope is created by connecting multiple points (D) from multiple P–V loops generated by changing the filling volume to the LV (**Fig. 7.2**). Increased contractility results in a steeper line, whereas diminished contractility results in a flatter line. The P–V loop analysis permits illustration of stroke volume and ejection fraction. Stroke volume is defined as difference in volume from the end of filling to the end of ejection (EDV–ESV), whereas the ejection fraction is the ratio of stroke volume to total volume in the heart at peak filling (SV/EDV). Therefore, the P–V loop analysis permits illustration of the volume–pressure relations and their changes with each of the four valvular lesions.

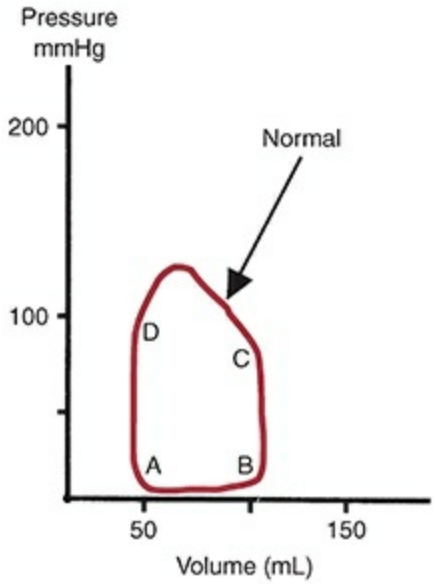

FIGURE 7.1. Normal P–V loop and valve positions. A, mitral valve (MV) opening; AB, left ventricular filling; B, MV closure; BC, isovolumetric contraction; C, aortic valve (AV) opening; CD, ejection; D, AV closure; DA, isovolumetric relaxation.

A.4. What are representative P–V loops for the four valvular lesions?

The hallmarks of AS, illustrated by the P–V loop analysis, are an increased left ventricular systolic pressure and an upward and counterclockwise rotation in the end-diastolic P–V relation (AB) indicative of decreased chamber compliance (**Fig. 7.3**). Stroke volume and ejection fraction are well preserved, but the ejection

phase of the loop occurs at much higher pressures. This is accomplished by an increase in contractility (counterclockwise rotation of the ESPVR line).

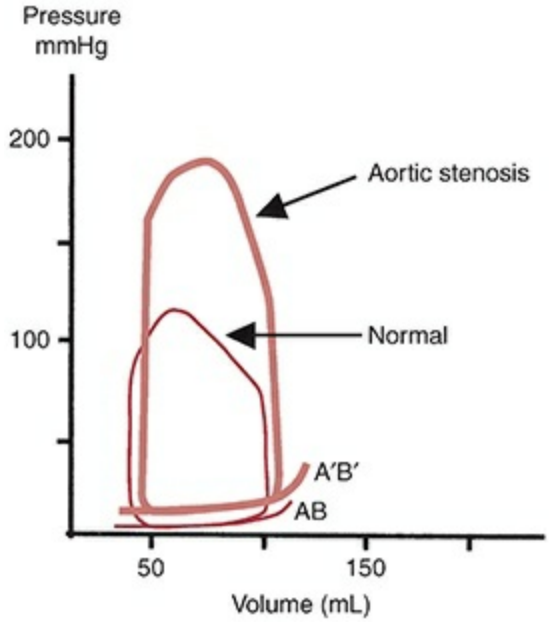

FIGURE 7.3. P–V loop of AS.

The schematic P–V loop for chronic AI depicts an enlarged LV. The minimal change in LVEDP despite the large volume overload is seen by the shift in the diastolic P–V curve to the right (A″B″) (**Fig. 7.4**). Low systemic diastolic pressures result in a brief isovolumetric phase (B″C″) and early complete ejection. The isovolumetric relaxation phase is absent because the incompetent valve permits regurgitant filling of the LV from the aorta during diastole even before opening of the MV. In contrast, when acute AI occurs, the left ventricular compliance is unchanged. Rapid increases in LVEDP from volume overload along the unshifted left ventricular diastolic P–V curve (A′B′) rapidly lead to increased left atrial pressure and pulmonary congestion.

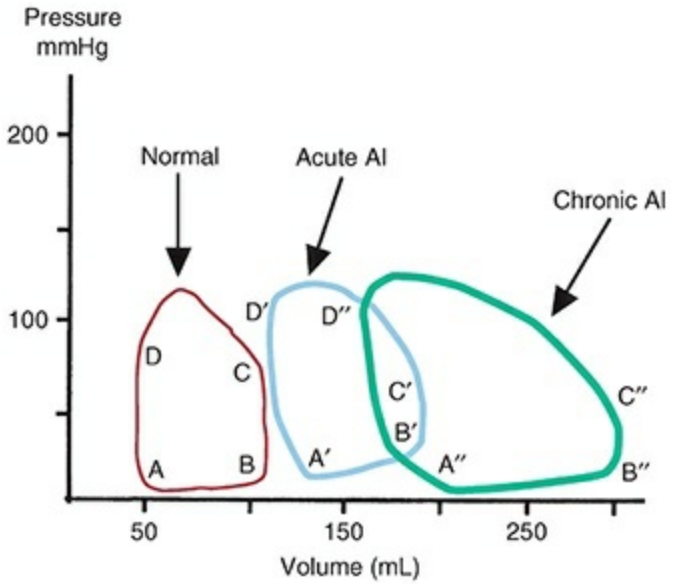

FIGURE 7.4. **P–V loops of acute and chronic aortic insufficiency (AI).**

The P–V loop of MS illustrates hypovolemia, the cause of which cannot be determined from the loop alone (**Fig. 7.5**). Because the predominant impact of MS occurs proximal to the LV, the P–V analysis format is less useful.

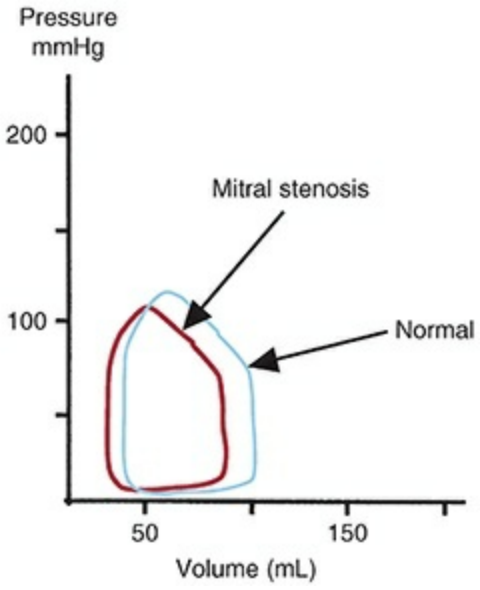

FIGURE 7.5. **P–V loops of MS.**

In MR, the diastolic P–V relation (line AB) is shifted to the right, as it is in chronic AI, consistent with a marked increase in compliance (**Fig. 7.6**). The isovolumetric phase (BC) is nearly

absent because the left atrium generally serves as a low-pressure/high-compliance route for ejection through an incompetent MV. Decreases in contractility are depicted by a decrease in the slope of the end-systolic-PV line (line through D).

A.5. Draw the pressure/time curves for the LV, left atrium, pulmonary artery, and aorta for a normal patient and for patients with each of the four valvular lesions.

Normal curves are shown in **Figure 7.7**. The points A, B, C, and D correspond to the same points in the P–V loops.

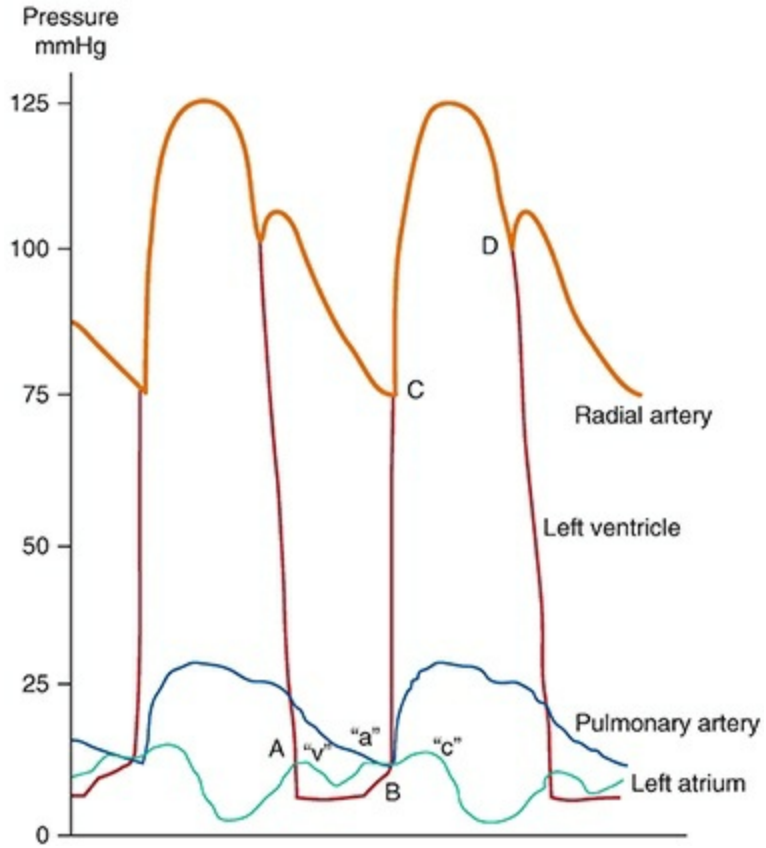

FIGURE 7.7. Pressure curves for the LV, left atrium, pulmonary artery, and aorta in a healthy individual.

Aortic Stenosis

The additional systolic pressure work of AS can be seen in the left ventricular pressure tracing (**Fig. 7.8**). Elevations in LVEDP (point B) can be seen to diminish the perfusion gradient for coronary flow to the LV. The augmentation in left ventricular filling late in diastole secondary to atrial contraction (left atrial "kick" from sinus rhythm) is highlighted in the inset. Rising left ventricular diastolic pressures secondary to decreased compliance necessitate elevations in left atrial pressures to permit complete left ventricular volume loading. Atrial systole provides this elevation in left atrial pressure synchronous with elevations in LVEDP while keeping left atrial pressures relatively low during the remaining cardiac cycle facilitating pulmonary venous drainage.

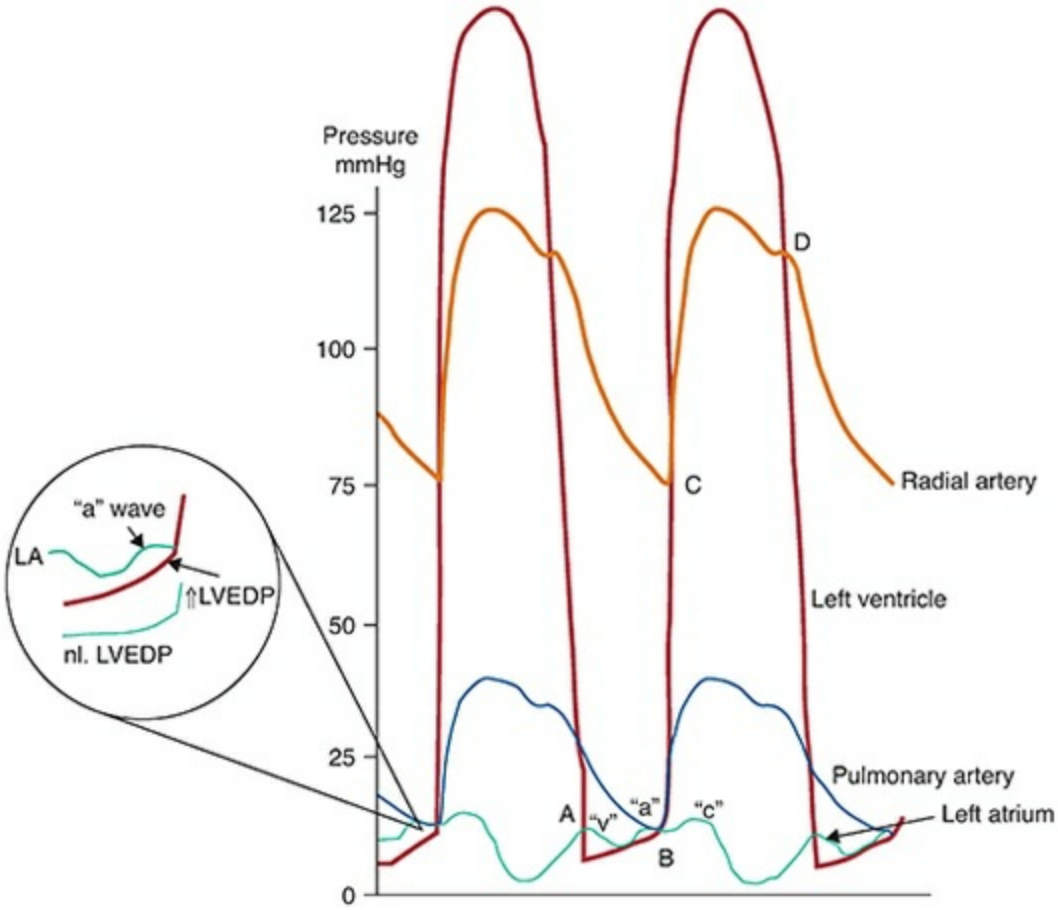

FIGURE 7.8. Pressure curves for the LV, left atrium (LA), pulmonary artery, and aorta in patients with AS. LVEDP, left ventricular end-diastolic pressure.

Aortic Insufficiency

The rapid upstroke and rapid decline of arterial pressure indicate absence of AV closure and low end-diastolic aortic pressure (**Fig. 7.9**). Elevations in LVEDV and LVEDP are typical of AI. The early increase in LVEDP can result in left ventricular pressures exceeding those of the left atrium during diastole, with resultant premature closure of the MV.

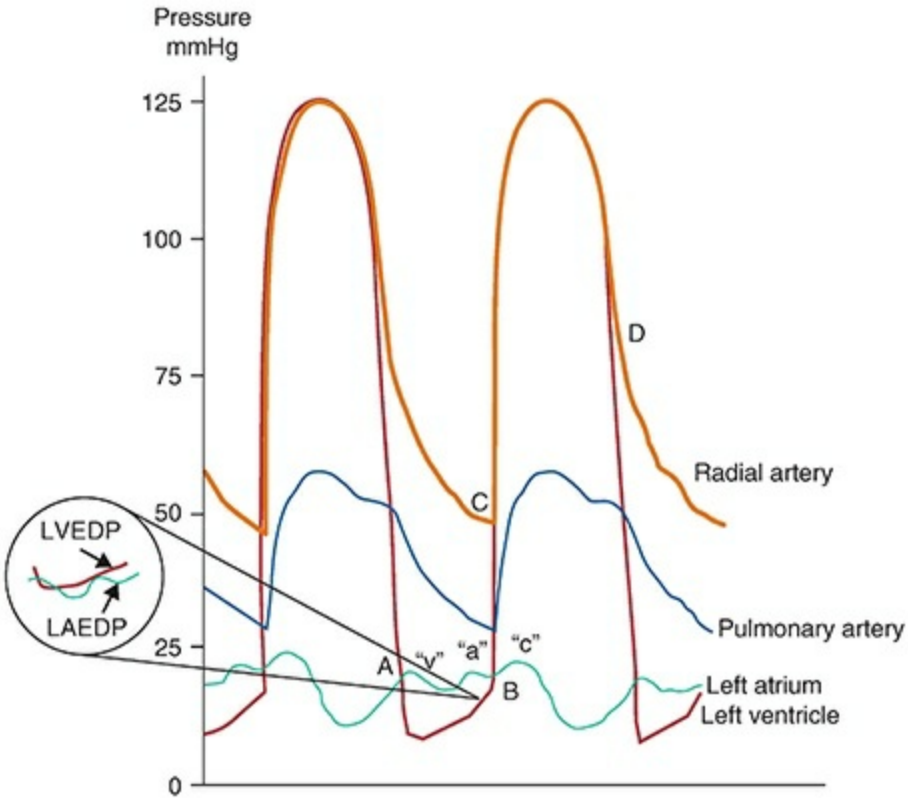

FIGURE 7.9. Pressure curves for the LV, left atrium, pulmonary artery, and aorta in patients with aortic regurgitation. LAEDP, left atrium end-diastolic pressure; LVEDP, left ventricular end-diastolic pressure.

Mitral Stenosis

Elevations in pressure are seen in both the left atrial and pulmonary artery tracing with MS (**Fig. 7.10**). The large gradient between left atrial and left ventricular pressures is highlighted in the inset. Chronic elevation in pulmonary volume induces changes the pulmonary arterial vascular bed and results in pulmonary hypertension.

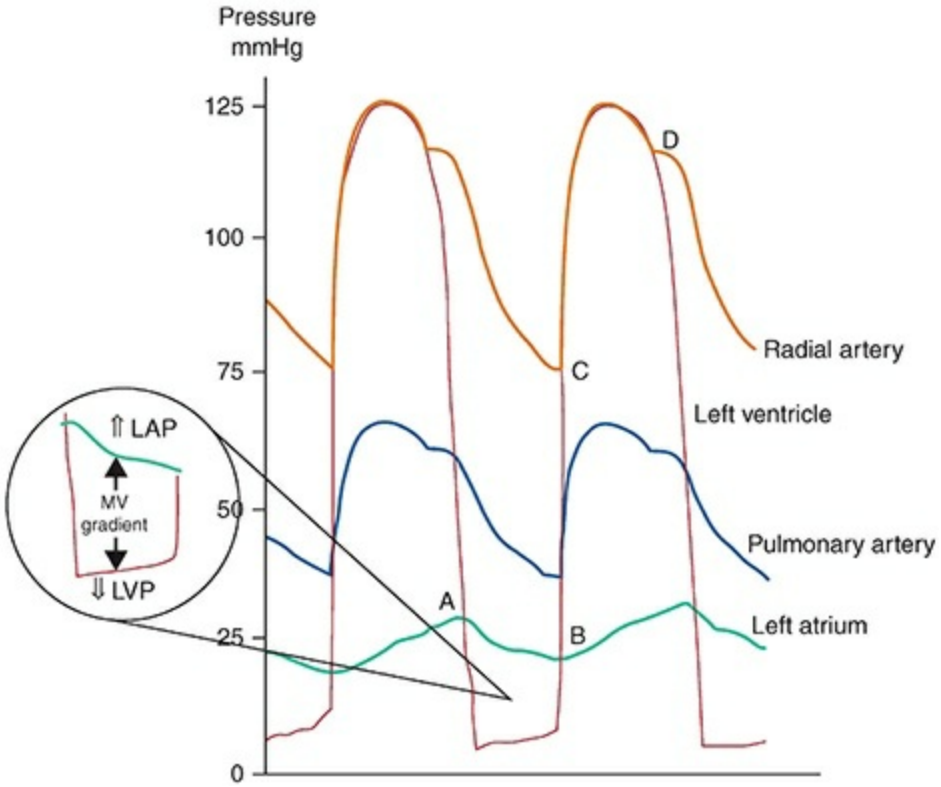

FIGURE 7.10. Pressure curves for the LV, left atrium, pulmonary artery, and aorta in patients with MS. LAP, left atrial pressure; LVP, left ventricular pressure; MV, mitral valve.

Mitral Regurgitation

The hallmark of MR is the marked elevations of left atrial pressure during systole and the occurrence of a giant "cv" wave and elevated pulmonary artery pressures (**Fig. 7.11**).

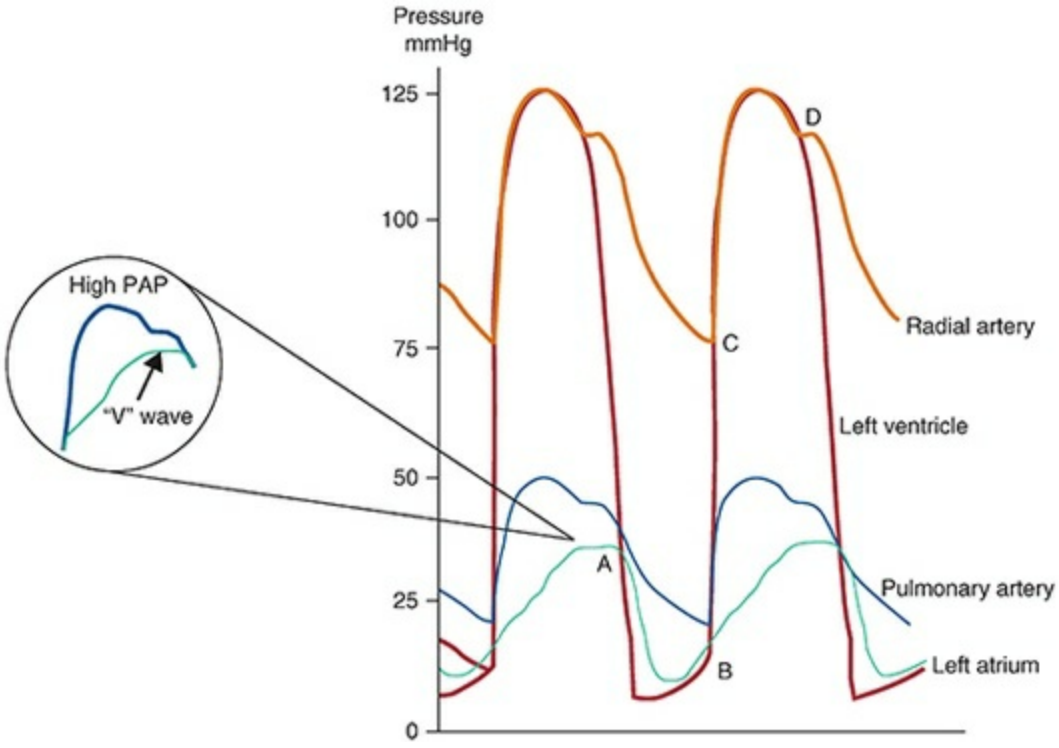

FIGURE 7.11. Pressure curves for the LV, left atrium, pulmonary artery, and aorta in patients with MR. PAP, pulmonary artery pressure.

A.6. What are the basic principles of echocardiography? What are M-mode, B-mode, and Doppler color modalities? How do TTE and transesophageal echocardiography (TEE) differ?

Echocardiography is the use of sound waves to image structures and blood flow within the heart and great vessels. To image tissue, sound waves are emitted from a transducer at known speeds and constant intervals. The sound packets bounce off structures in their path, and the reflected sound waves are received by the transducer during its "listening" mode. The time it takes for the reflected waves to return to the crystal is measured, and because the velocity of sound in tissues is relatively constant (1,540 m per second), solving for distance can be easily accomplished:

$$\text{Distance} = \tfrac{1}{2}\,(\text{velocity} \times \text{time})$$

(½ because the distance is traversed twice, once to the object and again on returning).

In this manner, the spatial orientation of cardiac structures can be determined. The strength of the returning signal can be quantified as an amplitude, thus "A" or amplitude mode (**Fig. 7.12B**). The echocardiographic system codes this amplitude on a black and white scale, thereby converting the amplitude to brightness or B-mode scanning (**Fig. 7.12C**). **Figure 7.12D** shows this "ice-pick" view through the LV of the heart. Each change in tissue density results in some sound waves being reflected and hence an interface. In this example, bold lines are seen at the epicardial, the endocardial–chamber, the chamber–endocardial, and the epicardial borders. If these amplitude bars are displayed in real time, a motion or M-mode display results (**Fig. 7.12E**). These images were difficult to reliably obtain and interpret because the views represent a linear slice without surrounding structural images for referencing. If the probe is moved in a sweeping mode, back and forth repetitively, multiple M-mode images can be obtained in a given instant and a two-dimensional (2D) image formed. This rapid back and forth sweep of the ultrasound beam is performed electronically in a phased array transducer. The images derived in this manner appear as a cineradiographic display of myocardial movement. Echocardiography can provide information about the size, shape, location, and movement of myocardial structures.

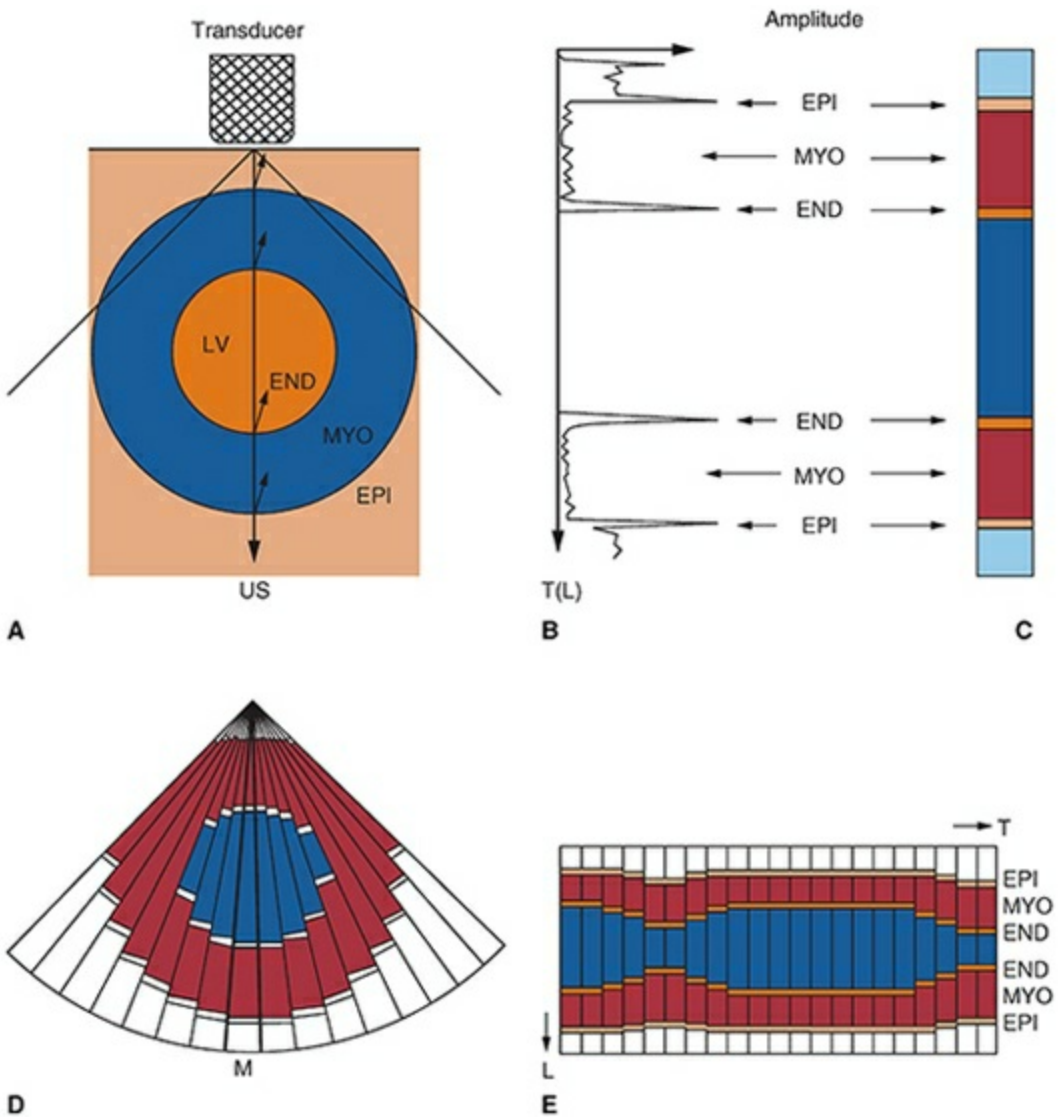

FIGURE 7.12. The process of producing the B-mode and M-mode images. A. A pulse of ultrasound is emitted into the object, and the backscattered echo is received by the same transducer. **B.** The received acoustic signal is converted to the electric signal (A-mode). **C.** The amplitude is modulated into brightness (B-mode). **D.** As subsequent pulses of ultrasound are emitted with the sequentially changing angles and the obtained one-dimensional (1D) B-mode images are compounded according to the direction of each ultrasound emission, the first frame of the sector-shaped image is formed. **E.** When the ultrasound is repeatedly transmitted in one direction, a series of 1D B-mode images is obtained. As these are arranged against time, an M-mode image is obtained. END, endocardium; EPI, epicardium; L, length; LV, left ventricle; M, motion; MYO, myocardium; T, time; US, ultrasound. (*Reprinted with permission from Oka Y, Goldiner PL, eds.* Transesophageal Echocardiography. *Philadelphia, PA: JB Lippincott; 1992:12.*)

In addition to determining how long it takes for a given sound wave to return and thereby deriving the distance from the transducer, contact of the sound wave packet with the reflecting

object (tissue, blood cells, air) will alter the wavelength of the sound packet according to the Doppler principle. When the object coming in contact with the sound wave is moving toward the source of the ultrasound, the reflected ultrasound wavelengths are compressed (shorter). The opposite occurs when the contacted object is moving away from the sound source. These shifts in frequency (ΔF) are proportional to the velocity of the contacted structure, and thereby, the velocity and direction of the encountered object (usually of blood flow) can be calculated. With Doppler ultrasound, only the component of blood flow parallel to the Doppler beam will be analyzed because the Doppler equation velocity = $c\ (\Delta F) / 2\ F_T\ (\cos \theta)$ contains the cosine of the angle of incidence between the ultrasound beam and the moving object (F_T is the transmitted frequency). Because the cosine of 90 degrees is zero, blood flow that is perpendicular to the ultrasound beam will not cause any Doppler shift and, therefore, cannot be measured. For this reason, it is important to choose an ultrasound "window" in which the expected blood flow direction is most parallel to the ultrasound. This velocity information can be displayed on a color map (Doppler color flow) or on a time/velocity scale (spectral Doppler display). Doppler-derived blood flow velocity information can determine laminar and turbulent flow patterns, regurgitant or stenotic lesions, and congenital anomalies and can permit quantification of pressure gradients.

Pressure gradients (ΔP) can be estimated from the measured blood flow velocity using the modified Bernoulli equation ($\Delta P = 4 \times \text{velocity}^2$). Simply, the greater the velocity of blood flow, the higher is the ΔP. TTE uses imaging points or "acoustic windows" obtained with the transducer handheld on the chest wall. TTE is simple and noninvasive. Most standard echocardiograms are obtained from this position. During cardiac

surgery, the chest wall is in the sterile field and therefore unavailable. The esophagus lies immediately adjacent to the heart outside of the operative field and affords an excellent imaging vantage point. In 1976, Yasu Oka from the Albert Einstein College of Medicine developed a practical method of intraoperative imaging. She mounted an ultrasound crystal on the end of a gastroscope and, thereby, obtained images of the heart during surgery. This has been refined considerably since. TEE has become the standard of care for heart surgery at many institutions. The close proximity of the probe to the heart affords excellent resolution. The probe is not in the operative field, so surgery is unhindered and sterility is not an issue. Although mildly invasive, the risk for esophageal injury in the anesthetized state is very low.

Intraoperative TEE is beneficial for quantification of cardiac contractility, for determination of the severity of regurgitant and stenotic valvular disease, for detection of intracardiac shunts and the occurrence of dissections, and as a guide for catheter placement.

A.7. What are the three TEE vantage points for the comprehensive imaging of the LV? How are pressure gradients measured by echocardiography? How do the pressure gradients derived from Doppler echocardiography differ from those obtained in the catheterization laboratory by direct pressure measurement?

The heart has two main axes: the longitudinal axis running from

the base to the apex and the short axis perpendicular to that. Multiple scan planes are required to completely image a 3D structure, such as the heart. The LV is divided into 17 segments: 6 at the basal level, 6 at the midpapillary level, 4 at the apical level, and 1 apical cap (**Fig. 7.13**). By moving the TEE probe in the esophagus and rotating the crystal within the transducer tip, the LV can be imaged from three acoustic windows. These are the midesophageal four-chamber, the transgastric short axis, and the transgastric two-chamber view. Normal ventricular motion requires that each wall segment thickens and moves toward the left ventricular cavity at systole. Segmental wall function is usually quantified as normal, hypokinesis, akinesis, and dyskinesis.

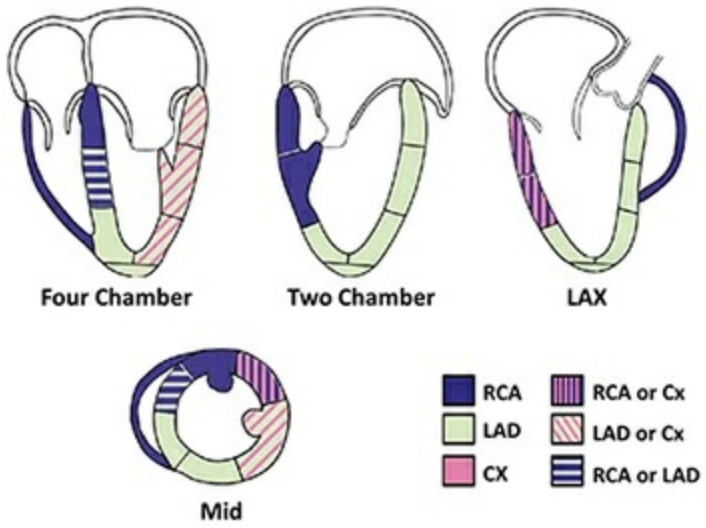

FIGURE 7.13. Wall segments of the LV. CX, circumflex; LAD, left anterior descending; LAX, long axis; RCA, right coronary artery. (*Reprinted from Lang RM, Bierig M, Devereux RB, et al. Recommendations for chamber quantification: a report from the American Society of Echocardiography's Guidelines and Standards Committee and the Chamber Quantification Writing Group, developed in conjunction with the European Association of Echocardiography, a branch of the European Society of Cardiology.* J Am Soc Echocardiogr. *2005;18[12]:1440–1463. In addition to function, TEE permits the determination of wall thickness and chamber size—important parameters in understanding the pathophysiology of valvular heart disease.

As mentioned previously, pressure gradients are derived through analysis of the Doppler profiles of blood flow. A commonly determined echocardiography gradient is that which is present from the LV to the aorta in the setting of AS. To obtain the change in blood flow velocity across the AV with TEE, the probe is advanced far into the stomach and sharply anteflexed and left deflected to obtain the window from the apex of the heart (deep transgastric long axis) and align the ultrasound beam most parallel to the path of blood flow. From this window, the continuous-wave Doppler cursor is directed across the left ventricular outflow tract and AV. An example of such a spectral Doppler display is seen in **Figure 7.14**. The large increase in blood flow velocity in this display occurs at the narrowest point along its path, which, in this case, is the stenosed orifice of the AV. Using the modified Bernoulli equation mentioned previously, a gradient is calculated (100 mmHg in the example). This represents the maximum instantaneous systolic pressure difference between the LV and the aorta. AS is also quantified at the time of catheterization by measuring the pressures from within the LV and the aorta as a rapid response pressure transducer catheter is withdrawn from the LV back to the aorta across the stenotic valve. The standard reported pressure gradient is the difference between the maximum LV and aorta pressures. **Figure 7.15** illustrates that these peaks are not simultaneous events. Therefore, Doppler-derived AS gradients are usually higher than those derived at the time of left heart catheterization.

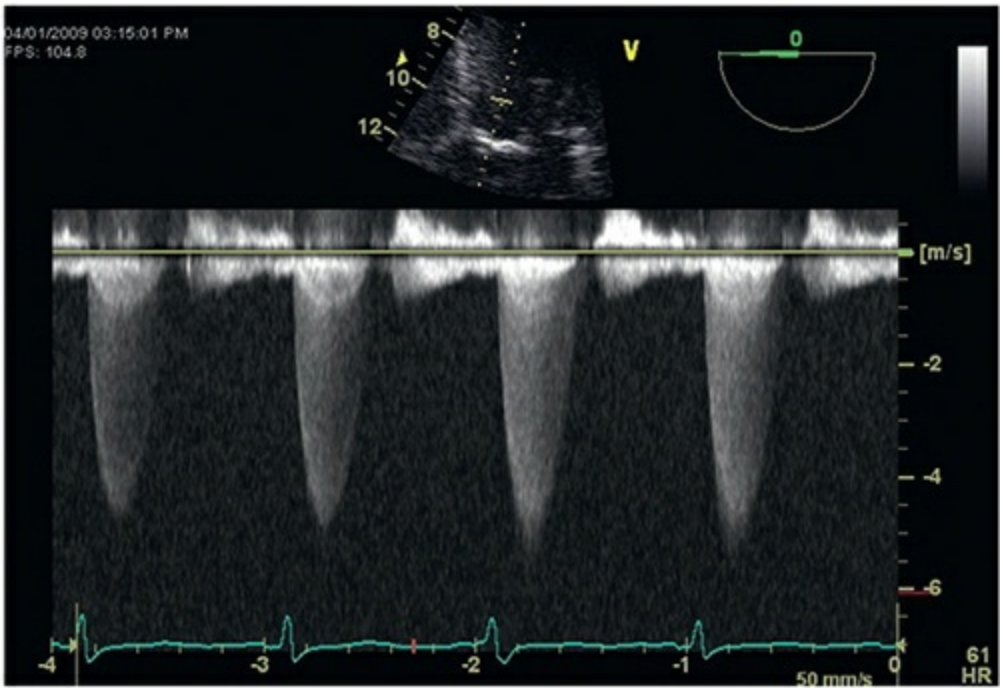

FIGURE 7.14. Continuous-wave Doppler across the AV in the deep transgastric apical view from a patient with severe AS.

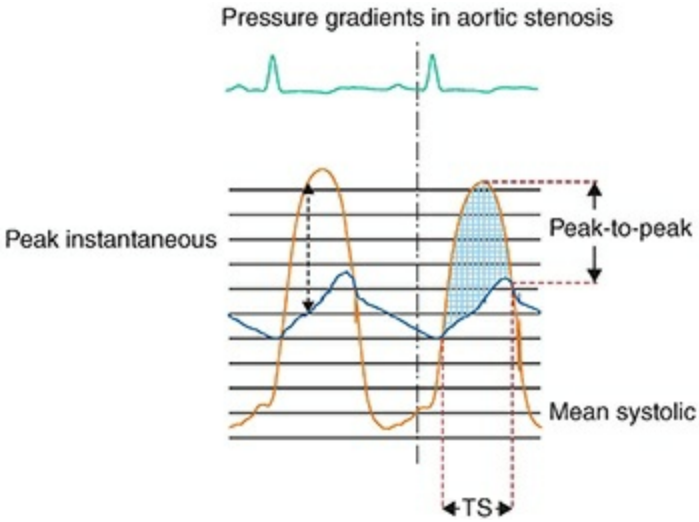

FIGURE 7.15. Pressure gradients in severe AS are measured during systole as the difference between aortic and left ventricular pressures displayed using a scale of 0 to 20 mmHg. The peak instantaneous gradient is the maximum gradient noted; the peak-to-peak gradient is the difference between peak left ventricular and aortic pressures. The mean systolic gradient is the average of all systolic pressure gradients noted during systolic ejection (TS). A.8. What is the role for three-dimensional (3D) echocardiography in the operating room?

Modern TEE technology has progressed from 2D multiplane images to real-time 3D displays of the heart. The 3D probes are etched in such a way to allow for a pyramidal scanning sector (volume). There are different 3D imaging modalities used to assess cardiac anatomy (real-time, zoom, and full-volume, usually gated to ECG signal). The 3D images can be further modified by cropping in any plane to investigate details in morphology. Studies have shown that intraoperative assessment of the MV with 3D TEE examinations have decreased interobserver variability and provided better correlation with surgical findings.

Left ventricular assessments including volume and wall motion can easily be done in the operating room. After identification of the left ventricular walls and apex from two orthogonal 2D views, a 3D model of the heart is created using endocardial border tracking. Stroke volume and ejection fraction can be automatically calculated. However, 3D echocardiography can only be combined with color, not spectral, Doppler ultrasound and is prone to all limitations related to 2D echocardiography.

A.9. What are the echocardiographic and cardiac catheterization criteria for the four valvular lesions?

The TEE severity scales of the various valvular lesions are summarized in **Table 7.1**.

TABLE 7.1 Transesophageal Echocardiography Severity Scales of Valvular Lesions

	Severity Scale			
Measurement	**Normal**	**Mild**	**Moderate**	**Severe**
MS				
MVA (cm^2)	4.0–6.0	>1.5	1.0–1.5	<1.0
Mean pressure gradient (mmHg)	<2.0	<5.0	5.0–10.0	>10.0
AS				
AVA (cm^2)	2.5–3.5	>1.5	1.0–1.5	<1.0
Mean pressure gradient (mmHg)	<5	<20	20–40	>40
MR				
Jet area/LA area	0	<20%	20%–40%	>40%
Jet area (cm^2)	0	<4.0	4.0–10.0	>10.0
Pulmonary vein Doppler	S wave » D wave	S > D	S < D	Systolic flow reversal
AI				
Jet width/LVOT width	0	<25%	25%–60%	>60%

AI, aortic insufficiency; AS, aortic stenosis; AVA, aortic valve area; LA, left atrium; LVOT, left ventricular outflow tract; MR, mitral regurgitation; MS, mitral stenosis; MVA, mitral valve area.

Aortic Stenosis

Echocardiographic criteria for AS include 2D imaging demonstrating limited AV cusp motion, small orifice, and left

ventricular concentric hypertrophy (**Fig. 7.16**, **Video 7.1**). Doppler examination will reveal a turbulent, high-velocity jet across the AV, and color flow Doppler will demonstrate a turbulent, mosaic-appearing color map. The gradient across the AV measured at cardiac catheterization is different from that measured by echocardiography as mentioned previously. Quantification of the Doppler-derived AS pressure gradient relies on the modified Bernoulli equation.

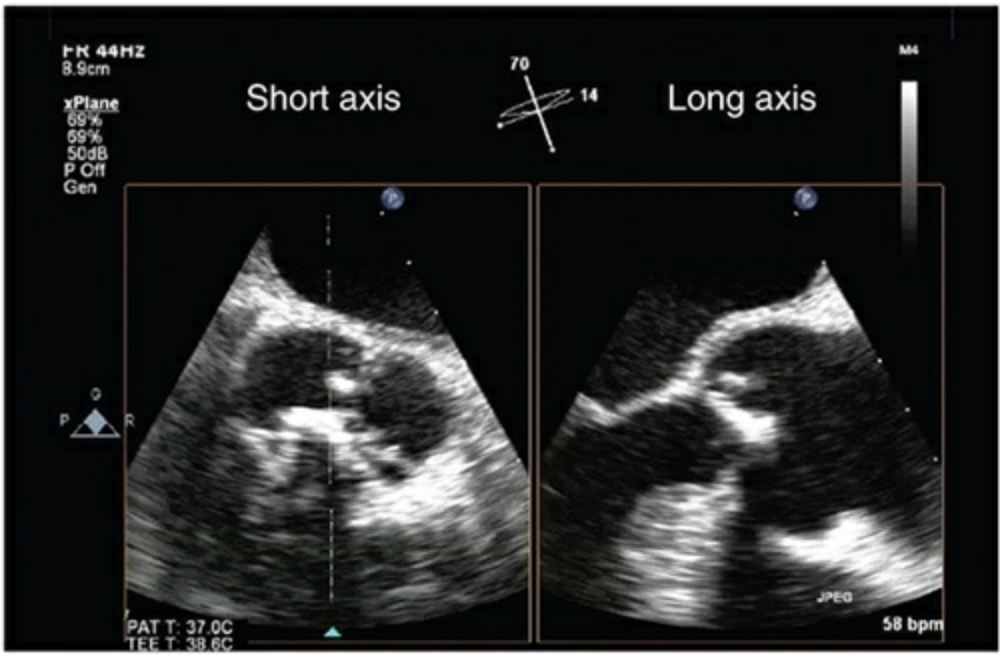

FIGURE 7.16. Transesophageal echocardiographic findings of moderate AS (midesophageal AV short-axis view [left] and long-axis view [right]). The AV cusps are calcified and demonstrate limited systolic excursion.

$$\text{Pressure gradient (mmHg)} = 4\ (\text{transaortic valve velocity, m/s})^2$$

Because flow is an important determinant of pressure gradients, both the catheterization and Doppler-derived values must be interpreted along with cardiac output. Calculations permit the determination of a valve area. Severe AS is present when the mean pressure gradient exceeds 40 mmHg or the valve area is less than 1.0 cm^2.

Aortic Insufficiency

Catheterization criteria for AI rely on the qualitative estimation of the regurgitation volume and an estimation of left ventricular size and ejection fraction. Similar quantification can be made from Doppler color echocardiography–derived data. A commonly used echocardiographic criterion compares the width of the regurgitant jet at the level of the AV to the width of the left ventricular outflow tract. A ratio of greater than 0.6 corresponds with severe AI (**Fig. 7.17**, **Video 7.2**). Another sign of severe AI can be observed in the spectral Doppler display of blood velocity in the descending thoracic aorta. The TEE probe is advanced to the level of the descending thoracic aorta and rotated to 90 degrees to obtain a long axis view. Under normal conditions, flow remains forward (to distal beds) during diastole. In severe AI, regurgitation of blood back into the ventricle decreases proximal pressure in the aorta, and thus, the spectral display of blood velocities will demonstrate a reversal of blood flow during diastole back toward the aortic root.

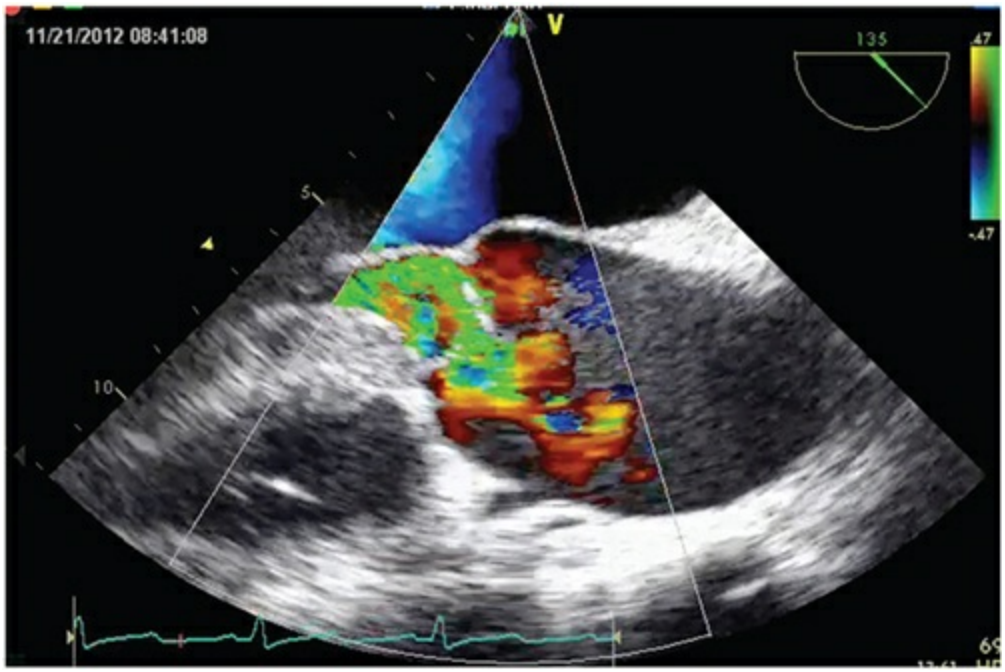

FIGURE 7.17. Transesophageal echocardiographic findings of moderate aortic regurgitation (midesophageal AV long-axis view; color flow Doppler).

Mitral Stenosis

The severity of MS can be obtained by the direct measurement of a diastolic gradient between the left atrium and ventricle at the time of cardiac catheterization. This requires a transatrial puncture, a procedure largely replaced by echocardiographic techniques. Echocardiographic diagnosis is based on gradient estimation by Doppler and by measuring the rate of decay in the pressure with the time spent in diastole (pressure halftime). The MV area (cm^2) can be derived from an empirical formula wherein the MV area equals 220 divided by this pressure halftime. Severe MS is present when the mean diastolic gradient exceeds 10 mmHg, corresponding to a valve area of less than 1.0 cm^2 (**Fig. 7.18**, **Video 7.3**).

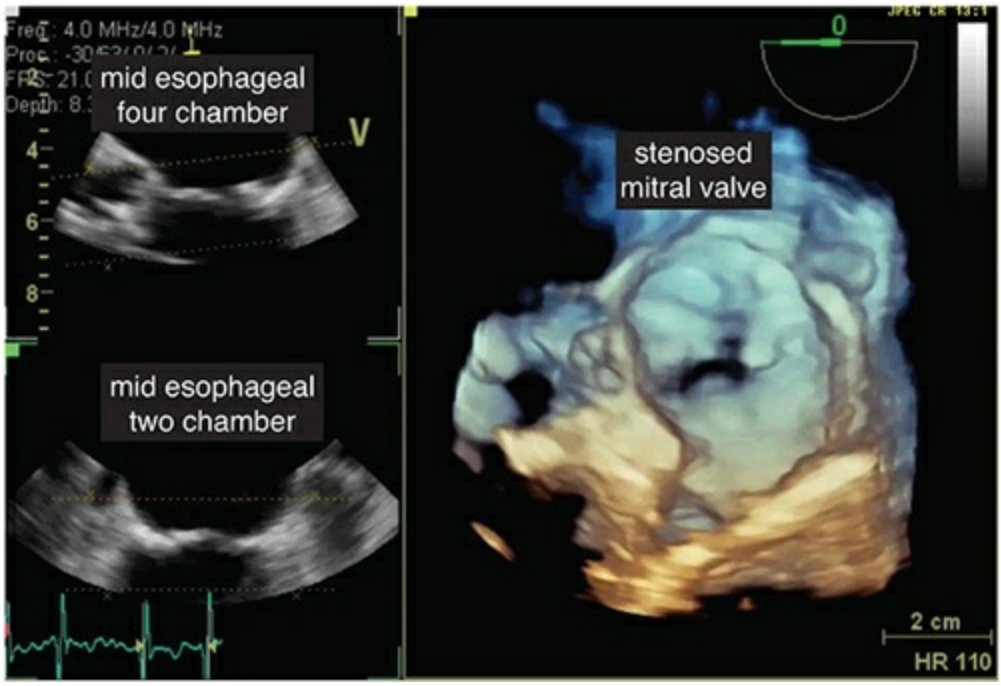

FIGURE 7.18. Transesophageal echocardiographic findings of severe MS with 2D view (left) and 3D view (right).

Mitral Regurgitation

In the presence of MR, ventriculography will demonstrate the reflux of dye from the LV into the left atrium. Severe MR is

diagnosed when dye refluxes into the pulmonary veins. Color Doppler echocardiography permits similar quantification. Estimation relies on an estimation of regurgitant jet area as compared with the left atrium area and through analysis of pulmonary venous flow profiles (**Fig. 7.19**, **Video 7.4**).

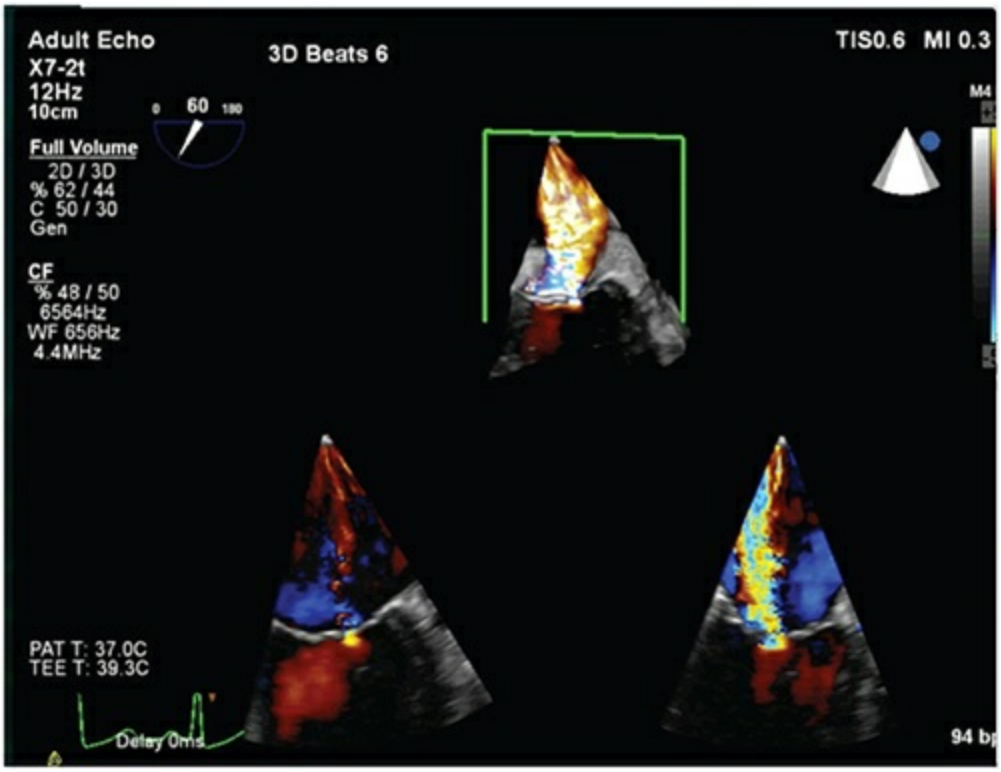

FIGURE 7.19. Transesophageal echocardiographic findings of moderate MR (color flow Doppler) with 3D view (top) and 2D view (bottom).

In every case, color Doppler echocardiography is often useful in identifying the cause of the valvular lesion, its extent of involvement within and around the valve, and the associated hemodynamic changes. Therefore, for many valvular lesions, it may be sufficient for the diagnosis. Catheterization, however, is often performed to assess the presence of concomitant coronary artery disease, especially in patients of advanced age.

B. Preoperative Evaluation and Preparation

B.1. What are the presenting signs and symptoms of the four valvular lesions listed previously?

See **Table 7.2**.

TABLE 7.2 The Signs and Symptoms for the Various Valvular Lesions

Lesion	Signs and Symptoms
AS	Angina, syncope, dyspnea/CHF
AI	
Chronic	Fatigability, dyspnea
Acute	Severe pulmonary edema, CHF
MS	Pulmonary congestion, AFib
MR	
Chronic	DOE, PND, AFib
Acute	Severe pulmonary edema, CHF

AFib, atrial fibrillation; AI, aortic insufficiency; AS, aortic stenosis; CHF, congestive heart failure; DOE, dyspnea on exertion; MR, mitral regurgitation; MS, mitral stenosis; PND, paroxysmal nocturnal dyspnea.

Aortic Stenosis

The triad of angina, syncope, and congestive heart failure represents the progression of symptoms associated with AS. These symptoms correlate directly with mortality; the 50% survival data for these symptoms are 5, 3, and 2 years from the onset of these symptoms, respectively. Angina results from both

increased demand for and a decrease in supply of coronary blood flow. Increased muscle mass from left ventricular hypertrophy and the high energy requirements to generate increased (high) systolic pressure combine to increase demands for coronary blood flow. In addition, insufficient supply secondary to decreased perfusion gradients and a decrease in coronary vasculature relative to the increased myocardial mass add up to diminish relative myocardial blood supply. Therefore, up to one-third of patients with AS can have angina in the absence of significant coronary artery disease.

Aortic Insufficiency

Patients with AI have variable clinical presentations based primarily on the rapidity with which the left ventricular volume overload develops. When the volume increase occurs gradually as in chronic AI, there is usually a long asymptomatic period. The onset of fatigue and dyspnea signals either reduced cardiac output or increased LVEDP, indicative of impairment of left ventricular contractile function. When AI occurs acutely, the ventricular compliance is unchanged; increased left ventricular diastolic volumes from regurgitant flow, therefore, lead to rapid rises in LVEDP and the clinical picture of congestive failure.

Mitral Stenosis

In MS, the slow and progressive obstruction to flow across the MV leads to gradual increase in left atrial pressure and volume. Symptoms of pulmonary congestion result from elevations in left atrial pressures and *not* from poor left ventricular systolic function. Atrial fibrillation develops secondary to atrial dilation.

Mitral Regurgitation

The time course for the development of MR determines the severity of the symptoms. When the volume of regurgitant flow from the LV to the left atrium increases gradually, the left

atrium compensates by gradual dilation. In contrast, the onset of acute MR can lead to rapid increases in left atrial pressures, severe pulmonary congestion, and congestive heart failure.

B.2. What is the New York Heart Association classification of heart failure?

The New York Heart Association heart failure classification is based on the severity of symptoms, specifically dyspnea and fatigue. The classes are the following:

Class I—no symptoms (fatigue, palpitations, dyspnea, or angina) during ordinary physical activity; no limitations of physical activity

Class II—symptoms with ordinary activity but comfortable at rest; slight limitation of physical activity

Class III—symptoms with less than ordinary activity but comfortable at rest; marked limitation of physical activity

Class IV—symptoms at rest; inability to carry on any physical activity without discomfort

Raphael C, Briscoe C, Davies J, et al. Limitations of the New York Heart Association functional classification system and self-reported walking distances in chronic heart failure. *Heart*. 2007;93(4):476–482.

B.3. Discuss the role of premedication for patients with the four different valvular lesions.

The role of premedication is to allay the anxiety of the impending surgical procedure, thereby controlling the sympathetic outflow that may accompany the stress response. Acute changes in heart rate, venous return, and systemic resistance can have particularly profound effects on patients with valvular heart disease.

Patients with AS may benefit from premedication to prevent unnecessary increases in heart rate. Concern must be taken to ensure adequate venous return and preservation of sinus rhythm (see later discussion).

Patients with AI can similarly benefit from premedication because any increases in afterload, which may accompany sympathetic stimulation, can increase regurgitant volume. Drug doses should be adjusted based on the severity of debilitation and degree of systemic hypoperfusion.

Patients with MS should be premedicated with caution. Elevations in carbon dioxide resulting from opioid-induced hypoventilation can dramatically elevate pulmonary pressures, further compromising right ventricle output. Equally important, venodilation may excessively diminish filling pressures.

Patients with MR can respond similarly to those with MS, particularly when pulmonary hypertension is present. However, elevations in systemic pressure from stress can also compromise forward left ventricular output. Proper premedication can be delivered by careful dose selection and the provision of supplemental oxygen.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1077–1111.

B.4. How would you premedicate the patient with severe AS and MR?

Premedication of a patient with severe AS and MR must be approached with caution. The patient should receive supplemental oxygen. A light premedication could be provided with small doses of benzodiazepines by mouth. However, it would preferable to titrate in small intravenous doses of sedation (e.g., midazolam 0.5 mg) while the patient is closely monitored in the operating room or holding area with oxygen supplementation. It is important to remember that there may be significant delay in the onset of sedation secondary to pooling in the pulmonary circulation, and adequate waiting periods must be observed to avoid inadvertent overdose, which may herald respiratory depression, pulmonary hypertension, and systemic hypotension. In the elderly, use of benzodiazepines has been linked to postoperative delirium, which can be quite severe and difficult to treat increasing their length of stay and resource utilization.

C. Intraoperative Management

C.1. Outline the hemodynamic management goals for each of the four valvular lesions. What are the anesthetic goals with respect to heart rate and rhythm, preload, afterload, and contractility?

Table 7.3 summarizes the hemodynamic goals with respect to heart rate and rhythm, preload, afterload, and contractility.

TABLE 7.3 Hemodynamic Goals for the Various Valvular Lesions

		Hemodynamic Goals		
Lesions	**HR and Rhythm**	**Preload**	**Afterload**	**Contractility**
AS	60–70, sinus	Full	Maintain	—
AI	80–90	Maintain	Lower	May need support
MS	60–70	Full	—	—
MR	80–90, sinus if possible	Maintain	Lower	May need support

AI, aortic insufficiency; AS, aortic stenosis; HR, heart rate (beats per minute); MR, mitral regurgitation; MS, mitral stenosis.

Aortic Stenosis

Patients with AS depend on left ventricular filling occurring through a well-timed atrial contraction. Similarly, left ventricular hypertrophy renders the LV stiff, and adequate preload is required. The stenotic AV is a fixed lesion that will not respond to pharmacologic intervention. Reducing vascular tone will only lower diastolic coronary perfusion gradients and should be avoided. Patients with AS experiencing angina may require the administration of an α-agonist such as phenylephrine rather than nitroglycerin to increase coronary perfusion pressure.

Aortic Insufficiency

The severity of AI is determined by the size of the regurgitant orifice, the diastolic pressure gradient between the aorta and LV, and the duration of diastole. Elevated heart rates decrease the time spent in diastole and can lead to a decrease in heart size. Afterload reduction can lessen the regurgitant driving forces, but therapeutic maneuvers to accomplish this may be limited by resulting systemic hypotension.

Mitral Stenosis

Slower heart rates permit adequate time for transfer of blood from the left atrium to the LV across the stenotic MV to occur. In addition, the pressure gradient across the MV is also reduced, thereby lowering left atrial pressure and diminishing pulmonary congestion. Patients with MS can swiftly deteriorate in the setting of rapid heart rates. The decreased filling time exacerbates the marked elevation of left atrial pressures, and pulmonary edema can rapidly ensue. Whereas left ventricular contractility is generally preserved in MS, use of β-blockade does result in decreased RV contractility, which in the setting of

pulmonary hypertension can further compromise the cardiac output and systemic blood pressure. However, the loss in RV contractility is more than offset by the beneficial effects of the reduction of heart rate. Because there is some variability in the individual response, the use of short-acting β-blockers, such as esmolol, is prudent because an adverse response could be catastrophic.

Mitral Regurgitation

Patients with MR can rapidly deteriorate with marked increases in systemic blood pressure, so afterload reduction is recommended. As with AI, slightly increased heart rates (80 to 90 beats per minute) should result in smaller left ventricular volumes. However, tachycardia should be avoided in patients with ischemic (functional) MR.

Frogel J, Galusca D. Anesthetic considerations for patients with advanced valvular heart disease undergoing noncardiac surgery. *Anesthesiol Clin*. 2010;28:67–85.

C.2. What are the hemodynamic goals for this patient with the combination of severe AS and MR?

In this patient with combined AS and MR, therapy benefiting AS may exacerbate the severity of the MR. A good rule of thumb is to prioritize the management based on the character of the paramount symptoms. Patients with AS and MR who present with syncope or angina are best managed for their AS, whereas patients with dyspnea and pulmonary edema are best managed for their congestive symptoms. Preoperative echo and ECG findings can also be used to determine the predominant lesion. It is prudent to maintain the patient's own usual hemodynamics. Early aggressive intervention is the key to these combined lesions. A lower margin for error usually exists because minor hemodynamic aberrations can rapidly lead to cardiac collapse. TEE evaluation of left ventricular performance can be helpful in

separating pulmonary congestion secondary to left heart failure from that due to decreased diastolic left ventricular compliance from AS.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1077–1111.

Frogel J, Galusca D. Anesthetic considerations for patients with advanced valvular heart disease undergoing noncardiac surgery. *Anesthesiol Clin*. 2010;28:67–85.

Silbiger, JJ. Pathophysiology and echocardiographic diagnosis of left ventricular diastolic dysfunction. *J Am Soc Echocardiogr*. 2019;32:216–232.

C.3. How would you monitor this patient with severe AS and MR?

In addition to the standard American Society of Anesthesiologists–recommended monitors, the patient should have a radial artery and a pulmonary artery catheter. Following induction of anesthesia and endotracheal intubation, a TEE probe would be inserted to confirm the valvular pathology and to assess ventricular function. Following valve replacement, the TEE probe would be used to check for adequacy of valvular function and the absence of paravalvular leaks and to assess postbypass ventricular function.

American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. Practice guidelines for perioperative transesophageal echocardiography. An updated report by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography. *Anesthesiology*. 2010;112(5):1084–1096.

C.4. Should the patient have a pulmonary artery catheter placed before induction?

Volume status may be particularly difficult to assess in patients with valvular heart disease and yet of critical importance in the management of these patients. Patients with stenotic lesions depend on adequate filling pressures for diastolic filling of the

ventricle. Patients with the volume overload lesions of AI and MR can benefit from the careful reductions in pulmonary pressure guided by the simultaneous assessment of cardiac performance. In these capacities, the pulmonary artery catheter is useful. Patients with current hemodynamic stability, without severe respiratory distress, can be safely anesthetized before placement of the pulmonary artery catheter. Overall, there is no evidence that use of the pulmonary artery catheter improves outcome in the setting of surgery.

American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists Task Force on Pulmonary Artery Catheterization. Practice guidelines for pulmonary artery catheterization: an updated report by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization. *Anesthesiology*. 2003;99(4):988–1014.

C.5. Is a pulmonary artery catheter with pacing capabilities indicated?

Patients with AS can become severely compromised with the loss of atrial kick or the presence of slow junctional rhythms. Patients with AI or MR can experience left ventricular dilation in the setting of slow heart rates. In such cases, a pulmonary artery catheter with atrial and ventricular pacing capacity can be useful. In patients with intact conduction systems, rate manipulation can often be achieved pharmacologically. Transesophageal atrial pacing is another option. Transthoracic pacing elicits a ventricular response only and does not permit atrial stimulation. Transcutaneous pacing is indicated when the ability to rapidly open the pericardium and obtain epicardial pacing is limited. This occurs in the setting of reoperations or in patients with a history of inflammatory pericardial disease. Pacing will be limited to capture of the ventricle alone. The loss of atrial contraction can lead to underfilling and hemodynamic compromise in patients dependent on the added volume from atrial systole. One of the other pacing modalities is best in this

setting.

Raiten JM, Ghadimi K. Atrial fibrillation after cardiac surgery: clinical update on mechanisms and prophylactic strategies. *J Cardiothorac Vasc Anesth*. 2015;29(3):806–816.

C.6. What anesthetic technique would you employ? Why?

For the patient undergoing CPB and AV replacement, general anesthesia with endotracheal intubation is the obvious choice. Both narcotics and inhalation anesthetics can be safely administered. The modern anesthetic technique for cardiac surgery has focused on the use of techniques permitting earlier tracheal extubation. Anesthetic combinations, using smaller total narcotic doses, inhalation anesthetics, and short-acting intravenous sedatives such as propofol, are gaining popularity. For uncomplicated valve replacements with good ventricular function, the advantages of early tracheal extubation can be safely achieved. In complicated cases with longer bypass periods, poor ventricular function, or postbypass bleeding, the hemodynamic stability of a high-dose narcotic technique may be advantageous.

Barry AE, Chaney MA, London MJ. Anesthetic management during cardiopulmonary bypass: a systematic review. *Anesth Analg*. 2015;120(4):749–769.

De Hert SG, Van der Linden PJ, Cromheecke S, et al. Choice of primary anesthetic regimen can influence intensive care unit length of stay after coronary surgery with cardiopulmonary bypass. *Anesthesiology*. 2004;101(1):9–20.

C.7. What muscle relaxant would you use for this patient?

The use of high-dose narcotics results in bradycardia secondary to the vagotonic actions. Although slowing of heart rates usually benefits the patient with angina, it may have severe

consequences in patients with valvular heart disease. If a high-dose narcotic technique is employed, muscle relaxants, such as pancuronium, may be chosen to beneficially counteract the resultant bradycardia via histamine-mediated tachycardia. With a limited narcotic technique, hemodynamically "neutral" relaxants such as vecuronium, rocuronium, or cisatracurium are now commonly used with attention to redosing at key points in the procedure.

It is important to choose a combination of agents that will promote hemodynamic stability in a particular patient with his or her unique hemodynamic presentation. In this patient, the judicious use of any muscle relaxant would be indicated.

C.8. What are the usual TEE findings in a patient with AS or MR? How do you grade the severity of AS by TEE? How do you quantify the severity of MR? What is the impact of AS on the severity of MR?

The *echocardiographic* severity of AS is usually determined by AV area and transaortic valve pressure gradient. Normal AV area is 2.5 to 3.5 cm^2. Moderate stenosis is when the AV area is within the range of 1.0 to 1.5 cm^2 and severe AS when the AV area is less than 1.0 cm^2. A patient with a large mean pressure gradient (usually more than 40 mmHg) in the absence of excessively high cardiac output is usually considered to have severe AS as well. In the setting of low cardiac outputs, the pressure gradient may not be as great, and additional investigation may be necessary. The *clinical* severity of AS is determined by a combination of echocardiographic and clinical

factors. Even a patient with less than severely stenosed AV may be considered to have severe AS if his or her daily activities of life are reduced, he or she experiences symptoms, or left ventricular systolic dysfunction is present.

MR is graded by the amount of blood regurgitated backward into the left atrium during systole. Doppler color flow permits the estimation of this flow. Common methods for MR quantification include calculation of the area of the regurgitant orifice (effective orifice area) or the width of the MR jet (vena contracta) and by analysis of pulmonary vein flow profiles. It is important to remember that the amount of regurgitant blood flow in the setting of MR is determined by the amount of time spent in systole, the size of the MV defect, and the pressure gradient across the defect. Therefore, MR severity by Doppler color flow is load dependent. Lower systemic pressure or relative hypovolemia due to the anesthetic state can often mask more severe degrees of MR, which are found in the awake state.

Left ventricular pressures are increased in the setting of AS. Therefore, the gradient across the MV is increased often leading to more severe MR. Following replacement of the stenotic AV and elimination of the obstruction to systolic flow, left ventricular pressures are markedly reduced. In cases of functional MR without major structural defects in the MV apparatus, the MR will be less severe following replacement of AV.

C.9. What special considerations particular to

cardiopulmonary bypass (CPB) operations do you have for each of the four lesions? Focus on these concerns with respect to the induction and prebypass, bypass, and postbypass periods.

Aortic Stenosis

Critical to the management of a patient with AS is the avoidance of hypotension. Low blood pressure can initiate a cascade of events leading to cardiac arrest. Hypotension decreases the gradient for coronary perfusion with resultant ischemia. Ischemia leads to diminished cardiac output and decreased blood pressure further compromising coronary perfusion. The occurrence of cardiac arrest in a patient with AS is particularly catastrophic because closed-chest cardiac massage will provide little gradient for blood flow across a stenotic AV.

Patients with AS are particularly dependent on their atrial kick for adequate ventricular filling volume and can rapidly become hypotensive and ischemic following the onset of supraventricular tachycardia or atrial fibrillation. These rhythms are not uncommon during atrial cannulation. Therefore, it is of particular importance that every preparation for the initiation of CPB be made before atrial manipulation. The increased muscle mass of ventricular hypertrophy can be more difficult to adequately protect with cardioplegia. Careful attention to surface cooling, myocardial temperature measurement, and the use of retrograde cardioplegia can be helpful. Following AV replacement, hypertension from left ventricular output now unopposed by any valvular lesion can result in stress on suture lines and excessive bleeding. It is important to remember that the compliance of the LV is unchanged by surgery and still critically dependent on adequate preload and sinus rhythm. Hypertension is best managed with an afterload-reducing agent, such as nicardipine, versus a preload-reducing agent, such as

nitroglycerin.

Aortic Insufficiency

Patients undergoing AV replacement for AI can often present difficult management decisions. The usual treatment measures for hypotension (α-agonist) may have deleterious effects by increasing regurgitant volume. The use of combined α- and β-agonists (ephedrine, epinephrine, or infusions of dopamine or dobutamine) may be required. Although it would serve to lessen regurgitant volume, afterload reduction is beneficial in only a subset of patients with AI. Those patients with elevated LVEDP, reduced ejection fraction, diminished cardiac output, and systemic hypertension usually benefit from afterload reduction. In contrast, those patients without the previously mentioned constellation may experience a decrease in forward cardiac output secondary to diminished preload from reduced venous return. Systemic hypotension usually limits the utility in the acute setting. The presence of AI makes initiation of CPB a critical period. Periods of bradycardia or ventricular fibrillation can lead to rapid volume overload of the LV through the incompetent AV. Pacing, electrical defibrillation, and/or cross-clamping should be performed to prevent ventricular distention. Similarly, myocardial protection is compromised by AI. Generation of adequate root pressures is usually not obtainable; hence, delivery of cardioplegia requires aortotomy and cannulation of the coronary ostia. Use of retrograde cardioplegia is advantageous. Following AV replacement, the ventricle no longer has the lower pressure/impedance outflow afforded by the low aortic diastolic pressure. Inotropic support is often required. As with AS, the presence of an aortic suture line necessitates rapid response to hypertension to avoid bleeding and dissection.

Mitral Stenosis

Patients undergoing MV replacement for MS are particularly challenging. Marked elevations in pulmonary vascular resistance can be present with associated right-sided heart failure. Stasis in the left atrium necessitates careful echocardiographic examination for the presence of atrial thrombi. Manipulation of the heart before cross-clamping should be avoided. Following replacement, the chronically underfilled, underworked LV may be unable to handle the new volume load. Inotropic support is often required for RV failure and occasionally to improve left ventricular function. Afterload reduction and improved systemic perfusion using an IABP may be beneficial.

Mitral Regurgitation

Similarly, patients with MR may have pulmonary hypertension and right-sided heart failure. In contrast to AI, almost all patients with MR can be greatly benefited by afterload reduction, both pharmacologically and through an IABP. Diminution of left ventricular systolic pressure through afterload reduction decreases the pressure gradient from the LV to the left atrium during systole, with a resultant decrease in regurgitant volume.

Prebypass assessment can be misleading. Preserved ejection fractions and elevated stroke volumes may mask marked left ventricular systolic dysfunction. It should be remembered that much of the left ventricular volume is ejected into the low-pressure/impedance outflow path of the left atrium. This route is no longer available after valve replacement. Following MV replacement, dysfunctional ventricles may be unable to provide adequate forward flow into the systemic circuit with its elevated vascular resistance, which usually necessitates the use of inotropic support.

Patients previously in atrial fibrillation without marked atrial enlargement often revert to or can be converted to sinus rhythm following valve replacement. When the diameter of the atrium is

more than 5 cm, the likelihood of maintaining sinus rhythm dramatically decreases.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1077–1111.

C.10. The patient cannot be weaned from CPB following an AV replacement and MV replacement. What are the possible causes?

The adequacy of myocardial preservation should be considered. Left ventricular hypertrophy without or with accompanying coronary artery disease increases myocardial oxygen demands. The prolonged cross-clamp time necessitated by dual valve replacement can lead to inadequate and/or nonhomogeneous myocardial protection. In addition, there may be residual effects from the cardioplegia solution. Therefore, some degree of postbypass left ventricular dysfunction can be anticipated. Inotropic support may be required. It is important to remember that although the obstruction to left ventricular ejection is acutely relieved by replacement of the stenotic valve, left ventricular compliance is largely unchanged. Adequate preload still depends on sinus rhythm and sufficient left ventricular filling pressures (pulmonary artery occlusion pressure [PAOP] or LVEDP). Elevations in pulmonary vascular resistance may render estimation of left atrial pressure through the pulmonary artery catheter inaccurate. In this setting, placement of a left atrial catheter is indicated. TEE may prove invaluable in identifying surgically correctable causes for inability to wean from CPB. Evaluation of left ventricular filling and contractility can help resolve the situation of low cardiac output and high filling pressures. A small underfilled LV with hyperdynamic contractility and a dilated, overfilled, hypokinetic LV can both give the same hemodynamic parameters but obviously require different pharmacologic interventions. Abnormal valve seating

may compromise flow into the coronary ostia and return to bypass with valve repositioning or coronary artery bypass grafting may be indicated. Similarly, paravalvular leaks or aortic dissections can be readily identified. Iatrogenic injury to the circumflex artery, although rare, can occur during MV annuloplasty or replacement. The course of the circumflex artery along the posterior path of the MV annulus makes it a potential target for errant valve stitches. New regional wall motion abnormalities in the inferior-lateral territory may help make this unusual diagnosis or influence the decision to pursue diagnostic testing, such as emergent cardiac catheterization. The coronary sinus can also be damaged during MV repair and replacement because the suture line is placed in the lateral mitral annulus. TEE may demonstrate abnormal echodensities in the area of the atrioventricular groove, and color flow Doppler can demonstrate high-velocity flow jets from the chambers to the sinus.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1077–1111.

Ender J, Selbach M, Borger MA, et al. Echocardiographic identification of iatrogenic injury of the circumflex artery during minimally invasive mitral valve repair. *Ann Thorac Surg*. 2010;89:1866–1872.

C.11. How would you diagnose right-sided heart failure and pulmonary hypertension? How would you treat it?

Right-sided heart failure is diagnosed by elevations in right-sided filling pressures, specifically central venous pressure. Careful examination is required to rule out tricuspid insufficiency as the cause of the central venous pressure elevation. A high central venous pressure indicates the inability of the right heart to adequately propel the venous return volume into the pulmonary circulation. Elevation in pulmonary artery pressures is indicative of pulmonary hypertension. The

combination of high central venous pressure and high pulmonary artery pressures indicates severe right-sided heart failure. This scenario can be difficult to manage. Attempts to elevate systemic perfusion pressure with α-agonists can worsen pulmonary hypertension. Administration of vasodilators to lower pulmonary pressures results in systemic hypotension. In this setting, it is often prudent to return to CPB, relieve ventricular distention, and improve myocardial perfusion. During this "rest period," adjustments in inotropic therapy, ventilation, and cardiac rhythm can be instituted. Optimization of acid–base status and hemoglobin concentration should also be performed. Separation from bypass can then be reattempted.

Typical inotropic agents effective in this setting are those with high degrees of β-adrenergic potency and potent vasodilation in the pulmonary vasculature. Commonly employed agents include dobutamine, epinephrine, prostaglandin E_1, and the phosphodiesterase-III (PDE-III) inhibitors amrinone and milrinone. It is not uncommon to require the administration of α-agonists to counteract the systemic vasodilating effects of prostaglandin E_1 and the PDE-III inhibitors. Some selective pulmonary vasodilating action and systemic vasoconstricting effects can often be achieved by administering pulmonary vasodilating agents such as prostaglandin E_1 through the right-sided access (central venous pressure or pulmonary artery catheter) and infusing the α-agonists through the left arterial line, thereby minimizing vasoconstriction of the pulmonary arterial bed. Vasopressin can also be used for systemic vasoconstriction and has little effect on the pulmonary vasculature.

Nitric oxide is a potent, inhaled pulmonary vasodilator. Its half-life in the systemic circulation is extremely short, permitting its administration to the pulmonary vasculature with

minimal systemic hypotensive effects. Nitric oxide can selectively and effectively dilate the pulmonary vasculature. The exact method of delivery, scavenging of waste gases, and high cost remain as obstacles to its clinical application.

Galiè N, Humbert M, Vachiery JL, et al. 2015 ESC/ERS guidelines for the diagnosis and treatment of pulmonary hypertension: the Joint Task Force for the Diagnosis and Treatment of Pulmonary Hypertension of the European Society of Cardiology (ESC) and the European Respiratory Society (ERS): endorsed by: Association for European Paediatric and Congenital Cardiology (AEPC), International Society for Heart and Lung Transplantation (ISHLT). *Eur Heart J*. 2016;37(1):67–119.

C.12. How does an intra-aortic balloon pump (IABP) work to benefit the failing heart?

An IABP is a catheter with a large balloon (40 to 60 mL) at its tip. It is positioned in the thoracic aorta distal to the left subclavian artery origin and proximal to the takeoff of the renal vessels. It is timed to inflate during diastole to increase diastolic perfusion pressure to the coronary arteries, great vessels, and major abdominal organs and to deflate just before systole, creating a void in volume within the aorta and thus a low pressure with a resultant decrease in afterload. The decreased afterload increases stroke volume and hence forward cardiac output. It is a unique modality that can improve coronary perfusion pressures while reducing myocardial oxygen demand.

Baskett RJ, Ghali WA, Maitland A, et al. The intraaortic balloon pump in cardiac surgery. *Ann Thorac Surg*. 2002;74:1276–1287.

Kucuker A, Cetin L, Kucuker SA, et al. Single-centre experience with perioperative use of intraaortic balloon pump in cardiac surgery. *Heart Lung Circ*. 2014;23(5):475–481.

C.13. What role does the IABP have in this setting?

An IABP may be useful because unlike any pharmacologic maneuver, it is capable of increasing mean pressure during diastole critical for coronary perfusion while lowering afterload to systolic left ventricular ejection. Myocardial dysfunction secondary to inadequate protection during bypass can be reduced by decreased afterload and augmentation of diastolic pressures through IABP counterpulsation. Studies have shown superior survival among patients with isolated cardiac artery bypass graft (CABG) treated with IABP compared with patients undergoing non-CABG cardiac surgeries. The IABP can only aid patients in whom ventricular function can recover in a relatively short time. Outside of this population, ventricular assist devices may be more appropriate.

Baskett RJ, Ghali WA, Maitland A, et al. The intraaortic balloon pump in cardiac surgery. *Ann Thorac Surg*. 2002;74:1276–1287.

C.14. What role does TEE play in the placement, timing, and demonstration of efficacy of an IABP?

The thoracic aorta and aortic arch can be clearly imaged by TEE. Imaging of the takeoff of the left subclavian artery facilitates optimal positioning of the IABP. In addition, before insertion, the aorta can be evaluated for dissection or the presence of severe atheromatous disease; both are contraindications to IABP insertion. TEE can demonstrate the efficacy of an IABP by showing enhanced ventricular emptying during systole and filling during diastole.

Klopman MA, Chen EP, Sniecinski RM. Positioning an intraaortic balloon pump using intraoperative transesophageal echocardiogram guidance. *Anesth Analg*. 2011;113(1):40–43.

C.15. How would you properly time the IABP cycle?

Inflation should occur just following the dicrotic notch and

deflation before the upstroke in the aortic pressure curve. Augmentation in pressures during diastole and mean pressures should occur. Diastolic pressure (the lowest pressure in the cardiac cycle) should in fact fall. Peak pressure generated by the left ventricular or systolic pressure should fall while the balloon-generated pressure during ventricular diastole (augmented pressure) should increase.

Baskett RJ, Ghali WA, Maitland A, et al. The intraaortic balloon pump in cardiac surgery. *Ann Thorac Surg*. 2002;74:1276–1287.

Cheung AT, Savino JS, Weiss SJ. Beat-to-beat augmentation of left ventricular function by intraaortic counterpulsation. *Anesthesiology*. 1996;84:545–554.

C.16. What are the contraindications to the use of an IABP?

The most common contraindications are severe AI and severe aortic disease, atheromatous, aneurysmal, or a dissection. Although often listed as absolute contraindications, there are reports of the effective use of the IABP in these settings. TEE can be helpful in evaluating the effect of an IABP on overall ventricular function. End-systolic areas should decrease, and end-diastolic areas should at least not increase but may decrease as well.

White JM, Ruygrok PN. Intra-aortic balloon counterpulsation in contemporary practice—where are we? *Heart Lung Circ*. 2015;24(4):335–341.

C.17. What is the role for ventricular assist devices?

Ventricular assist devices are used in the management of chronic heart failure after exhausting medical therapy. These devices can be used as a bridge to transplantation or as a destination therapy in those who do not qualify for transplantation. The short-term use of ventricular assist devices includes patients with refractory heart failure in the immediate postoperative setting. Historically, the operative mortality associated with postcardiotomy assist

devices was very high. Newer machines utilize smaller cannulas and have smaller, more efficient pumps. The magnetically suspended centrifugal pumps are associated with minimal trauma to red blood cells or pump failures. The use of these devices is rapidly expanding, and early indications show a decreased mortality for patients experiencing postcardiotomy shock with recoverable myocardium. Ventricular assist devices are used for right, left, and biventricular support.

D. Postoperative Management

D.1. In the intensive care unit (ICU) 4 hours later, the patient became hypotensive with a low cardiac output. How could you distinguish between cardiac tamponade and pump failure? How would the TEE images differ?

The differentiation between cardiac tamponade and primary pump failure in the immediate postbypass-ICU setting can be difficult. Elevations in filling pressures, systemic hypotension, and low cardiac output are consistent with both diagnoses. The classic teaching of equalization of cardiac pressures seen in a "fluid" tamponade may not be present because areas of focal compression from clot can markedly reduce filling of only one chamber in the absence of an intact pericardium. Echocardiography can be beneficial in this setting by permitting

visualization of chamber volume and function. The TEE approach has particular advantage over TTE in the postoperative setting in which the usual transthoracic window may be obscured by dressings and drainage tubing. Focal compression of the cardiac chambers from a clot or pericardial effusion can readily be distinguished from a volume-overloaded, failing heart with poor myocardial contractility. When the diagnosis is not clear, however, surgical reexploration may be indicated. (See Chapter 12, Cardiac Tamponade.)

Society of Thoracic Surgeons Task Force on Resuscitation After Cardiac Surgery. The Society of Thoracic Surgeons expert consensus for the resuscitation of patients who arrest after cardiac surgery. *Ann Thorac Surg*. 2017;103(3):1005–1020.

D.2. Would you extubate this patient early in the ICU? Why?

No. This patient has undergone a double valve replacement. In this more complex procedure, coagulopathy and postoperative bleeding, hypothermia from incomplete and nonuniform rewarming, and pulmonary hypertension are not uncommon occurrences in the immediate postoperative period. Sedation, paralysis, and mechanical ventilation can reduce the oxygen requirements during this early phase of recovery, minimize pulmonary hypertension secondary to hypercarbia, and permit reestablishment of core temperatures.

Cheng DC. Pro: early extubation after cardiac surgery decreases intensive care unit stay and cost. *J Cardiothorac Vasc Anesth*. 1995;9:460–464.

Guenther CR. Con: early extubation after cardiac surgery decreases intensive

care unit stay and cost. *J Cardiothorac Vasc Anesth*. 1995;9:465–467.

D.3. What are the advantages and disadvantages of early extubation?

The advantages of early extubation are both medical and financial. Early extubation can lessen the adverse sequelae from prolonged endotracheal intubation, including epithelial damage, decreased ciliary motility, and diminished mobilization of secretions. Positive pressure ventilation can have adverse effects on venous return. Nevertheless, the overwhelming drive toward early extubation is cost and patient comfort. Early extubation can decrease cost by decreasing ICU staff requirements, decreasing the cost of sedatives, lessening the duration of ICU stays, and improving operating room use by lessening cancellation of cases secondary to blocked ICU beds.

The potential advantages of early extubation, both financial and physiologic, must be weighed against the potential disadvantages of early extubation. The potential for respiratory compromise leading to hypoxemia, hypercarbia, ischemia, and the potential for infarction and neurologic injury is real. Any savings realized from early extubation can be rapidly lost by one adverse event. Success relies on careful integration of all players in the care of the patient undergoing cardiac surgery, from the management of intraoperative anesthetic techniques to the organization of the ICU and staff and the provision of postoperative analgesia. Equally important to the success of an early extubation program is appropriate patient selection.

E. Alternative Treatments

E.1. What are the percutaneous options for MV repair?

In 1991, a surgical correction of MR was described using a technique of suturing the middle portions of the two mitral leaflets together. The resultant double orifice valve is an adequate solution for many MV lesions. Based on this principle, a percutaneous treatment for MR has emerged. The safety and efficacy of various transcatheter MVs for mitral replacement are currently underway.

Sherlock KE, Muthuswamy G, Basu R, et al. The Alfieri stitch: the advantages for mitral valve repair in difficult circumstances. *J Card Surg*. 2011;26(5):475–477.

E.2. How is percutaneous MV repair performed?

The MitraClip is a small, polyester fabric-covered cobalt-chromium clip that is applied to the mitral leaflets to mimic the surgical procedure described earlier. The device is delivered percutaneously via a transfemoral venous approach and a transseptal puncture, and favorable results are associated with a reduction of MR to less than moderate. General anesthesia is typically used.

Buzzatti N, Taramasso M, Latib A, et al. Transcatheter mitral repair and replacement: state of the art and future directions. *J Heart Valve Dis*. 2014;23(4):492–505.

Feldman T, Kar S, Elmariah S, et al. Randomized comparison of percutaneous repair and surgery for mitral regurgitation: 5-year results of EVEREST II. *J Am Coll Cardiol*. 2015;66(25):2844–2854.

Guarracino F, Baldassarri R, Ferro B, et al. Transesophageal echocardiography during MitraClip® procedure. *Anesth Analg*. 2014;118(6):1188–1196.

E.3. What are the percutaneous options for AV repair and replacement?

Aortic balloon valvuloplasty has been a nonsurgical option since the 1980s. Although it is far less invasive than surgery, high complication rates and in-hospital mortality have reserved this treatment for a select population. In addition, high restenosis rates make this a short-lived solution. Surgical valve replacement was previously the treatment of choice for severe AS. Alternative treatment options are now becoming available to patients at high and intermediate risk for surgery.

Arora S, Misenheimer JA, Ramaraj R. Transcatheter aortic valve replacement: comprehensive review and present status. *Tex Heart Inst J*. 2017;44(1):29–38.

E.4. How is percutaneous AV replacement performed?

Currently, two prosthetic devices are used in the United States. The percutaneous devices are bioprosthetic valves mounted in nitinol stents. The valves may be delivered by retrograde (femoral artery, axillary artery, or directly in the aorta) or antegrade (transapical) approaches. After balloon valvuloplasty, the valve stent is deployed. Rapid ventricular pacing is used to decrease cardiac translation and minimize ejection pressure during deployment. TEE and fluoroscopic guidance are used. The most frequent complications are cerebral embolism, coronary obstruction, conduction abnormalities, and paravalvular leaks.

Arora S, Misenheimer JA, Ramaraj R. Transcatheter aortic valve replacement: comprehensive review and present status. *Tex Heart Inst J*. 2017;44(1):29–38.

E.5. What anesthetic techniques and monitors are used?

Intravenous sedation with local infiltration can be used in carefully selected patients. Those patients with a nonreassuring airway, severe gastroesophageal reflux disease (GERD), anxiety, low ejection fraction, and pulmonary hypertension are

not typically good candidates for sedation. General anesthesia facilitates simultaneous TEE examination and access to alternate approaches if surgical challenges are encountered. Large-bore central venous access is necessary in the event of vascular injury or to administer vasoactive medications. Pulmonary artery catheters may be indicated in patients with RV dysfunction with or without pulmonary hypertension and in those with reduced ejection fraction. In sedation cases, TTE examination is performed for evaluation at the conclusion of the procedure. Radial artery catheters are placed before induction for continuous monitoring and for arterial blood gases analysis.

Neuberger PJ, Patel PA. Anesthetic techniques in transcatheter aortic valve replacement and the evolving role of the anesthesiologist. *J Cardiothorac Vasc Anesth*. 2017;31(6):2175–2182.

E.6. What is minimally invasive cardiac valve surgery?

The Society of Thoracic Surgeons database considers "any procedure not performed with a full sternotomy and CPB support" a minimally invasive procedure. The practical applications of "mini-valve surgery" include partial sternotomy, thoracotomy, and video-assisted and robot-assisted procedures. The downside to minimally invasive approaches includes difficulty converting to a sternotomy in the case of cannula displacement or aortic dissection and complications of femoral artery cannulation (including arterial dissection, infection, and hematoma). The anesthetic management varies from standard sternotomy cases, including single-lung ventilation for thoracotomy approaches and transjugular coronary sinus catheters to provide retrograde cardioplegia. Intraoperative TEE is especially critical in these cases to monitor for cardiac distention, removal of air, and cannula placement. There is clearly a significant learning curve to provide an equivalent surgical outcome with a "mini" versus traditional strategy. In

successful procedures, patients enjoy improved cosmesis and decreased bleeding, wound infection, pain, and hospital length of stay. Unfortunately, in high-risk patients, the increased time of aortic cross-clamping and CPB may be deleterious. Also, complications are extremely morbid, including aortic dissection and death. Mini-valve surgery is limited to patients with an isolated valve disease.

8 Pacemakers, Implantable Cardioverter-Defibrillators, and Cardiac Resynchronization Therapy Devices

Alan Cheng and Fun-Sun F. Yao

A 63-year-old woman was scheduled for urgent open cholecystectomy. She underwent a dual-chamber permanent pacemaker (PPM) implantation 10 years ago for sick sinus syndrome and intermittent heart block. Over time, she developed systolic heart failure from greater amounts of ventricular pacing that resulted in an upgrade to a cardiac resynchronization therapy-defibrillator (CRT-D) 9 months ago. Her blood pressure was 110/68 mmHg, and her heart rate was regular at 60 beats per minute. An electrocardiogram (ECG) obtained on admission demonstrated atrioventricular (AV) sequential pacing.

A. Medical Disease and Differential Diagnosis

1. What are the indications for PPMs?
2. What is sick sinus syndrome? What is chronotropic incompetence?
3. How would you diagnose first-, second-, and third-degree AV block; bifascicular block (right bundle branch block [RBBB] with left anterior fascicular hemiblock or left posterior fascicular hemiblock); and trifascicular block?
4. Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?
5. What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?
6. How many modes of pacing are available in modern PPMs? How do they work? What is the difference between DDD pacing and DDI pacing?
7. The patient was mechanically hyperventilated during surgery, and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?
8. What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of right ventricular pacing only?
9. What are the indications for and complications associated with AV sequential PPMs?
10. How would you know if the patient's PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?
11. What is a biventricular PPM or CRT device? What are the indications for such a device?
12. What are the usual lifespans of PPMs and implantable cardioverter-defibrillators (ICDs)?
13. What is an ICD? How does it work? What is a subcutaneous ICD?

14. What are the indications for ICDs?
15. What is the NASPE and BPEG generic defibrillator (NBD) code?

B. Preoperative Evaluation and Preparation

1. How would you preoperatively evaluate the patient described earlier?
2. How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?
3. How do you determine whether the patient is dependent on the pacing from the CIED?
4. How do you know if the implanted PPM or ICD is working?
5. What information would you like to obtain from interrogating this device?
6. How do you preoperatively prepare the patient for surgery and anesthesia?
7. Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?
8. The patient requires an abdominal magnetic resonance imaging (MRI) prior to the surgery. What considerations should you make regarding her CIED?

C. Intraoperative Management

1. How would you monitor this patient?
2. What drugs and equipment would you like to have on hand in the operating room?
3. How would you set up the transcutaneous external pacer and defibrillator?
4. Had this patient's ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?
5. Electromagnetic interference (EMI) from electrocautery results

in significant noise on your cardiac monitor. You recall that EMI also can inhibit pacing function from the PPM. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the PPM is occurring?

6. What are the potential responses of pacemakers and ICDs to electrocautery?
7. How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?
8. What are the effects of a magnet on pacemakers and ICDs?
9. In the middle of surgery, the patient developed ventricular tachycardia. What would you do?
10. What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?
11. Is electroconvulsive therapy (ECT) contraindicated in patients with pacemakers or ICDs?
12. What precautions should be taken during radiofrequency ablation for a patient with a CIED?
13. During surgery, the patient developed frequent premature ventricular complexes and some of these resulted in rapid ventricular pacing (see **Fig. 8.8**). What is accounting for the pacemaker's behavior?

D. Postoperative Management

1. How would you monitor this patient in the postanesthesia care unit?
2. How would you confirm that the CIED is functioning properly after surgery?

A. Medical Disease and Differential Diagnosis

A.1. What are the indications for PPMs?

Artificial pacing is generally indicated for the treatment of symptomatic bradycardia or abnormalities in AV conduction

that suggest a high risk for progression to complete heart block. The two main indications for permanent pacing are failure of impulse formation and failure of cardiac conduction. Clinically, sick sinus syndrome and complete heart block are the most common indications for pacemakers. The following conditions are class I and IIa indications for a PPM:

- Sinus node dysfunction with documented symptomatic bradycardia, symptomatic chronotropic incompetence, or symptomatic sinus bradycardia secondary to required drug therapy for medical conditions
- Sinus node dysfunction for heart rates less than 40 beats per minute when a clear association between symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented
- Recurrent syncope caused by spontaneous carotid sinus hypersensitivity or greater than 3-second episode of ventricular asystole induced with carotid sinus pressure
- Third-degree or advanced second-degree AV block associated with bradycardia with symptoms or ventricular arrhythmias presumed secondary to AV block
- Asymptomatic third-degree or advanced second-degree AV block in patients with sinus rhythm and documented periods of asystole greater than 3 seconds, escape rate less than 40 beats per minute, or an escape rhythm that is below the AV node (as suggested by a wide QRS complex)
- Ventricular pauses of greater than 5 seconds in patients with persistent atrial fibrillation
- Third-degree or advanced second-degree AV block resulting from catheter ablation or cardiac surgery
- First- or second-degree AV block associated with symptoms similar to those of pacemaker syndrome or hemodynamic compromise
- Chronic bifascicular block with advanced second-degree AV

block or intermittent third-degree AV block

- Chronic bifascicular block with alternating left bundle branch block (LBBB) and RBBB conduction
- High-risk patients with congenital long QT syndrome or those with documented sustained pause-dependent ventricular tachycardia
- New York Heart Association (NYHA) class III or class IV heart failure symptoms despite optimal medical therapy in patients with dilated cardiomyopathy (ejection fraction [EF] less than 35%), QRS duration greater than 120 milliseconds, and sinus rhythm (e.g., biventricular pacing)

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–806.

A.2. What is sick sinus syndrome? What is chronotropic incompetence?

Sick sinus syndrome describes an array of clinical disorders resulting from irreversible sinus node dysfunction. This may be manifested by episodes of sinus arrest, sinus pause, or bradycardia secondary to inadequate sinus node automaticity. When the sinus node fails to adequately generate an electrical impulse, ectopic atrial foci fire and at times can result in episodes of atrial tachyarrhythmias. The diagnosis is made when a correlation is made between a patient's symptoms and electrocardiographic evidence of bradycardia. Hence, extended ambulatory cardiac telemetry such as 24-/48-hour Holter, event monitoring, or implantable loop monitors may be helpful to make a diagnosis. When episodes of tachycardia and bradycardia coexist, it is often referred to as *tachy-brady* syndrome. This is one of the most common indications for pacemakers and is characterized by the following:

- Unexpected persistent symptomatic sinus bradycardia

- Episodes of sinus arrest or sinoatrial exit block
- Episodes of atrial fibrillation, atrial tachycardia, or atrial flutter
- Slow return to sinus rhythm following cardioversion (prolonged sinus node recovery time)

Chronotropic incompetence is loosely defined as the inability to achieve at least 80% to 85% of an individual's maximum predicted heart rate (MPHR) at peak exercise. Use of medications including β-blockers, calcium channel blockers, and antiarrhythmic medications can confound this diagnosis. In the presence of these medications, some people have used a modified definition of failure to achieve at least 62% of the MPHR. Chronotropic incompetence has been shown to increase mortality and morbidity especially in those with heart failure. Rate-adaptive pacing is often used in these instances and has been shown to increase peak oxygen consumption during exercise. It is important to point out that not all patients with sick sinus syndrome have chronotropic incompetence and not all patients with chronotropic incompetence have sick sinus syndrome.

Dobrzynski H, Boyett MR, Anderson RH. New insights into pacemaker activity: promoting understanding of sick sinus syndrome. *Circulation*. 2007;115:1921–1932.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:772–779.

A.3. How would you diagnose first-, second-, and third-degree AV block; bifascicular block (right bundle branch block [RBBB] with left anterior fascicular hemiblock or left posterior fascicular hemiblock);

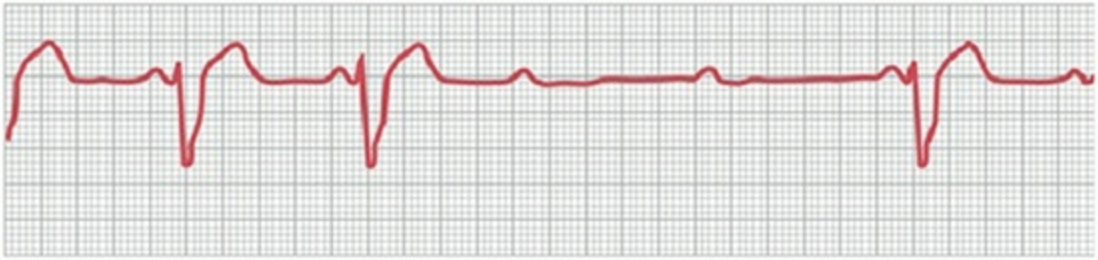
and trifascicular block?

First-degree AV block (some refer to as “delay” rather than “block” because the impulse is still being conducted) is characterized by a PR interval of greater than 0.20 seconds during normal sinus rhythm (**Fig. 8.1**). Second-degree AV block is subdivided into two types, Mobitz type I and Mobitz type II. Mobitz type I, or Wenckebach block, is characterized by a progressively lengthening PR interval, which occurs until a P wave is not conducted down the AV node and a QRS complex is dropped. The PR interval of the first beat after the blocked P wave is almost always shorter than the PR interval of the beat prior to being blocked. The site of block is usually in the AV node, and the natural history of Mobitz type I may or may not involve progression toward complete heart block. Mobitz type II block is characterized by a loss of AV conduction with no progressive lengthening of the PR interval before the sudden dropping of one or more QRS complexes. Additionally, the PR interval of the first beat after the blocked P wave is usually the same (<25 milliseconds) as the PR interval of the beat prior to the blocked P wave. The site of block is typically below the AV node and within the His bundle or in the Purkinje system. The natural history of Mobitz type II block is often progression toward complete heart block over time. Third-degree AV block, also called *complete heart block*, occurs when all electrical activity from the atrium fails to conduct to the ventricle. The site of block can lie in either the AV node or the His-Purkinje system. The atrial and ventricular contractions have no relation with each other, with the atrial rate almost always faster than the ventricular rate. As a result, the QRS complexes seen result from an ectopic focus either from the ventricular myocardium (wide QRS complex) or in an area of the AV node/His-Purkinje system below the site of block (narrow QRS complex). The typical rate of these ventricular escape beats range between 40

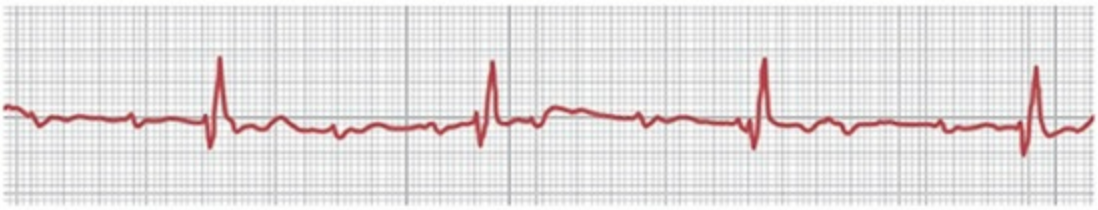
and 60 beats per minute.

First-degree heart block. Sustained prolongation of the PR interval with no dropped QRS complexes.

Second-degree heart block, Mobitz type I. Also referred to as Wenckebach block, there is progressive prolongation of the PR interval before the dropped QRS complex. The PR interval of the first return QRS complex has normalized compared to the PR interval of the QRS complex of the last beat before dropping. This behavior suggests that the location of block occurs in the AV node.



Second-degree heart block, Mobitz type II. There is no progressive increase in the PR interval before the dropped QRS complex. This suggests that the location of the block occurs below the AV node. Note also the QRS morphology during conducted beats. The wide QRS complex suggests the presence of fascicular disease, which is often seen in the presence of Mobitz type II heart block.



Third-degree heart block. The P waves march through with no communication with the ventricular beats.

FIGURE 8.1. Atrioventricular heart block.

The term *bifascicular block* often refers to block in the right bundle and one of the two major fascicles of the left bundle. RBBB with left anterior hemiblock is present when the ECG shows an RBBB with a left axis deviation (usually greater than −60 degrees) in the absence of an inferior myocardial infarction.

Complete RBBB with right axis deviation (greater than 90 degrees) is indicative of RBBB and left posterior hemiblock in the absence of a lateral myocardial infarction or evidence of right-sided heart failure. The term *trifascicular block* is used to describe first-degree AV block in the presence of bifascicular block.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:772–779.

A.4. Is it necessary to insert a temporary pacemaker before general anesthesia for an asymptomatic patient with bifascicular or trifascicular block?

The risk for progression to complete heart block in asymptomatic patients with bifascicular block is low. Furthermore, no clinical characteristics have been identified that accurately predict the risk of development of complete heart block. Therefore, routine PPM implantation in patients with asymptomatic bifascicular block is not recommended. Observations made in the perioperative period have suggested that development of complete heart block during general anesthesia is also rare; therefore, it is generally not recommended that patients undergo temporary pacemaker insertion before general anesthesia. However, it is advisable to have an external pacemaker available in the operating room. The term *trifascicular block* is somewhat of a misnomer because, in truth, if all three fascicles (i.e., right bundle, left anterior fascicle, and left posterior fascicle) were blocked, the patient would be in complete heart block. Although it is generally agreed that individuals with trifascicular block have a higher risk for sudden death, there is no single clinical variable that predicts a higher risk for complete heart block during surgery. Small case series have shown that the development of

intraoperative complete heart block in asymptomatic patients with trifascicular block is uncommon. Therefore, routine temporary pacemaker insertion before general anesthesia in these patients is not recommended.

Gauss A, Hübner C, Radermacher P, et al. Perioperative risk of bradyarrhythmias in patients with asymptomatic chronic bifascicular block or left bundle branch block: does an additional first-degree atrioventricular block make any difference? *Anesthesiology*. 1998;88:679–687.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–799.

A.5. What are the three-letter and five-letter identification codes of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) generic (NBG) code for pacemaker classification?

Given the complexity of current pacemaker systems, the Intersociety Commission for Heart Disease Resources established a classification code in the 1970s that is still used widely. The original nomenclature involved a three-letter identification code, as shown in the first three columns of **Table 8.1**. In 1980, this code was extended to five letters; the last two letters are omitted when not applicable. In 1987, this five-letter coding system become known as the NBG pacemaker code after being adopted by both the NASPE (now known as the *Heart Rhythm Society*) and BPEG (now referred to as the *British Heart Rhythm Society*). The first letter describes the chamber(s) that the pacemaker can pace, the second letter describes the chamber(s) that it senses, and the third letter describes the response of the pacemaker to sensed intrinsic activity. The last two letters describe additional features such as rate responsiveness that are commonly omitted when not used. For example, a VVI pacing mode paces in the ventricle, can sense

intrinsic activity in the ventricle, and inhibits pacing when it senses intrinsic activity. A VOO pacing mode paces in the ventricle but does not sense intrinsic activity nor does it inhibit pacing—it simply paces regardless of the heart's intrinsic electrical activity.

TABLE 8.1 NASPE/BPEG Generic Pacemaker Identification Code[a]

Letter I	Letter II	Letter III	Letter IV	Letter V
Chamber(s) Paced	Chamber(s) Sensed	Mode of Response	Programmability Rate Modulation	Antitachyarrhythmi Function(s)
O = None	O = None	O = None	O = None	O = None
A = Atrium	A = Atrium	T = Triggered	P = Single programmable	P = Pacing
V = Ventricle	V = Ventricle	I = Inhibited	M = Multiprogrammable	S = Shock
D = Dual (A + V)	D = Dual (A + V)	D = Dual (T + I)	C = Communicating	D = Dual (P + S)
			R = Rate modulation	

[a]Although the pacemaker identification coding involved the use of five letters, few modern pacemakers have antitachyarrhythmia functions. Therefore, most pacemakers are currently described by the first four letters of the coding system.
BPEG, British Pacing and Electrophysiology Group; NASPE, North American Society of Pacing and Electrophysiology.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–799.

A.6. How many modes of pacing are available in modern PPMs? How do they work? What is the difference between DDD pacing and DDI pacing?

Modern pacemakers are programmable into one of three modes of pacing: asynchronous pacing, single-chamber demand pacing, and dual-chamber AV sequential demand pacing. Asynchronous or fixed-rate (e.g., AOO, VOO, DOO [see section A.5 for details]) modes pace at a programmable preset rate that is independent of the heart's intrinsic activity. They can be atrial, ventricular, or dual-chamber. When pacing occurs without coordinating with the heart's intrinsic electrical activity, this can result in pacing competition, pacemaker syndrome, and rarely induction of ventricular arrhythmias. Ventricular tachyarrhythmias in those with structural heart disease can theoretically occur because the pacing spike can potentially be delivered during a time when the myocardium is vulnerable to arrhythmogenesis, but this is extremely rare.

Single-chamber demand pacing (e.g., AAI, VVI) paces at a preset rate only when the spontaneous heart rate drops below the programmed preset rate. For example, if this patient's device was programmed to VVI 70, the device would pace in the ventricle only when the native ventricular rate fell below 70 beats per minute. Once the native ventricular rate resumed above 70 beats per minute, the device would sense this activity and inhibit further pacing. Single-chamber demand pacing in the atrium functions in a similar way but is rarely used alone in the United States.

Dual-chamber AV sequential pacing requires two pacemaker leads: one in the right atrium and one in the right ventricle. The atrium is stimulated to contract first; then, after an adjustable PR interval (also referred to as the *AV interval*), the ventricle is stimulated to contract if no intrinsic ventricular activity is sensed by the ventricular pacing lead. For example, if this patient's device was programmed to DDD 70 with an AV interval of 200 milliseconds, the device would begin pacing the atrium first if the intrinsic sinus rate fell below 70 beats per minute. After the

atrium has been paced, the device will wait for 200 milliseconds to sense intrinsic ventricular activity that presumably would have been conducted down the AV node. If it does not see intrinsic activity within 200 milliseconds, it will then pace in the ventricle as well. DDD pacemakers can also pace in the ventricle in response to intrinsic atrial activity. For example, if the intrinsic atrial rate was 80 beats per minute, the device would inhibit pacing in the atrium because the base rate was set to 70 beats per minute. But because it is a dual-chamber device programmed to inhibit and trigger pacing in both chambers (i.e., the third "D" in the coding sequence), it will wait 200 milliseconds from the time of the intrinsic atrial activity and watch for intrinsic ventricular activity. If it sees intrinsic ventricular activity (i.e., the atrial signal conducted down the AV node and to the ventricle), it will inhibit ventricular pacing. If it does not see intrinsic ventricular activity occurring within 200 milliseconds from the intrinsic atrial activity, the pacemaker will then "trigger" the ventricular pacing lead to pace the ventricle. Dual-chamber pacemakers programmed to DDI differ slightly from devices programmed to DDD, and the main difference is that AV sequential pacing occurs only when atrial pacing is present. This is in contrast to DDD pacing in which AV sequential pacing is preserved regardless of whether atrial pacing or atrial sensing is occurring. Suppose we have a dual-chamber pacemaker programmed to DDI 70 with an AV interval of 200 milliseconds. If the sinus rate fell below 70 beats per minute, the atrial pacing lead would pace the atrium. After a 200 millisecond interval, if intrinsic ventricular activity was seen by the ventricular lead the ventricular lead would be inhibited from pacing the ventricle. If ventricular activity was not seen after 200 milliseconds, the ventricular lead would pace the ventricle. Suppose now that the sinus rate is 80 beats per minute. Because the DDI pacemaker is programmed to 70 beats per minute, no

atrial pacing is occurring. Because DDI pacemakers do not track atrial sensed events, ventricular pacing would not be "triggered" after 200 milliseconds by these atrial sensed events and ventricular pacing would only occur if the *ventricular* rate fell below the preset rate of 70 beats per minute.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–799.

A.7. The patient was mechanically hyperventilated during surgery, and her pacemaker gradually increased her heart rate. What feature of the PPM is accounting for this?

All modern pacemakers have the ability to adjust the pacing rate according to the patient's level of activity in an effort to obtain a more physiologic response to exercise. This is known as *rate-response* (adaptive) pacing and is denoted by an "R" in the fourth position of the NBG coding schema. This is often applied in patients with chronotropic incompetence or those with permanent atrial fibrillation who have undergone AV node ablation. Various activity-detecting systems have been developed to create a reliable rate-responsive pacemaker (e.g., muscle movement, respiratory rate, minute ventilation, central venous temperature, QT interval, myocardial contractility [dP/dt], oxygen saturation and pH in mixed venous blood, and ventricular depolarization gradient), but currently PPMs used in the United States rely on sensors of motion or changes in minute ventilation through measurements of intrathoracic impedance. Because of the latter phenomenon, patients undergoing general anesthesia who are subjected to mechanical hyperventilation (e.g., neurosurgery) can experience an increase in the rate of pacing. Although it is generally not required to disable rate-responsive features before surgery, pacemaker-induced changes

in heart rate resulting from intraoperative hyperventilation or significant motion may sometimes be mistaken for inadequate anesthesia. Hence, it is important that the anesthesia team be aware of the programmed settings of the pacemaker. If reprogramming the device to disable rate-responsive features is not readily available, a magnet may be placed over the pacemaker site to temporarily convert it to asynchronous pacing. Although the response to a magnet may be programmed off in some pacemakers, all properly functioning pacemakers within the United States have magnet-responsive features activated as a default.

A.8. What are the advantages and disadvantages of atrial pacing only? What are the disadvantages of right ventricular pacing only?

Atrial pacing only increases cardiac output by 26% over the cardiac output of ventricular pacing only because atrial contraction contributes to approximately 15% to 25% of the diastolic filling of the ventricle in normal hearts. It has been shown that coronary blood flow increases and coronary resistance decreases during atrial pacing only. Atrial pacing has also been associated with a reduction in the incidence of atrial fibrillation. Atrial pacing only is seldom used in the United States and often is implanted with the addition of a ventricular pacing lead in the event AV block develops over time.

Ventricular pacing, occurring individually or sequentially with atrial pacing, has been shown to result in dyssynchronous

left ventricular electrical activation and mechanical contraction. Under normal circumstances, electrical activation along the His-Purkinje system results in a near simultaneous activation of the entire left ventricle. This allows for efficient contraction and is said to be synchronous. When right ventricular pacing is introduced (the lead often at the right ventricular septum or apex), this results in activation of the right ventricular septum first, followed by passive activation of the left ventricle toward the free wall. This form of contraction is said to be dyssynchronous and has been shown to potentially worsen congestive heart failure and the left ventricular EF. Prior studies have shown that individuals at greatest risk for developing reductions in EF from right ventricular pacing are those who exhibit ventricular pacing greater than 40% of the time. Studies have shown that individuals requiring ventricular pacing for AV block with an EF less than 50% have a 56% risk for developing a composite end point of death, urgent visit for heart failure, or left ventricular dilatation over an average of 37 months. As a result, this has led to increased interest in finding alternative, more physiologic ways of pacing the heart. These include directly pacing the His-Purkinje system (e.g., His bundle pacing, peri-left bundle branch pacing) or application of resynchronization therapy. In fact, the patient in this case likely developed heart failure as a result of right ventricular pacing and underwent upgrade to a resynchronization system to help restore left ventricular synchrony.

3114.

A.9. What are the indications for and complications associated with AV sequential PPMs?

When ventricular pacing alone cannot maintain adequate cardiac output and atrial pacing alone is not justified, as in complete AV block, AV sequential pacing is indicated. Because of the success of transvenous leads, bioengineering advances such as thinner polyurethane insulation and improved device programmability, the indications for dual-chamber pacing, have broadened. It can be used for sick sinus syndrome and all degrees of heart block. PPMs programmed to DDD pacing are the ultimate form of physiologic pacing. Programmable features include the mode of pacing, the AV delay, the maximum atrial rate that the ventricle will follow (atrial tracking), and the minimum atrial rate for sensing at which atrial pacing commences. The major advantage of such pacing is the ability to significantly increase the cardiac output under extreme stress and a reduced incidence of atrial fibrillation development. Historically, the major disadvantage of DDD pacing has been the possibility of pacemaker-mediated tachycardia (see section C.13). Another disadvantage recognized has been the development of ventricular dyssynchrony (see section A.8) as a result of right ventricular only pacing. Long-term follow-up of patients with dual-chamber pacemakers demonstrated reductions in left ventricular EFs when compared to atrial pacing alone, especially in the setting of preexisting left ventricular dysfunction.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–799.

A.10. How would you know if the patient's PPM was atrially, ventricularly, or atrioventricularly sequentially pacing?

Modern-day cardiac monitors are equipped with filters that can accentuate and highlight artificial pacing potentials. In atrial pacing, an electrical spike often appears before the P wave and the QRS complex is usually normal, provided there is normal intrinsic AV conduction. One may need to adjust the monitor so that pacing spikes are accentuated and can readily be seen. In ventricular pacing, the electrical spike is followed immediately by a widened QRS complex. In fact, most right ventricular pacing leads are positioned at the right ventricular apex. Because of this location, pacing would result in a QRS complex that has a QS pattern in lead V_1 and a QS pattern in the inferior limb leads (II, III, and aVF). In AV sequential pacing, there are two spikes: one before the P wave and another preceding the QRS complex.

Zipes DP, Libby P, Bonow RO, et al, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 11th ed. Philadelphia, PA: Elsevier; 2019:780–799.

A.11. What is a biventricular PPM or CRT device? What are the indications for such a device?

It has long been recognized that individuals with interventricular conduction abnormalities have a predilection toward impaired left ventricular systolic function. In fact, one of the more common interventricular conduction delays seen in patients with congestive heart failure is LBBB. On a mechanistic level, individuals with LBBB demonstrate ventricular dyssynchrony, a phenomenon whereby the left ventricle contracts in a stepwise process. Unlike normal individuals where the left ventricular septum and the left ventricular lateral free wall are electrically activated nearly simultaneously, patients with LBBB have a delay in the activation of the left lateral free wall. As a result, there is marked impairment in left ventricular systolic function and increased myocardial work and oxygen consumption. One

approach to correct this dyssynchrony is to "resynchronize" the heart through the use of a biventricular pacemaker/ICD. These devices are capable of pacing both the left ventricular septum (through a pacemaker lead in the right ventricle) and the left ventricular lateral free wall simultaneously (through a pacemaker lead in the coronary sinus), thereby allowing for activation of the entire left ventricle at the same time. Candidates for implantation of a biventricular device include individuals on optimal heart failure medications with

- Sinus rhythm, EF ≤35%, LBBB with QRS >120 milliseconds, NYHA II to IV symptoms
- Sinus rhythm, EF ≤35%, non-LBBB with QRS >150 milliseconds, NYHA III to IV symptoms
- Patients requiring >40% of ventricular pacing with EF ≤35%

A.12. What are the usual lifespans of PPMs and implantable cardioverter-defibrillators (ICDs)?

Modern-day pacemakers are lithium-powered and can on average last 10 to 15 years. The lifespan of current ICDs relies not only on the battery but also on the high-voltage capacitor. Hence, typical lifespans are 8 to 12 years. Recently, leadless pacemakers and subcutaneous ICDs have been introduced into the market. These devices have typical lifespans of 7 and 5 years, respectively.

Ellenbogen KA, Wilkoff B, Kay GN, et al, eds. *Clinical Cardiac Pacing, Defibrillation and Resynchronization Therapy*. 5th ed. Philadelphia, PA: Elsevier; 2016:251–269.

A.13. What is an ICD? How does it work? What is a

subcutaneous ICD?

An ICD system consists of a pulse generator and leads for tachyarrhythmia detection and therapy. ICDs provide antitachycardia and antibradycardia pacing, synchronized (cardioversion) or nonsynchronized (defibrillation) shocks, telemetry, and diagnostics including stored event electrograms and history logs. Essentially, the pulse generator is a self-powered computer within a hermetically sealed titanium casing (can). A battery with high power density is used to power the pulse generator, circuitry, and aluminum electrolytic storage capacitors. Most ICD designs use two capacitors in series to achieve a maximum voltage for defibrillation. A major challenge in ICD design is the large range of voltages that must be controlled in a very small package. Modern devices can charge up to 41 joules of energy.

ICDs commonly use transvenous lead systems for sensing, pacing, and shocks. Epicardial leads are still used in infants and small children. Ventricular demand pacing for bradycardia is a standard feature of all ICDs. Modern-day ICDs have all the capabilities of modern-day pacemakers, including rate-adaptive pacing and automatic mode switching. However, the response of ICDs to magnets differs from that of a pacemaker (see section C.8).

Current ICDs have many programmable features, but essentially, they measure each cardiac R-R interval and categorize the rate as normal, too fast (short R-R interval), or too slow. When the device detects a sufficient number of short R-R intervals within a period of time (all programmable), it will declare a tachycardia episode. The internal computer will decide between antitachycardia pacing (less energy use, painless therapy) and shock based on its programmed algorithm. If shock is chosen, an internal capacitor is charged that takes approximately 5 to 13 seconds depending on the amount of

energy to be delivered and age of the device. Most devices are programmed to reconfirm ventricular tachycardia or ventricular fibrillation immediately after charging to confirm that the arrhythmia persists. Once therapy is delivered, the ICD will redetect to determine whether or not the therapy successfully terminated the arrhythmia. A tachycardia episode is considered terminated when sinus rhythm has been restored for a certain period (varies by manufacturer). Typically, ICDs deliver no more than six shocks for a given episode.

The subcutaneous ICD was approved for use in the United States on September 28, 2012. Unlike traditional ICD systems, this device does not require implantation of transvenous leads within the heart. The ICD can is implanted along the left midaxillary line, and the defibrillator lead is tunneled subcutaneously across the left costal margin to the xiphoid process. From there, the lead is then tunneled superiorly along the left sternal border toward the sternal notch so that the defibrillator coil is positioned alongside the sternum (**Figs. 8.2** and **8.3**). The vector for defibrillation is defined between the can and the defibrillator coil. These systems are unique and provide a solution to patients who have vascular issues or may not want indwelling transvenous leads. Because sensing and defibrillation occurs from the chest wall, a couple of unique considerations exist. First, the size of the surface T waves can complicate device sensing so some patients may not be eligible. Second, the amount of energy required for defibrillation is typically higher compared to traditional ICD systems because there is more energy that gets dissipated because energy is being delivered further away from the heart. As a result, the battery and capacitors are larger and result in a larger device. Lastly, these systems differ from traditional ICDs in that they do not provide pacing support or deliver antitachycardia pacing because of the pain that is associated with transcutaneous pacing delivery.

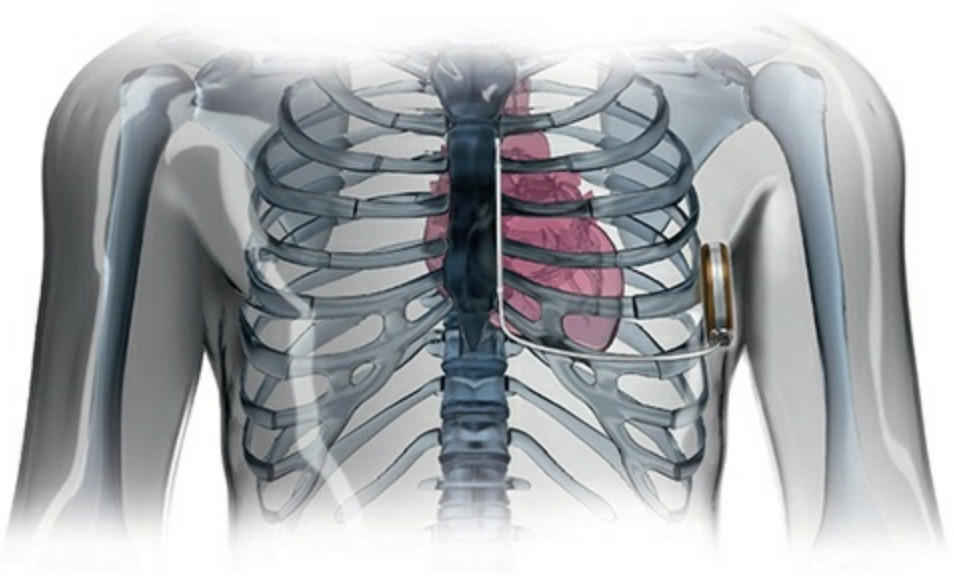

FIGURE 8.2. The subcutaneous ICD. ICD can is implanted along the left midaxillary line, and the lead is tunneled across the left lower chest to the xiphoid process. The lead is then directed superiorly along the left sternal border so that the lead's defibrillator coil is alongside the sternum. Defibrillation vector involves the can to the coil. A.14. What are the indications for ICDs?

Initially, ICDs were indicated for hemodynamically significant ventricular tachycardia or ventricular fibrillation. Newer indications include the following and continue to evolve:

- Survivors of cardiac arrest because of ventricular tachycardia/ventricular fibrillation not resulting from a transient or reversible cause
- Spontaneous or induced at electrophysiology study sustained ventricular tachycardia in the presence of structural heart disease
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained ventricular tachycardia or ventricular fibrillation-induced at electrophysiology study
- Ischemic cardiomyopathy (EF ≤30%) without a recent myocardial infarction (within the last 40 days) or revascularization in the past 3 months
- Ischemic or nonischemic dilated cardiomyopathy (EF ≤35%) with NYHA class II or III heart failure symptoms
- Inherited channelopathies including Brugada syndrome (RBBB and ST-segment elevation leads V_1 to V_3), catecholaminergic polymorphic ventricular tachycardia, long QT syndrome, short QT syndrome, idiopathic ventricular fibrillation
- Inherited or acquired high-risk states including arrhythmogenic right ventricular dysplasia, hypertrophic cardiomyopathy, cardiac sarcoidosis, or Chagas

cardiomyopathy.

A.15. What is the NASPE and BPEG generic defibrillator (NBD) code?

Like pacemakers, ICDs have a generic code to indicate lead placement and function. The NBD code is shown in **Table 8.2**. The most robust form of identification, referred to as the "label form," replaces the fourth letter of the NBD with the appropriate generic pacemaker code.

TABLE 8.2 NASPE/BPEG Generic Defibrillator Code

Letter I	Letter II	Letter III	Letter IV
Shock Chamber(s)	Antitachycardia Pacing Chamber(s)	Tachycardia Detection	Antibradycardia Pacing Chamber(s)
O = None	O = None	E = Electrogram	O = None
A = Atrium	A = Atrium	H = Hemodynamic	A = Atrium

V = Ventricle	V = Ventricle	(Not yet available)	V = Ventricle
D = Dual (A + V)	D = Dual (A + V)		D = Dual (A + V)

B. Preoperative Evaluation and Preparation

B.1. How would you preoperatively evaluate the patient described earlier?

Preoperative evaluation should include the routine systemic workup, paying particular attention to cardiovascular disorders. The comprehensive evaluation includes complete blood count, urinalysis, coagulation screening with prothrombin time and partial thromboplastin time, serum electrolytes, blood urea nitrogen, blood sugar, chest radiograph, and ECG. Special attention should be paid to the history, symptoms and signs of myocardial infarction, congestive heart failure, and arrhythmias. Serum electrolytes, especially potassium level, must be in the normal range. For the patient with a CIED, recent guidelines have recommended that all CIEDs be properly interrogated within 3 to 6 months before surgery. This evaluation should include the following:

- Establish whether a patient has a CIED—this is best accomplished by a detailed history and verifying by reviewing a recent chest x-ray.
- Define the type of CIED—patients typically have a CIED information card.
- Determine dependency on the pacing function of the CIED—

review recent device interrogation report.

- Determine CIED function and programming details—review recent device interrogation report.
- Determine magnet behavior and whether CIED requires reprogramming on the day of surgery to avoid inappropriate device behavior from EMI.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: facilities and patient management this document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8:1114–1154.

B.2. How do you determine whether the patient has a cardiac implantable electronic device (CIED) and define what type of CIED?

Determining whether a patient has a CIED should be based on (1) a focused history including but not limited to the patient interview, medical records review, review of available chest radiograph, ECG, or any available monitor or rhythm strip information and (2) a focused physical examination (e.g., checking for scars, palpating for device). Of note is the recent introduction of leadless pacemakers (all three major device manufacturers are developing one, but only one is currently US Food and Drug Administration (FDA) approved [Micra, Medtronic, Mounds View, MN]), which are small capsule-sized devices delivered through a catheter inserted in the groin and fully implanted into the heart (**Fig. 8.4**). Therefore, there are no

obvious signs of a device by physical examination and one must review a recent chest radiograph to confirm its presence (**Fig. 8.5**).

FIGURE 8.4. Micra leadless pacemaker. (*Reproduced with permission of Medtronic, Inc.*)

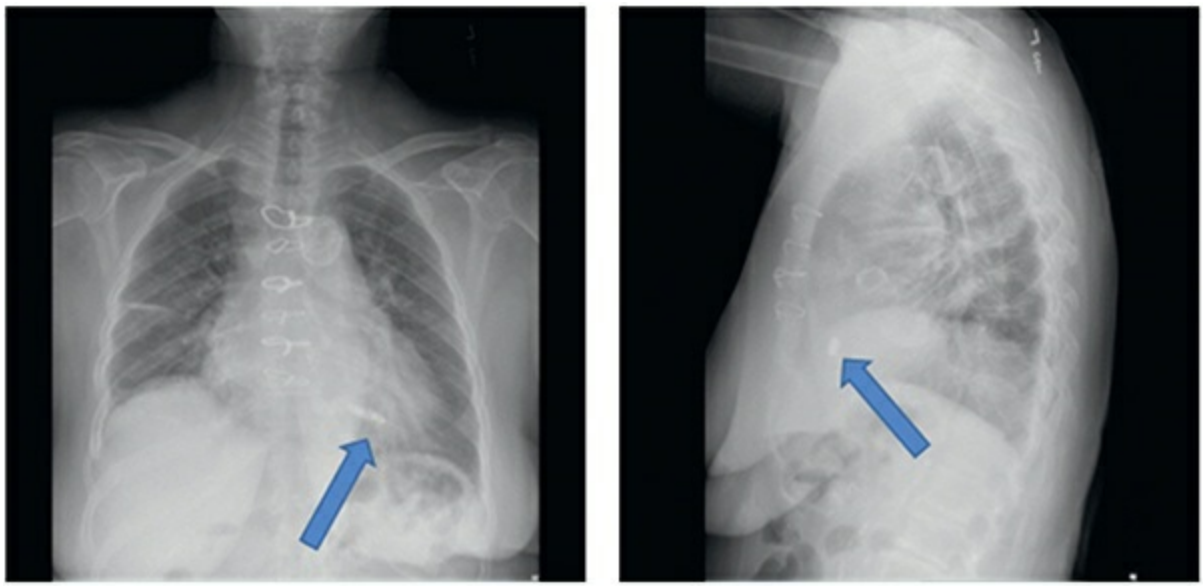

FIGURE 8.5. Chest x-ray of Micra leadless pacemaker implanted in the right ventricle (*blue arrows*) in anterior-posterior and lateral views. (*With courtesy of Hiroshi Ashikaga, MD, PhD.*)

Defining the type of device is accomplished by (1) obtaining the manufacturer's identification card from the patient or other source, (2) ordering chest radiography studies if no other data are available, or (3) referring to supplemental resources (e.g., manufacturer's databases, pacemaker clinic records,

consultation with a cardiologist).

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Sideris S, Archontakis S, Dilaveris P, et al. Leadless cardiac pacemakers: current status of a modern approach in pacing. *Hellenic J Cardiol*. 2017;58(6):403–410.

B.3. How do you determine whether the patient is dependent on the pacing from the CIED?

Pacemaker dependency is not defined by an absolute amount of pacing seen over time. Rather, it is defined by how functionally dependent a patient is to pacing support. For instance, a patient with a dual-chamber pacemaker may not pace 100% of the time. But during periods of pacing, if pacing were to be temporarily discontinued and the patient developed light-headedness or presyncope, then he or she would be considered functionally dependent. Functional dependency on pacing support may be determined by one or more of the following: (1) a verbal history or an indication in the medical record that the patient has experienced a bradyarrhythmia that has caused syncope or other symptoms requiring CIED implantation, (2) a history of successful AV nodal ablation that resulted in CIED placement, or (3) a CIED evaluation that shows clinically evidenced hemodynamic compromise when the pacing function of the CIED is temporarily disabled or programmed to the lowest programmable rate.

For emergency surgery, an ECG or rhythm strip should be examined for pacing spikes. If pacing spikes are noted before most or all of either the P waves or QRS complexes, then the patient should be treated as if pacemaker dependent. All

pacemaker-dependent patients and patients with ICDs should have transcutaneous pacing and defibrillator pads available during surgery. A magnet should always be available, and its use is recommended in the pacemaker-dependent patient as well as the patient with an ICD. Regardless of the type of device, interrogation of the CIED under the direction of a physician knowledgeable in the function of devices should occur as soon as possible.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

B.4. How do you know if the implanted PPM or ICD is working?

The CIED function is best assessed by interrogating the device, and this is the recommended approach. But if interrogating the device is not an option and this information is urgently needed, one can attempt to slow the intrinsic heart rate to a rate below that of the pacemaker by carotid massage or the Valsalva maneuver. Carotid massage to slow the heart rate should be used cautiously because it could result in an arteriosclerotic plaque embolizing to the cerebral circulation. If the rate does not slow down enough for the pacemaker to take over the ventricle, the device can be tested by placing a magnet over it that will temporarily program it to a fixed-rate pacing mode. In this mode, pacing spikes march through the rhythm strip with no regard for the intrinsic electrical activity of the heart. The rate at which the pacemaker will pace in the presence of a magnet varies among device manufacturers and is dependent on the battery life. Once the magnet is removed, the device returns to its normal programming. Of note, placing a magnet over an ICD

does not temporarily program the device to pace asynchronously. The magnet on an ICD will only temporarily disable the ICD therapies and will have no effect on the pacing function. Additionally, leadless pacemakers also do not respond to the magnet by pacing asynchronously.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Sideris S, Archontakis S, Dilaveris P, et al. Leadless cardiac pacemakers: current status of a modern approach in pacing. *Hellenic J Cardiol*. 2017;58(6):403–410.

B.5. What information would you like to obtain from interrogating this device?

Device interrogations provide information on the status and current programmed settings of a PPM or ICD. The important primary information for anesthesiologists include (1) battery life, (2) programmed pacing mode such as VVIR and DDDR, (3) pacemaker dependency, (4) intrinsic rhythm, (5) behavior to a magnet, (6) prior recorded arrhythmic events, and (7) pacemaker lead parameters (including pacing threshold, ability to sense intrinsic activity, and lead impedance).

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

B.6. How do you preoperatively prepare the patient for surgery and anesthesia?

Preparation for patient safety and proper maintenance of the device during a procedure includes the following:

- Determining whether EMI is likely to occur during the planned procedure as well as the location of the EMI
- Properly positioning the electrocautery grounding pad so that device exposure to the path of conduction from the electrocautery instrument to the grounding pad is minimized to the fullest extent
- Determining whether reprogramming the CIED pacing function to an asynchronous pacing mode or disabling any special algorithms, including rate-adaptive features, is needed
- Suspending antitachyarrhythmia functions if present
- Advising the surgeon performing the procedure to minimize prolonged bursts of monopolar cautery or consider use other less EMI-generating sources of energy including bipolar electrocautery or ultrasonic (harmonic) scalpel
- Ensuring the availability of temporary pacing and defibrillation equipment
- Evaluating the possible effects of anesthetic techniques and of the procedure on CIED function and patient—CIED interactions

---

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

B.7. Would you recommend reprogramming this device to asynchronously pace before surgery? What would you recommend regarding the ICD functions of the device?

Given the number of patients with CIEDs, recommending that all patients undergo reprogramming immediately before surgery is untenable and would significantly compromise perisurgical throughput. Moreover, reports have described individuals with

ICDs or PPMs who later expired because the device was not reactivated before discharge after surgery. These issues raise the need for proper triaging of patients who truly need their devices reprogrammed before surgery. The patient in this example has a CRT-D. It is likely that the patient is functionally dependent on the CIED. Furthermore, the location of the EMI delivered in this case is close to the device system and therefore would likely result in inappropriate inhibition of pacing and/or sensing of EMI that the device would inappropriately mark as ventricular fibrillation. Given functional dependency on the device and the location of the EMI delivered, reprogramming the device would be recommended to deactivate the ICD and pace asynchronously before surgery for the following reasons:

- Electrocautery during surgery may inhibit pacing function.
- A magnet cannot convert the pacemaker in an ICD system to asynchronous mode pacing. A magnet placed over an ICD only disables tachycardia detection and therapy of the ICD. This is true of all devices used in the United States. One notable exception are ICDs manufactured by LivaNova Medical (London, United Kingdom), which, in the presence of a magnet, will not only disable tachycardia detection therapy but also convert pacing to a fixed rate at 96 beats per minute.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

B.8. The patient requires an abdominal magnetic resonance imaging (MRI) prior to the surgery. What considerations should you make regarding her CIED?

MRIs were generally contraindicated in patients with a CIED, but more recent generation generators and leads have been engineered to be labeled as "MRI conditional." These newer devices have the ability to manage the increased energy introduced to the CIED during the scan while minimizing the potential risks of myocardial ablation and induction of arrhythmias. Hence, patients with these newer device systems can undergo MRI scanning if clinically indicated and the CIED appears to be functioning normally. Although a patient may have a CIED system that is conditionally approved to undergo MRI scanning, there are other aspects of the system that need to be evaluated to confirm that it is safe. Patients with abandoned or fractured leads, for example, may not be appropriate candidates for MRI scanning despite the CIED system being labeled as MRI conditional. If MRI must be performed, consult with the ordering physician, the patient's cardiologist or electrophysiologist, the diagnostic radiologist, and the CIED manufacturer.

MRIs can cause rapid pacing, inhibition, resetting of DDD pacemakers, and transient reed switch malfunction with asynchronous pacing. Serious malfunction with no output or rapid pacing may occur because pulsed energy from MRIs can enter the lead by capacitive coupling and cause rapid ventricular pacing. All CIEDs being exposed to MRIs should be checked before and after MRI scanning.

C. Intraoperative Management

C.1. How would you monitor this patient?

Intraoperative monitoring should include both continuous ECG and continuous peripheral pulse monitoring. Peripheral pulse can be monitored by palpation of the pulse, auscultation of heart sounds, pulse plethysmography or oximetry, a tracing of arterial wave form, or ultrasound peripheral pulse monitoring.

Arterial line and central venous pressure or pulmonary artery pressure monitoring may need to be used in patients with poor ventricular function. The pacing detection feature on the ECG monitor should be enabled to detect the pacing spikes. The ECG monitor should be set in diagnostic mode instead of monitoring mode.

American Society of Anesthesiologists. Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: facilities and patient management this document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8:1114–1154.

C.2. What drugs and equipment would you like to have on hand in the operating room?

A complete array of drugs and equipment must be immediately

available for cardiopulmonary resuscitation. The minimal requirements include ECG monitor, a transcutaneous external pacing and direct current (DC) defibrillator as well as the usual drugs for resuscitation.

Atlee JL, Bernstein AD. Cardiac rhythm management devices (part I): indication, device selection, and function. *Anesthesiology*. 2001;95:1265–1280.

C.3. How would you set up the transcutaneous external pacer and defibrillator?

We prefer applying defibrillating electrodes such as ZOLL® pads to paddles because the electrodes can be placed before surgery at the desired positions and connected to a defibrillator/pacemaker for pacing and defibrillation. The electrodes should be placed as far (more than 6 in. or 15 cm) from a CIED as possible. The three recommended electrode placements are as follows:

- *Anteroposterior placement*. The right arm (RA) electrode placed under the left scapula and the left leg (LL) electrode at apex of the heart (as shown in **Fig. 8.6**).
- *Apex-anterior placement*. The RA electrode placed under the right clavicle and the LL electrode at the apex of the heart (**Fig. 8.7A**).
- *Apex-posterior placement*. The RA electrode placed over the right scapula and the LL electrode at the apex of the heart (**Fig. 8.7B,C**).

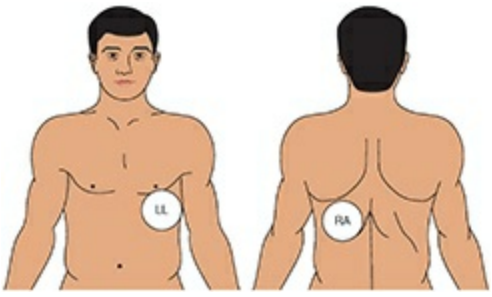

FIGURE 8.6. Anteroposterior placement of defibrillating electrodes. The right arm (RA) electrode

is placed under the left scapula, and the left leg (LL) electrode is placed at the apex of the heart.

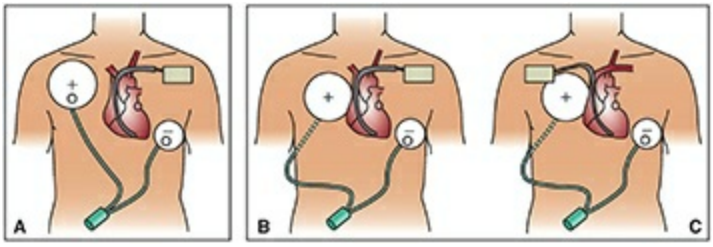

FIGURE 8.7. Placement of defibrillating electrodes. A. Apex-anterior placement with both pads placed anteriorly. **B and C.** Apex-posterior placement shown with the device in the left prepectoral region **(B)** and the right pectoral region **(C)**. (*Adapted from Ellenbogen KA, Kay GN, Wilkoff BL, eds.* Clinical Cardiac Pacing and Defibrillation. *2nd ed. Philadelphia, PA: Saunders; 2000:944. Copyright © 2000 Elsevier. With permission.*)

It is important to remember that the presence of a CIED should not deter standard resuscitation efforts.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med*. 2004;32(suppl 4):S155–S165.

C.4. Had this patient's ICD been implanted the day before surgery, would you consider avoiding certain inhalational gases for anesthesia?

It has been reported that nitrous oxide could cause pacemaker malfunction by increasing gas in the prepectoral pacemaker pocket. Despite air evacuation with antibiotic solution before closure of the prepectoral pocket, a small amount of air remains entrapped in the pocket. In general, this small amount of air should have no clinical significance. Nitrous oxide is 35 times more soluble in blood than nitrogen. When nitrous oxide is used for anesthesia, the amount of nitrous oxide diffused from blood to the air pocket is much more than the amount of nitrogen diffused from the air pocket to blood. Therefore, this causes an expansion of the gas in the pocket that leads to loss of anodal contact and pacing system malfunction. It is advisable not to use nitrous oxide in a patient with a newly implanted pacemaker.

Lamas GA, Rebecca GS, Braunwald NS, et al. Pacemaker malfunction after nitrous oxide anesthesia. *Am J Cardiol*. 1985;56:995.

C.5. Electromagnetic interference (EMI) from electrocautery results in significant noise on your cardiac monitor. You recall that EMI also can inhibit pacing function from the PPM. In this pacemaker-dependent patient, how can you determine whether inappropriate inhibition of the PPM is occurring?

During electrocautery, the ECG is frequently useless because of interference. The best monitor available to determine if inhibition is taking place is a hand on the pulse. The precordial or esophageal stethoscope, pulse oximeter, or blood pressure is also acceptable.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

C.6. What are the potential responses of pacemakers and ICDs to electrocautery?

The responses of pacemakers to electrocautery or other EMI include the following:

- Inhibition of pacing
- Asynchronous pacing
- Reset to backup mode
- Myocardial burns, rare
- Ventricular fibrillation, rare

The responses of ICDs include the following:

- Inhibition of pacing
- Asynchronous pacing
- Inappropriate tachy therapy

- Inhibition of tachy therapy

Salukhe TV, Dob D, Sutton R. Pacemakers and defibrillators: anaesthetic implications. *Br J Anaesth*. 2004;93:95–104.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med*. 2004;32(suppl 4):S155–S165.

C.7. How would you prevent the effects of EMI on the pacemaker or ICD from the electrocautery?

The safest way to prevent intraoperative EMI response is appropriate reprogramming. The following precautions should be taken to minimize the effects of electrocautery:

- Place the cautery grounding plate as close to the operative site and as far from the CIED as possible to make sure that the current pathway does not pass through or near the CIED system. For some cases, the grounding plate might need to be placed on a site different from the thigh (e.g., the superior posterior aspect of the shoulder contralateral to the CIED generator position for a head and neck case).
- Do not use cautery within 15 cm of the pacemaker because it may interfere with the battery circuitry. If in contact with a break in the insulation of the electrode, it may cauterize the myocardium at the electrode tip, rendering it insensitive to pacing impulses.
- Limit cautery use to 1-second bursts every 10 seconds to prevent repetitive asystolic periods (if possible).
- If the pacemaker is inhibited by the cautery, place a high-powered magnet over the demand nonprogrammable pacemaker to convert it to fixed-rate mode.
- Using bipolar electrocautery forceps or ultrasonic (harmonic) scalpel reduces EMI.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices:

pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Stone KR, McPherson CA. Assessment and management of patients with pacemakers and implantable cardioverter defibrillator. *Crit Care Med*. 2004;32(suppl 4):S155–S165.

C.8. What are the effects of a magnet on pacemakers and ICDs?

The effect of placing a magnet over a pacemaker or ICD can vary quite considerably depending on the device manufacturer, model, and individual programmed modes. This information may be obtained by consulting the device manufacturer's representative. Most pacemakers will switch to a fixed-rate pacing mode when a magnet is placed. The exception to this is that the Micra leadless pacemaker will not respond to the magnet by pacing asynchronously.

The response of an ICD to magnet placement is different from the response of a pacemaker. Magnets will disable tachyarrhythmia detection and therapy that, except in some Boston Scientific devices, are reenabled when the magnet is removed. Magnets generally will, with a few exceptions, not affect the pacing mode or rate of ICDs. Therefore, the pacemaker in an ICD can be inappropriately inhibited by electrocautery even when a magnet is placed.

It is important to remember that some early generation Boston Scientific ICDs are permanently disabled when a magnet is placed for more than 30 seconds. The ICD will not be reactivated when the magnet is removed. To reactivate the Boston Scientific ICDs, the magnet has to be reapplied over the ICD for more than 30 seconds and then removed. If a magnet is to be used during surgery, the magnet effects should be tested in

the operating room before surgery to ensure that the desired effects will occur during surgery.

Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: facilities and patient management this document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8:1114–1154.

Salukhe TV, Dob D, Sutton R. Pacemakers and defibrillators: anaesthetic implications. *Br J Anaesth*. 2004;93:95–104.

C.9. In the middle of surgery, the patient developed ventricular tachycardia. What would you do?

For a patient with an ICD and magnet-disabled therapies:

- Advise the surgeon performing the procedure to terminate all sources of EMI.
- Remove the magnet to reenable antitachycardia therapies.
- Observe the patient and the monitors for appropriate CIED therapy. This can be delayed for as long as 10 to 12 seconds as the ICD is charging.
- If the activities mentioned in the preceding text do not restore ICD function, proceed with emergency external defibrillation.

For a patient with an ICD and programming-disabled therapies:

- Advise individual performing the procedure to terminate all sources of EMI while magnet is removed.
- Reenable therapies through programming if the programmer is immediately available and ready to be used.
- Observe the patient and the monitors for appropriate CIED therapy.
- If the activities mentioned in the preceding text do not restore ICD function, proceed with emergency external

defibrillation.

For external defibrillation (see also section C.3):

- Position defibrillation/cardioversion pads or paddles as far as possible from the CIED generator.
- If it is technically impossible to place the pads or paddles in locations that help to protect the CIED, defibrillate/cardiovert the patient in the quickest possible way and be prepared to provide pacing through other routes.
- Use a clinically appropriate energy output.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

C.10. What precautions should be taken when a patient with a CIED is undergoing extracorporeal shock wave lithotripsy (ESWL)?

ESWL is no longer contraindicated for patients with pacemakers. The only exception to this general statement is the abdominally placed pacemaker generators. Because these generators are in the blast path of the shock wave, such patients should not be treated with ESWL. Nevertheless, most transvenous pacemaker generators are placed in a pectoral location that is at a safe distance from the blast path. Consider preoperative disabling of atrial pacing if the lithotripsy system triggers on the R wave. Avoid focusing the lithotripsy beam near the pulse generator.

Although most pacemakers are not affected by ESWL, sometimes it may cause pacemaker malfunctions that include the following:

- Switching to magnet mode
- Reaching upper rate limit

- Pacing irregularity
- Oversensing of asynchronous shocks
- Damage to rate-sensing piezoelectric crystal
- Intermittent inhibition of ventricular output in dual-chamber pacemaker
- EMI

There may be a rate increase in a rate-response (adaptive) pacemaker after ESWL shocks. Therefore, special precautions should be taken preoperatively. The type of pacemaker, indications for its placement, degree of patient dependence, and pacemaker programmability must be determined before lithotripsy. A dedicated pacemaker programmer should be available in the lithotripsy suite should pacemaker malfunction be caused by the shock waves. In addition, an alternative means of pacing, such as transcutaneous pacing, should also be available in case the pacemaker becomes permanently damaged. Low-energy shock waves (less than 16 kV) should be used initially; then the energy level is gradually increased while pacemaker function is monitored carefully. It is best to disable tachycardia detection of an ICD during ESWL and to thoroughly test the ICD following the procedure.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

C.11. Is electroconvulsive therapy (ECT) contraindicated in patients with pacemakers or ICDs?

It is advisable to consult with the ordering physician, the patient's cardiologist, a cardiac rhythm management device service, or the device manufacturer. ECT appears safe for patients with pacemakers or ICDs because little current flows

within the heart due to the high impedance of body tissues. Nevertheless, the seizure and succinylcholine fasciculations may generate sufficient myopotentials for pacemaker inhibition (unipolar devices) or ventricular tracking (adaptive-rate devices). Therefore, it is advisable to program the pacemaker to a nonsensing (asynchronous) mode for pacemaker-dependent patients either by reprogramming prior to the procedure or using a magnet during the case. It is also important to keep in mind that a magnet placed over an ICD will only disable tachytherapies and will not cause the ICD to pace asynchronously. An external pacemaker should also be available. Current guidelines also suggest that all ICDs should be programmed so that tachycardia detection is disabled before ECT and reprogrammed to its original programmed parameters prior to discharge.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

C.12. What precautions should be taken during radiofrequency ablation for a patient with a CIED?

- Avoid contact of radiofrequency catheter with the CIED generator and leads.
- Radiofrequency current path as far away from the CIED generator and leads as possible.
- Discuss these concerns with the operator.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

C.13. During surgery, the patient developed frequent premature ventricular complexes and some of these resulted in rapid ventricular pacing (see Fig. 8.8). What is accounting for the pacemaker's behavior?

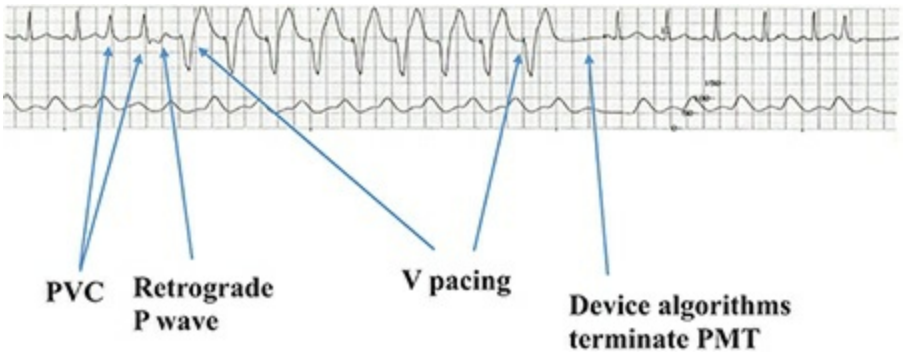

FIGURE 8.8. Rhythm strip of pacemaker-mediated tachycardia (PMT). Premature ventricular complexes (PVCs) are seen initially followed by a run of wide complex tachycardia with each QRS complex preceded by a pacing spike suggesting ventricular (V) pacing. This phenomenon occurs because the PVCs conducted through the atrioventricular node in a retrograde fashion and resulted in an atrial sensed event that the DDD device detects. Because of the DDD programming, ventricular pacing is triggered and the paced ventricular beat perpetuates the cycle by conducting through the atrioventricular node again in a retrograde fashion and resulting in another atrial sensed event. The tachycardia eventually terminates because the device has an anti-PMT algorithm.

Ventricular ectopy can often interfere with proper functionality of a dual-chamber pacemaker or defibrillator. In many instances, premature ventricular complexes can conduct retrograde up the AV node and result in atrial sensed events that are detected by the atrial lead. Depending on when this occurs, a dual-chamber pacemaker programmed to DDD may track this and trigger ventricular pacing, thus resulting in what is often termed *pacemaker-mediated tachycardia* (**Fig. 8.8**).

Current devices are equipped with algorithms that can limit the duration of these episodes. During surgery, it is important to be aware of this phenomenon and not mistake these runs of pacing induced wide complex tachycardia as ventricular tachycardia. Look for pacing spikes in front of the wide complex beats as a quick way to determine if they are being caused by

pacing.

Ellenbogen KA, Kaszala K, eds. *Cardiac Pacing and ICDs*. 6th ed. Hoboken, NJ: Wiley Blackwell; 2014:211–271.

D. Postoperative Management

D.1. How would you monitor this patient in the postanesthesia care unit?

Cardiac rate and rhythm should be continuously monitored throughout the immediate postoperative period. Backup pacing capability and cardioversion-defibrillation equipment should be immediately available at all times.

American Society of Anesthesiologists. Practice advisory for the perioperative management of patients with cardiac implantable electronic devices: pacemakers and implantable cardioverter-defibrillators: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Implantable Electronic Devices. *Anesthesiology*. 2011;114:247–261.

Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers and arrhythmia monitors: facilities and patient management this document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8:1114–1154.

D.2. How would you confirm that the CIED is functioning properly after surgery?

Postoperative interrogation and restoration of CIED function are basic elements of postoperative management. But given the robustness of modern devices, not all CIEDs require postoperative interrogation before discharge, especially in cases in which the EMI is remote from the device system. CIEDs that should be interrogated postoperatively before discharge include

the following:

- CIEDs that were reprogrammed or deactivated before surgery so that baseline settings can be restored
- Patients who underwent hemodynamically embarrassing surgeries such as cardiac surgery or significant vascular surgery
- Patients who experienced significant intraoperative events, including cardiac arrest, requiring temporary pacing or cardiopulmonary resuscitation, and/or tachyarrhythmias requiring external electrical cardioversion during surgery

All other individuals should have their devices evaluated as an outpatient within the next 3 months.

American Society of Anesthesiologists. 9 Thoracic and Thoracoabdominal Aortic Aneurysms

Yong Zhan, Frederick C. Cobey, Sharon L. McCartney, Madhav Swaminathan, and Jamel Ortoleva

A 68-year-old man presents for surgical repair of a thoracoabdominal aortic aneurysm (TAAA). He has a significant past medical history that includes a type A aortic dissection (TAAD) 12 years ago, for which he underwent a Bentall repair; poorly controlled hypertension; chronic obstructive pulmonary disease (COPD); tobacco use (45 pack-years); and stage III chronic kidney disease (CKD). His type A dissection event was complicated by end-organ ischemia, including ischemic colitis and renal failure. He has been undergoing routine surveillance of his aorta, and computed tomography (CT) reveals his aortic aneurysm has recently enlarged to 5.5 cm starting at the innominate artery and extending into the abdominal aorta, proximal to the renal arteries. Chest radiograph demonstrates thoracic aortic aneurysmal dilation, without compression of surrounding structures. Transthoracic echocardiogram demonstrates normal left and right ventricular function, trivial aortic insufficiency (AI), and trivial mitral insufficiency. Laboratory studies indicate a hemoglobin of 14.5 g per dL, hematocrit 44%, blood urea nitrogen (BUN) 22 mg per dL, and

creatinine 1.8 mg per dL.

A. Pathophysiology and Differential Diagnosis

1. What is a thoracic aortic aneurysm (TAA) and TAAA, and how do they typically present?
2. How are TAAs and TAAAs classified?
3. What is the pathogenesis of aortic aneurysms and what genetic conditions predispose to their formation?
4. What are the risk factors for TAA rupture?
5. What is the natural history and medical management of thoracic aneurysms?
6. What is a thoracic aortic dissection, and how does it typically present?
7. How are thoracic aortic dissections classified?

B. Preoperative Evaluation and Preparation

1. What are the indications and timing of surgical intervention for TAAs?
2. Which patients are candidates for endovascular aortic repair, and what are the advantages to this approach?
3. What are the preoperative considerations for the anesthesiologist before TAA repair?
4. What is the preoperative management of a patient presenting with an acute aortic dissection (AAD)?
5. What is the spinal cord blood supply?

C. Intraoperative Management

1. What are the surgical approaches to thoracic aneurysm repair?
2. How is the open repair performed?
3. How are endovascular repairs of TAAAs performed?
4. What are the surgical approaches to aortic dissections?
5. What are the specific considerations for anesthetic management of the patient presenting for open TAAA repair?

6. What are the specific considerations for anesthetic management of the patient presenting for endovascular TAAA repair?
7. What hemodynamic monitors should be used for the patient undergoing thoracic aneurysm repair?
8. What strategies are used for spinal cord protection during a TAAA repair?
9. What strategies are used for mesenteric and renal preservation?
10. What is the pathophysiology of aortic clamping and unclamping?
11. Why does a coagulopathy ensue and how is it prevented/treated?

D. Postoperative Anesthetic Management

1. What are the postoperative complications after open TAAA repair?
2. What are the postoperative complications after endovascular TAAA repair?

A. Pathophysiology and Differential Diagnosis

A.1. What is a thoracic aortic aneurysm (TAA) and TAAA, and how do they typically present?

TAAs and TAAAs are abnormal dilations of the thoracic and/or abdominal aorta to greater than 150% of its expected diameter. They can occur at any point along the aorta, including the root, ascending, arch, and descending portions with occasional extension into branching vessels. The dimensions that define normal aortic size are determined by patient age, gender, and body surface area.

One of the greatest challenges in the care of patients with thoracic aortic disease is identifying them prior to the onset of a catastrophic aortic event. Despite their propensity for life-

threatening complications, TAAs are often clinically silent and are often diagnosed during imaging for an unrelated disorder. When symptoms do occur, they are often nonspecific, and diagnosis requires a high index of clinical suspicion. Symptoms of TAAs frequently result from compression of adjacent structures. Patients may exhibit hoarseness from recurrent laryngeal nerve compression, stridor from bronchial or tracheal compression, dyspnea from lung compression, dysphagia from esophageal compression, and/or facial edema from superior vena cava (SVC) compression. Pain in the neck, jaw, back, shoulders, or abdomen may also be present. Additionally, new-onset heart failure symptoms may occur as aortic enlargement results in progressive AI (**Fig. 9.1**).

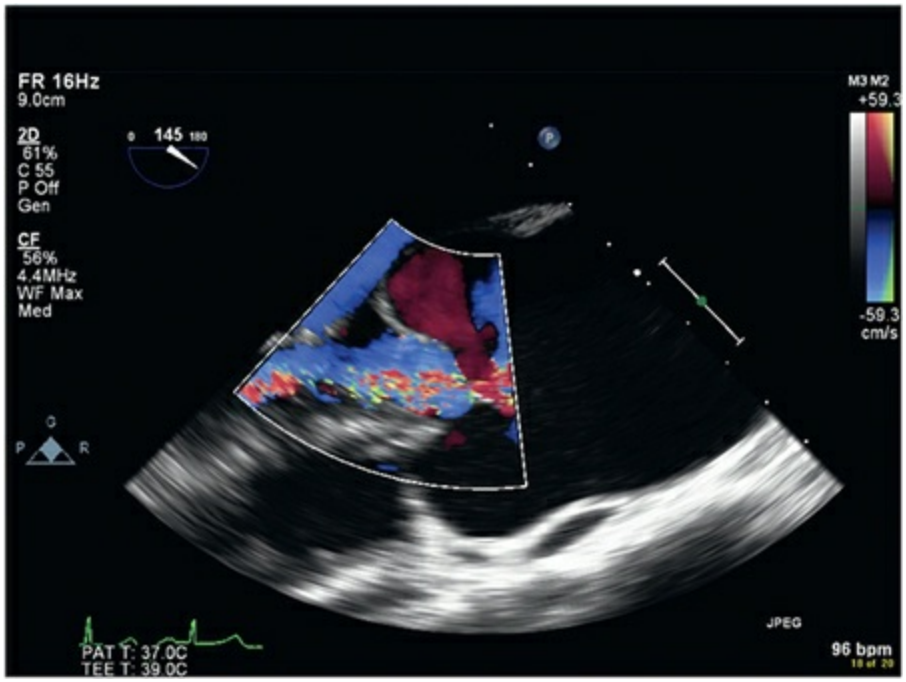

FIGURE 9.1. Midesophageal AV long-axis view on TEE demonstrating moderate central AI secondary to aortic root and ascending aortic dilatation in a young woman with Turner syndrome.

Once identified, dedicated imaging with either CT (**Fig. 9.2**) or magnetic resonance imaging (MRI) should be undertaken to delineate the extent of the aneurysm, its maximum dimension,

branch vessel involvement, and the presence or absence of a coexisting intramural hematoma or penetrating aortic ulcer. Transesophageal echocardiography (TEE) is also performed to assess for valvular disease, evaluate cardiac function, and more carefully assess the anatomy of the aortic root (**Fig. 9.3**).

FIGURE 9.2. Three-dimensional (3D) CT reconstruction demonstrating a thoracoabdominal aneurysm that begins in the descending thoracic aorta and extends to the infrarenal aorta, above the bifurcation into the iliac arteries. Also seen is a chronic type B aortic dissection.

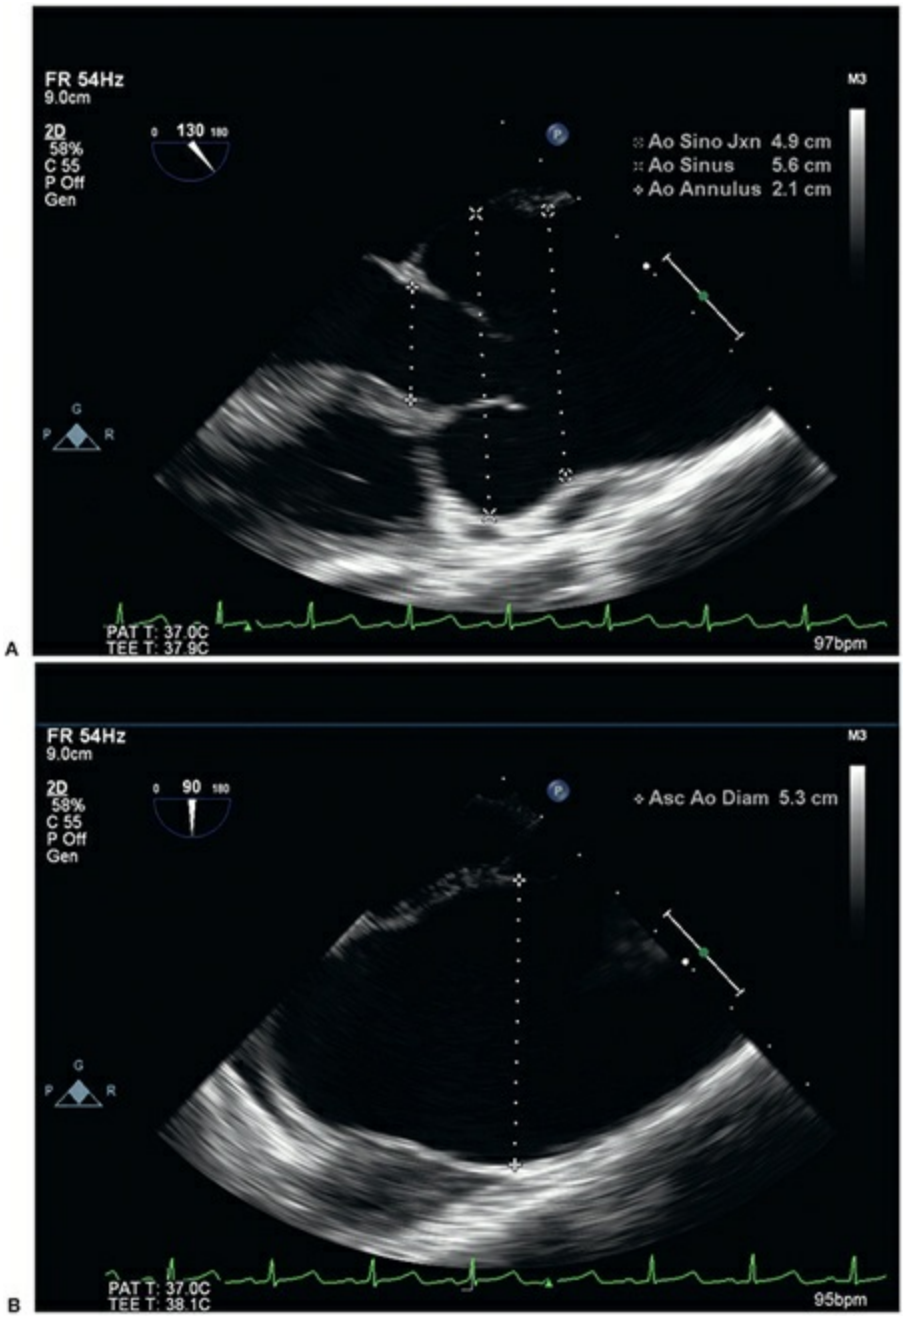

FIGURE 9.3. **A.** Midesophageal AV long-axis view on TEE demonstrating AV annulus, sinus, and sinotubular junction dimensions at mid-systole. **B.** Ascending aorta in short axis demonstrating aneurysmal enlargement with a diameter of 5.3 cm in a young woman with Turner syndrome.

Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. A report of the American College of Cardiology Foundation/American Heart Association

Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *J Am Coll Cardiol*. 2010;55(14):e27–e129.

A.2. How are TAAs and TAAAs classified?

TAAs do not follow a specific classification system but are described by the extent of the aorta that is involved, including the aortic root, ascending aorta, aortic arch, and descending thoracic aorta. TAAAs are described using the modified Crawford classification, which subdivides TAAAs into five types according to the extent of the surgical repair required (**Fig. 9.4**).

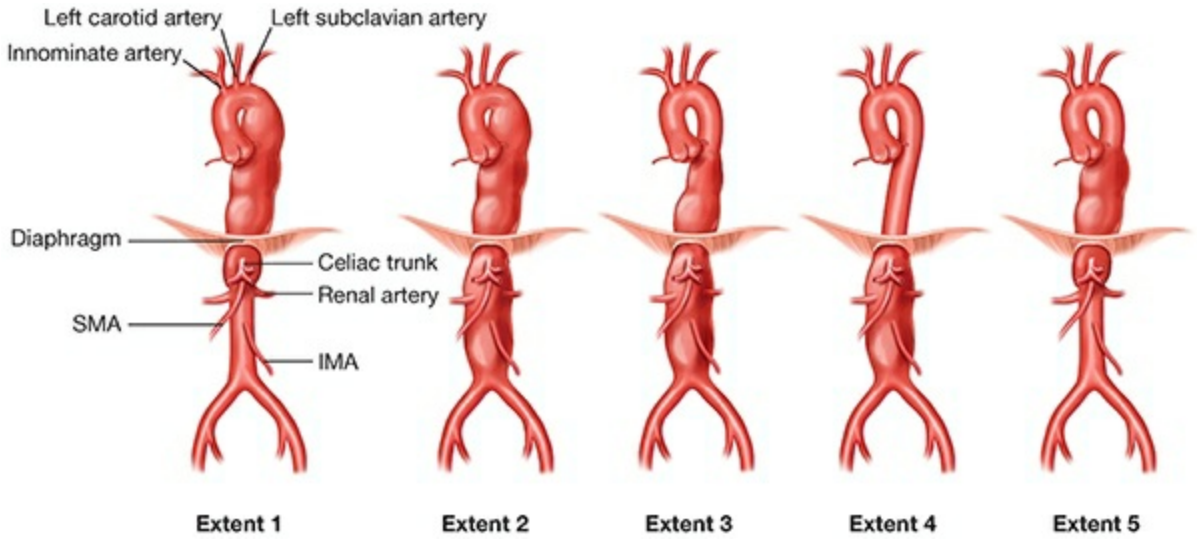

FIGURE 9.4. The modified Crawford classification of TAAAs. (*Reprinted with permission from Bolman R, Kaneko T. Open thoracoabdominal aneurysm repair. In: Darling RC, Ozaki CK, eds.* Vascular Surgery: Arterial Procedures. *Philadelphia, PA: Wolters Kluwer; 2016:74.*)

- *Type I* begins distal to the left subclavian artery and extends down below the diaphragm to above the renal arteries.
- *Type II* begins distal to the left subclavian above the sixth intercostal space. It extends through the diaphragm and ends below the renal arteries.
- *Type III* begins below the sixth intercostal space but above

the diaphragm. It extends below the renal arteries.

- *Type IV* begins below the diaphragm but above the renal arteries, with extension to below the renal arteries.
- *Type V* begins above the diaphragm and ends above the renal arteries.

Hoel AW. Aneurysmal disease: thoracic aorta. *Surg Clin North Am*. 2013;93:893–910.

A.3. What is the pathogenesis of aortic aneurysms and what genetic conditions predispose to their formation?

TAAs primarily arise from focal degeneration of the elastic and muscular tissue of the aortic wall. The resulting tissue weakness predisposes the wall to dilate under the stress of high pressures within the aorta. The dilation of the aorta is associated with decreased vessel wall compliance, increased wall stress, and a propensity for subsequent rupture of the aneurysm. Although the majority of TAAs follow a degenerative pattern, there are a number of congenital disease processes that are associated with aneurysm formation.

Marfan syndrome (MFS) is an autosomal dominant disorder caused by a mutation in the fibrillin-1 gene. Patients with MFS have characteristic overgrowth of the long bones of the arms and legs, increased finger length (arachnodactyly), and joint laxity. They can also demonstrate ocular abnormalities, most commonly lens dislocation. In addition to the musculoskeletal and ocular manifestations of MFS, patients are also at increased risk of aortic root dilation, ascending and descending aortic

aneurysms, and aortic dissection. Valvular disease can also be present, with mitral regurgitation and associated pulmonary hypertension being the most common cause of MFS-related infant mortality. On a molecular level, mutations in the fibrillin-1 gene result in disordered formation of the microfibril matrix, leading to disruption of the elasticity of the aorta. More recent evidence suggests that excessive transforming growth factor β (TGF-β) signaling also plays a role in the clinical phenotype of MFS.

Vascular Ehlers-Danlos syndrome (vEDS) is the result of mutation in the COL3A1 gene coding for type III procollagen. Mutations in type III procollagen can result in a number of complications, including spontaneous intestinal or uterine rupture, fragile skin, and vascular dissection. Children may also present with inguinal hernias, pneumothoraces, or recurrent joint dislocations. Although diagnosis is often made clinically, many patients are only diagnosed after a major arterial or gastrointestinal event.

Loeys-Dietz syndrome (LDS) is a heterogeneous disease stemming from mutations in either the TGFBR1 or TGFBR2 gene, resulting in a relative increase in TGF-β signaling. LDS presents with characteristic craniofacial, skeletal, and cardiovascular anomalies with a broad range of phenotype. Because patients with milder disease exhibit limited skeletal features and no typical ophthalmologic manifestations of the disease, the diagnosis is often made within a family after a significant aortic event. These patients are also at risk for complicated cerebral aneurysms, and imaging of all major arterial structures is recommended after diagnosis.

Turner syndrome is a genetic disorder characterized by the lack of an X-chromosome in a female patient (45, X). Women with Turner syndrome are often short in stature, have dysfunctional ovaries, and are at increased risk of cardiovascular

disease. Bicuspid aortic valve (AV) disease is present in between 10% and 25% of women with Turner syndrome, and approximately 8% have coarctation of the aorta. The risk of AAD is also increased in women with Turner syndrome and tends to occur at a younger age and smaller aortic diameter than the general population.

Less common genetic etiologies of thoracic and thoracoabdominal aortic disease include mutations in the MYH11, ACTA2, MYLK, SLC2A10, or SMAD3 gene. Despite progress in discerning the genetic mechanisms of familial TAAs, up to 80% are without a clear molecular etiology.

There are a number of rheumatologic diseases that may affect the thoracic aorta. Takayasu arteritis, giant cell arteritis, Behçet disease, and ankylosing spondylitis have all been demonstrated to contribute to the development of aneurysmal dilation of the aorta with varying degrees of frequency.

Patients may also develop aneurysms with an infectious etiology, although this is rare. There are several mechanisms by which this can occur, including direct spread from adjacent structures, septic embolic events from bacterial endocarditis, and hematogenous seeding of the aorta from bacteremia. Although most infections are caused by bacteria, immunosuppressed patients are also susceptible to fungal and mycobacterial infection. Interestingly, HIV infection also appears to be associated with an increased risk of TAA formation.

Finally, patients with a *bicuspid AV* have a markedly increased risk of TAA formation. Aortic dilation in bicuspid AV disease most commonly involves enlargement of the ascending aorta in addition to dilation of the aortic root (**Fig. 9.5**). Risk factors for aneurysm development include older age, male sex, systolic hypertension, valve stenosis or regurgitation, and the specific morphology of the valve itself. Although a specific unifying gene remains elusive, bicuspid aortic disease

demonstrates familial inheritance.

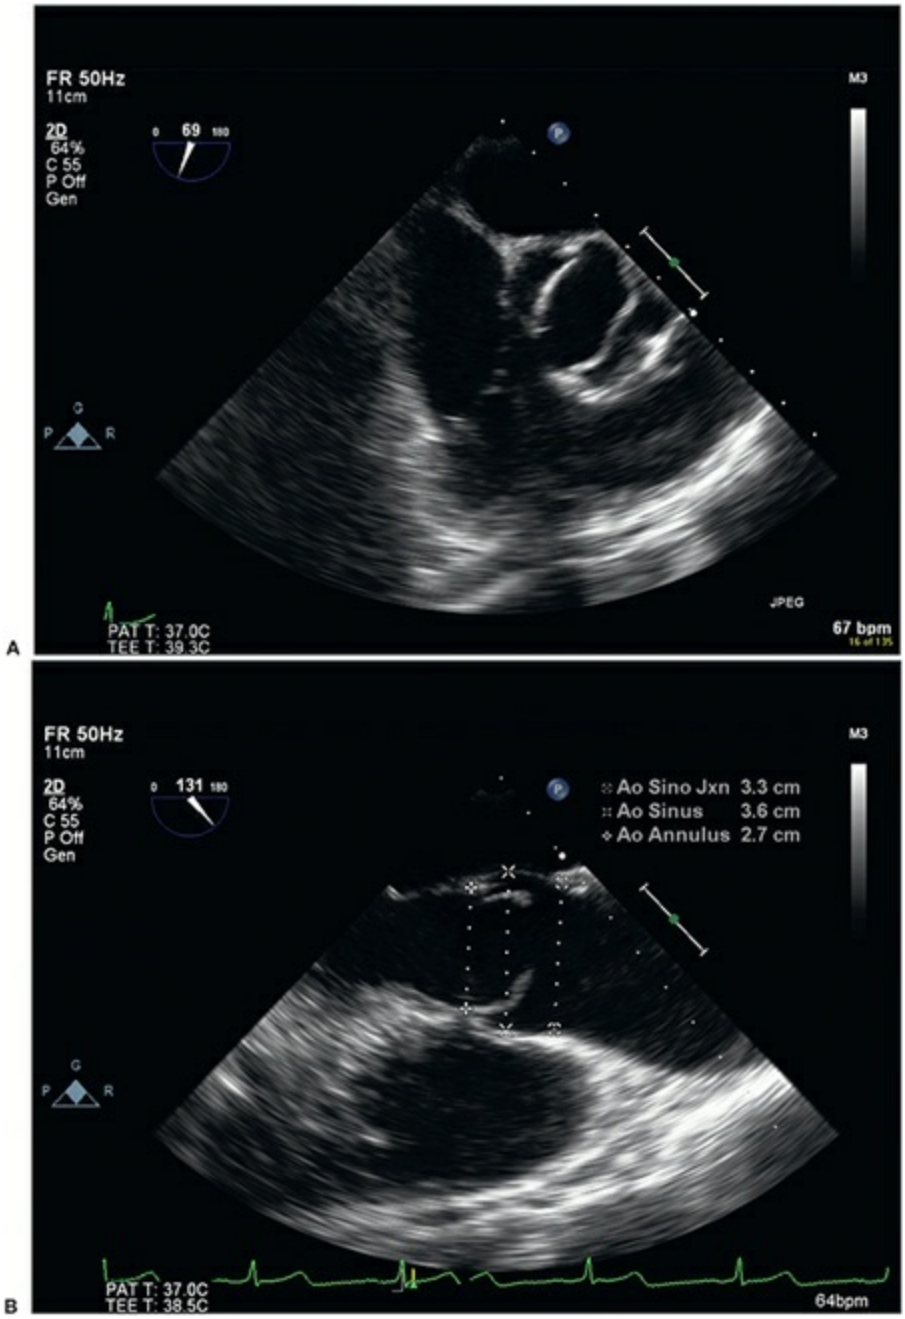

FIGURE 9.5. **A.** Midesophageal AV short-axis view on TEE showing a bicuspid valve, with fusion of the left and right coronary cusps. **B.** Midesophageal AV long-axis view on TEE demonstrating the characteristic doming of a stenotic bicuspid AV and blunting of the sinotubular junction due to aortic root (ascending aortic) dilatation.

A.4. What are the risk factors for TAA rupture?

The size of a TAA is the most important predictor of rupture (**Table 9.1**). For every 1 cm increase in aneurysm diameter, the risk of rupture roughly doubles. The "hinge point" at which the risk of rupture increases dramatically is approximately 6 cm in diameter for ascending aneurysms and 7 cm for descending aneurysms, although 31% and 43%, respectively, of patients will have experienced rupture or dissection by the time they reach this point. Patients with COPD, advanced age, and symptomatic aneurysms appear to have an increased risk of rupture. Although women tend to develop TAAs later in life, they appear to also have an increased risk of aneurysm rupture relative to their male counterparts.

A.5. What is the natural history and medical management of thoracic aneurysms?

The location and etiology of thoracic and thoracoabdominal aneurysms determines their rate of growth and subsequent propensity for rupture. Ascending TAAs typically grow at a rate of 0.1 cm per year, whereas descending aneurysms grow slightly faster at 0.3 cm per year. The rate of growth is greater in patients with larger aneurysms, dissected aortas, and certain familial causes of TAA. The aortic size is a strong predictor of the risk of complications, with a marked increase in risk profile as the aneurysm increases to greater than 6 cm.

Medical therapy to slow aneurysm growth or to reduce the risk of dissection or rupture has only been modestly successful thus far. Initial therapy consists of lifestyle modifications including smoking cessation and minimization of heavy lifting to avoid significant spikes in systolic blood pressure, which may precipitate rupture or aortic dissection.

Despite a relative paucity of clinical evidence, β-blocker therapy is often prescribed with the goal of reducing the rate of aortic dilatation by decreasing left ventricular contractility and subsequently decreasing shear stress. Although this has been demonstrated to be beneficial in patients with MFS, evidence for its use in the broader population of patients with TAAs is still lacking.

Statins have also recently been shown to be beneficial in the medical management of TAAs, with patients receiving statin

therapy showing a slower rate of aneurysmal growth, a smaller percentage requiring surgery, and a decrease in the overall number of adverse events.

Angiotensin receptor blockade has shown promise in the murine model of MFS, with a small human study showing a decrease in the rate of aneurysmal growth. This data formed the basis for the ongoing MARFANSARTAN trial (study of the efficacy of losartan on aortic dilatation in patients with MFS). Current recommendations suggest aggressive blood pressure reduction with β-blockers and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers to the lowest level that patients can tolerate without adverse effects.

A.6. What is a thoracic aortic dissection, and how does it typically present?

An AAD typically develops when a tear in the intimal layer of the aorta permits blood to enter into the medial layer, creating a false lumen that may rapidly expand both proximally and distally (**Fig. 9.6**). This can cause ischemia of the brain and viscera when the vasculature supplying these organs is occluded. Proximal dissections may cause AI, cardiac ischemia from coronary artery occlusion, or accumulation of blood in the pericardium resulting in tamponade (**Fig. 9.7**). Finally, the false lumen can rupture, resulting in rapid exsanguination.

FIGURE 9.6. Midesophageal AV short-axis view on TEE demonstrating an AAD *(arrow)* that extends proximally to the AV in a young patient with MFS.

FIGURE 9.7. Transgastric midpapillary view on TEE demonstrating accumulation of blood in the posterior pericardial space *(arrow)* after AAD.

Hypertension is the most common comorbid disease in patients experiencing aortic dissection, although hyperlipidemia,

tobacco use, and cocaine use are other risk factors. Pregnancy can also increase the risk of AAD, with most women typically presenting during their third trimester or in the early postpartum period. There are several genetic conditions that increase the risk of AAD, including MFS, Ehlers-Danlos syndrome, familial aortic dissection, LDS, and annuloaortic ectasia. AAD can also occur iatrogenically during cardiac surgery, cardiac catheterization, and insertion of an intra-aortic balloon pump.

Patients typically present with the acute onset of severe chest and back pain, although this is not a universal finding. Less commonly, patients can present with abdominal pain, syncope, or symptoms of limb or visceral malperfusion. In roughly 6% of cases, the aortic dissection is painless and presents as new-onset heart failure, stroke, or syncope. These patients tend to be diabetic, have a history of aortic aneurysm, or have a history of prior cardiac surgery. Hypertension is common on initial presentation, and the diastolic murmur of AI is present in 44% of patients with a type A dissection. Hypotension is an ominous sign and portends a poor clinical prognosis.

It is important to differentiate AAD from acute coronary syndrome (ACS) because they may have similar presentations. Symptomatically, patients with AAD typically present with acute, severe chest pain, whereas patients with ACS typically have pain that is more gradual in onset. This differentiation is important because the treatment of ACS (antiplatelet agents, anticoagulation, and occasionally thrombolytics) is potentially catastrophic in patients with an aortic dissection. AAD should be in the differential diagnosis for any patient presenting with syncope; new-onset chest, abdominal, or back pain; acute heart failure; or clinical evidence of malperfusion. The diagnosis is most commonly made via spiral CT scan or TEE, although aortography and MRI may also be used.

A.7. How are thoracic aortic dissections classified?

There are several systems used to classify aortic dissections that focus on anatomic or clinical factors noted on presentation (**Fig. 9.8**).

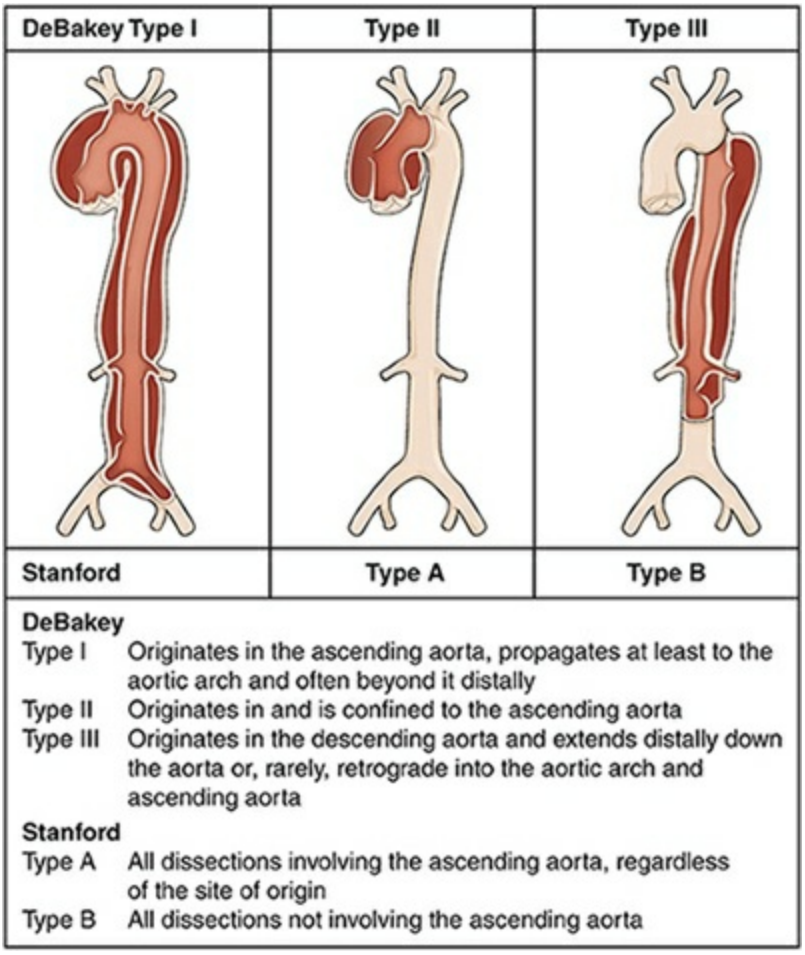

FIGURE 9.8. The Stanford and DeBakey classifications of aortic dissections. (*Reprinted with permission from Nienaber CA, Eagle KA. Aortic dissection: new frontiers in diagnosis and management: part I: from etiology to diagnostic strategies.* Circulation. *2003;108:628–635.*)

DeBakey Classification

The DeBakey classification system categorizes aortic dissections

based on their site of origin and degree of distal extension.

Type I dissection originates in the ascending aorta and propagates to at least the level of the aortic arch and often beyond, sometimes extending as distal as the iliac arteries.

Type II dissection begins in, and is limited to, the ascending aorta. Although these occur on occasion in patients with MFS, they are the rarest form of aortic dissection. Type I and type II dissections are almost always treated surgically.

Type IIIa dissection begins beyond the origin of the left subclavian artery and is limited to the descending thoracic aorta.

Type IIIb dissection begins beyond the left subclavian origin and extends more distally beyond the diaphragm. Type III dissections are often managed medically.

Stanford Classification

The Stanford classification system is similar to the DeBakey system in that it describes aortic dissections based on their anatomic site of origin.

Stanford type A aortic dissections originate in the ascending aorta and include DeBakey type I and type II dissections.

Stanford type B aortic dissections originate in the descending aorta and include DeBakey type IIIa and IIIb dissections. These may occasionally also propagate proximally into the ascending aorta or aortic arch.

A notable limitation to both the Stanford and DeBakey classification systems is their inability to classify dissections originating in the aortic arch.

Penn Classification

More recently, patients with acute Stanford TAAD have been subcategorized according to ischemic symptoms noted on presentation in what has been termed the Penn classification. This has been successfully validated as a predictor of perioperative mortality.

Penn Class Aa patients have no ischemic symptoms on presentation. This is the most common clinical finding in TAAD, encompassing approximately 60% of all patients. It is also associated with the best clinical outcome with a 30-day mortality of 3% and a 5-year cumulative survival approaching 85% in one cohort.

Penn Class Ab patients present with branch vessel malocclusion producing clinically significant organ ischemia. This includes patients presenting with stroke, paraplegia, renal dysfunction, mesenteric malperfusion, and occlusion of vascular supply to the extremities.

Penn Class Ac patients present with circulatory collapse with or without cardiac involvement. Class Ab and Ac patients have similar perioperative and long-term survival profiles.

Penn Class Abc patients present with symptoms of both local and generalized ischemia. These patients have the worst prognosis with a 30-day perioperative mortality of 40%. Most deaths are secondary to multisystem organ failure, hemorrhage, cardiac failure, or central nervous system (CNS) dysfunction.

B. Preoperative Evaluation and Preparation

B.1. What are the indications and timing of surgical intervention for TAAs?

Patients diagnosed with aneurysms of the thoracic aorta require frequent surveillance to assess for aneurysmal expansion. The goal is to facilitate surgical intervention prior to the onset of aortic dissection or aneurysm rupture. Important considerations include the appropriate interval for surveillance imaging and the diameter at which surgical intervention should be recommended.

Patients diagnosed with TAAs and TAAAs should undergo initial CT or MRI to define the size and extent of the aneurysm. Follow-up surveillance imaging is typically performed 6 months after diagnosis, with continued follow-up imaging at an interval determined by the rate of growth. These aneurysms tend to grow slowly, with arch and ascending aneurysms growing 0.1 cm per year and descending aneurysms growing 0.3 cm per year.

Determining when to intervene depends on the underlying pathology, size, rate of expansion, and presence or absence of symptoms (**Table 9.2**). In patients without known connective tissue disease, surgical repair is recommended at 5.5 cm in ascending aortic aneurysms and 6.5 cm in descending aneurysms. In patients with concomitant AV disease who are scheduled to undergo AV replacement, an aneurysm should be repaired if it is greater than 4.5 cm in diameter. Patients with symptomatic aneurysms of any size should be considered for

surgical intervention. Very large and very small patients may be better managed by indexing aortic diameter to body size to determine the appropriate timing of repair.

TABLE 9.2 Guidelines for Elective Intervention in Patients with Ascending or Descending Thoracic Aortic Aneurysms

Normal aorta	5.5 cm for ascending aneurysms 6.5 cm for descending aneurysms
Normal aorta + valvular indication	4.5 cm
Marfan syndrome	5.0 cm for ascending aneurysms 6.0 cm for descending aneurysms
Marfan syndrome + pregnancy	4.0 cm
Loeys-Dietz syndrome	4.2 cm as measured by TEE 4.4–4.6 cm as measured by CT scan

CT, computed tomography; TEE, transesophageal echocardiography.

Special recommendations exist for patients with underlying connective tissue disorders because these patients tend to suffer significant aortic events at smaller aortic diameters. Patients with MFS require frequent surveillance, with CT imaging 6 months after initial diagnosis and then annually if aortic diameter is stable. More frequent imaging may be recommended with larger aneurysms (>4.5 cm) or if significant growth is noted. Earlier repair is recommended in MFS, and patients with ascending aneurysms of greater than 5 cm in diameter or descending aneurysms of greater than 6 cm in diameter should be considered for surgical intervention. MFS patients with a family history of early aortic dissection at less than 5 cm are often referred for early correction. Finally, women with MFS considering pregnancy should be counseled for elective aortic aneurysm surgery if the aorta is greater than 4 cm in diameter. After surgery on an ascending aortic aneurysm, continued surveillance with CT imaging is necessary to evaluate for the development of aneurysms of the arch and descending aorta.

Patients with LDS also represent a population requiring early

repair. Surveillance imaging is similar to patients with MFS, but operative repair is recommended earlier in the disease process. Patients with aneurysms that demonstrate an internal diameter of 4.2 cm on TEE or an external diameter of 4.4 to 4.6 cm on CT are referred for surgical intervention. Similarly, patients with a bicuspid AV with an accompanying TAA are typically repaired at 5 cm, although patients with a valvular indication for surgery are typically repaired if the aortic diameter exceeds 4.5 cm. First-degree relatives of patients with a suspected familial TAA syndrome should be screened with CT imaging at 5-year intervals.

Once the decision is made to proceed with surgery, there are several decision points that dictate the course of the operation. These include the decision to employ hypothermic circulatory arrest (HCA) or cardiopulmonary bypass (CPB) and whether to utilize an open or endovascular approach. If an endovascular approach is utilized, some patients may require additional aortic debranching procedures prior to endograft placement, depending on the extent of the aneurysm.

Overall, surgical decision making in patients with TAAs, thoracoabdominal aneurysms, and combined aneurysmal and AV disease require a careful comparison of a patient's operative risk with his or her risk of a significant aortic event. Consideration of medical comorbidities and the underlying pathology adds additional nuance to the decision of whether to undertake a surgical repair, and when that repair is recommended, what surgical technique should be utilized.

B.2. Which patients are candidates for endovascular aortic repair, and what are the advantages to this approach?

Thoracic endovascular aortic repair (TEVAR) is a commonly used alternative to open repair. It is less invasive, and evidence suggests it is associated with lower rates of perioperative respiratory, renal, and neurologic complications, which facilitates shorter intensive care unit (ICU) and hospital stays with similar long-term outcomes. In recent years, aortic stent grafting has undergone a significant liberalization in its use for many aortic pathologies. In addition to repair of TAAs, many centers are now treating complicated type B aortic dissections (TBADs), traumatic aortic injuries, intramural hematomas, and penetrating aortic ulcers via the endovascular approach.

Determination of whether to undertake open or endovascular approach is dependent on multiple factors, including patient age, comorbidities, life expectancy, aneurysm morphology and diameter, the presence of "landing zones" of normal aorta on either side of the aneurysm, and the experience of the operating surgeon. Relative contraindications to TEVAR include mycotic aneurysms, aneurysms secondary to connective tissue disease (MFS, Ehlers-Danlos, etc.), and aneurysms extending proximal to the left subclavian artery. Connective tissue disease presents a relative contraindication due to concern for the longevity of the

endovascular repair in this patient population.

Many patients with extensive visceral involvement or multiple comorbidities now undergo "hybrid" procedures, which consist of debranching of the visceral arterial supply followed by endovascular repair of the aneurysm. Advantages of this approach include decreased visceral ischemic time, avoidance of aortic cross-clamping, and avoidance of the need for thoracotomy that accompanies an open repair.

B.3. What are the preoperative considerations for the anesthesiologist before TAA repair?

Surgery for TAA repair involves the potential for significant morbidity and mortality. A thorough preoperative workup is important to define the patient's risk of postoperative complications and to facilitate a coordinated anesthetic and surgical plan that provides the greatest likelihood of a good clinical outcome. Particular attention should be given to the patient's cardiac, respiratory, renal, and neurologic function because threats to these systems present the greatest risk to increase morbidity and mortality. Although thoracic and thoracoabdominal aneurysm repairs represent high-risk surgical procedures at baseline, patients presenting for urgent or

emergent intervention are at the greatest risk of postoperative complications. Unfortunately, these patients may also be clinically unstable and thorough preoperative workup may not be feasible.

Cardiovascular

Detailed evaluation of the patient's cardiovascular system is essential prior to undertaking complex aortic repair. Major fluid shifts, aortic cross-clamping, and the physiologic stress of intraoperative and postoperative blood loss represent a significant threat to the cardiovascular system. Major thoracic aortic surgery falls into the highest risk group for perioperative cardiac morbidity. Up to two-thirds of patients demonstrate diastolic dysfunction with aortic cross-clamping, and 30% of patients manifest some degree of cardiac dysfunction postoperatively. Hypertension is a common comorbidity, and elderly patients may also have coexisting coronary artery disease (CAD). Evidence of congestive heart failure may also be present as a result of progressive AI due to aneurysm enlargement.

Cardiac workup should at least include an electrocardiogram (ECG) and a TTE, although stress testing and/or coronary angiography are routinely performed at many centers. Patients who are found to have unstable CAD, left main stenosis, or three-vessel disease are typically revascularized prior to or during the repair of the aneurysm. There is debate whether or not to perform percutaneous coronary intervention (PCI) on less complex lesions because the antiplatelet therapy that accompanies PCI may complicate surgical hemostasis. Occasionally, aneurysmal expansion can result in ischemia from compression of the coronary arteries. Patients taking antihypertensive and antianginal drugs should continue these until the time of surgery, and titrated preoperative anxiolysis medication is important to prevent stress-induced hypertension

and tachycardia, which could precipitate aneurysm rupture. Therapeutic anticoagulation or antiplatelet agents should be discontinued or bridged with short-acting alternatives prior to surgical intervention.

Respiratory

The respiratory system also deserves special attention in the preoperative evaluation of patients undergoing thoracic aneurysm repair. Perioperative respiratory failure is the most common serious complication of thoracic and thoracoabdominal aneurysm repair, and patients with a history of smoking or COPD are at especially high risk. Pulmonary function should be evaluated preoperatively because one-lung ventilation (OLV) is important for open surgical repair of Crawford type I, II, III, and V aneurysms. Patients with very poor pulmonary reserve may require CPB because of an inability to tolerate OLV. Preoperative smoking cessation should be encouraged.

In addition to the evaluation of pulmonary mechanics, history should include consideration of positional dyspnea or stridor, which may indicate aneurysmal compression of the trachea or, more commonly, the left mainstem bronchus. Review of the CT or MRI is important to determine whether significant bronchial compression is present because this may complicate airway management and double-lumen endotracheal tube placement. Finally, patients with significant preoperative respiratory dysfunction should be counseled about the possible need for prolonged postoperative mechanical ventilation, including tracheostomy placement.

Renal

Many patients also have baseline renal insufficiency, which places them at risk for subsequent postoperative renal failure. Up to 25% of patients undergoing TAAA repair develop some degree of postoperative renal insufficiency, with 8% of patients

requiring hemodialysis. Although evidence for preoperative hydration is minimal, at many centers, it is common practice to admit patient the night before surgery for intravenous (IV) hydration.

Neurologic

Finally, the neurologic system deserves special consideration given the risk to both the brain and spinal cord during aneurysm repair. In an effort to minimize stroke risk, carotid and brachiocephalic angiography are often performed preoperatively, especially in patients with a prior history of stroke or transient ischemic attack. Patients should also be counseled about the risk of possible postoperative paralysis from spinal cord ischemia. Although the risk was historically much higher, the current incidence of postoperative spinal cord injury is between 2% and 6%, depending on the anatomy of the aneurysm. Onset can either be immediate or delayed. Risk factors for postoperative paralysis include preoperative renal dysfunction, Crawford type II aneurysm repair, and AAD. Preoperative identification and preservation of the artery of Adamkiewicz decreases the risk of paraplegia from 50% to roughly 5%.

In summary, preoperative assessment prior to thoracic aneurysm repair is important for both anesthetic and surgical planning. Although aortic surgery represents a high-risk procedure, evaluation of clinical risk factors, multisystem assessment, thoughtful preoperative testing, and, when appropriate, referral to subspecialists for medical optimization can improve perioperative outcome.

B.4. What is the preoperative management of a patient presenting with an acute aortic dissection (AAD)?

Patients presenting with an AAD will either be admitted to the ICU or progress immediately from the emergency department to the operating room. Invasive monitoring of blood pressure in both arms, large-bore IV access, and aggressive control of blood pressure and heart rate are priorities.

Blood pressure reduction is typically accomplished with β-blockers and vasodilators aiming to reduce myocardial contractility and minimize further extension of the dissection. The goal systolic blood pressure and heart rate are 100 to 120 mmHg and less than 60 beats per minute, respectively. If heart rate and blood pressure control remain inadequate after initializing β-blocker and vasodilator therapy, calcium channel blockers may be an additional adjunct. Hydralazine is typically not used because it may precipitate a reflex tachycardia, which can worsen the dissection. Conversely, patients who are hypotensive on presentation should be treated aggressively with vasopressors and fluid resuscitation in an effort to maintain end-organ perfusion until the patient can undergo definitive operative repair.

A Stanford TAAD is typically treated as a surgical emergency because it is a highly lethal condition with a mortality of 1% to

2% per hour after onset. After 24 hours, 20% of patients will die without surgical intervention. Conversely, patients with a Stanford TBAD that is not complicated by limb ischemia, malperfusion, or rupture may be managed medically with aggressive blood pressure and heart rate reduction.

B.5. What is the spinal cord blood supply?

The spinal cord blood supply consists of both longitudinal and segmental components (**Fig. 9.9**). The longitudinal arteries include the anterior and paired posterior spinal arteries. The anterior spinal artery (ASA) arises from paired feeding vessels that originate in the vertebral arteries near the foramen magnum. It extends the length of the spinal cord and is situated in the anterior spinal sulcus. The ASA is fed by a series of radicular arteries, and the areas between these radicular contributions are watershed areas that are at the greatest risk of ischemia. The most significant of these radicular arteries is the artery of Adamkiewicz. It is a large radicular contribution that most commonly arises between T8 and L2, although it can originate as high as T5 and as low as L4. The artery of Adamkiewicz is critical to the maintenance of adequate collateral blood supply to the lower two-thirds of the spinal cord. The ASA supplies the anterior two-thirds of the spinal cord, including the corticospinal and spinothalamic tracts and is dependent on a robust collateral circulation, making it particularly susceptible to ischemic injury.

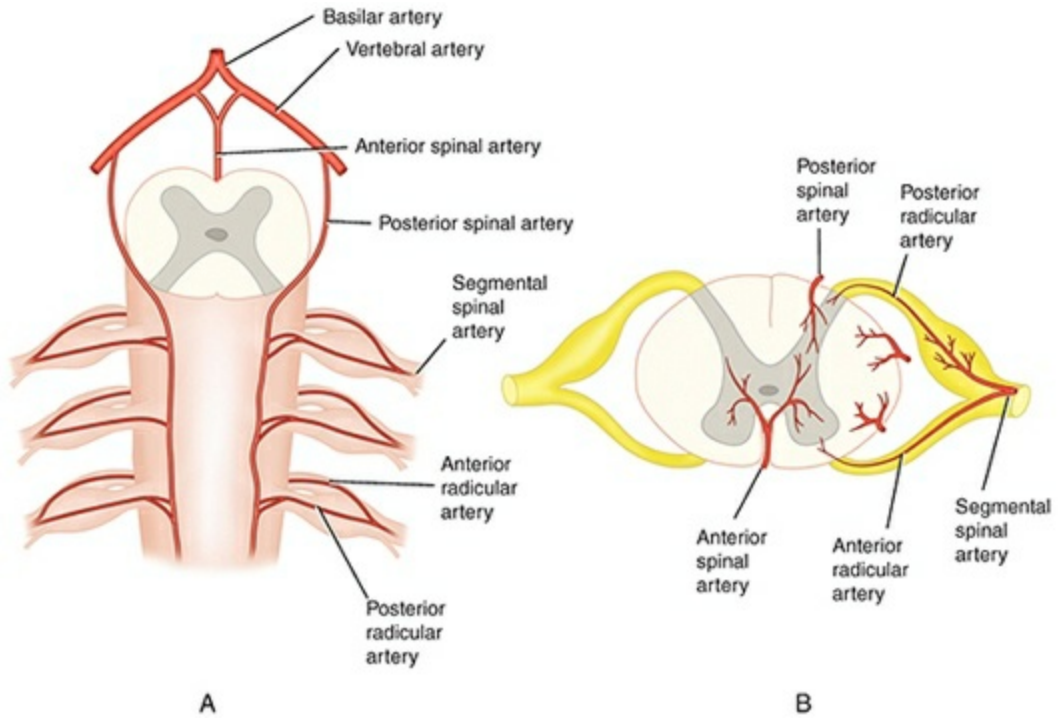

FIGURE 9.9. Spinal cord blood supply. (*Reprinted with permission from Splittgerber R. Blood supply of the brain and spinal cord. In:* Snell's Clinical Neuroanatomy. *8th ed. Philadelphia, PA: Wolters Kluwer; 2018:471.*)

There are two paired posterior spinal arteries that originate as branches of either the vertebral or posterior inferior cerebellar arteries and descend along the posterolateral portion of the spinal cord. The posterior spinal arteries are also fed by numerous radicular arteries. The anterior and posterior spinal arteries are connected to each other via a circular anastomosis known as the vasocorona medullaris.

In addition to the longitudinal arteries, there are multiple segmental branches that arise from the posterior portion of the aorta. These include the intercostal, subcostal, and lumbar segmental arteries. These arteries travel posteriorly and branch to supply the vertebral bodies, muscle and cutaneous structures, and spinal cord. The spinal division enters through the intervertebral foramen and subdivides to supply either the vertebral and ligamentous structures or the nerve roots and dura. At some levels, the arteries supplying the nerve roots and dura

also supply the spinal cord. These vessels are termed radiculomedullary arteries and play an important role in supplying accessory flow to both the anterior and posterior spinal arteries.

C. Intraoperative Management

C.1. What are the surgical approaches to thoracic aneurysm repair?

Ascending and Arch Aortic Aneurysms

Proximal ascending aneurysms not only cause aortic rupture and dissection but also alter the three-dimensional conformation of the aortic root and AV complex, leading to AI (**Fig. 9.1**). The extent of involvement of the aortic root determines the surgical procedure necessary for repair (**Table 9.3**). When the AV and aortic root are not diseased, a graft can be implanted above the sinuses of Valsalva, called a supracoronary tube graft. The Wheat procedure is performed when the AV and proximal aorta are diseased, without dilation of the aortic root. It involves a supracoronary graft and an AV replacement but spares the sinuses of Valsalva, making coronary artery reimplantation unnecessary.

TABLE 9.3 Types of Thoracic Ascending Aorta Aneurysm Repairs

Aortic Valve	Root	Ascending Aorta	Surgical Approach	Name of Procedure
Normal	Normal	Aneurysmal	Supracoronary tube graft	
Diseased	Normal	Aneurysmal	AVR + supracoronary tube	Wheat procedure

			graft	
Diseased	Aneurysmal	Aneurysmal	AVR + replacement of aortic root and reimplantation or coronary arteries	Bentall
Normal	Aneurysmal	Aneurysmal	Valve-sparing root replacement	David procedure

AVR, aortic valve replacement.

The Bentall procedure is performed when the aortic root and AV are involved in the aneurysm. The Bentall procedure involves replacement of the AV, replacement of the aortic root, and reimplantation of the coronary buttons onto the neoaorta. Modifications of the Bentall procedure have focused on resuspending the AV to the neoaorta in patients with normal AV leaflets but poor coaptation due to the dilated aortic root. Resuspension of the AV to the neoaorta can decrease AI without requiring AV replacement. This is referred to as the David procedure.

Sixty percent of aortic arch aneurysms are located in the proximal arch and involve the distal ascending aorta. Surgical options for aortic arch aneurysms include hemiarch replacement or total arch replacement with or without a distal elephant trunk. A hemiarch replacement is performed in patients whose aneurysm does not extend to the proximal descending aorta. In patients whose aneurysm extends to the proximal descending aorta, either a total arch replacement with reimplantation of the great vessels separately or as a button can be performed (**Fig. 9.10**), or the elephant trunk procedure can be performed. The elephant trunk procedure includes an aortic arch graft and reimplantation of the great vessels to the prosthetic graft, in addition to a distal 5- to 7-cm “trunk” that dangles in the proximal descending aorta and is available for grafting for current or future descending aortic aneurysms (**Fig. 9.11**).

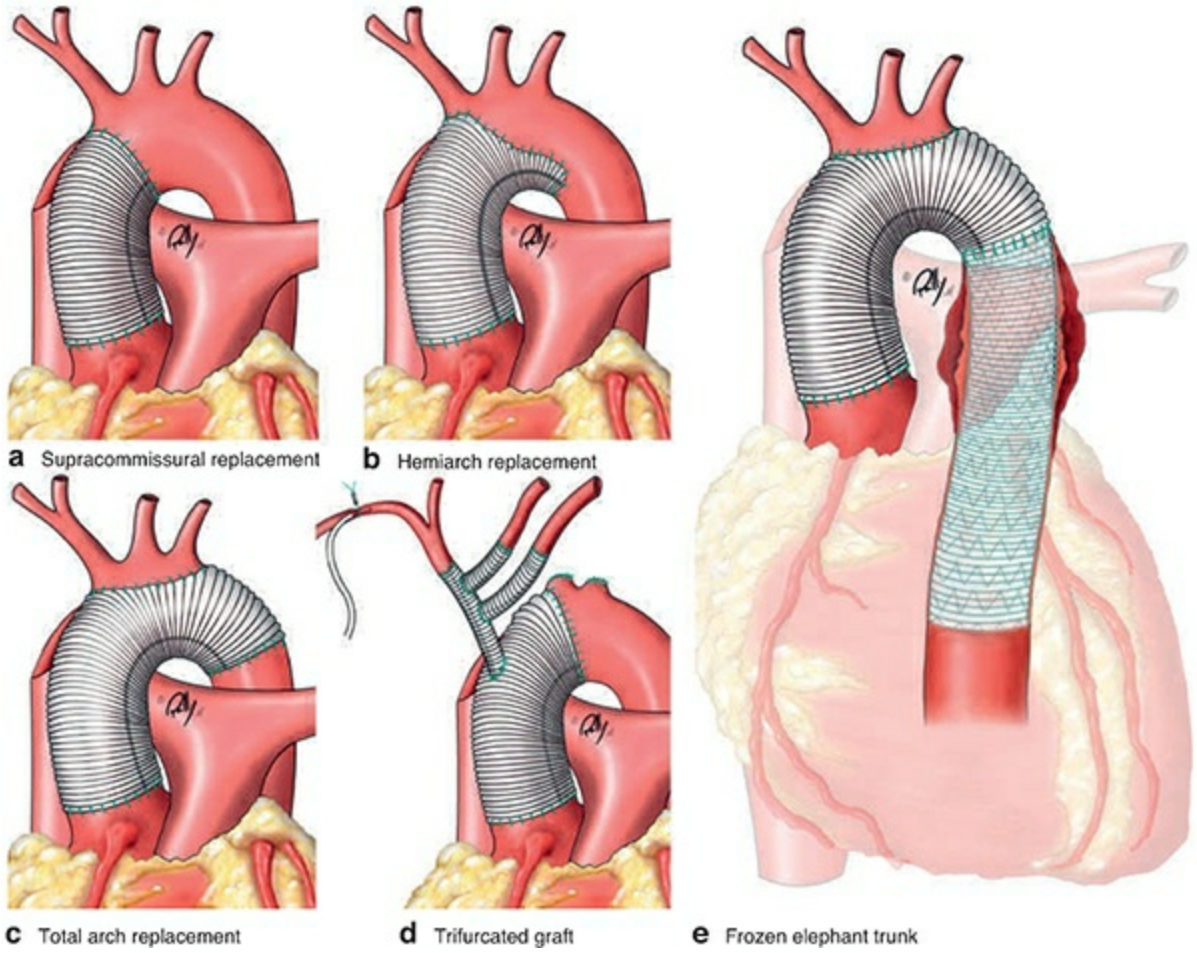

FIGURE 9.10. Surgical options for TAAs and thoracic aortic dissections. A. Supracommissural replacement of the ascending aorta. **B.** Hemiarch replacement, aortic resection is extended to the lesser curvature (inferior portion) of the aortic arch. Reimplantation of the arch branches is not necessary. **C.** Total arch replacement, the aortic arch is resected and the arch branches are reimplanted either as a button or with a composite graft. **D.** Trifurcated graft. **E.** FET procedure. Surgery for the proximal ascending aorta, including Bentall, Wheat, David, and hemiarch procedures, is performed through a median sternotomy with CPB, with or without HCA. If the procedure involves the aortic arch, HCA is necessary.

Thoracoabdominal Aneurysms

Open repair of TAAAs is the treatment of choice for appropriate surgical candidates. Open repair includes a large thoracoabdominal incision and reimplantation of branch arteries on the surrounding aorta, after resection of the diseased aorta and graft placement. Additionally, total arch replacement and elephant trunk procedures are performed by utilizing a left

thoracotomy approach with the patient in the right lateral decubitus position.

Endovascular treatment of TAAAs has become common, particularly in patients with comorbid diseases precluding them from open repair. Endovascular treatment includes deployment of a stent graft into the diseased segment of the aorta via the femoral artery (**Fig. 9.12**). For TAAAs, endovascular treatment usually incorporates visceral arteries in the repair. This is accomplished via application of branched or fenestrated aortic grafts, which allow perfusion of the major visceral arteries. The branched or fenestrated aortic grafts can be custom-made or commercially available.

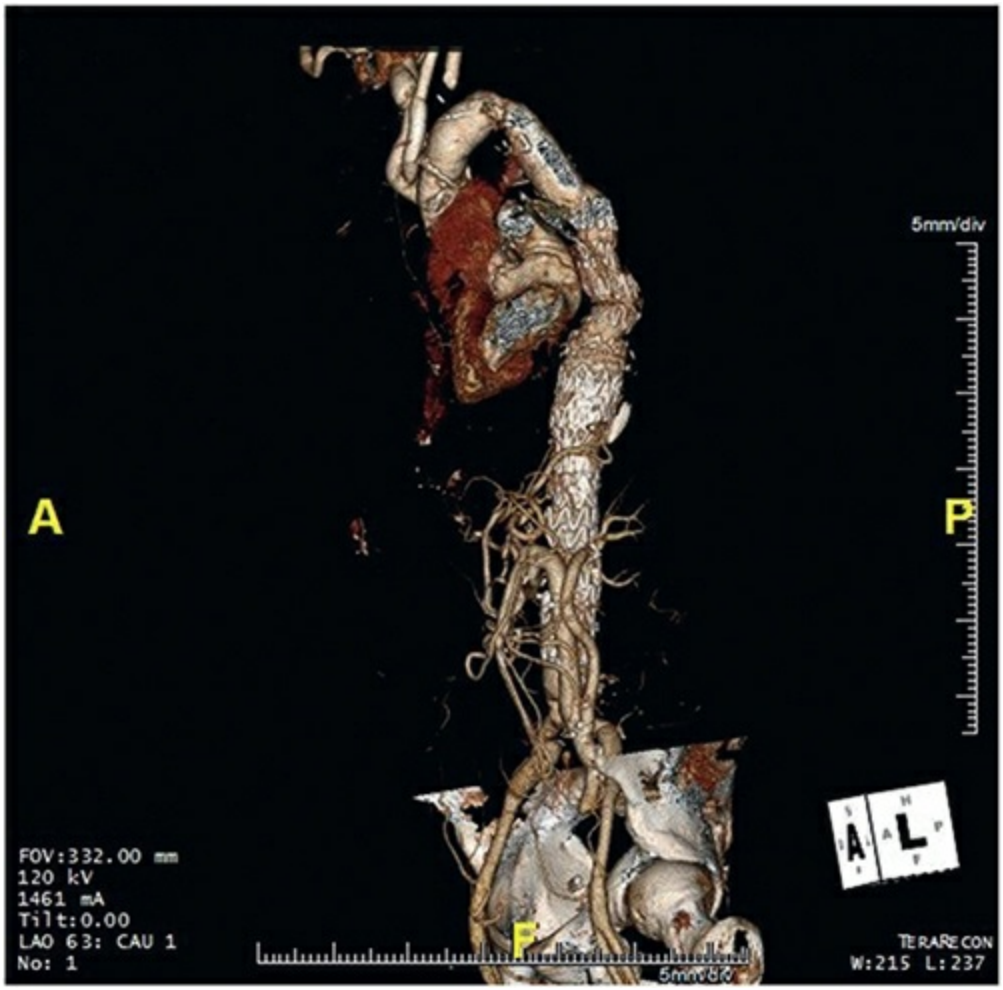

FIGURE 9.12. Three-dimensional (3D) CT reconstruction demonstrating endovascular exclusion of the descending thoracic aorta aneurysm after abdominal and arch debranching.

A hybrid procedure combines an open surgical approach with an endovascular stenting procedure to expand the anatomic suitability for deployment of stent grafts into the aorta. Hybrid procedures can either be staged or performed concurrently. In patients who have transverse aortic arch aneurysms without an adequate proximal landing zone for the stent graft, a first-stage total arch replacement is performed to create a proximal landing zone using CPB and HCA. This procedure is followed by a concomitant or second-stage endovascular repair of the distal portion of the aortic aneurysm.

Aortic visceral debranching procedures allow for endovascular stenting of TAAAs that involve the visceral arteries. Open debranching procedures can revascularize the visceral and renal arteries from the iliac arteries in a retrograde fashion or from the descending thoracic aorta above the aneurysm being treated (**Fig. 9.13**). After open debranching, the patient undergoes endovascular stent placement in the diseased segment of the aorta to exclude the aneurysm. The hybrid procedure exploits the benefit of both techniques and provides a favorable treatment option for high-risk patients. The hybrid technique avoids the need for custom-designed fenestrated or branched grafts and avoids the dangers of occluding vital visceral vessels.

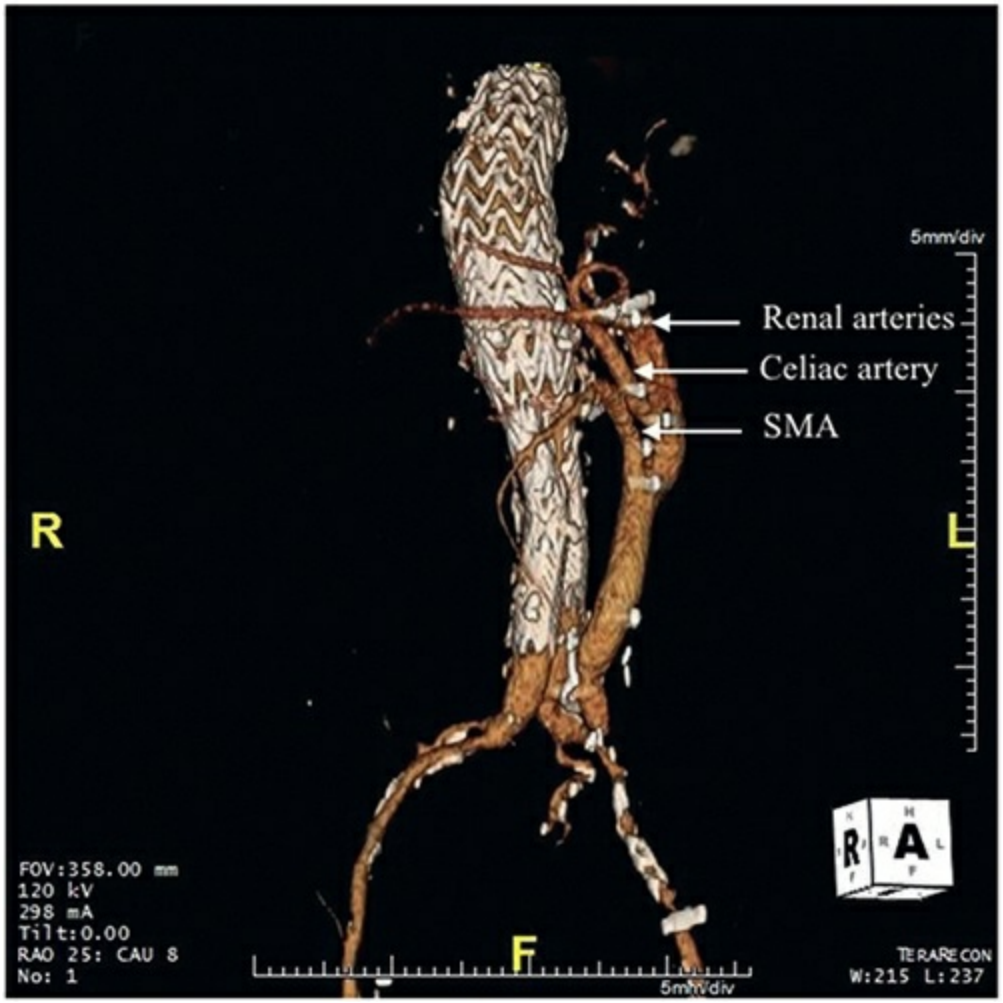

FIGURE 9.13. Three-dimensional (3D) CT reconstruction after abdominal debranching. The superior mesenteric artery (SMA), celiac artery, and renal arteries arise from a left iliac artery graft.

C.2. How is the open repair performed?

Ascending and Arch Aortic Aneurysms

Position: The surgical approach is through a median sternotomy with the patient positioned supine.

Cannulation for CPB: The CPB circuit requires a venous cannula that provides blood to the CPB pump and an arterial cannula that provides blood from the CPB pump to the patient. For aortic surgery, the arterial cannula can reside in any large artery, including the femoral, axillary, innominate, or carotid artery. Direct aortic cannulation can also be performed away from the site of the aneurysm if the anatomy allows. Arterial cannulation can be accomplished either directly or with the use of a graft anastomosis to the target artery. Direct aortic and femoral cannulations are used less frequently because they carry a risk of embolization or malperfusion in patients with aortic dissection or atherosclerosis. Commonly, the axillary or innominate arteries are used for cannulation sites because they can provide adequate arterial flow from the CPB pump during CPB and can also provide antegrade cerebral perfusion (ACP) during HCA. Cannulation of these smaller arteries is achieved with end-to-side anastomosis with a synthetic graft. The venous cannula for CPB is commonly inserted into the right atrium or femoral vein.

Hypothermic circulatory arrest: Neurologic injury remains a major cause of morbidity and mortality after open aortic arch repair. Cerebral protection depends on decreasing metabolic demand and providing metabolic supply with adequate cerebral perfusion while excluding blood flow through the great vessels. The safe limit of deep hypothermic circulatory arrest (DHCA) at 18°C is 30 minutes. Moderate HCA provides 10 to 20 minutes of safe circulatory arrest time. Regional cerebral perfusion both assists with metabolic supply and increase the safe duration of

circulatory arrest. Regional cerebral perfusion can be achieved in either an antegrade or retrograde fashion. ACP is accomplished by cannulating the axillary artery and clamping the proximal portion of the brachiocephalic artery, which provides perfusion to the right common carotid artery without disrupting the surgical site. A retrospective study of nearly 400 patients shows ACP can be either unilateral or bilateral. Commonly, a unilateral approach is performed via the right axillary artery, and DHCA with unilateral ACP of less than 50 minutes is tolerated. With bilateral ACP, DHCA can be tolerated for a longer period of time, up to 160 minutes. Retrograde cerebral perfusion (RCP) can be achieved by SVC cannulation, delivering oxygenated blood via the venous system. The SVC is clamped above the right atrium to separate this system from the venous return to the CPB pump. The proposed advantages of RCP include de-airing of arch vessels and decreased cerebral embolic events, whereas the disadvantage is a possible increase in transient postoperative neurologic dysfunction. Traditionally, the use of DHCA, with temperatures less than 20°C had been most commonly used. More recently, use of moderate (20°C to 28°C) or even mild HCA (28°C to 34°C) with antegrade or RCP has been advocated due to possible beneficial effects on transfusion rates and shortened bypass time. There is no apparent difference in the rate of renal dysfunction with DHCA and RCP compared to moderate HCA with ACP. The decision to use mild, moderate, or deep HCA with retrograde or ACP is still debated, and formal recommendations do not yet exist with respect to the superiority of techniques. Regardless of the technique, it is important that rewarming not be undertaken at too rapid a rate; sources recommend a temperature differential of no more than 10°C between perfusate and nasopharyngeal or oropharyngeal temperature to avoid cerebral hyperactivity and subsequent ischemia due to elevated oxygen consumption.

Other neuroprotective strategies are used at variable rates including topical head cooling, barbiturates, corticosteroids, mannitol, lidocaine, and nimodipine. Most providers endorse the use of some neuroprotective strategies in addition to hypothermia, but high-quality evidence supporting their use is lacking. Topical head cooling is used to assist in maintaining low temperatures during HCA as well as the prevention of rapid rewarming during emersion from DHCA. Strong human evidence to support this practice is lacking, although there are some animal studies. Concerns about this method include pressure on the eyes from the application of ice as well as interference with monitors such as electroencephalogram (EEG) and cerebral saturation probes. Barbiturates, specifically thiopental, have been used to minimize cerebral oxygen consumption by achieving electrical silence. Barbiturates also result in cerebral vasoconstriction, which may be beneficial during the rewarming period to reduce the risk of embolic phenomena. Barbiturates are also significant myocardial depressants and result in significant venous and arterial dilation, which can contribute to hypotension after the HCA period. Strong human evidence to support the use of barbiturates is lacking. Corticosteroids are frequently given (typically high doses of methylprednisolone: 500 to 1,000 mg) in hopes of attenuating the inflammatory response in the CNS. Concerns include hyperglycemia, which is known to be detrimental to patients with potential or known neurologic injury. As before, strong evidence for the use of corticosteroids is lacking. Mannitol is used by some to reduce cerebral edema and has free radical scavenging capabilities. The use of a continuous lidocaine infusion, through the induction of EEG silence has theoretical benefits but has not been definitively shown to improve neurologic outcomes in studies. Finally, nimodipine, recognized for the treatment of vasospasm, is no longer

commonly used after a study was stopped early due to worsening outcomes in the intervention group.

Thoracoabdominal Aneurysms

Position: The surgical approach is typically through the left chest, with the patient positioned in a partial right lateral decubitus position, with the shoulders at 60 degrees and the hips at 30 degrees. The patient is supported with the use of a bean bag.

Incision: A thoracoabdominal incision is the preferred approach for the majority of aneurysms. The proximal extent of the incision is dictated by the patient's body habitus and the aortic pathology. Typically, if the distal aortic arch and proximal descending aorta are to be exposed (Crawford types I and II), an incision to the 5th intercostal space is necessary. If the proximal extent of the aneurysm involves the distal thoracic aorta (Crawford types III and V), an incision to the 7th or 8th intercostal space is required. If the aneurysm is localized to the abdominal aorta (Crawford type IV), the proximal incision is made at the 9th or 10th intercostal space. The abdominal portion of the incision is typically limited to the retroperitoneum. Diaphragm preservation, defined as division only of the muscular portion of the diaphragm with preservation of the central tendinous portion, is performed to help improve postoperative respiratory mechanics.

Cannulation for left-heart bypass (LHB): Open surgical procedures on the thoracoabdominal aorta require a period of ischemia to the lower portion of the body during the period of time that the aorta is cross-clamped. This poses the risk of ischemia to the spinal cord, viscera, and kidneys during complex procedures requiring long cross-clamp times. LHB is utilized to reduce the risk of ischemia to the abdominal organs and spinal cord. LHB delivers oxygen-rich blood to the lower body and

viscera while permitting longer cross-clamp times for the surgeon to perform the repair. In LHB, the left atrium or pulmonary vein is cannulated and blood is directed to the femoral artery via a centrifugal pump (**Fig. 9.14**). Alternatively, passive axillary artery to femoral artery bypass can be used, which is dependent on the mean arterial blood pressure (MAP) proximal to the cross-clamp. In addition to the benefit of distal aortic perfusion, atrial-femoral bypass reduces preload to the left ventricle, reducing myocardial stress during cross-clamping. The use of LHB requires less systemic heparinization (100 units per kg given 5 minutes prior to cannulation) than CPB. It also minimizes ischemia to the lower extremities, thereby decreasing the acidosis that can develop after cross-clamp release. During the period of aortic cross-clamp, flow through the LHB is maintained to provide a proximal aortic pressure of 90 mmHg or distal aortic pressure of 70 mmHg.

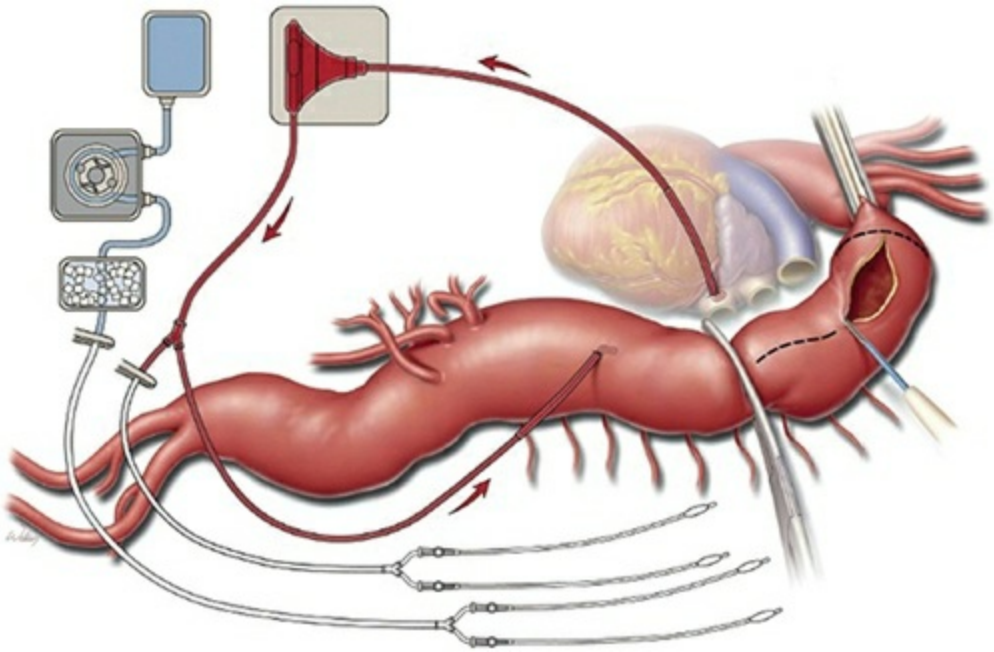

FIGURE 9.14. LHB is utilized for distal perfusion during TAAA repair. The drainage cannula is placed in the left atrium, and the outflow cannula is placed in the thoracic aorta distal to the site of aortic cross-clamping. Additional catheters are available for selective perfusion of visceral arteries with blood during operative repair. A separate line may be set up to provide cold lactated Ringer's solution through the renal arteries for renal protection. (*Used with permission from de la Cruz KI, LeMaire SA,*

Weldon SA, et al. Thoracoabdominal aortic aneurysm repair with a branched graft. Ann Cardiothorac Surg. *2012;1[3]:381–393.*)

Cannulation for CPB with or without hypothermic circulatory arrest: Similar to ascending aorta repairs, the use of CPB with HCA obviates the need for proximal aortic cross-clamping and therefore reduces the potential for spinal cord injury. Preserved end-organ function and decreased incidence of paraplegia are some of the benefits of using CPB with HCA. Typically, a venous cannula is placed via the femoral vein prior to or after right lateral positioning of the patient. Arterial cannulation can reside in the distal aortic arch, proximal descending aorta, axillary artery, or femoral artery. During circulatory arrest, antegrade or RCP may be used for neuroprotection and direct cannulation of the visceral segments with antegrade perfusion may be used for gastrointestinal protection.

Cross-clamp: The surgeon must develop an operative plan for safe aortic cross-clamping such that an adequate aortic cuff is available for proximal anastomosis and is not compromised by aortic cross-clamp placement.

Anastomoses: In type I and II repairs, the aorta is first dissected away from the esophagus to help prevent the formation of an esophageal-aortic fistula. The proximal aorta is cross-clamped, and the proximal anastomosis of the graft is sewn on to the aorta in an end-to-end fashion. Intercostal arteries in the T4–T8 region are often ligated if they exhibit excessive retrograde bleeding indicative of good collateral flow. When feasible, patent intercostal arteries from T8 to L1 are reattached to the graft. The clamp is then moved distally and reapplied above the visceral vessels. The superior mesenteric artery, renal arteries, and celiac artery are then anastomosed to the graft. Finally, the clamp is moved distally past the visceral vessels, allowing for the distal anastomosis of the graft to the descending aorta.

Clamp and sew technique: The "clamp and sew" technique involves cross-clamping the proximal aorta and replacing the aneurysmal aorta with a graft. In this technique, distal aortic perfusion with the use of LHB or HCA are not utilized. The technique poses a time limit to the surgeon as the patient's organs are not being supported during cross-clamp. This technique is typically inadequate for difficult repairs and has been largely abandoned.

C.3. How are endovascular repairs of TAAAs performed?

Position: Endovascular repair of TAAAs are performed with the patient supine for adequate access to the femoral artery.

Incision: During endovascular repair, the endograft is typically introduced via the femoral artery, although the iliac artery or infrarenal aorta may be used if the femoral artery is inadequate in size or is heavily calcified.

Deployment: Branched and fenestrated grafts are handmade for each individual case and require over a month before they can be delivered and implanted. Due to the emergent need for surgery in some patients with aortic aneurysms or dissections, commercially available endovascular grafts are often modified by the surgeon with fenestrations to accommodate the patient's anatomy.

The left subclavian artery may need to be covered by the endograft in order to achieve an adequate proximal landing zone. The proximal left subclavian artery is covered, with the distal subclavian artery gaining perfusion from collateral vessels, including the left internal mammary artery (LIMA) and vertebral artery. In some instances, occlusion is not tolerated, necessitating left carotid to subclavian bypass.

In patients with aneurysms involving the mid transverse arch, aortic arch debranching with reimplantation to the ascending aorta may be performed (**Fig. 9.15**), without the use of CPB via a median sternotomy with extension of the incision along the anterior border of the sternocleidomastoid muscle.

C.4. What are the surgical approaches to aortic dissections?

Type A Aortic Dissection

Unlike elective surgery for TAAs, TAAD repair is generally an emergency surgery, and the real-time operative approach can deviate from the original plan. As the extent of surgical repair is dictated primarily by the location(s) of the intimal entry tear(s), intraoperative decision making is critical.

A median sternotomy is generally performed for exposure,

preceded or followed by arterial and venous cannulation, initiation of CBP, and cooling to the desired temperature for circulatory arrest. Placement of a left ventricular vent and retrograde cardioplegia cannula is usually necessary in the setting of aortic regurgitation. Basic principles of surgery for TAAD include excision of the primary intimal tear, obliteration of the false lumen, resumption of forward blood flow through the true lumen, and correction of associated pathologic conditions such as aortic regurgitation and malperfusion. After aortic resection is performed, the aorta is repaired by reapproximating the intimal and the adventitial layers using either sutures or endovascular stent grafts. Resecting to the level of the lesser curve of the aortic arch allows for maximal removal of the diseased aorta, known as a hemiarch repair.

Selection of cannulation site is important and can be challenging. Right axillary artery cannulation is preferred because it also facilitates selective ACP during HCA. Despite a meta-analysis failing to confirm improved neurologic results, there is evidence that right axillary artery cannulation is associated with superior outcomes compared to femoral artery cannulation. These results may be explained by inadequate cerebral perfusion and retrograde atherosclerotic embolization in patients undergoing femoral artery cannulation. However, femoral cannulation is still commonly performed especially when prompt initiation of CPB is desired. In recent years, central cannulation, which aims to supply blood flow to the true lumen in a timely fashion, is increasingly being used. This approach involves access of the true lumen of the ascending aorta using the Seldinger technique to direct the insertion of the aortic cannula into the true lumen via an undissected area or through the false lumen. TEE or epiaortic ultrasound is used for guiding the insertion. Placement of the guidewire into the true lumen needs to be confirmed.

Other vascular access points for aortic cannulation, including the innominate artery, the apex of the left ventricle, and insertion of the cannula into the true lumen by dividing the ascending aorta, are usually used in the event of hemodynamic instability or aortic rupture, when emergent institution of CPB is necessary.

The minimal surgery for TAAD is a “standard” supracoronary ascending aortic replacement with distal anastomosis performed under HCA to allow inspection of the aortic arch and ensure that excision and repair of the entire aorta within the pericardium is adequate to minimize the risk of aortic rupture. When an intimal tear extends into the aortic root, an aortic root procedure such as a Bentall procedure or valve-sparing aortic root repair may become necessary especially when the left and right coronary sinuses are involved. Limited repair of the aortic root, for instance, an isolated repair of the noncoronary sinus can be done without the need for reimplantation of the coronary arteries. Other circumstances that necessitate aortic root operations include connective tissue disorders known at the time of aortic dissection, such as MFS, or aortic root aneurysms. In selected patients, valve-sparing root repair can be performed. However, patients’ characteristics, hemodynamical stability, institutional preference, and individual surgeon’s experience should be taken into consideration.

Distal extent of the TAAD repair is more controversial. The surgical approaches to the distal dissected aorta vary from an ascending aorta replacement to hemi- or total-aortic arch repair with or without a frozen elephant trunk (FET) procedure (**Fig. 9.10**). Traditionally, hemiarch repair where the inferior portion of the aortic arch is resected and repaired in conjunction with the ascending aorta is recommended to avoid reimplantation of the aortic arch branches, thereby reducing the complexity of the operation and associated procedural risks. Some aortic surgery experts advocate a standard total arch repair approach to reduce

the risk of future reinterventions. However, there appears to be no one-size-fits-all operation for TAAD. The likelihood of future reintervention should always be weighed against the operative risk. The generally accepted criteria for aortic arch replacement is an aortic arch aneurysm greater than 4.5 cm at the time of TAAD and the presence of intimal tear in the greater curvature of the aortic arch such that the preservation of arch vessels would preclude adequate repair.

On average, 20% to 30% of patients who survive the initial surgery for aortic dissections extending into the abdominal aorta (DeBakey type I) require reinterventions on the distal aorta at later stage. Although the utmost goal of TAAD surgery is operative survival and the surgical outcomes have been improving over time, identifying patients at risk for future intervention and preparing accordingly has become an area of interest to aortic surgeons. The FET procedure has shown promises as an adjunct to the standard surgical repair. In the FET procedure, an endovascular stent graft is deployed under direct vision during the period of circulatory arrest into the true lumen of the distal aorta. It has been shown to facilitate false-lumen thrombosis and aortic remodeling and to expedite the second-stage surgery for the downstream aorta. Questions have been raised about a potential increase in spinal cord ischemia associated with the procedure, and for this reason, short endografts (10 to 15 cm in length) are used. The endograft can also serve as the extended landing zone for future endovascular repair. Some user-friendly devices designed for utilization with the FET have been developed for this purpose, and some are on the horizon for commercial use. In the current era, the conventional elephant trunk (CET) procedure is rarely performed in the setting of TAAD. Instead, the FET procedure is gaining popularity because it offers the advantage of improved effectiveness in the remodeling of the downstream aorta,

although endoleak can sometimes be an issue. Several modified approaches to hybrid aortic arch repair have been reported. These simplified techniques for arch repair do not require extensive arch resection, thereby reducing the impact on operative morbidity and mortality (**Fig. 9.16**). The long-term outcomes of these procedures are being investigated.

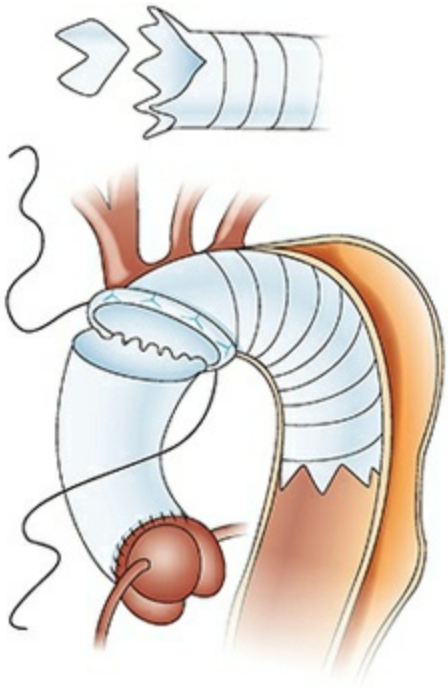

FIGURE 9.16. Illustration demonstrating a hybrid aortic arch repair, where an endograft is placed in the aortic arch and the proximal descending aorta to facilitate aortic remodeling and create the landing zone for future reinterventions. (*Adapted from Roselli EE. We should replace the aortic arch and more in DeBakey type I dissection—a perspective from the Cleveland Clinic.* Ann Cardiothorac Surg. *2013;2[2]:216–221.*)

Type B Aortic Dissection

TBAD is managed medically unless complications have developed or are impending. The notion that surgical repair of an uncomplicated TBAD does not improve survival is evolving with recent studies revealing the benefits of early endovascular repair. Surgical intervention is currently reserved for treatment of TBAD with concerns for complications, such as rupture, rapid expansion, and malperfusion. It is clear that traditional

open surgical treatment of TBAD is associated with an exceedingly high mortality and considerable morbidity. In the current era, open surgical repair is rarely considered for TBAD. Instead, endovascular repair has been accepted as the procedure of choice when intervention is indicated.

Although the role of TEVAR in treatment of complicated TBAD is well acknowledged, as recommended per the American College of Cardiology Foundation (ACC)/American Heart Association (AHA) guidelines (2010) and the European Society of Cardiology (ESC) guidelines (2014), its use in the treatment of uncomplicated TBAD remains to be elucidated. The INvestigation of STEnt Grafts in Patients With Type B Aortic Dissection (INSTEAD) trial, which is a prospective, multicenter, randomized trial investigating the outcomes for TEVAR in patients with uncomplicated TBAD in comparison to optimal medical treatment, failed to show a survival benefit in patients who underwent TEVAR. Nevertheless, it showed a much higher rate of aortic remodeling (91.3% in 2 years vs. 19.4% for optimal medical treatment). After 5 years follow-up (INSTEAD-XL trial), the TEVAR group has exhibited improved all-cause and aorta-specific mortality, suggesting that TEVAR may be beneficial in a subset of patients who have favorable anatomy but carry high risks of aortic events.

The goal of TEVAR for TBAD is to obliterate the blood flow into the false lumen by covering the intimal entry tear, therein promote thrombosis and expansion of the true lumen. Due to the anatomic restraints of TBADs that are typically located in proximity to the left subclavian artery, partial or complete coverage of the left subclavian artery is frequently necessary. Intravascular ultrasound can be used during the procedure to identify the intimal tear in conjunction with aortic angiography. Left subclavian revascularization via carotid-subclavian bypass or transposition is recommended for patients at relatively young

age, with left dominant vertebral arteries, in non-emergent situations, or with a patent LIMA after coronary artery bypass graft.

It is a common practice to cover only the segment of the aorta at risk for expansion or rupture and follow with serial imaging studies to rule out aortic growth because extensive coverage increases the risk of paraplegia. The presence of multiple intimal tears is attributable to the persistence or even continuous growth of the false lumen after TEVAR for TBAD, potentially requiring reinterventions.

TEVAR can be associated with retrograde dissection that results in new-onset TAAD requiring emergent surgical repair. TEE is proven to be a useful tool in the intraoperative setting to identify retrograde dissection expansion in a timely fashion preventing fatal complications. In addition, TEE also helps identify intimal tears and guides operative planning.

C.5. What are the specific considerations for anesthetic management of the patient presenting for open TAAA repair?

Patients presenting for TAAA repair typically have multiple preexisting comorbid conditions, and open repair of the TAAA poses a direct and immediate threat to the cardiac, pulmonary, renal, gastrointestinal, and neurologic systems.

Induction of anesthesia should include a slow and hemodynamically stable induction, avoiding hypertension and tachycardia. Short-acting antihypertensive agents such as nitroglycerin, nicardipine, esmolol, and labetalol are useful to assist in hemodynamic stability.

Anesthetic management must seek to avoid hemodynamic changes that will increase the risk of aneurysm rupture while maintaining adequate end-organ perfusion. As surgical dissection exposes the aorta, the counterforce to the systemic blood pressure on the aneurysm wall is decreased, increasing the risk of aneurysm rupture. Prior to cross-clamp removal and reperfusion of the visceral organs and lower extremities, systemic blood pressure should be increased because removal of the cross-clamp and reperfusion can lead to profound hypotension.

Lung isolation is necessary for repair of type I, II, and some type III TAAAs. A double-lumen endotracheal tube is superior to a bronchial blocker because it provides access to the

nonventilated lung for suctioning and addition of continuous positive airway pressure (CPAP) when oxygenation is inadequate. Either right- or left-sided double-lumen endotracheal tubes may be used; however, a type I or II aneurysm may distort the anatomy of the left mainstem bronchus, making a left-sided double-lumen tube difficult and possibly unsafe to place. An alternative to double-lumen tube placement involves the use of the EZ-Blocker, a bronchial blocker with a Y configuration and two balloons that can isolate either lung and allows for lung isolation via a single-lumen tube. Tube exchange at the end of surgery in a potentially edematous airway is avoided with this technique, and it is generally easier to place a larger single-lumen tube with this blocker than with a double-lumen tube.

If motor-evoked potentials (MEPs) are being monitored, either succinylcholine or a short-acting nondepolarizing neuromuscular blocker should be used to facilitate tracheal intubation and then discontinued. Anesthetic maintenance may be achieved using a low concentration of volatile anesthetic, combined with an infusion of propofol and/or narcotics. If MEPs are not being monitored, neuromuscular blockers can be used with inhalation agents and narcotics.

Some institutions will institute a wake-up test prior to transportation to the ICU. If this is performed, anesthetic management must take this into consideration. During the wake-up test, the patient is asked to move his lower extremities. After completion of the wake-up test, the patient is resedated and the double-lumen endotracheal tube is changed to a single-lumen endotracheal tube.

C.6. What are the specific considerations for anesthetic management of the patient presenting for endovascular TAAA repair?

Endovascular treatment of thoracic aneurysms is typically less invasive than open surgical repair, but preparation for possible open repair must be undertaken. General and regional anesthetic techniques have been described, but general anesthesia remains the primary choice because TEE and neuromonitoring can occur when the patient is under general anesthesia. Hemodynamic stability must be sought, avoiding hypertension and tachycardia. During deployment of the stent, transient balloon occlusion of the aorta may result in significant transient hemodynamic instability, particularly if the patient has poor cardiac function. Vasopressors and inotropes must be available to treat hemodynamic instability.

Although the risk of spinal cord ischemia is lower in endovascular procedures, it does occur. Cerebrospinal fluid (CSF) drains may be placed selectively in patients considered high risk for spinal cord ischemia for neuroprotection. Neuromonitoring of somatosensory evoked potentials (SSEPs) and MEPs may be used. If MEPs are used for neuromonitoring, this may necessitate the use of a total IV anesthetic.

Blood loss during the endovascular surgery may be difficult to quantify, necessitating frequent hemoglobin checks.

C.7. What hemodynamic monitors should be used for the patient undergoing thoracic aneurysm repair?

In addition to the standard monitoring recommended by the American Society of Anesthesiologists, there are additional monitors that should be applied to the patient undergoing open repair of a TAA. Electrocardiographic monitoring with ST-segment analysis is essential because the incidence of intraoperative myocardial ischemia and arrhythmias is significant. During open repair of TAAs, systemic blood pressure should be measured with the use of an arterial line, which may be placed awake to allow strict blood pressure control during induction. Patients presenting for TAA repair frequently have peripheral vascular disease and as such, reviewing imaging studies for subclavian or other arterial stenosis may affect the placement of arterial catheters. During repair of Crawford type I and II aneurysms, the arterial catheter should be placed in the right radial artery because flow to the left subclavian artery may be disrupted from the proximal aortic cross-clamp. Left radial monitoring may be useful to determine the patency of the left subclavian artery but should not be used independently because left subclavian flow can be altered. If distal aortic perfusion through bypass or a shunt is performed, a femoral arterial line is inserted to monitor distal perfusion pressure. A femoral arterial line is also useful in determining the pressure gradient across the surgical repair by comparing the femoral blood pressure to the radial blood pressure. Depending on the extent of ascending aortic repair, bilateral upper extremity arterial catheters may need to be used. The left radial arterial line is used to monitor the systemic pressure reliably prior to and during CPB, whereas the right radial arterial catheter will measure the blood pressure during HCA with ACP. The right radial arterial catheter is not used during other intraoperative periods because the presence of an axillary aortic cannula can

make the readings unreliable.

The potential for rapid blood loss during the repair is significant; therefore, large-bore IV access should be obtained. The ability to transfuse blood products rapidly with a rapid infusion device should be available. Left upper extremity IV access should be avoided during aortic arch repairs because the left innominate vein may be injured or ligated during the procedure. Pulmonary artery (PA) catheters are often used to allow hemodynamic monitoring and assess cardiac output, but the routine use of PA catheters during these procedures varies among different institutions.

TEE should be used in all open thoracic aorta repairs, unless contraindications exist. TEE can assess the extent and severity of aortic disease, evaluate valvular and functional abnormalities, and assist with cannula placement. TEE should also be used in endovascular thoracic aorta procedures for cardiac monitoring, procedural guidance, and endovascular graft leak detection. During balloon occlusion of the aorta, TEE can monitor the cardiac performance and guide vasoactive therapies.

C.8. What strategies are used for spinal cord protection during a TAAA repair?

Spinal cord injury with resultant paraplegia remains one of the most serious complications of surgical procedures on the descending and thoracoabdominal aorta despite major advances in surgical technique. Several components of TAAA surgery impart risk to the spinal cord. Temporary occlusion of the aorta with a cross-clamp, permanent deletion of intercostal arteries,

and embolization of air or particulate matter to the aorta may contribute to the development of spinal cord injury. Several techniques have been instituted to minimize the risk of postoperative paraplegia.

Left-Heart Bypass

LHB is commonly used to provide distal aortic perfusion during aortic cross-clamp and repair (**Fig. 9.14**). During LHB, the arterial inflow cannula typically resides in the femoral artery and provides antegrade flow to the lower extremities with retrograde flow to the visceral organs and spinal cord. The venous cannula resides in the left atrium or pulmonary veins and drains oxygenated blood. LHB circuits can be equipped with or without an oxygenator.

Intraoperative Neuromonitoring

Neuromonitoring of SSEPs and MEPs has been instituted at various centers as a means of timely diagnosis of ischemia and modification of the surgical technique when ischemia occurs. SSEPs monitor the dorsal column of the spinal cord by stimulating the posterior tibial nerve and recording the responses from the somatosensory cortex. MEPs monitor the function of the corticospinal tract and anterior horn motor neurons by stimulating the motor cortex or cervical spinal cord and recording the response from the anterior tibial muscle. Unfortunately, monitoring of SSEPs produces a significant amount of false-positive results, and relying on SSEPs alone for determining the need for revascularization does not affect the incidence of postoperative neurologic injury. Current guidelines state that the use of neurophysiologic monitoring with SSEPs and MEPs may be considered.

Cerebrospinal Drainage

During aortic cross-clamp and surgical retraction, CSF pressure

may acutely increase. Additionally, the spinal cord may suffer from spinal cord reperfusion injury, whereby spinal canal edema forms following reperfusion. Spinal cord perfusion pressure is the difference between MAP and CSF pressure. The rationale for CSF drainage is based on this premise because decreasing the compartment pressure of the spinal cord should improve spinal cord perfusion pressure. Studies have shown that reducing the CSF pressure to less than 15 mmHg is beneficial, and meta-analysis supports the use of CSF drainage as an adjunct to prevent paraplegia. The current guidelines recommend the use of CSF drainage in open and endovascular thoracic aortic repair in patients at high risk for spinal cord ischemia.

Hypothermia

Mild hypothermia to 32°C may provide neuronal protection by reducing excitatory neurotransmitter release, decreasing free oxygen radical production, decreasing post-ischemic edema, and stabilizing CNS blood flow.

Moderate systemic hypothermia has been associated with improved neurologic outcomes after TAAA surgery. Hypothermia is achieved via passive heat loss during surgery or active cooling by heat exchangers on bypass circuits. Current guidelines state that the use of moderate hypothermia is reasonable for protection of the spinal cord.

Some institutions implement regional hypothermia to avoid the detrimental effects of systemic hypothermia on the coagulation system. Epidural cooling can be instituted with the insertion of a T12–L1 epidural catheter and an L3–L4 intrathecal thermistor catheter, selectively cooling the spinal cord after aortic cross-clamp. The spinal cord is cooled at the T8–L1 region, a watershed area with variation in collateral blood supply most susceptible to ischemic injury. The thermistor catheter allows measurement of temperature and CSF pressure.

After full TAAA reconstruction is completed, epidural cooling is stopped.

Similar to ascending aortic aneurysms, HCA may be used during repair of TAAAs. The use of HCA obviates the need for an aortic cross-clamp and the use of LHB to protect the spinal cord and viscera.

C.9. What strategies are used for mesenteric and renal preservation?

Over the past few decades, strategies have been developed to minimize ischemic damage to downstream organs while the aorta is clamped. One strategy is the use of a passive shunt to provide distal aortic perfusion. Passive shunting is uncommonly utilized due to the popularity of mechanical circulatory support and the inability to adjust flow rates through the shunt.

LHB, as previously described, is now a common approach to

maintain distal aortic perfusion. The advantage of LHB is that flow rates can be adjusted to help provide stable hemodynamics. The disadvantage of LHB is that it is associated with increased incidence of postoperative renal dysfunction. Selective visceral perfusion may be used in combination with LHB, perfusing the four branching arteries with cold blood or crystalloid.

Femoro-femoral CPB with a range of protective hypothermia strategies, from mild (34°C) to profound (18°C), have been described to provide end-organ protection. Separate roller pumps may be used to selectively perfuse the celiac artery, superior mesenteric artery, and renal arteries during CPB. Lastly, HCA may be combined with CPB to avoid aortic cross-clamping and preserve end-organ function.

Selective renal artery perfusion can be performed by infusing a cold (4°C) crystalloid or blood solution into the renal artery ostia during aortic cross-clamp occlusion to achieve renal hypothermia. Mannitol and methylprednisolone may also be added to the perfusate. Mannitol decreases renal oxygen demand, and steroids stabilize cell membranes during ischemia. Mannitol also assists in maintaining urine output during the cross-clamp period. Additives such as histidine-tryptophan-ketoglutarate have recently shown promise in decreasing renal dysfunction. Current guidelines support the use of either cold crystalloid or blood perfusion to the kidneys but do not recommend the use of furosemide, mannitol, or dopamine solely for renal protection.

As concomitant atherosclerotic disease is commonly present in this patient population, the renal and visceral arteries often contain occlusive disease. Endarterectomy and balloon-expandable stent placement may be beneficial in decreasing postoperative renal dysfunction.

C.10. What is the pathophysiology of aortic clamping and unclamping?

Aortic Clamping

Hemodynamics: As for any major vascular surgery, it is imperative to be familiar with the pathophysiology of aortic cross-clamping to understand and treat the hemodynamic disturbances appropriately. The most reliable response to aortic cross-clamping is systemic arterial hypertension. This is due to both an increase in afterload and redistribution of the blood volume. Blood volume redistributes after aortic cross-clamping, with a decrease in venous capacitance below the clamp, expelling blood from the splanchnic and nonsplanchnic vascular beds, and an increase in venous capacitance above the clamp. The increase in upper body blood volume results in increased filling pressures. Central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP), and left ventricular end-diastolic pressure (LVEDP) all increase with aortic cross-clamp placement. Differences in hemodynamic responses are observed with occlusion of different levels of the aorta and may be the result of different degrees and patterns of blood volume

distribution. Supraceliac cross-clamp application results in the most consistent redistribution of blood flow, whereas infraceliac aortic cross-clamp has inconsistent effects on blood flow redistribution and preload.

Oxygen consumption: Oxygen consumption in the part of the body distal to the aortic occlusion decreases. Paradoxically, oxygen uptake above the aortic occlusion also decreases. The reason for the decrease in oxygen consumption above the cross-clamp is unclear but may be related to sympathetic discharge from the adrenal glands, arteriovenous shunting, or blood volume redistribution and proximal hypervolemia. Mixed venous oxygen saturation increases during aortic cross-clamp, indicating decreased extraction. Plasma levels of epinephrine and norepinephrine significantly increase after thoracic aorta cross-clamping.

Coronary blood flow and contractility: Aortic cross-clamping is associated with increases in preload and afterload, leading to an increase in myocardial oxygen demand. In an intact coronary blood supply, an increase in demand would lead to coronary artery vasodilation and a concomitant increase in oxygen supply. When coronary blood flow increases, the subendocardium is perfused and contractility will increase in response to aortic cross-clamping. In the presence of inadequate coronary blood flow, the LVEDP increases, the subendocardium is not perfused, and the cardiac output decreases.

Level and duration of aortic cross-clamp: The level of the aortic cross-clamp affects the hemodynamic response observed. Changes in MAP, filling pressures, ejection fraction, and wall motion are minimal during infrarenal aortic cross-clamping but exaggerated during supraceliac aortic cross-clamping. With increased duration of aortic cross-clamping, systemic vascular resistance (SVR) increases and cardiac output decreases.

Renal effects: Cross-clamping of both the suprarenal and

infrarenal aorta results in an increase in renin and angiotensin. The increase in angiotensin is thought to contribute to the hypertension observed during cross-clamping. Cross-clamping of the thoracic aorta is associated with severe decreases in renal blood flow, glomerular filtration rate, and urine output. Ischemia-reperfusion injury to the kidneys plays a central role in renal dysfunction after aortic surgery and is also present after infrarenal cross-clamping.

Effects on spinal cord: Cross-clamping of the aorta is associated with a decrease in distal aortic pressure (decreasing ASA pressure, depending on the anatomy and presence of collateral supply), increase in CSF pressure, and a decrease in the compliance of the spinal fluid space. Vasodilators used to decrease proximal aortic pressure should possess minimal cerebral vasodilating properties because these will decrease spinal cord perfusion pressure by decreasing distal aortic pressure and increasing CSF pressure. In this regard, sodium nitroprusside, which decreases distal aortic pressure and increases CSF pressure, and nitroglycerin, which predominantly decreases distal aortic pressure, both decrease spinal cord perfusion pressure, which can lead to worse neurologic outcome.

Aortic Unclamping

Hemodynamics: Unclamping of the thoracic aorta leads to a decrease in SVR with a resultant decrease in arterial blood pressure. Cardiac output may increase, decrease, or remain the same. Myocardial blood flow increases and LVEDP decreases. Central hypovolemia develops due to pooling of blood into reperfused tissues distal to the aortic occlusion. Hypoxia-mediated vasodilation, in addition to accumulation of myocardial-depressant metabolites contributes to the hypotension that is seen after cross-clamp removal.

Acidosis: Metabolic acidosis and an increase in lactate

concentration are seen after release of the aortic cross-clamp. The degree of acidosis present depends on the underlying pathology and is greatest in patients undergoing abdominal aortic aneurysm repair. Aortic cross-clamp removal is also associated with a transient increase in carbon dioxide release and oxygen consumption.

Renal effects: Unclamping of the aorta results in a significant increase in renin and angiotensin that lasts for 6 hours but is unrelated to hypertension. A maldistribution of renal blood flow is seen, with a decrease in renal cortical blood flow. Glomerular filtration rate and renal plasma flow are decreased after unclamping and can remain at decreased values for 6 months following surgery.

C.11. Why does a coagulopathy ensue and how is it prevented/treated?

TAA or TAAA repair is associated with significant hemorrhage from multiple causes, including surgical dissection, hypothermia, CPB, fibrinolysis, dilution or consumption of coagulation factors, anticoagulant therapy, preoperative antithrombotic therapy, and congenital or acquired coagulopathies. Communication with the blood bank should occur early to ensure an adequate supply of blood products for the patient. Five to 10 units of packed red blood cells (pRBCs) should be immediately available in the operating room, with a similar number of units available in the blood bank. Five to 10 units of fresh frozen plasma, typically given in a ratio of 1 per 1 to 2 pRBCs transfused should be readily available.

Thrombocytopenia and platelet dysfunction develop secondary to hypothermia and use of extracorporeal mechanical support, and the need for platelet transfusion is common.

In cases with refractory international normalized ratio (INR) elevation as the cause of coagulopathy or in patients with depressed cardiac or renal function, consideration of the use of prothrombin complex concentrates (PCCs) may be prudent. PCCs offer the advantage of rapid correction of INR with a minimal volume load and crossmatching is not required. Caution must be exercised given the possibility of thrombosis. Additionally, in the rare patient with heparin-induced thrombocytopenia (HIT), PCCs should not be administered because they contain heparin.

Fibrinolysis develops from the use of CPB, but supraceliac aortic cross-clamping and peripheral ischemia have also been shown to cause fibrinolysis that can be attenuated by the use of selective superior mesenteric artery perfusion. Supraceliac cross-clamping and peripheral ischemia promote activation of tissue-type plasminogen activator and decrease plasminogen activator inhibitor. The use of lysine analogs epsilon-aminocaproic acid and tranexamic acid is common in TAA repairs, but its use has been derived from studies in other cardiac surgeries and is not currently supported by the literature in TAA repair.

The use of a blood-salvaging device ("cell saver") is essential to decrease allogenic red blood cell transfusions. Unfortunately, the use of a cell saver is associated with the loss of platelets, plasma proteins, and coagulation factors. In heparinized patients, the use of cardiotomy suction permits the autotransfusion of filtered unwashed whole blood, which preserves platelets and coagulation factors.

D. Postoperative Anesthetic Management

D.1. What are the postoperative complications after open TAAA repair?

Respiratory Failure

Respiratory failure after TAAA repair remains one of the most commonly reported complications. The large thoracoabdominal incision, diaphragmatic incision, and need for lung isolation all predispose the patient to pulmonary dysfunction. The diaphragmatic incision may lead to hemidiaphragm dysfunction or paralysis. Preoperative pulmonary dysfunction, tobacco use, postoperative cardiac complications, and postoperative renal complications are independent risk factors for postoperative respiratory failure.

Renal Failure

Postoperative renal dysfunction is a common postoperative complication, occurring in as many as 28% of patients and necessitating dialysis in 8% of patients. Risk factors associated with postoperative renal failure include age >50 years, preexisting renal dysfunction, administration of greater than 5 units of either pRBCs or salvaged washed autologous blood, and aortic cross-clamp time of more than 100 minutes. Postoperative renal dysfunction of any degree is associated with an increased perioperative mortality.

Spinal Cord Injury

Spinal cord injury remains one of the greatest fears after TAAA repair. Spinal cord injury can be immediate or delayed. Spinal cord injury occurs more often with type I and II TAAAs, emergent operations, intercostal sacrifice, and intraoperative hypotension. Spinal cord injury of any severity occurs in 11% of patients undergoing open TAAA repair, with 2% to 6% having total paraplegia. The majority of the deficits are immediate; however, delayed deficits can occur hours to weeks postoperatively. Immediate-onset deficits are irreversible and portend a poor prognosis, whereas delayed-onset deficits typically have a better prognosis with partial and reversible deficits and acceptable functional outcomes. Management of delayed-onset deficits focuses on CSF drainage (to a CSF pressure of 10 mmHg) and increasing systemic blood pressure (to an MAP of 100 mmHg) for improved spinal cord perfusion.

Levine WC, Lee JJ, Black JH, et al. Thoracoabdominal aneurysm repair: anesthetic management. *Int Anesthesiol Clin*. 2005;43(1):39–60.

D.2. What are the postoperative complications after endovascular TAAA repair?

Left Upper Extremity Ischemia

Aneurysms involving the aortic arch can pose a significant risk to cerebral and upper extremity blood flow with endovascular repair. Intentional coverage of the left subclavian artery with the endovascular graft can occur in approximately 50% of thoracic endograft implants. Most patients can tolerate left subclavian artery coverage without left upper extremity ischemia. However, if the right subclavian and vertebral arteries are not patent, ischemia can ensue. Additionally, the patient may experience

decreased blood flow to the LIMA, leading to significant ischemia to a prior coronary artery bypass graft. If left upper extremity ischemia occurs, a left subclavian artery bypass should be performed postoperatively.

Stroke

Intravascular wires and endografts that are introduced into the atherosclerotic aorta can come in contact with mobile thrombi in the arch and brachiocephalic vessels, leading to cerebral ischemia. Iatrogenic dissection of the carotid or vertebral arteries and retrograde dissection of the aorta have been described as devastating complications. If the left subclavian artery is covered during endograft deployment, cerebral ischemia may develop due to decreased flow from the left vertebral artery. A left carotid to left subclavian bypass graft should first be placed if the left subclavian will be covered by the graft. The incidence of stroke after TEVAR ranges from 2% to 8%. Risk factors for perioperative stroke include severe atheromatous aortic disease (grade IV or V aortic disease on TEE), endovascular coverage of aortic arch vessels, history of prior stroke, long extent of aortic coverage, preexisting CAD, longer procedure duration, and female gender.

Spinal Cord Ischemia

Spinal cord ischemia is also a possible complication of endovascular treatment of TAAAs, although with less incidence than after open repair. Intercostal arteries are intentionally covered during endovascular stent placement of a TAAA, possibly compromising spinal cord perfusion by obliterating the collateral circulation. Endovascular coverage of the left subclavian artery may compromise spinal cord perfusion in patients with a left dominant vertebral artery, solitary vertebral artery, carotid artery disease, or an incomplete circle of Willis. Spinal cord injury after TAAA repair is a heterogeneous

syndrome manifesting as a spectrum of impairments that varies depending on the severity and extent of ischemia. Additionally, delayed-onset neurologic deficits, similar to that seen after open repair, can also be seen after endovascular treatment. Delayed-onset deficits are thought to be due to postoperative events such as hypotension, thrombosis, hematoma, embolization, and elevated CSF pressure. Injury to the spinal cord is directly related to the extent of the aorta that is involved and is highest with Crawford type II repairs. Risk factors for spinal cord injury after TEVAR include left subclavian artery coverage without revascularization, concomitant open abdominal aortic surgery, and the use of three or more stent grafts.

Renal Failure

Similar to open repair of TAAAs, renal insufficiency can develop after endovascular repair with an incidence rate of 14%. Deployment of the endograft in a diseased, atherosclerotic aorta can lead to embolic showers, infarcting mesenteric, splenic, and renal arteries. This phenomenon contributes to the development of renal insufficiency. Risk factors for postoperative renal dysfunction after TEVAR include preoperative chronic renal insufficiency, perioperative blood transfusions, and the thoracoabdominal extent of the aneurysm.

Postimplantation Syndrome

This commonly observed phenomenon consisting of fever, leukocytosis, and an elevation in inflammatory markers normally occurs in the early postoperative period, although it may occasionally have a delayed presentation. It is usually mild and self-limiting, responding to conservative management with nonsteroidal anti-inflammatory drugs.

Endograft Collapse

Endograft collapse is a rare but serious complication after

TEVAR, typically presenting in the first 3 months after endovascular repair. Endograft collapse can present asymptomatically or can present with diminished or absent femoral pulses, abdominal pain, or multiorgan failure. Excessive oversizing of the endograft and poor apposition of the proximal endograft to the aortic wall are the primary causes of endograft collapse. Maldeployment of the endograft and progression of the aortic disease are rare causes of endograft collapse.

Endoleaks

An endoleak is a leakage of blood into an aneurysm sac previously excluded during TEVAR. Endoleaks after TEVAR occur in about 5% to 30% of patients. Endoleak is a complication unique to the endovascular approach to aortic repair, and there are four types.

Type I endoleak is caused by incomplete seal at the end of the graft, leading to blood flow into the aneurysm sac.

Type II endoleak is caused by leaking of blood into the aneurysm from collateral vessels excluded during repair.

Type III endoleak is caused by inadequate sealing of overlapping graft joints or rupture of graft fabric, leading to blood flow into the aneurysm sac.

Type IV endoleak is caused by the direct leakage of blood through a porous graft.

Management includes aggressive endovascular repair of type I and III endoleaks, with observation of type II endoleaks. Type IV endoleaks are of historical interest because new graft material has virtually eliminated the incidence of this complication. Risk factors for development of endoleaks include larger preoperative aneurysm sac diameter, greater length of stent coverage, and the use of multiple stent grafts.

10 Abdominal Aortic Aneurysm Repair

Fun-Sun F. Yao and Anup Pamnani

The patient is a 76-year-old man with a 6-cm infrarenal aortic aneurysm discovered on routine physical examination and confirmed by abdominal computed tomography (CT) scan. He is a former smoker and complains of dyspnea on exertion and claudication. His electrocardiogram (ECG) shows Q waves in leads II, III, and aV_F; chest x-ray film displays mild hyperinflation of the lung fields; and his hematocrit is 46%. His baseline serum creatinine is 1.9.

A. Medical Disease and Differential Diagnosis

1. What risk factors are associated with an abdominal aortic aneurysm (AAA)?
2. What other diseases are commonly found in patients with aortic aneurysms?
3. What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the natural history of the disease without surgical repair?
4. What should be done for smaller aortic aneurysms that are found in patients?
5. What is the risk of perioperative myocardial infarction (MI) in

patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?

6. Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?

B. Preoperative Evaluation and Preparation

1. Which preoperative laboratory tests would you require for this patient?
2. What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what would they tell you?
3. Is it necessary to evaluate this patient's pulmonary status?
4. Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $Paco_2$, 47 mmHg; and Pao_2, 68 mmHg on room air. What is the significance of this result?
5. How would you measure creatinine clearance in this patient, and what is its value in this case?
6. Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?
7. How do you detect spinal cord ischemia?
8. What are the various surgical approaches to repair an AAA?
9. How does the choice of surgical technique affect the anesthetic management?
10. How would you premedicate this patient?

C. Intraoperative Management

1. Would you use an arterial line? What are the complications of arterial line placement?
2. What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?
3. What additional monitors would you employ?
4. Is there a role for somatosensory evoked potential (SSEP)

monitoring during aortic clamping?

5. How would you anesthetize this patient for an open repair of the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.
6. This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?
7. What are your plans for fluid and blood replacement during surgery?
8. What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?
9. Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?
10. What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?

D. Postoperative Management

1. What are the parameters used to extubate this patient?
2. What are the anticipated changes in postoperative pulmonary

function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?

3. How would you control postoperative pain? What are the alternatives in the management of this patient's postoperative pain?

A. Medical Disease and Differential Diagnosis

A.1. What risk factors are associated with an abdominal aortic aneurysm (AAA)?

AAA is a full-thickness dilatation of a segment of the abdominal aorta located between the diaphragm and the bifurcation of the aorta to the common iliac arteries. Approximately 200,000 AAAs are annually diagnosed, resulting in about 13,000 deaths per year in the United States. Risk factors for AAA include older age, male sex, family history of AAA, smoking, hypertension, hyperlipidemia, atherosclerotic occlusive disease, and obesity. Lifestyle factors reducing risk for AAA include regular exercise, smoking cessation, and favorable diet (includes fruit, vegetables, and nuts). Interestingly, diabetes mellitus is associated with *decreased* risk of AAA. The prevalence of AAA is lower in African Americans, Hispanics, and Asians in comparison to Whites and Native Americans.

Kent KC, Zwolak RM, Egorova NN, et al. Analysis of risk factors for abdominal aortic aneurysm in a cohort of more than 3 million individuals. *J Vasc Surg*. 2010;52:539–548.

A.2. What other diseases are commonly found in patients

with aortic aneurysms?

The major pathologic cause of aneurysmal disease is atherosclerosis. In addition, hypertension (55%), heart disease (73.5%), peripheral vascular disease (21%), stroke and transient ischemic attacks (22%), diabetes mellitus (7%), and renal insufficiency (10%) are the most common comorbid illnesses. Smoking history has been reported in as many as 80% of patients presenting for AAA repair.

Howard DP, Banerjee A, Fairhead JF, et al. Age-specific incidence, risk factors and outcome of acute abdominal aortic aneurysms in a defined population. *Br J Surg*. 2015;102(8):907–915.

A.3. What is the incidence of morbidity and mortality in these patients if they undergo elective open surgical repair? What is the natural history of the disease without surgical repair?

Morbidity in this patient group is most commonly due to cardiovascular, pulmonary, and renal complications. Perioperative mortality for elective open AAA repair is 2% to 5%. Increased postoperative mortality was associated with older age, elevated serum creatinine, lower forced expiratory volume in 1 second (FEV_1), and gender. One retrospective study demonstrated higher mortality in women in comparison to men: 7% versus 5% for open repair and 2% versus 1% for endovascular repair. Despite the increasing fraction of patients undergoing endovascular repair, numerous large studies have not shown significant long-term differences in mortality between open and endovascular repair. The major cause of death

in the nonsurgically treated patient is rupture, which carries a mortality of up to 80%. Ruptured AAAs account for approximately 9,000 deaths per year in the United States. One study demonstrated a doubling of expectancy after resection of AAA. The incidence of rupture within 5 years of diagnosis of AAA is 80%. The incidence of rupture increases with aneurysmal size: 25% for lesions of 4 to 7 cm in diameter, 45% for lesions 7 to 10 cm, and 60% for lesions larger than 10 cm. Repairing aneurysms smaller than 5.5 cm has not been shown to improve survival. Thus, only patients with aneurysms 5.5 cm or larger should be considered for surgical intervention.

A.4. What should be done for smaller aortic aneurysms that are found in patients?

The U.S. Preventive Services Task Force (USPSTF) 2015 update on screening recommendations for AAA reinforces that early surgical intervention of smaller AAAs <5.5 cm (open or endovascular) does not reduce mortality. USPSTF recommends

repeat ultrasonography every 3 to 12 months for AAAs 3 to 5.4 cm with surgical referral for rapid growth (>1 cm per year) or when the aneurysm reaches 5.5 cm or larger. Therefore, watchful waiting is suggested for aneurysms that are smaller than 5.5 cm.

A.5. What is the risk of perioperative myocardial infarction (MI) in patients with ischemic heart disease? What can be done to reduce the risk of ischemic events in these patients?

A retrospective analysis confirmed that cardiac mortality is high for patients who undergo vascular surgery and experience postoperative myocardial ischemia. Key factors that determine perioperative morbidity and mortality rates include the stress of surgery (aortic, peripheral vascular, emergency surgery), increased blood loss, poor preoperative cardiac functional status, history of congestive heart failure (CHF), a low ejection fraction, known coronary artery disease (CAD), and preoperative history of coronary artery bypass grafting.

The occurrence of a recent MI is an important independent predictor of perioperative morbidity and mortality. In a prospective cohort examining perioperative reinfarction by Rao et al., the statistical rate of reinfarction was related to the length of time since the initial MI, decreasing to less than 2% if the infarction occurred more than 6 months earlier. Acute screening and care of the MI patient has improved; risk stratification and noninvasive testing allows for a more tailored approach to the

timing of surgery in these patients.

Special consideration needs to be given to patients who have recently undergone percutaneous coronary intervention procedures for coronary revascularization, maintained on antiplatelet therapy. This is due to the significant risk of acute stent restenosis or thrombosis if antiplatelet therapy is prematurely terminated. The management of the dual antiplatelet therapy regimen should be customized to each patient depending on the type and urgency of surgery, type of coronary stent, time since the coronary intervention, and complexity of the coronary intervention. The current recommendations for perioperative management of patients with drug-eluting stent (DES) are shown in **Figure 10.1**. For patients identified at high risk for stent thrombosis, surgery should be planned in a hospital with cardiac catheterization facilities. Postoperatively, these patients require a monitored setting and immediate resumption of antiplatelet therapy. Signs and symptoms of stent thrombosis should be promptly recognized and aggressively treated with percutaneous coronary intervention.

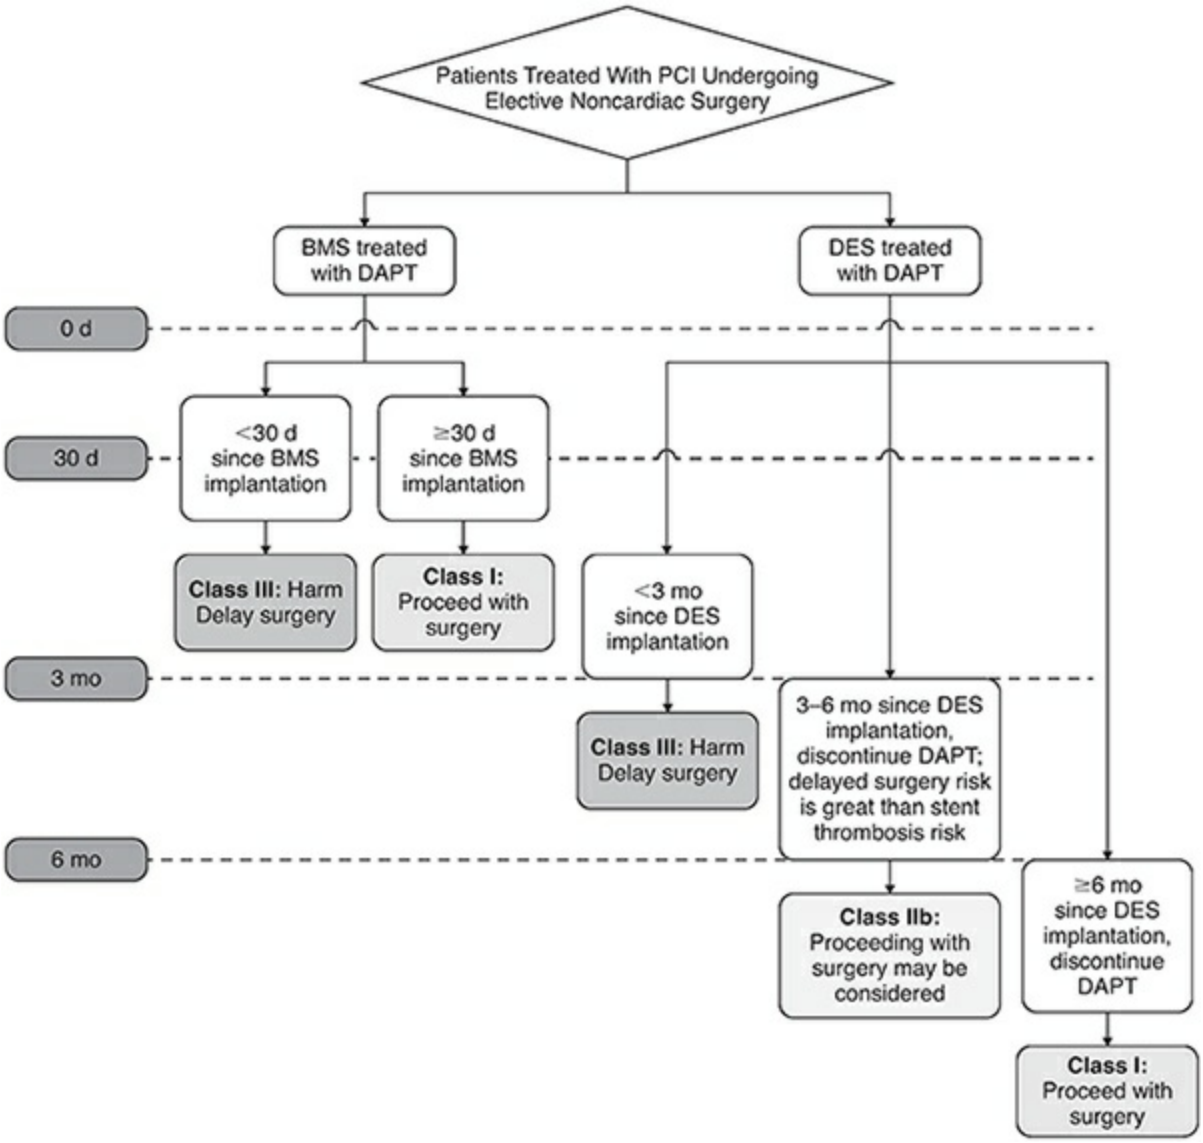

FIGURE 10.1. Treatment algorithm for timing of elective noncardiac surgery in patients with coronary stents. BMS, bare metal stent; DAPT, dual antiplatelet therapy; DES, drug-eluting stent; PCI, percutaneous coronary intervention. (*Reprinted with permission from Levine GN, Bates ER, Bittl JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on clinical practice guidelines.* Circulation*. 2016;134[10]:e123–e155.*)

The 2016 American College of Cardiology (ACC)/American Heart Association (AHA) guideline focused update on duration of dual antiplatelet therapy in patients with CAD recommended the following:

- Elective noncardiac surgery should be delayed 30 days after bare metal stent (BMS) implantation and optimally 6 months

after DES implantation.

- In patients who must undergo surgical procedures that mandate the discontinuation of $P2Y_{12}$ inhibitor therapy, aspirin be continued if possible and the $P2Y_{12}$ platelet receptor inhibitor be restarted as soon as possible after surgery.
- When noncardiac surgery is required in patients currently taking a $P2Y_{12}$ inhibitor, a consensus decision among treating clinicians as to the relative risks of surgery and discontinuation or continuation of antiplatelet therapy can be useful.
- Elective noncardiac surgery after DES implantation in patients for whom $P2Y_{12}$ inhibitor therapy will need to be discontinued may be considered after 3 months if the risk of further delay of surgery is greater than the expected risks of stent thrombosis.

In most studies, the morbidity following a perioperative MI approaches 50%. The risk after an MI may be best linked to the ongoing risk of ischemia. Patients who have survived a non–Q-wave infarction are potentially at great risk for further ischemia. Badner et al. reported a 17% post-MI mortality rate after noncardiac surgery. The mortality rate was higher in the presence of intraoperative ST-segment and T-wave changes. These patients should be evaluated by symptom-limited exercise testing and/or cardiac catheterization. The prevention of perioperative myocardial ischemia is the goal of the anesthesiologist regardless of the technique chosen. This entails reduction of myocardial oxygen demand (avoid tachycardia and hypertension), while increasing oxygen supply (prevent hypotension and anemia). Oxygen demand on the left ventricle is dependent on heart rate, contractility, and the ventricular loading conditions. Of the three, the increase in heart rate

imposes the greatest demand and should be readily controlled by the anesthesiologist. Left ventricular preload and afterload also affect oxygen demand by end-diastolic and systolic wall tension. Other factors, such as coronary collateral blood flow, hematocrit, and blood rheology may also influence myocardial ischemia.

β-Adrenergic antagonists are a well-established class of drugs effective in reducing myocardial oxygen consumption. Some studies suggest that *β*-blockers reduce perioperative ischemia and may reduce the risk of MI and cardiovascular death in patients undergoing high-risk procedures such as vascular surgery. The mechanism of reduction of myocardial oxygen consumption with *β*-antagonism is related to decreases in heart rate and myocardial contractility, counteracting the deleterious effects of sympathetic stimulation. In addition, this class of drugs has antiarrhythmic qualities. Currently, the only class I recommendation for perioperative *β*-blockers use by the AHA is to continue their use in the patients who are already on *β*-blockers. Patients undergoing vascular surgery who have multiple risk factors or have reversible ischemia on preoperative testing may benefit from perioperative *β*-blockers (class IIa). Although there are some differences between the European Society of Cardiology and the AHA guidelines, both agree that if *β*-blockers are used for prophylactic purposes, they should be slowly titrated (at least a week prior to elective surgery) and acute administration of high-dose *β*-blockers in high-risk population is not recommended.

Nitrates also can reduce myocardial oxygen demand by decreasing preload and by dilating large epicardial coronary arteries and collateral conduit vessels. However, the benefit of perioperative nitroglycerin prophylaxis has not been proven.

The use of statins in patients with cardiovascular disease is increasingly supported by multiple studies that display a

reduction in the risk of MI, stroke, and mortality. Furthermore, accumulating data suggests that continuation of statin therapy in the preoperative period reduces the risk of postoperative death and acute coronary syndromes. The mechanisms by which statin medications attenuate cardiovascular disease extend beyond their lipid-lowering properties. In addition to anti-inflammatory and antioxidant actions, they also improve endothelial function and stabilize plaques. Thus, current ACC/AHA guidelines recommend continuation of statin therapy in the perioperative period.

A.6. Does the morbidity and mortality of elective repair of an aortic aneurysm differ significantly from that of an emergency repair?

The overall mortality for a ruptured aortic aneurysm is greater than 50%. One study showed an overall survival rate of 19.8% as compared with an elective surgical survival rate of 95%. The worst prognosis occurred in patients older than 80 years; a systolic blood pressure of less than 80 mmHg on admission; a prior history of hypertension, angina, or previous MI; and an operating time of greater than 4 hours. Other risk factors include a systolic blood pressure less than 100 mmHg at the end of surgery and blood loss greater than 11,000 mL. Retroperitoneal rupture was more likely to be associated with a higher rate of survival. Elective surgical intervention should be considered if the size of the aneurysm changes rapidly or if its diameter is greater than 5.5 cm.

B. Preoperative Evaluation and Preparation

B.1. Which preoperative laboratory tests would you require for this patient?

The patient should have the following laboratory tests as part of the preoperative evaluation: complete blood count and platelet count, serum electrolytes, blood urea nitrogen (BUN), creatinine, and coagulation profile. Chronic hypercarbia may be gleaned from the serum bicarbonate value. A chest radiograph will help ascertain whether signs of heart failure, pulmonary disease, or acute pneumonia are present. Spirometry should be considered in the patient with severe disease and those in whom an adequate medical history is not available. In addition, spirometric data may be useful in assessing the effects of inhaler therapy.

An ECG should be obtained because this patient displays multiple risk factors for ischemic disease. The ECG is a sensitive and simple screening test for active cardiac conditions, such as unstable coronary syndromes and significant arrhythmias, which necessitate further management prior to proceeding to surgery. Additionally, preoperative laboratory tests should be defined by positive findings on history and physical exam.

Edwards AF, Forest DJ. Preoperative laboratory testing. *Anesthesiol Clin*. 2018;36(4):493–507.

B.2. What is the significance of the preoperative ECG? Would you wish to pursue a preoperative cardiac workup? What tests would you request, and what

would they tell you?

The patient's preoperative ECG is consistent with a prior inferior wall MI. Patients with a history of a prior MI or angina in conjunction with an abnormal ECG have a fivefold increase in postoperative mortality when compared with those with no clinical indication of CAD. This patient's history of claudication suggests peripheral vascular disease. Peripheral artery disease is associated with a fourfold increase in risk for MI and a twofold to threefold increase in risk of stroke. In selected patients with severe or unstable cardiac ischemia, evaluation may be needed to assess if prior myocardial revascularization is indicated.

When coronary angiography was performed on 1,000 patients undergoing elective peripheral vascular surgery, it was revealed that more than half of the patients had significant CAD (greater than 50% stenosis), and 33% had severe stenosis (greater than 70%). Of the asymptomatic patients with no history or electrocardiographic evidence of ischemic heart disease, 15% had severe CAD and 22% of these seemingly normal patients had impaired left ventricular function. Hertzer et al. found that only 8% of patients undergoing elective vascular surgery had normal coronary arteries.

A comparison of this patient's current ECG with a prior ECG may aid in assessing the timing of the previous infarction if the history alone is not helpful. The 2014 update to the joint AHA/ACC guidelines concerning perioperative cardiovascular assessment suggest incorporating clinical risk factors, exercise tolerance, and surgical risk when determining whether further testing is necessary. Vascular surgeries, such as AAA repair, are categorized as high-risk procedures. In addition, clinical risk factors include a history of ischemic disease, compensated or prior heart failure, cerebrovascular disease, diabetes mellitus, and renal insufficiency. The algorithm for the cardiac assessment of patients undergoing surgical procedures

associated with a high perioperative cardiac risk is shown in **Figure 10.2**.

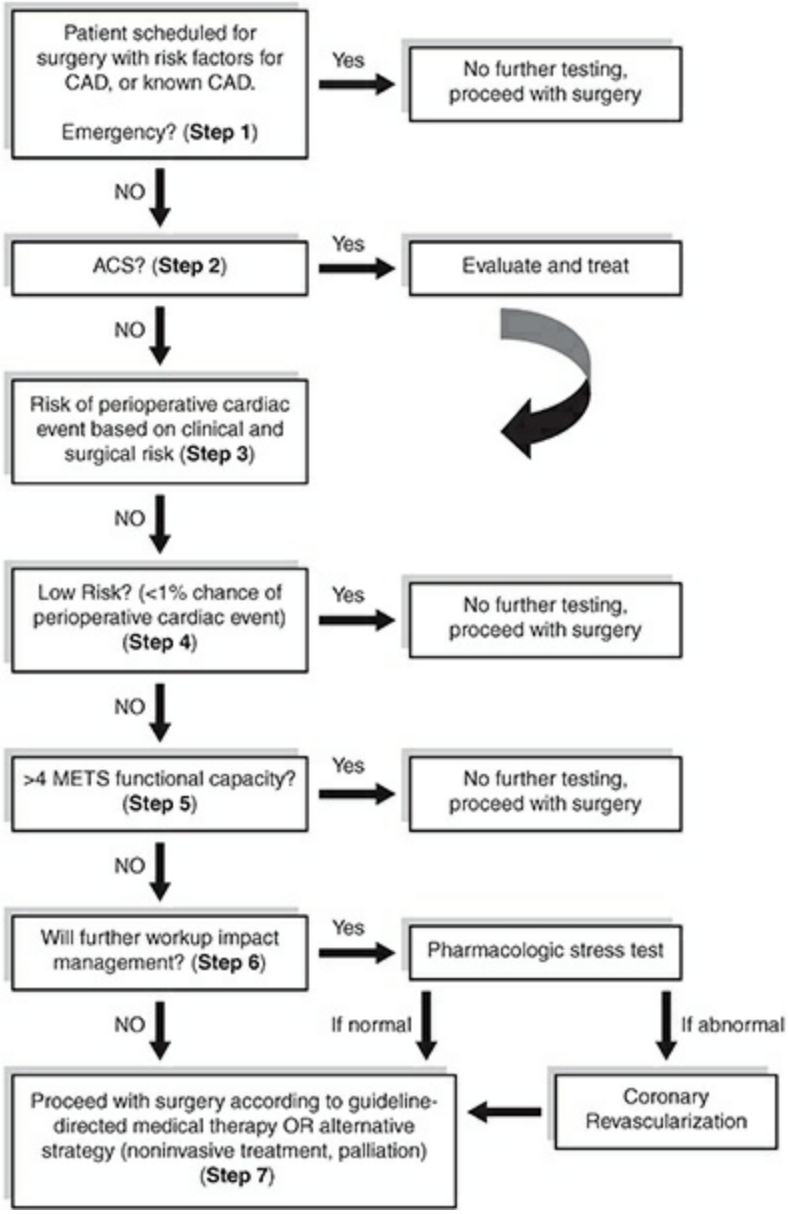

FIGURE 10.2. Stepwise algorithm for preoperative assessment for patients with coronary artery disease (CAD) undergoing noncardiac surgery. ACS, acute coronary syndrome; METS, metabolic equivalents. (*Reprinted with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guidelines on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* Circulation*. 2014;130:2215–2245. Copyright © 2014 American Heart Association, Inc.*)

Many vascular surgery patients are unable to undergo

exercise stress testing because of limitations presented by their cardiac, pulmonary, or peripheral vascular disease. A dipyridamole-thallium stress test or a dobutamine stress echocardiogram is a pharmacologic test to assess ischemic potential. Dipyridamole causes vasodilation of normal coronary arteries. This results in a "steal" of blood flow from the area beyond a coronary stenosis. Blood flow redistributes as the drug dissipates.

Positive results on preoperative stress testing may not always necessitate revascularization. There is evidence to suggest that vascular patients who undergo coronary revascularization have an increased risk of periprocedural and long-term complications. The decision to perform coronary revascularization procedures, rather than employ medical management, should be undertaken in close consultation with a cardiologist and a cardiac surgeon. Recent evidence also suggests that patients at significant risk for ischemic heart disease may benefit from an endovascular approach, if anatomically feasible.

Perioperative cardiovascular care for noncardiac surgery is clearly evolving with the publication of large-scale clinical trials, and the focus on determining the value of different assessment and treatment strategies to patient clinical outcome and long-term improvement in quality of life can be better determined. Although there is a growing trend to move from extensive preoperative testing to more targeted surveillance and treatment, the key question will be ensuring that patients make the most informed decision regarding the indication for surgery given the patient's trajectory for recovery, including returning to baseline or improved functional status and health.

B.3. Is it necessary to evaluate this patient's pulmonary status?

The patient's smoking history and the chronic changes present on his chest radiograph are evidence of chronic obstructive pulmonary disease (COPD). Provided the patient is minimally symptomatic and has good functional status, a detailed history and thorough physical exam can provide significant information regarding pulmonary status. A chest radiograph can be particularly useful at detecting underlying lung infection. If the radiograph displays the absence of acute pulmonary processes, as in this patient, further pulmonary testing may not be indicated. In the patient with severe signs and symptoms of COPD, ABG analysis can evaluate the patient's ability to oxygenate and ventilate. Patients with severe COPD tend may be chronically hypercarbic and hypoxic. A preoperative ABG can guide perioperative ventilatory management and predicting the likelihood of postoperative mechanical ventilation in these patients.

In those patients with severe disease, particularly those with poor functional status and significant findings on physical exam

and chest radiograph, pulmonary function testing may be indicated. Preoperative pulmonary function testing evaluates baseline forced vital capacity (VC) and FEV_1. Maximum midexpiratory flow rate (MMEFR) is an effort-independent value that is a sensitive index of small airway obstruction. Peak expiratory flow rate is related to the FEV_1 and MMEFR, although often it is less reproducible. These tests should be performed before and after bronchodilator therapy to assess reversibility of airway obstruction. A 15% improvement is considered a positive response.

This patient is a 2-pack-per-day smoker with dyspnea on exertion, and the anticipated surgery required an upper abdominal incision. These factors likely affect his baseline pulmonary function and presage postoperative ventilatory problems. A VC less than 50% of predicted, or less than 2 L total, is an indicator of increased risk of pulmonary complications as a VC at least 3 times the tidal volume is necessary for an effective cough. FEV_1 less than 2 L, maximum breathing capacity less than 50% of predicted, and MMEFR less than 50% of predicted are also values associated with increased risk of postoperative mechanical ventilation.

Discontinuation of smoking for 48 hours preoperatively increases oxygen tissue availability and, if stopped 4 to 6 weeks before surgery, may decrease postoperative complications. Pulmonary function tests should be viewed as a management tool to optimize preoperative pulmonary function should not be the sole means of assessing risk. Functional status, severity of illness, and comorbid medical conditions also have significant predictive value.

B.4. Preoperative arterial blood gas (ABG) measurement shows pH, 7.35; $PaCO_2$, 47 mmHg; and PaO_2, 68 mmHg on room air. What is the significance of this result?

The normal value for Pao_2 in young adults ranges from 85 to 100 mmHg with an average of about 95 mmHg. This value falls steadily with aging to an average Pao_2 of 80 mmHg at age 60 years. One formula for estimating Pao_2 is $Pao_2 = 100 - (\text{age in years} / 3)$. The normal range for $PaCO_2$ is 37 to 43 mmHg and is unaffected by aging. For every 10 mmHg increase in $PaCO_2$, pH decreases by 0.05. For every 10 mmHg decrease in $PaCO_2$, pH increases by 0.1.

The main causes of arterial hypoxemia are hypoventilation, diffusion impairment, shunting, and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch. The major causes of hypercarbia or carbon dioxide retention are hypoventilation and $\dot{V}/\dot{Q}$ mismatch. Mild $\dot{V}/\dot{Q}$ mismatch does not necessarily cause an increase in arterial CO_2. This is due to the fact that CO_2 is a highly diffusible gas and central chemoreceptors compensate for increasing CO_2 tension by causing an increase in ventilation. The same is not true of arterial oxygenation, however, as even mild degrees of $\dot{V}/\dot{Q}$ mismatch can lead to hypoxemia.

The assessment of this patient's blood gas analysis reveals moderate hypoxemia with a mildly elevated CO_2 tension. The pH is consistent with a mild respiratory acidosis. The most likely reason for this patient's blood gas abnormality is $\dot{V}/\dot{Q}$ mismatch, secondary to COPD, which is likely the result of his extensive smoking history.

B.5. How would you measure creatinine clearance in this patient, and what is its value in this case?

Preoperative renal dysfunction indicates potential postoperative impairment. Despite maximal medical management, including hemodialysis, acute renal failure (ARF) after aortic reconstruction carries a mortality of greater than 30% postoperatively. Maintenance of intravascular volume and adequate blood pressure are the best means of avoiding postoperative renal failure. This complication is more likely in patients requiring a suprarenal cross-clamp but also occurs with infrarenal clamping.

Operative mortality is 19% when aortic reconstruction is performed on patients with a creatinine greater than 2 mg per dL, but mortality is only 4.6% if the levels are lower. Therefore, if the creatinine is greater than 2 mg per dL, reversible factors, such as renal stenosis, should be investigated. The most direct measurement of glomerular filtration rate (GFR) is the measurement of creatinine clearance. Although BUN and serum creatinine are related to renal function, they are altered by such nonrenal factors as protein metabolism, diet, liver dysfunction, or skeletal muscle mass. A 24-hour collection of urine is measured, and the following equation is used to calculate GFR: $GFR = U \times V / P$. U, urine concentration of creatinine (mg per dL); V, volume of urine measured (mL per minute); P, plasma concentration of creatinine (mg per dL). A 2-hour sample collected through a Foley catheter has been shown to correlate well with a 24-hour sample collection.

In spite of the widespread use of creatinine clearance to detect renal impairment, it should be noted that as much as 50% of functional nephron mass may be lost before changes in creatinine concentration become apparent. As a result, patients

with lower baseline creatinine concentration can have acute kidney injury (AKI) despite normal creatinine clearance. Several novel biomarkers are being studied now that may be able to detect AKI earlier than traditional markers such as urinary output and serum creatinine. Neutrophil gelatinase-associated lipocalin (NGAL) is a protein found in excess in urine and plasma in patients with AKI as many as 48 hours prior to increase in serum concentration. Serum cystatin C, a protease inhibitor that is less affected by sex, age, muscle mass, and diet than creatinine, also allows earlier detection of AKI.

B.6. Describe the blood flow to the spinal cord. What is its relevance to surgery involving the abdominal aorta?

The spinal cord has a system of longitudinal arteries and a system of transverse arteries as shown in **Figure 10.3**. Anatomic studies have shown that the most important longitudinal arteries are a single anterior spinal artery supplying 75% of the cord and a pair of posterior spinal arteries supplying 25% of the cord. Although in humans the anterior spinal artery is a continuous vessel, modern anatomy has emphasized the reinforcing transverse arteries rather than the meager longitudinal vessels. The territory supplied by the anterior spinal artery is divided into three functionally distinct levels: cervicodorsal, intermediate or midthoracic, and thoracolumbar. The cervicodorsal region receives its blood supply from the vertebral, subclavian, thyrocervical, and costocervical arteries. The midthoracic region is supplied by a meager left or right intercostal artery arising

between the fourth and the ninth thoracic vertebrae. The thoracolumbar region of the anterior spinal artery receives the bulk of blood supply from one of the intercostal arteries—the *arteria radicularis magna* or the *artery of Adamkiewicz*. It arises at the level of T5–T8 in 15%, T9–T12 in 60%, L1 in 14%, and L2 in 10% of patients. The *arteria radicularis magna* is often involved in the surgical repair.

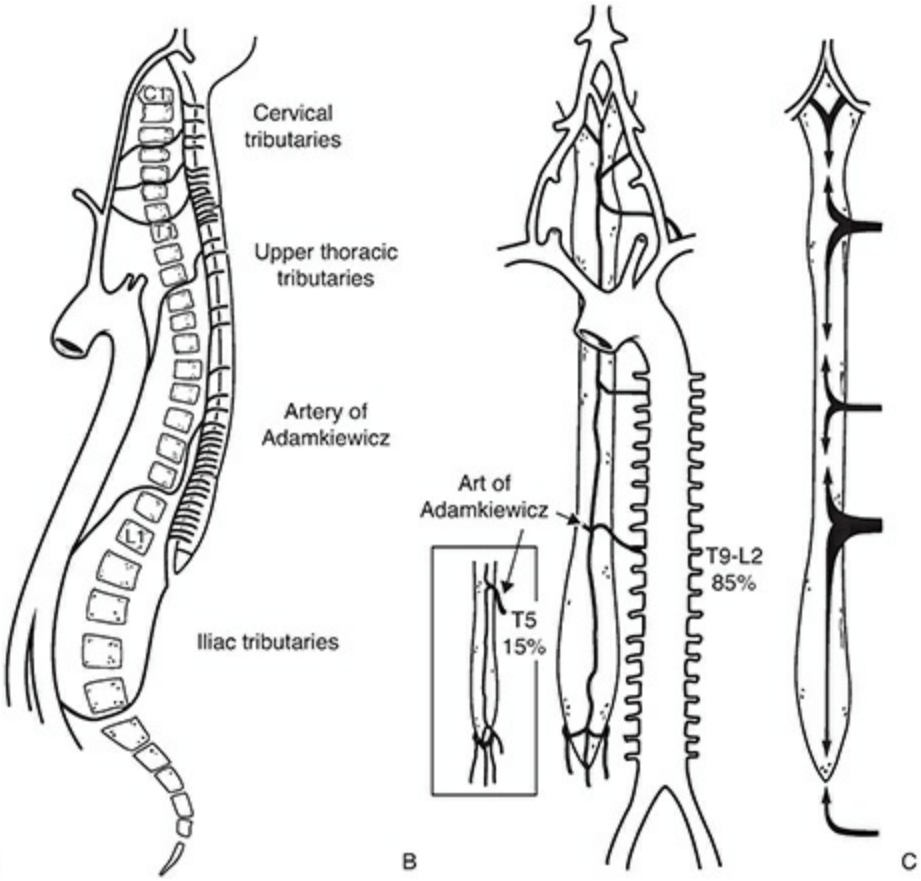

FIGURE 10.3. Diagram to show components of the anterior spinal artery. A. Arterial view. **B.** Anterior-posterior view showing origins of artery of Adamkiewicz. **C.** Schematic representation of direction and volume of flow from nutrient vessels supplying the anterior spinal artery. Size of arrows is proportional to flow contribution. (*Adapted from Bromage PR.* Epidural Anesthesia*. Philadelphia, PA: WB Saunders; 1978:50–54. Copyright © 1978 Elsevier. With permission.*)

The anterior spinal artery is smaller above than below the entry of the *arteria radicularis magna*. Resistance to blood flow is 51.7 times greater going up the anterior spinal artery as compared with coming down the artery. Therefore, distal aortic

perfusion during thoracic aortic cross-clamping protects the spinal cord below the *arteria radicularis magna* but not above it. This is why paraplegia still occurs in approximately 2% to 15% of patients having thoracic aortic surgery with distal aortic perfusion. However, reimplantation of intercostal arteries during surgery has been shown to reduce the incidence of neurologic injury.

Spinal cord ischemia can develop during aortic cross-clamping as a result of one of two mechanisms: decreased blood flow through critical intercostal arteries (important in infrarenal cross-clamping) and hypotension in the aorta distal to the cross-clamp, leading to a "steal" phenomenon through the collateral circulation to the distal aorta (important in thoracic cross-clamping). There are many strategies to prevent spinal cord ischemia: moderate hypothermia (local and systemic), cerebrospinal fluid drainage, and femoral–femoral bypass. The only definitive methods of preservation are expeditious surgery and maintenance of cardiac output.

B.7. How do you detect spinal cord ischemia?

Evoked potential is used in thoracoabdominal surgery to detect spinal cord ischemia. Two varieties of evoked potential are used in thoracoabdominal aortic aneurysm repair. SSEPs travel through the dorsal root ganglia to the posterior columns of the spinal cord. The potentials continue along the lemniscal pathways on to the thalamus and the cortex. Comparison of the latency and amplitude of the potentials, tested minutes apart, define the degree of change in the SSEP. Temperature,

anesthetic depth, and changes in blood flow can alter the evoked potentials. Changes in blood flow through the anterior spinal artery are not reflected in the posterior columns. It is possible, therefore, to have paralysis with normal SSEPs.

Ischemia of the spinal cord is indicated by increases in latency and/or decreases in amplitude of evoked potential tracing. The typical SSEP trace is shown in **Figure 10.4**, and its response to aortic cross-clamping is shown in **Figure 10.5**. The latency increases as early as 4 minutes following aortic cross-clamping, with progress to cessation of spinal cord conduction within 7 minutes of cross-clamping. Return of spinal cord conduction occurs 47 minutes following distal aortic reperfusion, with return to normal spinal cord conduction within 24 hours after operation. It has been shown that the loss of SSEP signals for longer than 14 to 30 minutes was associated with postoperative neurologic deficit.

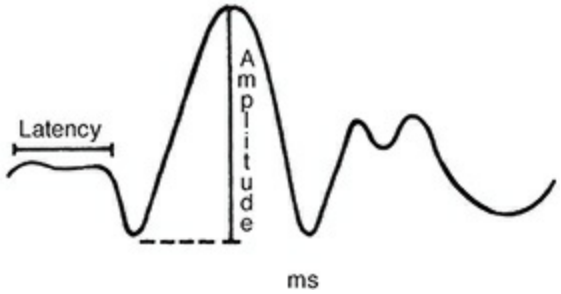

FIGURE 10.4. Typical SSEP trace. (*Reprinted with permission from Cunningham JN Jr, Laschinger JC, Merkin HA, et al. Measurement of spinal cord ischemia during operations upon the thoracic aorta: initial clinical experience.* Ann Surg. *1982;196[3]:285–296.*)

Motor evoked potentials (MEPs) relate monitor areas of the cord supplied by the anterior spinal artery. To assess MEP, patients require partial paralysis and light plane of anesthesia. Both of these requirements are suboptimal anesthetic options for a thoracoabdominal aortic aneurysm repair.

Finally, the signal-to-noise ratio of evoked potentials make interpretation of the data in the operating room more difficult and less reliable.

B.8. What are the various surgical approaches to repair an AAA?

The classic approach to the abdominal aorta is through a vertical

anterior midline incision with a transperitoneal approach to the retroperitoneal space. This gives access to all major arteries in the abdomen and pelvis. A transverse abdominal incision (supraumbilical) is also adequate for a transperitoneal approach. Although the entry is slower, there is less pain and pulmonary impairment postoperatively. The transperitoneal approach, with the necessary exposure of the abdominal organs, causes major heat and fluid loss and prolonged postoperative ileus.

The retroperitoneal approach is performed through a left flank incision with the patient in the right lateral decubitus position. In some studies, this approach has been shown to have less respiratory and wound complications, less postoperative ileus, less blood loss, lower fluid requirements, and earlier discharge from the hospital. Monitoring and line placement must take the lateral position into consideration.

A less invasive approach to aortic aneurysm repair is endovascular aneurysm repair (EVAR) surgery. The EVAR technique has the advantage of a shorter length of stay (LOS) relative to open repair and a shortened recovery period. Due to the cost of the stent grafts and imaging equipment, this does not necessarily translate to overall cost reduction. Anatomic issues can significantly complicate stent placement. A common problem is iliac and common femoral arteries that are of insufficient caliber. Successful aneurysm exclusion has been achieved in 50% to 90% of selected cases. Problems of the procedure include vessel perforation, inability to seal the aneurysm (endoleaks), and inability to advance the device past the iliac artery, ultimately necessitating the conversion to an open repair.

In the EVAR-1 and Dutch Randomized Endovascular Aneurysm Management (DREAM) randomized clinical trials, reinterventions were required in 2 to 3 times as many patients in the endovascular group as in those who had open repair.

Endovascular leaks are one of the leading causes of postoperative complications necessitating reintervention in up to 15% of patients. The various types of endovascular leaks are shown in **Figure 10.6**. In the EVAR-1 trial, postoperative complications were 5 times more frequent with endovascular repair when compared to the open repair group. This highlights the importance of close follow-up in these patients and necessitates periodic reimaging for the remainder of these patients' lives. It is also worthy to note that endovascular repair has not been shown to improve survival in patients who have medical contraindication to open repair.

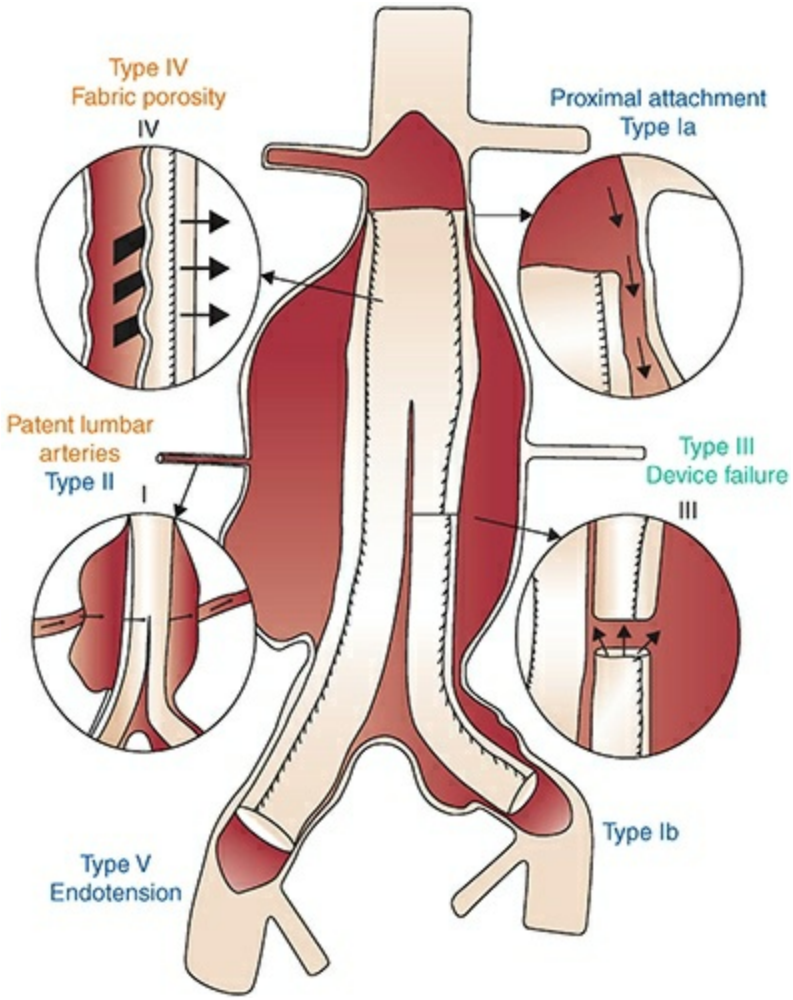

FIGURE 10.6. Types of endovascular leaks. (*Illustrations courtesy of the Society for Vascular Surgery ©.*)

In contrast, when compared with open abdominal repair in the perioperative period, endovascular surgery is associated with 60% less blood loss, and decreased ventilator days, decreased ICU LOS and decreased hospital LOS. Currently, overall mortality of the procedures appears similar, with slightly a slight decrease in morbid cardiac events (6% in the open repair group vs. 4.8% in the endovascular group).

B.9. How does the choice of surgical technique affect the anesthetic management?

Debate exists over the advantages of general anesthesia compared with regional anesthesia or combined approaches to the management of patients with CAD. Meticulous control of heart rate and blood pressure should be the goals regardless of technique. Regional anesthesia blunts sympathetic tone, potentially decreasing coronary perfusion pressure; general

anesthesia increases in sympathetic stimulation with intubation and emergence. Regional anesthesia may decrease hypercoagulability and thrombotic events in patients undergoing vascular surgery, and confers significant postoperative pain control.

The goals for the management of patients with CAD include prevention and mitigation of sympathetic stimulation. This can be achieved by using β-antagonists, narcotics, or volatile anesthetics during the perioperative period. Coronary perfusion pressure, defined as aortic diastolic pressure minus left ventricular end diastolic pressure, should be meticulously maintained. Myocardial contractility and heart rate should not be increased as this will increase oxygen demand.

B.10. How would you premedicate this patient?

Typically, a low-dose anxiolytic is likely to be sufficient premedication for most patients. Any other preoperative medications can be given intravenously upon arrival to the operating room. If oral medications are used, they may be taken with a sip of water 1 hour prior to the procedure.

Additional specific pharmacologic regimens should be tailored to individual patient needs. Various medications and combinations have been used, including narcotics, anticholinergics, barbiturates, and benzodiazepines. No single agent or combination has been demonstrated to be superior to

others. Respiratory depressants should be avoided in patients with chronic hypercapnia).

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1112–1143.

C. Intraoperative Management

C.1. Would you use an arterial line? What are the complications of arterial line placement?

Arterial pressure monitoring is exceedingly important in this case, from induction of anesthesia through emergence. In this patient with a history of CAD, an arterial line is particularly important for blood pressure management during induction and should be placed prior to the institution of anesthesia.

Vascular insufficiency and infection are the two major complications of arterial line placement. Catheter size and duration of cannulation are implicated in vascular occlusion. The causes of most vascular injuries are embolic. Radial artery cannulation is a low-risk, high-benefit method that can be used to closely monitor blood pressure in this patient. Open AAA repair is frequently associated with blood pressure lability, particularly on clamping and unclamping, and arterial blood pressure monitoring is particularly helpful in this situation. In addition, frequent sampling of ABGs to assess hematocrit, ventilation, perfusion, electrolyte levels, glucose, and level of anticoagulation may be necessary. If a radial artery catheter cannot be placed, cannulation attempts can be made at the brachial and axillary arteries. Concerns have been raised that brachial artery cannulation might be inadvisable given the lack of adequate collateral supply to the forearm and hand. In practice, however, complications from brachial artery cannulation have been reported rarely and the risk of vascular

insufficiency appears to be no different from that of radial cannulation. Axillary artery cannulation, however, may carry an added risk of vascular insufficiency and nerve injury from thrombosis and hematoma formation. This added risk is likely due to the fact that the axillary neurovascular bundle travels in the confined space of the axillary sheath.

Handlogten KS, Wilson GA, Clifford L, et al. Brachial artery catheterization: an assessment of use patterns and associated complications. *Anesth Analg*. 2014;118(2);288–295.

C.2. What various monitors are available for myocardial ischemia? Is a pulmonary artery catheter (PAC) helpful in determining the occurrence of ischemia?

Monitoring of the patient undergoing aortic reconstruction surgery should be aimed at preserving myocardial, pulmonary, and renal function as well as maintaining intravascular volume. Therefore, it is mandatory, particularly in this patient with known CAD, to monitor for myocardial ischemia and maintain volume status in the face of fluid shifts. Monitoring of the ST segments of the V_5 and II leads of the ECG is the most common method used to assess for intraoperative myocardial ischemia. However, in some studies, this alone was insufficient to recognize from 40% to 75% of intraoperative ischemic events detected by wall-motion abnormalities seen with a two-dimensional transesophageal echocardiogram.

Monitoring the pulmonary artery (PA) pressure tracing for the appearance of V waves and increasing PCWP with decreasing cardiac output are other methods of detecting intraoperative myocardial ischemia. Unfortunately, the PAC is not a particularly sensitive technique for detecting ischemic events. Wall-motion abnormalities, detected by transesophageal echocardiography (TEE), are highly sensitive markers of myocardial ischemia and appear earlier than either ST segment

or PAC waveform changes.

A microcomputer-based ECG reader (ST-segment trend monitor) also has been advocated as a monitor of myocardial ischemia. These systems can pick up more subtle changes in ST segments than by simple observation. Multilead ECG systems are most helpful. The most sensitive means for monitoring patients to determine the development of myocardial ischemia at its earliest presentation is, in fact, wall-motion abnormalities demonstrated by two-dimensional TEE. As yet, no improvement in outcome has been demonstrated by the use of any of these monitors.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1112–1143.

C.3. What additional monitors would you employ?

An invasive monitor of volume status is recommended in patients undergoing open AAA repair. The choice of invasive monitoring, central venous pressure (CVP) or PAC can be based on the level of aortic cross-clamping and the severity of the patient's underlying cardiac disease. The CVP is informative at low and high extremes. As the right side of the heart is usually a compliant system, large shifts of intravascular volume may occur without significant CVP alteration. The PCWP, obtained by a PAC, may be more accurate in determining intravascular volume status. In addition, the PAC allows for measurement of

cardiac output, helpful during aortic cross-clamp in the patient with left ventricular dysfunction. In this situation, CVP may not accurately represent left-sided pressures reflected by the PCWP. This is also true of the patient with significant pulmonary disease. The decision of PAC placement can also be influenced by the level at which the cross-clamp is applied. Suprarenal and supraceliac cross-clamping are associated with greater hemodynamic lability than infrarenal clamp application. Thus, PAC insertion may be of greater utility during proximal procedures, particularly if cardiac dysfunction is also present.

The American Society of Anesthesiologists (ASA) practice guidelines support the prudent use of a PAC in select situations. PAC should be employed in high-risk procedures (cardiac, aortic reconstruction, anticipated hemodynamic instability, and large-volume fluid shifts), used in patients with a minimal risk of complication from catheter placement, and used when appropriate staff (familiar with PAC troubleshooting) is available. Furthermore, when such monitoring is employed, it should only be utilized by those who are trained to appropriately interpret and intervene on the data.

TEE is another monitoring modality that is being increasingly utilized in aortic reconstruction procedures. TEE has several potential benefits over other invasive monitors such as the PAC and the CVP. Currently, TEE is the most sensitive modality for detecting myocardial ischemia. It is able to detect regional wall motion abnormalities well before changes appear on other heart monitors such as the ECG or PAC. In addition, TEE allows for detailed analysis of valvular dysfunction, which may significantly alter perioperative anesthetic management. The ASA practice guidelines state the use of perioperative TEE may be appropriate when the nature of the planned surgery or the patient’s cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise. In

addition, TEE should be used when unexplained life-threatening circulatory instability persists despite corrective therapy.

Another useful measure of intravascular volume status, as well as renal blood flow, is the collection of urine through a Foley catheter. Urine output will diminish with decreasing glomerular filtration caused by decreased renal blood flow. Assessment of urine output, provided kidney function is unimpaired, can be an accurate and cost-effective measure of volume status.

Temperature monitoring should also be employed as with any case under general anesthesia. Body temperature should be closely monitored and aggressively maintained. These patients can undergo tremendous heat and insensible fluid loss as a result of the enormous incisional surface area exposed to room air. If forced hot air thermal blankets are used, they are contraindicated on the lower extremities when an aortic cross-clamp is applied. They may, however, be used on the upper body throughout the procedure, along with fluid warmers, to maintain temperature.

Finally, pulse oximetry, capnography, and mass spectral analysis of inhaled agents also should be utilized. This data combined with ABG analysis, will permit efficient ventilatory management and accurate delivery of anesthetic gases.

C.4. Is there a role for somatosensory evoked potential (SSEP) monitoring during aortic clamping?

SSEPs can be used during aortic reconstruction surgery to monitor spinal cord function. For thoracic aortic surgery, SSEPs remain stable if the distal aortic pressure is maintained above 60 mmHg. At lower pressures, SSEPs gradually disappear. In one study, paraplegia occurred in 5 of 6 patients whose SSEPs remained absent for more than 30 minutes. Patients should be monitored for SSEP changes if they are at higher risk of spinal cord ischemia. SSEPs are most commonly altered in patients with baseline risk for neurologic complications. Proximal (especially thoracic) or prolonged cross-clamp placement increases risk for neurologic embarrassment. With a conduction block in place, such as epidural or spinal anesthesia, SSEPs will be ablated.

C.5. How would you anesthetize this patient for an open repair of the aorta? What techniques could be used for an endovascular aortic aneurysm repair? Discuss the various anesthetic techniques that can be employed for this surgery.

All anesthetic techniques have been used and advocated for abdominal aortic surgery. General anesthesia, regional blockade,

or combined general and regional techniques, have all have been described. Outcome studies are equivocal among the various techniques, affording flexibility in the anesthetic approach to these patients. Tailoring this plan to each patient's medical condition is the most effective strategy. The primary goals in the anesthetic management of patients undergoing aortic reconstruction include protection of myocardial, neurologic, and renal function.

When combined regional (epidural) and general anesthesia techniques are employed, fluid requirements may be increased in order to maintain hemodynamic stability. Typically, this additional fluid requirement can be up to 2 L per case. In addition, neuroaxial sympathectomy can predispose to hypotension upon clamp removal. The use of α-agonist vasoconstriction, will counteract the vasodilatory effects of epidural anesthesia and may reduce fluid requirements. In addition, the placement of an epidural catheter will afford optimal postoperative pain management of the patient.

Anesthesia for endoluminal repair has ranged from general, general combined with epidural anesthesia, lumbar epidural with sedation, or sedation with local anesthesia. Considerations for choice of anesthesia include the need for patient immobility, the need for systemic anticoagulation (heparin), the possibility of exsanguination, and prevention of heat loss. Blood pressure stability is imperative during aortic balloon occlusion, to prevent distal migration of the stent. If neuraxial techniques are used, coagulation status must be carefully monitored in the perioperative period.

C.6. This patient is to be heparinized intraoperatively, and anticoagulation may be continued postoperatively. Is this a contraindication to the preoperative placement of either an epidural or intraspinal catheter? What if the patient is receiving anticoagulants in the preoperative period?

Epidural catheter placement in the setting of anticoagulation increases the risk of an epidural hematoma and subsequent neurologic deficit. Procedural risk of spinal cord ischemia will confound the diagnosis of neuroaxial hematoma and may preclude the placement of an epidural catheter. However, an epidural catheter can be placed with a relative degree of confidence in patients who are not anticoagulated at the time of the puncture but who will receive anticoagulation later. Current guidelines suggest administration of intravenous heparin at least 1 hour after neuraxial catheter placement. Furthermore, in patients who have undergone systemic heparinization, heparin should be discontinued for at least 2 to 4 hours prior to epidural catheter removal. Coagulation status must be assessed prior to catheter manipulation, and frequent lower extremity neurologic assessment must continue for at least 12 hours after catheter removal.

Low molecular weight heparins (LMWHs), which are increasingly being employed for thromboprophylaxis, pose a significant potential for increased risk of neuraxial hematoma. In

patients receiving these drugs, needle placement should occur at least 12 hours after the last dose of LMWH. If higher doses have been used (e.g., enoxaparin 1 mg per kg twice daily), needle placement should be delayed at least 24 hours. It is currently recommended that indwelling catheters be removed prior to initiation of LMWH thromboprophylaxis. In addition, the first dose should be administered at least 2 hours after catheter removal.

In those patients who are on chronic anticoagulation with oral warfarin, several recommendations are applicable with regard to perioperative management of neuraxial anesthesia. Oral warfarin should be discontinued at least 4 to 5 days prior to surgery. International normalized ratio (INR) should be measured at least 24 hours prior to the procedure. Neuraxial manipulation must commence only when INR has normalized. Neurologic testing of sensory and motor function should be performed routinely during epidural analgesia for patients on warfarin therapy. The type of analgesic solution should also be tailored to minimize the degree of sensory and motor blockade so as to allow frequent neurologic monitoring. As thromboprophylaxis with warfarin is reinitiated in the postsurgical period, neuraxial catheters should be removed while the INR is less than 1.5.

Fibrinolytic and thrombolytic drugs predispose to a high risk of hematoma formation in conjunction with neuraxial technique. Recent American Society of Regional Anesthesia and Pain Medicine (ASRA) practice guidelines, addressing regional anesthesia in the anticoagulated patient, recommend avoidance of all neuraxial manipulation in patients who have received thrombolytic or fibrinolytic therapy. There appears to be no clear data detailing the length of time neuraxial puncture should be avoided after discontinuation of these drugs.

Although the use of antiplatelet agents such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) do not

contraindicate the use of neuraxial techniques, care should be exercised when combinations of anticoagulants and antiplatelet drugs are used. Such combinations increase the risk of hemorrhagic complications in the perioperative period. Neurologic testing of sensory and motor function should be routinely performed on patients with indwelling catheters undergoing simultaneous anticoagulation.

C.7. What are your plans for fluid and blood replacement during surgery?

Fluid replacement should maintain the patient's intravascular filling pressures. Isotonic crystalloid should be used because there is little evidence to suggest that colloid administration poses any advantage over crystalloid administration.

There has been much controversy in recent literature regarding the use of "liberal" versus "restrictive" fluid protocols during open abdominal procedures. Most of this data has been gathered on patients undergoing bowel procedures but applicable to the patient undergoing open AAA repair. There is a lack of consensus regarding the optimal fluid management protocol. What has emerged from this data is the use of fluid therapy to optimize tissue perfusion rather than predefined volume replacement.

Current paradigm suggests a shift away from the classic model of calculation of nothing by mouth (NPO) fluid deficit, intraoperative insensible losses, and third-space losses. Increasingly, most clinicians are employing "demand-related"

regimens with the goal of maximizing tissue blood flow while minimizing interstitial edema. Surrogates for intravascular losses include visual blood loss, vital signs, urinary output, hematocrit, acid–base status, and invasive hemodynamics (as available). Insensible losses are replaced at 0.5 to 1 mL/kg/hr, a significantly lower rate than what has previously been utilized. The traditional concept of a third-space compartment is increasingly being abandoned. Instead, it is now recognized that fluid shift into the interstitium is a function of crystalloid overload and deterioration of vascular integrity.

The concurrent use of an autotransfuser (e.g., Cell Saver) decreases the need for exogenous blood transfusions. Liberal blood product administration should be avoided due to increased risk of immune suppression, hemolytic transfusion reactions, infectious vector transmission, and lung injury.

C.8. What are the hemodynamic changes of aortic cross-clamp placement? What efforts can be made to minimize these changes both before and during cross-clamping? If the patient develops ST-segment depressions with a rising pulmonary capillary wedge pressure (PCWP) during cross-clamp, what maneuvers should be taken?

The systemic hemodynamic response to aortic cross-clamping is shown in **Figure 10.7**.

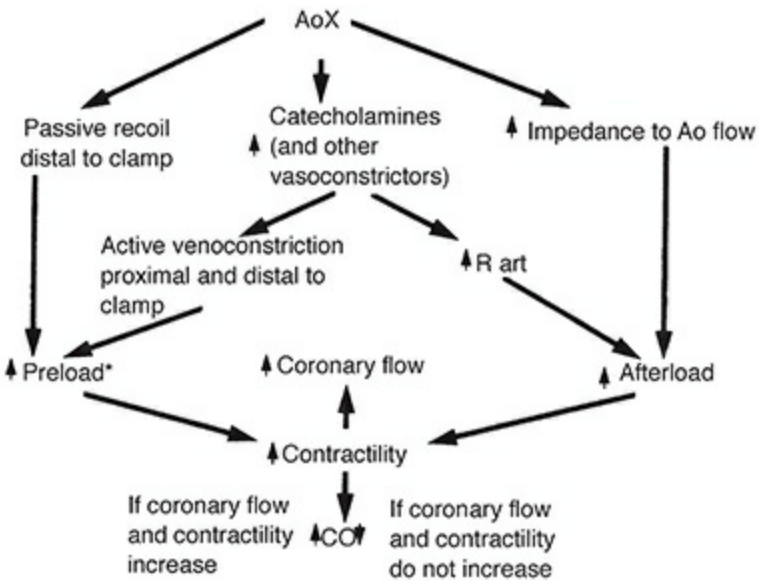

FIGURE 10.7. Systemic hemodynamic response to aortic cross-clamping (AoX). Ao, aortic; R art, arterial resistance; ↑ and ↓, increase and decrease, respectively. *Different patterns are possible. (*Reprinted with permission from Gelman S. The pathophysiology of aortic cross-clamping and unclamping.* Anesthesiology. *1995;82:1026–1060.*)

Arterial hypertension is the most dramatic and consistent result of the application of an aortic cross-clamp. This is the result of sudden increases in afterload and left ventricular end-diastolic wall stress. Usually, these changes are accompanied by decreased cardiac output. Some of these changes may also be due to redistribution of blood volume from the venous vasculature to the upper part of the body. All of the previously stated factors are more profound in the case of supraceliac or thoracic cross-clamp placement. Variations in blood volume status or splanchnic vascular tone are affected anesthetic depth, anesthesia technique, and intravascular volume status. These factors all determine the pattern of blood volume redistribution.

A sudden increase in afterload can lead to left ventricular failure, particularly in the patient with a noncompliant left ventricle. Ideally, the patient should have lower filling pressures for the half hour prior to cross-clamp placement. This mitigates the adverse response to sudden increased afterload. The PAC is helpful in accurately assessing and maintaining preclamp values

for the left side of the heart. A potent anesthetic agent and/or a vasodilator such as nicardipine is used to revert afterload to near normal. This also helps increase the cardiac output and decrease stress on the left ventricle. If this is insufficient to reverse left ventricular failure, the addition of an inotrope may be necessary.

The increase in afterload, following cross-clamp placement, may also result in myocardial ischemia. Ischemia, reflected as a rising PCWP and ST-segment depressions, can be managed with intravenous nitroglycerin, a potent dilator of the capacitance vessels. This drug is used to decrease left ventricular end-diastolic volume and left ventricular end-diastolic pressure. Decreasing left ventricular end-diastolic pressure also decreases the transluminal pressure across the coronary vasculature and augments blood flow to the myocardium.

Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology*. 1995;82:1026–1060.

C.9. Because this case involves an infrarenal aneurysm, is renal blood flow affected with the placement of the cross-clamp? If an endovascular repair is chosen, what are the risks to the kidneys? Are there any treatment maneuvers that can be taken to minimize these risks in either repair?

ARF after aortic aneurysm repair is associated with a mortality of greater than 30%. Decreased renal function is observed in many patients after aortic cross-clamping, even when the clamp is placed distal to the renal arteries. Although it is clear that a suprarenal cross-clamp will decrease renal blood flow up to 80%, an infrarenal cross-clamp also causes a decrease in renal cortical blood flow with an associated decrease in GFR. The degree of decrease in urine output does not correlate with the

decrease in GFR nor does it predict postoperative renal failure. The most dangerous complication of alteration in renal blood flow is acute tubular necrosis and ARF.

The maintenance of cardiac output and adequate circulating blood volume is of cardinal importance in sustaining renal blood flow and in the prevention of renal failure. Low-dose dopamine (2 to 3 μg/kg/min) increases renal blood flow and may improve urine output, although decreased incidence of postoperative renal failure has not been proven. Renal protection may, however, be provided by the administration of mannitol (0.25 g per kg). The use of mannitol attenuates the reduction of renal cortical blood flow—before, during, and after renal ischemia—increases glomerular ultrafiltration flow, and is a hydroxyl free radical scavenger. Fenoldopam and furosemide may be utilized during aortic reconstruction procedures to minimize nephrotoxicity. Unfortunately, strong clinical evidence is currently lacking for any of these measures.

During endovascular repair, radiocontrast material may cause further insult to the kidneys. There is some suggestion that the use of a bicarbonate infusion or pretreatment with N-acetyl cysteine may be protective. It is prudent to minimize exposure to nonionic contrast or replace with gadolinium dimeglumine.

C.10. What are the hemodynamic consequences of aortic cross-clamp removal? What can be done to minimize the effects of removing the aortic cross-clamp? If the systemic blood pressure remains depressed after removal of the cross-clamp, what is the differential diagnosis? How would you diagnose and correct the problem?

The hemodynamic response to aortic unclamping is shown in **Figure 10.8**.

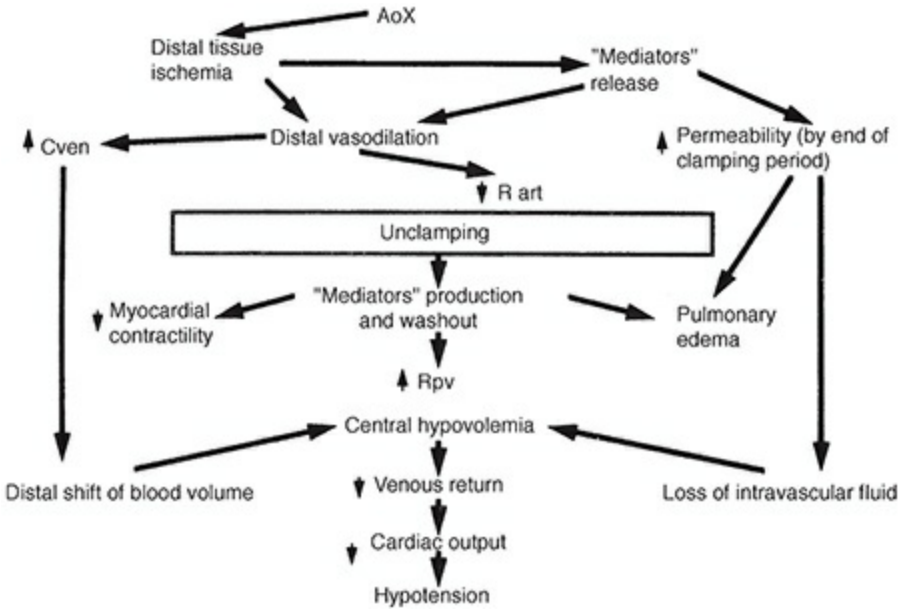

FIGURE 10.8. Systemic hemodynamic response to aortic unclamping. AoX, aortic cross-clamping; Cven, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance; ↑ and ↓, increase and decrease, respectively. (*Reprinted with permission from Gelman S. The pathophysiology of aortic cross-clamping and unclamping.* Anesthesiology. *1995;82:1026–1060.*)

During cross-clamping, blood flow to the lower extremities is grossly decreased. Metabolism switches from aerobic to anaerobic as ischemia develops. This results in maximal vasodilation and lactic acid production. When the cross-clamp is released, systemic vascular resistance and arterial blood pressure decreases dramatically. Peripheral vasodilation can result in relative volume depletion and hypotension. Vasodilation may

become systemic as the lactic acid is washed out of the extremities into the central circulation. This condition is sometimes known as “declamping shock.”

To minimize the hypotensive response, volume loading in the period prior to cross-clamp release is suggested to raise filling pressures to slightly above normal. Vasodilators such as nitroprusside and/or nitroglycerin during this period allow additional volume loading with maintenance of filling pressures. In addition, gradual release of the clamp allows time for adjustments in volume, pressors, and correction of acidosis.

Sometimes, even in the face of adequate volume loading, the blood pressure remains low following cross-clamp removal. Proximal cross-clamping is associated with a higher incidence of hypotension. In this situation, it is advisable to ask the surgeon to reapply the aortic cross-clamp to varying degree depending on the severity of hypotension. Such maneuvers allow more time for correction of blood volume or acidosis.

Other causes of sustained hypotension in the face of adequate management include a continued site of hemorrhage and myocardial ischemia and/or failure. Measurement of filling pressures or use of TEE can particularly help in the differentiation of the etiology of sustained hypotension. Ischemia or failure can be detected by wall motion abnormalities or elevated filling pressures accompanying systemic hypotension. In contrast, hemorrhage is diagnosed by low filling pressures and increased systemic vascular resistance (due to reflex vasoconstriction).

D. Postoperative Management

D.1. What are the parameters used to extubate this patient?

The following ventilatory criteria can be used to assess suitability for extubation: The patient is awake and alert, has an adequate gag reflex, displays signs of adequate reversal of neuromuscular blockade, and meets minimum respiratory parameters for extubation. The typical respiratory parameters used to assess suitability for extubation are shown in **Table 10.1**.

TABLE 10.1 Typical Respiratory Parameters Used to Determine Suitability for Extubation

Vital capacity greater than 15 mL/kg
pH greater than 7.30
PaO_2 greater than 60 mmHg at FIO_2 less than 50%
$PaCO_2$ less than 50 mmHg
Maximal negative inspiratory force greater than −20 cm H_2O
Stable hemodynamic status
Respiratory rate less than 30 breaths per minute

FIO_2, fraction of inspired oxygen

It is important to recognize that such parameters should serve merely as a guide in the clinical assessment of suitability for extubation. The decision to extubate should be ultimately guided by assessment of the patient's overall status and clinical judgment. Extubation may need to be delayed in those patients who display labored breathing on physical exam, inadequate pain control, or hemodynamic instability.

Perioperative fluid management also should be carefully considered when assessing a patient's suitability for extubation. For shorter cases with minimal anticipated fluid shifts, the patient can be extubated in the immediate postoperative period. For longer cases, instances of large volumes of fluid

replacement and significant blood product administration, extubation should be delayed until the hemodynamics are stabilized and temperature is normalized. In these cases, airway swelling also can be a significant concern and may lead to ventilatory failure in the postoperative period. A "cuff leak" test may be somewhat indicative of the degree of airway edema. It is performed by occluding the endotracheal tube of a spontaneously breathing patient and auscultating for breath sounds with the cuff deflated.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:237–264.

D.2. What are the anticipated changes in postoperative pulmonary function in these patients? How does the surgical technique affect postoperative pulmonary function? Are there any postoperative maneuvers that can improve respiratory parameters?

The transabdominal approach to the aorta involves an upper abdominal incision. Total lung capacity and its subdivisions decrease after upper abdominal surgery. VC decreases 25% to 50% and returns to normal in 1 to 2 weeks, and residual volume increases 13%. Functional residual capacity declines 30% and recovers over 3 to 4 days. Expiratory reserve volume declines 20% after lower abdominal surgery and up to 60% after upper abdominal and thoracic incisions. Tidal volume decreases 20% on the first postoperative day and gradually returns to normal. The retroperitoneal approach to the aorta involves a flank incision, which leads to far less respiratory compromise.

In a series of adult men undergoing abdominal surgery, postoperative pulmonary complications occurred more frequently than cardiac complications (9.6% vs. 5.7%) and were associated with significantly greater length of hospitalization. In

addition, the effects of surgical trauma are most pronounced after upper abdominal surgery. Lower abdominal and thoracic incisions impact the respiratory muscles to a lesser degree. This occurs through surgical disruption of the respiratory muscles, postoperative pain, and abdominal contents, preventing normal diaphragm excursion. The patient follows a rapid shallow breathing pattern without sighs.

The overall effect of postoperative regional analgesia on the breathing mechanics is complex, but epidural analgesia may decrease the risk for postoperative pulmonary complications. Ambulation and control of postoperative pain diminish splinting and help maximize respiratory parameters. Maneuvers to encourage deep breathing are of proven benefit.

Warner DO. Preventing postoperative pulmonary complications: the role of the anesthesiologist. *Anesthesiology*. 2000;92:1467–1472.

D.3. How would you control postoperative pain? What are the alternatives in the management of this patient's postoperative pain?

The goal of effective postoperative pain relief is to produce a high quality of pain control with the fewest number of side effects and complications. Neuraxial analgesia in the immediate postoperative period is the preferred method of pain management in this high-risk patient population. The ideal opiate, its concentration, and combination with local anesthetic have yet to be defined. (For suggested protocols, see **Table 10.2**.)

TABLE 10.2 Epidural Opioid/Bupivacaine Combinations Administered by Continuous Infusion[a]

	Bolus Dose

Drug Combinations	Solution[b] of Bupivacaine	Basal Infusion[c]	Breakthrough Doses	Increments Breakthrou
Morphine	0.01%	6–8 mL/hr	1–2 mL every 10–15 min	1 mL of the solu
Bupivacaine[e]	0.05%–0.1% 0.5%–0.25%			
Hydromorphone	0.0025%–0.005%	6–8 mL/hr	1–3 mL every 10–15 min	1 mL of the solu
Bupivacaine[f]	0.05%–0.1% 0.5%–0.25%			
Fentanyl	0.001%	0.1–0.15 mL/kg/hr	1–1.5 mL every 10–15 min	1 mL of the solu
Bupivacaine[g]	0.05%–0.1% 0.5%–0.25%			
Sufentanil	0.0001%	0.1–0.2 mL/kg/hr	1–1.5 mL every 10–15 min	1 mL of the solu
Bupivacaine[h]	0.05%–0.1% 0.5%–0.25%			

[a]Catheter insertion site is the dermatome corresponding to the middle of the surgical incision. Administer a bolus dose of 0.5% bupivacaine or 2% lidocaine to establish surgical anesthesia or 0.25% bupivacaine to induce postoperative analgesia in 5-mL aliquots.

[b]Due to infectious control, a total volume of 150 mL is recommended.

[c]Initial basal infusion rates will depend on the age, general condition, and weight of the patient.

[d]If analgesia is inadequate after 1 hour, increase the breakthrough dose by the recommended amount. If analgesia is inadequate after one additional hour, decrease the lockout interval by 5 minutes.

[e]Prepare this solution by mixing 75–150 mg of bupivacaine with 15 mg of preservative-free morphine in a total volume of 150 mL of preservative-free normal saline.

[f]Prepare this solution by mixing 75–150 mg of bupivacaine with 3.75–7.5 mg of hydromorphone in a total volume of 150 mL of preservative-free normal saline.

[g]Prepare this solution by mixing 75–150 mg of bupivacaine with 1,500 μg of fentanyl in a total volume of 150 mL of preservative-free normal saline.

[h]Prepare this solution by mixing 75–150 mg of bupivacaine with 150–300 μg of sufentanil in a total volume of 150 mL of preservative-free normal saline.

Reprinted with permission from de Leon-Casasola OA, Lema MJ. Postoperative epidural opioid analgesia: what are the choices? *Anesth Analg*. 1996;83:867–875.

Complications of the epidural route of analgesia include dural puncture, epidural hematoma, and epidural abscess. The risk of epidural hematoma is small in patients receiving appropriate doses of anticoagulation postoperatively but is prohibitively high in patients receiving thrombolytic treatment or LMWHs. Careful consideration should be given to the timing of insertion

and removal of the catheter. The risk of complications is similar whether the catheter is placed at the thoracic or lumbar level. Other complications include pruritus, nausea, urinary retention, and delayed respiratory depression. The latter is less than 1% when epidural morphine is used, similar to the oral and parenteral route. Difficulty ambulating and orthostatic hypotension are minimized when catheters are placed in the thoracic region with low infusion rates and bupivacaine concentrations used are less than 0.08%.

Systemic narcotic analgesia can be used to provide effective postoperative pain control. Intravenous narcotics are commonly administered by a patient-controlled analgesia (PCA) pump after this type of procedure, allowing the patient to titrate the dose of narcotic to achieve adequate pain control. These modified infusion pumps are able to administer infusions of narcotics, small preprogrammed bolus doses on patient demand, and larger bolus doses by prescription. The PCA technique allows the patients to self-titrate narcotic doses to achieve optimal analgesic doses while avoiding the toxic side effects that result from high peak serum levels.

11 Hypertension

Christopher W. Tam and Fun-Sun F. Yao

A 70-year-old man with cholelithiasis was scheduled for a cholecystectomy. His blood pressure (BP) was 230/120 mmHg; pulse, 60 beats per minute. Hematocrit was 38%; serum sodium, 140 mEq per L; and serum potassium, 2.7 mEq per L. His medications included metoprolol, aspirin, atorvastatin (Lipitor), and hydrochlorothiazide.

A. Medical Disease and Differential Diagnosis

1. Define hypertension and categorize its severity.
2. What is the prevalence of hypertension?
3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.
4. What are the clinical patterns of hypertension encountered?
5. What is the pathophysiology of essential hypertension?
6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?
7. What are the end-organ damages caused by long-standing hypertension?
8. Are hypertensive patients at an increased risk for perioperative cardiac morbidity?
9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?

10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?
11. What are the BP goals for patients with hypertension and when should antihypertensive drugs be initiated?
12. What is the mechanism of action of antihypertensive drugs?
13. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?
14. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

B. Preoperative Evaluation and Preparation

1. How would you evaluate this patient preoperatively?
2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?
3. Should all or any of the chronic medications be discontinued before the operation?
4. Should hypokalemia be treated before anesthesia? Why?
5. Should hypomagnesemia be treated before anesthesia? Why?
6. Does an asymptomatic carotid bruit increase the risk in these patients?
7. The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mmHg and potassium 4.0 mEq per L. How would you premedicate this patient?
8. If the patient is an untreated hypertensive patient with BP 170/70 mmHg, would you treat the patient preoperatively with an antihypertensive agent?

C. Intraoperative Management

1. How would you monitor this patient?
2. What are the anesthetic goals for hypertensive patients?

3. How would you induce anesthesia for the hypertensive patient?
4. How does tracheal intubation produce hypertension?
5. What happens to the left ventricular ejection fraction during and immediately following intubation?
6. What other measures can prevent hypertension and tachycardia at the time of intubation?
7. After induction and intubation, the BP decreased to 70/40 mmHg. What would you do?
8. What is your choice of agents for maintenance of anesthesia? Why?
9. How would you manage fluid therapy for hypertensive patients?
10. During the surgery, BP increased to 220/120 mmHg. How would you treat the hypertension?
11. What could you do to prevent hypertension during extubation and emergence?
12. Would you consider regional anesthesia for this patient?

D. Postoperative Management

1. The patient developed hypertension, BP 210/110 mmHg, in the postanesthesia care unit. What would you do?

A. Medical Disease and Differential Diagnosis

A.1. Define hypertension and categorize its severity.

Systemic hypertension is the leading cause of cardiovascular death in the United States among modifiable risk factors and the second leading preventable cause of death. According to the seventh report on classification and characterization of BP by the Joint National Committee (JNC) on Evaluation, Detection, and Prevention of High Blood Pressure in 2003, hypertension is defined as an average systolic BP greater than 120 mmHg and a

diastolic pressure greater than 80 mmHg. The classification stages of hypertension have been updated since 2003 with tightened guidelines for diagnosis of hypertension. According to the American College of Cardiology (ACC)/American Heart Association (AHA) recommendations from 2017, hypertension is classified as normal, elevated, stage 1 hypertension, and stage 2 hypertension. The term "pre-hypertension" as seen in the JNC 7 report has been replaced by "elevated blood pressure" in the current guidelines. The current recommended BP ranges for each category can be seen on **Table 11.1**. The tightened BP classification is expected to increase the prevalence of hypertension by 14% in the United States and about 2% increase in antihypertensive therapy usage.

TABLE 11.1 Categories of Blood Pressure in Adults

BP Category	SBP	DBP
Normal	<120 mmHg and	<80 mmHg
Elevated	120–129 mmHg and	<80 mmHg
Hypertension		
Stage 1	130–139 mmHg or	80–89 mmHg
Stage 2	≥140 mmHg or	≥90 mmHg

BP, blood pressure; DBP, diastolic BP; SBP, systolic BP.

Reprinted with permission from Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension*. 2018;71:e13–e115. Copyright © 2018 American Heart Association, Inc.

The definition of hypertension in children and adolescents has also been updated by the American Academy of Pediatrics in 2017. Similar to the adult recommendations, the pediatric definition for hypertension has also been tightened in the most current updated guidelines. According to American Association of Pediatrics (AAP), pediatric hypertension is classified as

normal, elevated, stage 1 hypertension, and stage 2 hypertension. As in the adult update, the term "pre-hypertension" has been replaced by "elevated blood pressure" in the current guidelines. The current recommended BP ranges can be seen on **Table 11.2**.

TABLE 11.2 Categories of Blood Pressure in Pediatrics

BP Category	Children Aged 1–<13 Years Old	Children Aged ≥13 Years Old
Normal	<90th percentile	<120/<80 mmHg
Elevated	≥90th percentile to <95th percentile or 120/80 mmHg to <95th percentile (whichever is lower)	120/<80–129/<80 mmHg
Stage 1 hypertension	≥95th percentile to <95 percentile + 12 mmHg or 130/80–139/89 mmHg (whichever is lower)	130/80–139/89 mmHg
Stage 2 hypertension	≥95th percentile + 12 mmHg or ≥140/90 mmHg (whichever is lower)	≥140/90 mmHg

Reproduced with permission from Flynn JT, Kaelber DC, Baker-Smith CM, et al. Clinical practice guideline for screening and management of high blood pressure in children and adolescents. *Pediatrics*. 2017;140(3):e20171904. Copyright © 2017 by the American Academy of Pediatrics.

It is important to note that the classification of hypertension defines and specifies hypertension according to systolic and/or diastolic limits, each representing different pathophysiologic processes. Systolic hypertension is a marker of macrovascular disease and large arterial stiffening (atherosclerosis), and diastolic hypertension is a consequence of microvascular disease involving typically vessels less than 1 mm in size.

Uncontrolled hypertension can escalate to a hypertensive crisis defined as systolic BP greater than 180 mmHg or diastolic BP greater than 120 mmHg and categorized as urgent and emergent. According to the ACC/AHA guidelines 2017, hypertensive emergency is defined as elevated BP (usually >180/120 mmHg) complicated by evidence of impending or progressive end-organ damage, whereas hypertensive urgency is

severe elevation of BP without progressive end-organ damage.

Flynn JT, Kaelber DC, Baker-Smith CM, et al. Clinical practice guideline for screening and management of high blood pressure in children and adolescents. *Pediatrics*. 2017;140(3):e20171904.

A.2. What is the prevalence of hypertension?

The prevalence of hypertension depends on both the racial composition of the population and the criteria used to define hypertension. In a white suburban population like that in the Framingham study, nearly one-fifth has a BP greater than 160/95 mmHg and almost one-half has a BP greater than 140/90 mmHg. A higher prevalence of hypertension has been found in the non-white population. The frequency increases with the age of the population with nearly two-thirds of hypertensive patients being older than 50 years, and by the age of 75 years, almost 90% will have hypertension. According to the JNC 7, the overall prevalence of hypertension was 32%. In the United States, however, with the updated ACC/AHA definition of hypertension, the prevalence increases to 46%. The highest prevalence is found in the non-Hispanic black population with an overall prevalence of close to 60% with the current updated definition. However, the prevalence of pharmacologic therapy has not increased with this updated definition because for the percentage of population where patients are now considered hypertensive, the recommended therapy is conservative lifestyle changes. The number of hypertensive persons in the United States in 1983 was estimated to be 57.7 million—more than double the estimate made in 1960 to 1962. Currently, approximately 1 in 3 or 75 million Americans suffer from

hypertension.

A.3. What is the general classification of hypertension? Enumerate the causes of each type of hypertension.

Hypertension is classified according to its subtypes: systolic, diastolic, and pulse pressure (**Table 11.3**). Historically, only diastolic hypertension—essential hypertension—was recognized, but more recently, there has been increasing emphasis and recognition of systolic hypertension, namely, ISH. ISH is the most common subtype of hypertension affecting predominantly individuals older than 60 years of age. In fact, approximately 70% of hypertensive patients have ISH with approximately half of these individuals having very wide pulse pressure (>65 mmHg) or PPH. Isolated diastolic hypertension is most prevalent in individuals younger than 50 years and is an important marker of coronary heart disease and mortality in this age group. Some hypertensive patients have both systolic and diastolic hypertension categorized as *combined systolic and diastolic hypertension*. The ranges of systolic, diastolic, and pulse pressure that define each subtype of hypertension are presented in **Table 11.1**.

TABLE 11.3 Classification of Hypertension

Systolic and diastolic hypertension
- Essential
- Renal
- Endocrine
- Neurogenic
- Miscellaneous

Systolic hypertension with wide pulse pressure
- Increased cardiac output
- Rigidity of aorta

Etiology of Hypertension

- *Essential hypertension*. Unknown etiology
- *Renal*. Acute and chronic glomerulonephritis, chronic pyelonephritis, polycystic kidney, diabetic nephropathy, hydronephrosis, renovascular stenosis, renin-producing tumors, primary sodium retention
- *Endocrine*. Adrenal—Cushing syndrome, primary aldosteronism, congenital adrenal hyperplasia, pheochromocytoma, acromegaly, hypothyroidism, carcinoid, hyperthyroidism, oral contraceptives, corticosteroids
- *Neurogenic*. Psychogenic, increased intracranial pressure, spinal cord section, familial dysautonomia, lead poisoning, Guillain-Barré syndrome, sleep apnea
- *Miscellaneous*. Coarctation of aorta, increased intravascular volume, pregnancy-induced hypertension, polyarteritis nodosa, acute porphyria, hypercalcemia, alcohol and drug use, acute stress including surgery

A.4. What are the clinical patterns of hypertension

encountered?

- "Vasoconstricted" hypertension—in medical patient with chronic renovascular hypertension, characterized by diastolic hypertension and systemic vascular resistant with normal or even decreased cardiac output and heart rate
- "Hyperdynamic" hypertension—in postoperative surgical patient, characterized by acute systolic hypertension; widened pulse pressure; and increased cardiac output, heart rate, and systemic vascular resistant

A.5. What is the pathophysiology of essential hypertension?

The underlying mechanism of essential hypertension is unknown. A variety of abnormalities, including heredity, fetal undernutrition, abnormal sympathetic nervous system activity, cell membrane defects, renal retention of excess salt, microcirculatory alterations, endothelial cell dysfunction, hyperinsulinemia secondary to insulin resistance, vascular hypertrophy, and altered renin–angiotensin system regulation are implicated. There is increasing evidence that "local renin–angiotensin" paracrine factors may be involved in the development of hypertension. However, characteristic hemodynamic changes are present as follows:

- Increased systemic vascular resistance with normal cardiac

output

- Markedly increased sympathetic response to stress such as endotracheal intubation
- A greater increase in BP with vasoconstriction and a greater decrease in BP with vasodilation because of the increased thickening of arterial wall and high ratio of wall thickness to internal diameter

The higher the level of BP, the more likely that various cardiovascular diseases will develop prematurely through acceleration of arteriosclerosis. If untreated, approximately 50% of hypertensive patients die of coronary heart disease or congestive heart failure (CHF), approximately 33% of stroke, and 10% to 15% of renal failure.

A.6. What is the pathophysiology of isolated systolic hypertension (ISH) and of pulse pressure hypertension (PPH)?

ISH is a manifestation of atherosclerotic disease involving predominantly the aorta and its major branches. Both ISH and PPH reflect arterial stiffening and represent the pulsatile component of BP, whereas the mean arterial pressure (MAP) represents the static state. Systole, then, is directly influenced by the ventricular contractile state, the ejected volume, heart rate, and, importantly, compliance of the aorta and pulse wave velocity. With increasing age and factors such as diabetes, smoking, and increased cholesterol as well as some genetic factors, compliance of the aorta diminishes markedly (**Fig. 11.1**). The net result is stiffening of the arterial tree and inability

to absorb the pulsatile load, causing the systolic pressure to rise sharply. Pulse wave velocity has gained much attention lately because it may be a richer substrate for characterizing the physiology of blood flow and pressure. Under normal physiologic conditions, the ejected blood volume is transmitted peripherally as a propagated wave. After reaching the periphery, in particular, at the bifurcation sites, a reflected wave or a retrograde wave is generated from the encountered impedance. Under normal conditions, wave reflection arrival coincides with the beginning of diastole, thereby augmenting the diastolic pressure. However, with stiffening of the aorta as occurs with aging, both the propagated and the reflected waves travel much more rapidly, and early return of the reflected arterial wave during late systole augments the systolic component, effectively increasing afterload. The ensuing loss of diastolic augmentation results in a disproportionate increase in the systolic BP and lower diastolic BP—a hallmark of ISH and of PPH.

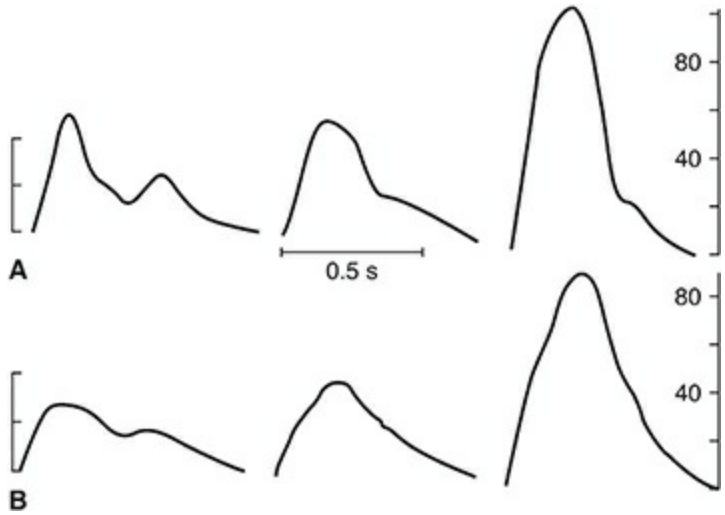

FIGURE 11.1. Change in amplitude and contour of the upper limb (A) and ascending aortic (B) pressure wave with age, as recorded in three female members of a family: at age 18 (left), at age 48 (center), and at age 97 years (right). Upper limb pulse pressure was just more than twice as high in the old compared with the young subject (102 vs. 46 mmHg), whereas aortic pulse pressure was more than three times higher (104 vs. 27 mmHg). (*Reprinted with permission from O'Rourke MF, Nichols WW. Aortic diameter, aortic stiffness, and wave reflection increase with age and isolated systolic hypertension.* Hypertension*. 2005;45[4]:652–658.*)

Mechanistically, pulse pressure is also an index of the stiffness of conduit vessels and the rate of pressure wave propagation and reflection within the arterial tree. Approximately half of patients with ISH also have wide pulse pressure; however, both individuals who are normotensive (systolic, <120 mmHg) with a low diastolic pressure or persons with combined systolic and diastolic hypertension (systolic >130 mmHg and diastolic >80 mmHg) can have wide pulse pressure (normal values being ≤40 mmHg).

A.7. What are the end-organ damages caused by long-standing hypertension?

The end-organ damages caused by long-standing hypertension are as follows:

Cardiac Involvement

Left ventricular hypertrophy (LVH)
Angina or myocardial infarction (MI)
Arrhythmias
Congestive failure

Eye Involvement

Vascular changes in the fundus reflect hypertensive retinopathy and arteriosclerotic retinopathy.

Renal Involvement

Nephropathy

Cerebral Involvement

Stroke or transient ischemic attack

Complications of hypertension to vascular disease probably involve three interrelated processes: pulsatile flow, endothelial cell dysfunction, and smooth muscle cell hypertrophy. These three interrelated processes are probably responsible for the arteriolar and arterial sclerosis that is the usual consequence of long-standing hypertension. Large vessels such as the aorta may be directly affected and be at risk for aneurysms and dissection. As discussed previously, the consequences of long-standing hypertension need be addressed according to the subtypes of hypertension; for the associated risks for cerebral, cardiac, and renal vascular complications differ according to systolic, diastolic, and PPH. For example, diastolic hypertension being a better predictor of coronary heart disease in younger patients, whereas systolic and PPH being associated with greater risk of stroke, coronary heart disease, and mortality in persons older than 60 years.

A.8. Are hypertensive patients at an increased risk for perioperative cardiac morbidity?

Hypertensive patients are at increased risk for coronary artery disease, silent myocardial ischemia, CHF, and stroke. However, whether preoperative hypertension is predictive of perioperative major cardiac morbidity remains controversial. Some investigators have shown that patients with untreated, poorly controlled, or labile preoperative hypertension are at increased risk for perioperative BP lability, dysrhythmias, myocardial

ischemia, and transient neurologic complications. Some suggested that preoperative hypertension predicted perioperative MI. However, Goldman and Caldera demonstrated that mild-to-moderate hypertension did not increase the risk of major morbid events. Instead, preoperative hypertension may predict several intermediates of outcome, such as BP lability and myocardial ischemia. The controversy may be due to the wide variability in the hypertensive population. Hypertension may affect perioperative morbidity through the extent of end-organ damage and not the manifestation of the disease itself. LVH, which signifies long-standing poorly controlled hypertension, can increase the risk of myocardial ischemia from imbalances of myocardial oxygen (O_2) supply and demand regardless of the presence or absence of coronary artery disease.

ISH (systolic BP >140 mmHg and diastolic BP <90 mmHg) has been identified as a risk factor for cardiovascular complications in the general population, and treatment reduces the future risk of stroke. Aronson et al. and Fontes et al. found that among the various components of BP, preoperative PPH was independently and significantly associated with postoperative stroke, renal failure, and mortality in patients undergoing coronary artery bypass. Neither ISH nor isolated diastolic hypertension was predictive of vascular complications. This finding is consistent with results of longitudinal studies finding that increase in pulse pressure is a better predictor of major vascular complications than increase in either systolic or diastolic BP. Interestingly, rises in pulse pressure as few as 10 mmHg in both normotensive and hypertensive individuals are associated with 20% or more increase risk of renal, coronary, and cerebral events.

A.9. Perioperative cerebral and renal complications are mostly associated with which subtype of hypertension?

Both systolic hypertension and high pulse pressure are strongly associated with risk for perioperative cerebrovascular accidents and acute renal failure. The brain and the kidneys as well as the heart differ from most organs in that they receive large amount of blood flow and have very low resistance. As such, the pulsatile load (pulse pressure) tends to be very high. Over a period of many years of poorly or untreated hypertension, endothelial injury and vascular remodeling changes can promote both arteriosclerosis and atherosclerosis, which are known risk factors for cerebral and renal vascular complications. The pulsatile stress also can cause dislodgment of plaques from the aorta and its major branches, resulting in embolic stroke.

In hypertensive patients, autoregulation of cerebral blood flow is reset to a higher range than normal, and although it protects the brain against sudden increases in pressure, it makes it more vulnerable to hypotension. Therefore, when BP is lowered acutely, hypertensive patients will show signs of

cerebral ischemia at a higher level of BP than normotensive patients.

Hypertension may accelerate cognitive decline with age. Hypertension, particularly systolic, is a major risk factor for initial and recurrent stroke and for transient ischemia attacks caused by extracranial atherosclerosis.

Chronic renal insufficiency is a common sequela of hypertension. Patients with hypertension should have a measurement of baseline serum creatinine. In the original Cardiac Risk Index, an elevated serum creatinine level (>3.0 mg per dL [>265.2 mmol per L]) was one of the independent risk factors for perioperative cardiovascular morbidity and mortality. This has been confirmed in the revised Cardiac Risk Index in which a preoperative serum creatinine level greater than 2.0 mg per dL (176.8 mmol per L) was one of six independent factors that predicted increased cardiovascular risk.

A.10. Would you employ a controlled hypotensive technique for hypertensive patients? How much would you safely lower the BP?

Uncontrolled or untreated severe hypertension is a contraindication to controlled hypotension. However, controlled hypotension may be used with caution in treated hypertensive patients. Because cerebral autoregulation is shifted to the right

with chronic hypertension, the lower limit of controlled hypotension should be higher for hypertensive patients. However, with long-term treatment, the autoregulation curve shifts leftward to approach that in normals. Strandgaard found that the lower limit of autoregulation was 113 mmHg in severe untreated or uncontrolled hypertensives; 96 mmHg in formerly severe, now-treated hypertensives; and 73 mmHg in normotensive patients. The lowest level of mean BP tolerated without symptoms of hypoperfusion was 65 mmHg in severe hypertensives, 53 mmHg in treated hypertensives, and 43 mmHg in normal patients. However, although the autoregulation may shift toward normal with treatment, in many patients, the autoregulation did not shift toward normal even after 12 months of treatment. Because one cannot measure patients' autoregulation, a useful clinical guide is that a 25% decrease in MAP reaches the lower limit of autoregulation and a 55% decrease in MAP reaches symptomatic cerebral hypoperfusion. Another suggested rule is that the systolic pressure of controlled hypotension should not be lower than the diastolic pressure of the patient's usual pressure. It is important to note that peripherally measured BP do not match central aorta BP, which is more reflective of actual cerebral BP.

Recently, noninvasive cerebral oximeter using near-infrared spectroscopy has been used to monitor O_2 saturations of the cerebral cortex. The values of cerebral O_2 saturations correspond with those of a mixture of 85% jugular venous O_2 saturation and 15% of arterial O_2 saturation. It reflects the balance between cerebral O_2 delivery and O_2 demand. In a steady state of anesthesia, the cerebral O_2 demand does not change significantly. Therefore, cerebral O_2 saturations will not decrease until the BP falls below its autoregulation range. Therefore, the cerebral oximeter may be employed to determine

the lower limit of autoregulation and to ensure adequate cerebral oxygenation. Unfortunately, there is wide variability in measured cerebral saturations with some individual's baseline oximetric saturation values being near 50% at baseline. Furthermore, the measured value is reflective of regional saturation such that distant areas that may be ischemic are not detected.

It should be mentioned that neither the threshold for upper nor lower limits of systolic and diastolic BP have been established. Frequently, these limits have been chosen arbitrarily and the relation of perioperative hypertension to outcomes has been inconsistent among the studies that have addressed this question. In part, the limitation comes from grouping all types of hypertension together. Moreover, available vasoactive agents are not selective in lowering or raising systolic BP, and diastolic BP without a concomitant increase or fall in the other component. Undermining the broad-based reliance on systolic BP and diastolic BP are a number of studies in humans over the past several decades that clearly show that both morbidity and mortality do not always linearly correlate with rises or fall in BP. In individuals with demonstrable coronary disease, namely, those with previous infarcts, coronary mortality was significantly related to diastolic pressure in a U-shaped configuration—occurring more frequently in those with very high or very low diastolic BP. Unfortunately, the emphasis on BP management perioperatively has been to control the systolic component with no attention paid to the diastolic component. This is particularly concerning in patients with ISH and with very wide pulse pressure where the diastolic BP is already critically low. By reducing the systolic component, further lowering of the diastolic BP can result in ischemic complications in most sensitive vascular beds such as the brain, the heart, and the kidneys. Lastly, it is critical to recognize that

peripheral arterial pressures do not necessarily reflect central pressures with exception of the MAP. In a subset of hypertensive individuals, both the systolic and the pulse pressures are grossly higher peripherally as compared to central aortic pressures, such that lowering of the peripheral BP may result in critical reduction in perfusion pressure.

A.11. What are the BP goals for patients with hypertension and when should antihypertensive drugs be initiated?

The current ACC/AHA guidelines outline the BP treatment goals based on systematic review of the literature. According to the current ACC/AHA guidelines 2017, it is a class Ia recommendation to treat patients with antihypertensive drug therapy in addition to lifestyle modification as secondary prevention if patients currently have cardiovascular disease and an average systolic BP ≥130 mmHg or diastolic BP ≥80 mmHg or as primary prevention in patients with no history of cardiovascular disease but with an estimated 10-year cardiovascular disease risk of <10% and systolic BP ≥140 mmHg or diastolic BP ≥90 mmHg. Cardiovascular disease includes coronary heart diseases, CHF, and stroke. For patients in the elevated BP category, lifestyle modification alone is the recommended treatment modality.

Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation*. 2018;138:e484–e594.

A.12. What is the mechanism of action of antihypertensive drugs?

Antihypertensive drugs are categorized by their mechanism of action as follows.

Diuretics

They include thiazides (e.g., hydrochlorothiazide), loop diuretics (e.g., furosemide, ethacrynic acid), and potassium-sparing agents (e.g., spironolactone, triamterene). All diuretics initially lower the BP by increasing urinary sodium excretion and by reducing plasma volume, extracellular fluid volume, and cardiac output. Within 6 to 8 weeks, the cardiac output returns to normal. The lowered BP is related to a fall in peripheral resistance. Diuretics may cause hypokalemia, hypomagnesemia, hyperuricemia, hyperlipidemia, hypercalcemia, and hyperglycemia. For patients with ST-segment changes and evidence of pulmonary edema and hypertension or with increased intracranial cerebral pressure and hypertension, intravenous furosemide may be appropriate.

Antiadrenergic Agents

- *Centrally acting drugs*. Clonidine, dexmedetomidine, and mivazerol. These drugs and their metabolites are primarily α_2-receptor agonists. Stimulation of α_2 receptors in the vasomotor centers of the brain reduces sympathetic outflow.
- *Peripherally acting drugs*
  - α-Receptor blockers
    α_1 and α_2 Receptors—phenoxybenzamine (Dibenzyline),

phentolamine (Regitine)
α_1 Receptor—prazosin (Minipress), doxazosin (Cardura)
By blocking α-mediated vasoconstriction, these drugs induce a fall in peripheral resistance with both arteriolar and venous dilation.

- β-Receptor blockers—atenolol (Tenormin), metoprolol (Lopressor), nadolol (Corgard), pindolol (Visken), propranolol (Inderal), esmolol (Brevibloc). These drugs lower the BP by decreasing heart rate, contractility, cardiac output, and renin levels. BP is decreased without reflex tachycardia or widening of the pulse pressure. They also have antiarrhythmic activity and suppress both ventricular and supraventricular ectopic rhythms.
- α- and β-Receptor blockers—labetalol (Trandate)
- Endothelin receptor antagonists—act on endothelin A and B receptors to block the effect of endothelin-1, which is the most potent vasoconstrictor that is secreted primarily from vascular smooth muscle and endothelial cells. Bosentan (receptor A and B antagonist) and sitaxsentan (receptor A antagonist) are examples of a few of this class of agents used in the management of pulmonary hypertension and less so for hypertension-related heart failure.

Direct Vasodilators

They include hydralazine, nitroprusside, nitroglycerin, and calcium channel blockers. These drugs directly relax the smooth muscle of resistance and capacitance vessels to different degrees.

Dopaminergic Agonists

Dopaminergic agonists (DAs) are classified into DA_1 and DA_2 subtypes.

Stimulation of DA_1 receptors causes vasodilation, and inhibition of active sodium transport in the proximal tubule, leading to natriuresis.

Stimulation of DA_2 receptors inhibits norepinephrine release and promotes peripheral vasodilation.

Fenoldopam, a dopamine receptor (DA_1 selective) agonist and a systemic and renal vasodilator, offers significant advantages as a parenterally administered agent for the management of BP in hypertensive emergencies and in the perioperative setting. Parenteral fenoldopam has a rapid onset and offset of effect, with an elimination half-time of approximately 10 minutes. Prepared in concentration of 10 mg in 250 mL (40 μg per mL), the recommended starting dose is 0.05 μg/kg/min. This should be titrated to effect by 0.025 μg/kg/min every 10 to 15 minutes to a maximum dose of 0.5 to 0.8 μg/kg/min. The drug should not be administered in boluses; the incidence of reflex tachycardia is related to rapidity of upward titration. Unlike dopamine, it has no β- or α-adrenergic activity, and increasing doses result in increasing vasodilation without tachycardia or tachyarrhythmias.

Calcium Channel Blockers

The cardiovascular effects of calcium antagonists are listed in **Table 11.4**. These drugs decrease BP mainly by peripheral vasodilation. Renin and aldosterone secretion may be reduced as well.

TABLE 11.4 Cardiovascular Effects of Calcium Channel Blockers

	Verapamil	Diltiazem	Nifedipine	Nicardipine	Clevidipine
Heart rate	↓	↓	↓ or –	↑ or –	–
Nodal conduction	↓↓	↓	↓ or –	–	–
Myocardial depression	↑↑	↑	–	–	–
Vasodilation	↑	↑	↑↑	↑↑	↑↑

↑↑, more increase; ↓↓, more decrease; ↑, increase; ↓, decrease; −, no change.

Angiotensin-Converting Enzyme Inhibitors

They include captopril, enalapril, lisinopril, quinapril, and ramipril. The renin–angiotensin system may be inhibited in four ways as shown in **Figure 11.2**. These drugs inhibit the conversion of the inactive decapeptide angiotensin I to the active octapeptide angiotensin II. Lower levels of angiotensin II may decrease BP by reducing angiotensin II–induced vasoconstriction and by decreasing aldosterone synthesis. ACE inhibitors also retard the degradation of a potent vasodilator (bradykinin), alter prostaglandin production (most notably with captopril), and can modify the activity of the adrenergic nervous system.

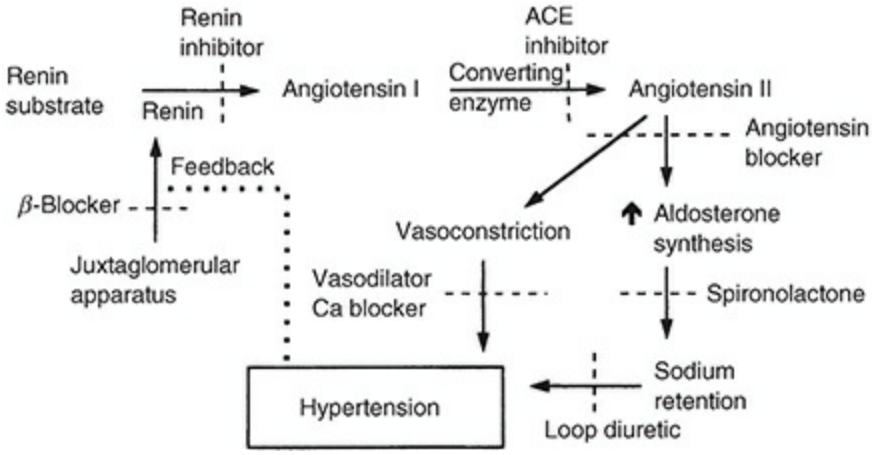

FIGURE 11.2. The renin–angiotensin system and the mechanism of action of antihypertensive drugs. ACE, angiotensin-converting enzyme.

ACE inhibitors provide predominantly arterial vasodilation and have become primary therapy for the treatment of CHF by afterload reduction. Cardiac output is increased without excessive decrease in preload, with a favorable effect on survival.

Angiotensin II Receptor Blockers

Angiotensin II receptor antagonists or blockers (ARBs)

represent the third class that antagonizes the renin–angiotensin–aldosterone system. Blockade of the action of angiotensin II leads to elevations in plasma levels of renin, angiotensin I, and angiotensin II. However, this build-up of precursors does not overwhelm the receptor blockade, as evidenced by a persistent fall in both BP and plasma aldosterone levels. There are several possible differences between ACE inhibitors and angiotensin II receptor antagonists. These include the following:

- ACE is a kininase. Therefore, inhibiting this enzyme, which normally degrades bradykinin, with an ACE inhibitor leads to increased kinin levels, an effect not seen with an angiotensin II receptor antagonist. High bradykinin levels may also provide additional vasodilation and other benefits not observed with angiotensin II receptor antagonists.
- ACE inhibitors, by decreasing angiotensin II production, reduce the effect of both angiotensin II receptor type 1 (AT1) and type 2 (AT2); only the former are inhibited by the ARBs. Chronic stimulation of the AT2 receptor may be beneficial.
- In the heart, kidney, and perhaps the blood vessels, the production of angiotensin II may be catalyzed by enzymes other than ACE, such as chymase. The effect of the angiotensin II produced by this reaction can be inhibited by the angiotensin II receptor antagonists but not by ACE inhibitors.

There is evidence that ARBs are more effective in treating ISH and PPH particularly in combination with ACE inhibitors and with endothelin receptor blockers.

Other Vasodilators

They include brain natriuretic peptides such as nesiritide that is primarily used in acute exacerbation of heart failure to improve forward flow and reduce symptoms and signs of heart failure. There has been recent controversy about the clinical efficacy of

these agents. Importantly, there have been several reports suggesting that the renal outcome is worsened in patients receiving nesiritide.

A.13. Does the choice of antihypertensive therapy influence hemodynamic responses to induction, laryngoscopy, and intubation?

The pressor responses to induction, laryngoscopy, and intubation differ little whether patients with mild-to-moderate hypertension receive a β-blocker, a calcium channel blocker, an ACE inhibitor, or a diuretic. Even changes of a similar magnitude are also observed in untreated hypertensive patients. On the other hand, hypotensive responses may be magnified in those patients with poorly controlled hypertension following induction—generally due to a reduced intravascular volume in the face of increased vascular sympathetic tone. As mentioned previously, attention should be directed not only to the systolic but also to pulse and diastolic pressures.

Sear JW, Jewkes C, Tellez JC, et al. Does the choice of antihypertensive therapy influence haemodynamic responses to induction, laryngoscopy and intubation? *Br J Anaesth*. 1994;73:303–308.

A.14. Does chronic angiotensin-converting enzyme (ACE) inhibition influence anesthetic induction?

Coriat et al. reported that, in hypertensive patients chronically treated with ACE inhibitors, therapy until the day of surgery is a major factor influencing BP responsiveness to anesthetic induction for vascular surgery. If enalapril (a long-acting ACE inhibitor) treatment is continued, a very low plasma-converting enzyme activity will be observed and an exaggerated hypotensive response may occur at induction. If captopril (a short-acting ACE inhibitor) treatment is continued, the magnitude of the decrease in BP in response to induction, although lower than with enalapril, is enhanced compared with that noted in patients in whom captopril had been stopped. All of the hypotensive episodes in patients who received ACE inhibitors until the day of surgery were easily corrected by administration of an α agonist. The temporary withdrawal of these two ACE inhibitors attenuated the hypotensive response to induction but did not lead to an abnormal BP response to induction and intubation. However, Ryckwaert and Colson reported that ACE inhibitor treatment in patients with infarction-induced myocardial dysfunction does not increase the incidence of severe hypotension after induction of anesthesia. Additionally, a retrospective analysis of patients who underwent shoulder surgery in the sitting position by Trentman et al. showed that timing of the last dose of ACE inhibitors or angiotensin receptor antagonists had no impact on intraoperative hypotensive episodes. Hollmann et al. published in 2018 in *Anesthesia and Analgesia* a meta-analysis where they found that ACE inhibitors and ARBs did not demonstrated to have an increased incidence of perioperative mortality even though there was an increased association with intraoperative hypotension. In all, the overwhelming opinion is to continue all antihypertensive medication including the day of surgery and resumption of such therapy postoperatively. A number of studies have shown an improvement in outcome when therapy is continued versus a

worsening in outcome when either ACE inhibitors or β-blockers have been withdrawn.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate this patient preoperatively?

In addition to the routine systemic preoperative physical and history, special attention should be paid to the following: etiology and severity of hypertension, the subtype of hypertension, current therapy, and the end-organ damage from chronic hypertension.

The underlying cause of hypertension should be clear. Surgical mortality is relatively high in patients with renovascular hypertension. Moreover, failure to diagnose a pheochromocytoma preoperatively, albeit a rare finding, may prove fatal because anesthetic agents are well known to precipitate a crisis in such patients. Meanwhile, the severity of

hypertension alters anesthetic risk.

Antihypertensive drugs have different anesthetic implications. Diuretics frequently cause chronic hypokalemia and hypomagnesemia, which may increase the risk of arrhythmia. Therefore, serum electrolytes should be checked preoperatively.

The presence of target-organ damage in the brain, heart, and kidney signifies long-standing, poorly controlled hypertension. Unfortunately, markers of organ damage become demonstrable only after significant end-organ damage has occurred.

For cardiac evaluation, electrocardiogram and chest x-ray film serve as minimal tests. The echocardiogram will be helpful. LVH can increase the risk of perioperative myocardial ischemia from imbalances of myocardial O_2 supply and demand regardless of the presence or absence of coronary artery disease. There is a very high correlation between LVH, ISH, and PPH—it is uncertain which comes first. Some authorities believe that hypertensive patients without evidence of LVH or other risk factors are at a lower perioperative cardiac risk and do not require further evaluation for most operations. Patients with severe hypertension are also at an increased risk for diastolic dysfunction causing CHF.

For renal evaluation, urinalysis, serum creatinine, and blood urea nitrogen should be measured to define the presence and extent of renal parenchymal disease. If chronic renal failure exists, hyperkalemia and elevated plasma volume may be of concern. Normal saline crystalloid intravenous solution is recommended for such cases.

For cerebrovascular evaluation, a history of cerebrovascular accidents and transient ischemic attacks and the presence of hypertensive retinopathy should be looked for.

B.2. Would you postpone the surgery? Why? What BP would you like the patient to achieve before surgery?

It is prudent to postpone elective surgery with a BP of 230/120 mmHg. This patient should be considered to have hypertensive emergency if additional end-organ sequelae are present, in which case he needs to be admitted for intravenous control of BP. Otherwise, for hypertensive urgency, it is recommended that the patient be placed in a quiet environment and managed with rest and oral antihypertensives. The patient should be discharged and instructed to follow-up with his internist for management and control of hypertension. Prior to rescheduling for surgery, if time permits, the BP should be gradually lowered over 6 to 8 weeks to less than 140/90 mmHg. Acute control within several hours is inadvisable before elective surgery because this practice may put the cerebral or other circulations at risk for ischemia.

In moderate hypertensive patients with severe end-organ involvement, preoperative BP should be normalized as much as possible, although in asymptomatic patients with mild-to-moderate hypertension (diastolic BP <110 mmHg), elective surgery may proceed without increased cardiovascular risks. Goldman found that patients with mild and moderate hypertension were not at increased risk of vascular complications unless they had other risks of coronary heart disease. In all, the thresholds being recommended apply only in part to today's surgical population. Most hypertensive patients presenting for surgery are elderly patients who suffer almost exclusively from ISH and PPH. It is uncertain what acute changes in BP preoperatively will have on outcome giving that

the pathologic changes are chronic and unlikely to normalize with treatment. In patients with medically refractory coronary disease requiring coronary artery bypass grafting (CABG) surgery, PPH was associated with an increased risk of major vascular complication.

B.3. Should all or any of the chronic medications be discontinued before the operation?

Current opinion generally favors continuation of antihypertensive medications, especially β-blockers, up to the time of surgery. There is concern that acute withdrawal of these medications may precipitate ischemic myocardial events. Because β-blockade does not impair the hemodynamic response to hemorrhage and does not adversely affect responses to hypoxia, the medications should be continued. The withdrawal syndrome is characterized by an enhanced sensitivity to sympathetic stimulation and has been attributed to various factors, including sympathetic overactivity and increased triiodothyronine levels, but most probably, it is a result of increased β-receptor density.

The safety of β-blockers and their benefits (prevention of hypertensive responses, dysrhythmias, and myocardial ischemia) have been long established. Similarly, treatment with calcium

channel blockers, ACE inhibitors, statins, and diuretics can be maintained. Indeed, the responses to induction of anesthesia, laryngoscopy, and intubation differ little whether patients receive a β-blocker, a calcium channel blocker, an ACE inhibitor, or a diuretic. Withdrawal of clonidine has been associated with rebound hypertension.

B.4. Should hypokalemia be treated before anesthesia? Why?

Hypokalemia is a frequent finding in hypertensive patients treated with the diuretic thiazides. It is important to maintain normal electrolyte balance in patients with heart or coronary artery disease. A low value of potassium (3.0 to 3.5 mEq per L) in these patients may cause arrhythmias, increase sensitivity to digitalis, and depress neuromuscular function. In patients without risk of cardiac complications of surgery and anesthesia, this modest reduction (3.0 to 3.5 mEq per L) should not prompt postponement of surgery or immediate potassium replacement. Patients with more severe potassium depletion ($\leq$2.9 mEq per L) should be treated and/or undergo workup for such profound hypokalemia. For those patients, at least 1 week before surgery, supplemental potassium should be given if renal function is not impaired. In surgical emergencies, potassium may be given at a rate not to exceed 0.5 mEq per kg of body weight per hour. Administration should be stopped during surgery and restarted postoperatively, depending on serial potassium determinations. Vitez et al. concluded that chronic hypokalemia per se is not

associated with a higher incidence of intraoperative arrhythmia.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:384–418.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:407–424.

Vitez TS, Soper LE, Wong KC, et al. Chronic hypokalemia and intraoperative dysrhythmias. *Anesthesiology*. 1985;63:130–133.

B.5. Should hypomagnesemia be treated before anesthesia? Why?

The normal level of magnesium is between 1.5 and 2.5 mEq per L. Magnesium ion is essential for the proper function of most enzyme systems. Depletion is characterized by neuromuscular and central nervous system hyperexcitability. These signs are similar to those of calcium deficiency. Cardiovascular abnormalities include coronary artery spasm, cardiac failure, and dysrhythmias. When severe, hypomagnesemia may induce seizures, confusion, and coma. Replacement should be done only in cases of severe depletion. Magnesium should not be given to the oliguric patient and should be given very carefully to patients with renal insufficiency. Small intravenous doses should be used, with careful observation for toxicity (lethargy, weakness, and loss of deep tendon reflexes).

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:384–418.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:407–424.

B.6. Does an asymptomatic carotid bruit increase the risk in these patients?

Yes. The incidence of stroke is increased in such patients, although the stroke may not be thrombotic or related to the carotid artery in which the bruit was heard. Bruits are general predictors of vascular disease and may be predictors of

perioperative strokes. It is important to note that in patients who are asymptomatic from their carotid stenosis, endarterectomy is no longer recommended. Nevertheless, there continues to be much debate on this topic.

De Feo M, Renzulli A, Onorati F, et al. The risk of stroke following CABG: one possible strategy to reduce it? *Int J Cardiol*. 2005;98(2):261–266.

Yatsu FM, Hart RG. Asymptomatic carotid bruit and stenosis: a reappraisal. *Stroke*. 1983;14:301–304.

B.7. The surgery was postponed for 6 weeks. The patient was on metoprolol, aspirin, atorvastatin, captopril, hydrochlorothiazide, and potassium chloride. His BP was 160/60 mmHg and potassium 4.0 mEq per L. How would you premedicate this patient?

Because half or more of hypertensive patients still have elevated BP despite treatment, the anesthesiologist should determine the anxiety level of the patient. With this knowledge, the premedication with diazepam, lorazepam, or midazolam can be regulated to have the patient arrive in the operating room sedated. However, due to a high occurrence of delirium in the elderly receiving benzodiazepines, premedication with such agents is being discouraged. This will help to prevent a starting BP well above the optimal level. All the antihypertensive medications are continued up to the day of surgery.

Lepousé C, Lautner CA, Liu L, et al. Emergence delirium in adults in the post-anaesthesia care unit. *Br J Anaesth*. 2006;96(6):747–753.

B.8. If the patient is an untreated hypertensive patient with BP 170/70 mmHg, would you treat the patient preoperatively with an antihypertensive agent?

Yes. The preoperative administration of clonidine, β-blockers, or

ACE inhibitors has been advocated to reduce the intraoperative hemodynamic lability and myocardial ischemia in hypertensive patients. Clonidine, a central α_2-agonist, decreases sympathetic outflow and reduces plasma catecholamines, aldosterone levels, and renin activity. A single dose of clonidine, 5 μg per kg orally, 2 hours before surgery significantly decreases anesthetic requirements and hemodynamic lability in patients with mild-to-moderate hypertension. However, preoperative clonidine did not decrease BP lability during aortic operation. Perioperative use of clonidine also has been shown to have short- and long-term benefits related to cardiac morbidity and survival.

The best treatment may be cardioselective β-blocker therapy. A single small oral dose of a β-adrenergic blocking agent such as labetalol, atenolol, or metoprolol given preoperatively to untreated, asymptomatic, mildly hypertensive patients effectively attenuated tachycardia with tracheal intubation and emergence. The incidence of myocardial ischemia was reduced from 28% in the control group to 2% in the β-blocker groups. An oral-dose ACE inhibitor such as enalapril given preoperatively also attenuates the hemodynamic responses to intubation and surgical stimulation.

C. Intraoperative Management

C.1. How would you monitor this patient?

- *Electrocardiogram*. Simultaneous leads V_5 and II, multiple-lead ST-segment analysis, if possible, are essential because hypertensive patients are at increased risk for myocardial ischemia regardless of the presence or absence of coronary disease.
- *BP*. A continuous monitoring of BP is essential because of lability of BP in these patients. Direct intra-arterial measurement of BP permits beat-to-beat observation. However, noninvasive automatic oscillometric techniques usually are sufficient.
- *Pulmonary artery catheter (PAC)*. Only for those hypertensive patients with a history of CHF or a recent MI, a PAC may be helpful in managing fluid replacement and monitoring ventricular function. Of note, there is a strong correlation between hypertension and LVH, which results in poor ventricular compliance reflected by elevated pulmonary artery occlusion pressure in the face of low or normal ventricular volumes and normal contractility. Presence of CHF in hypertensive patients is frequently a marker of diastolic dysfunction and *not* systolic dysfunction.
- *Pulse oximeter*. This should be used to monitor peripheral blood flow and oxygenation.
- *End-tidal CO_2 analyzer*. This monitor will help maintain normocarbia.

C.2. What are the anesthetic goals for hypertensive patients?

The anesthetic goal is to minimize wide lability of BP in response to anesthetic and surgical stimuli to prevent the following:

- Myocardial ischemia from tachycardia or less common from either hypertension or hypotension
- Cerebral hypoperfusion from hypotension

- Cerebral hemorrhage and hypertensive encephalopathy resulting from hypertension or embolic stroke from rupture of plagues either locally or from the aorta and the neck vessels
- Renal failure from renal hypoperfusion

Particular attention to diastolic BP is strongly recommended while attempting to reduce systolic BP. It is unfortunate that clinical practice perioperatively hinges on manipulation of the systolic BP without attention to the diastolic component. This is particularly troublesome in most elderly patients who suffer from ISH and/or wide pulse pressure. In both subtypes of hypertension, the already lower diastolic pressure can easily be reduced further—predisposing to myocardial hypoperfusion and ischemia.

Lee et al. showed that patients with wide pulse pressure have an increased risk for thrombogenesis marked by elevated levels of D-dimers, von Willebrand factor, and platelet activation. This along with extensive atherosclerotic disease of the aorta, carotid, and renal arteries, which is also common in patients with ISH, provides a pathophysiologic basis for the increase incidence of perioperative stroke, MI, and renal dysfunction observed in hypertensive patients.

Lastly, careful control of the hemodynamic responses to noxious stimuli such as endotracheal intubation, surgical incision and manipulation, and emergence from anesthesia is essential in the hypertensive patient.

Lovett JK, Howard SC, Rothwell PM. Pulse pressure is independently associated with carotid plaque ulceration. *J Hypertens*. 2003;21:1669–1676.

C.3. How would you induce anesthesia for the hypertensive patient?

While the patient is being preoxygenated, fentanyl, 2 to 5 μg per kg, is given slowly to achieve drowsiness. Then, either thiopental in 50-mg increments or propofol in 30- to 50-mg increments is titrated to produce unconsciousness, followed by succinylcholine, 1 mg per kg, or nondepolarizing muscle relaxants to facilitate tracheal intubation.

All anesthetic agents are acceptable with the possible exception of ketamine, which may produce significant hypertension and tachycardia. However, deeper anesthesia with potent inhalation agents to attenuate tachycardia and hypertension should be done with caution because of higher incidence of hypotension arising from both vasodilation and cardiac depression.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:183–198.

Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. *Anesth Analg*. 1982;61:680–684.

C.4. How does tracheal intubation produce hypertension?

Translaryngeal intubation of the trachea stimulates laryngeal and tracheal receptors, resulting in marked increase in the elaboration of sympathomimetic amines. This sympathetic stimulation results in tachycardia and a rise in BP. In normotensive patients, this rise is approximately 20 to 25 mmHg; it is much greater in hypertensive patients. This increase in BP results from vasoconstriction because of unopposed α stimulation in hypertensive patients taking α-blocking drugs.

Prys-Roberts C, Greene LT, Meloche R, et al. Studies of anaesthesia in relation to hypertension. II. Haemodynamic consequences of induction and endotracheal intubation. *Br J Anaesth*. 1971;43:531–547.

C.5. What happens to the left ventricular ejection fraction during and immediately following intubation?

During and immediately following intubation associated with tachycardia and hypertension, there is a decrease in the left ventricular ejection fraction. This is particularly marked in patients with coronary artery disease. Nevertheless, such hemodynamic perturbations can be anticipated and treated accordingly with β-blockade, narcotic, and titration of hypnotic and/or inhalation agents.

Giles RW, Berger JH, Barash PG, et al. Continuous monitoring of left ventricular performance with the computerized nuclear probe during laryngoscopy and intubation before coronary artery bypass surgery. *Am J Cardiol*. 1982;50:735–741.

C.6. What other measures can prevent hypertension and tachycardia at the time of intubation?

The rise in BP and heart rate occurs approximately 14 seconds after the start of laryngoscopy and becomes maximal after 30 to 45 seconds of direct laryngoscopy. If possible, laryngoscopy time should be 15 seconds or less to minimize BP elevation. Simultaneous administration of fentanyl, 5 μg per kg with the induction dose of thiopental or propofol, can blunt the cardiovascular response to tracheal intubation. Other measures are described as follows:

- Lidocaine, 1.5 mg per kg, is given 2 minutes before intubation.
- Esmolol, up to 2 mg per kg, appears to be especially effective in providing consistent and reliable protection against hypertension and tachycardia with intubation. It is easy to titrate and does not exacerbate postintubation hypotension because of its short duration of action.
- Labetalol, 0.15 to 0.45 mg per kg, is comparable to esmolol, 1.5 to 4.5 mg per kg, in attenuating hemodynamic effects.

However, the half-lives of intravenous esmolol and labetalol are 9 minutes and 5 hours, respectively. Additionally, labetalol has minimal effects on heart rate, and through its action on α receptors, it acts similar to a vasodilator, particularly with chronic use.

- Nicardipine, 1 mg intravenously, 2 minutes before tracheal intubation maintained hemodynamic stability during the intraoperative period. Both doses of 0.015 and 0.03 mg per kg attenuated BP but not heart rate responses during emergence and extubation. Greater BP control occurred with the larger nicardipine dose of 0.03 mg per kg.

It is important to remember that all the previously mentioned doses are used with a single agent only. If a combination of different agents or anesthetics is used, doses should be decreased accordingly. Otherwise, severe hypotension may ensue.

Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. *Anesth Analg*. 1982;61:680–684.

C.7. After induction and intubation, the BP decreased to 70/40 mmHg. What would you do?

Hypotension after induction of anesthesia is usually due to combination of vasodilation, hypovolemia, and cardiac depression. Vasodilation can be caused by inducing agents such as thiopental, propofol, or midazolam; moderate-to-high doses of narcotics; and potent inhalation agents. Hypertensive patients are in relative hypovolemia because of chronic vasoconstriction and/or diuretic therapy. Preoperative bowel preparation and nothing by mouth further contribute to hypovolemia. Barbiturates, benzodiazepines, and inhalation agents can cause a mild-to-moderate degree of cardiac depression.

Hypotension after induction of anesthesia usually can be easily corrected by volume replacement and simultaneous titration of vasopressors such as ephedrine 5 to 10 mg or phenylephrine in 0.1-mg increments.

Coriat P, Richer C, Douraki T, et al. Influence of chronic angiotensin-converting enzyme inhibition on anesthetic induction. *Anesthesiology*. 1994;81:299–307.

C.8. What is your choice of agents for maintenance of anesthesia? Why?

No particular anesthetic technique or specific drug combinations have been demonstrated to be superior to others in hypertensive patients. Potent inhalation anesthetics or narcotics should be titrated to the desired level of central nervous system depression while the BP is monitored continuously.

Narcotics and nitrous oxide provide an anesthetic with less overall lability of BP, but commonly, intraoperative hypertension is difficult to control by moderate doses of narcotics. High doses of narcotics are not suitable for early extubation. Likewise, use of nitrous oxide is debatable in open cholecystectomy given its propensity to increase bowel distention—the severity being related to higher concentration of nitrous oxide and to longer duration of use. This concern is less

pertinent for laparoscopic cholecystectomy whereby insufflation of gas to pressurize the abdomen should counteract the distensible property of nitrous oxide (also see Chapter 26, section C.4).

Potent inhalation agents provide greater control of hypertension but seem to produce less stability. Isoflurane, desflurane, and sevoflurane possess the advantage of more peripheral vasodilation and less cardiac depression.

Akca O, Lenhardt R, Fleischmann E, et al. Nitrous oxide increases the incidence of bowel distension in patients undergoing elective colon resection. *Acta Anaesthesiol Scand*. 2004;48(7):894–898.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:183–198.

Taylor E, Feinstein R, White PF, et al. Anesthesia for laparoscopic cholecystectomy. Is nitrous oxide contraindicated? *Anesthesiology*. 1992;76(4):541–543.

C.9. How would you manage fluid therapy for hypertensive patients?

Patients with essential hypertension are usually hypovolemic because of vasoconstriction and diuretic therapy. Hydration of the hypertensive patient should be started before induction of anesthesia to minimize the "roller coaster" often seen with hypertension. However, overhydration should be avoided because it may contribute to postoperative hypertension when the vasodilating effects of anesthetics are gone. Therefore, careful estimation of fluid intake and output is essential. Foley catheter and central venous pressure monitor are indicated for major surgery with extensive fluid exchange.

As discussed previously, presence of LVH in hypertensive patients shifts the left ventricular compliance curve upward and leftward such that for the same ventricular volume, a higher left ventricular diastolic pressure is attained as compared to a nonhypertrophied ventricle. When managing these patients with

a PAC, higher pulmonary artery occlusion pressure (sometimes >20 mmHg) is necessary to achieve normovolemia. Cardiac output also must be checked frequently during volume challenges.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:183–198.

C.10. During the surgery, BP increased to 220/120 mmHg. How would you treat the hypertension?

Intraoperative control of hypertension is outlined in **Table 11.5**. Severe hypertension that occurs during a surgical procedure is most frequently due to inadequate anesthesia. Inadequate blockade of sensory input from the surgical procedure stimulates the elaboration of sympathomimetic amines, resulting in hypertension and tachycardia. If a potent inhalation anesthetic is being used, the level of anesthesia should be deepened by increasing the inspired concentration of the anesthetic. A narcotic may not control the rise in BP, and it may be necessary to switch to a potent inhalation anesthetic.

TABLE 11.5 Intraoperative Control of Hypertension

Anesthetics
Narcotics, inhalation agents, butorphanol, lidocaine
Antihypertensives
Adrenergic blockers
α-Blocker: phentolamine
β-Blocker: propranolol, metoprolol
α- and β-Blocker: labetalol
Calcium channel blockers
Diltiazem, nicardipine, verapamil
ACE inhibitors
Enalapril
Direct vasodilators
Hydralazine, nitroglycerin, nitroprusside
Dopaminergic agonists
Fenoldopam

ACE, angiotensin-converting enzyme.

Hydralazine, 5-mg increments, may be titrated to decrease BP safely with little chance of excessive reduction. The onset of action is in 10 to 15 minutes with 1 to 2 hours duration.

Labetalol, 5- to 10-mg increments, is very useful in controlling hypertension and tachycardia. It makes the most sense to use β-blockers after a significant rise in BP because these agents act directly to antagonize the effects of the catecholamines. Although other agents may lower the BP, it is highly possible that the excessive availability of both norepinephrine and epinephrine will continue to exert their effects at the receptor site—compromising tissue perfusion from microcirculatory vasoconstriction. This view may explain the broad anti-ischemic effects of perioperative β-blockers on the brain, the heart, and the kidneys.

Rarely, continuous infusion of nicardipine, nitroglycerin, or nitroprusside, direct arteriolar vasodilators, is needed to control hypertension during anesthesia.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:183–198.

Lindenauer PK, Pekow P, Wang K, et al. Perioperative beta-blocker therapy and mortality after major noncardiac surgery. *N Engl J Med*. 2005;353(4):349–361.

C.11. What could you do to prevent hypertension during extubation and emergence?

It is logical to use antihypertensive agents during extubation and emergence because the patient is awakened at the end of surgery. Many drugs or combinations are effective, including intravenous lidocaine, esmolol, labetalol, verapamil, or diltiazem 2 minutes before extubation. If BP goes over desired levels after extubation, additional doses may be titrated to control BP.

Mikawa K, Nishina K, Maekawa N, et al. Attenuation of cardiovascular responses to tracheal extubation: verapamil versus diltiazem. *Anesth Analg*.

1996;82:1205–1210.

C.12. Would you consider regional anesthesia for this patient?

Certainly, regional anesthesia can avoid marked increases in sympathetic tone and hemodynamic changes that occur with intubation and extubation. Spinal or epidural anesthesia may be used for lower abdominal surgery. For cholecystectomy, higher levels of regional anesthesia are needed and may compromise respiratory function or unmask hypovolemia. In addition, prolonged surgery in a nonsedated patient can cause anxiety and irritability that may induce hypertension and tachycardia.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:183–198.

D. Postoperative Management

D.1. The patient developed hypertension, BP 210/110 mmHg, in the postanesthesia care unit. What would you do?

The management of postoperative hypertension depends on the etiology of the hypertension, the clinical scenario, and the level of hypertension. First, the cause of hypertension should be determined and treated accordingly. Hypertension per se should also be treated by an antihypertensive agent. The causes of postoperative hypertension include pain, emergence excitement, hypoxemia, hypercarbia, reaction to endotracheal tube, full bladder, hypothermia, relative hypervolemia from intraoperative administration of excess fluid, and chronic medication and withdrawal. The most common cause of postoperative hypertension is incisional pain. As the patient awakens, pain triggers an outpouring of catecholamines. The extreme lability of BP in many hypertensive patients makes this rapid increase

critical to control. Depending on the cause of hypertension, intravenous analgesics and antihypertensives or diuretics should be titrated to control hypertension. If both tachycardia and hypertension occurred postoperatively, calcium channel blockers such as verapamil, diltiazem, or nicardipine and β-blocking agents such as propranolol, esmolol, labetalol, or metoprolol are preferred agents. Hypertension resulting from pain can be preventable or attenuated by asking the surgeon to inject a long-lasting local anesthetic along the incision or to perform a local nerve block.

Barash PG, Cullen BF, Stoelting RK, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1562–1606.

Cardiac Tamponade

June M. Chan

12

Four days after a two-vessel coronary artery bypass graft procedure with a mitral valve replacement, a 69-year-old, 90 kg, 167-cm tall woman presents with shortness of breath, orthopnea, oliguria, and overt weakness. On examination, she is sitting fully upright and appears anxious; her skin is cold and clammy. Her vital signs are as follows: heart rate (HR), 120 beats per minute (sinus tachycardia); respiratory rate, 38 breaths per minute; and systemic blood pressure, 115/66 mmHg.

A pulmonary artery catheter (PAC) is inserted and reveals: pulmonary artery (PA) pressure, 55/21 mmHg; pulmonary artery occlusion pressure (PAOP), 14 mmHg; central venous pressure (CVP), 23 mmHg; and cardiac output (CO), 2.7 L per minute.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of low CO following cardiac surgery?
2. Describe the pathophysiology of cardiac tamponade.
3. What are the common etiologies of cardiac tamponade?
4. What is the difference between acute and delayed cardiac tamponade?
5. What is regional cardiac tamponade?
6. Describe the ventricular interaction in cardiac tamponade.

7. How is coronary blood flow affected in cardiac tamponade?
8. What is the Beck triad? Describe the typical signs and symptoms of cardiac tamponade.
9. Define pulsus paradoxus and describe its pathophysiology.
10. What is Kussmaul sign? Is this finding consistent with tamponade physiology?
11. Which medical conditions mimic cardiac tamponade?

B. Preoperative Evaluation and Preparation

1. Interpret and explain the pathophysiologic basis for this patient's hemodynamic findings.
2. How would you optimize this patient's cardiovascular status prior to definitive diagnosis and treatment?
3. What are the radiographic findings in tamponade?
4. A limited bedside transthoracic echocardiogram is performed, demonstrating a layer of clotted blood anterior to the right atrium (RA) and ventricle. What echocardiographic findings support the diagnosis of tamponade?
5. What additional information should be obtained from a limited echocardiographic study?
6. Describe the procedures for treating cardiac tamponade. What are the clinical indications for each approach?
7. Having made the diagnosis of tamponade, what additional investigations are required prior to surgery?
8. Explain the technical and physiologic principles behind rotational thromboelastometry.
9. A rotational thromboelastometry was performed, and a 10-minute analysis reveals the following results (see **Fig. 12.9** and **Table 12.8**). How do you interpret this information?
10. Given the ROTEM® findings and high clinical suspicion for occult postsurgical bleeding, what hemostatic products would you arrange to have in the operating room?
11. How would you organize and conduct the transport of this

patient to the operating room?

C. Intraoperative Management

1. What are the cardiovascular effects of commonly used intravenous anesthetic and coinduction agents?
2. What is the effect of supine positioning and positive pressure ventilation on the hemodynamics of a patient with tamponade?
3. Describe the induction process for cardiac tamponade.
4. Following induction and intubation, the systemic blood pressure decreases to 55/30 mmHg. Describe your management.
5. What hemodynamic changes are frequently associated with opening the pericardial space?
6. Following the removal of approximately 500 mL of dark blood and clots from the mediastinum, the patient's CO remains low. What are your differential diagnoses?
7. What is pericardial decompression syndrome (PDS)?

D. Postoperative Management

1. A pericardial drain is placed following mediastinal decompression. How should this drainage tube be managed?
2. How would you manage hypertension in the intensive care unit?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of low CO following cardiac surgery?

CO is the product of stroke volume (SV) and HR:

$$CO = HR \times SV$$

A prima facie interpretation of this relationship is that a low SV and/or low HR will cause a low CO state. However, fast HR of either ventricular or atrial origin (i.e., atrial fibrillation) may

also cause a low CO state because the diastolic filling time is decreased or the atrial contribution to the ventricular filling is altered. Preload, afterload, and contractility all contribute to SV and their alterations can also result in a decrease in CO (**Table 12.1**). A decrease in preload will decrease SV if the ventricle becomes underfilled. An increase in preload can also decrease SV if it causes ventricular overdistension, thereby stretching the ventricular myocytes beyond the working limits of the length-tension relationship. A decrease in myocardial contractility can compromise CO. Finally, in a ventricle with systolic dysfunction, an increase in afterload can further impair ejection and SV. A combination of different hemodynamic disturbances can coexist in the same patient. For example, a patient can have both a decrease in contractility and a reduced preload to account for the low CO state. Therefore, correcting one problem alone may not produce the optimal hemodynamic condition.

TABLE 12.1 Differential Diagnoses of a Low Cardiac Output

Parameter	Change	Examples
Heart rate	Decrease	Bradycardia
		Heart block causing loss of AV synchrony
	Increase	Atrial fibrillation
		Ventricular tachyarrhythmias
Preload	Decrease	Hypovolemia
		Mitral stenosis
	Increase	Ventricular overdistension and systolic dysfunction
		Mitral regurgitation
Afterload	Increase	Embolism
		Outflow tract obstruction
Contractility	Direct decrease	Right and/or left ventricle • Ischemia/infarction • Stunning/hibernation
	Indirect decrease	Tamponade
		Embolism

	Negative inotropic agents
	Toxins (endotoxin, inflammatory cytokines)

AV, atrioventricular.

A.2. Describe the pathophysiology of cardiac tamponade.

The pericardium is a two-layered blind sac surrounding the atria, ventricles, proximal great vessels, and distal venae cava and pulmonary veins. Normally, 10 to 50 mL of fluid exist within the pericardial space. This plasma-like fluid is produced by the serous pericardium and is drained by the lymphatic system. The serous pericardium consists of a visceral portion, which is adherent to the epicardium, and a parietal layer, which is adherent to the outer, fibrous pericardium. The relatively noncompliant fibrous pericardium constrains the heart within the thoracic cavity. The normal physiologic functions of this pericardial constraint include limiting acute ventricular dilatation with increases in preload, preserving the "optimal" ventricular shape for mechanical efficiency, and maintaining the normal coupling of right (RV) and left ventricular (LV) function.

Cardiac tamponade may be defined as a pathologic increase in intrapericardial pressure causing a decrease in CO. In normal conditions, intrapericardial pressure is very close to intrathoracic pressure, being slightly negative relative to atmosphere at rest. In tamponade, intrapericardial pressure increases and approaches atrial and ventricular diastolic pressures. This forms a Starling resistor system that progressively impairs diastolic cardiac filling and SV, eventually causing hypotension and

shock depending on the rate of pericardial pressure increase relative to intracardiac filling pressures and the compliance of the pericardial sac (**Table 12.2**).

TABLE 12.2 Three Phases of Cardiac Tamponade

Phase	Pathophysiologic Events	Pressure Relationship
I	Pericardial fluid increases ventricular stiffness, increasing filling pressures.	LVEDP > RVEDP > IPP
II	Pericardial pressure approaches right-sided filling pressures, exerts Starling resistor forces on RV filling. Respirophasic variation in stroke volume appears.	LVEDP > IPP = RVEDP
III	Pericardial pressure approaches left-sided filling pressures. Hemodynamic instability is prominent.	IPP = LVEDP = RVEDP

IPP, intrapericardial pressures; LVEDP, left ventricular end-diastolic pressure; RVEDP, right ventricular end-diastolic pressure.

In defining tamponade as a state where intrapericardial pressure approaches cardiac diastolic pressures, it is important to note that tamponade can result from a decrease in cardiac filling pressures in the presence of modest elevations in intrapericardial pressure. This has been described as "low pressure cardiac tamponade."

A.3. What are the common etiologies of cardiac tamponade?

Common causes of increased intrapericardial pressure include blood, exudate, transudate, and air (**Table 12.3**). In the United States, the most common cause of pericardial effusions complicated by tamponade are due to malignancies, followed by iatrogenesis from interventional cardiologic procedures and surgical cardiotomy.

TABLE 12.3 Causes of Cardiac Tamponade

Category	Differential Diagnoses
Blood	• Iatrogenic/postcardiotomy • Trauma • Aortic dissection • Anticoagulation
Exudate	• Locoregional inflammation – Infectious: viral, bacterial, tuberculous – Postmyocardial infarction – Dressler syndrome • Systemic inflammation – Systemic lupus erythematosus – Rheumatoid arthritis – Sarcoidosis – Malignancy
Transudate	• Congestive heart failure • Uremia • Hypothyroidism • Radiation • Pulmonary hypertension • Hypoalbuminemia
Air	• Iatrogenic/postsurgical • Trauma • Mechanical ventilation

A.4. What is the difference between acute and delayed cardiac tamponade?

Normal adult pericardial reserve is limited to acute increases in volume of approximately 150 to 250 mL. Beyond this point, further increases will cause dramatic changes in intrapericardial pressure. In slowly accumulating effusions, the pericardium is able to remodel and stretch, thereby increasing its capacitance (**Fig. 12.1**). Massive, slowly accumulating pericardial effusions therefore can exist with little to no clinical evidence of tamponade.

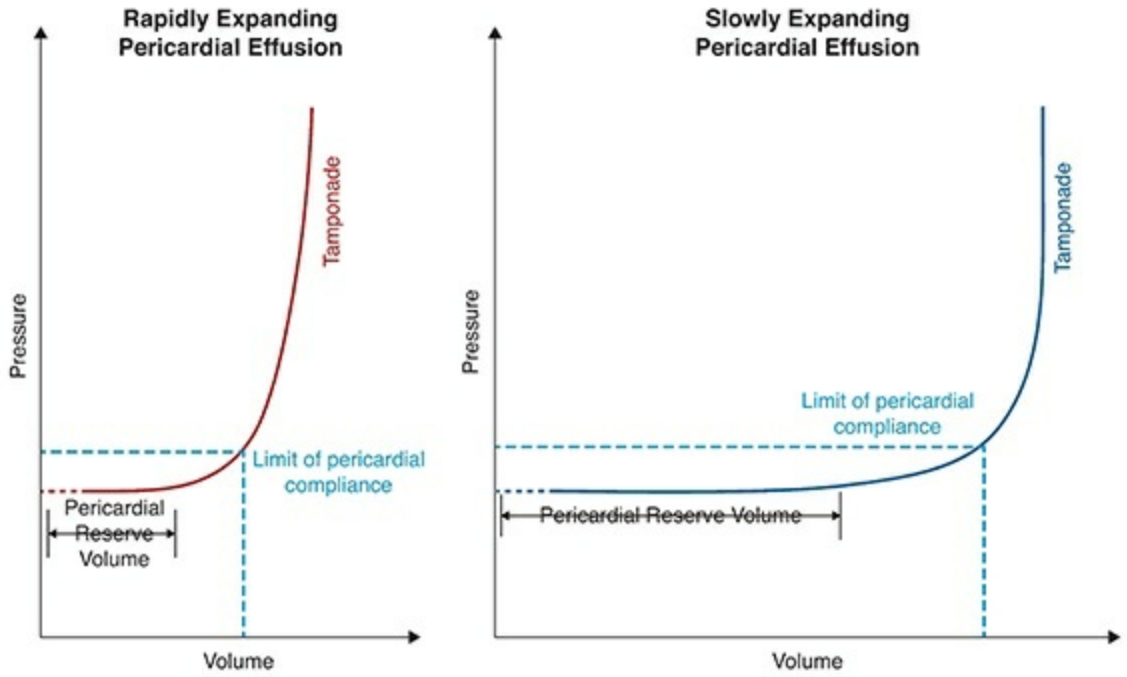

FIGURE 12.1. Acute versus delayed tamponade. In acute effusions, normal pericardium has a reserve volume of approximately 150 to 250 mL. Until this volume is exceeded, intrapericardial pressure remains relatively stable. Beyond this reserve, pericardial pressure rises until the limit of pericardial compliance is met. Once this inflection point is reached, pericardial pressure rises rapidly,

which clinically corresponds to tamponade as cardiac structures become compressed. In slowly accumulating effusions, the pericardium remodels and increases its mass and surface area, thereby increasing its overall compliance. This increases its pericardial reserve volume relative to rapidly growing effusions. (*From Imazio M, Adler Y. Management of pericardial effusion.* Eur Heart J. *2013;34[16]:1186–1197. A.5. What is regional cardiac tamponade?

In contrast to typical cardiac tamponade, where pericardial volume and pressure is evenly distributed around the heart, regional tamponade describes localized cardiac compression due to a loculated intrapericardial collection. This can occur as a result of hematoma formation in a postcardiotomy patient or subacutely from effusions developing around adhesions and septation of the pericardial space (**Figs. 12.2** and **12.3**).

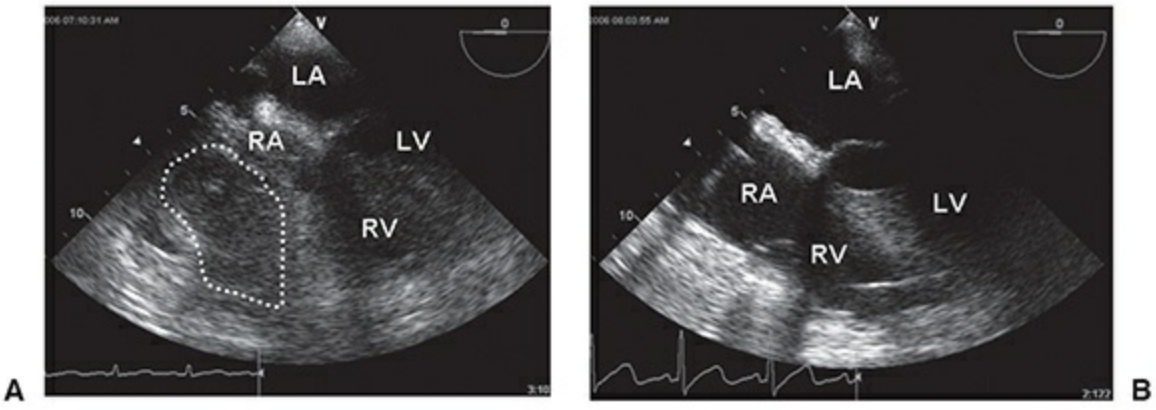

FIGURE 12.2. Acute regional pericardial effusion, right atrial compression. The heart is viewed in the midesophageal four-chamber view. In **A**, a loculated pericardial clot *(dotted line)* is seen around the right atrium (RA), almost obliterating its cavity and partially compressing the right ventricle (RV). **B** shows the same heart following decompression. LA, left atrium; LV, left ventricle.

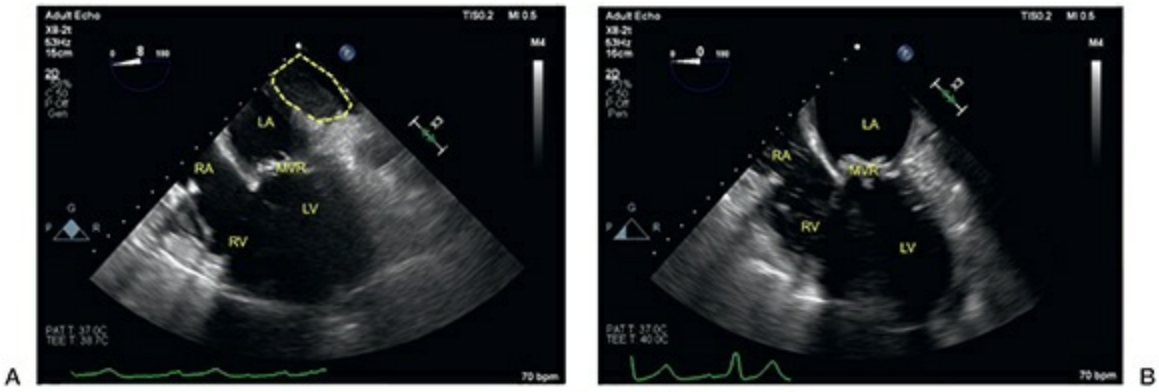

FIGURE 12.3. Acute regional pericardial effusion, left atrial compression. A and **B** show an example of regional pericardial effusion posterior to the heart, compressing the left atrium (LA). The heart is shown in a midesophageal four-chamber view, with **A** rotated leftward to center the view on the localized pericardial effusion *(dotted line)*. In both views, the left ventricle (LV) is partially obscured by shadowing artifact from a bioprosthetic mitral valve replacement (MVR). In **A**, the LA is partially compressed by the effusion. **B** shows the same heart following decompression, showing restoration of LA size. Agitated blood can be seen in the right atrium (RA) and right ventricle (RV) during intravenous fluid administration.

The low-pressure RA, right ventricle, and left atrium (LA) are most susceptible to postcardiotomy regional tamponade. Clot arising from right atrial bleeding typically localizes anteriorly and along the right lateral pericardial recess. Clot can also settle posteriorly behind the LA within the oblique sinus. In postcardiac surgery patients, the majority of effusions are anterior (especially after coronary artery bypass surgery), whereas posterolateral effusions are more commonly seen in valve replacement patients. Clinical signs and symptoms in regional tamponade can be subtle and atypical, corresponding to the discontinuous compression of cardiac chambers. Regional tamponade has been mistaken for congestive heart failure, acute ventricular dysfunction, septic shock, or pulmonary embolism.

A.6. Describe the ventricular interaction in cardiac tamponade.

RV and LV function are interdependent due to their shared septum and pericardial constraint, sometimes termed *parallel ventricular interdependence*. Under normal conditions, there is sufficient compliance in the cardiac chambers and pericardium to accommodate the distension that results from diastolic filling of one ventricle with minimal change in the filling and function of the other. In tamponade, this shared septum becomes the figurative battleground for optimal diastolic filling in the face of increasing pericardial constraint. Pericardial fluid competes with the cardiac chambers for a portion of a relatively fixed pericardial volume. Furthermore, increasing pericardial pressure increases filling pressures of all the cardiac chambers. Under these conditions, instead of free wall distension, RV filling during inspiration shifts the interventricular septum toward the left ventricle; this accommodates the diastolic volume augmented by negative pressure inspiration but at the expense of LV cavity size and compliance (**Fig. 12.4**).

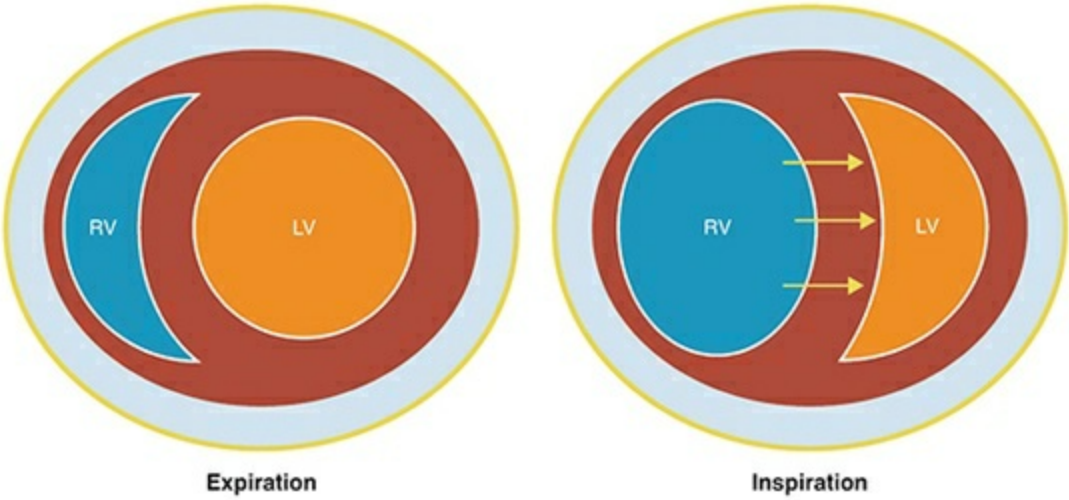

FIGURE 12.4. Parallel ventricular interdependence. In tamponade, diastolic ventricular filling is constrained by increased pericardial pressure. To accommodate increased right ventricular diastolic volume during inspiration, the interventricular septum shifts toward the left ventricle (LV). This alters LV compliance and mechanics, leading to a decrease in LV SV during inspiration. RV, right ventricle.

Series ventricular interdependence refers to the dependence of LV filling on RV output. Changes in RV SV will affect LV diastolic volume, albeit with a delay of several seconds as it crosses the pulmonary circulation to the left heart. This pulmonary transit time is highly variable, lasting 5 to 10 seconds in normal subjects at rest. In tamponade, the increasing dependence of RV filling on intrathoracic pressure will result in similar respirophasic changes in pulmonary venous return and LV SV.

Taken together, tamponade causes an exaggeration of both parallel and series ventricular interdependence: in order to fill the right ventricle, LV filling and SV becomes compromised, and LV filling is decreased if RV SV is impaired. This augmented variability in ventricular filling can be measured with Doppler echocardiography of the transmitral and transtricuspid inflow velocities, demonstrating an increase in one while simultaneously showing a decrease in the other.

Depending on the chronicity, size, and etiology of tamponade (i.e., fluid vs. clot, regional vs. global tamponade), exaggerated

atrioventricular interdependence can develop as they become subject to worsening pericardial constraint and pressure. Normally, venous return to the atria is maximal during ventricular systole and early diastole (corresponding to the *x*-descent, *v*-wave, and *y*-descent). With tamponade, the atria fill more readily when the ventricles are small (i.e., during ventricular systole) and passive atrioventricular filling becomes increasingly influenced by intrapericardial pressure as a Starling resistor. This leads to a deep *x*-descent as atrial filling occurs almost solely during ventricular systole and the loss of the early diastolic *y*-descent, both characteristic findings in cardiac tamponade (**Fig. 12.5**). Eventually, pericardial pressure increases sharply as pericardial compliance becomes exhausted. This pressure first compresses the thin-walled atria, followed by the low-pressure right ventricle, and finally the left ventricle.

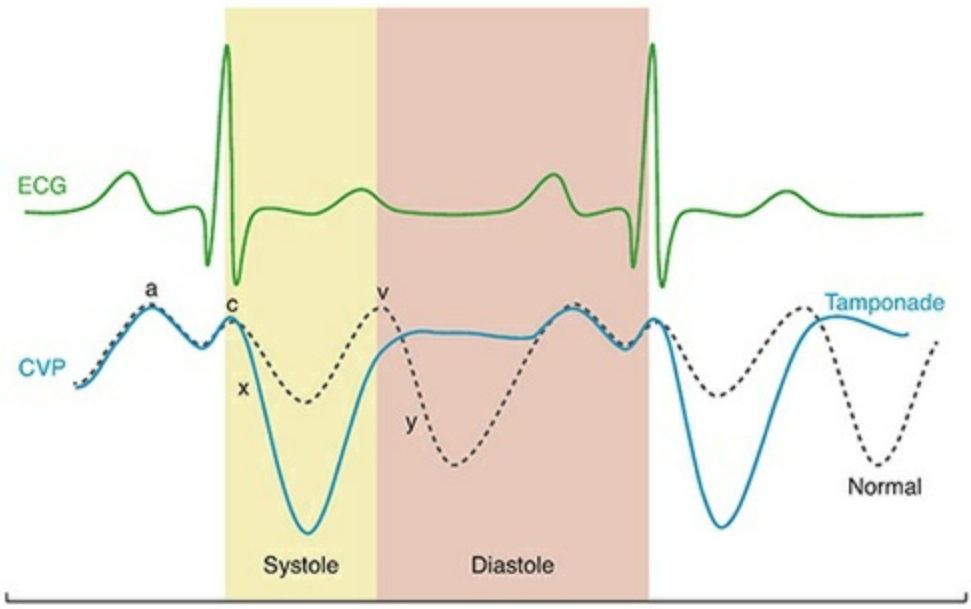

FIGURE 12.5. Central venous pressure (CVP) waveform abnormalities in tamponade. Compared with normal conditions, the CVP trace in tamponade is characterized by a deep x-descent, signaling increased atrial filling during ventricular systole (i.e., when the ventricles are small) and a loss of the y-descent. The y-descent normally coincides with opening of the tricuspid and mitral valves. During this period of diastole, the atrium acts as a conduit between the large central veins and the ventricle with venous return travelling down its hydrostatic pressure gradient to the ventricle. In tamponade, pericardial pressure acts as a Starling resistor to venous return on the atrium, dampening and eventually

eliminating the y-descent as a result. ECG, electrocardiogram.

A.7. How is coronary blood flow affected in cardiac tamponade?

In the absence of coronary artery disease, coronary blood flow can be reduced in tamponade due to the direct effect of pericardial pressure on the epicardium and extracardiac epicardial vessels. Although it has been argued that this reduction is not sufficient to add an ischemic insult to the heart because of a proportionate decrease in ventricular preload, the compensatory sympathetic outflow leading to tachycardia and increased contractility shifts the balance toward increasing myocardial demand. More recent reports have demonstrated a marked decline in coronary blood flow due to increased coronary vascular resistance with increasing pericardial pressures, with direct coronary arterial flow studies demonstrating decreased diastolic coronary blood flow and increased retrograde flow in systole.

A.8. What is the Beck triad? Describe the typical signs

and symptoms of cardiac tamponade.

The eponymous Beck triad was described in 1935 by Claude Beck, the American cardiac surgeon. In fact, he reported two characteristic triads for acute and chronic cardiac compression.

In acute tamponade, the presence of the full classic triad of distended neck veins, diminished heart sounds, and hypotension is quite uncommon occurring in only 10% to 40% of patients. The individual components are seen with varying frequency. Hypotension is present in 14% to 35% of patients, diminished heart sounds in 24% to 34%, and elevated jugular venous pressure in 53% to 88%. The most common presenting symptom in patients with symptomatic pericardial effusions requiring drainage is dyspnea (87% to 88% sensitive), and the most sensitive and specific physical finding is pulsus paradoxus (98% sensitive, 83% specific with a >12 mmHg change in pressure). Other signs and symptoms are listed in **Table 12.4**. It should be noted that patients with loculated effusions or regional tamponade may present with very few or with an atypical constellation of these signs and symptoms.

TABLE 12.4 Signs and Symptoms of Cardiac Tamponade

Symptoms	Dyspnea
	Fatigue
	Weakness
	Palpitations
	Orthopnea
Signs	Tachycardia
	Tachypnea
	Hypotension
	Diminished heart sounds
	Jugular venous distension
	Narrow pulse pressure
	Pulsus paradoxus
	“Unable to lie flat”

The second of the Beck triads, that of chronic cardiac

compression, is characterized by elevated jugular venous pressures, ascites, and diminished heart sounds. Beck described this triad most commonly in patients with tuberculous, idiopathic pericarditis, or constrictive pericarditis without effusion. The shift in symptomatology from hypotension to ascites reflects the longer-term restriction of venous return to the RA and right ventricle, leading to chronic passive hepatic congestion.

Hypertensive tamponade is an unusual variant thought to be a result of an exuberant sympathetic response to impaired cardiac filling in patients who develop tamponade over days to weeks. These patients challenge the classic aphorism of tamponade being a clinical diagnosis, with average systolic pressures of between 127 and 144 mmHg at presentation from six retrospective reviews encompassing 239 patients. These patients all had features of supportive echocardiographic criteria for tamponade, including right atrial and RV collapse and exaggerated respiratory variation of RV and LV inflow velocities. Draining the effusion leads to the normalization of blood pressure.

A.9. Define pulsus paradoxus and describe its

pathophysiology.

Pulsus paradoxus describes an abnormal, exaggerated fall in arterial pressure during inspiration, conventionally defined as a fall in systolic pressure greater than 10 mmHg. Pulsus paradoxus was first described in 1873 by Adolf Kussmaul, the German pathologist who saw a “paradox” in three patients with constrictive pericarditis; their palpated pulse would disappear during inspiration and reappear during expiration, despite the uninterrupted presence of a precordial cardiac impulse.

In healthy individuals, quiet negative pressure inspiration decreases intrathoracic pressure by approximately 5 to 10 mmHg, which is transmitted to the atria and ventricles. This augments venous return to the right heart, leading to maximal RV SV during inspiration. LV SV respiratory variation also occurs, influenced by both the lungs and the right ventricle. During inspiration, lung expansion exerts radial traction on the pulmonary vasculature and increases their capacitance. This decreases LV filling and SV, with the reverse occurring in expiration. Changes in RV SV affects LV filling with a delay of several seconds as it crosses the pulmonary circulation to the left heart. If both ventricles are “out of phase” with respect to pulmonary transit time, the effect of inspiration-augmented RV SV on LV filling is increased, increasing LV SV and systemic arterial pressure respirophasic variation. The opposite can occur if the two ventricles are “in phase.” This accounts for the respiratory variation in arterial pressure in healthy individuals with fluctuations in systolic arterial pressure ≤10 mmHg. This becomes increasingly notable when both ventricles are preload sensitive (i.e., on the steep part of the Starling curve when the left ventricle is constrained and made small by tamponade).

In tamponade, elevated pericardial pressure is transmitted to all cardiac chambers, increasing their filling pressures relative to extrapericardial structures including the majority of the venae

cava. Furthermore, increasing pericardial constraint on the cardiac chambers exaggerates parallel and series ventricular interdependence. Both factors lead to an augmentation of the respirophasic rise and fall in LV SV.

Pulsus paradoxus is not a particularly sensitive or specific sign of tamponade. It can also be seen in patients with respiratory distress due to increased negative intrathoracic pressures during inspiration, constrictive pericarditis, and RV failure. It may be absent, even in tamponade, in patients who cannot generate negative intrathoracic pressures (e.g., neuromuscular diseases, chest wall trauma) or in patients with aortic regurgitation or an atrial septal defect. Patients who are ventilated with positive pressure may display a "reversed" pulsus paradoxus, that is, an exaggerated increase in systolic arterial pressure with inspiration due to increased RV afterload causing a leftward septal shift during positive inspiratory pressure.

A.10. What is Kussmaul sign? Is this finding consistent with tamponade physiology?

Kussmaul sign describes an abnormal rise or absence of fall in jugular venous pressure with negative pressure inspiration. It is typically quantified as a <5 mmHg fall in inspiratory right atrial pressure. It is classically associated with constrictive pericarditis, but it can be seen in conditions associated with restricted right-sided filling including tricuspid stenosis and RV dysfunction.

Some controversy exists as to whether Kussmaul sign can be present in tamponade. If defined solely as a pathologic *rise* in jugular venous pressure with negative pressure inspiration, it is said that Kussmaul sign cannot be present in tamponade unless there is concurrent constriction from abnormal pericardium, pericardial clot, or adhesions. The difference between tamponade, assuming free-flowing intrapericardial fluid, and constrictive physiology is the influence of intrathoracic pressure on the intracardiac filling pressures. In constrictive pericarditis, changes in intrathoracic pressure are not well transmitted through the abnormally thickened pericardium. This effectively disassociates the cardiac chamber pressures from intrathoracic pressure changes. The RA and RV, invested within a constrictive pericardium, have abnormally high filling pressures with little to no respirophasic variation. During the rapid filling phase of diastole, right atrial and RV pressures equalize rapidly as they encounter pericardial constraint, and venous return from the inferior vena cava (IVC) and superior vena cava (SVC) compete for entry into the high-pressure RA. Because IVC inflow is favored over that from the SVC due to augmentation by transdiaphragmatic pressure, jugular venous pressure rises due to constricted SVC inflow. This causes the characteristic, paradoxical rise in jugular venous pressure in Kussmaul sign.

In tamponade, respiratory changes in intrathoracic pressure are exerted on intrapericardial fluid. right atrial and RV pressures will fall together with intrathoracic pressure during spontaneous inspiration despite the presence of tamponade, augmenting the gradient for venous return in both the SVC and IVC. This would result in a fall in jugular venous pressure with inspiration.

A.11. Which medical conditions mimic cardiac tamponade?

Cardiac tamponade is the pathologic increase in intrapericardial volume and pressure that impairs diastolic filling and CO. It is often classified as a form of "obstructive shock," which is clinically characterized by hemodynamic compromise with signs of elevated filling pressures and other evidence of great vessel obstruction or cardiac compression. Other causes of obstructive shock include pulmonary embolism, tension pneumothorax, dynamic ventricular inflow or outflow obstruction (e.g., from asymmetrical septal hypertrophy, hyperdynamic mid-cavitary ventricular obstruction, or cardiac myxoma), and effusive constrictive pericarditis. An unusual cause of tamponade is a large pleural effusion, which can cause clinical and echocardiographic findings of tamponade in the presence of a small "low-pressure" pericardial effusion. Experimental data in canines have demonstrated increasing intrapleural fluid and pleural pressure is transmitted to the pericardial sac, which then compresses the heart. In this situation, only thoracentesis will relieve tamponade.

Cardiogenic shock, and RV failure in particular, can also have similar signs and symptoms to tamponade, including jugular venous distension, pulsus paradoxus, dyspnea, and hypotension. The presence of a fever, especially in inflammatory pericarditis and tamponade, can confound the diagnosis. However, some forms of sepsis are hyperdynamic, vasodilatory shock, whereas tamponade is notable for low SV and vasoconstriction, which is an important discriminator.

B. Preoperative Evaluation and Preparation

B.1. Interpret and explain the pathophysiologic basis for this patient's hemodynamic findings.

This patient is normotensive but tachycardic, which together with her physical findings suggests a compensated shocked state. This is confirmed by her low CO and high calculated systemic vascular resistance (SVR) (**Table 12.5**). The differential diagnoses for low SV are hypovolemia, impaired LV and/or RV contractility, and obstruction of the heart or great vessels by pericardial fluid or embolism. To some degree, PAC data can assist in narrowing the diagnosis.

TABLE 12.5 Measured and Calculated Hemodynamic Parameters

Measured Parameters	Patient Data	
Heart rate (HR, bpm)	120	
Systemic blood pressure (BP, mmHg)	115/66	
Pulmonary artery pressure (mmHg)	55/21	
Central venous pressure (CVP, mmHg)	23	
Pulmonary artery occlusion pressure (PAOP, mmHg)	14	
CO (L/min)	2.7	
Calculated Parameters	**Patient Data**	**Equation**
Stroke volume (SV, mL)	22.5	SV = CO / HR
Mean arterial pressure (MAP, mmHg)	82.3	MAP = dBP + 1/3 PP
Systemic vascular resistance (SVR, dynes/sec/cm^5)	1,758	SVR = [(MAP − CVP) / CO] × 80
Pulmonary vascular resistance (PVR, dynes/sec/cm^5)	543	PVR = [(mPAP − PAOP) / CO] × 80

CO, cardiac output; dBP, diastolic systemic blood pressure; mPAP, mean pulmonary arterial pressure;

PP, systemic pulse pressure.

The patient's CVP is markedly elevated, which can be a result of potential intracardiac or extracardiac pathology. In the absence of significant tricuspid valve stenosis or regurgitation, intracardiac causes include hypervolemia (unlikely, given this patient's clinical presentation) and RV dysfunction from ischemia or outflow obstruction. This dysfunction increases RV end-diastolic pressure (EDP) and leads to a correspond rise in the venous filling pressures. Extracardiac causes of an elevated CVP include extrinsic cardiac compression by pericardial or intrapleural conditions, including tamponade and tension pneumothorax. It is important to note that in cases of extrinsic compression, the CVP is measuring the intracardiac pressure *and* the pressure applied to the RA (e.g., a hypovolemic patient with a transmural right atrial pressure of 3 mmHg can have a measured CVP of 23 mmHg once 20 mmHg of pressure is applied to the RA, creating a false impression of the patient's true filling pressures).

The patient's PA pressure is elevated. With a PAOP <15 mmHg and elevated diastolic pulmonary gradient, this points to a precapillary cause and is confirmed by the elevated calculated pulmonary vascular resistance (PVR) (**Table 12.5**). In this patient, the most likely causes are long-standing pulmonary vascular remodeling from chronic mitral disease and more acutely from pulmonary atelectasis from this patient's dyspnea and altered respiratory mechanics.

The PAOP is a surrogate measure for left atrial pressure (LAP) and can inform about LV filling as well as LV and mitral valve function. This patient's PAOP is normal and makes prosthetic mitral valve dysfunction from obstruction or regurgitation unlikely. As with CVP, caveats apply in the interpretation of PAOP and LAP with regard to LV volume

status. Furthermore, any alteration in the thick-walled LV's compliance will affect the degree to which LAP represents LV preload, which is ultimately represented by LV end-diastolic volume (EDV). For example, acute ischemia will decrease LV compliance, which would result in a higher EDV for the same EDP.

Taken together, the patient's clinical and hemodynamic findings suggest a low CO state due to either tamponade and/or RV dysfunction from ischemia or from increased RV afterload due to embolism. Concurrent LV dysfunction cannot be excluded based on PAC data alone. Echocardiography can assist with further refinement of the differential diagnoses by defining RV and LV function, relative atrial pressures and the presence of pericardial fluid.

Note that the absence of "equalization of pressures" in this patient—that is, the fact that CVP, PA diastolic, and PAOP are not within 5 mmHg of each other—does not exclude the diagnosis of tamponade. Equalization of pressures presumes that intrapericardial pressure is equally distributed through the pericardial sac and is usually a late finding when compensatory mechanisms are almost exhausted.

B.2. How would you optimize this patient's cardiovascular status prior to definitive diagnosis and treatment?

The key resuscitation goals prior to definitive management are

a. To optimize CO (which is determined by HR and SV), and
b. To maintain adequate perfusion pressure to critical organs (i.e., heart, brain, kidneys).

This patient requires SV correction to increase her CO; however, without a clear etiology for her low CO state, this should be approached cautiously. This patient's high CVP is due to either tamponade or RV dysfunction; the effect of aggressive volume administration can either improve SV or precipitate RV failure because both conditions exist on different points of the Frank-Starling curve (**Fig. 12.6**). In the absence of further diagnostic information, a prudent approach would be to administer a small fluid challenge and assess for volume responsiveness in the form of a blood pressure and/or CO increase.

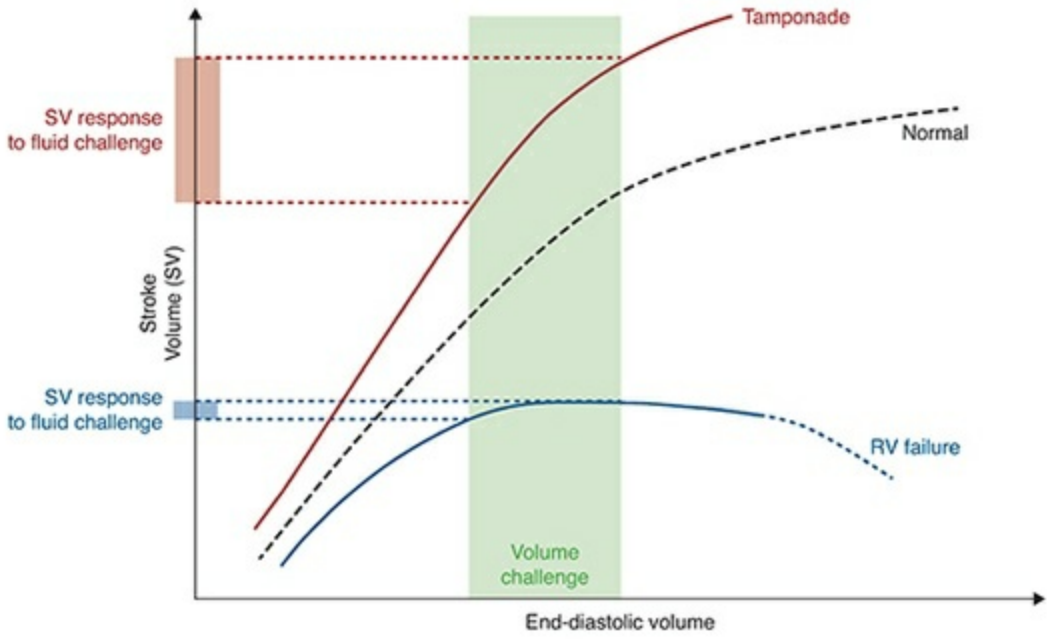

FIGURE 12.6. Predicted response to volume challenge in tamponade versus right ventricular (RV) dysfunction. This figure shows two different Frank-Starling curves referenced to a hypothetical normal curve. In tamponade, the right ventricle is underfilled and hyperdynamic. This is in contrast to the curve in RV dysfunction, where the decreased slope and early plateau reflects its depressed inotropic state. Applying the same volume to these two models leads to a large SV response in tamponade, but a minimal change in RV dysfunction, and, in this example, pushes the right ventricle into failure.

Because RV and possibly LV dysfunction are important differential diagnoses, a positive inotrope should be initiated to increase contractility and SV, especially if the patient does not exhibit a response to fluid challenge. This effectively increases the slope of the ventricle's functional Frank-Starling curve (**Fig. 12.6**). The choice of inotrope should take into account this patient's clinical trajectory as well as the pharmacologic profile for the inotropes being considered. Epinephrine, dopamine, and dobutamine are highly titratable with shorter half-lives than milrinone. Dopamine, however, is associated with severe arrhythmias and increased mortality when used in cardiogenic shock at higher doses. Dobutamine and milrinone, as inodilators, cause decreases in SVR and PVR that can improve myocardial performance in a failing ventricle but can also compromise organ perfusion pressures. In this patient, a low-dose infusion of epinephrine (0.02 to 0.05 μg/kg/min) may confer the greatest benefit in inotropy and titratability while minimizing unexpected afterload reduction and dose-related tachyarrhythmia from dobutamine. If severe RV dysfunction remains a concern, targeted pulmonary vasodilation with inhaled nitric oxide or iloprost can further optimize RV SV while limiting alterations in systemic blood pressure.

Together with SV optimization, a systemic mean arterial pressure (MAP) of at least 60 to 65 mmHg should be targeted to maintain adequate cerebral and renal perfusion. Myocardial perfusion in this patient is compromised due to depressed coronary blood flow, preexisting tachycardia, and potential tamponade. Any attempts, however, to lower HR in an effort to reduce myocardial oxygen demand without correcting SV will risk a further decline in CO that will correspondingly lower all organ blood flow, including the heart.

B.3. What are the radiographic findings in tamponade?

On standard posteroanterior chest radiography, cardiomegaly is a common finding in patients with pericardial effusions, especially those measuring 200 mL or more; the overall sensitivity is 89%. Evolving cardiomegaly in absence of pulmonary vascular congestion supports the diagnosis of effusion over cardiomyopathy and associated congestive heart failure. A pathognomic finding on an erect chest radiograph for massive effusions, often >1,000 mL, is the “water bottle” heart. This reflects the dependent distribution of fluid within the pericardial space when upright, tapering up toward the pericardial reflection at the level of the proximal great vessels. Another finding associated with pericardial effusions is the “Oreo cookie” or “fat pad” sign on lateral chest radiography. This describes a vertical radiopaque line sandwiched by two vertical radiolucent stripes located between the sternum and RV border. The opaque line represents pericardial fluid separating epicardial fat from pericardial fat within the pericardial space. In the case of tension pneumopericardium, the air surrounding the heart creates a sharply delineated air pericardiogram.

Cardiac computerized tomography can define not just the presence of a pericardial effusion but also cardiac anatomy and pericardial pathology. However, its utility in a patient with unstable hemodynamics is limited and unfeasible. Intravenous contrast enhances pericardial inflammation and hemopericardium including active extravasation. Attenuation

values of pericardial fluid can aid in characterizing the type of effusion. Transudates have lower radiodensity than exudates, which in turn are less dense than blood or clots. Other computerized tomography findings consistent with tamponade include compression of cardiac chambers, distension of the venae cavae, and reflux of contrast into the IVC or azygos vein suggesting impaired right-sided filling.

Two-dimensional and Doppler echocardiography are considered first-line imaging for tamponade. Advantages include a high sensitivity for detecting pericardial fluid and its effects on the cardiac structures, the ability to assess cardiac function and filling patterns, portability, and the lack of ionizing radiation. However, the utility of transthoracic echocardiography is limited in postcardiac surgery patients due to increased artifact from sternal wires, chest tubes, and surgical dressings.

B.4. A limited bedside transthoracic echocardiogram is performed, demonstrating a layer of clotted blood anterior to the right atrium (RA) and ventricle. What echocardiographic findings support the diagnosis of tamponade?

A key concept when interpreting imaging in a patient with suspected tamponade is that the size of a pericardial effusion does not correspond to severity of clinical symptoms; a small acute pericardial effusion can cause life-threatening tamponade but remain occult on imaging. For example, the presence of mediastinal clot is an anatomical finding that may simply reflect

a postsurgical state. Echocardiographic findings that correspond to the pathophysiology of tamponade in this patient include the following:

a. *Increased intrapericardial pressures causing diastolic collapse of the atria and/or right ventricle*. The RA is most sensitive to compression just after the atrial kick (i.e., P wave on electrocardiogram [ECG]), when atrial pressure is lowest (**Fig. 12.7**). The period of collapse extends further through the cardiac cycle with increasing pericardial pressures, so that right atrial collapse exceeding one-third of the cardiac cycle is nearly 100% sensitive and specific for tamponade. The right ventricle, with a higher chamber pressure than the atria, is less susceptible to compression, but the finding of RV diastolic collapse remains a highly specific sign of tamponade. The right ventricle is most sensitive to compression in early diastole (i.e., after T wave on ECG), when its chamber pressure is lowest.

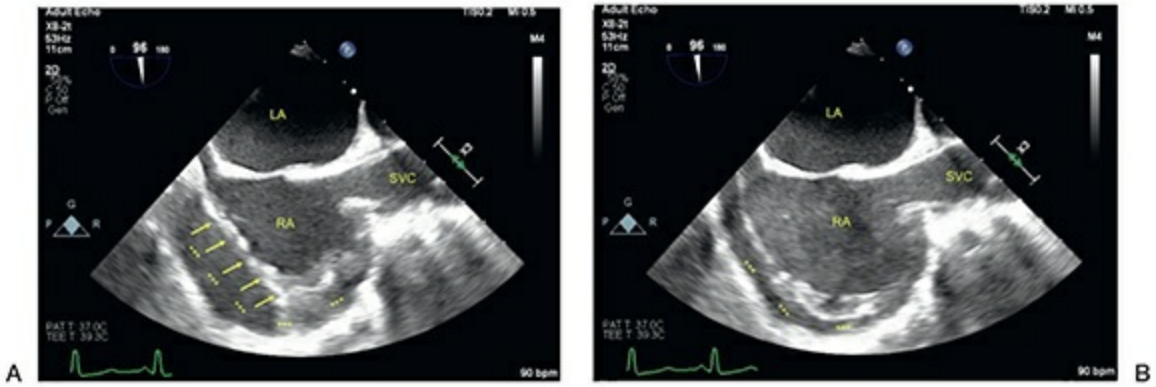

FIGURE 12.7. Right atrium (RA) collapse from early tamponade. The figures show the RA in the midesophageal bicaval view in the same patient with an acute pericardial effusion (labeled with *asterisks*). In **A**, the RA is compressed by the effusion (*arrows*) in early ventricular systole as denoted by the ECG, corresponding approximately to the x-descent on a CVP waveform when the RA is most susceptible to compression. **B** shows the RA in late ventricular systole, corresponding to a point just before the V-wave, when the atrium is at its fullest just before tricuspid valve opening. LA, left atrium; SVC, superior vena cava.

b. *Exaggerated ventricular interdependence*. Doppler

interrogation of mitral and tricuspid inflow velocities will demonstrate increased RV filling and decreased LV filling during spontaneous inspiration. This increased RV filling will cause a ventricular septal “bounce” toward the LV as RV free wall expansion meets pericardial constraint. Pulsed-wave Doppler of tricuspid inflow will show an increase in peak E-wave velocity by 40% compared with expiration, whereas mitral inflow will show a 25% inspiratory decrease in peak E-wave velocity (**Fig. 12.8**). Venous inflow to the RA can also be interrogated via pulsed-wave Doppler of the hepatic vein, which will initially show systolic blunting of systolic velocities, with increased respiratory variation in diastolic velocity. In critical tamponade, diastolic velocities may be near-absent except during spontaneous inspiration or mechanical expiration.

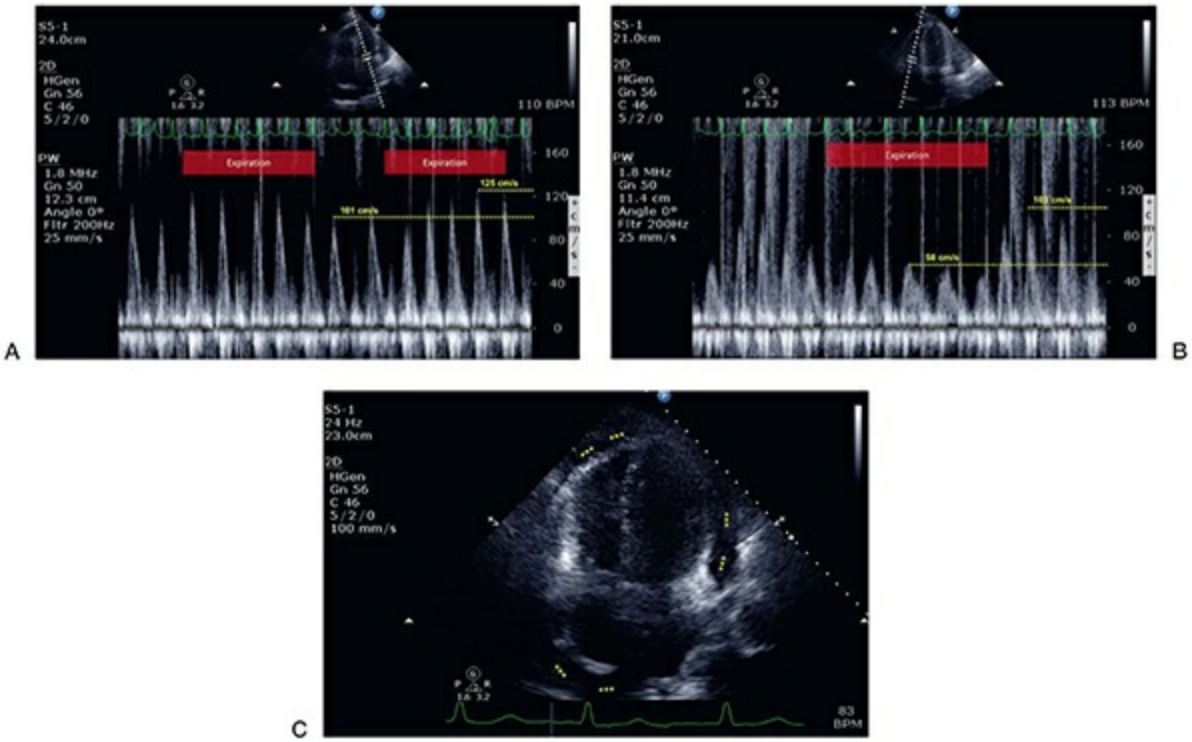

FIGURE 12.8. Exaggerated ventricular interdependence. A and **B** show pulsed-wave Doppler interrogation of transmitral and transtricuspid velocities obtained during a transthoracic echocardiographic study in a patient with suspected tamponade. The patient is breathing spontaneously;

although there is no respirogram on the original images, the patient's marked sinus arrhythmia clearly defines inspiratory and expiratory phases. During negative pressure inspiration, **A** demonstrates a 25% decrease in transmitral E-wave velocities, whereas **B** shows a >45% increase in transtricuspid E-wave velocities. This exaggerated, reciprocal change in ventricular filling is a hallmark of cardiac tamponade and constrictive physiology. **C** shows an apical four-chamber view of this patient's heart, demonstrating a large effusion outside the right and left ventricles as well as a deep pool surrounding the RA (*labeled by asterisks*). Although not evident on this still image, interventricular septal "bounce" was prominent.

c. *Decreased volume within cardiac chambers*. This is suggested by decreasedLV cavity size and exaggerated interatrial septal motion (in the presence of a high measured CVP) reflecting low transmural LA and RA pressures and the abnormal ventricular filling patterns due to increased interdependence. The IVC may be distended due to obstructed venous return.

B.5. What additional information should be obtained from a limited echocardiographic study?

Once the diagnosis of tamponade is established, a focused assessment of concurrent conditions by an appropriately trained echocardiographer is prudent as long as it does not delay clinical stabilization and definitive management. The right and left ventricles should be grossly assessed for size and systolic function. A distended right ventricle with or without worsening tricuspid regurgitation raises concern for outflow obstruction or systolic dysfunction. Regional wall motion abnormalities may be apparent if there is active myocardial ischemia. The mitral

valve prosthesis should be evaluated for malfunction using color flow Doppler, which may reveal stenosis or intravalvular regurgitation from leaflet dysfunction or paravalvular leak from suture line dehiscence.

B.6. Describe the procedures for treating cardiac tamponade. What are the clinical indications for each approach?

Pericardial decompression can be performed percutaneously or surgically. Percutaneous echocardiographically guided catheter decompression is the treatment of choice in patients with nonloculated, free-flowing pericardial fluid. Subxiphoid, parasternal, and apical approaches each have advantages and disadvantages (**Table 12.6**). Existing cardiology literature and guidelines advocate taking the approach with the maximal effusion depth on ultrasound to minimize the risk of cardiac puncture. Percutaneous options are unlikely to be appropriate for this patient because there is a high likelihood of compression from clotted blood on imaging.

TABLE 12.6 Approaches to Pericardiocentesis

Approach	Insertion Site	Approach-Specific Complications
Subxiphoid	Between xiphoid process and left costal margin	Peritoneal injury
Apical	Near apex beat, at fifth to seventh intercostal space in the anterior axillary line	Left pneumothorax
Parasternal	Fifth intercostal space, left sternal	Pneumothorax

margin	
	Internal mammary artery injury

Adapted from De Carlini CC, Maggiolini S. Pericardiocentesis in cardiac tamponade: indications and practical aspects. *e-J Cardiol Pract*. 2017;15(19). Available at https://www.escardio.org/Journals/E-Journal-of-Cardiology-Practice/Volume-15/Pericardiocentesis-in-cardiac-tamponade-indications-and-practical-aspects.

In patients with an intact pericardium and free-flowing pericardial fluid, surgical decompression can be performed in conjunction with a limited pericardiectomy, opening a drainage "window" to the pleural space to prevent recurrence. Minor pericardial adhesions can be manually divided and loculated effusions drained. Subxiphoid, transthoracic via anterior mini-thoracotomy, and thoracoscopic approaches have all been described. It should be noted that the subxiphoid approach does not technically create a "pericardial window"; rather, it provokes inflammatory fusion of the pericardium to the epicardium, thereby obliterating the potential space for recurrence. In unstable patients, only subxiphoid and anterior thoracotomy approaches are suitable. An important advantage of the subxiphoid approach is that it can be performed under local anesthesia and conscious sedation in anatomically suitable patients (e.g., nonobese body habitus, absence of ascites) who are otherwise too unstable for induction of general anesthesia. Local anesthesia for the anterior thoracotomy approach has also been described but may be poorly tolerated because it requires dissection through the pectoralis muscles and intercostal spaces. In postcardiac surgery patients, a limited sternal reopening under local anesthesia and conscious sedation may be tolerated and can confer some physiologic benefit prior to definitive exploration. However, most patients within this population are typically not candidates for limited rescue techniques and will require full sternotomy to evacuate clotted blood, drain residual fluid, and identify the source of ongoing bleeding.

B.7. Having made the diagnosis of tamponade, what additional investigations are required prior to surgery?

This patient has cardiac tamponade likely arising from postcardiac surgery bleeding. Although her vital signs are adequate, she is at risk for decompensation and should undergo a focused, expedited workup so that surgical treatment is not unnecessarily delayed. Point of care blood tests such as arterial blood gases (ABGs) and rotational thromboelastometry can provide rapid, relevant information to guide preoperative preparation. An ABG may reveal a low pH and/or elevated lactate from hypoperfusion, gas exchange abnormalities, electrolyte derangements, and anemia. Rotational thromboelastometry provides real-time information on coagulation factor activity and clot kinetics. Formal laboratory investigations should include a complete blood count, coagulation profile, and type and screen. The presence of anemia, thrombocytopenia, or coagulation abnormalities guides the type and amount of blood products required and should be immediately available in the operating room prior to surgery. A baseline ECG can provide additional information if the suspicion for ischemia is high and may provide supportive

information such as low voltage QRS complexes, electrical alternans, and RV strain. Although radiographic findings were discussed earlier, a chest x-ray or CT is unlikely to add diagnostic value in this patient and should not delay surgery unless there is a strong clinical indication.

Carmona P, Mateo E, Casanovas I, et al. Management of cardiac tamponade after cardiac surgery. *J Cardiothorac Vasc Anesth*. 2012;26(2):302–311.

B.8. Explain the technical and physiologic principles behind rotational thromboelastometry.

Rotational thromboelastometry measures the viscoelastic properties of blood samples. Citrated blood is introduced into a cuvette together with an activator, which is heated to 30°C to 40°C. A pin with a rotating axis is suspended into the cuvette during the test, and as the blood becomes more viscous, pin rotation is impeded. This impedance is detected by an optical detector system. The time course of changing viscoelasticity is plotted graphically and numerically. The parameters defining a typical a rotational thromboelastometric assay correlate to the events of coagulation as described by the cell-based model of hemostasis and are summarized in **Table 12.7**.

TABLE 12.7 Rotational Thromboelastometry Numerical Parameters

Parameter	Definition	Physiologic Correlate
Clotting time (CT)	Time for trace to reach 2 mm amplitude	Clot initiation phase
Clot formation time (CFT)	Time for trace to increase from 2 to 20 mm	Clot amplification and propagation phase
Amplitude 10 min (A10)	Trace amplitude 10 min after CT	Fibrin-platelet interaction via glycoprotein IIb/IIIA receptors
Maximum clot firmness (MCF)	Maximum amplitude (MA) of the trace, when test is run for 20 min	
Lysis Index 30 (LI30)	Percentage reduction in amplitude 30 min after MA is reached	Plasmin, thrombin-activatable fibrinolysis inhibitor (TAFI) and plasminogen activator inhibitor (PAI) activity

ROTEM *delta* and ROTEM *sigma* (Instrumentation Laboratories, Bedford MA, USA) are two commercially-available devices that can perform up to four tests concurrently. ROTEM *delta* requires manual pipetting of the blood samples and test reagents, whereas ROTEM *sigma* is a fully-automated system that uses a cartridge with integrated freeze-dried reagents. Depending on the activator reagents used, assays targeting specific components of the coagulation cascade can be performed. The INTEM reagent contains ellagic acid and phospholipid, which produces contact activation of the intrinsic pathway. EXTEM contains tissue factor and preferentially actives the extrinsic pathway. FIBTEM also activates the extrinsic pathway but contains cytochalasin D, which blocks the platelet contribution to clot formation; this isolates the fibrinogen contribution to clot formation. APTEM contains aprotinin, an antifibrinolytic, and will "correct" an EXTEM assay in the presence of hyperfibrinolysis.

Dias JD, Haney EI, Mathew BA, et al. New-generation thromboelastography: comprehensive evaluation of citrated and heparinized blood sample storage effect on clot-forming variables. *Arch Pathol Lab Med*. 2017;141(4):569–577.

B.9. A rotational thromboelastometry was performed, and a 10-minute analysis reveals the following results (see Fig. 12.9 and Table 12.8). How do you interpret this information?

There are significant derangements across the EXTEM, INTEM, FIBTEM, and APTEM assays. The CT EXTEM and INTEM are prolonged, which occurs in the presence of low coagulation factors (i.e., usually below 30% of normal levels). The A10 EXTEM and INTEM are decreased, indicating inadequate clot

firmness. This can be due to a lack of platelets or fibrinogen, because the FIBTEM A10 is also decreased, fibrinogen deficiency is implicated. Because the EXTEM and INTEM A10 are so far below the lower reference range, and platelet function contributes approximately 80% of clot amplitude, platelet deficiency or dysfunction also may coexist. The APTEM does not significantly differ from EXTEM, which suggests that hyperfibrinolysis is unlikely. However, fibrinolysis may not be apparent at 10 minutes. The assays should continue running for at least 30 minutes to more fully assess hyperfibrinolysis.

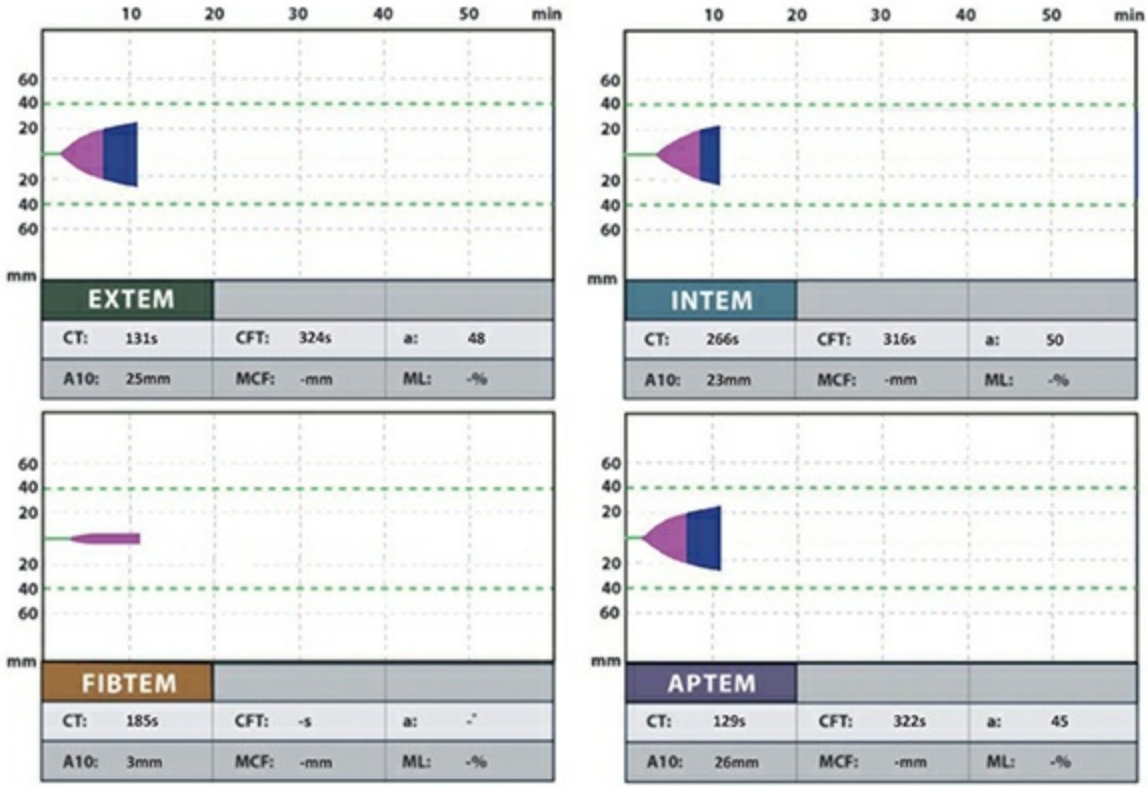

FIGURE 12.9. ROTEM® assay data. See section B.9.

TABLE 12.8 Rotational Thromboelastometry Data for Section B.9

Parameters	Patient Data	Reference Range	Parameters	Patient Data	Reference Range
EXTEM			**INTEM**

B.10. Given the ROTEM® findings and high clinical suspicion for occult postsurgical bleeding, what hemostatic products would you arrange to have in the operating room?

Clinical coagulopathy usually occurs when coagulation factor levels are <30% normal levels, fibrinogen levels are below approximately 70 mg per dL, and platelet count is ≤10,000 per mL. On ROTEM®, there is evidence of coagulation factor, fibrinogen, and possibly platelet deficiency. Therefore, sufficient plasma, cryoprecipitate, and platelets to normalize coagulation function should be arranged before the start of surgery.

Plasmas, be it fresh frozen (i.e., fresh frozen plasma, frozen within 8 hours of phlebotomy) or frozen within 24 hours of phlebotomy (FP24), differ slightly in their levels of the labile factors, factors VIII and V, but are dosed the same. A 15 mL per kg of plasma will increase most coagulation factors by 25%. Therefore, it is reasonable to have 15 mL per kg of plasma available. In this patient, using her ideal or adjusted body weight, which is approximately 60 to 70 kg, it corresponds to 4 units.

Cryoprecipitate is a concentrated blood component made from frozen plasma thawed to 1°C to 6°C. At this temperature, residues that constitute cryoprecipitate appear in plasma and are separated from the supernatant. One unit of cryoprecipitate is prepared from one unit of plasma, and contains approximately 10 to 15 mL plasma, 150 to 250 mg fibrinogen (i.e., 300 to 3,000 mg per dL, 32% of original plasma content), and factors VIII and XIII. This is often pooled into a single bag containing 5 to 10 units from multiple donors. One unit of cryoprecipitate increases plasma fibrinogen by 10 mg per dL; therefore, the equivalent of 5 to 10 units should be available.

Platelets are apheresed directly from the donor or separated from whole blood. The volume of one apheresed unit of platelets is approximately 200 to 400 mL, whereas 4 to 6 units of platelets spun from whole blood will need to be pooled to produce the equivalent volume. A dose of 10 mL per kg will raise platelet count by 30,000 to 50,000 per mL. For an ideal or adjusted body weight of between 60 and 70 kg, 1 to 2 units of apheresed or pooled platelets should be available.

Nascimento B, Goodnough LT, Levy JH. Cryoprecipitate therapy. *Br J Anaesth*. 2014;113(6):922–934.

B.11. How would you organize and conduct the transport of this patient to the operating room?

Proper transport of this patient to the operating room requires specific attention to patient monitoring and safety, essential medications and equipment, and team coordination. Patient monitoring should consist of a continuous ECG trace for arrhythmia and HR, invasive arterial access for continuous blood pressure monitoring, and audible pulse oximetry. The

transport monitor should be confirmed to be functional, positioned so that the vitals are clearly displayed, and the battery fully charged. An adequate oxygen supply and an effective oxygen delivery device for the patient's respiratory requirements should be initiated before transport. Emergency airway equipment and a defibrillator should accompany the patient. Intravenous access should be functional and secured with clearly identified injection ports for medication administration. Vasoactive infusions initiated by the treatment team should be verified and infusions pump settings confirmed. Syringes of vasopressors and inotropes, including phenylephrine, epinephrine, norepinephrine, and calcium, and intravenous fluid for volume resuscitation, if required, should be available.

Given her respiratory distress, this patient should be transported in her position of comfort, likely sitting up. Transport to the operating room should not begin until there is sufficient transport personnel present to monitor, treat the patient, and safely operate the bed; the operating room should be ready to receive the patient with the scrub technicians and perfusionists prepared, surgeon immediately available, and blood products in the room.

Fanara B, Manzon C, Barbot O, et al. Recommendations for the intra-hospital transport of critically ill patients. *Crit Care*. 2010;14(3):R87.

C. Intraoperative Management

C.1. What are the cardiovascular effects of commonly used intravenous anesthetic and coinduction agents?

Propofol

Propofol is a potent sympatholytic and vascular smooth muscle dilator. This results in hypotension from vasodilation, preload reduction from venodilation, and myocardial depression. It

blunts the baroreceptor reflex while preserving vagal tone, and bradycardia has been reported with its use. The overall effect is a decrease in venous return, CO, and systemic blood pressure, which would hasten cardiovascular collapse in this patient if given in standard induction doses.

Etomidate

Etomidate is characterized by its stable hemodynamic profile when used for induction of anesthesia. Its imidazole-based structure bears structural similarities to α_2-agonists and is thought to be responsible for peripheral vasoconstriction and the occasional hypertensive response when injected rapidly as the sole agent. Minor decreases in SVR, to a much lesser degree than propofol or thiopental, have also been reported when used in conjunction with a volatile agent. Baroreceptor and sympathetic reflexes are preserved, and there is minimal effect on myocardial contractility. Because hemodynamic responses to laryngoscopy are not affected by etomidate, a significant increase in HR and BP should be expected when given as a sole induction agent. The primary disadvantage of etomidate is the established connection between adrenocortical suppression and its use, which can occur after a single dose. However, this has not translated into increased postoperative hypotension, morbidity, or mortality in cardiac surgery patients. Taken together, etomidate is the most cardiostable intravenous anesthetic and is the drug of choice in patients with impending hemodynamic collapse.

Ketamine

Ketamine is associated with an increase in norepinephrine release that increases sympathetic outflow and is largely responsible for its stable hemodynamic profile. The mechanism by which it causes this norepinephrine release is unclear, but a direct central effect and reuptake inhibition has been postulated.

An induction dose of ketamine increases blood pressure, HR, CO, and myocardial oxygen consumption. Ketamine should be used with caution in patients with depleted endogenous catecholamine levels, such as those who are critically ill because this can unmask the direct negative inotropic effects of ketamine. This patient's sympathetic outflow appears intact, as evidenced by her tachycardia and increased SVR. In the absence of myocardial ischemia, ketamine is a reasonable choice for induction.

Thiopental

Thiopental is included here for historical interest. It is a direct myocardial depressant and also has indirect negative inotropic effects through the suppression of sympathetic outflow. It also causes vascular dilation, but because the baroreceptor reflex is preserved, there is less hypotension when compared with an equivalent dose of propofol, and the subsequent tachycardia minimizes the decrease in CO from venodilation. In a patient with tamponade, however, the hypotensive effects are exaggerated, and its use is not recommended.

Fentanyl

The hallmark of fentanyl is that it causes minimal to no myocardial depression. However, its strong vagotonic effect leads to a decrease in HR, which may lead to a decrease in SV. It preserves coronary autoregulation and has no histaminergic effects. When given in combination with midazolam or other sedatives, however, fentanyl may produce more clinically significant hypotension.

Midazolam

Midazolam exerts a dose-related veno- and vasodilatory effect. When given in typical anxiolytic doses, it can decrease SV and SVR by 10%, but because the baroreceptor reflex is preserved,

CO is maintained. Hypotension can become marked if it is used in higher doses or in combination with fentanyl. It suppresses sympathetic outflow and decreases myocardial oxygen consumption. Because of its rapid onset and MAC-sparing, midazolam can be a useful coinduction agent in this patient. Some hypotension should be expected because of her dependence on sympathetic tone to compensate for her shocked state.

C.2. What is the effect of supine positioning and positive pressure ventilation on the hemodynamics of a patient with tamponade?

Instituting positive pressure ventilation in a patient with tamponade can result in cardiovascular collapse due to critical impedance of cardiac filling. The increase in intrathoracic pressure is added to intrapericardial pressure, which worsens the Starling resistor pathophysiology of tamponade. Supine positioning, with or without positive pressure, can also further impede filling. An anterior clot or effusion can, with gravity, worsen right atrial and RV compression when the patient is supine. Increased diaphragmatic splinting in a patient already in respiratory distress will limit the negative intrathoracic pressures generated in spontaneous ventilation; this further compromises the gradient for venous return to the RA.

C.3. Describe the induction process for cardiac tamponade.

Standard monitoring, secure intravenous access, functional equipment, and skilled assistance should be prepared per usual practice. As previously discussed, intravenous fluids, vasopressors, positive inotropes, and blood products should be immediately available. Preinduction invasive arterial pressure monitoring is required due to expected hemodynamic instability during the procedure. Although PAC data may be useful for intra- and postoperative optimization, it is not essential for safe induction. Transesophageal echocardiography (TEE) is a useful adjunct and should be utilized postinduction if a skilled operator is available. A rapid sequence induction with etomidate or ketamine as the induction agent; a rapid-acting muscle relaxant; and additional modifiers, such as midazolam, lidocaine and an opioid, to ensure amnesia and to blunt the hemodynamic responses to intubation, should be the primary induction plan. During the preoxygenation process, the patient should be positioned in a way that considers the patient's comfort (e.g., sitting upright) while allowing for quick conversion to a more favorable intubating stance with induction of anesthesia. Because of the potential for hemodynamic collapse with general anesthesia and positive pressure ventilation, it is imperative that induction only takes place once the patient is surgically draped and the surgeons are gowned and gloved ready for immediate chest decompression.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:883–973.

C.4. Following induction and intubation, the systemic blood pressure decreases to 55/30 mmHg. Describe your management.

This is likely a culmination of the anticipated effects of anesthetic agents, the supine position, and positive pressure ventilation. Pericardial decompression is the definitive treatment; the surgeons should be informed immediately to begin without delay while resuscitative efforts continue. Preload should be maximized with fluid challenges and minimization of positive pressure ventilation—a combination of hand ventilation with low tidal volumes and limited apnea with 100% inspired oxygen may be required. Contractility should be maintained with boluses of epinephrine and calcium if deficient, and anesthetic agents should be titrated to ensure amnesia without excessive negative inotropy. Afterload should be maintained by titrating in norepinephrine to achieve a MAP of 60 to 65 mmHg for preservation of critical organ perfusion. In the event of worsening CO, cardiac massage may be required. It should be noted that external cardiac massage has reduced efficacy in tamponade due to the elevated cardiac filling pressures, which continues to impede venous return during the relaxation phase of chest compressions. In a situation where chest compressions are being seriously considered, opening the pericardium should occur immediately instead.

Kaplan JA, Augoustides JGT, Manecke GR, et al, eds. *Kaplan's Cardiac Anesthesia: For Cardiac and Noncardiac Surgery*. 7th ed. Philadelphia, PA: Elsevier; 2017:883–973.

C.5. What hemodynamic changes are frequently associated with opening the pericardial space?

When opened, the pericardial space is exposed to atmospheric pressure. For free-flowing pericardial effusions, this will immediately decompress the cardiac chambers leading to a rapid rise in preload, SV, and CO. This can often be seen on hemodynamic monitoring as a dramatic rise in systemic blood pressure, a reduction in pulmonary artery pressure (PAP) and CVP, and normalization of tachycardia (**Fig. 12.10**). In a patient who may have required high doses of vasopressors to maintain perfusion prior to pericardiotomy, this can result in severe hypertension. In patients who have had an overly aggressive fluid resuscitation, the sudden release of cardiac constraint can lead to acute pulmonary overcirculation and edema as well as RV dysfunction. For this reason, it is important to be aware of the surgical progression in order to properly anticipate the effects of pericardial opening. Should extremes of hypertension occur, it is effectively treated with rapid weaning of vasopressors, deepening the level of anesthesia, administering analgesia, and titrating short-acting vasodilators until the blood pressure is normalized.

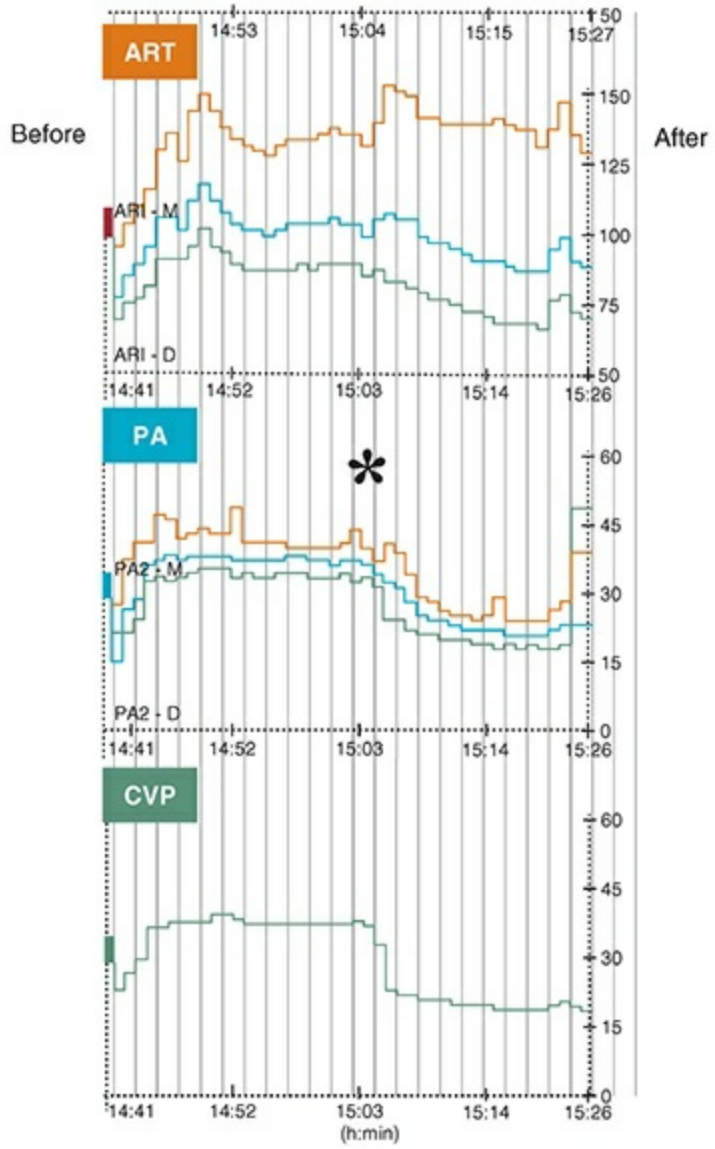

FIGURE 12.10. Intraoperative hemodynamics before and after pericardial decompression. Arterial blood pressure (ART), pulmonary artery pressure (PA), and central venous pressure (CVP) are shown during mediastinal exploration for cardiac tamponade. The moment of pericardial decompression is marked by the *asterisk*. Note the elevated CVP, PA diastolic pressure, as well as the narrow systemic pulse pressure prior to decompression, demonstrating extrinsic pericardial pressure on the RA and LA and its effect on decreasing LV SV. Shortly following pericardial decompression, CVP and PA pressures decrease almost immediately accompanied by an increase in systemic arterial pressure. Systemic pulse pressure continues to increase, reflecting the recovery of SV and presumably CO.

Carmona P, Mateo E, Casanovas I, et al. Management of cardiac tamponade after cardiac surgery. *J Cardiothorac Vasc Anesth*. 2012;26(2):302–311.

C.6. Following the removal of approximately 500 mL of dark blood and clots from the mediastinum, the patient's CO remains low. What are your differential diagnoses?

Persistent hypotension following pericardial decompression can be a result of deficient preload, afterload, and/or contractility. If there is surgical evidence of ongoing hemorrhage, treating hypovolemia should be a priority. Because this patient has a PAC in situ, a review of CVP and diastolic PAP trends can be helpful in assessing ventricular filling pressures and optimizing fluid resuscitation. Residual clot and regional tamponade should be evaluated with TEE and careful surgical exploration; in particular, clot located posteriorly within the oblique sinus can continue to compress the LA (**Fig. 12.3**) and may not be immediately apparent on initial surgical survey.

TEE is also invaluable in evaluating myocardial contractility. Ventricular function may be impaired from coronary insufficiency and active ischemia or it may persist even after restoration of adequate coronary perfusion (i.e., "myocardial stunning"). Both conditions may present as cardiogenic shock and manifest wall motion abnormalities on TEE and should be managed by optimizing myocardial oxygen supply and demand while preserving critical organ perfusion with careful use of inotropic support if required.

A low SVR state may result from vasodilatory medications, including anesthetics and inotropes (e.g., milrinone, dobutamine, low-dose epinephrine). Isolated vasoplegia, although not typically associated with this procedure, can occur in the presence of an exuberant surgical inflammatory response, stress-related depletion of endogenous vasopressin, and acquired catecholamine resistance. Norepinephrine is recommended as a first-line agent for treating vasoplegia, although this is largely

extrapolated from septic shock study data. If high doses of norepinephrine are required to maintain adequate perfusion pressures, the addition of vasopressin may be useful to overcome catecholamine resistance, limit catecholamine doses, and possibly reduce the incidence of postoperative renal failure.

C.7. What is pericardial decompression syndrome (PDS)?

PDS describes paradoxical cardiogenic shock and pulmonary edema following drainage of pericardial effusions. It can present immediately following percutaneous or surgical drainage but can be delayed by up to 24 to 48 hours. The exact etiology of PDS is unclear but has been attributed to many causes including myocardial stunning from impaired epicardial perfusion, acute RV failure from volume overload with decompression, acute septal shift from RV filling causing LV dysfunction, stress cardiomyopathy from postdrainage neurohormonal alterations, acute severe postdrainage hypertension, and abrupt catecholamine withdrawal following restoration of normal cardiac filling dynamics. In a retrospective review of 35 cases, almost all of the patients presented with cardiac tamponade (94%) with normal predrainage ventricular function and large pericardial effusions, although PDS occurring after drainage of effusions as small 250 mL, has been described. The majority of patients presented with LV or biventricular failure (60%), followed by isolated cardiogenic pulmonary edema (29%) and RV failure (9%). There is a paucity of information regarding preventive measures apart from slow, rather than rapid,

pericardial decompression, and treatment is supportive. The timeline to myocardial recovery is variable.

D. Postoperative Management

D.1. A pericardial drain is placed following mediastinal decompression. How should this drainage tube be managed?

Following open surgical drainage, a pericardial drain is connected to a closed, underwater seal system to prevent air entry into the mediastinum during negative pressure inspiration. Low-pressure suction (in the range of −15 to −25 cm H_2O), is typically applied to facilitate clearance of effusions and air, but clots can still form within the tubing leading to a recurrence of tamponade if not cleared. Although a small respiratory "swing" may be present in drain tubing fluid or in the water seal, "bubbling" is not typical unless there is a concurrent pneumomediastinum or a pneumothorax in direct connection to the drain. For percutaneous drainage, a pigtail catheter is typically connected to a closed drainage system for gravity drainage with a stopcock for aspiration and flushing to maintain

catheter patency. Some percutaneous drain care protocols advocate regular aspiration every 4 to 6 hours with instillation of heparinized saline after each aspiration attempt. Regardless of the type of drainage tube, all patients should be monitored closely for reaccumulation of pericardial fluid from catheter malfunction. The dwell time for the catheter should be minimized to prevent infective complications. Drains are typically removed when there is <30 to 50 mL drainage over a 24-hour period or after 24 to 72 hours.

D.2. How would you manage hypertension in the intensive care unit?

Hypertension following resolution of tamponade is common. The etiology can be directly related to the posttamponade state, a postprocedural complication, or from issues that are generally applicable to any postsurgical patient. In posttamponade patients, hypertension is typically due to ongoing sympathetic activation and relative baroreceptor insensitivity, although residual consequences of tamponade such as acidosis, hyper- or hypovolemia, and/or systemic inflammatory response can also be responsible. Serious complications that may present with hypertension such as heart failure with pulmonary edema, stroke, hemorrhage, and myocardial ischemia should be actively ruled out. More general causes of postoperative hypertension including pain, anxiety, cold, hypoxemia, hypercarbia, and delirium should be individually addressed with specific pharmacologic and nonpharmacologic therapies.

Controlling hypertension is important not only in order to prevent myocardial strain and end-organ damage but also to

limit direct complications including surgical bleeding and worsening reperfusion injury. Initiating antihypertensive therapy takes into account not only the likely mechanism of hypertension but also the patient's comorbidities and baseline systemic blood pressure. The evidentiary basis for maintaining MAP within 20% of baseline values comes from clinical data showing an increased risk of end-organ hyperperfusion and damage with sustained blood pressures (i.e., >10 minutes) beyond this range. By targeting the patient's baseline MAP, organ perfusion pressures are maintained within the individual's autoregulatory range.

Assuming reversible causes of hypertension are corrected, the ideal antihypertensive for acute control should be short acting and titratable. Maintenance antihypertensive therapy should also have an evidence base demonstrating benefit when contextualized to the patient's comorbidities. In acute perioperative hypertension with or without associated excess sympathetic discharge, intravenous dihydropyridine calcium channel blockers such as nicardipine and clevidipine are recommended. Clevidipine has a rapid onset–offset profile due to its metabolism by tissue and blood esterases, resulting in a half-life of approximately 1 minute and is an ideal agent for acutely controlling hypertension. Nicardipine, by contrast, has a rapid distributive α half-life of 2.7 minutes, which increases to 44.8 minutes and 14.4 hours for its intermediate β and γ half-lives, respectively. Outside of acute antihypertensive therapy, the dihydropyridine calcium channel blockers play an adjunctive role for maintenance therapy in patients with ischemic heart disease and are not recommended in patients with heart failure with reduced ejection fraction.

Labetalol is an alternate agent that is particularly useful in the presence of tachycardia. Given intravenously, it has an approximately 7:1 nonselective β- to α_1-antagonist effect with an

onset of effect in 2 to 5 minutes. Its peak hypotensive effect occurs within 10 minutes, and its elimination half-life is 3 to 5 hours. If warranted, maintenance β-blocker therapy, with carvedilol, the nonselective β- and α_1-blocker or cardioselective agents such as metoprolol, confers additional survival benefit in this patient with ischemic heart disease and is a first-line therapy for chronic treatment.

13 Heart Transplantation and Subsequent Noncardiac Surgery

Jeff T. Granton , Ranjana Bairagi, and Davy Cheng

A 41-year-old man with a history of idiopathic dilated cardiomyopathy (IDCM) is admitted to the cardiac care unit in a quaternary cardiac center for potential heart transplantation assessment. He has known systolic dysfunction, with an ejection fraction of <20% on transthoracic echocardiogram. Recurrent ventricular arrhythmias necessitated the insertion of an implantable cardioverter-defibrillator (ICD). Right heart catheterization revealed a pulmonary vascular resistance (PVR) of 4 Wood units. Recently, his symptoms have worsened and have progressed to New York Heart Association class IV. He is subsequently placed on the transplant list with high priority. However, due to further deterioration, consideration is being given to the insertion of a left ventricular assist device (LVAD) to maintain adequate end-organ perfusion while waiting for a donor heart to become available.

A. Medical Disease and Differential Diagnosis

1. What are the common diagnoses requiring adult heart transplantation?

2. What are the indications and relative contraindications for recipient selection?
3. What are the criteria for donor heart selection?
4. What is the role of donation after cardiac death (DCD) for heart transplantation?
5. What are the principles of perioperative donor management?
6. What are the risk factors associated with posttransplant mortality?
7. What is the difference between the biatrial and bicaval surgical techniques of heart transplant?
8. When is a combined heart-lung transplant indicated? What are the important differences?
9. What are the medical and surgical alternatives to cardiac transplantation?
10. What is the role of ventricular assist devices (VADs) in this type of patient?
11. What are the considerations in anesthetizing patients for LVAD insertion?

B. Preoperative Management

Three weeks after insertion of an LVAD, a donor heart becomes available.

1. How would you assess this patient preoperatively?
2. How would you premedicate this patient? Why?

C. Intraoperative Management

1. What anesthetic equipment and monitors would you set up? Why?
2. What is the role of transesophageal echocardiography (TEE)?
3. Describe the induction and maintenance of anesthesia.
4. How would you manage this patient during cardiopulmonary bypass (CPB)?

D. Postoperative Management

1. What are the early postoperative complications?
2. What are the mechanisms of early right ventricular (RV) failure?
3. How would you treat RV failure following heart transplantation?
4. How does inhaled nitric oxide (NO) work as a selective pulmonary vasodilator?
5. What is the pathophysiology of the denervated heart?
6. What are the common cardiac dysrhythmias following heart transplant?
7. What are the causes of posttransplant bleeding?
8. How would you treat posttransplant bleeding?
9. What are the causes of early graft failure?
10. How would you manage this patient in the intensive care unit?

E. Subsequent Noncardiac Surgery

The patient recovers successfully following heart transplant. However, 2 years postoperatively, he fractures his left radius after a fall. He then presents for open reduction and internal fixation of the fracture.

1. How would you monitor this patient?
2. What type of anesthetic is best for the heart-transplanted patient?
3. What anesthetic technique would you choose for this patient?
4. Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle relaxant in heart-transplanted patients?
5. What are the anesthetic implications for heart-transplanted patients?
6. What is the significant implication of the denervated heart?
7. What is the significance of allograft rejection?
8. What is the significance of infection in these patients?
9. What are the significant implications of drug interactions?

10. What is cardiac allograft vasculopathy (CAV)? Why is this important?
11. What is the significant implication of posttransplant hypertension?
12. What is the significant implication of renal dysfunction?
13. What types of malignancy are found in recipients?
14. Is ambulatory surgery appropriate for heart transplant recipients?

A. Medical Disease and Differential Diagnosis

A.1. What are the common diagnoses requiring adult heart transplantation?

Heart transplantation is now considered to be a viable treatment option for selected patients with end-stage heart disease. At present, more than 5,800 heart transplants are done annually worldwide. The indications for adult heart transplantation, as reported to the Registry of the International Society for Heart and Lung Transplantation in 2018, are shown in **Figure 13.1**. Ischemic coronary artery disease (33.1%) and nonischemic cardiomyopathy (50.5%) represent the most frequent causes for transplantation.

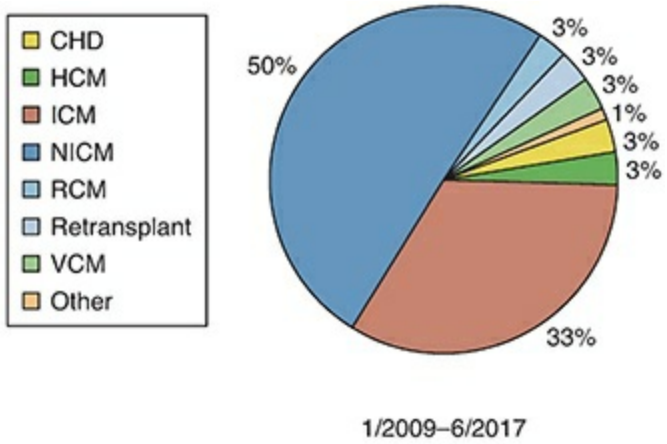

FIGURE 13.1. International Society for Heart and Lung Transplantation: Adult Heart Transplant Diagnosis for transplants performed between January 1, 2009, and June 30, 2017.

CHD, congenital heart disease; HCM, hypertrophic cardiomyopathy; ICM, ischemic cardiomyopathy; NICM, nonischemic cardiomyopathy; RCM, restrictive cardiomyopathy; VCM, valvular cardiomyopathy. (*Data from Lund LH, Khush KK, Cherikh WS, et al. The registry of the International Society for Heart and Lung Transplantation: thirty-fourth adult heart transplantation report—2017; focus theme: allograft ischemic time*. J Heart Lung Transplant. *2017;36[10]:1037–1046.*)

A.2. What are the indications and relative contraindications for recipient selection?

It should be noted that indications/contraindications can be flexible and can vary from center to center.

Criteria for selection can include the following:

- End-stage heart disease with poor quality of life or poor survivability
- Refractory arrhythmias or angina despite optimal medical and surgical care
- Physiologic age younger than 70 years. However, in 2016, greater than 13.2% of heart transplant recipients were 65 years of age or older. There are cases of patients older than 70 years receiving a heart transplant.
- Maximal oxygen uptake ($\dot{V}O_{2max}$) during cardiopulmonary exercise testing is considered. Although the cut-offs are highly variable and have many caveats, generally, patients with a peak $\dot{V}O_{2max}$ <10 mL/kg/min have an indication for transplantation.
- A heart failure prediction scoring system can also be used.

Contraindications (not necessarily absolute)

- Neoplasm with significant chance of recurrence
- Obesity (body mass index [BMI] >30 kg per m^2)
- Fixed (nonresponsive) pulmonary hypertension: PVR greater than 6 Wood units or pulmonary artery transpulmonary gradient greater than 15 mmHg
- Nonreversible renal dysfunction
- Age older than 70 years
- Peripheral vascular disease, carotid stenosis (depending on

severity)

- Diabetes with end-organ damage neuropathy, nephropathy, or retinopathy
- Psychosocial impairments
- Drug or alcohol addiction, smoking, mental defect that will limit compliance with postoperative care or history of noncompliance
- Other diseases that may limit survival (HIV, pulmonary disease, hepatitis, etc.)

Steinman TI, Becker BN, Frost AE, et al. Guidelines for the referral and management of patients eligible for solid organ transplantation. *Transplantation*. 2001;71:1189–1204.

A.3. What are the criteria for donor heart selection?

The limiting factor in heart transplantation is the shortage of donor organs. In Canada, there were 202 heart transplants performed in 2016, with 189 people on the waiting list at the end of that year. In the United States, 2,655 heart transplants were performed in 2014, with over 4,000 patients on the waiting list. Following the diagnosis of brain death, organ procurement may be considered for the purpose of donation. Preferably, the donor should not have sustained prolonged cardiac arrest, severe chest trauma, intracardiac injections, septicemia, or excessive

inotropic support and should be younger than 55 years of age. In all cases, a careful clinical examination of the potential donor is undertaken to rule out coronary artery atherosclerosis and contractile dysfunction; investigations may include angiography and echocardiography. The use of coronary angiography would be dictated by patient age, sex, and risk factors. In general, a contrast left ventriculogram is avoided to reduce the risk of nephrotoxicity.

Poor ejection fraction, despite optimization of physiologic variables, would exclude a potential donation. Transplantation can proceed with mild left ventricular hypertrophy; however, wall thickness >13 mm or electrocardiogram (ECG) criteria for left ventricular hypertrophy would make transplantation unadvisable. In general, severe congenital or valvular abnormalities would preclude donation, with the exception of abnormalities in which “bench” repair can be undertaken before transplant.

Blood group ABO compatibility is important because mismatch may result in hyperacute rejection. The donor body weight should be within 20% of that of the recipient. However, in the case of a small donor matching, using BMI or height is more accurate than using weight. Preferably, donor heart ischemic time should be less than 4 hours. Prolonged ischemic time may contribute to early allograft failure; however, techniques to allow improved tolerance of ischemia may be on the horizon.

The concept of “extended-donor criteria” is becoming popular, and outcomes are favorable. At times, donor hearts are considered for transplant with one or more of the following: size mismatch, ischemic time longer than 4 hours, ventricular hypertrophy, donor age older than 55 years, malignant brain tumors, long-standing death by poisoning, and significant inotropic requirements. In fact, looking at a wide variety of

traditional reasons not to accept a donor heart, only diabetes mellitus was found to be predictive of 1-year mortality in a recipient, leading to concerns that many viable and "less than perfect" donor hearts are not being used for transplant.

Non–heart-beating (DCD) donors are now used in multiple jurisdictions for kidney, liver, and lung transplantation. There have been cases of heart transplantation from non–heart-beating donors. However, the ethical and legal issues surrounding the technique for this form of heart donation are controversial.

A.4. What is the role of donation after cardiac death (DCD) for heart transplantation?

Cardiac transplantation is limited by a critical shortage of suitable organs from brain-dead donors. As a result, there has been renewed interest in DCD. Hearts from DCD donors suffer significant ischemic injury prior to organ procurement.

Therefore, the traditional approach to the transplantation of hearts from brain-dead donors is not applicable to the DCD context. Advances in the understanding of ischemic postconditioning have facilitated development of DCD heart resuscitation strategies that can be used to minimize ischemia-reperfusion injury at the time of organ procurement. Clinically approved ex-situ heart perfusion devices allow for DCD heart preservation in a normothermic beating state and minimize exposure to incremental cold ischemia. Organ viability can then be assessed prior to transplantation, thereby minimizing the risk of primary graft dysfunction. One study in which 28 DCD heart transplants were performed showed comparable short-term outcomes to traditional donation before cardiac death (DBD) heart transplants with respect to hospital length of stay, treated rejection episodes, allograft function, and 1-year survival (DCD 86%; DBD 88%; p = 0.98). Limited data currently available suggest that 29% of DCD heart transplant recipients will require temporary mechanical circulatory support. However, all patients were successfully weaned from support and the majority exhibited normal biventricular function on follow-up echocardiogram. Further investigation into optimizing resuscitation, preservation, evaluation, and long-term outcomes is vital to ensure a broader application of DCD heart transplantation in the future.

A.5. What are the principles of perioperative donor

management?

The goals of management are to maintain euvolemic, achieve relatively normal afterload, and optimize cardiac output (CO) without excessive use of inotropic medications, in particular *β*-agonists. Unfortunately, the brain-dead patient often can become extraordinarily unstable and achieving hemodynamic stability can be a challenge. In addition, the treatment modalities to support certain end organs for donation are often at odds with each other. The onset of diabetes insipidus needs to be considered when excessive urine output (>300 mL per hour) is observed and must be treated promptly with desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]). As a result of dysfunction of the hypothalamic-pituitary system, it is suggested that hormonal replacement therapy be undertaken. This includes the use of intravenous (IV) exogenous thyroid therapy, arginine vasopressin, and methylprednisolone. In addition, adequate glycemic control should be achieved.

A.6. What are the risk factors associated with posttransplant mortality?

Overall survival at 1 year was 85.3% for recipients between 50 and 64 years of age for transplants performed from January 1,

2013, to December 12, 2016. Having congenital heart disease as the indication for transplant is a powerful predictor of postoperative 1-year mortality. In addition, the requirement of extracorporeal circulatory support, dialysis, preoperative mechanical ventilation, female gender, nonidentical ABO matching, previous blood transfusions, coronary artery disease as the indication for transplant, and being hospitalized immediately before transplant all are risk factors for 1-year mortality. Mortality during the first year is greater than the next 4 years combined; so, risk factors associated with 1-year mortality are also powerful predictors of 5-year mortality. For those who have survived after 1 year, allograft vasculopathy during the first posttransplant year, diabetes mellitus, treatment for rejection during the first posttransplantation year, recipient age, donor age, recipient weight, and transplant center volume are risk factors for 5-year mortality. Older age is associated with lower survival. Older donor age is more strongly associated with recipient posttransplant mortality, especially in the early posttransplant period.

The most common causes of death are the following:

Within 30 days posttransplant

- Graft failure, multiorgan failure, non-cytomegalovirus (CMV) infection

From 31 to 365 days posttransplant

- Non-CMV infection, graft failure, acute rejection

After 5 years

- Allograft vasculopathy, late graft failures, malignancies, non-CMV infections

A.7. What is the difference between the biatrial and bicaval surgical techniques of heart transplant?

The older biatrial technique involves anastomoses of the recipient and donor atrial cuffs. The bicaval technique maintains the aforementioned left atrial anastomoses and attempts to maintain cardiac anatomy with separate recipient's bicaval anastomoses to the donor's right atrium. There may be an advantage of decreased need for pacemakers and improved mortality with the bicaval technique.

Davies RR, Russo MJ, Morgan JA, et al. Standard versus bicaval techniques for orthotopic heart transplantation: an analysis of the United Network for Organ Sharing database. *J Thorac Cardiovasc Surg*. 2010;140:700–708.

Morgan JA, Edwards NM. Orthotopic cardiac transplantation: comparison of outcome using biatrial, bicaval, and total techniques. *J Card Surg*. 2005;20:102–106.

A.8. When is a combined heart/lung transplant indicated? What are the important differences?

Congenital cardiac disease and primary pulmonary hypertension are the most common indications for combined heart/lung transplant. Other indications include cystic fibrosis, α_1-antitrypsin deficiency, and other forms of lung disease, such as emphysema and idiopathic pulmonary fibrosis. The procedure is performed through a transverse thoracotomy incision, and the donor heart/lungs are transplanted en bloc. Important postoperative problems include bleeding and reperfusion lung injury, which may require inhaled NO or occasionally extracorporeal membrane oxygenation (ECMO). Survival following heart/lung transplant is 68% and 51% at 1 and 3 years,

respectively.

International Society for Heart and Lung Transplantation: Quarterly Data Report. Survival Rates for Transplants performed between April 1, 2010 and March 31, 2014.

A.9. What are the medical and surgical alternatives to cardiac transplantation?

An ongoing worldwide shortage of donor hearts has put ongoing pressure to medically manage patients with end-stage cardiac failure. Patients need to adhere to strict lifestyle modifications and diet; otherwise, any other therapy will have limited usefulness. As heart failure progresses, patients may respond to a variety of medications. Angiotensin-converting enzyme (ACE) inhibitors have been shown to improve symptoms and decrease mortality in patients with heart failure. Angiotensin II receptor blockers can be considered for patients who cannot tolerate ACE inhibitors. Patients with severe forms of heart failure also may benefit from a low-dose aldosterone antagonist (spironolactone), with attention paid to the potential for hyperkalemia. Tailored doses of diuretic therapy may offer some symptomatic relief. β-Blockade with carvedilol, sustained-release metoprolol or bisoprolol has been shown to reduce the risk of death. Therapy to maintain sinus rhythm is also recommended. In addition, the risk of sudden cardiac death in patients with advanced heart failure may be reduced by inserting an ICD. Furthermore, ICD implantation combined with cardiac resynchronization therapy (this can also be done alone) has been shown to improve functional class and survival in medically optimized advanced heart failure patients. Intra-aortic balloon pump (IABP) and increasingly, VAD implantation or semi-implantable paracorporeal devices also are finding a role in the management of patients as a bridge to transplant, particularly for those presenting in acute decompensated heart failure.

A.10. What is the role of ventricular assist devices (VADs) in this type of patient?

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database has tracked over 15,000 patients, with total implants approaching 2,500 per year. There were 2,380 LVAD placements in 2014. The indications for LVAD insertion seem to be changing since 2006, when 40.8% were due to life-threatening cardiogenic shock. In 2014, only 15.0% of the patients had cardiogenic shock, and progressive decline of cardiac function (37%) remains the largest single indication. Of those who received an LVAD, 53.5% were listed or were being considered for heart transplant in 2014. In general, three major categories of patients considered for VAD include (1) temporary insertion while cardiac function recovers from insult (bridge to recovery), (2) insertion while awaiting transplant or transplant assessment (bridge to transplant), and (3) patients who need long-term support but are not transplant candidates (destination therapy). Interestingly in 2014, the INTERMACS registry found that in 38.2% of patients, LVAD insertion was considered a destination therapy. The vast majority of VADs are continuous-flow pumps instead of pulsatile flow. A variety of composite risk scores have been developed to help guide patient selection for LVAD implantation. LVADs are inserted to improve end-organ function ahead of a heart transplant. Issues such as aortic valve incompetence and the presence of intracardiac shunts need to be

investigated because these may make LVAD insertion unadvisable without repair. RV function needs to be carefully assessed before and after LVAD insertion because it may preclude the insertion of an LVAD or require a biventricular device.

A.11. What are the considerations in anesthetizing patients for LVAD insertion?

Significant cardiac abnormalities (e.g., aortic insufficiency, patent foramen ovale) should be identified preoperatively and, if possible, addressed at the time of surgery. The choice and dose of agents for induction and maintenance of a general anesthetic should be done cautiously in the context of a patient with severe cardiac dysfunction. These patients may have an ICD in place, and if deactivated, placement of external defibrillator pads is advisable. LVADs can be inserted via a sternotomy or a left thoracotomy. Patients are at high risk for significant perioperative blood loss; large-bore IV access is essential, and antifibrinolytics are often administered. TEE is mandatory for LVAD insertion to assess the presence of a patent foramen ovale, ensure aortic valve competence, confirm proper position of device and cannulae, assess the amount of air in cardiac chambers, guide fluid management, and monitor the RV function. Inadequate right heart function is a potential complication after LVAD insertion and can be treated with phosphodiesterase inhibitors and inhaled NO. Vasopressin

and/or norepinephrine may be required to maintain adequate systemic vascular resistance post-CPB. However, caution needs to be exercised with vasoconstrictors because excessive afterload can impair the device function.

B. Preoperative Management

Three weeks after insertion of an LVAD, a donor heart becomes available.

B.1. How would you assess this patient preoperatively?

Prospective transplant candidates usually have been fully preoperatively evaluated by a multidisciplinary team, including cardiologists, pulmonologists, surgeons, as well as anesthesiologists. The anesthesiologist should review the recipient's current cardiac status, including medications and level of mechanical support, with particular attention to hemodynamic parameters and reversibility of elevated PVR. Pertinent anesthetic history, concomitant diseases, and fasting status also must be ascertained. Baseline electrolytes, urea, creatinine, blood glucose, international normalized ratio (INR)/prothrombin time (PT), and complete blood count should be obtained. In addition, specific preoperative investigations need to be reviewed, such as echocardiogram, pulmonary function tests, ECG, and chest radiograph. A plan also needs to be devised regarding how to handle an ICD on induction of anesthesia, and preoperative consultation with a cardiologist or

electrophysiologist may be appropriate to achieve this.

There are typically two types of patients presenting for heart transplantation. The first type of patient is relatively compensated, possibly being ambulatory in the nonhospital setting or requiring IV inotropic support. The second type is moribund and decompensated, requiring mechanical ventilation and/or mechanical circulatory support. It should be noted, however, a third type of patient is emerging, the stable and ambulatory patient with an LVAD in place. Based on data from 2009 to 2017, at the time of transplant, 39.7% of patients were on IV inotropes, 41.7% had an LVAD, 7.0% had an IABP, and 1.9% were mechanically ventilated. As the use of VADs increases, one would expect more patients to be presenting for transplant with LVADs in place. Recipients who have undergone prior cardiac surgery need to be identified because this will increase the surgical time to establish CPB due to adhesions and bleeding. Large-bore IV access must be secured and crossmatched blood should be readily available in the operating room before surgery begins. The use of antifibrinolytics is routine for these cases.

B.2. How would you premedicate this patient? Why?

Patients should be transported to the operating room with oxygen supplementation. Caution should be exercised with sedative or narcotic premedication. Sedation may blunt the patient's respiratory and sympathetic drive and can lead to hypoxemia, hypercapnia, and even hypotension. Antibiotic prophylaxis often is achieved with 1 to 2 g of cephazolin or 1 g vancomycin.

Jhaveri R, Tardiff B, Stanley TE III. Anesthesia for heart and lung transplantation. *Anesthesiol Clin North Am*. 1994;12:729–747.

C. Intraoperative Management

C.1. What anesthetic equipment and monitors would you set up? Why?

Anesthetic equipment includes a ventilator/anesthesia machine, airway and intubation setup, fluid/blood warmer, forced air warming blanket, ultrasound for central line insertion, extracorporeal bypass machine (CPB machine), and inhaled NO delivery and monitoring system. Ultrasound may also be useful for arterial line insertion due to the nature of nonpulsatile flow with LVADs. All invasive lines are placed with meticulous attention to sterile technique and under titrated sedation with supplemental oxygen. Monitors include a five-lead ECG, pulse oximeter, noninvasive blood pressure cuff, capnography, urinary

catheter, temperature probe(s), and peripheral nerve stimulator. At least one large-bore peripheral IV may be very useful if bleeding becomes excessive during the case. Routinely, a pulmonary arterial (PA) catheter is inserted via the right internal jugular vein for pre-CPB, post-CPB, and postoperative measurement of PA pressure, PVR, and CO. The PA catheter is withdrawn back to about a 20-cm position before cardiectomy. TEE also is very useful in the intraoperative management of the pretransplant and posttransplant periods. Electroencephalogram (EEG) monitoring may be applied before induction to assess depth of anesthesia. In some centers, cerebral oximetry also would be used as a monitor of cerebral oxygen delivery.

C.2. What is the role of transesophageal echocardiography (TEE)?

The echocardiographer can provide feedback to the surgeon regarding overall function of the transplanted heart. In particular, wall motion abnormalities, end-diastolic volume, valvular function, and the presence of anomalies (such as a patent foramen ovale) not appreciated prior to transplant can be assessed. Of particular interest is RV function assessment. TEE also may be useful in the assessment of surgical anastomosis. Specifically, the main PA anastomosis should be evaluated for stenosis. The long-axis view of the left atrium is composed of recipient and donor tissue and may appear large. If excessive tissue is present, an acquired cor triatriatum may develop. In addition, the stored images of the baseline function of the transplanted heart may serve as a useful comparison after transplantation.

C.3. Describe the induction and maintenance of anesthesia.

It is important to time the anesthesia induction and surgery carefully to achieve CPB at the time of donor heart arrival in order to minimize ischemia time, particularly for a resternotomy patient. Prompt securing of the airway may be required because the recipient is not always properly fasted for transplantation surgery; however, a rapid sequence induction needs to be balanced against the risk of hemodynamic compromise. The patient can be anesthetized with a variety of agents in combination, such as midazolam and fentanyl or sufentanil, which are titrated based on hemodynamic status and level of consciousness. Muscle relaxation may be achieved with pancuronium, rocuronium, or other nondepolarizing agents. In particular, when an LVAD is not in place, succinylcholine is usually not used because of the concern about bradycardia during induction because blood pressure in pre–heart transplant recipients often is heart rate dependent. The maintenance phase uses a balanced anesthetic technique. Volatile agents (sevoflurane or isoflurane) are combined with fentanyl or sufentanil, midazolam, and muscle relaxation as needed. Nitrous oxide is avoided due to its effect on PVR.

Previously, transplant centers used aprotinin as an antifibrinolytic therapy. However, Bayer, the manufacturer of aprotinin, removed it from the market after concerns of increased mortality surfaced in clinical trials. Tranexamic acid is now used in many cardiac transplant centers.

At times, a great deal of bleeding can occur during the reopening the sternum after a previous LVAD insertion. Blood should be readily available to deal with what at times is the most challenging part of the case for anesthetic management.

Fergusson DA, Hébert PC, Mazer CD, et al. A comparison of aprotinin and lysine analogues in high-risk cardiac surgery. *N Engl J Med*. 2008;358:2319–2331.

Mangano DT, Tudor IC, Dietzel C. The risk associated with aprotinin in cardiac surgery. *N Engl J Med*. 2006;354:353–365.

C.4. How would you manage this patient during cardiopulmonary bypass (CPB)?

The anesthetic management of CPB in these patients is often not different from that in nontransplant cardiac surgery patients except that rewarming usually is prolonged because of the profound cooling of the donor heart and the prolonged ischemic time. Early in the perfusion, mixed venous oxygen desaturation and metabolic acidosis must be corrected. The fluid balance, hematocrit, electrolyte composition, and serum glucose must be monitored closely. During CPB, anesthesia maintenance includes narcotic supplementation, an inhalational agent, and/or a benzodiazepine. Once a cardiac rhythm has been established and the anastomosis of the pulmonary artery is completed, the patient is placed in the head-down position for air evacuation from the left side of the heart. An isoproterenol infusion (1 to 5 μg per minute) may be considered to improve contractility and to increase heart rate to about 90 to 110 beats per minute. The heart may be externally paced via epicardial leads. Milrinone and NO are also often started as the patient is weaned from CPB to augment the RV function. The anesthesia team should be prepared for significant bleeding after separation from CPB,

especially in cases where VADs have been in place.

D. Postoperative Management

D.1. What are the early postoperative complications?

The early postoperative complications include the following:

- RV failure/pulmonary hypertension
- Denervated heart
- Bleeding
- Early graft failure

D.2. What are the mechanisms of early right ventricular (RV) failure?

Right-sided heart failure is an important cause of posttransplant morbidity and mortality. It has a diverse number of causes related to both increases in flow and resistance across the pulmonary vascular bed. One prime cause is long-standing elevation in left ventricular pressure, leading to an increase in pulmonary pressure and vasoconstriction. This pulmonary vasoconstriction may become fixed over time, compromising RV function after transplant. However, a normal preoperative PVR does not rule out the potential for RV failure posttransplant. Poor organ preservation and CPB also can have deleterious effects on graft ventricular function.

Iyer A, Kumarasinghe G, Hicks M, et al. Primary graft failure after heart transplantation. *J Transplant*. 2011;2011:175768.

Stobierska-Dzierzek B, Awad H, Michler RE. The evolving management of acute right-sided heart failure in cardiac transplant recipients. *J Am Coll Cardiol*. 2001;38:923–931.

Wagner F. Monitoring and management of right ventricular function following cardiac transplantation. *Appl Cardiopulm Pathophysiol*. 2011;15:220–229.

D.3. How would you treat RV failure following heart transplantation?

RV failure is associated with dilation, ischemia, and poor contractility. This can result in a shift of the ventricular septum to the left, with a reduction in left ventricular filling and reduced CO. Basic therapeutic goals are to maintain adequate coronary perfusion, optimize oxygen delivery, prevent further distention of the right ventricle by judicious use of fluids, minimize myocardial oxygen consumption, and reduce PVR to decrease RV afterload.

Phosphodiesterase inhibitors, such as milrinone, which have systemic and pulmonary vasodilatory effects in addition to positive inotropy, are particularly useful. Prostacyclin (PGI_2), isoproterenol (1 to 5 μg per minute), dobutamine, and nitrates also have been used with success to treat RV failure. However, vasodilator use can often be accompanied by arterial hypotension, requiring the administration of vasopressors to maintain adequate coronary perfusion. Inhaled NO also is widely used as a selective pulmonary vasodilator in severe pulmonary hypertension and RV failure. Sildenafil also can be considered when trying to reduce PVR. It should be remembered that the simple management of avoiding hypoxia and hypercarbia will help avoid elevated PVR.

In severe cases of refractory RV failure, posttransplant mechanical support should be considered, including IABP, right VAD (RVAD), or ECMO.

Wagner F. Monitoring and management of right ventricular function following cardiac transplantation. *Appl Cardiopulm Pathophysiol*. 2011;15:220–229.

D.4. How does inhaled nitric oxide (NO) work as a selective pulmonary vasodilator?

The advantage of inhaled NO as a pulmonary vasodilator lies mainly in the fact that its smooth muscle relaxant effect is limited to the pulmonary vasculature—the in vivo half-life of inhaled NO is only a few seconds. Therefore, it has little effect on the systemic circulation, unlike IV vasodilators, such as nitroprusside, nitroglycerin, prostaglandins, and calcium channel blockers. Furthermore, inhaled NO selectively causes vasodilation in ventilated lung units, thus decreasing ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and shunt. Inhaled NO (1 to 20 ppm) can result in significant decreases in PA pressure, PVR, and central venous pressure (CVP) while increasing mean arterial pressure, CO, and arterial oxygenation. In addition, a TEE-documented alteration of the ventricular septal shift with a significant reduction in RV chamber and tricuspid valvular annulus size can be seen.

Konstadt S. Nitric oxide: has it progressed from molecule of the year to wonder drug of the decade? *J Cardiothorac Vasc Anesth*. 1995;9:625–626.

D.5. What is the pathophysiology of the denervated heart?

Following cardiac transplantation, the cardiac plexus is interrupted, and the heart is denervated. The recipient atrium remains innervated but hemodynamically unimportant, whereas the donor atrium is denervated and is responsible for the electrophysiologic responses of the transplanted heart. The ECG often contains two P waves. The denervated heart retains its

intrinsic control mechanisms, which include the Frank-Starling mechanism and intact α- and β-adrenoreceptor responses to circulating catecholamines. This denervated heart lacks the ability to respond acutely to hypovolemia or hypotension with reflex tachycardia but responds to stress primarily by an increase in stroke volume. This reflects dependence of the donor heart sinus node on direct stimulation by endogenously released catecholamines and the absence of control via neural mechanisms. Interestingly, however, some studies have demonstrated reinnervation within a year after transplantation. This has led to symptoms of angina pectoris when ischemia develops in the transplanted heart.

Kobashigawa JA. Postoperative management following heart transplantation. *Transplant Proc*. 1999;31:2038–2046.

D.6. What are the common cardiac dysrhythmias following heart transplant?

A wide variety of arrhythmias can occur in the heart transplant recipient. Early on in the course of recovery from heart transplant, bradyarrhythmia is common and often self-limited. However, this underscores the utility of epicardial pacemaker placement at the time of surgery. The spectrum of other arrhythmias includes premature ventricular complexes, atrioventricular (AV) blockade, and supraventricular tachycardia. In fact, 5% to 24% of heart transplant recipients suffer from atrial fibrillation. The causes of arrhythmia include surgical disruption of normal conduction pathways and the sinus node, denervation, rejection, and coronary allograft vasculopathy. The presence of persistent arrhythmia, in particular ventricular in origin, is associated with increased long-term morbidity and mortality.

Chang HY, Lo LW, Feng AN, et al. Long-term follow-up of arrhythmia characteristics and clinical outcomes in heart transplant patients. *Transplant Proc*. 2013;45(1):369–375.

Stecker EC, Sterlich KR, Chugh SS, et al. Arrhythmias after orthotopic heart transplantation. *J Card Fail*. 2005;11(6):464–472.

D.7. What are the causes of posttransplant bleeding?

Perioperative bleeding is a significant contributor to mortality following heart transplantation. The causes of posttransplant bleeding are anastomosis leaks and coagulopathy. Immediately before weaning from CPB with the heart filled, the posterior anastomosis is carefully checked again by the surgeon for "water-tightness" because leaks in this area are more difficult and riskier to repair later. A coagulopathy, or what some term "medical bleeding," often results from a combination of mechanisms, including inadequate heparin reversal, dilution of platelets and coagulation factors, hypothermia, and CPB effects on fibrinolysis, platelet function, and factor activation. In addition, those patients with a VAD in place before transplant are at particular risk for perioperative hemorrhage, possibly exacerbated by the development of a von Willebrand syndrome.

Wegner JA, DiNardo JA, Arabia FA, et al. Blood loss and transfusion requirements in patients implanted with a mechanical circulatory support device undergoing cardiac transplantation. *J Heart Lung Transplant*. 2000;19:504–506.

D.8. How would you treat posttransplant bleeding?

Prevention of potential causes of bleeding is key. The use of antifibrinolytics is a strategy, especially if re-do sternotomy is to be undertaken. Avoidance of excessive crystalloid in the prebypass period may reduce the dilutional component of coagulopathy. Maintaining normothermia with forced air warming devices and fluid warmers also is imperative. When bleeding is evident in the postoperative period, the judicious use of packed red blood cells, fresh frozen plasma, and platelets is a starting point. If hemorrhage is not responsive to conservative measures, disseminated intravascular coagulopathy must be ruled out. If serum fibrinogen is low (less than 1.5 g per L), then the use of cryoprecipitate should be considered. Although not routine, desmopressin (0.3 μg per kg) also may have a role in refractory cases. Finally, recombinant factor VIIa has been used successfully to treat hemorrhaging in cardiac transplant patients. However, the risk of thrombosis needs to be weighed against the risk of ongoing bleeding, and consultation with a hematologist is advisable before administration. It always should be remembered that bleeding that is excessive and not clearly secondary to coagulopathy warrants surgical reexploration.

D.9. What are the causes of early graft failure?

Graft failure, primary and nonspecific, is the most common cause of death in the first 30 days after heart transplant. Etiologies include biventricular failure, RV failure often due to high PVR, flow-limiting coronary stenosis, and hyperacute rejection.

Luckraz H, Goddard M, Charman SC, et al. Early mortality after cardiac transplantation: should we do better? *J Heart Lung Transplant*. 2005;24:401–405.

Lund LH, Edwards LB, Kucheryavaya AY, et al. The registry of the International Society for Heart and Lung Transplantation: thirty-first official adult heart transplant report—2014. *J Heart Lung Transplant*. 2014;33(10):996–1008.

D.10. How would you manage this patient in the intensive care unit?

Within the first 30 days, posttransplant graft failure (primary and nonspecific), multiorgan failure, and non-CMV infection are the most common causes of death at 39%, 18%, and 12.7%, respectively. Early management goals include prevention of infection and rejection, treatment of bleeding and dysrhythmias, cardiovascular support, and avoidance of elevated PA pressures. If possible, one should aim to wean the patient from the ventilator and extubate within 24 hours. In order to facilitate oxygenation and weaning, strict supervision of fluid balance and body weight is required. Immunosuppression often is achieved with a cocktail of medications, including steroids (methylprednisolone followed by prednisone), a calcineurin inhibitor (e.g., tacrolimus), and an antiproliferative agent (e.g., mycophenolate mofetil). Some patients may benefit from induction therapy using interleukin-2 (IL-2) antagonists and/or polyclonal antibodies, for example, highly sensitized patients, those with reactive donor-specific antigens, or those with renal dysfunction on tacrolimus-delaying immunosuppression strategies. It should be noted that a significant number of centers no longer routinely administer induction immunosuppression with good results. Secondary to immunosuppression, patients sometimes are covered with ganciclovir for CMV prophylaxis.

E. Subsequent Noncardiac Surgery

The patient recovers successfully following heart transplant. However, 2 years postoperatively, he fractures his left radius after a fall. He then presents for open reduction and internal fixation of the fracture.

E.1. How would you monitor this patient?

This patient should be monitored like for nontransplant patients undergoing similar procedures. Smooth and safe anesthesia is contingent upon careful preoperative assessment, which may reduce the need for invasive monitoring with all its attendant risks. Adequate preload must be attained preoperatively and intravascular volume status maintained intraoperatively because these patients are often “preload dependent.” Monitors in the given case should include an ECG, noninvasive blood pressure cuff, capnometer, and peripheral oxygen saturation probe, and if a general anesthetic is delivered, a temperature probe, agent-specific gas monitor, and a neuromuscular stimulator should be used. For cases with potential for blood loss and fluid shifts, however, additional intraoperative monitors, including an arterial line, central venous line, pulmonary artery catheter, and TEE, should be considered. Postoperatively, increased attention should be paid to preload status, renal function, and prevention of infection. Immunosuppressants should be continued postoperatively and their blood levels should be monitored.

Choudury M. Post-cardiac transplant recipient: Implications for anaesthesia. *Indian J Anaesth*. 2017;61(9):768–774.

E.2. What type of anesthetic is best for the heart-transplanted patient?

In a series of 86 heart-transplanted recipients, 18 returned for 32 noncardiac surgical procedures. The anesthetic breakdown included 18 neurolept-anesthesia cases, 12 general anesthesia cases with a combination of N_2O/O_2/narcotic/relaxant and low doses of volatile agents, and 2 spinal cases. The patients had normal requirements of IV and inhalational agents, muscle relaxants, and local anesthetics. There was no prolonged action of any anesthetic agents. Generally, the choice of general or regional anesthesia does not affect postoperative outcome in heart-transplanted recipients undergoing subsequent noncardiac surgery.

Blasco LM, Parameshwar J, Vuylsteke A. Anaesthesia for noncardiac surgery in the heart transplant recipient. *Curr Opin Anaesthesiol*. 2009;22:109–113.

Cheng DC, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth*. 1993;40:981–986.

E.3. What anesthetic technique would you choose for this patient?

This patient could safely receive a general anesthetic or a regional blockade of his brachial plexus for the upcoming surgery. No anesthetic technique has been shown to be superior as long as preload is maintained.

Cheng DC, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth*. 1993;40:981–986.

E.4. Do you need to use a muscarinic antagonist with cholinesterase inhibitors to reverse the muscle

relaxant in heart-transplanted patients?

Although it does not compromise other hemodynamic parameters, neostigmine has been shown to produce a dose-dependent decrease in heart rate in heart-transplanted patients. A muscarinic antagonist should be administered simultaneously with cholinesterase inhibitors to block the cardiac and muscarinic side effects because slow development of cardiac reinnervation may be possible.

E.5. What are the anesthetic implications for heart-transplanted patients?

The anesthetic implications for heart-transplanted patients include the following:

- Denervated heart
- Allograft rejection
- Infection due to immunosuppression
- Drug interaction
- Allograft coronary artery disease
- Hypertension
- Renal dysfunction
- Immunosuppression-related malignancy

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Dis*. 2002;4:191–198.

Cheng DC, Ong DD. Anaesthesia for non-cardiac surgery in heart-transplanted patients. *Can J Anaesth*. 1993;40:981–986.

Ejtehadi F, Carter S, Evans L, et al. General anaesthesia and emergency surgery in heart transplant recipient. *Case Rep Surg*. 2015;2015:256465.

E.6. What is the significant implication of the denervated heart?

The denervated heart retains its intrinsic control mechanisms, which include the Frank-Starling mechanism, impulse formation and conductivity, and responsiveness to circulating catecholamines in the form of increased heart rate and contractility. However, the normal respiratory variations or response to carotid sinus massage and Valsalva maneuvers are absent. At rest, the heart rate reflects the intrinsic rate of depolarization of the donor sinoatrial node and, in the absence of any vagal tone, is faster than normal at about 90 to 100 beats per minute. The heart rate shows minimal response to drugs, such as muscle relaxants (pancuronium), anticholinergics (atropine, glycopyrrolate, and scopolamine), cholinesterase inhibitors (neostigmine, edrophonium, pyridostigmine, physostigmine), digoxin, nifedipine, phenylephrine, or nitroprusside, but will respond to isoproterenol, ephedrine, dopamine, and epinephrine.

Cardiac dysrhythmias may occur in heart-transplanted patients. Atrial, and less frequently ventricular, tachyarrhythmias are common. Bradyarrhythmia therapy in these patients should be a direct β-adrenergic stimulating agent (epinephrine, isoproterenol). Medications used to treat tachyarrhythmias (calcium channel blockers, β-blockers) need to be used with caution due to their negative inotropic effects.

Stein KL, Darby JM, Grenvik A. Intensive care of the cardiac transplant recipient. *J Cardiothorac Anesth*. 1988;2:543–553.

E.7. What is the significance of allograft rejection?

Most rejection episodes occur in the first 6 months posttransplant. These patients can present with fever, malaise, arrhythmias, and shortness of breath. Hemodynamic compromise is considered a late sign of rejection. The gold standard for diagnosis is endomyocardial biopsy. Rejection episodes are treated primarily with steroids; however, more severe forms may require more aggressive immunosuppression with antithymocyte antibodies or plasmapheresis. The type of therapy is guided by symptom severity and the type of rejection (cellular mediated vs. antibody mediated).

Kobashigawa JA. Postoperative management following heart transplantation. *Transplant Proc*. 1999;31:2038–2046.

E.8. What is the significance of infection in these patients?

Immunosuppressive drugs are continued indefinitely in heart-transplanted patients, and infection remains a major cause of death, with 10% of mortality 5 years posttransplant secondary to non-CMV infections. Early postoperative bacterial infections (e.g., mediastinitis) and opportunistic infections (e.g., CMV, *Pneumocystis jirovecii*, *Toxoplasma*) are of great concern. Invasive monitoring techniques and all forms of instrumentation should be kept to the minimum consistent with safe anesthesia. Attention to sterile technique should be paramount. Intubation via the orotracheal route is preferable to the nasotracheal route

because the latter is associated with infection by diphtheroids and staphylococcal organisms from the nasopharynx and skin.

E.9. What are the significant implications of drug interactions?

Chronic steroid treatment may result in an abnormal stress response; so, patients should receive perioperative steroid coverage. Azathioprine has been reported to antagonize the competitive neuromuscular blocking drugs due to its phosphodiesterase-inhibiting properties; therefore, larger doses of relaxants may be required. In experimental animals, cyclosporine infusions have been shown to potentiate the neuromuscular blocking effects of atracurium and vecuronium. A single dose of cyclosporine may also result in a prolonged duration of action of both barbiturates and narcotics.

Ashary N, Kaye AD, Hegazi AR, et al. Anesthetic considerations in the patient with a heart transplant. *Heart Dis*. 2002;4:191–198.

E.10. What is cardiac allograft vasculopathy (CAV)? Why

is this important?

The transplanted heart is vulnerable to an accelerated process of coronary atherosclerosis called CAV. Between the 1st and 10th year posttransplant, over 40% of patients develop CAV. It is characterized by concentric intimal proliferation and diffuse narrowing along the coronary vessel. The etiology is likely multifactorial with both immunologic and nonimmunologic factors. Traditional risk factors, such as pretransplant coronary artery disease, diabetes, and hyperlipidemia, put a recipient at risk for CAV. Donor characteristics, such as advanced donor age and mechanism of donor death, are also risk factors. The type of immunosuppression regime, CMV infections, and episodes of rejection also impact CAV development.

E.11. What is the significant implication of posttransplant hypertension?

After 5 years, 91% of surviving patients have developed hypertension. Calcineurin inhibitors often are cited as a causative factor. Current therapy may consist of a calcium channel blocker such as diltiazem. However, care must be taken because diltiazem may increase cyclosporine serum levels. Nifedipine has a tendency to cause significant vasodilatation and may be tolerated poorly in these patients. When necessary, an ACE inhibitor may be added. Because cardiac responsiveness during exercise is dependent on circulating catecholamines, β-blockers often are avoided after heart transplantation.

Costanzo MR, Dipchand A, Starling R, et al. The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients. *J Heart Lung Transplant*. 2010;29:914–956.

Lund LH, Edwards LB, Kucheryavaya AY, et al. The registry of the International Society for Heart and Lung Transplantation: thirty-first official adult heart transplant report—2014. *J Heart Lung Transplant*. 2014;33(10):996–1008.

Valerio R Jr, Durra O, Gold ME. Anesthetic considerations for an adult heart transplant recipient undergoing noncardiac surgery: a case report. *AANA Journal*. 2014:82(4):293–299.

E.12. What is the significant implication of renal dysfunction?

Renal dysfunction is found in 51.1% of recipients at 5 years. Due to the nephrotoxic effects of calcineurin inhibitors, serum creatinine concentrations often gradually increase after cardiac transplantation, with 6.7% of recipients requiring dialysis after 10 years. Anesthetic drugs that are excreted mainly by renal clearance should be avoided if renal function is compromised. Also, one needs to be mindful of medications that may further compromise renal function, such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Kobashigawa JA. Postoperative management following heart transplantation. *Transplant Proc*. 1999;31:2038–2046.

E.13. What types of malignancy are found in recipients?

Chronic immunosuppression puts patients at risk for the development of cancer. After 10 years, 27.7% of survivors have some form of malignancy. The vast majority are skin cancers, whereas a much smaller percentage suffers from posttransplant lymphoproliferative disorder. Malignancies account for 23% of the deaths 5 years after transplant.

E.14. Is ambulatory surgery appropriate for heart transplant recipients?

Unfortunately, there is a paucity of information about ambulatory surgery in heart transplant recipients. In addition, the choice of anesthetic technique seems to have no influence on outcome. Regardless, these patients should be seen in preadmission clinics before the day of surgery and have appropriate screening tests done preoperatively, including but not limited to, an assessment of complete blood count, electrolytes, renal function, ECG, and an accurate blood pressure measurement. They also should be evaluated by the cardiology transplant service, and if any concern is raised, further testing, such as echocardiography, coronary angiography, or endomyocardial biopsy, may be suggested. Recommendations also should be obtained from the cardiac transplant service regarding perioperative antibiotic prophylaxis and immunosuppression.

14 Ischemic Heart Disease and Noncardiac Surgery

Christopher Szabo and
Manuel Fontes

A 72-year-old man is scheduled for right hemicolectomy for colon cancer. Past history reveals a myocardial infarction (MI) 5 months ago and placement of a right coronary second-generation drug-eluting stent (DES). He also has type 2 diabetes mellitus. He is currently treated with dual antiplatelet therapy (DAPT) (aspirin and clopidogrel), atenolol, diltiazem, metformin, losartan, and an occasional sublingual nitroglycerin (NTG).

A. Medical Disease and Differential Diagnosis

1. What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?
2. What are the determinants of myocardial oxygen demand? How are they measured clinically?
3. What factors determine myocardial oxygen supply?
4. What is the mechanism of perioperative myocardial ischemia and MI?
5. What is the incidence of perioperative reinfarction for noncardiac surgery?

6. State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.
7. Based on his MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?
8. you recommend that this elective colectomy be postponed if the patient underwent placement of a right coronary artery, second-generation DES, and is taking aspirin and clopidogrel (Plavix)?

B. Preoperative Evaluation and Preparation

1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?
2. Would you recommend further cardiac testing or coronary revascularization before surgery?
3. How would you classify the cardiac risk according to the type of surgery?
4. What is the role of exercise or pharmacologic stress test for this patient?
5. Would you discontinue any medication before surgery?
6. How would you premedicate this patient?
7. Is there a role for α_2-agonist in premedication?

C. Intraoperative Management

1. What are the intraoperative predictors for perioperative MACE?
2. How would you monitor the patient in the operating room?
3. What electrocardiogram (ECG) leads would you monitor? Why lead V_5?
4. Would you use a pulmonary artery catheter (PAC)?
5. Would you use transesophageal echocardiography (TEE) as a monitor?
6. Is regional anesthesia better than general anesthesia for patients with cardiac disease?

7. How will you induce general anesthesia?
8. Would you induce anesthesia with etomidate? Why?
9. What is the best choice of anesthetic agents for maintenance of anesthesia? Why?
10. You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?
11. Would you give prophylactic intravenous NTG to prevent myocardial ischemia?
12. What is the significance of tight control of the heart rate intraoperatively?
13. When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?

D. Postoperative Management

1. What are the postoperative predictors of perioperative MACE?
2. How would you control postoperative pain?
3. Is postoperative anemia associated with adverse cardiac outcome?
4. Is postoperative hypothermia associated with postoperative myocardial ischemia?
5. How would you make a diagnosis of perioperative MI (PMI)?
6. How would you manage the patient with a suspected PMI?

A. Medical Disease and Differential Diagnosis

A.1. What are the preoperative predictors for major adverse cardiac events (MACE) perioperatively?

PMI is one of the most important predictors of short- and long-term mortality and morbidity associated with noncardiac surgery. Therefore, the prevention of PMI can improve postoperative outcomes. Numerous risk indices and predictors for perioperative cardiac morbidity (PCM) have been published

over the last 40 years.

In 1999, Lee et al. revised the Goldman Cardiac Risk Index, now called the Revised Cardiac Risk Index (RCRI), utilizing six independent predictors of cardiac risk, which are as follows:

- High-risk type of surgery
- History of ischemic heart disease (IHD)
- History of congestive heart failure (CHF)
- History of cerebrovascular disease
- Preoperative treatment of diabetes mellitus with insulin
- Preoperative serum creatinine greater than 2.0 mg per dL

They concluded that the rate of major cardiac complications (MI, pulmonary edema, ventricular fibrillation, and primary cardiac arrest) with 0, 1, 2, and more than or equal to 3 predictors were 0.5%, 1.3%, 4%, and 9%, respectively.

The 2014 American College of Cardiology (ACC)/American Heart Association (AHA) guidelines categorize the patients into two groups: *low risk* and *elevated risk* based on the presence of clinical risk factors and risk of surgical procedures. Patients with less than 1% chance of MACE are categorized as low risk, whereas patients with cumulative risk of MACE more than 1% are categorized as elevated risk. Patients who have two or more RCRIs are considered at elevated risk. The other two indices are the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) Myocardial Infarction and Cardiac Arrest (MICA), and American College of Surgeons NSQIP Surgical Risk Calculator (http://riskcalculator.facs.org). Both are readily available on the web to evaluate patient risk. The European Society of Cardiology (ESC) guidelines define surgical risk procedures as low- (<1%), intermediate- (1% to 5%), and high-risk procedures (>5%). By ACC guideline criteria, this patient will be considered elevated risk, scheduled to undergo an intermediate-risk procedure (by ESC guidelines).

Although the new guidelines do not categorize the clinical

predictors of MACE into major, intermediate, and minor factors, in addition to the RCRI mentioned earlier, the following clinical factors significantly increase the risk of perioperative MACE.

- Unstable coronary syndromes: Acute (MI ≤7 days before examination) or recent MI (>7 days but ≤1 month) with evidence of important ischemic risk by clinical symptoms or noninvasive study. A study using discharge summaries demonstrated that the postoperative MI rate decreased substantially as the length of time from MI to operation increased (0 to 30 days = 32.8%; 31 to 60 days = 18.7%; 61 to 90 days = 8.4%; and 91 to 180 days = 5.9%), as did the 30-day mortality rate. However, risk was modified by coronary intervention. It is suggested that more than 60 days should elapse after MI before noncardiac surgery is undertaken in the *absence* of coronary intervention.
- Unstable or severe angina (Canadian class III): marked limitation of ordinary physical activity; walking one to two blocks on the level and climbing one flight of stairs in normal conditions at normal pace; and Canadian class IV: inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest
- Decompensated heart failure (HF): Patients with active HF have significantly higher risk of postoperative death than do patients with coronary artery disease (CAD). Survival after surgery for those with a left ventricular ejection fraction (LVEF) less than 30% is significantly worse than for those with an LVEF ≥30%.
- Severe valvular disease (severe aortic stenosis [AS] with valve area less than 1 cm^2 or symptomatic) have a 2 to 3 times higher risk of 30-day mortality than patients without AS. Similar observations have been noted for severe mitral stenosis. Left-sided regurgitant lesions convey increased cardiac risk during noncardiac surgery but are better tolerated

than stenotic valvular disease.

- Significant arrhythmias, such as high-grade atrioventricular block, Mobitz type II atrioventricular block, third-degree heart block, or unanticipated symptomatic supraventricular and ventricular arrhythmias, increase operative risk. Risk of other supraventricular and ventricular arrhythmias seems to be lower than reported before.
- Age is considered a risk factor especially when it is associated with frailty. However, its exact role still needs to be defined further.
- Pulmonary hypertension: Patients with pulmonary artery hypertension are at an increased risk of cardiopulmonary complications after noncardiac surgery. Mortality rates of 4% to 26% and cardiorespiratory morbidity rates of 6% to 42% have been reported.

A.2. What are the determinants of myocardial oxygen demand? How are they measured clinically?

The three major determinants of myocardial oxygen demand are (1) myocardial left ventricular (LV) wall tension (LV preload and afterload), (2) cardiac contractility, and (3) heart rate.

A.3. What factors determine myocardial oxygen supply?

The factors determining myocardial oxygen supply include cardiac output, arterial oxygen content, heart rate, aortic diastolic pressure, LV end-diastolic pressure, patency of coronary arteries, and coronary vascular tone.

A.4. What is the mechanism of perioperative myocardial ischemia and MI?

Myocardial ischemia occurs whenever myocardial oxygen supply does not match myocardial oxygen demand. Intraoperative ischemia can be precipitated by increases in myocardial oxygen demand caused by tachycardia, hypertension, anemia, surgical stress, sympathomimetic drugs, or discontinuation of β-blockers. Potential etiologies for decreased supply include hypotension, tachycardia, increased cardiac filling pressures, anemia, hypoxemia, and decreased cardiac output. In one study, ischemia occurred (67%) at the end of anesthesia or immediately after surgery, during a period characterized by high sympathetic output, hypercoagulability, hypertension, and tachycardia. Ischemia in this period is usually silent, with only ST-segment depression as a marker. And in at least one-third of the patients, this ST-segment depression goes unnoticed. Hypotension is strongly correlated with PMI. In addition, internal factors such as acute coronary artery thrombosis and spasm may also play a role.

PMI is one of the most important predictors of short- and long-term morbidity and mortality associated with noncardiac surgery. Unfortunately, the exact nature of PMI remains uncertain and a subject of debate and controversy. The interaction between morphologic and functional factors is

unpredictable. Some older pathologic and angiographic studies suggested that the etiology of PMI resembles that in the nonsurgical setting, that is, plaque rupture was the cause of PMI in 50% of the cases. However, newer analysis suggests that myocardial oxygen supply/demand imbalance predominates in the first 3 to 4 postoperative days and patients suffer PMI from demand ischemia. In PMI, the severity of underlying coronary artery stenosis does not necessarily predict the infarct territory. The high incidence of histologically confirmed transmural infarctions seems to be contradictory to the ECG finding of almost exclusively non–Q-wave PMIs. On the other hand, the presence of subendocardial PMIs is consistent with a myocardial oxygen supply/demand mismatch being the main trigger of myocardial injury. However, myocardial oxygen supply/demand mismatch and plaque rupture are not mutually exclusive mechanisms, and PMIs may be developed by different mechanisms at different locations in the same patient.

Most PMIs occur early after surgery (0 to 4 days) and 90% occur within 7 days, are asymptomatic, of the non–Q-wave type (60% to 100%), and are commonly preceded by ST-segment depression rather than ST-segment elevation. Long duration (single duration >20 to 30 minutes or cumulative duration >1 to 2 hours intraoperatively or postoperatively) rather than just the presence of postoperative ST-segment depression seems to be the important factor associated with adverse cardiac outcome.

A.5. What is the incidence of perioperative reinfarction for noncardiac surgery?

The risk assessment for noncardiac surgery of patients with CAD is based on the time interval between the MI and surgery. Using a discharge database of more than half million patients, it was shown that postoperative MI rate for the recent MI cohort decreased substantially as the length of time from MI to operation increased (0 to 30 days = 32.8%; 31 to 60 days = 18.7%; 61 to 90 days = 8.4%; and 91 to 180 days = 5.9%), as did 30-day mortality (0 to 30 days = 14.2%; 31 to 60 days = 11.5%; 61 to 90 days = 10.5%; and 91 to 180 days = 9.9%). MI within 30 days of an operation was associated with a highest risk of postoperative MI. However, with improvements in perioperative care, this difference has become blurred. The importance of the timing of the MI in relation to the proposed surgical procedure may no longer be valid in the era of thrombolytics, angioplasty, and risk stratification. Although many patients with a history of an MI may continue to have myocardium at risk, others may not. If a stress test does not indicate residual myocardium at risk, the likelihood of reinfarction is low. The current AHA/ACC guidelines for

perioperative cardiovascular evaluation suggests that more than 60 days should elapse after MI, before noncardiac surgery is undertaken in the *absence* of coronary intervention. Landesberg et al. reported that early mortality after PMI ranges from 3.5% to 25% and is higher among patients with marked troponin elevation compared with patients with minor troponin elevation (0% to 7%). This is in contrast to older data that reported a very high incidence of mortality.

A 2016 study, using information in a large administrative database of United States hospital admissions (2004 to 2013), found a 3% incidence of major adverse cardiovascular and cerebrovascular events (in-hospital, all-cause death, acute MI, or acute ischemic stroke). These events were most common after vascular, thoracic, and transplant surgery.

A.6. State the perioperative medical therapy you would employ to reduce the incidence of myocardial ischemia.

β-Adrenergic Antagonists (Esmolol, Atenolol,

Metoprolol, Bisoprolol)

β-Blockers reduce myocardial oxygen consumption, improve coronary blood flow by prolonging diastolic perfusion period, improve supply/demand ratio, stabilize cellular membranes, improve oxygen dissociation from hemoglobin (Hgb), and inhibit platelet aggregation. *β*-Blockers suppress perioperative tachycardia and appear most efficacious in preventing perioperative myocardial ischemia. In view of their beneficial effects, prophylactic use of *β*-blocker to decrease PMI has been explored in many trials. Mangano et al. reported a beneficial effect of atenolol in a randomized double-blind, placebo-controlled trial on overall survival and cardiovascular morbidity in noncardiac surgery patients with or at risk for CAD. Poldermans et al. reported that the *β*-blocker, bisoprolol, reduced the perioperative incidence of death from cardiac causes and nonfatal MI in vascular surgical patients with known CAD. Bisoprolol, started before noncardiac surgery (30 days), can substantially reduce perioperative cardiac complications in all but the highest risk patients. However, results of subsequent large trials have not shown efficacy of high-dose, acutely administered, perioperative *β*-blockers to reduce overall mortality in patients undergoing noncardiac surgery. The largest of these trials, the PeriOperative ISchemic Evaluation (POISE) study, did show better perioperative *cardiac* outcomes with *β*-blocker use; however, *increased mortality* and stroke rate also was noted in the *β*-blocker group. ACC/AHA has conducted a systematic review on the topic, and the main findings are (1) preoperative use of *β*-blockers was associated with a reduction in cardiac events in the studies examined, but few data support the effectiveness of preoperative administration of *β*-blockers to reduce the risk of surgical death; and (2) a clear association exists between *β*-blocker administration and adverse outcomes, such as bradycardia and stroke. Currently, the only class I

recommendation for perioperative β-blockers use is to continue their use in the patients who are already on β-blockers (class I, level of evidence B). β-Blockers can be used in patients with elevated risk, such as ischemia during preoperative stress testing or in patients with three or more RCRI risk factors (class IIb, level of evidence B). Although there are some differences between the ESC and the AHA guidelines, both recommend that if β-blockers are used for prophylactic purposes, they should be slowly titrated (2 to 7 days prior to elective surgery) and acute administration of high-dose β-blockers in high-risk patients undergoing low-risk surgery is not recommended (class III, level of evidence B).

α_2-Adrenergic Agonist (Clonidine)

α_2-Agonist (clonidine) decrease sympathetic outflow, blood pressure, and heart rate. Although older studies suggested possible beneficial effect of α_2-agonists, the most recent POISE-2 trial that enrolled 10,010 patients did not show any statistically beneficial effect of clonidine. Clonidine did not reduce the rate of 30-day risk of all-cause death or nonfatal MI in patients with or at risk of atherosclerotic disease who were undergoing noncardiac surgery. Clonidine did increase the rate of nonfatal cardiac arrest and clinically important hypotension. Based on the ACC/AHA guidelines, α_2-agonists for prevention of cardiac events are not recommended in patients who are undergoing noncardiac surgery (class III, level of evidence B).

Nitrovasodilators (Nitroglycerin, Isosorbide Dinitrate)

Nitrates are associated with the following:

- Decreased LV preload (low dose)
  - Systemic venous dilation
  - Pulmonary arterial bed dilation

  - Pulmonary vein dilation
  - Decreased LV filling pressure
  - Decrease in LV diastolic compressive forces
  - Decreased LV diastolic chamber size
- Decreased LV afterload (high dose)
  - Decreased systolic pressure
  - Decreased systemic vascular resistance
  - Decreased aortic impedance
- Coronary circulation
  - Coronary artery and arteriolar dilation (high dose)
  - Spasm reversal or prevention
  - Stenosis dilation
  - Increased collateral flow
  - Improvement of regional subendocardial ischemia

NTG, one of the oldest antianginal therapies, has had very few trials in noncardiac surgery to evaluate its role in perioperative ischemia reduction. However, there are no significant studies within the past 10 years examining the effect of prophylactic NTG on perioperative myocardial ischemia. Prior studies yielded conflicting results, were small (<50 patients), and not blinded. A recent meta-analysis by Zhao et al. further strengthened the position of not using prophylactic nitrates for noncardiac surgery.

The current guidelines do not recommend the use of prophylactic intravenous NTG to reduce myocardial ischemia undergoing noncardiac surgery.

Calcium Channel Blockers (Verapamil, Diltiazem, Nifedipine, Nicardipine)

Calcium channel blockers reduce myocardial oxygen demand by depression of myocardial contractility and dilation of coronary and collateral vessels, which improves blood flow. However, the most important effect may be the prevention of sympathetically

mediated coronary vasoconstriction.

A meta-analysis of perioperative calcium channel blockers in noncardiac surgery (11 studies involving 1,007 patients) showed significantly reduced ischemia and postoperative supraventricular tachycardia. The beneficial effects were mostly due to the use of diltiazem, whereas the use of a 1,4-dihydropyridine (DHP) derivative nifedipine was associated with ischemia. Another study in 1,000 patients having acute or elective aortic aneurysm surgery showed that DHP calcium channel blocker use was independently associated with an increased incidence of perioperative mortality. The use of short-acting DHP, in particular nifedipine capsules, should be avoided. The AHA makes no specific recommendations for the prophylactic use of calcium channels blockers. Routine use of calcium channel blockers to reduce the risk of perioperative cardiovascular complications is not recommended (class III).

Aspirin

Aspirin (acetylsalicylic acid) inhibits platelet aggregation by blocking the production of thromboxane A_2. Observational data suggest that preoperative withdrawal of aspirin increases thrombotic complications. However, the value of aspirin in nonstented patients in preventing ischemic complications is uncertain. The Pulmonary Embolism Prevention (PEP) trial, which randomized 13,356 patients undergoing hip surgery to 160 mg aspirin or placebo, did not show benefit of aspirin. The POISE-2 trial randomized 10,010 patients who were undergoing noncardiac surgery to aspirin 200 mg or placebo. Aspirin did not have a protective effect for MACE or death in patients either continuing aspirin or starting aspirin. However, aspirin increased the chance of major bleeding especially in the first 5 days after surgery. This is supported by a previous large meta-analysis, including 41 studies in 49,590 patients, which compared

periprocedural withdrawal versus bleeding risks of aspirin, concluded that the risk of bleeding complications was increased by 1.5 but that aspirin did not lead to higher severity levels of bleeding complications. Initiation of aspirin is not beneficial in patients undergoing elective noncardiac, noncarotid surgery who have not had previous coronary stenting, unless the risk of ischemic events outweighs the risk of surgical bleeding.

Statins

Statins are primarily used for their lipid-lowering effects and are widely prescribed in patients with or at risk for IHD. Statins also induce coronary plaque stabilization by decreasing lipid oxidation, inflammation, matrix metalloproteinase, and cell death. These so-called non-lipid or pleiotropic effects may prevent plaque rupture and subsequent MI in the perioperative period. A meta-analysis of 223,010 patients from 12 retrospective and 3 prospective trials showed that statins reduced mortality significantly by 44% in noncardiac surgery and by 59% in vascular surgery. The accumulated evidence to date suggests a protective effect of perioperative statin use on cardiac complications during noncardiac surgery. Most of the data come from observational studies. The time of initiation of statin therapy and the duration of therapy are often unclear in the observational trials. Randomized clinical trials are limited in patient numbers and types of noncardiac surgery. Both the AHA and ESC guidelines recommend continuing statin therapy for patients currently taking statins and scheduled for noncardiac surgery (class I). ESC recommends that preoperative statin therapy should be considered in patients undergoing vascular surgery and initiated at least 2 weeks before surgery.

A.7. Based on his MI, would you recommend that the surgery be postponed for a certain period of time? If so, why?

The arbitrary delaying of a surgical procedure is not supported by the ACC/AHA guidelines. According to these guidelines, an acute MI (≤7 days) or recent MI (>7 days but ≤1 month) with

evidence of important ischemic risk by clinical symptoms or noninvasive study is a major predictor of PMI. A discharge database analysis showed that patients with a recent MI who were revascularized before surgery had an approximately 50% decreased rate of reinfarction (5.1% vs. 10.0%). Thirty-day (5.2% vs. 11.3%) and 1-year mortality (18.3% vs. 35.8%) was also decreased in the revascularized patients. Current management of MI provides for risk stratification during the convalescence period. If a recent stress test does not indicate residual myocardium at risk, the likelihood of reinfarction after noncardiac surgery is low. Although there are no adequate clinical trials on which to base firm recommendations, it appears reasonable to wait 60 days after MI in a nonrevascularized patient to perform elective surgery due to the decrease in incidence of fatal arrhythmias and ventricular rupture after this period of time. However, the guidelines do not recommend that routine coronary revascularization be performed before noncardiac surgery exclusively to reduce perioperative cardiac events (class III, level of evidence B).

A.8. Would you recommend that this elective colectomy be postponed if the patient underwent placement of a right coronary artery, second-generation DES, and is taking aspirin and clopidogrel (Plavix)?

Coronary stents are particularly predisposed to stent thrombosis. Typically, stent thrombosis is defined according to the time of

occurrence: (1) acute, within 24 hours; (2) early, 2 to 30 days; (3) late, >1 month to <1 year; and (4) very late, >1 year. Both bare metal stents (BMS) and DES are predisposed to stent thrombosis and require prolonged DAPT after stent placement: BMS, 4 to 6 weeks; DES, 12 months; and stents placed after acute coronary syndrome (ACS), 12 months. Second-generation DESs may require a minimum of 6 months DAPT after stent placement; however, data in this area is still evolving.

The cumulative incidence of noncardiac surgery after coronary stenting is more than 10% at 1 year and more than 20% at 2 years. Patients with a coronary stent pose a special challenge in the perioperative period. Bleeding is the major risk of continuing DAPT during the perioperative period. Surgical blood loss is increased 2.5% to 20% by aspirin alone and 30% to 50% by aspirin and clopidogrel—but with no increased risk of bleeding-related mortality, except during intracranial surgery. When surgery was performed within 180 days, discontinuation of DAPT was associated with an increased risk of stent thrombosis. Extremely high mortality rates (up to 20%) have been reported secondary to acute stent thrombosis if surgery is performed within weeks after coronary stenting with discontinuation of DAPT. Thus, the risks of stent thrombosis and bleeding should be balanced. Antiplatelet therapy should generally be continued throughout the perioperative period, except in cases where the risk of morbidity or mortality from bleeding significantly outweighs the risk of acute stent thrombosis, as in procedures likely to be associated with "major" blood loss or performed in a closed space.

Current recommendations for DAPT after percutaneous coronary intervention (PCI) with stenting (BMS) is that patients should take aspirin and other $P2Y_{12}$ platelet inhibitor (clopidogrel, prasugrel, ticagrelor) for at least 30 to 45 days to prevent restenosis and allow reendothelialization of the stent to

be completed. Therefore, it is prudent to postpone the elective surgery for a minimum of 30 days and ideally for up to 3 months after BMS implantation (ESC guidelines). Importantly, whenever possible, aspirin should be continued throughout surgery. A large meta-analysis, including 41 studies in 49,590 patients, which compared periprocedural withdrawal versus bleeding risks of aspirin, concluded that the risk of bleeding complications with aspirin therapy was increased by 50% but that aspirin did not lead to greater severity of bleeding complications. In subjects at risk of—or with proven—IHD, nonadherence/withdrawal of aspirin tripled the risk of MACE.

Although DES delays in-stent thrombosis, their major drawback is the need for prolonged DAPT by aspirin and $P2Y_{12}$ platelet inhibitors for at least 12 months. It is generally recommended that after DES implantation, elective surgery should not take place until after at least 6 months of continuous DAPT. Even after 6 months, patients should be sent for noncardiac surgery with continuation of at least aspirin therapy. If the risk of surgical delay is greater than risk of thrombosis, with the newer generation stents, the guidelines suggest to consider surgery between 3 and 6 months of DAPT. The patient should continue on aspirin (unless patient is scheduled for surgery associated with high risk of bleeding or consequence of bleeding) (**Fig. 14.1**). Typically, $P2Y_{12}$ platelet inhibitors should be stopped 5 days (clopidogrel, ticagrelor) or 7 days (prasugrel) before scheduled surgery and restarted as soon as possible.

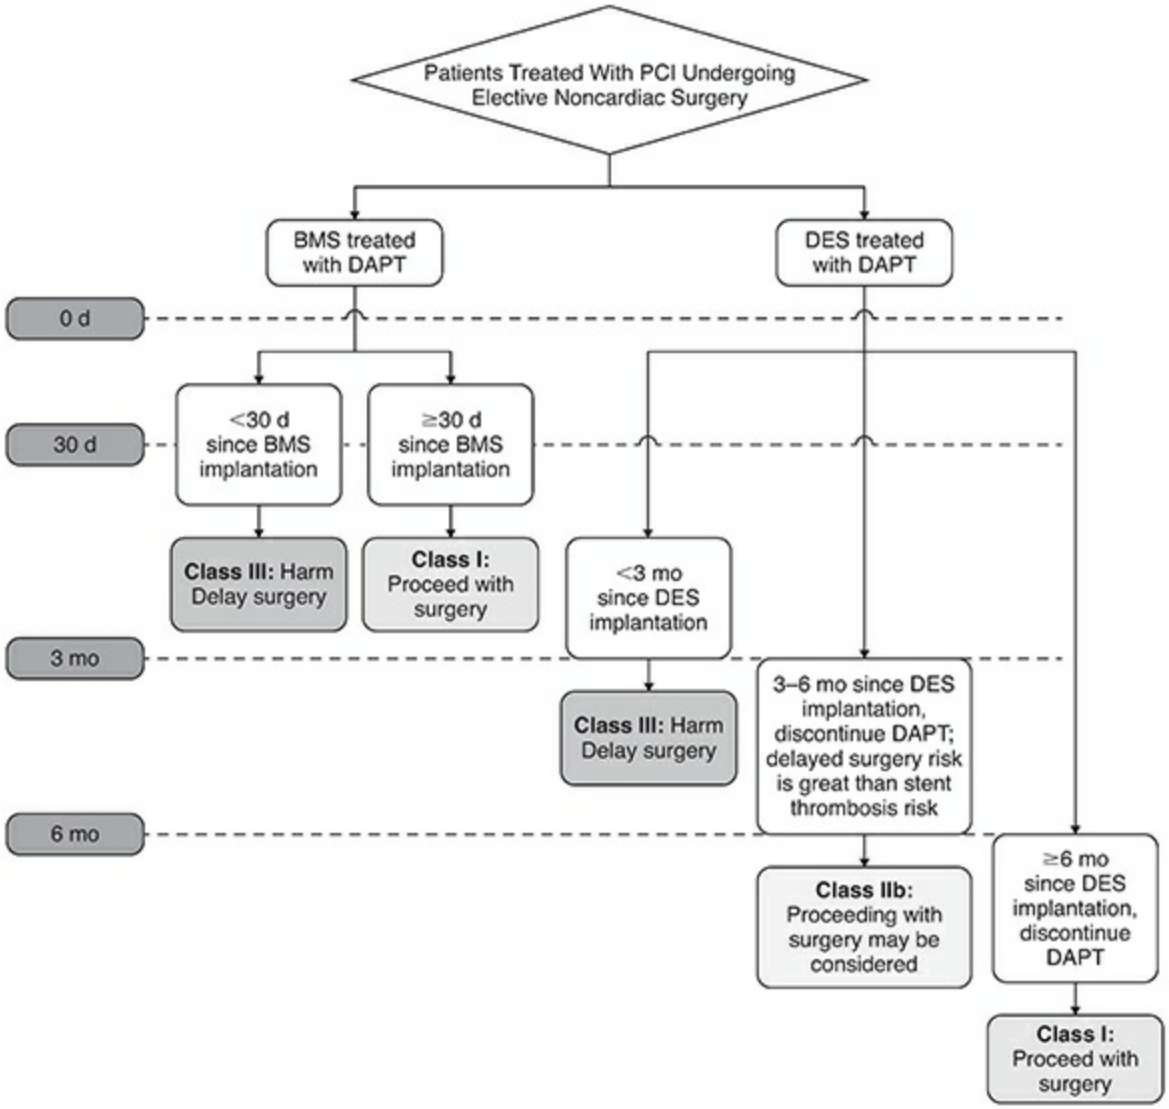

FIGURE 14.1. Treatment algorithm for timing of elective noncardiac surgery in patients with coronary stents. BMS, bare metal stents; DAPT, dual antiplatelet therapy; DES, drug-eluting stent; PCI, percutaneous coronary intervention. (*Reprinted with permission from Levin GN, Bates ER, Bittle JA, et al. 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease: a report of the American College of Cardiology/American Heart Association Task Force on clinical practice guidelines.* Circulation. *2016;134[10]:e123–e155.*)

In this patient, with a DES placed 5 months before surgery in the setting of ACS, the discontinuation of DAPT increases the risk of stent thrombosis. Furthermore, this is not high-risk surgery (laparoscopic colectomy), although risk of bleeding will be appreciably increased if patient is maintained on DAPT. This is a clinical situation where careful "case-by-case" consideration

is advisable and discussion between the anesthesiologist, the surgeon, and the treating cardiologist is recommended.

B. Preoperative Evaluation and Preparation

B.1. How would you evaluate the patient's cardiac condition? What laboratory tests would you like to order?

The initial history, physical examination, and electrocardiographic assessment should focus on the identification of potentially serious cardiac disorders such as CAD (e.g., prior MI, angina pectoris), CHF, and symptomatic arrhythmias and valvular heart disease. In addition to identifying the presence of preexisting heart disease, it is essential to define disease severity, stability, and prior treatment. For patients who have been revascularized, it is also important to determine the presence or absence of any coronary syndrome/symptoms after coronary revascularization and any results of stress test results post-MI/revascularization. The initial history should also elicit presence of other components of RCRI; that is, history of cerebrovascular accident (stroke or transient ischemic attack), presence of diabetes, or renal insufficiency.

This patient is an insulin-dependent diabetic. Diabetes is associated with a two- to fourfold increase in the risk of developing CAD. The risk of an MI in patients with diabetes and no evidence of CAD match that of patients without diabetes who have had a previous MI. In patients with CAD and diabetes, the mortality rate can be up to 70% in 10 years. In addition, patients

will have a worse outcome for any CAD manifestation.

Other factors that help determine cardiac risk include functional capacity, age, comorbid conditions (peripheral vascular disease, chronic pulmonary disease, and pulmonary hypertension), and type of surgery (vascular procedures and prolonged, complicated thoracic, abdominal, and head and neck procedures are considered elevated risk procedures) (see section B.3). Poor exercise tolerance has been associated by some with twofold higher odds for postoperative complications. It is a good indicator of global cardiopulmonary functional status of the patient, which can have direct impact on perioperative outcomes.

For this patient, the preoperative laboratory workup should include an Hgb/hematocrit (Hct), prothrombin time, partial thromboplastin time, electrolytes, creatinine, blood urea nitrogen, and an ECG. The preoperative ECG may provide a useful baseline standard against which to measure changes in the postoperative period. The value of the preoperative 12-lead ECG is likely to increase with the risk of the surgical procedure, particularly for patients with known coronary heart disease, arrhythmias, peripheral arterial disease, cerebrovascular disease, or other significant structural heart disease.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

B.2. Would you recommend further cardiac testing or coronary revascularization before surgery?

Successful perioperative evaluation and treatment of cardiac patients undergoing noncardiac surgery requires careful teamwork and communication between patient, primary care physician, cardiologist, anesthesiologist, and surgeon. In

general, indications for further cardiac testing and treatment are the same as those in the nonoperative setting, but their timing is dependent on factors such as the urgency of noncardiac surgery, the patient's risk factors, and specific surgical considerations. Preoperative testing should be limited to circumstances in which the results will affect patient treatment and outcomes. A conservative approach to the use of expensive tests and treatments is recommended. Coronary revascularization before noncardiac surgery to enable the patient to "get through" the noncardiac procedure is inappropriate. However, in a high-risk subset of patients, such as those with left main or severe multivessel disease, severe AS, and ejection fraction less than 20%, revascularization or valve replacement may be indicated. Currently, there is overwhelming agreement that aggressive medical management to provide myocardial protection during the perioperative period is a very important element in the reduction of perioperative cardiovascular complications.

Several studies have suggested that a stepwise approach to the assessment of CAD is both efficacious and cost-effective. The patient sustained MI 5 months ago and was managed with a DES and is scheduled for hemicolectomy, which is considered an intermediate-risk procedure. If the patient has more than 4 metabolic equivalents (METs) of physical activity (e.g., washing dishes, climbing one flight of stairs with a bag of groceries, walking on level ground at 4 miles per hour) without chest pain or shortness of breath, if no new cardiac symptoms are present since the revascularization, and if the resting ECG showed no new changes compared to 5 months ago, the patient can undergo anesthesia and surgery without further testing. If any of these factors are positive, then stress test is recommended. If the ischemic area is small, surgery is permissible with recommended aggressive medical therapy management. If the ischemic area is moderate to large, with a suspicion of new or

severe coronary stenosis, cardiac catheterization is recommended before the planned surgery. Also see Chapter 10, section B.2, **Figure 10.2**.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

McFalls EO, Ward HB, Moritz TE, et al. Coronary-artery revascularization before elective major vascular surgery. *N Engl J Med*. 2004;351:2795–2804.

B.3. How would you classify the cardiac risk according to the type of surgery?

Surgery-specific cardiac risk of noncardiac surgery is related to two important factors: the type of surgery and the degree of hemodynamic stress associated with the procedure(s). The duration and intensity of coronary and myocardial stressors can be helpful in estimating the likelihood of perioperative cardiac events, particularly for emergency surgery. Surgery-specific risk for noncardiac surgery can be stratified as high, intermediate, and low.

- *High-risk* surgery (cardiac risk >5%) includes major emergency surgery, particularly in the elderly; aortic and other major vascular surgery; peripheral vascular surgery; and anticipated prolonged procedures associated with large fluid shifts and/or blood loss.
- *Intermediate-risk* procedures (cardiac risk <5%) include carotid endarterectomy, head and neck surgery, intraperitoneal and intrathoracic, orthopedic, and prostate surgery. Endovascular aortic stent procedures also are included in this category.
- *Low-risk* procedures (cardiac risk <1%) include endoscopic and superficial procedures, cataract surgery, and breast surgery.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

B.4. What is the role of exercise or pharmacologic stress test for this patient?

The aim of functional cardiovascular testing is to elicit evidence and severity of CAD by subjecting the heart to physiologic stress. Noninvasive diagnostic testing must be used judiciously. Ideally, testing should be accurate, add useful information to the overall risk assessment, and avoid unnecessary delays in surgery. Noninvasive tests of myocardial perfusion are classified by the type of stress applied to elicit transient and reversible ischemia or by the mode of detecting the ischemic area. Myocardial stress can be induced by exercise (e.g., treadmill), by a pharmacologic agent that increases heart rate and myocardial contraction (e.g., dobutamine, atropine), or by a pharmacologic agent that can cause redistribution of coronary blood flow (e.g., dipyridamole). Physiologic exercise provides an estimate of functional capacity, provides blood pressure and heart rate response, and detects myocardial ischemia through ECG ST-segment or other imaging technique changes. The accuracy of exercise ECG varies significantly among studies. Preexisting ST-segment abnormalities at rest, especially in precordial leads V_5 and V_6, hamper reliable ST-segment analysis. However, most of these studies are dated and do not reflect the current protocols and contemporary practice. Meta-analysis of studies using treadmill testing in vascular surgery patients showed a rather low sensitivity (74%) and specificity (69%) to detect myocardium at risk, comparable with daily clinical practice.

A significant fraction of the high-risk population cannot

exercise to an adequate level and will require pharmacologic stress testing. Pharmacologic stress testing with dobutamine stress echocardiography (DSE), dipyridamole/adenosine/regadenoson myocardial perfusion imaging with thallium-201, and/or technetium-99m and rubidium-82 can be used in patients undergoing noncardiac surgery who cannot perform exercise to detect stress-induced myocardial ischemia and CAD. Reversible wall motion abnormalities on echocardiography or reversible perfusion defects on radionuclide imaging suggest reversible ischemia.

The myocardial perfusion imaging and DSE before vascular surgery predict PMI or death, with a positive predictive value of only 12% to 14% and a negative predictive value of 88% and 94%, respectively. However, the large majority of the cited thallium studies involved older planar imaging technology that is no longer used. The newer nuclear imaging studies have higher sensitivity for detecting IHD, and patients with normal scans have excellent prognosis. Cardiovascular magnetic resonance (CMR) imaging can also be used for detection of myocardial ischemia. Although its accuracy in assessment of myocardial ischemia is high, there is practically no data in the setting of preoperative risk stratification. Computed tomography can be used to detect coronary calcium, which reflects coronary atherosclerosis; however, currently, there is no data available in the setting of preoperative risk stratification.

Selection of the noninvasive stress test should be based primarily on patient characteristics, local availability, and expertise in interpretation. DSE is the preferred test if there is an additional question regarding valvular function or LV dysfunction.

B.5. Would you discontinue any medication before surgery?

Patients with CAD are usually on a variety of medications. All antianginal drugs, especially β-blockers and statins, should be continued up to the time of surgery. Sudden withdrawal of antianginal drugs may produce rebound tachycardia and hypertension that may precipitate acute myocardial ischemia or infarction.

Current management of hypertensive patients suggests the continuation of antihypertensive therapy up to the day of surgery. In particular, β-blockers, calcium channel blocker, and nitrates should be continued. There is continued controversy about withholding angiotensin-converting enzyme (ACE) inhibitors and angiotensin-2 receptor blockers (ARBs) 24 hours prior to surgery. Prolonged hypotension has been observed in patients who are undergoing general anesthesia and who have chronically been treated with ACE inhibitors. A meta-analysis demonstrated hypotension in 50% of patients taking ACE inhibitors or ARBs on the day of surgery but no change in cardiovascular outcomes such as death, MI, stroke, and renal failure. It is prudent to withhold ACE inhibitors and ARBs for 24 hours prior to surgical procedures involving major body fluid shifts on significant blood loss. If ACE inhibitors are withheld, it is important to restart them as soon as possible. Hypotension attributed to ACE inhibitors is frequently responsive to fluid and/or administration of sympathomimetic drugs, such as phenylephrine and ephedrine. If hypotension is refractory to these measures, treatment with vasopressin or its long-acting

analogue, terlipressin, may be effective.

B.6. How would you premedicate this patient?

The classical teaching has been to adequately sedate the patient prior to bringing to the operating room to avoid anxiety-induced tachycardia and hypertension. Benzodiazepines are typically used for this purpose. However, benzodiazepines have been associated with delirium, especially in elderly patients. Indiscriminate use of benzodiazepines is discouraged and should only be used in selected patients.

B.7. Is there a role for α_2-agonist in premedication?

The α_2-agonists stimulate prejunctional α receptors and decrease norepinephrine release from prejunctional terminals, thereby decreasing noradrenergic central nervous system transmission, producing sedation, anxiolysis, and analgesia. Studies have shown that clonidine as a premedication reduces hypertension, tachycardia, and norepinephrine levels in patients undergoing aortic reconstruction. Clonidine also suppresses the normal postoperative increase in fibrinogen levels and antagonizes epinephrine-induced platelet aggregation. It has also been shown

to decrease intraoperative myocardial ischemia. A small study evaluating the prophylactic use of clonidine showed a significant reduction in intra- and postoperative myocardial ischemia when compared to placebo. However, a much larger POISE-2 trial did not show any difference in rate of death or nonfatal MI. The rate of nonfatal cardiac arrest and significant hypotension was increased in the clonidine group. Both ACC and ESC guidelines do not advocate prophylactic use of clonidine to decrease MACE, in patients scheduled for noncardiac surgery.

C. Intraoperative Management

C.1. What are the intraoperative predictors for perioperative MACE?

Intraoperative Predictors

Classic intraoperative predictors for perioperative MACE include emergency surgery, major vascular surgery, and prolonged (>3 hours) thoracic or upper abdominal surgery. Among the dynamic predictors, both hypotension and tachycardia predict PCM. In a recent systematic review, the intraoperative predictors include a fall in mean arterial blood pressure >20 mmHg for >60 minutes, an increase in baseline systolic pressure >30%, or tachycardia in the recovery room

(>30 beats per minute from baseline) for >5 minutes. However, the most consistent factor that independently predicted greater risk of perioperative event was intraoperative blood transfusion. Most MIs occur early after surgery and are commonly associated with ST-segment depression. Prolonged duration of myocardial ischemia (>20 to 30 minutes or cumulative duration of >1 to 2 hours) seems to be the important factor associated with adverse cardiac outcome.

C.2. How would you monitor the patient in the operating room?

The patient should be monitored using the following American Society of Anesthesiologists standard guidelines:

- *ECG*—simultaneous leads V_5 and II
- *Blood pressure*—noninvasive automatic Doppler sphygmomanometer and an invasive arterial catheter
- *End-tidal carbon dioxide*—to determine continuous end-tidal CO_2 analysis
- *Oxygen saturation of arterial blood*—to assess arterial oxygenation
- *Fractional inspired oxygen concentration*—to determine

inspired fraction of oxygen

- *Respiratory rate*—which determined by multiple monitors
- *Availability of esophageal/bladder temperature probe*—to determine temperature changes

In addition to these monitors, this patient will also require the monitoring of urine output with a Foley catheter.

American Society of Anesthesiologists. *Standards for Basic Anesthetic Monitoring*. Schaumburg, IL: American Society of Anesthesiologists; 2005.

C.3. What electrocardiogram (ECG) leads would you monitor? Why lead V_5?

ECG ST-segment changes are most commonly used for detection of intraoperative myocardial ischemia. Multiple-lead ECG monitoring provides the best clinically available method of detecting perioperative ischemia, primarily by combining leads II, V_3, V_4, and V_5 (detection of ischemia is 80% with leads II/V_5 and 96% with leads II/V_4 and V_5).

Landesberg et al. were able to correlate the duration of ischemia observed in the ST-segment analysis of a continuously monitoring 12-lead ECG throughout the perioperative period with the incidence of postoperative MI. They also found that ischemia is transient even in patients who will develop an infarct.

Certain prerequisites must be met to use the ECG effectively:

- The diagnostic mode allows detection of ST-segment changes that are filtered out by the monitoring mode.
- The number of ECG leads and their location affects detection of ischemic events.
- Immediate availability of a hard copy of the ECG leads for more detailed analysis.
- Studies have reported that even trained observers recognize only 15% to 40% of electrocardiographic ischemic events

displayed on the monitor.

- The introduction of ST-segment trending helps as an early warning detection system but should not replace examination of the ECG printout.

C.4. Would you use a pulmonary artery catheter (PAC)?

Right heart catheterization is not recommended for monitoring patients for intraoperative ischemia. Large observational study and a randomized multicenter trial did not show benefit associated with the use of pulmonary artery catheterization after major noncardiac surgery. A meta-analysis of randomized controlled trials showed that the use of PAC neither increased mortality nor conferred any benefits to critically ill patients. A recent Cochrane review that included 13 studies (5,686 patients) concluded that use of a PAC did not alter the mortality and general intensive care unit (ICU) or hospital length of stay. PAC is a diagnostic and hemodynamic monitoring tool but not a therapeutic intervention. A number of studies report that PAC is an insensitive monitor for myocardial ischemia and should not be inserted with this as a primary indication.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;64:e77–e137.

Rajaram SS, Desai NK, Kalra A, et al. Pulmonary artery catheters for adult patients in intensive care. *Cochrane Database Syst Rev*. 2013;(2):CD003408.

C.5. Would you use transesophageal echocardiography (TEE) as a monitor?

TEE is a sensitive diagnostic method to detect new onset myocardial ischemia. The echocardiographic diagnosis of myocardial ischemia is based on the development of new regional wall motion abnormalities, decreased systolic wall thickening, and ventricular dilation. Usually, a cross-sectional view (transgastric mid-short axis) of the LV is imaged because this view displays the myocardial perfusion territories of the three major coronary arteries. TEE was found to be twice as predictive as ECG in identifying coronary artery bypass graft (CABG) patients who have an MI. In CABG patients, postbypass regional wall motion abnormalities were related to adverse clinical outcome.

However, practitioners should realize certain limitations of TEE. One, preintubation events are missed, as are the ischemic events that can occur frequently at the end of the surgery, when tachycardia and hypertension appear as part of the emergence from general anesthesia.

Notwithstanding TEE's limitations, ESC and the AHA guidelines recommend the use of TEE intraoperatively or perioperatively to determine the cause of an acute, persistent, and life-threatening hemodynamic abnormality (class IIa recommendation). However, its use as an ischemia monitor in noncardiac surgery is less validated and may only be considered in patients at high risk for developing myocardial ischemia who undergo major noncardiac surgery (class IIb recommendation by ESC). The routine use of intraoperative TEE during noncardiac surgery to screen for cardiac abnormalities or to monitor for myocardial ischemia is *not* recommended in patients without risk factors, or procedural risks for significant hemodynamic, pulmonary, or neurologic compromise.

C.6. Is regional anesthesia better than general anesthesia for patients with cardiac disease?

A number of studies in patients with cardiac disease have compared the effects of regional versus general anesthetics on the incidence of perioperative infarction, dysrhythmias, and CHF. No distinct advantage is apparent between them when considering PCM and mortality in patients undergoing peripheral vascular surgery. There is some evidence to support regional anesthesia over general anesthesia in an effort to optimize graft patency if the regional technique is extended into the postoperative period to provide neuraxial analgesia. The Multicenter Australian Study of Epidural Anesthesia (MASTER) trial randomized 915 patients undergoing major abdominal surgery to receive either combined general and epidural anesthesia/epidural analgesia or general anesthesia with opioid analgesia. Epidural anesthesia/analgesia did not decrease death or cardiovascular outcomes but modestly improved pulmonary outcomes compared with the general anesthesia group. A retrospective analysis, published in 2013, of nearly 400,000 patients undergoing total hip or knee arthroplasty, observed a significantly lower incidence of major morbidity and mortality in patients receiving neuraxial anesthesia. The most recent meta-analysis stated that, when epidurals or spinals were used to replace general anesthesia, there was a significant 29%

decrease in the risk of dying during surgery. In both situations, there was a significant decrease in the risk of pneumonia. However, neuraxial anesthesia failed to decrease the risk of MI. A 2011 Cochrane review meta-analysis of four studies examining neuraxial anesthesia versus general anesthesia for lower limb revascularization found an overall 4% MI rate in both groups. Thus, the current guidelines recommend that the choice of anesthesia is best left to the discretion of the anesthesia care team, which will consider the need for postoperative ventilation; pulmonary/neuromuscular comorbidities; cardiovascular effects, including myocardial depression; sympathetic blockade consequences; and dermatomal level of the procedure.

C.7. How will you induce general anesthesia?

It is essential to prevent hypotension, hypertension, and tachycardia, which can precipitate myocardial ischemia. Different induction techniques may be employed to achieve this goal. For example, while the patient is being preoxygenated,

fentanyl (up to 5 μg per kg) is given slowly to achieve drowsiness and to attenuate the sympathetic response to direct laryngoscopy and intubation of the trachea. Then, using lower doses of thiopental, propofol, or etomidate, unconsciousness is achieved. Succinylcholine or an intermediate duration nondepolarizing relaxant is administered to facilitate tracheal intubation. A few minutes before intubation, the use of a short-acting β-blocker (esmolol) could help to further attenuate the sympathetic response to intubation if necessary. Various techniques to induce general anesthesia have been used and tested in the past. High-dose opioid-based anesthesia was previously popularized because of cardiovascular stability; however, because of the need for prolonged postoperative mechanical ventilation and ICU stay, this technique is no longer considered the technique of choice. On the other hand, in patients undergoing cardiac surgery, volatile anesthetics have been shown to decrease troponin release, maintain LV function compared with propofol, midazolam, or balanced anesthesia technique with opioids. However, no real difference between volatile inhalational anesthesia versus intravenous anesthesia has been shown in randomized controlled trials or meta-analyses. A meta-analysis of more than 6,000 patients undergoing noncardiac surgery failed to demonstrate a difference in MI rates between patients who received volatile anesthesia and patients who received total intravenous anesthesia. The current AHA guidelines state that "use of either a volatile anesthetic agent or total intravenous anesthesia is reasonable for patients undergoing noncardiac surgery, and the choice is determined by factors other than the prevention of myocardial ischemia and MI."

Martin DE, Rosenberg H, Aukburg SJ, et al. Low-dose fentanyl blunts circulatory responses to tracheal intubation. *Anesth Analg*. 1982;61:680–684.

C.8. Would you induce anesthesia with etomidate? Why?

Although etomidate has a negative inotropic effect on failing and nonfailing human heart muscle in doses that exceed the clinical dose, it appears to have a better hemodynamic profile than other commonly used induction agents, especially in the setting of coronary heart disease. With an induction dose of 0.2 to 0.3 mg per kg, there are minimal changes in heart rate, stroke volume, or cardiac output, and the blood pressure may decrease up to 15% because of decrease of systemic vascular resistance. Etomidate does suppress adrenocortical function, cause myoclonus, and prolong duration of seizure when used for electroconvulsive therapy.

C.9. What is the best choice of anesthetic agents for maintenance of anesthesia? Why?

There appears to be no one best myocardial protective agent or technique. The knowledge of physiologic and pharmacologic effects of anesthetic agents in patients with cardiac disease will

allow flexibility in their selection. The use of inhalation versus opioid anesthesia in patients with cardiac disease is still debated, although the cardiovascular effects of both techniques and the physiologic differences between them are well documented. However, most outcome studies have not demonstrated a difference between the techniques. Studies of more than 3,000 noncardiac surgical patients with CAD have concluded that anesthetic type does not affect outcome.

Inhalation anesthetics are thought to possess ischemic preconditioning properties. Most investigations of anesthetic ischemic preconditioning have been done in patients undergoing cardiac surgery, but maybe there are potential beneficial effects in the high-risk cardiac patients undergoing noncardiac surgery as well. However, none of the trials to date were powered to evaluate MI or death as an outcome. The current consensus is that use of either a volatile anesthetic agent or total intravenous anesthesia is reasonable for patients undergoing noncardiac surgery.

The use of nitrous oxide in patients with history of CAD has been questioned since the early 1990s, when animal and human studies showed the increase in peripheral vascular resistance, diastolic dysfunction, and subsequently myocardial ischemia. Badner et al. demonstrated the increase on homocysteine plasma levels of patients during carotid endarterectomy when nitrous oxide was administered and the correlation of those levels with increased incidence of myocardial ischemia. However, the Evaluation of Nitrous Oxide in the Gas Mixture for Anaesthesia (ENIGMA-II) trial, which enrolled 7,110 patients, showed that nitrous oxide did not increase the risk of death and cardiovascular complications or surgical site infection.

The objectives during maintenance are not dissimilar to any other patient: amnesia, unconsciousness, and analgesia. These goals are constrained by the hemodynamic effect of each agent

in order to provide heart rate control, coronary pressure perfusion, and effects on LV function. The preferred anesthetic technique will be a balanced anesthetic approach: opioids, with low/moderate doses of volatile anesthetics and benzodiazepines.

Badner NH, Beattie WS, Freeman D, et al. Nitrous oxide-induced increased homocysteine concentrations are associated with increased postoperative myocardial ischemia in patients undergoing carotid endarterectomy. *Anesth Analg*. 2000;91(5):1073–1079.

C.10. You notice a new 3-mm ST-segment depression in lead V_5. How would you treat it?

ST-segment depression can be an indicator of myocardial ischemia. Initial efforts should be focused on determining its etiology. Management of ischemia should include pharmacologic manipulation of the determinants of myocardial oxygen supply and demand.

The crucial aspect of such management includes the following:

- Heart rate control and adequate coronary perfusion pressure. If ST-segment depression is associated with tachycardia and hypertension, the most common cause during surgery is inadequate anesthesia. Therefore, adequate levels of anesthesia should be achieved first. Heart rate control can also be achieved by the use of β-blockers. Caution should be exerted in patients with known contraindications and hemodynamic instability. The calcium channel blockers are considered the drug of choice if coronary spasm is suspected.
- Avoidance of hypotension and use of vasopressors to sustain coronary perfusion pressure
- The use of nitrates is advocated as long as it does not compromise coronary perfusion pressure. Nitrates decrease myocardial oxygen demand by decreasing preload, intracavitary pressure, and myocardial wall tension. In addition, NTG increases the ratio of endocardial to epicardial blood flow.
- Oxygen delivery should be increased by correcting significant anemia (<7 g per dL) and increasing the fraction of inspired oxygen.
- Oxygen demand also could be reduced by correction of hypothermia and/or shivering, if present.
- Secondary therapies should consider the use, if feasible, of antiplatelet therapy such as aspirin.

C.11. Would you give prophylactic intravenous NTG to prevent myocardial ischemia?

There are no randomized data that support the use of prophylactic intraoperative intravenous NTG in patients at high

risk. NTG should be used only when ischemia is detected and the hemodynamic effects of other agents in use are considered.

Beattie WS. Evidence-based perioperative risk reduction. *Can J Anaesth*. 2005;52(suppl 1):R3.

C.12. What is the significance of tight control of the heart rate intraoperatively?

Numerous studies have shown that intraoperative tachycardia and the duration of tachycardia could cause myocardial ischemia. Therefore, control of heart rate intraoperatively could significantly reduce the risk of perioperative myocardial events. It is clear that heart rate should be maintained to less than 100 beats per minute; however, the optimal heart rate for all patients has not been determined. Some recommend maintaining the heart rate between 60 and 70 beats per minute in high-risk patients. Slogoff et al. in the 1980s were able to correlate tachycardia with the occurrence of intraoperative myocardial ischemia. Raby et al. demonstrated that by identifying the high-risk patients, whose preoperative Holter tracing showed signs of ischemia, and controlling the heart rate 20% below the ischemia threshold or approximately 60 beats per minute with esmolol, during vascular surgeries could reduce the risk of perioperative myocardial ischemia. Feringa et al. demonstrated that tight heart rate control instead of just the use of β-blockers reduced perioperative myocardial ischemia and improved long-term outcome in vascular surgery patients.

C.13. When would you extubate the trachea in this patient? What could you do to prevent hypertension and tachycardia during extubation and emergence?

At the end of surgery, assuming no intraoperative complications, the trachea would be extubated when the patient is fully awake, breathing adequately, and neuromuscular blockade is fully reversed. To prevent tachycardia and hypertension associated with extubation and emergence, low doses of medications such as 1 mg per kg of lidocaine or esmolol, or 0.015 to 0.03 mg per kg of nicardipine, or 0.1 mg per kg of labetalol or diltiazem, before emergence in order to reduce sympathetic response of emergence and extubation can be administered.

D. Postoperative Management

D.1. What are the postoperative predictors of perioperative MACE?

In noncardiac surgical patient, the highest risk of cardiac morbidity is in the postoperative period. It is during this period where up to 67% of the ischemic events occur. This period is characterized by increase in heart rate, blood pressure, sympathetic discharge, and hypercoagulability. Heart rate commonly increases postoperatively by 25% to 50% over intraoperative values, and tachycardia occurs in 10% to 25% of patients. Postoperative myocardial ischemia occurs in 27% to 41% of high-risk patients. Most of these events (50% or higher) are silent (without angina). Postoperative MI is usually preceded by prolonged ST-segment depression. This change on ECG is easily missed if ECG is not continuously monitored because most of the changes will revert completely to baseline. However, routine continuous postoperative ECG monitoring is not recommended, and even routine daily ECG for 3 days is no longer advocated. In a study involving 337 vascular surgery patients in whom troponin I levels were collected within 48 hours of surgery and 12-lead ECGs were performed daily for 3 postoperative days, although 40% of the subjects had elevated troponin levels, only 6% of the patients had ischemic changes on the ECG. Postoperative MI may be associated with tachycardia and pain. Studies involving large numbers of patients suggest that postoperative ischemia is the most important marker of immediate and long-term adverse cardiovascular events. It is associated with a 2.8-fold increase in the odds of all adverse cardiac outcomes.

The highest incidence of troponin elevation, a biochemical marker of ischemia, frequently occurs 8 to 24 hours after the surgical procedure; even mild elevations are associated with postoperative cardiac ischemia and they could help to categorize the short- and long-term risk of the surgical patient as they are

independent predictors of mortality. Postoperative MI has also been associated with other clinical conditions as postoperative hypothermia, hypercoagulability, postoperative pain, and anemia.

D.2. How would you control postoperative pain?

The postoperative period can be stressful due to the onset of pain during emergence from anesthesia, fluid shifts, temperature changes, and alteration of respiratory function. Marked changes occur in plasma catecholamine concentration, hemodynamics, ventricular function, and coagulation following noncardiac surgery, particularly in patients with preexisting cardiac disease. These stressors place the patient at increased risk for development of adverse cardiac outcome. Severe postoperative pain reported in 5% to 10% of patients. Effective pain management is essential to prevent adverse outcome and promote early recovery. Intravenous patient-controlled analgesia and/or patient-controlled epidural analgesia are popular methods for reducing postoperative pain. Several studies suggest that effective pain management leads to a reduction in postoperative catecholamine surges and hypercoagulability. A meta-analysis published in 2013, which analyzed the impact of epidural analgesia versus systemic analgesia, concluded that epidural analgesia was associated with a 40% decrease in mortality and a

significant decrease in the risk of atrial fibrillation, supraventricular tachycardia, deep vein thrombosis, respiratory depression, atelectasis, pneumonia, ileus, and postoperative nausea and vomiting, and also improved recovery of bowel function. However, epidural analgesia also significantly increased the risk of arterial hypotension, pruritus, urinary retention, and motor blockade.

D.3. Is postoperative anemia associated with adverse cardiac outcome?

Patients with IHD may be adversely affected by anemia. Based on existing literature, the evidence is sufficient to state that transfusions are rarely beneficial if the Hgb level exceeds 10 g per dL (Hct >30%) in the absence of acute blood loss. It is also reasonable to state that the patient may benefit from a transfusion if the Hgb level falls below 7 g per dL. The controversy remains between Hgb concentrations of 8.0 to 10.0 g per dL. The 2016 American Association of Blood Banks Guideline, which is based on expert opinion and studies, recommends a restricted transfusion strategy (Hgb <7 to 8 g per dL) in asymptomatic, hemodynamically stable patients without CAD. The guideline also recommends adherence to a restrictive transfusion strategy in hospitalized patients with cardiovascular disease and consideration of transfusion for patients with symptoms (e.g., chest pain, orthostasis, CHF) or Hgb less than 8 g per dL. In postoperative patients, the recommended maintenance Hgb concentration is 8 g per dL or more, unless the

patient exhibits symptoms. There were no specific recommendations for hemodynamically stable patients with ACS because of the lack of high-quality evidence for either a liberal or a restrictive transfusion strategy in these patients. The consensus of those experts recommended a symptom-guided approach to evaluating an Hgb level to determine whether to transfuse a patient with anemia.

Simmons JW, Pittet JF. Revealing the real risks of perioperative transfusion: rise of the machines! *Anesthesiology*. 2015;122(1):1–2.

D.4. Is postoperative hypothermia associated with postoperative myocardial ischemia?

Hypothermia is common during anesthesia and surgery owing to anesthetic-induced inhibition of thermoregulatory control. The principal initial cause of hypothermia is core-to-peripheral redistribution of body heat.

Perioperative hypothermia is associated with numerous complications; it triples the incidence of adverse myocardial outcomes in high-risk patients, increases blood loss. Even mild hypothermia has been associated with an increased incidence of wound infection following colon resection. Also, it adversely affects oxygen availability in tissues, changes the kinetics and action of some anesthetic agents and muscle relaxants, and is associated with delayed postanesthetic recovery. It causes immune dysfunction and increased transfusion requirements.

Core hypothermia may increase circulating catecholamines levels, leading to tachycardia, hypertension, systemic vasoconstriction, and an imbalance between oxygen demand and supply. Frank et al. studied 100 patients undergoing lower extremity vascular surgery. They found that unintentional hypothermia (sublingual temperature less than 35°C [95°F]) on arrival to postoperative ICU is associated with a significantly higher incidence of myocardial ischemia (36% vs. 13%), angina (18% vs. 15%), and Pa_{O_2} less than 80 mmHg (52% vs. 30%) during the early postoperative period. However, a subsequent trial involving 1,000 patients with subarachnoid hemorrhage, which were randomized to perioperative hypothermia or normothermia, did not show a difference in perioperative cardiac events. Maintenance of normothermia may be reasonable to reduce perioperative cardiac events in patients undergoing noncardiac surgery.

D.5. How would you make a diagnosis of perioperative MI (PMI)?

The definition of MI, according to the third universal definition of MI, is based on elevation of biomarkers, in conjunction with cardiac symptoms, ECG changes, new echocardiographic changes, or angiographic findings of intracoronary thrombus.

Most ischemic episodes occur after and not during the operation. This is probably because of the high postoperative stresses related to anesthesia and surgery. Several studies have examined the optimal method for diagnosing a PMI. Most

patients suffering from PMI do not complain of chest pain and the value of routine serial postoperative ECG is limited. Cardiac-specific enzyme elevations such as troponin I (cTnI) and troponin T (cTnT) are currently the standard of care for biochemical diagnosis of a PMI because they demonstrate sensitivity and tissue specificity superior to other available biomarkers.

In the purest physiologic sense, any detectable necrosis is an acute MI; however, troponin elevation can be observed in many other conditions in which the heart is stressed. Even small elevations of specific markers of myocardial damage, such as cardiac troponins, should be acknowledged as indicative of myocardial injury. This has been categorized as myocardial injury in the third universal definition of MI and includes myocardial injury related to demand (type II) and related to plaque rupture (type I). From a clinical perspective, there is clear evidence that any amount of detectable cardiac troponin release is associated with an increased risk of new adverse cardiac events. Many investigators agree that the increase in cardiac troponins postoperatively, even if no cardiovascular signs and symptoms are present, carries poor long-term outcome.

Clinicians need to be sensitive to redundancy in testing. Some authors have demonstrated that routine cardiac troponin monitoring is an easy, effective, and inexpensive way to detect postoperative myocardial injury. However, the ACC/AHA guidelines reserve the use of this biomarkers for patients at high risk and those with clinical, ECG, or hemodynamic evidence of cardiovascular dysfunction. Routine measurement of postoperative troponins in asymptomatic or low-risk patients undergoing low-risk procedure is not warranted.

White HD, Thygesen K, Alpert JS, et al. Clinical implications of the third universal definition of myocardial infarction. *Heart*. 2014;100(5):424–432.

D.6. How would you manage the patient with a suspected PMI?

There is lack of control evidence regarding management of PMI in the postsurgical patient. PMI could include three different clinical scenarios/diagnosis: unstable angina (UA), non–ST-elevation MI (NSTEMI), and ST-elevation MI (STEMI).

The initial management should focus on the following diagnosis:

- Evaluation of chest pain if present
- 12-Lead ECG and determination of changes, if present
- Measurement of biomarkers of cardiac injury. A cardiac-specific troponin is the preferred marker.
- Immediate consultation of a cardiologist and risk stratification to determine high-risk patients

It is important to consider the recent surgical procedure and consultation with the surgical team regarding impact of aspirin and anticoagulant therapy.

Unless a contraindication exists, patients with an ACS of the type UA or NSTEMI should be treated with oxygen, aspirin (acetylene salicylic acid), sublingual/intravenous NTG for chest pain relief, as long as blood pressure is adequate, a β-blocker, unfractionated heparin or low molecular weight heparin, and/or a glycoprotein (GP) IIb/IIIa inhibitor.

The cardiology consultant should guide further management:

- Option 1 is a routine angiographic approach, in which coronary angiography and revascularization are performed unless a contraindication exists. Within this approach, the most common strategy advocates for a period of medical stabilization. A more aggressive approach calls for coronary angiography and revascularization performed within 24 hours of the onset of symptoms or diagnosis; the rationale for the more aggressive approach is the protective effect of carefully administered anticoagulant and antiplatelet therapy on reperfusion procedures outcome.
- The alternative approach, commonly referred to as the initially conservative strategy, is guided by ischemia, with angiography reserved for patients with recurrent ischemia despite medical therapy.

Regardless of the angiographic strategy, an assessment of LV function (echocardiography, ventriculogram, or nuclear ventriculography) should be strongly considered because of the importance of treating patients who have impaired LV function with ACE inhibitors, β-blockers, and surgical revascularization (CABG) when appropriate (e.g., three-vessel disease).

If the patient presents with a STEMI, recognized on the basis of the 12-lead ECG, the management will be initially similar to UA/NSTEMI (oxygen, acetylene salicylic acid, NTG, β-blockers), then one should attempt to complete restoration of flow in the infarct artery by PCI (balloon angioplasty with or without deployment of an intracoronary stent under the support of pharmacologic measures to prevent thrombosis), or surgical measures (CABG).

Evidence supports expeditious restoration of flow in the obstructed infarct artery after the onset of symptoms in patients with STEMI as a key determinant of short- and long-term outcomes. Early reperfusion of ischemic myocardium within the risk region of an occluded infarct-related artery interrupts the

occurring necrosis, reduces ultimate infarct size, preserves regional and global ventricular function, and improves survival. A subset of patients will have severe three-vessel or left main disease or anatomic features unfavorable for PCI and may be candidates for urgent or emergency CABG.

SECTION 3 The Gastrointestinal System

15 Intestinal Obstruction and Enhanced Recovery after Surgery

Leif Ericksen and Tong J Gan

A 73-year-old woman with an acute abdomen was scheduled to undergo an emergency exploratory laparotomy. She complained of severe abdominal pain with periodic bouts of bilious vomiting. Her past surgical history included a right hemicolectomy for colon cancer. She had a blood pressure (BP) of 85/60 mmHg, pulse of 115 beats per minute, and hematocrit of 45%.

A. Medical Disease and Differential Diagnosis

1. What is the differential diagnosis of the acute abdomen?
2. What are the causes of intestinal obstruction of the small bowel and of the large bowel?
3. Differentiate between simple and strangulated bowel obstruction.

4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why? How might the distinction be made?
5. What are the causes and effects of bowel distention?
6. Describe the fluid shifts during small bowel intestinal obstruction.
7. Discuss the systemic derangements that occur with intestinal obstruction.
8. What is an ileus? Discuss its causes and pathophysiology.

B. Preoperative Evaluation and Preparation

1. What is Enhanced Recovery after Surgery (ERAS)? What are the core tenants of these programs?
2. Can ERAS be used in this case?
3. What components of ERAS are applied in the preoperative phase of the care of colorectal surgery (CRS) patients?
4. Is it important to decompress the abdomen before induction of anesthesia? Why?
5. Describe the respiratory implications.
6. What are the implications of the tense abdominal wall?
7. Outline the methods of abdominal decompression.
8. Discuss the goals of fluid management.
9. What would you use as a guide to fluid volume replacement?

C. Intraoperative Management

1. What dangers are present during induction? How are they planned for?
2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?
3. In what position would you intubate this patient?
4. What is the best muscle relaxant to use for the rapid sequence induction?
5. Would you remove or leave the nasogastric tube (NGT) in

place before inducing anesthesia?
6. Would you use nitrous oxide in this patient?
7. Are there any benefits to using a high concentration of inspired oxygen (FIO_2)?
8. What components of ERAS are applied in the intraoperative phase of the care of CRS patients?
9. What are the strengths, weaknesses, benefits, and challenges of ERAS?
10. What are the indications for ERAS?

D. Postoperative Management

1. What are the principles of postoperative care in this patient?
2. Are there any postoperative respiratory problems associated with factors other than aspiration?
3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?
4. What is gram-negative sepsis? Describe the clinical picture and treatment.
5. What components of ERAS are applied in the postoperative phase of the care of CRS patients?

A. Medical Disease and Differential Diagnosis

A.1. What is the differential diagnosis of the acute abdomen?

An acute abdomen refers to a number of conditions with the most prominent feature being severe abdominal pain of abrupt onset that can necessitate urgent surgical intervention. The differential is challenging because there are a number of etiologies. The most common diagnoses vary by age; many organ systems may cause an acute abdomen, and the presenting symptom is often nonspecific. Some of the most common causes are listed in **Table 15.1**. Visceral and somatic afferents are the

two systems that transmit abdominal pain. Visceral pain is dull, deep, poorly localized, and transmitted by C fibers in the mucosa, muscularis, and visceral peritoneum. Visceral pain is generated by nerve endings without specialized structures that are primarily sensitive to tissue tension typically caused by distension, spasm, and ischemia. Somatic pain is sharp and well localized and transmitted by chemical (inflammation), thermal, or mechanical irritation of the aδ fibers of the parietal peritoneum. These fibers are derived from the same origin as those innervating muscle and skin, which cause the guarding and cutaneous sensitivity that can accompany an acute abdomen. Abdominal pathology frequently has a mixed picture of visceral and somatic pain.

TABLE 15.1 Acute Abdomen Differential

Surgical	Medical	Gynecologic
Inflammation	Cardiovascular	Ectopic pregnancy
Inflammatory bowel disease	Myocardial ischemia	Ovarian cyst
Acute appendicitis	Myocardial infarction (inferior)	Torsion
Acute diverticulitis	Gastrointestinal	Rupture
Acute pancreatitis	Gastritis	Hemorrhage
Acute cholecystitis	Gastroenteritis	Infarction
Acute cholangitis	Mesenteric adenitis	Infection
Meckel diverticulitis	Hepatitis	Pelvic inflammatory disease
Obstruction	Hepatic abscess	Fibroid degeneration
Intestinal obstruction	Fitz-Hugh-Curtis syndrome	Salpingitis
Biliary colic	Primary peritonitis	Mittelschmerz
Ureteric colic	Abdominal wall conditions	Endometriosis
Acute retention of urine	Rectus sheath hematoma	
Ischemia	Genitourinary	
Mesenteric ischemia	Urinary tract infection	
Torsion of a viscus	Pyelonephritis	
Perforation	Neurologic	
Perforated peptic ulcer disease	Tabes dorsalis	
Perforated small bowel (salmonella, cytomegalovirus, and tuberculosis infection)	Hematologic	
	Sickle cell disease	
	Malaria	

Perforated diverticular disease	Hereditary spherocytosis
Perforated appendix	Endocrine
Toxic megacolon with perforation	Diabetes mellitus
	Thyrotoxicosis
Acute cholecystitis and perforation	Addison disease
	Metabolic
Perforated oesophagus	Uremia
Perforated bladder	Hypercalcemia
Perforation of a length of strangulated bowel	Porphyria
	Infective
Ruptured abdominal aortic aneurysm	Herpes zoster

The colored cells represent pathophysiologies. Non-colored cells represent specific diagnoses. The table is presented in the context of forming a differential diagnosis for an acute abdomen. The table presents categories that become more specific (e.g., surgical/medical/gynecologic, then pathophysiology, then specific diagnoses) that can be matched to a patients presenting symptoms and history.

Reprinted from Garden JO, Parks RW, eds. *Principles and Practice of Surgery*. 7th ed. Edinburgh, United Kingdom: Elsevier; 2018:159. Copyright © 2018 Elsevier. With permission.

The two processes typically implicated in an acute abdomen are inflammation and obstruction. The inflammatory milieu causes a direct chemical irritation and causes the tissue to become edematous and distended. Impeded flow-through a hollow organ causes smooth muscle to contract in an attempt to overcome the obstruction resulting in increased tension and dilation. Both of these processes can contribute to ischemia and perforation, which can in turn also cause pain.

Etiologies of the acute abdomen may require either medical and/or surgical treatment, be intra- and/or extra-abdominal, and be associated with almost any organ system. Characteristics such as intensity, chronology, location, diffuse versus localized, radiation, and comorbidities in addition to testing may help to construct a differential diagnosis.

Edinburgh, United Kingdom; Elsevier; 2018:159–178.

A.2. What are the causes of intestinal obstruction of the small bowel and of the large bowel?

Obstruction occurs due to either an inhibition of physiologic peristalsis (ileus) or mechanical obstruction. Mechanical obstructions are broadly divided into extrinsic, intramural, and intraluminal categories.

Adhesions resulting from the inflammation and healing process of prior surgery account for the vast majority (>70%) of small bowel obstructions and are followed in order by hernias, malignancy, and then inflammatory bowel disease. Diagnoses of volvulus and hernia strangulation are less common but are surgical emergencies. Large bowel obstructions occur less frequently, but the most common etiologies are adenocarcinoma, volvulus, and sequelae from diverticulitis. Adenocarcinoma causes >50% of all large bowel obstructions.

Yeo CJ, ed. *Shackelford's Surgery of the Alimentary Tract*. 8th ed. Philadelphia, PA: Elsevier; 2019:842–850.

A.3. Differentiate between simple and strangulated bowel obstruction.

A simple bowel obstruction refers to a single section of occlusion, whereas a strangulated obstruction refers to an area of compromised perfusion. It is important to recognize bowel strangulation because it increases mortality 2- to 10-fold from generally <5% to 25% depending on comorbid conditions. Strangulation is typically discussed in concert with an incarcerated segment of bowel (e.g., a hernia or hole in

omentum) but can also be due to inadequate perfusion pressure secondary to an increased intraluminal or intramural pressure. As venous outflow decreases, the walls of the bowel become edematous, obstruction worsens, pressure increases, and eventually arterial inflow is compromised. Affected sections become ischemic, infarct, and perforate after which peritonitis ensues.

The classic signs of strangulation are constant (as opposed to intermittent) pain, fever, tachycardia, leukocytosis, and peritonitic signs (e.g., guarding and rebound tenderness). However, no clinical parameter reliably rules strangulation in or out, so a thorough history and physical examination and a high index of suspicion must guide the decision to operate. Risk factors for bowel strangulation may include female sex, femoral hernia, and history of hospitalization related to groin hernia.

A.4. Is it important to differentiate whether the bowel obstruction is located in the small bowel or large bowel? Why? How might the distinction be made?

Yes, it is important not only to differentiate between large and small bowel obstruction but also to determine the position of the

obstruction within those sections of bowel. Both small and large bowel obstructions may present with colicky abdominal pain, nausea and vomiting, distention, and obstipation. The location, however, will differentiate between the etiologies of the obstruction which will dictate the management strategy, systemic consequences, and possible special considerations. Prognosis can also vary widely. For instance, a large bowel obstruction presenting as a small bowel obstruction may have a mortality rate four times greater than from other causes.

Small bowel obstruction is associated with more bilious vomiting sooner after the obstruction occurs. Patients may continue to have bowel movements as the distal bowel continue to function. Time intervals between bouts of abdominal pain are shorter than the more proximal the obstruction is. The majority of small bowel obstructions are thought to be caused by adhesive disease, which typically resolve with nonoperative management including NGT decompression and fluid resuscitation. The small bowel is involved in a number of secretory and absorptive processes. During a trial of conservative management, a stable patient must be monitored for indications to proceed to surgery because altered function can lead to the accumulation of air and fluid, bowel distension, increased intraluminal pressure according to the law of Laplace, and possible bowel infarction and rupture. Small bowel obstruction also alters gut flora balance leading to translocation of bacteria. Vomiting occurs earlier and more frequently with a small bowel obstruction, which contributes to anesthetic concerns including decreased intravascular volume, metabolic alkalosis, and airway management. Crohn disease, irradiated bowel, and Richter hernias require additional considerations based on location and level of involvement.

Large bowel obstructions are usually slower in onset, more frequently associated with distension and lower abdominal pain,

and caused most frequently by adenocarcinoma. Surgical intervention is typically required before infarction and perforation occur. Fewer fluid shifts occur in the large bowel and vomiting occurs later in the disease process if at all, so less resuscitation and electrolyte correction is required. Plain film upright and flat x-rays are less accurate than computed tomography (CT) but are faster and may show other indications to proceed directly to surgery such as free air. CT, on the other hand, elucidates the etiology far better than x-ray. Depending on the location, surgical interventions may include resection, anastomoses, and/or ostomy, all of which have varying risks of leak and infection. Adjuvant radiation and chemotherapy may be part of the perioperative planning process. Stable patients with a sigmoid volvulus may undergo an attempt to relieve the torsion with a flexible sigmoidoscopy.

A.5. What are the causes and effects of bowel distention?

In a simple obstruction, the primary contributors to bowel distention are swallowed air and secretions from proximal sections of the gastrointestinal (GI) tract. Bacterial overgrowth may also contribute in the form of carbon dioxide and fermentation products that accumulate more rapidly due to an impaired ability to diffuse out of the bowel. Endotoxin-stimulated chemoreceptors and mechanoreceptors activated by distention activate autocrine, luminal, paracrine, and

immunoneuroendocrine systems (ALPINES) to attract neutrophils and macrophages. Prostaglandins and inflammatory mediators directly alter the activity of ion transporters (and therefore affect the flow of fluid) and the barrier function of the gut. The net result is increased secretion into the lumen of the intestine, decreased absorption, and further distention forming a feedback loop unless decompressed (**Fig. 15.1**). Interestingly, this effect is seen both proximally and distally to an obstruction and may lead to bowel movements even during a complete obstruction. Decreased intravascular volume and electrolyte imbalances are common which may present as hypotension and lactic acidosis. By the law of Laplace, as the lumen of the bowel grows larger, the pressure increases. Lymphatic drainage is impaired first, further increasing pressure which then impedes venous drainage and compromises perfusion. Ischemia, infarction, and perforation soon follow. Septic shock will ensue if it has not already been initiated by translocated bacteria.

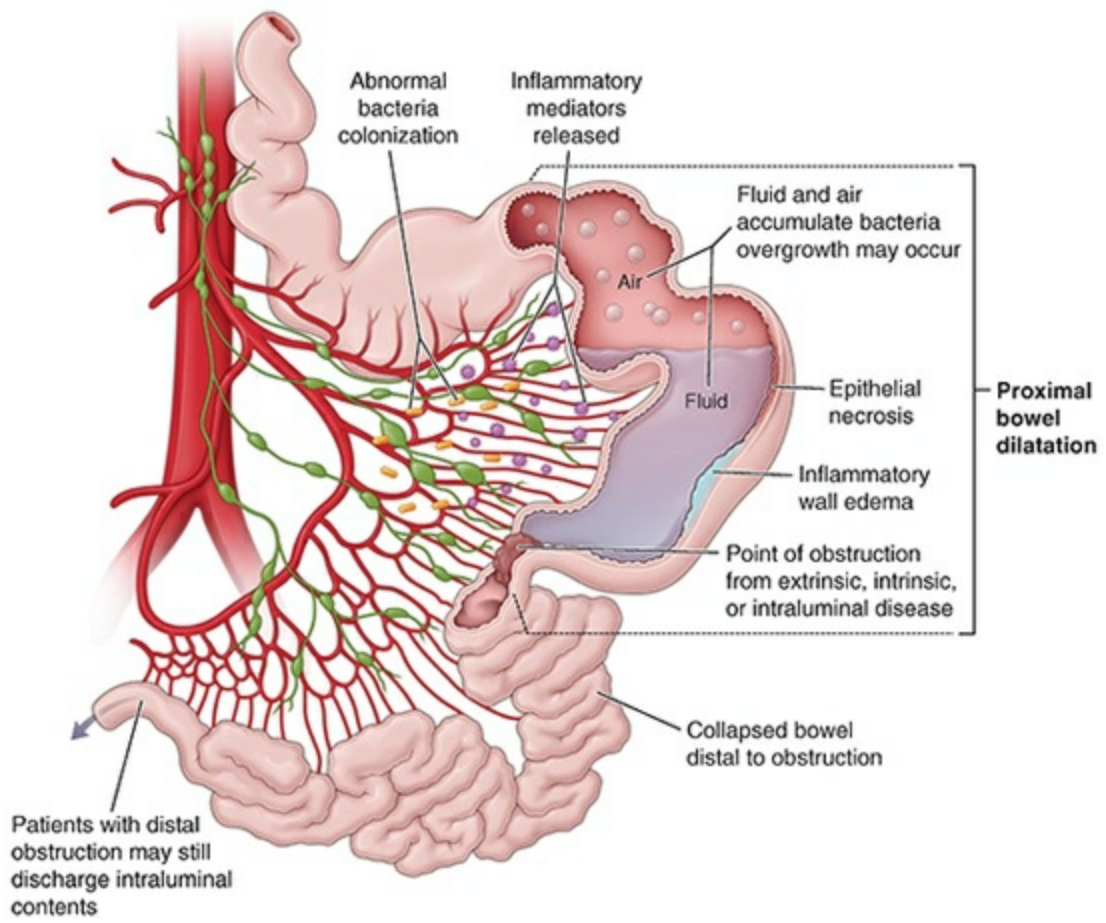

FIGURE 15.1. Pathophysiologic changes of intestinal obstruction. Note: Intraluminal obstruction is displayed. *(Republished with permission of McGraw-Hill Education, from Jameson JL, Fauci AS, Kasper DL, et al, eds*. Harrison's Principles of Internal Medicine. *20th ed. New York, NY: McGraw-Hill Education; 2018:chap 323:2296; permission conveyed through Copyright Clearance Center, Inc.)*

Closed loop obstructions result from volvulus, herniation, or a large bowel obstruction with a competent ileocecal valve. The same pathology applies but has an accelerated course due to an inability of the obstruction to be relieved proximally. Urgent operative management is typically required.

A.6. Describe the fluid shifts during small bowel intestinal

obstruction.

A normal physiologic small bowel fluid load is 8 to 9 L per day (**Fig. 15.2**). Obstruction causing distention increases the secretory activity of the bowel and decreases the absorptive capacity leading to fluid sequestration in the lumen of the bowel. The more proximal the obstruction is, the more severe the fluid loss is. Bowel wall edema, vomiting, NG suctioning, and transudative fluid loss into the peritoneum can all also contribute to the decrease in intravascular fluid. In general, vomiting occurs when 3 L of fluid have been sequestered. Hemodynamic parameters, such as heart rate (HR) and BP, become abnormal at ≥6 L of sequestered fluid.

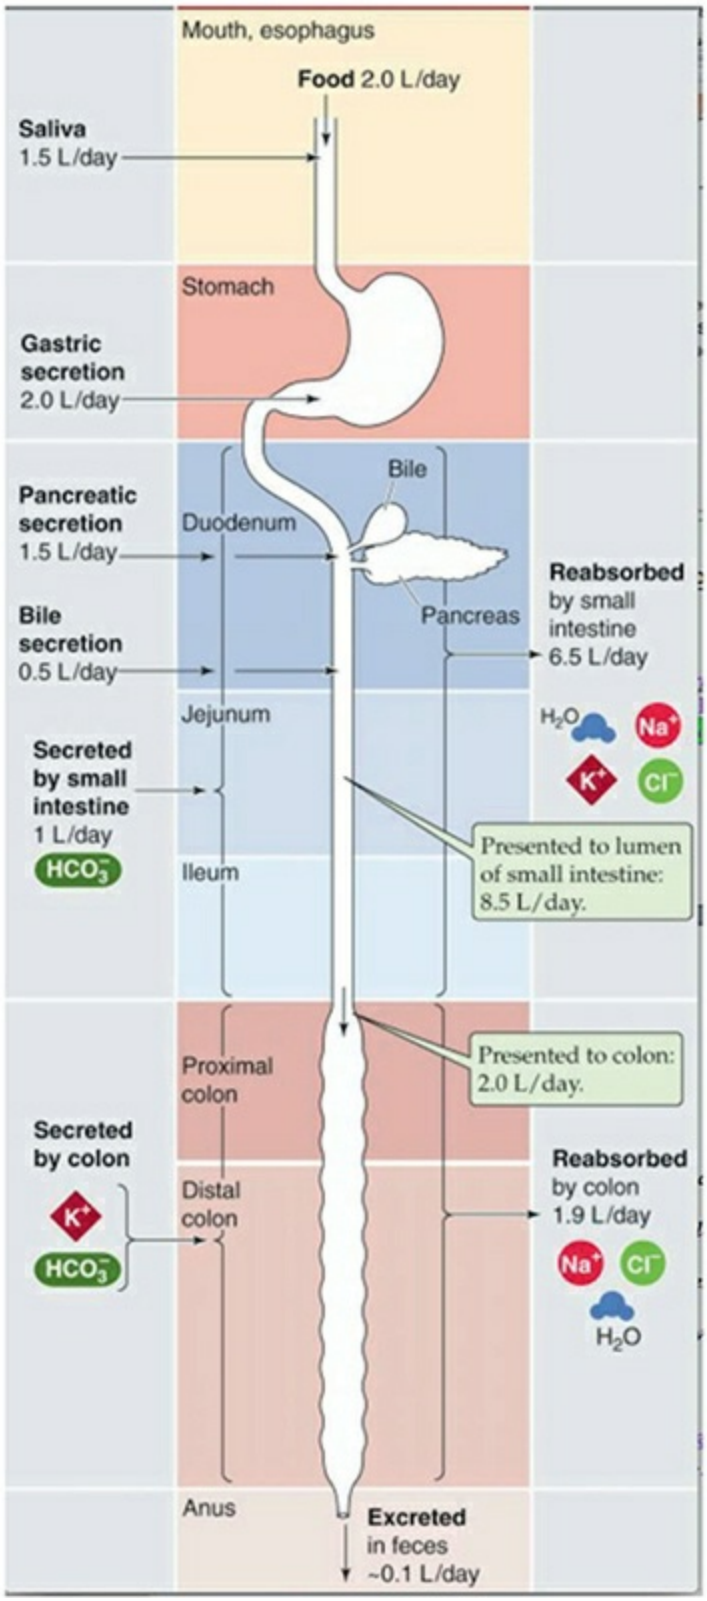

FIGURE 15.2. GI fluids. Fluid balance in the GI tract. For each segment of the GI tract, the figure shows substances flowing into the lumen on the left and substances flowing out of the lumen on the right. Of the approximately 8.5 L per day that are presented to the small intestine, the small intestine

removes approximately 6.5 L per day, delivering approximately 2 L per day to the colon. The large intestine removes approximately 1.9 L per day, leaving approximately 0.1 L per day in the feces. A.7. Discuss the systemic derangements that occur with intestinal obstruction.

Systemic derangements in intestinal obstruction can be severe and even fatal if left unchecked. Hypotension results from hypovolemia secondary to fluid sequestration in the bowel lumen and wall as well as loss from vomiting/NGT suctioning. When the bowel is distended and intra-abdominal pressure is high, venous return is impaired and hypotension worsens.

Other mechanical consequences of a distended abdomen may include a reduced functional residual capacity (FRC) and an increased work of breathing.

The proximal bowel secretes a great deal of potassium, sodium, and chlorine. A very proximal obstruction may result in a hypochloremic, hypokalemic metabolic alkalosis. A more common finding is a metabolic acidosis related to compromised perfusion. Hyponatremia may further contribute to intravascular fluid loss.

Normal bowel functions as a barrier keeping bacterial flora intraluminal if any exist (many are sterile). In obstruction, intestinal flora such as *Escherichia coli*, *Enterococcus faecalis*, and *Klebsiella* increase in count profoundly. Advanced stages can lead to translocation from the gut and contribute to gram-negative sepsis, shock, and death even in the absence of perforation. Finally, inflammatory mediators and relative

hypovolemia have been shown to cause damage to remote organs.

Yeo CJ, ed. *Shackelford's Surgery of the Alimentary Tract*. 8th ed. Philadelphia, PA: Elsevier; 2019:842–850.

A.8. What is an ileus? Discuss its causes and pathophysiology.

Ileus describes a lack of physiologic peristalsis in the absence of a mechanical obstruction. Different etiologies exist including spastic and disorganized motility, but the cause most germane to the perioperative world and this case study is the adynamic ileus from the inhibition of intestinal myocytes. The most frequent cause is surgical abdominal manipulation. However, a number of other factors including inflammation, iatrogenic drugs, electrolyte imbalances, excessive crystalloid administration, and trauma may also contribute.

Two mechanisms contribute to postsurgical adynamic ileus. The first is a short-lived neurogenic phase. Incision of the peritoneum activates adrenergic afferents linked to an inhibitory spinal reflex. Subsequent more intense manipulation of the bowel activates higher order supraspinal pathways which then stimulate both adrenergic and vagal pathways to release motility impairing neurohumoral substances, such as norepinephrine and nitric oxide (NO), and vasoactive intestinal polypeptide (VIP), respectively. Corticotropin-releasing factor (CRF) has been implicated in the coordination of this pathway.

A longer lasting inflammatory phase causes uncomplicated postoperative (3 to 5 days) ileus. Surgical manipulation activates macrophages naturally living in the myenteric plexus, stimulating the innate immune response. An inflammatory milieu is generated within 3 to 4 hours after surgery. Cytokines have been shown to alter the release of enteric neurotransmitters. Prostaglandins generated by cyclooxygenase-2 (COX-2) can

activate many of the splanchnic afferents and cause reflex spinal inhibition as discussed in the neurogenic phase. NO also continues to be generated by recruited monocytes and neutrophils.

Infection, sepsis, peritonitis, and trauma cause or contribute to an inflammatory state that may cause an ileus or independently prolong a postoperative ileus (POI). Opiate administration, hypomagnesemia, hyponatremia, and hypercalcemia may also contribute and must be monitored in the perioperative period.

Chapman SJ, Pericleous A, Downey C, et al. Postoperative ileus following major colorectal surgery. *Br J Surg*. 2018;105(7):797–810.

B. Preoperative Evaluation and Preparation

B.1. What is Enhanced Recovery after Surgery (ERAS)? What are the core tenants of these programs?

ERAS is a bundle of evidence-based interdisciplinary practices emphasizing early return to functional status. Some of the main tenants include attenuating the physiologic stress response to surgery, improving metabolic responses, and preventing perioperative organ damage. Common strategies include "optimal analgesia," encouraging metabolic optimization, aggressive postoperative nausea and vomiting (PONV) prophylaxis and treatment, goal-directed fluid therapy (GDFT), minimally invasive surgical techniques, avoidance of postoperative NGT and peritoneal drains, and early enteral feeding and ambulation. ERAS programs have demonstrated accelerated recovery, reduced complication rate, reduction in length of stay, reduced readmission rate, and increased healthcare value by increasing quality while decreasing cost.

Gan TJ, Thacker JK, Miller TE, et al. *Enhanced Recovery for Major Abdominopelvic Surgery*. New York: Professional Communications;

2016:xvi–xxii, 39–48, 105–109, 151–160, 191–194, 199–212, 215–223, 227–233, 237–247, 263–275.

B.2. Can ERAS be used in this case?

ERAS pathways were developed for elective surgical procedures, including CRS. However, many of the principles may be applied to urgent/emergent procedures as well.

Gan TJ, Thacker JK, Miller TE, et al. *Enhanced Recovery for Major Abdominopelvic Surgery*. New York: Professional Communications; 2016:189, 199.

B.3. What components of ERAS are applied in the preoperative phase of the care of colorectal surgery (CRS) patients?

Multimodal analgesia helps prevent ileus through an opioid-sparing strategy. Preoperative gabapentin, nonsteroidal anti-inflammatory drugs (NSAIDs), and intravenous (IV) acetaminophen have been demonstrated to have opioid-sparing effects. Thoracic epidural analgesia (TEA) (typically placed in the preoperative period) for open procedures is associated with earlier return of bowel function, superior postoperative analgesia, and decreased cardiopulmonary morbidity. Improved GI outcomes may be due to the combination of blockade of reflex sympathetic inhibition of gut function and opioid sparing. Hypotension may be a relative contraindication for TEA. The global benefit of TEA is not as clear in laparoscopic procedures. Single-shot spinal has been shown to reduce pain scores and reduce opioid consumption. A number of peripheral blocks have also been evaluated and have all demonstrated improved pain scores and decreased opioid use. The most well studied, transversus abdominal plane (TAP) block/catheters, have improved early postoperative pain scores, opioid consumption, and length of stay.

Preoperative nutritional optimization improves functional

recovery by encouraging an anabolic, rather than catabolic, state. Patients should be screened for malnutrition and when present should receive protein-rich nutritional supplementation for at least 7 days. Screening and correction of anemia improves oxygen (O2) delivery and end-organ function. Those without specific risk for aspiration may ingest solids up to 8 hours before induction. Clear fluids are given, preferably with at least 45 g of carbohydrates, to improve insulin resistance the evening before surgery and up to 2 hours before induction of anesthesia. Metabolic conditioning may also include prehabilitation programs aimed at improving functional capacity and immunonutrition both of which have demonstrated improved clinical outcomes.

Bowel preparation in elective CRS has been researched for more than 50 years, and a number of differing opinions still exist. The most current consensus guideline from the American Society for Enhanced Recovery (ASER) and the Perioperative Quality Initiative (POQI) endorse combined isosmotic mechanical bowel preparation with oral antibiotics (MBP-OAB). MBP-OAB has been demonstrated to lower surgical site infections and is associated with decreased rates of post-op gastric dysfunction.

Nausea and vomiting prophylaxis is routinely used in ERAS even in low-risk patients because it is difficult to predict precisely who is likely to develop symptoms. Managing modifiable risk factors preoperatively and planning an anesthetic which reduces baseline risk are encouraged. Strategies may include the use of propofol for induction and maintenance, avoiding nitrous oxide and inhalational agents, minimizing opioid use, and adequate hydration while avoiding excessive fluid administration.

Maintenance of normothermia improves surgical outcomes and is affected by preoperative interventions. Ambient

temperature maintained above 26°C, dry surgical garments, and warming blankets help ensure that the initial redistribution of blood at induction does not drop a patient's core temperature. Care must be taken not to overheat a patient, which may lead to evaporative heat loss.

B.4. Is it important to decompress the abdomen before induction of anesthesia? Why?

Yes. The most important reason for a preinduction NGT in obstructed and distended patients is to prevent aspiration. These patients are high risk, particularly for the need for postoperative

ventilatory support, which dramatically increases morbidity from 5% to 80%. Therefore, it is desirable to decompress the stomach while the patient has intact upper airway reflexes. NGTs have been demonstrated not to interfere with the function of the lower esophageal sphincter (LES) and do not reduce the efficacy of cricoid pressure (CP). NGTs may not be effective in removing particulate matter and may not always remove all gastric contents. In fact, it has been demonstrated that even when fully decompressed, the stomach can fill again via reverse peristalsis during intestinal obstruction. However, the volume of aspirate is one of the main determinants of morbidity, and NGTs have been shown to decrease residual volume in the stomach.

Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:235–248.

B.5. Describe the respiratory implications.

In addition to the increased risk of aspiration, a distended abdomen can transmit pressure via the diaphragm to reduce the compliance of the respiratory system; decrease the FRC and minute ventilation; and increase the work of breathing, atelectasis, shunt fraction, dead space, and airway pressures. Hypoxia, hypercapnia, and respiratory failure may result.

Bersten AD, Handy JM, eds. *Oh's Intensive Care Manual*. 8th ed. Philadelphia, PA: Elsevier; 2019:492–501.

Fleisher LA, Roizen MF, Roizen JD, eds. *Essence of Anesthesia Practice*. 4th ed. Philadelphia, PA: Elsevier; 2018:600.

B.6. What are the implications of the tense abdominal wall?

A tense abdominal wall can have significant hemodynamic implications. Increased abdominal pressure in both spontaneously and mechanically ventilated patients will make the inspiratory intrathoracic pressure more positive and decrease

venous return. A high-pressured abdomen will also cause venocaval compression, which decreases venous return and contributes to hypotension. A deeper level of abdominal muscle relaxation must also be targeted to optimize the surgical field.

Hines RL, Marschall KE, eds. *Stoelting's Anesthesia and Co-Existing Disease*. 7th ed. Philadelphia, PA: Elsevier; 2018:53–78.

Townsend CM, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier; 2017:1120–1138.

B.7. Outline the methods of abdominal decompression.

A sumping tube with a lumen for suctioning and a lumen for allowing air to be drawn into the stomach helps prevent the tube from sticking to the mucosa of the GI tract during suctioning. An NGT is advanced to approximately 50 to 60 cm for intragastric placement. The location of the tip of the tub should be confirmed before use. Inadvertent laryngeal placement of NGTs has been described with associated morbidity and mortality. Imaging is the gold standard. However, other reassuring signs may include auscultation of the stomach while insufflating air, absence of coughing and gagging during placement, pattern of resistance on placement, and commercial electromagnetic sensors have been developed. Once positioning has been confirmed, the tube must be secured (avoid the tube pressing forward on the nares causing ischemia and possibly erosion) and can then be set to gravity or suction. Tracking the output of the NGT may help to demonstrate resolution of obstruction over time.

Yeo CJ, ed. *Shackelford's Surgery of the Alimentary Tract*. 8th ed. Philadelphia, PA: Elsevier; 2019:663–672.

B.8. Discuss the goals of fluid management.

The goals of fluid management include maintaining an effective circulating volume to support O_2 delivery and avoiding organ hypoperfusion. At the same time, adverse effects of fluids, such as nonphysiologic electrolyte levels, toxicities, and excessive volume administration, must be avoided. Care is taken to prevent specific pathologic insults. For example, active bleeding decreases intravascular volume; gastric losses deplete Na^+, K^+, and Cl; small bowel losses deplete K^+, Cl^-, and HCO_3^-; and large bowel losses deplete K^+ (**Table 15. 2**). Sequestered fluid has a composition similar to plasma. Inflammation results in redistribution of fluid from the intravascular into the extracellular compartment. Sepsis impairs tissue O_2 extraction.

TABLE 15.2 Transcellular Fluid Composition

Daily Volume (L)	Daily Volume (L)	Cations				Anions		pH
Fluid		Na+	K+	Ca2+	Mg2+	Cl−	HCO3−	
Gastrointestinal tract								
Saliva	1–1.5	30–90	20–40	2.5	0.6	15–35	10–40	6–7
Gastric	1.5–2.5	20–60	10–20			20–160	0	1–3.5
Bile	0.7–1.2	130–150	5–12	10–50		25–100	10–45	7–8
Pancreatic	1–1.5	125–150	5–10			30–110	40–115	8–8.3
Small bowel (concentration from proximal to distal)	1.8	140–125	5–9			110–60	100–75	7–8
Large bowel	0.2 (lost in feces)	20–40	30–90			0–15	40	7–8

Reprinted from Miller RD, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 8th ed. Philadelphia, PA: Elsevier Saunders; 2015:1769. Copyright © 2015 Elsevier. With permission.

Both the volume and composition of resuscitative fluids must be considered. Hypovolemia predisposes to hypotension.

Hypervolemia causes the release of cardiac natriuretic peptides which degrade endothelial glycocalyx. This may contribute to capillary leakage, decreased oncotic pressure, and tissue edema. Edema of the lungs predisposes pulmonary infection, and edematous bowel can contribute to postoperative GI dysfunction. Other consequences of hypervolemia include impaired healing due to decreased oxygenation and increased myocardial work due to supraoptimal ventricular filling on the Frank-Starling curve.

The administration of different fluids with varying compositions may also lead to metabolic acidosis, renal dysfunction, and abnormalities in hemostasis. It is important to remember that clinical trials evaluating fluid administration have differing results between the healthy versus the critically ill or those with different pathologic processes. Interpatient responsiveness can also vary.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1480–1523.

B.9. What would you use as a guide to fluid volume replacement?

For this patient in an urgent/emergent setting, with possible sepsis, vascular compromise, and major abdominal surgery, a dynamic physiologic variable such as cardiac output (CO), stroke volume variation (SVV), or pulse pressure variation (PPV) coupled with a marker of global perfusion like successive lactate levels are reasonable choices to guide fluid volume replacement.

Approaches to fluid therapy prescribing milliliter per kilogram fluid administration based on estimations of the deficit and maintenance requirements lead to increased complications

when more than 3.5 to 5 L are given in the perioperative period. Current data suggest that tailoring fluid therapy to physiologic endpoints results in better outcomes. There is increasing evidence that traditional markers such as HR, BP, urine output, and central venous pressure (CVP) are nonspecific and should not be used as the sole end points for resuscitation. GDFT is a strategy used to optimize flow-related hemodynamic variables to optimize end-organ function by guiding the use of fluids, vasopressors, and inotropes. Numerous studies have shown that mortality can be improved by targeting CO or end-organ O_2 delivery, and patients with the highest mortality risk benefit the most. A number of minimally invasive CO monitors are available to measure physiologic variables including esophageal Doppler, arterial waveform analysis, bioimpedance and bioreactance, and a host of other increasingly less invasive devices. Recent meta-analyses evaluating all perioperative timeframes and GDFT tools have demonstrated decreased morbidity and hospital length of stay. Common algorithms involve constant assessment of the chosen variable coupled with suggested hemodynamic interventions as in this sample (**Fig. 15.3**). Heterogeneity in prospective studies and meta-analyses has prevented researches from determining the best hemodynamic targets, monitoring tools, and interventions. However, a few key points are evident.

- Fluid therapy produces better outcomes when tailored to the patient's physiologic state.
- Dynamic- and flow-related indicators of hemodynamic status perform better than static variables.

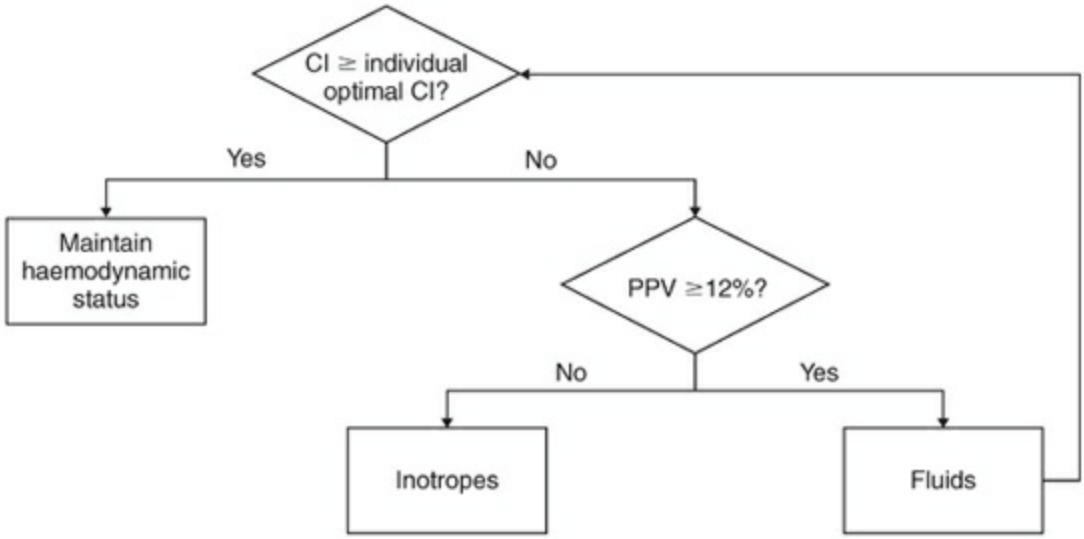

FIGURE 15.3. Sample GDFT algorithm. Intervention algorithm during mechanical ventilation. CI, cardiac index; PPV, pulse pressure variation. (*From Funcke S, Saugel B, Koch C, et al. Individualized, perioperative, hemodynamic goal-directed therapy in major abdominal surgery [iPEGASUS trial]: study protocol for a randomized controlled trial*. Trials. *2018;19[1]:273. http://creativecommons.org/licenses/by/4.0/. Copyright © The Author(s). 2018 Open Access*.)

- Timing of fluid intervention appears to affect outcomes.
- Consider early administration of vasopressors in fluid nonresponders with signs of hypoperfusion.
- As newer technology is developed, its utility in GDFT must be evaluated. New monitoring tools are valuable because they trigger intervention at critical times. The manipulation of physiologic variables is what improves outcomes, not so much the specific monitor used. This may explain why newer devices may not demonstrate a substantial benefit over existing monitors.

C. Intraoperative Management

C.1. What dangers are present during induction? How are they planned for?

Aspiration of gastric contents and hypotension are the biggest dangers on induction. Mortality from aspiration ranges widely from 5% to 80%. Patients scheduled for emergency surgery are at high risk for aspiration, and intestinal obstruction is the most common predisposing condition in patients that do aspirate.

If the airway does not appear difficult, rapid sequence induction and intubation (RSII) is used to shorten the time between loss of airway reflexes and placement of a cuffed endotracheal tube to minimize the chance of aspiration. Common components of RSII are CP, administration of an IV anesthetic followed immediately by a rapid acting muscle relaxant, avoidance of sedation, and foregoing (at least initially) positive pressure ventilation.

CP has been widely adopted in RSII, but we do not currently have prospective randomized control data to rate its effectiveness. Different aspects of CP have been the focus of intense study and are well summarized in the literature. The 2015 Difficult Airway Society guidelines for unanticipated difficult intubation in adults recommend CP be applied, release of CP if laryngoscopy is difficult, and reapplication in the event of vomiting. CP prevents regurgitated contents from reaching the oropharynx. A modified RSII uses CP to prevent air from entering the stomach allowing for gentle positive pressure ventilation during induction which may be helpful in septic patients.

Patients regurgitate when barrier pressure (LES pressure − gastric pressure) is reduced below zero (**Table 15.3**). Opioids and sedatives may negatively affect barrier pressure and are avoided.

TABLE 15.3 Factors that Increase Intragastric Volume and Pressure

Increased gastric filling
Air insufflation during mask ventilation
Increased gastric acid production
Gastrin
Histamine-2 (H_2) receptor stimulation
Recent ethanol ingestion
Recent hypoglycemic episode
Decreased gastric emptying
Intestinal obstruction
Diabetic gastroparesis
Opioids
Anticholinergics
Sympathetic stimulation (pain and anxiety)

Reprinted from Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:237. Copyright © 2018 Elsevier. With permission.

If the airway appears difficult or the patient has a history of difficult intubation, an awake intubation must be considered. The lips, tongue, and pharynx may be anesthetized, but the larynx's innervation should be kept intact in order to maintain protective reflexes.

Hemodynamics typically dictates the choice of induction agent. Propofol is the most popular agent. Ketamine and etomidate, however, are first-line agents when a patient is already hypotensive. Both agents produce similar intubating conditions, but even one intubating dose of etomidate has been shown to cause adrenal insufficiency in acutely ill patients. Ketamine may be the best choice for septic patients.

Frerk C, Mitchell VS, McNarry AF, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth*. 2015;115(6):827–848.

sequence intubation in acutely ill patients: a multicentre randomised controlled trial. *Lancet*. 2009;374(9686):293–300.

Warner MA, Warner ME, Weber JG. Clinical significance of pulmonary aspiration during the perioperative period. *Anesthesiology*. 1993;78(1):56–62.

C.2. Does the administration of antacids and/or histamine-2 (H_2) blockers before the induction of anesthesia have a significant value in patients with small bowel obstruction?

H_2 blockers have a decreased value in small bowel obstruction and even less value in emergency surgery. Acidic pH is one of the main determinants of morbidity in aspiration. H_2 blockers are used in patients at high risk for aspiration to increase gastric pH by blocking the ability of histamine to induce secretion of gastric fluid with high H^+ concentration. In patients with a high GI obstruction, however, a significant amount of acidic fluid is already present. Administration of an H_2 blocker has no immediate effect on the pH of this fluid. Studies evaluating the effect of H_2 blockers typically administered them more than 1 hour before surgery. The largest benefit is from a multidose regimen starting the night before, making this prophylaxis less valuable before induction of an emergency case. Some benefit may be derived, however, during extubation.

Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:235–248.

C.3. In what position would you intubate this patient?

This patient is at high risk for aspiration, is hypotensive, and has a clinical picture of sepsis. Positioning the patient with 25 to 30 degrees of head elevation, her head and neck in the sniffing position, and her legs up making her into a "V" shape may be

most beneficial. This combination should improve upper airway patency and access, increase FRC, and may reduce aspiration risk; the legs up position may help prevent hypotension on induction if her body habitus does not increase gastric pressure.

Higgs A, McGrath BA, Goddard C, et al. Guidelines for the management of tracheal intubation in critically ill adults. *Br J Anaesth*. 2018;120(2):323–352.

C.4. What is the best muscle relaxant to use for the rapid sequence induction?

A rapid sequence dose of rocuronium, assuming the availability of sugammadex, may be the best option for intubation. Succinylcholine had been the preferred agent, in spite of its side effects, because of its fast offset should a difficult airway be encountered. Both produce similar intubating conditions. An emergency dose of sugammadex (16 mg per kg), however, is capable of a more rapid return of spontaneous ventilation than succinylcholine. However, spontaneous ventilation is not guaranteed because the hypnotic agent may still interfere with the patient's respiratory effort. Succinylcholine-induced fasciculations also increase O_2 consumption which may be significant in the setting of a difficult airway.

Frerk C, Mitchell VS, McNarry AF, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth*. 2015;115(6):827–848.

Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:584–599.

Higgs A, McGrath BA, Goddard C, et al. Guidelines for the management of tracheal intubation in critically ill adults. *Br J Anaesth*. 2018;120(2):323–352.

C.5. Would you remove or leave the nasogastric tube (NGT) in place before inducing anesthesia?

A strong case can be made for leaving an NGT in place while inducing and intubating this patient. They are indicated for patients with obstruction and distended abdomens, and NGTs in

place on arrival to the operating room (OR) should be used to decompress the stomach before induction. Modern guidelines recommend against routine postoperative NGTs unless there is a specific indication. The decision then becomes timing of removal of the NGT. One may wish to leave an NGT in place during induction to act as a "blow off valve" for gastric pressure during induction when paralysis reduces muscle tone; removal may induce vomiting, and removal may be very stimulating and uncomfortable to an awake patient. Advocates for NGT removal point to decreased LES tone and obscured laryngoscopy from a foreign body in the airway. However, studies have shown that neither the presence nor the size of an NGT has an effect on gastric reflux, and effective CP can be maintained with an NGT in place. If an NGT is somehow obstructing laryngoscopy, it can always be removed. Of course, the presence of an NGT does not guarantee an empty stomach, and particulate matter is difficult to remove. Proper airway planning is always paramount.

Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:235–248.

C.6. Would you use nitrous oxide in this patient?

No. Nitrous oxide is relatively contraindicated in patients with an intestinal obstruction. Nitrous oxide can diffuse into gas-filled spaces more than 30 times faster than nitrogen can diffuse out. The increased gas and intraluminal pressure already present in the bowel during intestinal obstruction combined with the nitrous could cause ischemia and necrosis.

Zafirova Z, Sheehan C, Hosseinian L. Update on nitrous oxide and its use in anesthesia practice. *Best Pract Res Clin Anaesthesiol*. 2018;32(2):113–123.

C.7. Are there any benefits to using a high concentration of inspired oxygen (FIO_2)?

No, a high inspired concentration of O_2 does not prevent

infection or healing complications after major intestinal surgery. The dose-response curve for oxidative killing of bacterial is nonlinear. In the context of wound healing, O_2 is used as a cofactor for oxidant production rather than the energy-producing oxidative phosphorylation of aerobic respiration. Rate constants for collagen synthesis, angiogenesis, and epithelialization all fall within a physiologic range that is normally achieved with an F_{IO_2} of 30% to 40%. Normothermia, euvolemia, and appropriate prophylactic antibiotics are important determinants of infection and wound healing outcomes.

Typically, hemoglobin and CO are considered the main determinants of O_2 delivery which holds true in highly metabolically active tissue that is one cell away from a capillary. In subcutaneous tissue, the capillary distance is farther, O_2 consumption lower, and the O_2 is consumed during healing and immune function. The main determinant of oxygenation in these environments is Pa_{O_2}. Pa_{O_2} drives diffusion of O_2, especially where microvasculature has been damaged by surgical incisions. Vasoconstriction to the subcutaneous tissue will limit the O_2 delivered and diffused. Normothermia and avoidance of hypovolemia then become pillars of wound healing and immune function.

Hyperoxia can have deleterious effects. Even breathing 28% F_{IO_2} for 1 hour increases reactive O_2 species (ROS) in exhaled gas, which can damage DNA and cause lung injury. Supplemental O_2 impairs mucociliary function leading to plugging, atelectasis, and secondary infection; causes edema in large airways; and creates absorption atelectasis in healthy volunteers. There is also evidence that some specific populations may be harmed by hyperoxia, specifically patients with the comorbidities chronic obstructive pulmonary disease (COPD), postcardiac arrest, postmyocardial infarction (MI), stroke, and

traumatic brain injury (TBI). ROS may also reduce $PaCO_2$ by acting at respiratory centers in the brainstem which may lead to vasoconstriction and decreased delivery of O_2.

C.8. What components of ERAS are applied in the intraoperative phase of the care of CRS patients?

Intraoperative components of ERAS pathways focus on maintenance of euvolemia, the optimal analgesia paradigm for pain control, surgical stress response attenuation, PONV prophylaxis, optimal depth of anesthesia, and maintenance of normothermia. Both excessive and inadequate intravascular volumes are associated with poor surgical outcomes. Hypovolemia predisposes to renal injury and end-organ damage, whereas hypervolemia can lead to delayed return of gut function, decreased oxygenation, and increased myocardial work. GDFT has been shown to improve outcomes in high-risk patients and moderate-risk patients undergoing major abdominal surgery. Risk factors may include ischemic heart disease, heart failure, cerebrovascular disease, diabetes requiring insulin, and pre-op creatinine levels >2.0 mg per dL. Patient and procedure risk factors may be used to help guide the use of advanced hemodynamic monitors (**Fig. 15.4**). Patients are euvolemic at

the level portion of the Frank-Starling Curve. These protocols have reduced the variability with which fluid is administered. Some recent trials have suggested that GDFT may not show improved outcomes in the context of enhanced recovery pathways. This is likely due to redundant ERAS components that restrict fluid administration while avoiding hypovolemia within those pathways. The guiding principle of fluid therapy remains titration to dynamic physiologic endpoints rather than application of a particular GDFT tool.

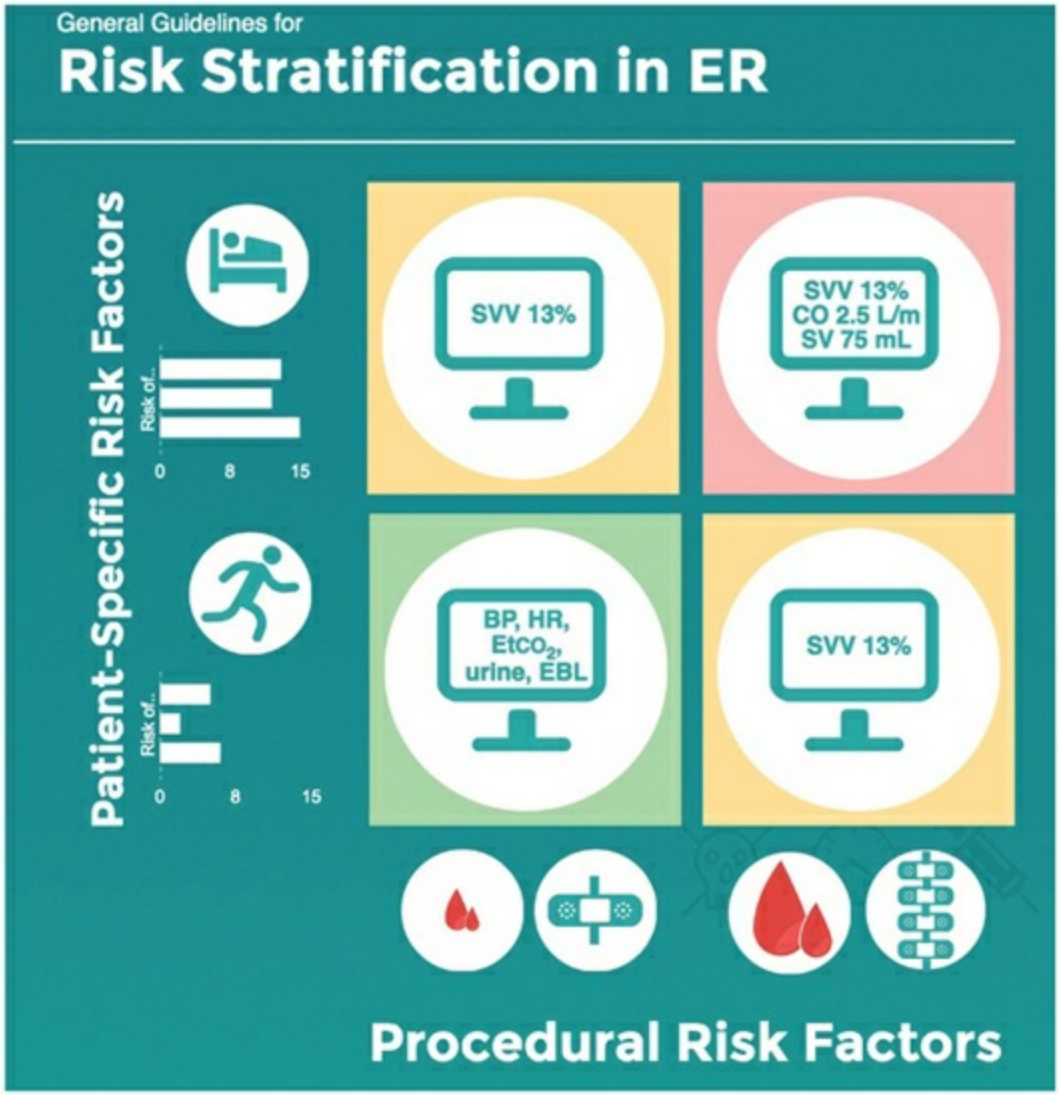

FIGURE 15.4. POQI risk stratification for monitoring in enhanced recovery protocol. Proposed risk stratification scheme for patients undergoing colorectal surgical procedures in the context of an enhanced recovery protocol. Patient-specific risk factors: poor functional status and elevated cardiac

risk **(top)**; good functional status and low cardiac risk **(bottom)**. Procedural risk factors: minimally invasive and small fluid shifts **(left)**; maximally invasive and large fluid shifts **(right)**. BP, blood pressure; CO, cardiac output; EBL, estimated blood loss; $EtCO_2$, end-tidal carbon dioxide; HR, heart rate; SV, stroke volume; SVV, stroke volume variation. (*From Thiele R, Raghunathan K, Brudney CS, et al. American Society for Enhanced Recovery [ASER] and Perioperative Quality Initiative [POQI] joint consensus statement on perioperative fluid management within an enhanced recovery pathway for colorectal surgery*. Perioper Med [Lond]. *2016;5:24. https://creativecommons.org/licenses/by/4.0/. Copyright © 2016 The Author[s].*)

Analgesia strategies intraoperatively continue to revolve around the paradigm of optimal analgesia by balancing comfort, early functional recovery, and minimizing side effects. A number of multimodal nonopioid adjuncts are efficacious and recommended in the ASER and POQI consensus statement (**Table 15.4**). They include NSAIDS, acetaminophen, gabapentinoids, single-shot and continuous nerve blocks, infusions of lidocaine, low-dose ketamine, and dexamethasone. The key point is that the combination of agents selected are not as important so long as they are effective. It is also important to note that ERAS focuses on minimizing opioid use. Pain is not perceived during general anesthesia (GA), and hemodynamic consequences of surgery can be controlled with β-blockers, calcium channel blockers, and lidocaine without increased opioid consumption postoperatively.

TABLE 15.4 Treatment Algorithm for Achieving Optimal Analgesia after Colorectal Surgery

Minimizing the harmful effects of the surgical stress response is a cornerstone of enhanced recovery. Patients experience stress if their typical homeostatic mechanisms are insufficient and they must alter their basic physiology. For instance, during hypoglycemia, neurohumoral mediators promote gluconeogenesis and insulin resistance in order to deliver the valuable but scarce glucose to glucose-dependent end organs. Mediators of the stress response like cortisol, glucagon, catecholamines, antidiuretic hormone (ADH), and cytokines affect multiple-organ systems and can lead to undesirable surgical outcomes including myocardial ischemia, large fluid shifts, breakdown of lean muscle, poor wound healing, and impaired immune function. Some of the challenges of perioperative homeostasis and their management are listed in the following table from the ASER (**Table 15.5**). Oxygenation,

perfusion, fluids, and nutrition can be artificially supported in the perioperative period. ERAS pathways to minimize components of the stress response focused on these variables. The most effective interventions are the ones that directly reduce a physiologic challenge, such as a laparoscopic rather than open surgical approach. A conceptual framework for the stress response is shown in **Figure 15.5**. Interventions shown to improve outcomes after surgery include TEA, high-dose corticosteroids, and intensive insulin therapy.

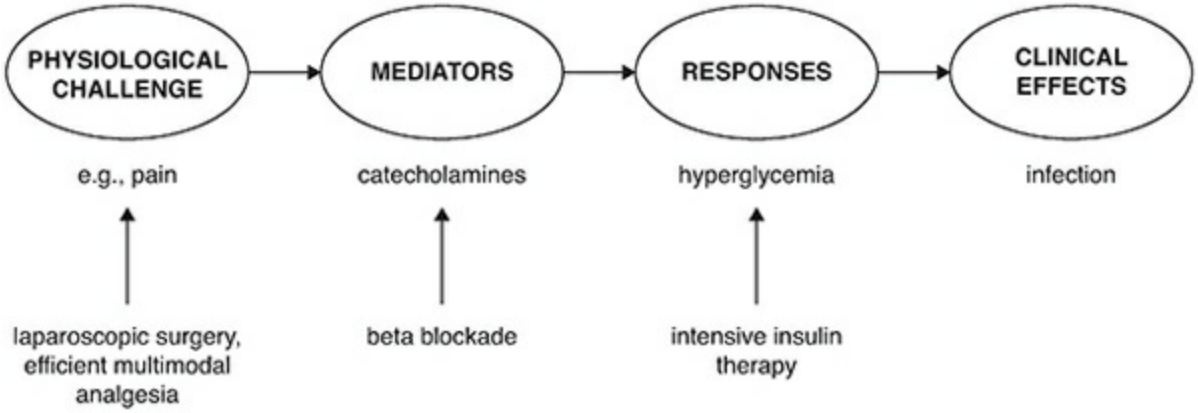

FIGURE 15.5. Conceptual framework of mechanisms of the surgical stress response. Conceptual framework of the surgical stress responses, showing potential opportunities for intervention for the example of pain, catecholamines, and hyperglycemia. Experience has shown that the most successful and feasible interventions aim to blunt the physiologic challenge in the first place (e.g., nociception), rather than blunt the release of the mediators (e.g., β-adrenergic receptor blockade) or the response itself (e.g., hyperglycemia). Successful enhanced recovery protocols (ERPs) consist of a series of interventions that target mainly the physiologic challenges. (*From Gan TJ, Thacker JK, Miller TE, et al*. Enhanced Recovery for Major Abdominopelvic Surgery. *1st ed. New York, NY: Professional Communications, Inc.; 2016:201. With permission*.)

TABLE 15.5 Physiologic Challenges to Homeostasis

Perioperative Physiologic Challenge	Management
Anxiety	Preoperative patient education Same-day admission
Preoperative dehydration	Adherence to modern preoperative fasting guidelines Avoidance of hyperosmolar oral bowel preparation
Preoperative fasting	Preoperative oral carbohydrate treatment
Preoperative transfusion	Preoperative iron infusion

Tissue injury and contamination	Minimally invasive surgical approaches Short incisions Atraumatic technique
Nociception and pain	Effective analgesia Regional analgesia Multimodal analgesia
Hypothermia	Active and passive warming
Intravenous fluid loading	Protocol-driven, balanced fluid therapy
Intra- and postoperative transfusion	Red-cell saving techniques Strict transfusion triggers
Postoperative fasting	Early oral diet Techniques to avoid or minimize ileus
Postoperative lack of physical activity	Protocol-driven postoperative mobilization

From Gan TJ, Thacker JK, Miller TE, et al. *Enhanced Recovery for Major Abdominopelvic Surgery*. 1st ed. New York, NY: Professional Communications, Inc.; 2016:203. With permission.

ERAS patients are risk stratified for PONV, and prophylaxis is tailored to risk level. A simplified Apfel risk score identifies female sex, nonsmoker, history of PONV, and postoperative opioids as factors increasing the risk of PONV. Intraoperative strategies to decrease the risk of PONV include use of regional over general anesthesia, propofol used as induction and maintenance agent, avoidance of nitrous oxide and volatile anesthetics, minimal opioid administration, adequate but not excessive fluid hydration, and administration of a number of antiemetic pharmacologic agents. ERAS pathways encourage multimodal antiemetic prophylaxis, even for low-risk patients (**Fig. 15.6**). If prophylaxis fails, a different pharmacologic class of antiemetic should be used. Dexamethasone and transdermal scopolamine do not need to be redosed within 24 to 48 hours. Other antiemetics, for example, 5HT-3 antagonists, readministered within 6 hours are ineffective (**Table 15.6**).

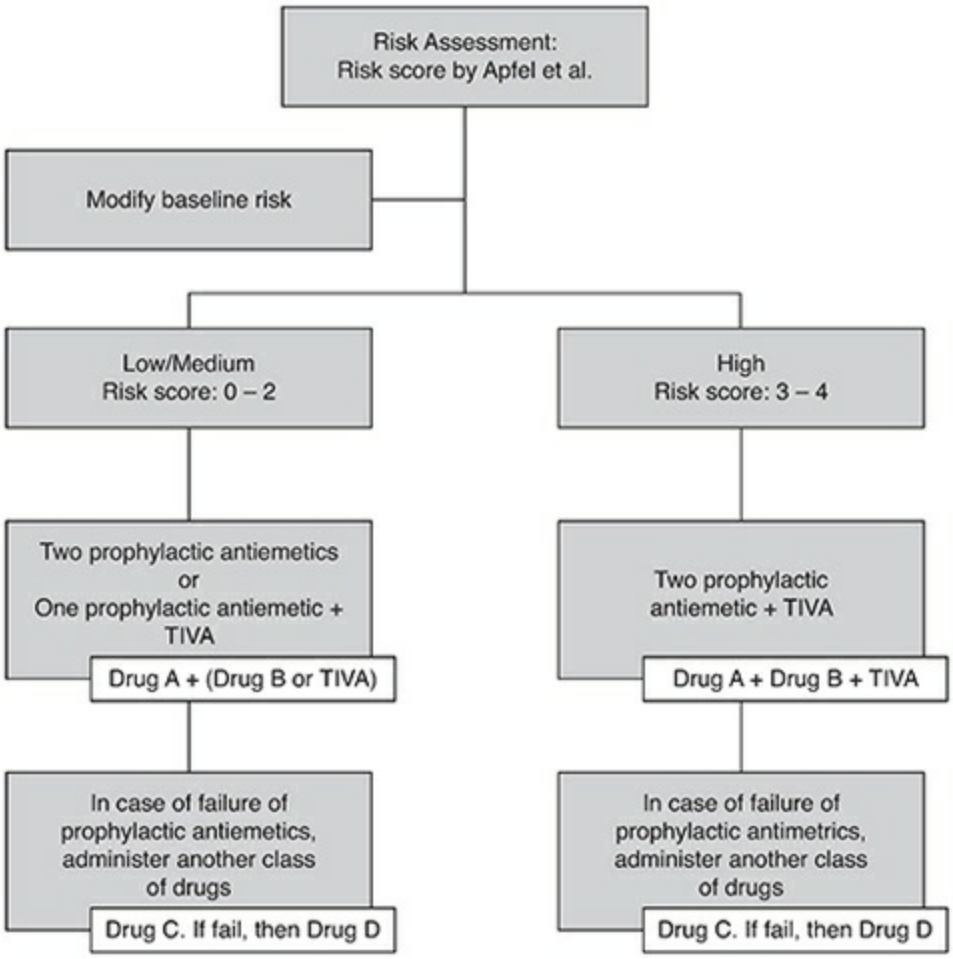

FIGURE 15.6. Flow chart for management of PONV in the context of enhanced recovery. Example interventions: drug A = dexamethasone 4 mg in adults or 0.15 mg per kg of body weight in children; drug B = ondansetron 4 mg in adults or 0.1 mg per kg of body weight in children; drug C = promethazine 6.25 mg in adults; drug D = dimenhydrinate 1 mg per kg of body weight in adults or 0.5 to 1.0 mg per kg of body weight in children. The given drug examples are used to illustrate how the algorithm may be actually implemented but may not represent the most favorable approach. The latter may be context sensitive (children, adults, or other issues). In the event of treatment failure, timely assessment is essential and an alternate antiemetic agent should be used. A multimodal treatment approach may be appropriate to increase the likelihood of success. TIVA, total intravenous anesthesia, that is, propofol induction and maintenance, no nitrous oxide. (*From Gan TJ, Thacker JK, Miller TE, et al*. Enhanced Recovery for Major Abdominopelvic Surgery. *1st ed. New York, NY: Professional Communications, Inc.; 2016:201. With permission*.)

TABLE 15.6 Choices of Antiemetic Agents in Adults: Dosage and Timing

Drugs	Dose	Evidence	Timing	Evidence
Aprepitant	40 mg PO	A2	At induction	A2
Casopitant	150 mg PO	A3	At induction	

Dexamethasone	4–5 mg IV	A1	At induction	A1
Dimenhydrinate	1 mg per kg IV	A1		
Dolasetron	12.5 mg IV	A2	End of surgery; timing may not affect efficacy	A2
Droperidol[a]	0.625–1.25 mg IV	A1	End of surgery	A1
Ephedrine	0.5 mg per kg IM	A2		
Granisetron	0.35–3 mg IV	A1	End of surgery	A1
Haloperidol	0.5–<2 mg IM/IV	A1		
Methylprednisolone	40 mg IV	A2		
Ondansetron	4 mg IV, 8 mg ODT	A1	End of surgery	A1
Palonosetron	0.075 mg IV	A2	At induction	A2
Perphenazine	5 mg IV	A1		
Promethazine	6.25–12.5 mg IV	A2		
Ramosetron	0.3 mg IV	A2	End of surgery	A2
Rolapitant	70–200 mg PO	A3	At induction	
Scopolamine	Transdermal patch	A1	Prior evening or 2 h before surgery	A1
Tropisetron	2 mg IV	A1	End of surgery	Expert opinion

IM, intramuscular; IV, intravenous; ODT, orally disintegrating table; PO, per os.
These recommendations are evidence based and not all the drugs have a US Food and Drug Administration (FDA) indication for postoperative nausea and vomiting (PONV). Drugs are listed alphabetically.

Postoperative delirium and postoperative cognitive dysfunction (POCD) may impair a patient's mental and motor functions preventing them from participating in their recovery, postponing their discharge, and increasing their risk of mortality. The pathophysiology is not yet well understood, but high-dose anesthetics, inflammation, stress response hormones, and other perioperative insults may contribute to neurologic dysfunction in the postoperative period. Inadequate anesthesia also prevents patients from gaining the neuroprotective benefits of anesthesia. In many situations, hemodynamic values alone are inadequate to reflect anesthetic depth. Methods to detect an optimal depth of

anesthesia using electroencephalographs (EEG), electromyographs (EMG), and auditory evoked potentials (AEP) have been shown to improve neurocognitive outcomes in older high-risk patients.

Normothermia is crucial because even mild hypothermia can increase rates of infection, platelet dysfunction, and protein catabolism; decrease drug metabolism, renal function, and wound healing; and have major cardiovascular implications such as arrhythmias, left shift of hemoglobin-O_2 saturation curve, and increased peripheral vascular resistance. Core temperature monitoring is recommended in all patients undergoing anesthesia. Interventions recommended for maintaining normothermia include warming the periphery prior to surgery to avoid the initial drop in core temperature on induction, maintaining an OR temperature above 21°C and possibly even at 26°C until the prep solution is dry and patient is draped, limiting areas of exposed skin, fluid warmers for boluses above 500 mL, heated and humidified gases, and, of course, forced air warmers over the largest available surface area.

C.9. What are the strengths, weaknesses, benefits, and challenges of ERAS?

Strengths

ERAS uses evidence-based interventions that are customized to the patient and the resources of the institution. Protocols reduce the variability in care and outcomes which help to continually evaluate and improve the pathway. Multidisciplinary care allows each member of the team to focus on what they do best.

Weakness

Individual interventions included in ERAS pathways show benefit in a general population but may be redundant with other components. Attributing a benefit to a specific intervention is difficult and only the bundled program can be credited. Also, many benefits come from suppressing the surgical stress response in elective major abdominal surgeries and older patients with comorbid disease. Cardiovascular, pulmonary, and infectious complications show improvement. Advantages are not

as clear cut in surgical complications. Therefore, ERAS may not offer marked improvement in the uncomplicated laparoscopic procedure in an otherwise healthy young patient.

Benefits

ERAS programs consistently demonstrate accelerated recovery, reduced complication rate, safe reduced length of stay, reduced readmission rate, increased value by improving quality while decreasing cost, and improved patient satisfaction.

Challenges

The biggest challenges in ERAS come in implementation and maintenance. Input and consensus from members of surgery, anesthesia, nursing, and a host of other services can be difficult on an organizational level. Additional resources, such as a program coordinator or patient education materials, order sets, and data tracking systems, can be extremely useful but take time to develop and implement. Sustaining improvements can also be challenging. When implementations are made, data is tracked. Outcomes may initially improve but later decline, and the reason why is not always clear. Documentation may not accurately reflect clinical activities, new staff may not be oriented to the pathway, or experienced providers may not realize how their contributions affect downstream portions of care. Mechanisms for regularly scheduled auditing and frequent opportunities for education have to be devised for sustained improvement.

C.10. What are the indications for ERAS?

Any patient may benefit from ERAS pathway elements implemented at their institution provided they do not have a contraindication to any of the components (e.g., anaphylactic acetaminophen allergy, antiplatelet therapy that cannot be interrupted for neuraxial analgesia, etc.). Larger, more invasive cases and patients with more comorbidities and more prolonged length of hospital stay may see the biggest benefit.

Gan TJ, Thacker JK, Miller TE, et al. *Enhanced Recovery for Major Abdominopelvic Surgery*. New York: Professional Communications; 2016:65.

D. Postoperative Management

D.1. What are the principles of postoperative care in this patient?

The ultimate goal of postoperative care is recovery of bowel function to the point where the patient can resume oral hydration and take in sufficient nutrition on their own. Many principles of postoperative care are the same as preoperative concerns including maintenance of euvolemia, correction of electrolyte and acid–base imbalances, nutritional support, avoiding bowel distention, and pain management. There are the additional considerations of anastomotic leak, perforation, infection, bleeding, thrombosis, and wound complications that need to be guarded against.

Tissue injury and inflammation continue after surgery which present a challenge to maintaining euvolemia. Increased endothelial permeability and damage to the glycocalyx are a result of systemic inflammation. Fluids are frequently required postoperatively. However, hypervolemia can cause release of cardiac natriuretic peptides which degrade the glycocalyx. Water and electrolytes are lost to the interstitium, which compromises

gut perfusion. When the systemic inflammatory response decreases, fluids mobilize back into the intravascular space and fluid administration must be decreased. Urine output is a poor indicator of volume status as sympathetic stimulation and increases in the renin-angiotensin-aldosterone system cause fluid retention despite adequate intravascular volume.

Bowel function must be monitored postoperatively, and physiologic POI must be differentiated from pathologic ileus. We now believe, in general, gastric and small intestinal mobility occurs within hours of surgery and colonic activity returns within 72 hours. Sections of bowel that were directly manipulated will take longer to recover and may extend to areas not directly manipulated. If the ileus is prolonged, metabolic derangements like hypokalemia, hyponatremia, and uremia can occur; iatrogenic medications, ischemia, hemorrhage, and sepsis should all be considered as contributing factors. Laparoscopic surgery can be associated with hernias and an obstructive point seen on imaging should prompt surgical reintervention.

Townsend CM, Beauchamp RD, Evers BM, et al, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. 20th ed. Philadelphia, PA: Elsevier; 2017:1237–1295.

D.2. Are there any postoperative respiratory problems associated with factors other than aspiration?

Yes, respiratory challenges exist in the immediate postoperative period as well as during the inpatient recovery phase. As with all general anesthetics, there is a decreased respiratory drive, increased airway resistance, and neuromuscular impairment caused by residual anesthetics. Immediately after surgery, the bowel may be edematous which increases the diaphragmatic work of breathing and shunt while decreasing FRC. As recovery

continues if fluids are not carefully managed, pulmonary edema can impair gas exchange and further increase the work of breathing. Carbon dioxide production can increase beyond ventilatory capacity in the face of parenteral nutrition and infection.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1538–1558.

D.3. If the patient did aspirate gastric contents, what are the possible sequelae of this event? What is the treatment?

Aspiration of gastric contents causes a chemical pneumonitis initially characterized by hypoxemia, bronchospasm, and atelectasis. Morbidity is increased with larger volumes of aspirate and/or a low pH aspirate. Particulate matter can also be more damaging because it can obstruct the airway, cause distal atelectasis, and act as a nidus for infection resulting in a superimposed pneumonia. If pneumocytes are injured and surfactant washed away, the clinical picture can resemble acute respiratory distress syndrome (ARDS) (**Table 15.7**). Pulmonary edema, decreased pulmonary compliance, increased pulmonary vascular resistance, and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching are seen in severe cases. Radiographic evidence may not develop until 6 to 12 hours after the event.

TABLE 15.7 Pathophysiology of Aspiration

Particulate aspiration → Airway obstruction →
Granulomatous inflammation → Acid aspiration →
Neutrophilic inflammation → Hemorrhagic pulmonary edema →
Destruction of airway epithelium → Loss of type 1 alveolar cells →
Loss of surfactant → Alveolar instability and collapse →
Disruption of alveolar-capillary membrane → Plasma leakage from pulmonary capillaries →
Noncardiogenic pulmonary edema → Hypovolemia

Reprinted from Hagberg CA, Artime CA, Aziz MF, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia, PA: Elsevier; 2018:238. Copyright © 2018 Elsevier. With

permission.

If a patient begins to vomit, their head should be placed in a lateral position with head down if possible. Treatment is similar to ARDS, mainly supportive with supplemental O_2. Intubation frequently has to be continued with mechanical ventilation and positive end-expiratory pressure (PEEP) to keep O_2 levels acceptable. If particulate matter was aspirated, lavage or bronchoscopy may be considered, but neither will be helpful if the aspirate was purely an acidic fluid because it is quickly distributed, diluted, and neutralized. If bronchospasm is present, pharmacologic bronchodilation is indicated. A superimposed infection does not always occur, and no evidence exists to support prophylactic antibiotics. If an infection does occur, treatment should start with broad-spectrum antibiotics covering gram-negative rods and anaerobes including *Bacteroides fragilis* and then narrowed to the appropriate antibiotics based on culture sensitivities. Steroids do not improve the clinical picture and may increase the incidence of bacterial infection. Pulmonary edema should not be treated with diuretics unless high filling pressures or hypervolemia exist.

D.4. What is gram-negative sepsis? Describe the clinical picture and treatment.

Sepsis is a clinical syndrome resulting from a dysregulated inflammatory response to infection. This response is aimed at eliminating a threat through generation of noxious O_2

metabolites and cytokines. When inflammation is systemic and long lasting, it can cause end-organ damage which may trigger further inflammation leading to a destructive positive feedback loop. Gram-negative sepsis causes the inflammatory response to certain highly conserved microbial molecules such as the lipid A moiety of lipopolysaccharides (LPS, also called endotoxin). Twenty percent to 50% of patients can progress to hypotension and shock.

Early signs of gram-negative sepsis include an abrupt onset of fever and chills, hyperventilation with respiratory alkalosis, and mental status changes. Neutropenia with increased immature polymorphonuclear leukocytes is the most common lab abnormality. Thrombocytopenia and coagulation abnormalities may also be present. As the condition progresses to septic shock, vascular endothelial damage from NO causes systemic vasodilation and fluid extravasation leading to a relative hypovolemia. Early shock is characterized by an increased CO, decreased systemic vascular resistance (SVR), hypotension, and warm extremities (warm phase). If the relative hypovolemia persists without adequate resuscitation, the resulting "cold phase" was characterized by an increased SVR and a low CO because blood flow is directed back to vital organs, and ultimately death. Both phases experience myocardial dysfunction due to circulating cytokines as evidenced by the left ventricular end systolic pressure–volume relationship (**Fig. 15.7**). Patients who survived were given fluid and were then able to maintain an adequate stroke volume through ventricular dilation without increases in pressure via the Frank-Starling mechanism. Nonsurvivors instead developed a diastolic dysfunction and were unable to maintain an adequate cardiac index. Fluid extravasation also leads to pulmonary edema and as many as 40% of patients may progress to ARDS. Adrenal insufficiency, disseminated intravascular coagulation, and

immunosuppression are also recognized complications of sepsis.

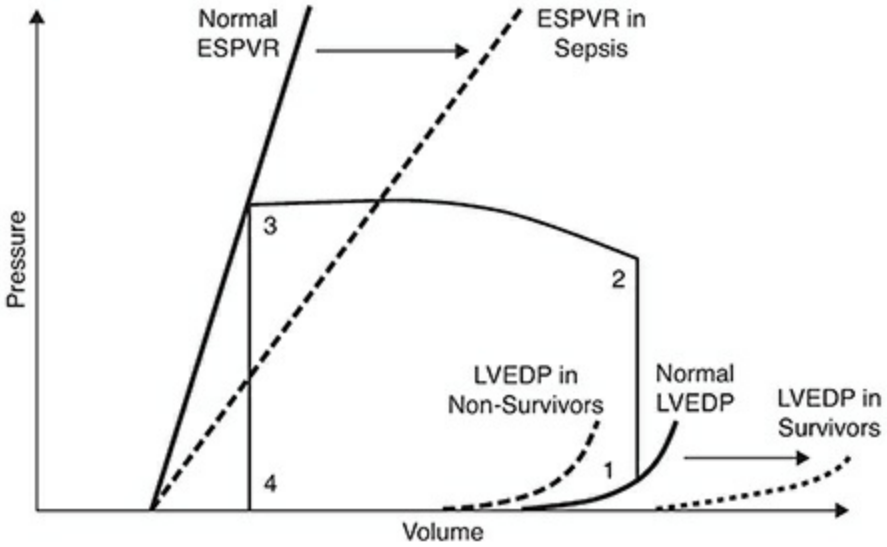

FIGURE 15.7. Myocardial dysfunction in sepsis. Left ventricular pressure–volume relationships. The *bold straight line* shows the normal end-systolic pressure–volume relationship (ESPVR), defining ventricular contraction. ESPVR is independent of changes in preload and afterload. The slope is maximal at end systole and has the units of elastance, $E = \Delta P / \Delta V$. It has therefore been designated E_{max}. The *bold curved line* shows normal end diastolic pressure–volume relationship (EDPVR). The straight section of the line represents addition of the initial volume. Whereas ventricular volume increases from 0 to approximately 50 mL, transmural pressure remains at 0. Left ventricular end diastolic pressure (LVEDP) then increases in a curvilinear manner during addition of further volume. The pressure–volume loop (1 to 4) represents one cardiac cycle (1 to 2, isovolumetric contraction; 2 to 3, stroke volume; 3 to 4, isovolumetric relaxation). The interrupted *straight line* represents E_{max} in sepsis, with depressed contractility indicated by a downward and right shift of the ESPVR. In survivors of septic shock, this is accompanied by a right shift of the EDPVR (*interrupted curved line*) caused by ventricular dilatation, enabling an increase in stroke volume. In nonsurvivors, diastolic stiffness develops represented by an upward and left shift of the EDPVR (*bold, interrupted curved line*), leading to impaired diastolic filling and a reduction in stroke volume. *Arrows* represent possible contribution of nitric oxide (NO) to the pressure–volume relationships in sepsis. Although NO may be responsible for the reduction in systolic contractility, the septic patient is able to maintain end-systolic volume because of a reduction in SVR; therefore, the overriding hemodynamic effect of NO in sepsis may be facilitation of ventricular dilatation, which acts to further stroke volume and maintain cardiac output. Potentially, NO blockade in sepsis may convert the EDPVR of a surviving septic patient to a nonsurvivor. (*Reprinted from Belcher E, Mitchell J, Evans T. Myocardial dysfunction in sepsis: no role for NO?* Heart. *2002;87[6]:508; with permission from BMJ Publishing Group Ltd.*)

Treatment guidelines are summarized in the “Surviving Sepsis” campaign bundles. Mechanical ventilation with lung protective strategies such as tidal volumes <6 mL per kg

predicted body weight and plateau pressures <30 cm H_2O are frequently required because acute lung injury is the most common complication. Circulatory support should be given in the form of an initial fluid bolus and then vasopressors. First line is usually norepinephrine, and if a goal of MAP >65 mmHg is not met, second- and third-line agents, usually vasopressin and epinephrine, may be added. Angiotensin II receptor agonists have also recently showed promise in treatment of catecholamine-resistant shock with a mechanism different from norepinephrine and vasopressin. Tissue oxygenation is not impaired in septic shock. The ability of mitochondria to use O_2 becomes impaired by bacterial endotoxins and results in lactate production. Therefore, efforts to improve tissue oxygenation with transfusions are not indicated. Broad-spectrum antibiotics should be administered within 1 hour of identifying a patient in septic shock and then be narrowed and targeted as soon as culture results are available. Corticosteroid administration has been controversial, but current guidelines recommend it be used in patients poorly responsive to vasopressors.

D.5. What components of ERAS are applied in the

postoperative phase of the care of CRS patients?

Postoperative components of ERAS include early oral feeding, ileus prevention, restrictive use of NGTs/lines/drains, early mobilization, and optimal analgesia. These components were developed for elective procedures, but many of the concepts may still be applied to urgent/emergent procedures.

Traditional dogma of postoperative care restricted oral intake in order to protect patients from aspiration, anastomotic leak, and wound dehiscence. Contemporary practice shows early postoperative nutrition is associated with reductions in mortality, complications, anastomotic dehiscence, hyperglycemia, length of stay, and time to return of bowel function. The benefits of parenteral and enteral feeding have been well described in the literature, but oral feeding is the only form of nutritional intake that elicits all of the guts' stimulating reflexes and most closely aligns with the theme of functional recovery. Early oral nutrition in an ERAS pathway has also been shown to decrease complications and hospital length of stay even if duration of ileus was not reduced significantly. We also now know that the presence of fluid and some semidigested material in the gut does not threaten fresh anastomoses any more than natural content such as enzymes, bile juice, and stomach acids. Oral feeding is tolerated within 24 hours by 80% to 90% of CRS patients and is an inexpensive intervention not shown to be associated with adverse events. Oral intake has to be adapted to individual tolerance, surgery, and risk factors but general recommendations for postoperative care of uncomplicated cases include encouraging drinking as soon as they are fully awake, resumption of normal diet when tolerating fluids, nutritional supplement beverages, glucose monitoring and treatment, and gum chewing.

Ileus as described in the pathophysiology section earlier describes abnormal GI motility. POI is a significant challenge in

ERAS pathways because it is a major factor in determining hospital length of stay, inhibits functional recovery, and causes discomfort to patients. We do not know the exact causes of ileus because it represents complex interactions between a number of processes (**Fig. 15.8**), but treatment involves managing inflammation, autonomic dysfunction and the stress response to surgery, intestinal opioid receptors, GI hormones, electrolyte imbalances, and impaired gut contractility. Many of the recommendations to limit POI are interventions already suggested for other indications but include minimal preoperative fasting; preoperative optimization including correction of electrolyte abnormalities and anemia; minimizing insulin resistance with a carbohydrate drink 2 hours before surgery and treatment of abnormal glucose levels; minimizing fluid shifts due to iso-osmolar bowel prep by only doing it when indicated; standardized protocols for fluid management; and multimodal pain management with thoracic epidural for open cases, minimizing systemic opioid use, and use of alvimopan when postoperative opioids are used. Other interventions that have limited evidence of decreased POI and are not yet included in consensus statements include nicotine gum chewing, magnesium, coffee, Dai-Kenchu-To (DKT), and polyunsaturated fats.

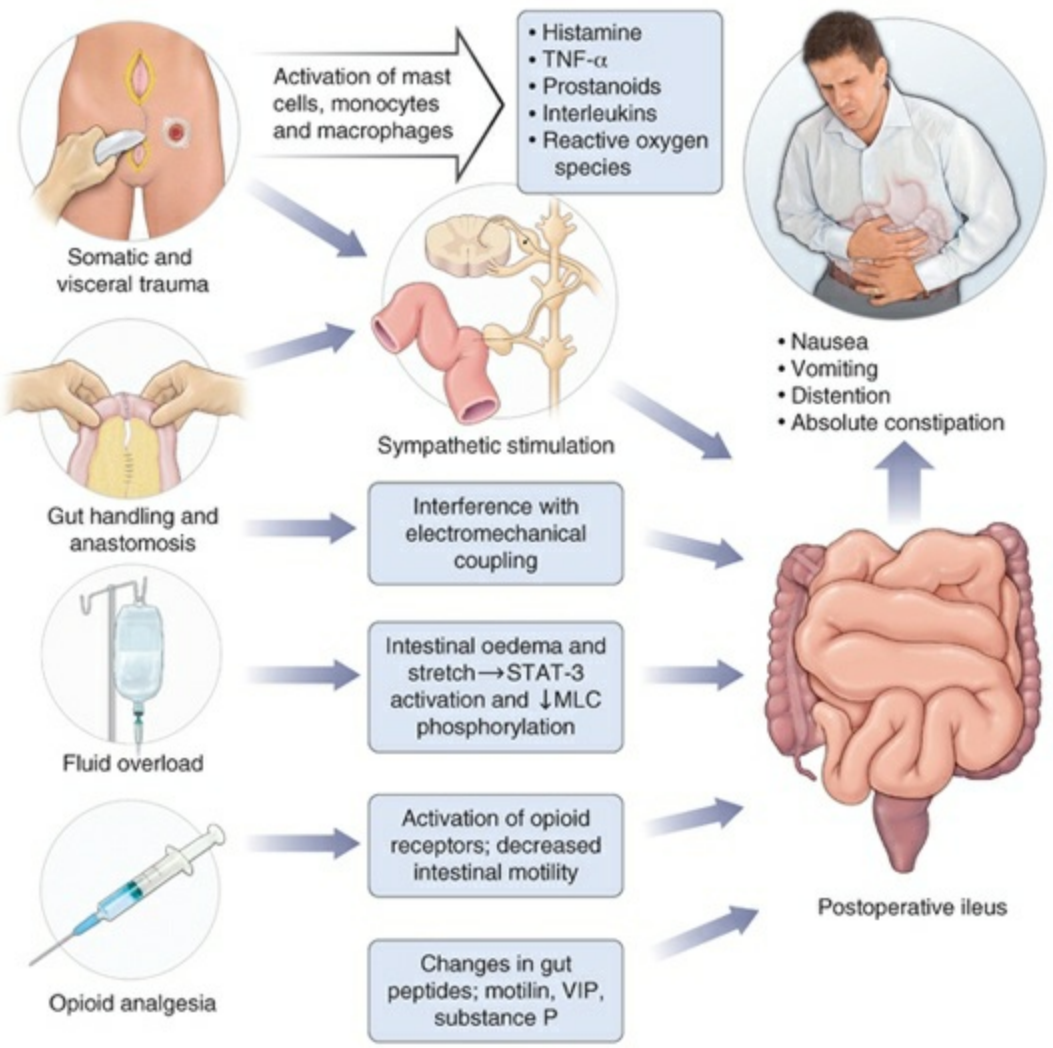

FIGURE 15.8. Proposed mechanism for POI. Schematic diagram showing proposed mechanism for the pathogenesis of POI. MLC, myosin light chain; STAT, signal transducer and activator of transcription; TNF, tumor necrosis factor; VIP, vasoactive intestinal polypeptide. (*Reprinted from Bragg D, El-Sharkawy AM, Psaltis E, et al. Postoperative ileus: recent developments in pathophysiology and management*. Clin Nutr. *2015;34[3]:367–376. Copyright © 2015 Elsevier. With permission*.)

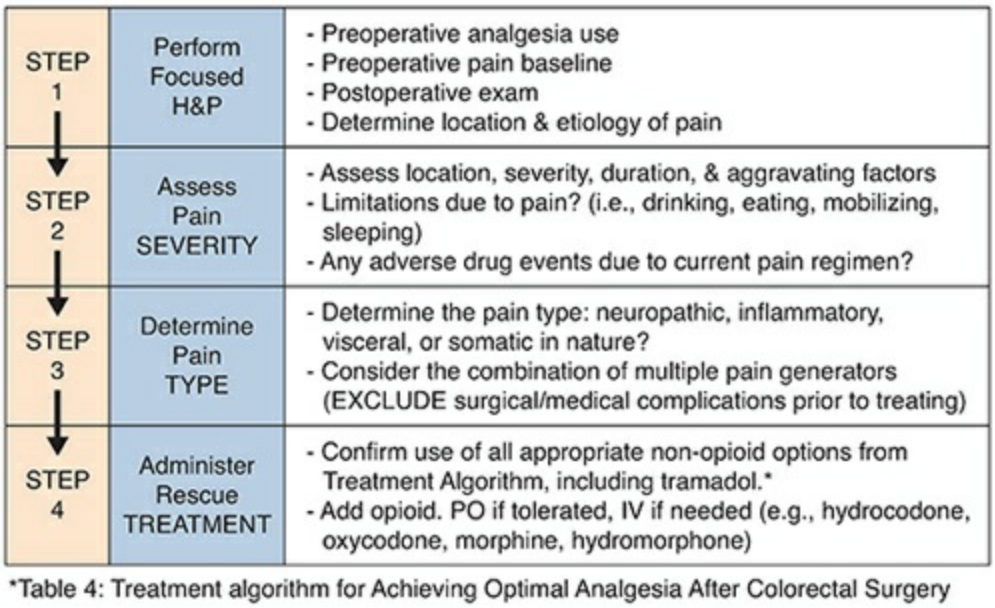
NGTs traditionally were maintained into the postoperative period until evidence of bowel function returned. The goal was to avoid an early gastric challenge and protect anastomoses by preventing distension. This practice was not evidence based. We now have good evidence that selective versus routine use of NGTs is associated with a decreased incidence of ileus, a shorter duration of ileus when it does occur, fewer fevers, less

atelectasis, and decreased incidence of pneumonia. We also know that tubes and drains are an obstacle to independent ambulation, are uncomfortable, and do not provide a benefit with regard to leaks or infections. Similarly, several reviews and meta-analyses now tell us that routine abdominal drains do not help detect leaks. Urinary catheters prevent ambulation and are not necessary to quantitate urine output. Reasonable policies in an ERAS pathway for colon surgery recommend against the routine continuation of NGTs, drains, and urinary catheters postoperatively. This recommendation refers to routine uncomplicated colon surgeries. Individual patients may have indications not present in a routine case. For instance, patients that received general anesthesia with epidural analgesia may be at increased risk for urinary retention and the catheter may be removed on postoperative day (POD) 1. Some hepatic and pancreatic procedures may require the use of early postoperative abdominal drains.

Early mobilization best exemplifies functional recovery in ERAS. Lack of physical activity suppresses cardiopulmonary and musculoskeletal systems after a short period of time. Early mobility is also correlated with a decreased incidence of atelectasis, pneumonia, thromboembolism, delirium, hospital length of stay, and an increase in muscle strength and tissue oxygenation. The amount of mobilization for each patient needs to be individualized, and the extent of mobility required to see a beneficial effect is unclear. Studies that have shown benefit have had the goals of 15 minutes of mobilization on day of surgery, and 3 hours on POD 1.

Postoperative optimal analgesia involves many of the same principles as other phases of the pathway including multimodal analgesia and minimizing opioid use. TEA is recommended for open abdominal surgery and ideally the infusion is started before the procedure. Laparoscopic surgery is typically associated with

a shorter duration of postoperative pain; routine TEA is not recommended. However, comorbid pulmonary disease or chronic opioid therapy with tolerance may be indications for TEA in laparoscopic surgery. If TEA is not used, paravertebral blocks, peripheral catheters, and TAP blocks may be helpful. IV lidocaine infusions administered in postanesthesia care unit (PACU) (or upon removal of catheter for patients receiving TEA) have been shown to lower opioid consumption, reduce nausea and vomiting, and decrease time to resumption of diet. Acetaminophen and NSAIDs are the backbone of postoperative pain control and are recommended to be scheduled, rather than ordered on as needed (PRN) basis along with the other adjuncts (**Table 15.4**). Patients still experiencing breakthrough pain *after* these interventions may be given a short-acting opioid (**Fig. 15.9**).



STEP 1	Perform Focused H&P	- Preoperative analgesia use - Preoperative pain baseline - Postoperative exam - Determine location & etiology of pain
STEP 2	Assess Pain SEVERITY	- Assess location, severity, duration, & aggravating factors - Limitations due to pain? (i.e., drinking, eating, mobilizing, sleeping) - Any adverse drug events due to current pain regimen?
STEP 3	Determine Pain TYPE	- Determine the pain type: neuropathic, inflammatory, visceral, or somatic in nature? - Consider the combination of multiple pain generators (EXCLUDE surgical/medical complications prior to treating)
STEP 4	Administer Rescue TREATMENT	- Confirm use of all appropriate non-opioid options from Treatment Algorithm, including tramadol.* - Add opioid. PO if tolerated, IV if needed (e.g., hydrocodone, oxycodone, morphine, hydromorphone)

16 Liver Transplantation

Christopher H. Choi and
Vivek K. Moitra

A 66-year-old woman with a history of alcoholic cirrhosis and portal hypertension is admitted to the intensive care unit with altered mental status and low urine output. She has ascites and encephalopathy. Her kidney injury is acute with a creatinine clearance of 30 mL per minute. Her international normalized ratio (INR) is 3.0. Her hemoglobin level is 10.2 g per dL. She has a model for end-stage liver disease (MELD) score of 28 points. Her respiratory rate is 30 breaths per minute. She is scheduled for orthotopic liver transplantation.

A. Medical Disease and Differential Diagnosis

1. What are the potential graft options for liver transplantation?
2. What are the indications and contraindications for liver transplantation?
3. What is acute liver failure (ALF)?
4. What is the MELD score, and how is it used in liver transplantation evaluation?
5. What is portal hypertension? What are the sequelae of portal hypertension?
6. Describe the cardiovascular system of patients with end-stage liver disease (ESLD).
7. What causes acute kidney injury (AKI) in patients with

cirrhosis?

8. What causes hyponatremia in patients with cirrhosis?
9. Discuss the neurologic manifestations of acute and chronic liver disease.
10. Why do patients with ESLD have abnormalities of hemostasis?
11. What is the differential diagnosis for hypoxemia in patients with cirrhosis?
12. What are the risk factors and treatment guidelines for spontaneous bacterial peritonitis (SBP)?

B. Preoperative Evaluation and Preparation

1. What preoperative workup is desirable?
2. How is ascites managed preoperatively?
3. How is hyponatremia managed preoperatively?
4. What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?
5. How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?
6. Should this patient be transfused with fresh frozen plasma prior to surgery?

C. Intraoperative Management

1. What monitors would you use? Why?
2. What are the considerations for the induction of anesthesia?
3. How does liver disease affect intraoperative medication management?
4. What happens during the first stage (preanhepatic phase) of the liver transplant operation?
5. What happens during the second stage (anhepatic phase) of the liver transplant operation?
6. What physiologic disturbances should be anticipated during the second stage (anhepatic phase) of the liver transplant operation?

7. What is venovenous bypass? What are the potential advantages and disadvantages of this procedure?
8. What surgical techniques anastomose the donor and recipient inferior vena cava (IVC)?
9. What are the potential advantages of the "piggyback" (vena cava preservation) technique?
10. What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome (PRS)?
11. How would you treat hyperkalemia?
12. Why should you anticipate hypocalcemia?
13. What happens during the third stage of the liver transplant operation?
14. What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What are thromboelastography (TEG) and rotational thromboelastography (ROTEM)?
15. What are the complications of massive transfusion?
16. How are the complications of massive transfusion prevented?
17. How is hyperfibrinolysis managed?
18. When is intraoperative renal replacement therapy indicated?
19. What intraoperative signs suggest that the hepatic graft is working?

D. Postoperative Management

1. What are the goals of immediate postoperative care of the liver transplant patient?
2. What postoperative findings suggest that the hepatic graft is functioning?
3. What coagulation disturbances should be anticipated in the postoperative period?
4. Can renal function change after liver transplantation?
5. What vascular and biliary complications occur after liver transplantation?

6. What immunosuppressive agents will be given after liver transplantation? What are the major side effects?

A. Medical Disease and Differential Diagnosis

A.1. What are the potential graft options for liver transplantation?

Liver grafts are harvested from deceased or living donors. Cadaveric livers are procured after brain or cardiac death. Because of the increasing number of patients who die waiting for a transplant, efforts to expand the donor pool have focused on donation after cardiac death (DCD), extending donor criteria, and partial grafts from live donors. DCD is the fastest growing source of transplant organs in the United States. Upon cardiac death (defined as the irreversible cessation of circulatory and respiratory function), the liver is harvested after a mandatory waiting period of 1 to 5 minutes. Warm ischemic time begins when the waiting period starts and ends when the liver is flushed with cold preservative solution. Transplantation of a DCD-donor liver that has been exposed to a longer warm ischemic time than a graft from a brain-dead donor may be associated with ischemia-reperfusion injury leading to early graft dysfunction and potential graft loss. Ideal organs have shorter warm and cold ischemic times and are harvested from hemodynamically stable donors younger than 50 years of age who are free of hepatobiliary or renal disease, infection, and cancer.

Extending donor criteria (age older than 65 years; positive viral serology; hypernatremia; prior carcinoma, steatosis, or high-risk behaviors; split livers) to harvest organs with initial poor function or primary nonfunction also expands the donor pool. Split liver transplantation creates two transplants from one allograft. This is especially important in pediatric patients, where size-matched whole liver allografts are scarce, resulting

in increased waiting list mortality.

A related or unrelated healthy individual may donate a portion of the liver for transplantation. Usually, the right hepatic lobe is removed and transplanted into an adult recipient. Transplantation of the smaller left hepatic lobe into pediatric or very small adults may decrease the incidence of complications in the donor. This chapter focuses on cadaveric liver transplantation into adult recipients.

A.2. What are the indications and contraindications for liver transplantation?

Patients with ALF, decompensated cirrhosis, or hepatocellular carcinoma are candidates for liver transplantation. In the United States, alcoholic liver disease is the most common cause of ESLD, but cirrhosis from hepatitis C is the most common indication for orthotopic liver transplant. With the rise of the obesity epidemic, nonalcoholic steatohepatitis (NASH) is the third most common indication for liver transplantation. Specific indications for transplantation include recurrent cholangitis in patients with primary sclerosing cholangitis or intractable pruritus in patients with primary biliary cirrhosis. Uncommon indications for liver transplantation include hepatic tumors such as carcinoid tumors and hepatic adenoma, metabolic disorders such as α_1-antitrypsin deficiency, vascular disorders such as

Budd-Chiari syndrome, cystic fibrosis, hemochromatosis, amyloidosis, sarcoidosis, hyperoxaluria, and adult polycystic liver disease. Biliary atresia is the most common indication for pediatric liver transplantation.

Most surgeons will not offer transplantation to patients with severe cardiopulmonary or neurologic disease, significant hemodynamic instability, sepsis, extrahepatic malignancy, active alcohol or drug use, or unfavorable psychosocial circumstances. The decision to offer transplantation considers age and infection with human immunodeficiency virus.

A.3. What is acute liver failure (ALF)?

In the absence of transplantation, ALF leads to death. ALF is defined by the absence of chronic liver disease, acute hepatitis (elevation in transaminases with an elevation in INR), encephalopathy, and illness less than 26 weeks. The most common causes of ALF are acetaminophen toxicity (39%), indeterminate (18%), idiosyncratic (19%), and acute viral hepatitis (12%, usually hepatitis B). Other etiologies include drugs (phenytoin and halothane), autoimmune disease, Wilson disease, Budd-Chiari syndrome, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), acute fatty liver of pregnancy, toxins (i.e., trichloroethylene and tetrachloroethane in cleaning solvents and sniffed glue), and *Amanita phalloides*, the "death-cap" mushroom that grows wild in parts of the United States.

Steadman RH, Van Rensburg A, Kramer DJ. Transplantation for acute liver failure: perioperative management. *Curr Opin Organ Transplant*. 2010;15:368–373.

A.4. What is the MELD score, and how is it used in liver transplantation evaluation?

Grafts from deceased donors are offered to patients with the highest risk of death. The MELD is a validated and widely used prognostic tool to prioritize organ allocation that estimates disease severity and 3-month survival in patients with chronic liver disease. Patients with a high score rank high on the transplant list and have a greater short-term risk of dying from liver disease than patients with lower scores. The MELD score ranges from 6 to 40 points and is calculated from the patient's serum bilirubin, serum creatinine, and INR. In 2016, the MELD score was modified to include sodium (MELD-Na) because hyponatremia is an important prognostic factor in patients with cirrhosis. After this change, wait-list mortality has decreased and transplant probability has increased (**Fig. 16.1**).

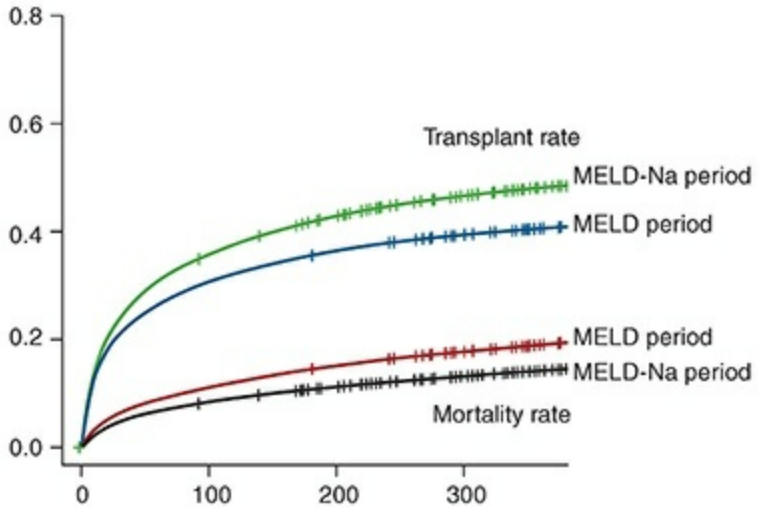

FIGURE 16.1. Comparison of waitlist mortality and transplantation rate between model for end-stage liver disease (MELD) and MELD-sodium (Na) scores in patients with cirrhotic liver disease. (*Reprinted from Nagai S, Chau LC, Schilke RE, et al. Effects of allocating livers for transplantation based on model for end-stage liver disease-sodium scores on patient outcomes*. Gastroenterology. *2018;155[5]:1451–1462. Copyright © 2018 American Gastroenterological Association Institute. With permission.*)

Formula 1

$$\text{MELD score} = 11.2 \times \ln(\text{INR}) + 9.57 \times \ln(\text{creatinine, milligrams per deciliter}) + 3.78 \times \ln(\text{bilirubin, milligrams per deciliter}) + 6.43 \text{ (an intercept)}$$

The score is rounded to the nearest whole number.

Formula 2

$$\text{MELD-Na} = \text{MELD} + 1.32 \times (137 - \text{Na}) - [0.033 \times \text{MELD} \times (137 - \text{Na})]$$

The score is rounded to the nearest whole number.

There is a lower limit of 1 for all variables.

The maximum creatinine value is 4 mg per dL. For patients who receive dialysis, creatinine is set to 4 mg per dL.

Exceptions to the MELD classification exist for patients with fulminant hepatic failure and life expectancy of less than 7 days without a liver transplant. These patients are classified as *status 1* and rank highest on the waiting list. This group includes patients who develop ALF without a history of liver disease, suffer from primary graft nonfunction or hepatic artery thrombosis within 7 days of a liver transplant, or have acutely decompensated Wilson disease. Special case exceptions also exist for patients with hepatocellular carcinoma, hepatopulmonary syndrome (HPS), familial amyloidosis, and primary oxaluria.

Pediatric patients younger than 12 years of age are ranked on the transplant waiting list according to the pediatric end-stage liver disease (PELD) model. The PELD score is similar in derivation to the MELD but does not consider creatinine and incorporates bilirubin, INR, albumin, age, and growth failure into the formula.

A.5. What is portal hypertension? What are the sequelae of portal hypertension?

The normal portosystemic gradient between the portal vein and hepatic vein is less than 5 mmHg. Greater intrahepatic vascular resistance and portal venous blood flow increases this gradient, which characterizes portal hypertension. Liver fibrosis, regenerative nodules, collagen deposition in the space of Disse, endothelial dysfunction, and an imbalance between endogenous vasoconstrictors (e.g., norepinephrine, thromboxane A, endothelin I, angiotensin II, leukotrienes) and vasodilators, such as nitric oxide, increase vascular resistance in the liver. As the pressure gradient between the portal vein and the hepatic vein increases, collaterals such as gastroesophageal and hemorrhoidal varices develop to decompress the portal system. Portal hypertension causes shear stress in the splanchnic vessels, which along with translocation of bacterial lipopolysaccharides produce endogenous vasodilators that cause vasodilation. Splanchnic vasodilation in turn increases portal blood flow and exacerbates portal hypertension.

Complications of portal hypertension include gastrointestinal bleeding from expansion and rupture of varices, intraoperative bleeding from intra-abdominal collaterals, and formation of ascites and pleural effusions.

A.6. Describe the cardiovascular system of patients with end-stage liver disease (ESLD).

The cardiovascular system of patients with ESLD mimics the hyperdynamic circulatory changes of patients with sepsis. Tachycardia, elevated cardiac output, low arterial blood pressure, and low systemic vascular resistance are characteristic. Enhanced endogenous production or diminished hepatic clearance of vasodilating substances, such as nitric oxide, carbon monoxide, and endogenous cannabinoids, and the inflammatory response to bacterial translocation cause splanchnic arterial vasodilation. Increased venous capacitance from formation of portosystemic shunts because of portal hypertension increases venous capacitance and contributes to a hyperdynamic circulation. During the perioperative period, the patient's circulatory system may be challenged with shunt insertion or greater afterload from surgical stress, unmasking an underlying cardiomyopathy. Cirrhotic cardiomyopathy is characterized by impaired systolic and diastolic dysfunction, resistance to β-adrenergic stimulation, and QTc prolongation.

Systemic conditions such as hemochromatosis (ventricular hypertrophy with increased end-diastolic and end-systolic volumes), amyloidosis (restrictive cardiomyopathy), Wilson disease (supraventricular extrasystolic beats), and alcoholism (systolic and diastolic dysfunction) can affect liver and cardiac function. Patients with portal hypertension may develop portopulmonary hypertension, leading to right ventricular dysfunction. A mean pulmonary artery pressure greater than 25 mmHg at rest, mean pulmonary capillary wedge pressure less than 15 mmHg, and a pulmonary vascular resistance greater than 240 dynes/sec/cm^5 define portopulmonary hypertension. The

mechanism is not fully understood, and histologically, there are no clear distinguishable features from idiopathic pulmonary arterial hypertension. A mean pulmonary artery pressure greater than 50 mmHg and/or a pulmonary vascular resistance (PVR) of greater than 250 dynes/sec/cm^5 are contradictions for liver transplantation due to risk of fulminant right heart failure.

A.7. What causes acute kidney injury (AKI) in patients with cirrhosis?

Patients with AKI and cirrhosis have more complications and increased risk of mortality after liver transplantation than those without renal failure. Gastrointestinal bleeding, diarrhea from infection or lactulose administration, and diuretic medications change circulatory function via hypovolemia and can cause renal injury. As cirrhosis progresses, there is compensatory activation of the renin–angiotensin and sympathetic nervous systems, which leads to ascites, severe renal vasoconstriction, and, ultimately, renal hypoperfusion. This in turn leads to electrolyte abnormalities, namely, hyponatremia and hypokalemia.

Hepatorenal syndrome (HRS) is caused by functional renal vasoconstriction in response to splanchnic arterial vasodilation. As such, histologic findings and diagnostic tests for HRS are lacking. Diagnostic criteria are used to categorize two types of HRS. Criteria for HRS include (1) cirrhosis with ascites, (2)

serum creatinine greater than 1.5 mg per dL, (3) no improvement of creatinine after 2 days of diuretic withdrawal and plasma volume expansion, (4) absence of shock, (5) no current or recent exposure to nephrotoxic drugs, and (6) absence of parenchymal kidney disease. Type I HRS involves rapid and progressive impairment of renal function (usually the result of an acute insult such as SBP or a large volume paracentesis) with a doubling of the initial serum creatinine to a level greater than 2.5 mg per dL or a 50% reduction in the 24-hour creatinine clearance to lower than 20 mL per minute in less than 2 weeks. The development of type I HRS is associated with an untreated median survival of less than 2 weeks. Patients with type II HRS have a serum creatinine greater than 1.5 mg per dL and do not meet the criteria for type I HRS; median survival in these patients is 4 to 6 months. Distinguishing between HRS and acute tubular necrosis is difficult. A fractional excretion of sodium less than 1% suggests tubular function and favors a diagnosis of HRS. The presence of renal tubular epithelial cells in urinary sediment favors a diagnosis of acute tubular necrosis.

The administration of terlipressin, a vasopressin analogue, with intravenous albumin has been shown to have benefit patients with type I HRS. The magnitude of blood pressure increase rather than a specific vasopressor type is best correlated with renal recovery. Medical management of HRS is marginally effective, but liver transplantation can reverse HRS. Kidneys transplanted from patients with HRS function normally in new hosts, suggesting the essential role of hepatic disease in the pathogenesis. Up to 40% of patients with HRS do not recover kidney function after transplantation. In these cases, systemic inflammation with hyperbilirubinemia may contribute to irreversible structural damage to the kidney.

A.8. What causes hyponatremia in patients with cirrhosis?

Patients with advanced cirrhosis have decreased effective blood volume and then circulatory dysfunction. They develop hypervolemic hyponatremia from increased secretion of antidiuretic hormone, which acts on the vasopressin-2 receptors of the renal tubular collecting duct to impair excretion of solute-free water. These patients have expanded extracellular volume, ascites, and edema.

Patients who develop hypovolemic hyponatremia via loss of extracellular fluid from the kidneys (overdiuresis) or gastrointestinal tract rarely have ascites or edema. These patients may have prerenal failure from low plasma volume and dehydration or hepatic encephalopathy from a rapid reduction in serum osmolality.

A.9. Discuss the neurologic manifestations of acute and chronic liver disease.

Hepatic encephalopathy is a neuropsychiatric complication of acute and chronic liver disease with features that range from

mild confusion to cerebral edema with intracranial hypertension. Patients have disturbances in consciousness, cognitive abilities, behavior, neuromuscular function, concentration, reaction time, memory, and/or electroencephalogram readings. The pathogenesis of hepatic encephalopathy is not understood, but most theories implicate elevated levels of ammonia, a gut-derived neurotoxin, which is shunted to the systemic circulation from the portal system. Bacteria in the gut produce ammonia, which crosses the blood–brain barrier into astrocytes that detoxify it to glutamine. Astrocytes regulate neurotransmission, but their function is decreased when they swell because of increased concentrations of intracellular glutamine. High serum ammonia levels characterize patients with hepatic encephalopathy, even though the degree of elevation of ammonia does not correlate with neurologic severity. This observation suggests that other factors, such as hyponatremia, gastrointestinal bleeding, and infection, contribute to the development of hepatic encephalopathy. Left untreated, cerebral edema can progress to intracranial hypertension and herniation of the brain. Multiple grading scales assess the severity of hepatic encephalopathy. The most common scales are the West Haven Criteria (Conn score), which has grades 0 through 4, and the Glasgow Coma Scale (GCS).

A.10. Why do patients with ESLD have abnormalities of hemostasis?

Patients with ESLD have hemostatic changes that promote both bleeding and thrombosis (**Fig. 16.2**). Inadequate synthesis of all coagulation factors (except for von Willebrand factor) thrombocytopenia, platelet function defects, dysfibrinogenemia, and elevated tissue plasminogen activator (tPA) levels cause bleeding. Elevations of von Willebrand factor and factor VIII and decreased levels of a disintegrin and metalloproteinase, with a thrombospondin type 1 motif, member 13 (ADAMTS-13), protein C, protein S, antithrombin, α_2-macroglobulin, plasminogen, and heparin cofactor II, favor thrombosis.

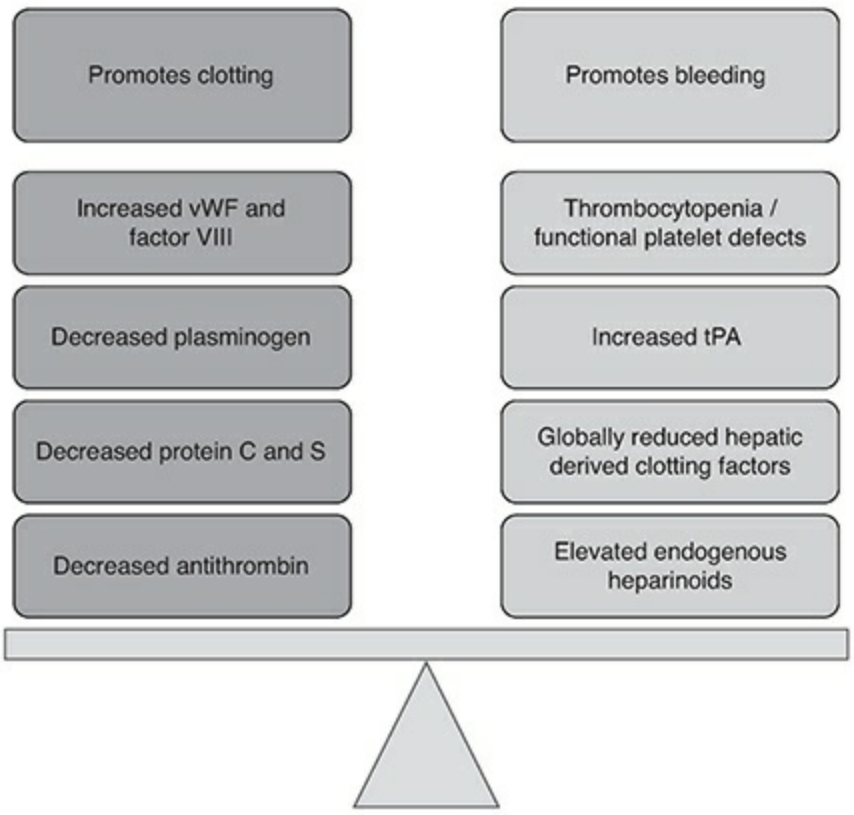

FIGURE 16.2. Changes of the coagulation and fibrinolytic system in ESLD. tPA, tissue plasminogen activator; vWF, von Willebrand factor. (*Modified from Intagliata NM, Davis J, Caldwell SH. Coagulation pathways, hemostasis, and thrombosis in liver failure*. Semin Respir Crit Care Med. *2018;39[5]:598–608. Copyright © Georg Thieme Verlag KG.*)

Factors VII, X, V, II (prothrombin), and I (fibrinogen) have a short half-life (hours to days) and are synthesized solely in the hepatocytes making possible a “semi-real time” evaluation of the liver’s synthetic function. Although patients with liver disease can have abnormal prothrombin times (PTs) from decreased production of procoagulant factors, the rebalanced state of pro- and anticoagulants in patients with liver disease makes the PT an unreliable tool for evaluating tendency to bleed or clot.

Levels of fibrinogen, an acute phase reactant, are normal or increased in liver disease. Patients with severe hepatic dysfunction, however, may synthesize fibrinogen poorly, which increases the risk of bleeding. Although high concentrations of fibrinogen are found in patients with chronic hepatitis, cholestatic jaundice, and hepatocellular carcinoma, clot formation is not enhanced because the fibrinogen is dysfunctional. Hyperfibrinolysis (from increased levels of tPA and reduced levels of thrombin-activatable fibrinolysis inhibitor [TAFI] and plasmin inhibitor) has been observed in cirrhotic patients, but its association with bleeding is unclear. Hypofibrinolysis (from increased levels of plasminogen activator inhibitor [PAI] and reduced levels of plasminogen) may restore the balance of fibrinolysis.

Thrombocytopenia and platelet dysfunction are also characteristic of ESLD. Thrombocytopenia results from several factors: hypersplenism, which sequesters platelets; consumption of platelets during systemic intravascular coagulation; and impaired hepatic synthesis of thrombopoietin, which produces platelets in the bone marrow. Defective signal transduction; uremia from AKI; and intrinsic defects of adenosine diphosphate (ADP), arachidonic acid, collagen, and thrombin prevent platelet aggregation.

There may be little evidence of deranged coagulation when

normal hepatic parenchyma is preserved, such as in an isolated hepatoma.

A.11. What is the differential diagnosis for hypoxemia in patients with cirrhosis?

Potential causes of preoperative hypoxemia and respiratory failure in patients with cirrhosis include atelectasis from the compressive effects of ascites, hepatic hydrothorax, HPS, and underlying chronic pulmonary disease. Muscle wasting and intra-abdominal hypertension from ascites increase the work of breathing.

Ascites fluid can enter the pleural space through small channels in the diaphragm to cause a hepatic hydrothorax (usually on the right side). Negative intrathoracic pressure during inspiration facilitates movement of fluid from the peritoneum to the pleural space to minimize ascites. A pleural fluid culture with polymorphonuclear cell count greater than 250 cells per μL or isolated polymorphonuclear cell count greater than 500 cells per μL diagnose spontaneous bacterial empyema.

A diagnosis of HPS is considered in patients without cardiopulmonary disease who have a room air Pa_{O_2} less than or equal to 70 mmHg in any position. The triad of liver disease and/or portal hypertension, widened age-corrected alveolar–arterial oxygen gradient (more than 15 or 20 mmHg) while breathing room air, and documented intrapulmonary vascular dilation (IPVD) define HPS. Enhanced production or impaired

hepatic clearance of endogenous vasodilators (i.e., nitric oxide, carbon monoxide, vasodilator prostaglandins, substance P) or inhibition of vasoconstrictive substances (i.e., tyrosine, serotonin, and endothelin) by a damaged liver may cause IPVD. IPVD causes hypoxemia via ventilation/perfusion mismatching, intrapulmonary shunt physiology, and diffusion limitation. Patients with HPS often complain of dyspnea and fatigue; they may have clubbing and spider angiomata on physical examination. Patients may experience platypnea (dyspnea in the upright position relieved by recumbency) or have orthodeoxia (arterial oxyhemoglobin desaturation in the upright position). Preferential perfusion of IPVD (while the patient is upright) may cause these clinical manifestations. Contrast-enhanced echocardiography or perfusion lung scanning with technetium-99m-labeled macroaggregated albumin detects intrapulmonary shunting suggestive of IPVD. There is no established medical therapy for HPS other than supplemental oxygen to correct hypoxemia. The only known treatment for HPS is liver transplantation, which improves oxygenation in almost all patients.

A.12. What are the risk factors and treatment guidelines for spontaneous bacterial peritonitis (SBP)?

The American Association for the Study of Liver Diseases recommends paracentesis for all hospitalized patients with ascites because infection of ascitic fluid is common. Delaying paracentesis and initiation of antibiotics is associated with

higher in-hospital and 3-month mortality (each hour delay increases in-hospital mortality by 3.3%). SBP is diagnosed by polymorphonuclear cell counts greater than 250 cells per μL without evidence of an intra-abdominal surgically treatable source of infection.

Cirrhotic patients have a disproportionate growth of pathogenic bacteria for numerous reasons. They have a smaller bile pool and less conversion of primary to secondary bile acids, which have bactericidal properties. This causes dysbiosis from an overgrowth of Enterobacteriaceae. Reduced gut motility and proton pump inhibitor use stimulates small intestinal overgrowth and may increase intestinal permeability and rate of bacterial translocation.

A minimum of 5 days of empiric treatment with a third-generation cephalosporin is usually adequate coverage for the typical organisms known to cause SBP (i.e., *Escherichia coli*, *Klebsiella*). There is little data to support the use of large-volume paracentesis for SBP. Administration of intravenous albumin as part of the routine treatment for SBP, however, can decrease overall mortality and incidence of HRS. A repeat paracentesis should be considered with ascitic fluid analysis in patients with inadequate response to treatment, an atypical organism in the culture, or suspected secondary peritonitis.

B. Preoperative Evaluation and Preparation

B.1. What preoperative workup is desirable?

Anesthesiologists face several preoperative challenges when patients with ESLD need surgery. Surgical and anesthetic management is complicated for patients who often have preoperative encephalopathy, AKI, electrolyte abnormalities, ascites, myocardial and pulmonary dysfunction, and/or coagulopathy. To anticipate and prevent complications from transplantation, underlying conditions should be thoroughly evaluated before surgery. A multidisciplinary team including an anesthesiologist, hepatologist, psychologist, and surgeon should be involved in preoperative preparation. Consultations may be requested with cardiology, pulmonary, infectious diseases, and nephrology for patients with comorbidities.

Electrolyte levels, blood urea nitrogen, creatinine levels, albumin levels, bilirubin levels, transaminases, complete blood count, coagulation studies, and glucose values should be routinely obtained. An electrocardiogram and chest radiograph to rule out pulmonary edema or cardiomegaly should also be obtained. Blood group and antibody screening needs to be done in advance for crossmatching large amounts of blood products, especially in those patients who have received prior transfusions. Echocardiography is useful to detect cardiac dysfunction and right ventricular systolic pressure as a marker for pulmonary hypertension. If elevated, pretransplant right heart catheterization may be warranted.

In cases of altered mental status, a head computed tomography (CT) scan often is indicated to evaluate intracranial bleeding, herniation, and/or the extent of cerebral edema. Pulmonary function studies may be indicated in smokers or patients with preexisting pulmonary disease.

The American Association for the Study of Liver Diseases recommends that patients older than 50 years, with clinical or family history of heart disease, or with diabetes undergo dobutamine stress echocardiography because cardiovascular

disease accounts for a majority of non–graft-related deaths. Of note, a vasodilatory (e.g., adenosine, dipyridamole [Persantine]) myocardial stress test is less useful because in patients with ESLD, the resting vascular tone is so low that provoking vasodilation with drugs is difficult. Other risk factors for adverse cardiac outcomes after liver transplantation include a history of stroke and increased intraventricular thickness.

If intraoperative renal replacement (continuous venovenous hemofiltration) therapy is a consideration, a nephrologist should be consulted.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

B.2. How is ascites managed preoperatively?

Ascites is initially managed with a low-sodium diet (<2 g per day) and diuretic therapy. Spironolactone as a sole agent or in combination with furosemide is typically used. Patients with ascites refractory to treatment with diuretics may require large volume paracentesis. If more than 5 L of ascites are drained, albumin is replaced to prevent hypotension and HRS. Patients with ascites should avoid nephrotoxic agents such as nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, angiotensin-converting enzyme (ACE) inhibitors, and α_1-blockers. Patients may be treated with a TIPS in refractory cases of ascites or hepatic hydrothorax.

B.3. How is hyponatremia managed preoperatively?

Hyponatremia is associated with HRS, ascites, death from liver disease, and postoperative mortality after transplantation. Cirrhotic patients typically have hypervolemic hyponatremia due to overstimulation of their renin–angiotensin–aldosterone system (RAAS), which is managed with fluid restriction (1 to 1.5 L per day) and withholding of diuretics. Vaptans, medications that block the vasopressin-2 receptor, are reserved for severe episodes of hyponatremia; they increase solute-free water excretion dose dependently and may preclude water restriction so that diuretics can be continued. Patients with hypovolemic hyponatremia are given saline instead of diuretics to increase plasma volume.

Patients who undergo orthotopic liver transplantation are at risk for perioperative osmotic demyelination syndrome (ODS), former known as central pontine myelinolysis. ODS is a neurologic condition characterized by myelinolysis or destruction of astrocytes, which can occur in the pons and other areas of the brain. The etiology of ODS is uncertain, but osmotic stress on central nervous system cells is theorized, and ODS correlates with rapid correction of hyponatremia. Rapid changes in concentration of serum sodium cannot be predicted and a "safe" rate of correction of hyponatremia has not been definitively established; some experts recommend sodium correction at a rate less than 12 mEq/L/day.

The incidence of ODS ranges from 0.5% to 1.5% in liver transplantation. Preoperative correction of hyponatremia may prevent a rapid rise in serum sodium intraoperatively and postoperatively. During intraoperative fluid replacement, high sodium loads may cause rapid swings in serum sodium, or even hypernatremia, by the end of the case. Sodium bicarbonate should be administered cautiously because it has a high concentration of sodium. Tris-hydroxymethyl aminomethane

(THAM), although a weaker base, is an alternative because of its lower sodium content.

B.4. What is a transjugular intrahepatic portosystemic shunt (TIPS) procedure? What is the role of TIPS in the management of patients with ESLD?

During a TIPS procedure, an expandable stent is deployed into the liver parenchyma to bridge the hepatic and portal vein and to decrease portal hypertension. Therefore, it reduces the portosystemic pressure gradient by acting as a side-to-side portocaval shunt. The strongest evidence for TIPS intervention is for secondary prevention of variceal bleeding and management of refractory ascites. The procedure is performed under local or general anesthesia as a "bridge" to liver transplantation in patients with severe liver disease. General anesthesia may be preferred because of the duration of the procedure and the potential for life-threatening events such as bleeding, hemobilia, arrhythmias, liver ischemia, and stent migration. Preoperative evaluation of cardiac function (particularly right ventricular function and presence of pulmonary hypertension) is essential because stent placement

can rapidly increase venous return and unmask an underlying cardiomyopathy. Unlike older, surgically created portosystemic and peritoneovenous shunts, a TIPS does not require abdominal operation or vascular diversion, both of which impose technical hazards to future liver transplantation.

Encephalopathy may worsen in 30% to 46% of patients from increased systemic delivery of biogenic amines normally cleared by the liver. The long-term patency of a TIPS is poor, especially prior to the introduction of polytetrafluoroethylene-covered stents, and multiple revisions may be required.

B.5. How are hepatic encephalopathy and elevated intracranial pressure (ICP) treated?

Initial therapy for hepatic encephalopathy identifies and treats reversible triggers (i.e., gastrointestinal bleeding and infection) of this neuropsychiatric syndrome. Nonabsorbable disaccharides such as lactulose decrease absorption of ammonia from the gut via catharsis. Excessive dosing of lactulose causes dehydration. Oral antibiotics (rifaximin, neomycin, vancomycin, paromomycin, or metronidazole) reduce ammonia-producing enteric bacteria. Rifaximin, in combination with lactulose, may prevent episodes of hepatic encephalopathy. L-ornithine L-aspartate also decreases ammonia levels by providing an

alternative substrate for the urea cycle.

Patients who develop fulminant hepatic failure are at risk for hepatic encephalopathy, cerebral edema with increased ICP, and a threat of herniation. A venous ammonia level of 255 to 340 μg per dL is a known risk factor for increased ICP in patients with fulminant hepatic failure. In cases of altered mental status, a head CT scan is often indicated to evaluate for intracranial bleeding, herniation, and/or the extent of cerebral edema. ICP monitoring should be considered for these patients with severe encephalopathy, even given the bleeding risks associated with invasive monitors. Bleeding risk seems to be the greatest deterrent to ICP monitoring; there is a risk of approximately 10% for intracranial hemorrhage with insertion of a monitor in this population. To minimize the risk, epidural transducers are recommended rather than intradural monitors. With or without ICP monitoring, 30-day outcomes are similar. Alternate noninvasive ultrasonographic modalities such as transcranial Doppler and optic nerve sheath diameter measurements can be used to estimate ICP.

Sustained ICP elevations greater than 20 mmHg should be treated with mannitol or hypertonic saline to achieve hyperosmolarity. Preoperative hyperventilation has not been shown to improve outcome, and corticosteroids are not indicated. Pentobarbital coma may be indicated for patients unresponsive to mannitol, but coma may worsen cerebral hypoperfusion by causing systemic hypotension and confound the neurologic exam. Extracorporeal albumin dialysis with the molecular adsorbent recirculating system (MARS) system has been studied as bridge to liver transplant; however, it can also lead to electrolyte disturbances and a worsening coagulopathy. Many centers consider sustained cerebral hypoperfusion (cerebral perfusion pressure <40 mmHg) a contraindication to transplant because of the high risk for brain death. In the future,

transcranial Doppler ultrasonography and near-infrared spectrophotometry may offer means of monitoring for elevated ICP in these patients. For anesthesia, drugs or conditions that exacerbate elevations in ICP should be avoided. Recent evidence shows that moderate hypothermia (32°C to 33°C) may reduce cerebral edema and intracerebral hypertension; however, the side effects of the maneuvers are a greater risk of infection, cardiac dysrhythmias, and coagulopathy.

B.6. Should this patient be transfused with fresh frozen plasma prior to surgery?

Management of the coagulopathy is challenging because conventional blood tests such as PT and activated partial thromboplastin time (aPTT) do not predict transfusion requirements during liver transplantation.

Patients who need an orthotopic liver transplant usually have severe perturbations in coagulation, but it is neither necessary nor possible to correct them preoperatively. In patients with active sites of bleeding, it is reasonable to administer fresh frozen plasma, packed red blood cells, cryoprecipitate, or platelets as dictated by clinical assessment and laboratory tests, including TEG. In addition, desmopressin (1-deamino-8-D-

arginine vasopressin [DDAVP]) may be considered for patients with concomitant renal dysfunction and uremic bleeding. Potentially curative transplant surgery should not be postponed to correct coagulation defects.

C. Intraoperative Management

C.1. What monitors would you use? Why?

In addition to the monitors recommended by the American Society of Anesthesiologists (electrocardiogram, pulse oximetry, capnography, temperature, and noninvasive blood pressure), a radial arterial catheter is placed for beat-to-beat blood pressure monitoring and frequent sampling of blood. Pulse pressure variation, calculated from the invasive arterial tracing, assesses fluid responsiveness. A second arterial catheter should be placed in the femoral artery to measure central aortic blood pressure. Peripheral arterial pressures may not be reliable in a patient with vasoconstriction, vasodilation, or compression of the subclavian artery with rib retraction.

Central line access is established to measure right atrial pressure and to administer drugs. Central venous pressure monitoring does not reliably measure blood volume or change in blood volume. The use of a pulmonary artery catheter depends on local practice and the physiologic state of the patient. Thermodilution measurements for cardiac output may be inaccurate with large-volume administration of intravenous fluids and the rapid return of cooled blood during reperfusion. Mixed venous oxygen saturation values are measured to assess

cardiac output, but these measurements also are influenced by changes in oxygen-carrying capacity and oxygen consumption.

Transesophageal echocardiography (TEE) assesses ventricular filling, contractility, and function in real time. Numerous case reports have reported its usefulness in diagnosing portopulmonary hypertension, ischemic heart disease, cirrhotic cardiomyopathy, and intraoperative thromboembolic events. While grade IV varices may be a contraindication, risk of rupture of grade I and II esophageal varices with TEE is rare.

C.2. What are the considerations for the induction of anesthesia?

If there is evidence of tense ascites, recent food ingestion, or a propensity for delayed gastric emptying, a rapid sequence induction of general endotracheal anesthesia is performed. AKI with elevated potassium levels or prolonged immobilization may preclude the use of succinylcholine. Compressive atelectasis from ascites and pleural effusions reduce functional residual capacity and decrease the time to oxygen desaturation. Vasodilating anesthetic agents may cause hypotension if intravascular volume is depleted (i.e., overdiuresis or gastrointestinal losses).

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

C.3. How does liver disease affect intraoperative

medication management?

The metabolic activity and clearance of anesthetic medications is impaired in patients with liver disease. Without adjusted doses of medications, duration of drug actions is extended and toxic levels result. Emergence from anesthesia may be delayed.

In the liver, metabolism takes place via two pathways: biotransformation via the cytochrome P450 system (which requires delivery of oxygen molecules via hepatic perfusion) and glucuronide conjugation. The first is decreased in liver disease; the second pathway is relatively spared when dysfunction begins. Many anesthetic drugs (i.e., opioids, barbiturates) bind to albumin in the circulation. Low albumin levels increase the free fraction of drug and can theoretically exaggerate the drug's effect. ESLD, however, alters many other aspects of normal pharmacokinetics such as drug volume of distribution, hepatic extraction and metabolism, renal excretion, and levels of serum proteins other than albumin. The net effect of these changes is unpredictable, making general recommendations for drug administration difficult. A safe approach in these patients is to titrate the drugs to their desired effects.

Patients with hepatic dysfunction may be sensitive to sedatives such as midazolam and diazepam. In contrast, the pharmacokinetics of lorazepam, which undergoes glucuronidation, is less likely to be affected by liver disease. Benzodiazepines may precipitate hepatic encephalopathy, and flumazenil can reverse this condition. Conversely, patients who have a history of alcohol abuse may require large doses of benzodiazepines. Rapid redistribution of bolused propofol determines its duration of action, which is not affected by impaired liver metabolism.

The adverse effects of morphine may be more pronounced in patients with severe liver disease. Morphine is metabolized by glucuronidation in the liver, and its intermediate metabolites are

eliminated renally. Although the pharmacokinetics of morphine may be unaltered in patients with mild hepatic disease, a prolonged half-life is associated with a prolonged PT, hypoalbuminemia, encephalopathy, ascites, and jaundice. The elimination of morphine's metabolites can also be prolonged in patients with HRS. Metabolism of fentanyl, sufentanil, and morphine, which have a high hepatic extraction ratio, is slowed by impaired hepatic blood flow.

In patients with liver disease and edema, muscle relaxant doses are increased because fluid retention increases volume of distribution. The duration of action of muscle relaxants that are metabolized by the liver (i.e., vecuronium and rocuronium) is prolonged. Liver disease reduces plasma cholinesterase activity, and prolonged neuromuscular blockade after succinylcholine has been reported.

Vasodilating anesthetic agents such as propofol and volatile anesthetics may cause hypotension if intravascular volume is depleted (i.e., overdiuresis or gastrointestinal losses) and reduce liver perfusion. In addition to perioperative hemorrhage and hypotension, volatile anesthetics can reduce hepatic blood flow and hepatic oxygen uptake. Compared to the vasoconstrictive effects of halothane, isoflurane and desflurane may improve hepatic blood flow and splanchnic perfusion via hepatic vasodilation.

Patients with ESLD often exhibit coagulation disorders. The presence of a coagulopathy is a contraindication to regional anesthesia, particularly epidural anesthesia.

Wiklund RA. Preoperative preparation of patients with advanced liver disease. *Crit Care Med*. 2004;32:S106–S115.

C.4. What happens during the first stage (preanhepatic

phase) of the liver transplant operation?

The preanhepatic phase begins with induction of anesthesia and ends with clamping of the hepatic artery. The diseased liver is mobilized; the suprahepatic and infrahepatic vena cava, portal vein, and hepatic artery are isolated; and the bile duct is divided. The anesthesia team manages disorders of coagulation and hemodynamic disturbances. Large losses of ascites cause hypotension and require early fluid resuscitation. Albumin solution and fresh frozen plasma are often used to replete intravascular volume.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

C.5. What happens during the second stage (anhepatic phase) of the liver transplant operation?

The second stage of the liver transplant operation, the anhepatic phase, begins after removal of the diseased liver and ends with reperfusion of the new liver. If the IVC and portal vein are clamped, venous return to the heart and cardiac output decrease. In preparation for clamping and dividing the IVC, a test clamp maneuver (occlusion of the suprahepatic IVC) is performed to assess the resilience of the circulatory system. Hypotension is managed with vasoactive medications, fluid repletion, adjustment of anesthetic agents, correction of hypocalcemia, and venovenous bypass. Anastomoses between the recipient and donor liver are performed in the following order: caval, portal, hepatic artery, and biliary.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant*. 2009;23:546–564.

C.6. What physiologic disturbances should be anticipated

during the second stage (anhepatic phase) of the liver transplant operation?

Without a liver, the patient may develop acidosis and hypocalcemia due to lack of lactate and citrate metabolism. Acidemia as well as reduced urine output leads to hyperkalemia. In the anhepatic phase, hepatic gluconeogenesis is absent; therefore, blood glucose levels are monitored regularly for both hyperglycemia and hypoglycemia.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

C.7. What is venovenous bypass? What are the potential advantages and disadvantages of this procedure?

Some centers routinely use venovenous bypass to divert blood flow from the portal circulation and IVC to the right atrium. Standard venovenous bypass uses a Y-shaped tubing. One limb of the tubing is inserted into the recipient's portal vein to drain the splanchnic beds. Another limb of the tubing is placed, through a groin cut, down into an iliac vein or the distal IVC. The outflow tubing passes through a pump. Blood returns to the patient through a cutdown access to an axillary vein or through percutaneous access to an internal jugular or subclavian vein (**Fig. 16.3**).

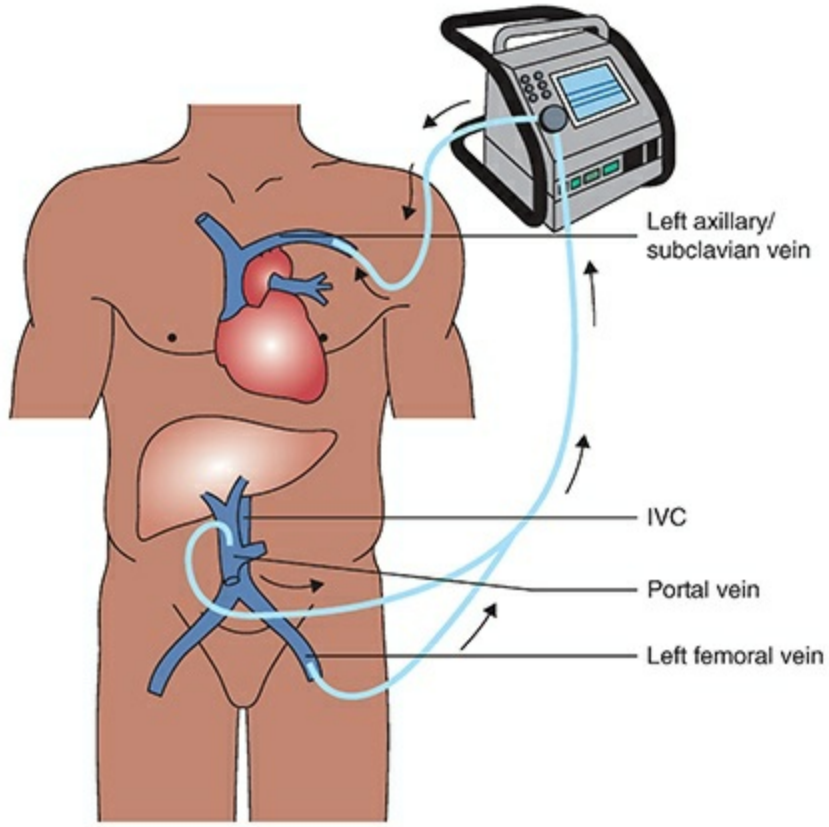

FIGURE 16.3. Schematic diagram of venovenous bypass circuit during liver transplantation. Venous return comes from the femoral and portal veins with the tubing connected together into a single venous return line. The centrifugal pump returns the blood into the axillary or subclavian vein. IVC, inferior vena cava.

Potentially, venovenous bypass can decompress the portal circulation and reduce congestion of the gut, decrease hemodynamic instability during clamping of the IVC, maintain normothermia via continuous warming of the bypass circuit, manage blood volume overload, preserve renal perfusion pressure, and improve surgical exposure during dissection. Disadvantages include the complications of venous cannula placement (bleeding, air, or thrombotic embolism); release of proinflammatory mediators; activation of complement, which may contribute to tissue injury and organ failure; and the time and cost of an expensive procedure.

The efficacy and benefits of routine use of venovenous bypass remain controversial. However, portal decompression

clearly improves surgical visualization in certain circumstances. Other centers reserve venovenous bypass for situations in which interrupted venous return through the IVC depresses the recipient's circulating system; with the increase in popularity of the piggyback anastomosis technique, this indication is less common. Budd-Chiari syndrome is a contraindication for bypass because there is an increased risk of pulmonary embolism and poor shunt flow rates.

C.8. What surgical techniques anastomose the donor and recipient inferior vena cava (IVC)?

There are several techniques to anastomose the donor and recipient IVC. Conventionally, blood flow through the IVC is completely interrupted and a cylinder of the recipient's IVC is removed with the diseased liver. An end-to-end anastomosis is created between the donor's and the recipient's IVC (**Fig. 16.4A**). In the piggyback method, the diseased liver is dissected off the IVC. The recipient's IVC is preserved, and blood flow is not completely interrupted. One end of the graft's segment of IVC is oversewn, and the orifice of the hepatic veins (the liver's venous outflow) is anastomosed to the preserved recipient's suprahepatic IVC (**Fig. 16.4B**). A third technique creates a side-to-side cavo-caval anastomosis (**Fig. 16.4C**).

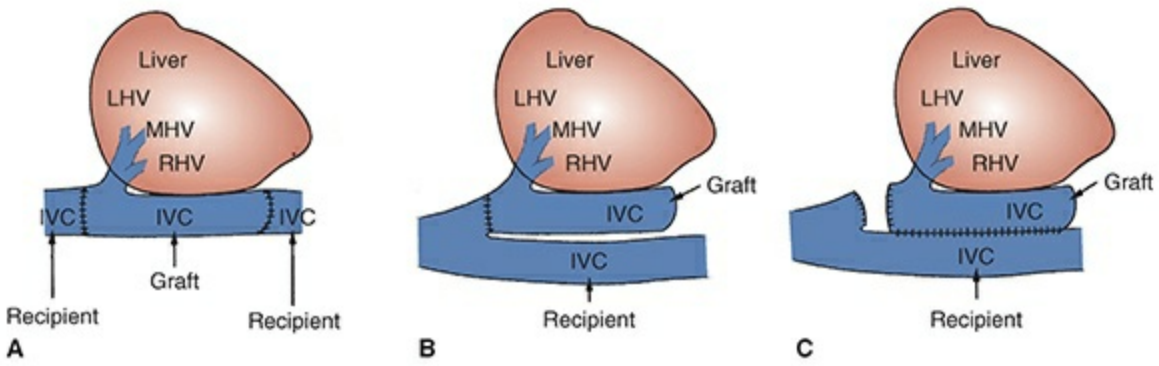

FIGURE 16.4. Three different techniques to reconstruct the hepatovenous outflow. A. End-to-end interposition of the donor vena cava to the recipient vena cava. **B.** End-to-end anastomosis of the vena cava to the hepatic veins. **C.** Side-to-side cavo-cavostomy. IVC, inferior vena cava; LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein. (*Modified by permission from Springer: Hesse UJ, Berrevoet F, Troisi R, et al. Hepato-venous reconstruction in orthotopic liver transplantation with preservation of the recipients' inferior vena cava and veno-venous bypass*. Langenbecks Arch Surg. *2000;385[5]:350–356. Copyright © 2000 Springer-Verlag.*)

C.9. What are the potential advantages of the "piggyback" (vena cava preservation) technique?

Potential advantages of the piggyback technique for vascular reconstruction include hemodynamic stability because cardiac filling is preserved; protected perfusion pressure; no need for the surgical interventions associated with venovenous bypass; reduced need for retrocaval dissection, which lessens the likelihood of damage to the adrenal vein; and shorter anhepatic time and warm ischemia time. A disadvantage of the technique is that outflow obstruction results in hepatic congestion. Unfavorable anatomy in the recipient may preclude the use of the piggyback technique.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant*. 2009;23:546–564.

C.10. What hemodynamic changes are expected after removal of vascular clamps? What is postreperfusion syndrome (PRS)?

Removal of the suprahepatic IVC clamp is not associated with hemodynamic changes. Unclamping the infrahepatic IVC restores venous return.

After unclamping of the portal vein, desaturated blood from the obstructed portal circulation, inflammatory mediators such as interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α), potassium, protons, and cold components are released into the systemic circulation. Hemodynamic instability, characterized by a decrease in blood pressure, heart rate, systemic vascular resistance, stroke volume index, and an increase in pulmonary arterial pressures, may follow unclamping of the portal vein and reperfusion of the liver. After reperfusion, an increase in serum potassium and a decrease in serum calcium are seen. A sustained 30% decrease in mean arterial blood pressure for more than 1 minute during the first 5 minutes after reperfusion defines PRS. A prolonged cold ischemic time, age of the donor, and mismatch in size between the recipient and grafted organ are associated with the development of PRS. Careful flushing of the graft just before completion of the anastomoses attenuates reperfusion disturbances by removing the cold hyperkalemic preservative solution as well as mediators of ischemia-reperfusion injury. Although venovenous bypass provides improved hemodynamic stability, it is not protective for PRS.

Before reperfusing the new graft, the following measures should be considered: (1) preemptive administration of calcium to correct hypocalcemia; (2) sodium bicarbonate, dichloroacetate, or THAM to adjust pH; and (3) inotropes or vasopressors for circulatory support. The surgical and anesthesia teams must be prepared to diagnose and treat dysrhythmias or

cardiac arrest.

Siniscalchi A, Gamberini L, Laici C, et al. Post reperfusion syndrome during liver transplantation: from pathophysiology to therapy and preventive strategies. *World J Gastroenterol*. 2016;22(4):1551–1569.

C.11. How would you treat hyperkalemia?

Hyperkalemia is treated with diuretics, aldosterone agonists, β-adrenergic agonists, insulin in combination with glucose, and alkalinization via hyperventilation. Calcium should be administered to temporarily stabilize the myocardium and prevent arrhythmias. Rarely, when hyperkalemia is refractory to the preceding treatments, dialysis with continuous venovenous hemofiltration may reduce the elevated serum potassium level.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

C.12. Why should you anticipate hypocalcemia?

The principal reason to anticipate hypocalcemia is a failure to clear citrate, which normally is metabolized by the liver. This calcium-chelating agent accumulates in patients who receive transfusions of citrated blood products.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

C.13. What happens during the third stage of the liver transplant operation?

The third stage of the liver transplant operation, the neohepatic phase, follows reperfusion of the new liver. In the neohepatic phase, the biliary drainage system is constructed. Reconstruction may be straightforward, with an anastomosis between the graft's common bile duct and the biliary stump of the recipient. More

complex reconstructions are sometimes required, such as the creation of a choledochojejunostomy. A donor cholecystectomy generally is performed. A T-tube is placed in the reconstructed biliary outflow system with external drainage. An intraoperative cholangiogram, with contrast dye instilled through the T-tube, is used to assess the patency and integrity of the biliary reconstruction. The third stage ends with closure of all wounds and transport to the intensive care unit.

During the third stage of the procedure, an insidious coagulopathy may develop, requiring transfusion.

Polak WG, Peeters PM, Slooff MJ. The evolution of surgical techniques in clinical liver transplantation. A review. *Clin Transplant*. 2009;23:546–564.

C.14. What causes intraoperative bleeding during each phase of liver transplantation? How is coagulopathy monitored and treated? What are thromboelastography (TEG) and rotational thromboelastography (ROTEM)?

The etiology of intraoperative bleeding during liver transplantation is multifactorial. Patients with ESLD have serious hemostatic defects, and coagulation is affected by alterations in body temperature, tissue perfusion, acid–base balance, and fluid balance.

During the preanhepatic phase, bleeding from the surgical technique is influenced by the patient's underlying coagulopathy. Excessive fluid administration may cause a dilutional coagulopathy and increase venous congestion of the splanchnic area, leading to more bleeding at the surgical site. Bleeding may be minimal in a hypercoagulable state such as hepatocellular carcinoma or cholestatic cirrhosis.

During the anhepatic phase, there is a net increase in systemic tPA derived from endothelial cells, which is normally cleared by

the liver. Although PT and aPTT values may not change, hyperfibrinolysis is possible. Hyperfibrinolysis is confirmed by a decrease in α_2-antiplasmin and plasminogen activity and an increase in fibrin and fibrinogen degradation products.

Nonsurgical and insidious bleeding during reperfusion can be profound. Disseminated intravascular coagulation, increased fibrinolysis, release of heparin or heparin-like substances, and trapped platelets in the graft cause coagulopathy. After reperfusion, platelet counts drop due to sinusoidal obstruction and entrapment by the new liver, generalized platelet aggregation, and a consumptive disseminated intravascular coagulation-like process.

The coagulation status should always be monitored by inspection of the surgical field. Routine laboratory tests (PT, aPTT, platelet count, fibrinogen levels) are used in some centers for evaluating the coagulation status and directing treatment. Multiple studies have shown that routine laboratory tests have limited utility in the ESLD population because of complex changes in hemostasis. Viscoelastic tests (TEG or ROTEM) assess the viscoelastic properties of a whole blood sample as a function of time to reflect the function and interaction of the plasma, blood cells, and platelets. These measurements detect a hypercoagulable state and distinguish hyperfibrinolysis from other causes of coagulopathy, such as factor depletion or thrombocytopenia, to offer a dynamic and rapid composite picture of the entire clotting cascade. Heparinase may be used to help diagnose coagulopathy resulting from the presence of heparinoids (also see Chapter 12, sections B.8, B.9, and B.10; Chapter 31, section A.1; and Chapter 57, section C.25).

C.15. What are the complications of massive transfusion?

Uncontrolled hemorrhage and massive transfusion may cause the lethal triad of acidosis, coagulopathy, and hypothermia. Left uncorrected, each of these abnormalities can exacerbate the other, creating a "blood vicious cycle." Additional early complications of massive transfusion include (1) acute hemolytic transfusion reactions, (2) febrile nonhemolytic transfusion reactions, (3) transfusion-related acute lung injury, (4) transfusion-associated circulatory overload, (5) allergic reactions, (6) bacterial sepsis, (7) hypocalcemia, (8) hyperkalemia, and (9) transfusion-related immunomodulation.

Sihler KC, Napolitano LM. Complications of massive transfusion. *Chest*. 2010;137:209–220.

C.16. How are the complications of massive transfusion prevented?

Warming the room, applying forced warming systems to the patient's body, administering blood products and fluids through a fluid warmer, and heating and humidifying inspired gases reduce the risk of hypothermia. Dilutional coagulopathy and thrombocytopenia traditionally were prevented by transfusing packed red blood cells, fresh frozen plasma, and platelets in a 1:1:1 ratio. Because of increased morbidity and mortality with blood product transfusion in liver transplantation, bedside-guided transfusion with TEG/ROTEM is encouraged. Platelet

transfusion has been implicated in overall mortality as well as decreased graft survival in liver transplants. Occasionally, prothrombin complex concentrate can be used to correct refractory coagulopathy. Potassium, magnesium, and calcium levels are frequently monitored to correct abnormal levels. Metabolic acidosis is managed by improving hemodynamic parameters, adjusting minute ventilation, and administering sodium bicarbonate or tromethamine for severe metabolic acidosis. The risk of transfusion-related acute lung injury may be reduced by minimizing transfusions and transfusing packed red blood cells with a short storage time and fresh frozen plasma from men or nulliparous women.

Sihler KC, Napolitano LM. Complications of massive transfusion. *Chest*. 2010;137:209–220.

C.17. How is hyperfibrinolysis managed?

The tPA has been implicated as a causal agent in hyperfibrinolysis. A functioning graft liver will eventually clear excess tPA from the circulation; however, levels seem to peak at reperfusion and are associated with greater intraoperative blood loss. Pharmacologic therapy with antifibrinolytic agents (tranexamic acid, ε-aminocaproic acid) blocks fibrin degradation by plasmin, but the full spectrum of their actions remains incompletely defined. The use of prophylactic antifibrinolytic agents in liver transplant surgery may reduce transfusion requirements, but this remains controversial because of concern for development of thromboses that may be catastrophic.

Badenoch A, Sharma A, Gower S, et al. The effectiveness and safety of tranexamic acid in orthotopic liver transplantation clinical practice: a propensity score matched cohort study. *Transplantation*. 2017;101(7):1658–1665.

Ortmann E, Besser MW, Klein AA. Antifibrinolytic agents in current anaesthetic practice. *Br J Anaesth*. 2013;111:549–563.

C.18. When is intraoperative renal replacement therapy indicated?

Managing patients with low urine output, renal dysfunction, or preoperative hyperkalemia, who undergo liver transplantation, is challenging. Continuous renal replacement therapy may be used intraoperatively to manage volume shifts, acid–base balance, and electrolyte disturbances. Patients who are receiving dialysis and patients who have AKI should have intraoperative continuous renal replacement therapy.

Townsend DR, Bagshaw SM, Jacka MJ, et al. Intraoperative renal support during liver transplantation. *Liver Transpl*. 2009;15:73–78.

C.19. What intraoperative signs suggest that the hepatic graft is working?

Good texture and color of the graft, evidence of bile production, and hemodynamic stability are signs that the graft is working. Hypocalcemia often resolves quickly, even with rapid fresh frozen plasma administration. Metabolic alkalemia can develop as a result of citrate metabolism. Potassium levels tend to normalize with the onset of hepatocyte function. A number of recipients exhibit hyperglycemia resistant to insulin.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1467–1471.

D. Postoperative Management

D.1. What are the goals of immediate postoperative care of the liver transplant patient?

After liver transplantation, patients are admitted to the intensive care unit for monitoring of organ function, management of intraoperative complications, correction of coagulopathy, evaluation of graft function, and initiation of immunosuppression. Although many patients are extubated within 6 hours after the operation, the lungs of liver transplant patients often are mechanically ventilated for 24 to 48 hours.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

D.2. What postoperative findings suggest that the hepatic graft is functioning?

Clearance of lactic acid, production of glucose, resolution of encephalopathy, normothermia, normalization of coagulopathy, decreasing total bilirubin levels, production of bile (through the biliary tube), and adequate urine output suggest a functioning graft. Preservation injury causes transaminases to rise immediately after surgery, but enzyme levels usually fall within 24 to 48 hours. New synthesis of coagulation factors will not correct factor depletion for hours to days after the transplant.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

D.3. What coagulation disturbances should be anticipated in the postoperative period?

Typically, heparin effects, disseminated intravascular coagulation, or hyperfibrinolysis has been resolved in the operating room. However, dilutional coagulopathy, along with ongoing platelet and factor consumption in the early postoperative phase and poor graft function, may contribute to clinical bleeding. Postoperative uremia also compromises platelet function. A functioning graft liver may not produce substantial levels of clotting factors for several days. Therefore,

plasma, cryoprecipitate, and/or platelets may be needed in the early postoperative period.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1973–1986.

D.4. Can renal function change after liver transplantation?

Postoperative renal function is correlated with preoperative glomerular filtration rate, and approximately 10% of liver transplant patients require postoperative dialysis. For patients on renal replacement therapy prior to surgery, rate of renal recovery is negatively associated with increasing age, presence of diabetes, and duration of renal replacement therapy greater than 8 weeks. For patients with cirrhosis who have HRS resistant to diuretics, renal function may improve after transplantation. Postoperatively, sepsis and the nephrotoxic calcineurin inhibitors, such as cyclosporin A and FK-506 (tacrolimus), may contribute to renal dysfunction. Balanced immunosuppression with steroids, mycophenolate mofetil, anti-CD25 (basiliximab/daclizumab), and antithymoglobulin can minimize posttransplant renal dysfunction. Chronic allograft nephropathy in patients who have received liver, heart, lung, or kidney transplants is now the third most common reason for patients to be on the waiting list for a kidney transplant.

D.5. What vascular and biliary complications occur after

liver transplantation?

Arterial and venous vascular complications include anastomotic bleeding leading to hypovolemia, acute stenosis or occlusion from thrombosis or kinking of the graft vessels, and development of an aneurysm or pseudoaneurysm. Thrombosis of the portal vein or hepatic artery compromises viability of the graft. Abdominal Doppler ultrasound is used to assess the hepatic vessels. Hepatic artery thrombosis, which is more common than portal vein thrombosis, may cause severe liver failure from necrosis. Portal vein thrombosis may cause liver dysfunction, tense ascites, and variceal bleeding.

Biliary complications include bile leak, bile duct stricture, ductal stones, and sphincter of Oddi dysfunction and are associated with the use of T-tubes, Roux-en-Y anastomoses, ischemia-reperfusion injury, cytomegalovirus infection, and hepatic artery thrombosis (leading to duct ischemia). Patients with bile leaks experience fever, abdominal pain, and peritoneal irritation. Bile leaks develop early in the postoperative course and may be identified by ultrasonography showing abdominal fluid collections or cholangiography. Bile leaks are managed with endoscopic placement of a biliary stent or relaparotomy.

Kochhar G, Parungao JM, Hanouneh IA, et al. Biliary complications following liver transplantation. *World J Gastroenterol*. 2013;19:2841–2846.

Mehrabi A, Fonouni H, Müller SA, et al. Current concepts in transplant surgery: liver transplantation today. *Langenbecks Arch Surg*. 2008;393:245–260.

D.6. What immunosuppressive agents will be given after liver transplantation? What are the major side effects?

The risk of organ rejection is balanced against the adverse side effects (i.e., neurotoxicity, nephrotoxicity, infection, metabolic abnormalities, malignancy, and recurrence of pretransplant

conditions such as hepatitis C virus, hepatocellular carcinoma, and sclerosing cholangitis) of immunosuppressive medications. Although protocols vary from center to center, newer regimens have reduced the degree of immunosuppression. A usual induction regimen includes a calcineurin inhibitor such as cyclosporine or FK-506 (tacrolimus), an antimetabolite such as azathioprine or mycophenolate mofetil, and a steroid such as methylprednisolone or prednisone. Antibodies directed against T-cell lymphocytes (e.g., OKT3 or antithymocyte globulin) or the interleukin-2 (IL-2) receptor (basiliximab) or mammalian target of rapamycin (mTOR) inhibitors (e.g., everolimus or sirolimus) may be substituted for cyclosporine or tacrolimus in patients with renal dysfunction or used in short courses to treat rejection. After 6 months to a year, many patients can be weaned to calcineurin inhibitor monotherapy. New drugs for immunosuppression in liver transplantation are monoclonal antibodies to IL-2 receptors (CD25) of T lymphocytes (basiliximab and daclizumab). The adverse effects of these medications are listed in **Table 16.1**.

TABLE 16.1 Adverse Effects of Immunosuppressant Medications

Medication	Adverse Effects
FK-506 (tacrolimus)	Nephrotoxicity Hypertension Neurotoxicity (tremors, seizures, posterior leukoencephalopathy)
Cyclosporine	Nephrotoxicity Hypertension
Mycophenolate mofetil	Hypertension Bone marrow suppression Abdominal pain Diarrhea Vomiting
Azathioprine	Leukopenia Anemia Thrombocytopenia

Glucocorticoid	Glucose intolerance Osteoporosis Peptic ulcer disease Adrenal suppression
OKT3	Symptoms of cytokine release (fever, chills, dyspnea, wheezing, chest pain) Leukopenia
Basiliximab	Gastrointestinal upset
Daclizumab	Gastrointestinal upset

SECTION 4 The Nervous System

17 Brain Tumor and Craniotomy

June M. Chan, Elena V. Christ, and Kane O. Pryor

A 47-year-old woman who was previously healthy presents with a 4-month history of headache, with intermittent diplopia and gait disturbance developing over the last month. She is admitted after her family witnesses an acute episode of profound lethargy, altered cognition, and vomiting. Neurologic examination is remarkable for abnormal right-sided cranial nerve V, VII, and VIII function; nystagmus; and ataxic gait. Magnetic resonance imaging (MRI) shows a large, right posterior fossa mass that is only slightly hyperintense on T2-weighted images but is clearly demarcated after the intravenous injection of gadolinium contrast. The impression is of a petroclival meningioma, with mass effect on the pons and fourth ventricle. Magnetic resonance angiogram shows a highly vascular tumor drawing principal blood supply from the ascending pharyngeal branch of the ipsilateral external carotid artery. The patient improves clinically following the administration of dexamethasone and mannitol and the infusion of 2% sodium chloride and is monitored in the neurosurgical intensive care unit (ICU). The day after admission,

the patient undergoes uneventful cerebral angiography and partial embolization of the tumor under general anesthesia. She is now scheduled for posterior fossa craniotomy and resection of the tumor.

A. Medical Disease and Differential Diagnosis

1. What is the pathology of intracranial tumors?
2. What is intracranial pressure (ICP), and what are its determinants?
3. How does the presence of a mass alter the ICP in this patient, and what are the clinical manifestations of these alterations?
4. What is cerebral blood flow (CBF), and what are its determinants?
5. What are the cerebral steal syndromes?
6. Are there any issues specific to posterior cranial fossa pathology?
7. What is the role of preoperative embolization therapy?

B. Preoperative Evaluation and Preparation

1. What are the special considerations in preoperative evaluation of the patient scheduled for posterior fossa craniotomy?
2. In a patient who presents with intracranial hypertension, what management might have already been initiated preoperatively, and what are the implications for anesthetic management?
3. What are the types of intraoperative neurophysiologic monitoring (IOM) that would likely be used for this procedure, and how will they affect the anesthetic management plan?
4. What are the options for patient positioning during posterior fossa surgery?
5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?
6. How does the sitting position affect your preoperative assessment and planning?

7. How should the patient position ultimately be determined?
8. Should this patient receive premedication?

C. Intraoperative Management

1. What are the anesthetic goals for craniotomy?
2. What monitors should be used during craniotomy?
3. Would you monitor for venous air embolism (VAE)? What are the monitoring options?
4. What specific risks are associated with induction of anesthesia?
5. How would you induce anesthesia?
6. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRO_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?
7. How would you manage ventilation and maintain arterial carbon dioxide (CO_2)?
8. How would you approach diuretic therapy?
9. How would you manage serum glucose?
10. How would you approach fluid management?
11. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still "tight." What would be your response?
12. If deliberate hypotension is indicated, how will you achieve it?
13. While the surgeon is resecting tumor from near the brainstem, the patient's heart rate suddenly drops to 20 beats per minute. What is your assessment and management?
14. Are there any measures you can take to prevent VAE?
15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($EtCO_2$) drops from 31 to 13 mmHg, and the systemic pressure from 121/63 to 64/32 mmHg. What is your assessment and management plan?
16. What is your approach to emergence? What if the patient does not regain consciousness?

D. Postoperative Management

1. What postoperative complications are of greatest concern? What level of monitoring is required?
2. What is your approach to postoperative pain control?
3. In the ICU, the patient's neurologic status deteriorates and ICP monitoring is instituted. What are the different methods of monitoring ICP, and what are their limitations?

A. Medical Disease and Differential Diagnosis

A.1. What is the pathology of intracranial tumors?

Intracranial tumors may be primary neoplasms or secondary to metastases, infection, inflammation, or vascular disruption. Primary cancers can be classified according to their cell origin, or according to their anatomic location (**Table 17.1**). The most common tumors in children are pilocytic astrocytomas and medulloblastomas compared with meningiomas, pituitary tumors, and glioblastomas in adults. Secondary metastases are far more common than primary intracranial tumors, although the exact incidence is unknown, and most likely originate from lung cancer, breast cancer, and melanoma.

TABLE 17.1 Classification of Intracranial Tumors

Anatomic Classification	Supratentorial • Glioma • Pituitary • Craniopharyngioma • Pineal • Lymphoma • Metastases	Infratentorial • Schwannoma • Medulloblastoma • Ependymoma • Hemangioblastoma • Glioma
Cell Origin	Primary • Neuroepithelial – Astrocytoma – Oligodendroglioma – Ependymoma • Neuronal/mixed neuronal-glial	Secondary • Metastases – Lung – Breast – Genitourinary – Melanoma

- Pineal
- Embryonal
  - Medulloblastoma, PNET
- Cranial and paraspinal nerves
  - Schwannoma, neurofibroma
- Meningioma
- Primary CNS lymphoma
- Germ cell
  - Gastrointestinal
- Infection
  - Abscess
  - Toxoplasmosis
  - Tuberculosis
- Inflammation
  - Sarcoidosis
- Vascular
  - Hemorrhage
  - Giant aneurysm

CNS, central nervous system; PNET, primitive neuroectodermal tumor.

Although the cause of primary intracranial neoplasms remains unclear, there are genetic conditions that predispose to tumor development. There is, for instance, a clear association between meningiomas and neurofibromatosis type 2. Other conditions linked with the development of brain tumors include neurofibromatosis types 1 and 2, von Hippel-Lindau syndrome, tuberous sclerosis, Li-Fraumeni syndrome, and Turcot syndrome. These conditions are associated with extra-tumor manifestations that should be carefully considered during preoperative evaluation (**Table 17.2**).

TABLE 17.2 Genetic Conditions Associated with Intracranial Tumors

Syndrome	Chromosome	Characteristic Tumor	Other Pathognomic Lesions
NF-1	17q11	Optic glioma Brainstem glioma	Café-au-lait spots, Lisch nodules
NF-2	22q12	Bilateral acoustic neuromas Multiple meningiomas	Subcutaneous schwannomas
Retinoblastoma	13q14	Trilateral retinoblastoma	
von Hippel-Lindau	3p25	Cerebellar, retinal, and spinal hemangioblastoma	
Tuberous sclerosis	9q34	Subependymal astrocytoma Retinal astrocytoma	Ash-leaf spots Shagreen patch Adenoma sebaceum

Sturge-Weber	9q21	Leptomeningeal angiomatosis Choroidal hemangioma	Port-wine nevus Glaucoma
Turcot	5q21	Glioblastoma Medulloblastoma	
Li-Fraumeni	17q	Malignant glioma PNET	

NF-1, neurofibromatosis type 1; NF-2, neurofibromatosis type 2; PNET, primitive neuroectodermal tumor.

A.2. What is intracranial pressure (ICP), and what are its determinants?

Normal ICP is 5 to 15 mmHg (6 to 20 cm H_2O). This pressure results from the physiologic interactions of intracranial structures within the rigid skull. Anatomically, these structures are enclosed within a cranial vault that is divided by tough dural partitions, the falx and tentorium cerebelli. Functionally, intracranial structures can be conceptualized as three compartments within a minimally compliant space:

- *Parenchyma*, consisting of cellular, extracellular, and intracellular fluid components, occupying 80% to 85% of total intracranial volume (approximately 1,400 mL in the average adult)
- *Cerebrospinal fluid (CSF) (circulatory component)*, occupying 10% of total intracranial volume (approximately 75 mL in the cisterns, 50 mL in the subarachnoid space, and 25 mL in the ventricles)

- *Intracranial blood volume (vascular component)*, consisting of both arterial and venous blood, which occupies 5% to 10% total intracranial volume (averaging 150 mL in the adult)

Without compensation, alterations in any one of these compartments will lead to increases in ICP, which may impede blood flow and result in ischemia. Monro (1783) and Kellie (1824) first hypothesized that an increase in the volume of one compartment results a compensatory decrease in the other compartments, thereby preserving normal ICP. Initially, CSF can drain to the spinal CSF reservoir and venous blood to the extracranial veins. This minimizes the change in ICP during the early phases of intracranial volume expansion. However, this compensation is limited, especially if the expansion is rapid. At a critical point, these compensatory mechanisms are exhausted, and even small increases in intracranial volumes will result in significant increases in ICP.

Early signs of increased ICP include headache (classically occipital), vomiting, behavioral changes, sedation, and cognitive slowing. Papilledema on funduscopy is an important sign that is often missed on examination. Further increases in ICP can eventually lead to compressive cranial neuropathies (typically cranial nerve VI, causing unilateral mydriasis) and herniation of brain tissue through a noncompliant partition—rapidly resulting in irreversible regional and global neuronal injury.

A.3. How does the presence of a mass alter the ICP in this patient, and what are the clinical manifestations of these alterations?

Within the constraints of the intracranial compliance model outlined earlier, there are certain characteristics of an intracranial mass that influence the degree of ICP alteration:

- *Size*: An intracranial mass exerts effects through its own intrinsic volume and any surrounding edema. Any space-occupying lesion within a relatively fixed intracranial compartment is compensated for through decreases in volume of other intracranial contents.
- *Rate of growth*: A rapidly expanding mass outpaces the rate in which compensatory volume shifts can occur, which leads to an increase in ICP.
- *Anatomic location*: The infratentorial space is notable for being highly susceptible to mass-related alterations in ICP. The area bound by the tentorium cerebelli and occiput is much lower in volume and compliance when compared with the supratentorial space. It also contains vital structures involved in CSF bulk flow between different compartments:

the fourth ventricle, which communicates with the supratentorial ventricles and subarachnoid cisterns, and the foramen magnum, which communicates with the spinal column. Any volume shift within the infratentorial space may therefore precipitate a noncommunicating hydrocephalus, which further compromises compensatory mechanisms for intracranial hypertension.

- *Local tissue dysfunction*: The presence of an intracranial tumor causes local effects on surrounding tissue through invasive destruction, induction of neoangiogenesis through the release of oncogenic factors, or compression with ischemic cellular disruption. This results in an inflammatory response that causes further tissue edema and increases in ICP.

Taken together, these considerations account for the differences in the clinical presentation of intracranial masses. A slow-growing mass, particularly in the peripheral supratentorial space, can become sizable with minimal symptoms due to compensatory volume remodeling, whereas a small infratentorial lesion can obstruct the fourth ventricle and rapidly cause significant intracranial hypertension.

In this patient, a slow-growing meningioma has been able to attain a large size before becoming symptomatic. The patient's earliest signs and symptoms were most likely due to a localized mass effect. The more acute decompensation, with rapidly developing signs and symptoms of elevated ICP, probably represents the added component of CSF outflow obstruction at the fourth ventricle. Even with the clinical improvement achieved by steroid therapy and osmotic diuresis, this patient has very little volume reserve and intracranial compliance so even small increases in volume—such as an increase in cerebral blood volume (CBV) precipitated by a minimum alveolar concentration (MAC) of volatile anesthetic—have the potential

to cause a precipitous spike in ICP.

A.4. What is cerebral blood flow (CBF), and what are its determinants?

Despite only constituting about 2% of the total body weight, the brain receives approximately 15% to 20% of resting cardiac output as CBF via the carotid and vertebral arteries. This disproportionately high blood flow is due to the brain's metabolic requirement of oxygen (MRO_2), which consumes approximately 3.5 mL O_2/min/100 g brain tissue, or 20% of total body MRO_2. CBF is approximately 750 mL per minute in the adult, or 50 mL/min/100 g averaged across gray and white matter. Gray matter, which contains neuronal nuclei, is metabolically more active than white matter and consumes 75 versus 45 mL/min/100 g brain tissue.

CBF is determined by cerebral perfusion pressure (CPP), which describes the pressure gradient for blood flow across the cerebral vascular bed, and cerebral vascular resistance (CVR):

$$CBF = CPP / CVR$$

On a global level, CPP is the difference between the inflow and outflow pressures of the brain's blood supply. However, the cerebral circulation behaves as a Starling resistor: Its enclosure within the rigid cranial vault allows extravascular pressure (ICP) to compress and compromise venous outflow. Hence, CBF can be expressed as:

CBF = (mean arterial pressure [MAP] – outflow pressure) /

where outflow pressure = CVP or ICP, whichever is higher.

CBF is highly regulated to ensure substrate delivery matches the metabolic demands of neural tissue in a phenomenon known as *flow-metabolism coupling*. Depending on neuronal activation and metabolic demands, regions of the brain may be either hypoperfused or hyperperfused. A sudden decrease in CBF (such as during the occlusion of a cerebral artery) results in an ischemic stroke with neurologic deficits and potentially irreversible tissue damage. An excess of blood flow leads to hyperemia and potential increases in ICP leading to tissue compression and damage. Therefore, it is essential to maintain brain homeostasis; this is achieved through alterations in CVR via four overlapping mechanisms occurring on a regional and global cerebral level:

- *Vascular myogenic autoregulation*
  - CBF is maintained constant across MAPs of approximately 50 to 150 mmHg. Based on recent studies in humans, the extremes of this range should be approached with caution, especially the lower boundary; CBF can decrease at MAPs of 60 or even 70 mmHg. Chronic hypertension causes a rightward shift in the CBF–MAP relationship. Hypocapnia has been demonstrated to broaden the autoregulatory range, whereas hypercapnia and elevated ICP decreases the responsiveness of pressure autoregulation.
- *Metabolic autoregulation*
  - CO_2: CO_2 is a potent cerebral vasodilator. It exerts its effects on the cerebral vasculature primarily by altering CSF pH, although there is evidence that CSF P_{CO_2} also has a direct effect on cerebral vascular smooth muscle. At normotensive ranges, CBF has a linear relationship with

acute changes in $Paco_2$ between 20 and 80 mmHg, with CBF changing by 2% to 4% for every mmHg change in $Paco_2$. Beyond this range, further changes are limited by extremes in vascular diameter. This response is blunted by systemic hypotension and volatile anesthesia. It is important to note that prolonged hypocarbia or hypercarbia (beyond 6 to 8 hours) will ultimately have little effect on CVR, as CSF pH normalizes with active transport of bicarbonate over the blood–brain barrier (BBB). Furthermore, subsequent correction of $Paco_2$ would likely result in rebound cerebral hyper- or hypoperfusion.

- Oxygen (O_2): Acute exposure to hypoxia causes an immediate increase in CBF in a curvilinear relation with respect to arterial PO_2 and linear with respect to hemoglobin saturation. Acute hypoxemia below 50 mmHg causes cerebral vasodilation, rapidly reaching maximal response at approximately 30 mmHg. The exact mechanism of how this occurs is unclear, but it likely involves the direct effects of by-products from anaerobic metabolism and cellular ischemia, such as lactic acid and adenosine. This mechanism is also impaired in the presence of volatile anesthesia.

- *Neurogenic autoregulation*
  - Compared with myogenic and metabolic mechanisms, the autonomic nervous system plays a minor role in cerebral autoregulation. Both sympathetic innervation of cerebral arterioles and circulating sympathomimetics attenuate increases in CBF during severe hypertension, hypoxia, and hypercapnia.

As stated earlier, the presence of an intracranial mass induces dysfunction in surrounding neural tissue resulting in ischemia

and inflammation. This acidic microenvironment promotes local vasodilatation and vasoplegia with subsequent narrowing of the pressure autoregulatory range. Regional CBF becomes dependent on MAP and ICP, with little ability to compensate for changes in systemic blood pressure. Mass effect alone can increase ICP enough to critically compromise CPP with apparently normal MAP.

A conservative approach to the management of CPP would suggest that it should not be allowed to fall below 70 mmHg for any extended period in the baseline normotensive patient. Although a more moderate approach targeting CPPs in the 60- to 70-mmHg range is commonly used, most neuroanesthesiologists agree that sustained CPP values under 60 mmHg place the brain at risk, despite the possible neuroprotection afforded by the presence of a gamma-aminobutyric acid (GABA)ergic anesthetic agent.

A.5. What are the cerebral steal syndromes?

Any intracranial pathology, including marginal ischemia and inflammation surrounding a mass lesion, can cause localized dysfunction of normal cerebral autoregulation and an impaired response to vasoactive agents. The microvasculature in the pathologic region can have an essentially fixed resistance. In this case, if vasodilation occurs in other normal regions of the brain, the decreased vascular resistance in the normal tissue can theoretically shunt blood flow away from the pathologic regions, which are already most vulnerable. This phenomenon is known as *cerebral steal*.

In anesthesia management, cerebral steal is most relevant in the context of hypercapnia and the use of volatile anesthetics. Both cause vasodilation of normal vasculature and potentially decrease regional CBF in pathologic areas. For volatile anesthesia, cerebral vasodilatation is usually considered to be significant when given in doses of 1 MAC or greater, but as a dose-dependent effect, it may be clinically apparent at 0.5 MAC. During hypocapnia, when there is vasoconstriction in normal tissue, the opposite may occur. In this case, blood flow to pathologic regions can actually increase. This phenomenon is known as *inverse steal* or the *Robin Hood effect*. Although both steal effects have been well reported in human literature, the clinical relevance of steal and inverse steal phenomena is unclear. Nonetheless, it is prudent to consider it in anesthetic management.

A.6. Are there any issues specific to posterior cranial fossa pathology?

Surgery for tumors in the posterior fossa presents several challenges not seen with supratentorial surgery (**Table 17.3**). The posterior fossa extends from tentorium cerebelli superiorly to foramen magnum inferiorly, housing the cerebellum and most of the brainstem—specifically the pons and medulla. The posterior fossa is a tightly enclosed space in which tumors are often in direct contact with critical brainstem structures, including the cranial nerves and brainstem nuclei. The smaller volume of the posterior fossa means that less mass effect is needed to produce symptoms from compression of the cerebellum, brainstem, or fourth ventricle, with the potential risk of superior vermian or inferior tonsillar herniation. The patient with a posterior fossa tumor, especially one close to the brainstem, can worsen neurologically in the hours following surgery as a result of postsurgical inflammation causing edema.

TABLE 17.3 Specific Anesthetic Considerations in Posterior Fossa Craniotomy

Specific Challenges	Management Considerations
Need for adequate surgical access	• High likelihood of nonsupine positioning – Sitting position – Prone/semiprone position • Reduced access to airway and precordium in case of emergency • Risk of disrupting airway, vascular access, and

	monitors during position changes • Specific hemodynamic effects of nonsupine positioning – Venous air embolism risk – Venous pooling in sitting position – External abdominal compression in prone position • Positioning-related nerve and soft tissue injury
Brainstem dysfunction	• Intraoperative autonomic instability • Postoperative central respiratory failure
Intraoperative neuromonitoring	• Limitations in the administration of volatile agents and neuromuscular blockade • Need to understand implications of pathologic alterations in intraoperative monitoring signals and the appropriate management response

In addition to the risk of neuronal damage, surgery in proximity to brainstem nuclei can trigger significant intraoperative autonomic and collateral hemodynamic instability, which can be extremely challenging to manage. The most common autonomic event is an acute increase in vagal tone, which can lead to a prolonged period of asystole, and can be immediately followed by a reflexive surge in sympathetic tone. Furthermore, the risk to cranial nerves and other structures often demands IOM—such as somatosensory evoked potentials (SSEPs), brainstem auditory evoked potentials, or electromyography (EMG)—all of which can substantially restrict and dictate anesthetic management.

Finally, the posterior fossa cannot be accessed with the patient in the conventional supine position. In the past, the sitting position was highly favored by neurosurgeons and presented marked anesthetic challenges because of the increased risk of VAE. Although still common in some centers, the sitting position has fallen out of favor; nonetheless, all of the positions that permit access to the posterior fossa pose management difficulties that must be considered. The risk of VAE, although reduced, often still exists. Other considerations include loss of

jugular outflow, deterioration of pulmonary compliance, strain on the cervical spine and brachial plexus, and a lack of access to central venous lines and the airway. In patients who are critically ill or otherwise at risk for life-threatening intraoperative events, it must be remembered that cardiopulmonary resuscitation will always require that the patient be rapidly returned to the supine position.

A.7. What is the role of preoperative embolization therapy?

Highly vascular tumors, especially those that are anatomically difficult to access, present a high risk for substantial intraoperative bleeding. In addition to the systemic risks associated with gross blood loss, peritumor bleeding can severely compromise surgical exposure and exacerbate neuronal and neurovascular inflammation.

To reduce this risk, patients often undergo embolization of the vessels feeding the tumor in the days immediately before surgery. An arterial catheter is inserted, usually in the femoral artery, and fluoroscopically guided until it rests in any of the vessels that have evolved to supply only the tumor and not normal brain. Low-dose systemic heparinization to achieve activated clotting times of 200 to 300 seconds is required to

prevent the formation of microthrombi. At this point, an embolic agent is slowly delivered to occlude the vessel, reducing the tumors vascular supply and thus the degree of bleeding during subsequent operative resection. Currently, the embolic agents available can be considered as two groups: particulate (using a variety of substances such as coils, gelatin sponges, fibrin glue, and polyvinyl alcohol) and liquid (ethylene vinyl alcohol, hyperosmolar mannitol). The choice of agent is determined by angiographic anatomy, tumor vascularity, and tumor histology. Because of collateralization and reestablishment of blood supply, embolization is effective for only a short period and is usually performed within 48 hours of the intracranial resection.

Tumor embolization comes with its own risks and challenges: Vascular anatomy might not always permit embolization, and the embolization itself can precipitate peri-tumor edema and hyperemic changes in blood flow dynamics. These changes are particularly relevant in this patient with a posterior fossa tumor proximate to the brainstem. Deposition of embolic agent into vessels supplying normal brain amounts to an embolic stroke and can have catastrophic consequences. Catheter-related complications including vessel dissection and rupture, and access site hematomas are well described. Furthermore, embolizations often require general anesthesia and thus assume all of the associated general and neuro-specific risks. Current literature reports embolization-related complication rates for meningiomas at between 2.9% and 4.6% but with significant decreases in intraoperative blood loss.

B. Preoperative Evaluation and Preparation

B.1. What are the special considerations in preoperative evaluation of the patient scheduled for posterior fossa craniotomy?

In addition to the routine thorough preoperative evaluation, the evaluation of the patient for craniotomy should answer several questions that critically influence anesthesia management:

- What is the ICP? If ICP is still in the normal range, how much intracranial compliance reserve is likely to exist?
- How is autoregulation likely to be affected by the pathology and chronic changes in blood pressure? What range of arterial pressures will be required to preserve adequate CPP and CBF?
- Does the patient have any of the electrolyte and endocrine abnormalities associated with intracranial pathology or treatment, such as neurogenic diabetes insipidus, or hypernatremia resulting from hypertonic saline therapy?
- Is the lesion highly vascular, difficult to access, or situated proximate to one of the large draining veins—all of which increase the probability of significant bleeding?
- What is the likely positioning, and does it incur a risk of VAE, obstruction of jugular venous outflow, or neck hyperextension? Are there preoperative patient conditions that would significantly increase the risk of or preclude certain positions, such as patent foramen ovale and right to left intracardiac shunts?
- Is the tumor located in a position close to the brainstem such

that severe autonomic dynamics are likely?

- Will the baseline neurologic status affect the ability to extubate or to establish an early neurologic assessment after general anesthesia?
- Will the anesthetic technique need to accommodate specific monitoring requirements, such as electroencephalography (EEG), electrocorticography, brainstem auditory evoked responses (BAERs), or SSEPs?

B.2. In a patient who presents with intracranial hypertension, what management might have already been initiated preoperatively, and what are the implications for anesthetic management?

A patient with evidence of intracranial hypertension will be aggressively monitored and treated preoperatively; it is likely that the preoperative assessment will occur in an intensive care setting. The anesthesiologist must be familiar with the management of intracranial hypertension as various therapies will likely need to be initiated or continued in the operating room. Furthermore, the anesthesiologist must be mindful of potential sequelae that can arise from various perioperative therapies and interventions such as:

- *Corticosteroids*. Treatment can lead to hyperglycemia, which should be aggressively treated to maintain plasma glucose less than 150 to 180 mg per dL while taking care to avoid

hypoglycemia.

- *Head elevation*. Care should be taken to maintain 30-degree head elevation, where possible, and to avoid rapidly lowering the head during transport.
- *Diuretics (mannitol, furosemide)*. These can result in electrolyte or acid–base abnormalities. Decreased preload can increase the risk of hypotension in the peri-induction period.
- *Isotonic or hypertonic saline therapy*. This can result in hypernatremia or a hyperchloremic, non–anion gap metabolic acidosis.
- *Intubation and institution of hyperventilation*. If prolonged, the CBF response to CO_2 can become diminished or absent, with a risk for dangerous increases in CBF and ICP if hyperventilation is rapidly ceased. It can also lead to a compensatory loss of bicarbonate and other basic metabolic buffers leading to the development of acidosis if ventilation was normalized. Care should be taken to avoid hypoventilation during transport.
- *Ventriculostomy*. This is usually clamped during transport to or from the ICU, as the level of the drain relative to the head is critical, and accidental changes in position can result in excessive draining of CSF. It should be attended to on arrival to the operating room because even relatively short periods of clamping can result in elevations of ICP.
- *Manipulation of systemic pressures to optimize CPP*. Care should be taken to ensure drug infusions are maintained during transport to avoid rebound hypertension or hypotension.
- *Drug-induced cerebral vasoconstriction and coma*. Propofol infusion and pentobarbital are the typical agents currently used in the United States, following the decline in the availability of thiopental. This signifies a critical neurologic status. The therapy is often continued as the primary

anesthetic.

- *Deliberate hypothermia*. This signifies a critical neurologic status and requires discussion of intraoperative temperature management goals with the neurosurgeon and neurointensivist because the neuroprotective benefits may be countered by hypothermia-induced coagulopathy.

B.3. What are the types of intraoperative neurophysiologic monitoring (IOM) that would likely be used for this procedure, and how will they affect the anesthetic management plan?

IOM uses a combination of stimulators and sensing electrodes to detect the functional integrity of sensory, motor, and cranial nerves and their associated nerve tracts and/or muscles. The primary monitoring modalities are EMG, evoked potentials (EPs), and EEG. EEG is rarely used for craniotomies for tumor resection and will not be considered in detail in this chapter.

EMG records the electrical activity within muscle in response to the stimulation of its innervating cranial or peripheral nerve. The most common EMG monitoring during posterior fossa surgery is for cranial nerve VII, although monitoring of cranial nerves V, IX, X, and XI is frequently encountered. Usually, the surgeon will deliver a very low current to a structure he or she believes could be the cranial nerve of interest, and muscular

activity is monitored in the distribution of the nerve. Mechanical manipulation of a nerve will often also cause muscular activity, which may herald potential inadvertent injury. EMG is relatively unaffected by volatile and intravenous anesthetic agents but requires intact functioning of the neuromuscular junction. Therefore, neuromuscular blockers cannot be used for EMG monitoring beyond anesthetic induction. Some anesthesiologists advocate the use of succinylcholine for intubation; however, with the use of sugammadex becoming more widely available, an intubating dose of a medium-duration nondepolarizing agent such as rocuronium, vecuronium can be used if needed and quickly reversed to allow adequate return of muscular function by the time monitoring is relevant.

EPs measure electrical activity generated within the nervous system in response to a stimulus. The most common EP monitoring encountered during resection of posterior fossa tumors is the BAER, which monitors cranial nerve VIII and auditory pathway function (including portions of the brainstem, midbrain, and the primary auditory cortex) in response to sounds generated in the auditory canal. SSEPs can also be used to monitor dorsal column-medial lemniscus tract integrity, which is useful for posterior fossa surgery given the superficial location of the medial lemniscus in the brainstem and pons. These are elicited via electrical stimulation of peripheral sensory nerves (most commonly median and posterior tibial nerves) and recorded via scalp needle electrodes directed over the somatosensory cortex. Similarly, motor evoked potentials (MEPs) are obtained through transcranial stimulation of cortical pyramidal cells and recorded distally along the spinal cord, motor nerves, and muscle.

EPs are recorded as positive and negative deflections from baseline. The time delay from stimulus to first recorded deflection is termed the latency, and the maximal deflection

from baseline is the amplitude. A significant increase in latency or decrease in amplitude of EPs can reflect injury along the nerve tract, or dysfunction due to physiologic or pharmacologic factors. Anesthetic agents can dramatically alter EPs in the absence of other abnormalities (**Table 17.4**). Although BAERs are reasonably robust, MEPs (and SSEPs to a lesser but still significant degree) are exquisitely sensitive to volatile anesthetics, which cause decreases in amplitude and increases in latency in a dose-dependent manner. Furthermore, neuromuscular blockers cannot be used if MEPs are proposed. Volatile agents should be kept at less than 0.5 MAC, and nitrous oxide (N_2O) should not be used. The anesthetic plan will often rely heavily on opioids; propofol and dexmedetomidine infusions are also often incorporated, the latter of which may also offer improvements in overall hemodynamic stability. Perhaps more important than the specific anesthetic regimen is that a maintenance equilibrium is established for the baseline neurophysiology measurements and is then kept constant throughout the procedure. Pseudo-equilibrated steady-state continuous infusions are key to this strategy.

TABLE 17.4 Anesthetic Effects on Intraoperative Neuromonitoring

	Affected By	Resistant To
SSEP	Volatile agents (goal <0.5 MAC) Nitrous oxide Intravenous agents	Muscle relaxants Opioids
BAEP		Volatile agents Nitrous oxide Muscle relaxants Intravenous agents Opioids
MEP	Muscle relaxants Volatile agents (avoid; use TIVA)	Opioids
EMG	Muscle relaxants	Volatile agents Propofol

	Nitrous oxide Opioids

BAEP, brainstem auditory evoked potential; EMG, electromyography; MAC, minimum alveolar concentration; MEP, motor evoked potential; SSEP, somatosensory evoked potential; TIVA, total intravenous anesthesia.

Although anesthetic agents are major influences on the accuracy of IOM, it should be remembered that physiologic factors such as hypothermia, acidosis, excessive hemodilution, and hypotension can also influence EPs as well as neuronal integrity and should be avoided (**Table 17.5**).

TABLE 17.5 Physiologic Effects on Intraoperative Neuromonitoring

	Effects
Temperature	• Progressive hypothermia predictably increases latency in SSEPs but has variable effects on amplitude (can increase in mild hypothermia and decreases with moderate hypothermia). • VEPs are completely lost at 25°C–27°C. • BAEPs are more resistant to hypothermia, but changes reflect those of SSEPs at lower temperature thresholds. • Hyperthermia to 40°C decreases latency but with further increases slowing occurs, likely reflecting neuronal injury.
Hematocrit	• Changes similar to ischemia in SSEPs and VEPs are seen with acute isovolemic hemodilution to hematocrit of 10%–15% in animals, with resolution when hematocrit was increased to 20%–22%.
Oxygen	• Mild hypoxemia has minimal effects on SSEPs and BAEPs. • Severe ischemia increases latency and decreases amplitude of SSEPs, with cortical responses being more sensitive than spinal responses. BAEPs are similarly affected.
Carbon dioxide	• Hypocarbia ($PaCO_2$ 20–25 mmHg) decreases latency in SSEPs. • Hypercarbia (to $PaCO_2$ 55 mmHg) has minimal effects on SSEPs.

BAEPs, brainstem auditory evoked potentials; SSEPs, somatosensory evoked potentials; VEPs, visually evoked potentials.

B.4. What are the options for patient positioning during posterior fossa surgery?

- *Sitting position*. Although used far less often now than two decades ago, it is critically important for the anesthesiologist to understand the sitting position partly because it could still have specific surgical advantages in some situations and partly because it provides the archetype for the risks and management of VAE. The patient is in a reclined sitting posture such that the feet are at or near the level of the heart. The head is held in a flexed position with a skull fixation device, and the arms are crossed over the chest.
- *Modified sitting position*. Due to concerns about the sitting position, a modified sitting position has been described. This involves the same reclining position as described earlier but with careful position of the hips and legs so that the feet and knees are above the level of the heart. The head is anteriorly flexed and held in place with a fixation device, and the arms are padded and placed on arm boards by the patient's side.
- *Prone position*. This is especially suitable for lesions in the midline but can be adapted for more lateral approaches by having the head slightly rotated. Depending on body habitus, supporting rolls are placed horizontally across the chest and hips or in parallel along the longitudinal axis of the body. The head is held with a skull fixation device with the neck in a neutral to flexed position.

- *Lateral decubitus position*. This position is suited to cerebellopontine angle tumors and cerebellar hemispheric lesions.
- *Park bench (semiprone) position*. The patient is turned toward a more prone position, moving the upper shoulder out of the surgeon's view and permitting better access to midline lesions.
- *Supine position*. This can sometimes be used with the patient's head rotated. To reduce the amount of rotation of the neck, which can obstruct venous outflow, a supporting roll can be placed under the ipsilateral shoulder and the whole bed rotated away from the surgeon.

B.5. What are the principal disadvantages associated with the common posterior fossa craniotomy positions?

The greatest concern for the sitting position is the increased risk of VAE. In this position, the head is elevated above the right atrium and beyond the height of the central venous fluid column. This will reduce venous bleeding; it will also enable large volumes of air to be entrained into the central venous circulation, especially through the large dural sinuses, which are tented open. When propagated to the right heart and pulmonary circulation, VAE can range in severity from subclinical to severe, precipitating acute hemodynamic collapse and death. In a patient with a patent foramen ovale—which is present in 25% of the general population and is often undetected—air can traverse to the arterial circulation, causing embolic stroke.

Although VAE can occur with other positions, the risk and severity are substantially higher in the sitting position, with recent reported incidences detected by precordial Doppler as high as 50% for minor and major VAE, and significant VAE causing hypotension at 2% to 6% (other literature using transesophageal echocardiography (TEE) for detection have reported even higher rates). Furthermore, the sitting position complicates the effective treatment of VAE, as it is difficult to rapidly lower the patient's head below heart level, and precludes easy access for airway manipulation and cardiopulmonary resuscitation maneuvers when required. The sitting position is also associated with a greater degree of hypotension (thus compromising CPP), an increased risk of pneumocephalus causing postoperative drowsiness, and compression of vulnerable structures including cervical spinal cord from neck flexion causing quadriplegia, oropharyngeal structures causing macroglossia, and peripheral nerves causing nerve palsies and pressure areas.

In the prone position, the head is usually slightly elevated above the heart; therefore, the risk of VAE remains present, although the risk of massive entrainment is reduced. Prone positioning can cause a significant decrease in pulmonary compliance and will increase ventilation/perfusion mismatch, leading to atelectasis, venous admixture, and shunting. Virtually no access is available to the airway, chest, or limbs, and in the event of an airway, pulmonary, or cardiovascular emergency, the prone position places the anesthesiologist in a substantially compromised position.

The supine position alleviates many of these issues. Nevertheless, to access even the lateral posterior fossa from the supine position usually requires substantial rotation of the neck. This can cause obstruction of jugular venous outflow, leading to cerebral venous engorgement, with potentially undesirable

effects on ICP, CPP, surgical exposure, and bleeding. The neck rotation can also cause brachial plexus injury as well as significant pressure on laryngeal structures with potential vocal cord injury. Placing supports to elevate the ipsilateral shoulder can reduce rotation at the neck.

B.6. How does the sitting position affect your preoperative assessment and planning?

In addition to the standard preanesthetic and neurologic assessment, preoperative evaluation should be focused on the following:

- *Presence of intracardiac shunts*. The presence of a patent foramen ovale, right-to-left intracardiac shunts, and pulmonary arteriovenous malformations are generally considered absolute contraindications to the sitting position due to the risk of VAE and subsequent paradoxical air embolism (PAE), which can have disastrous clinical consequences. In the era of increasing litigation, preoperative contrast echocardiography with Valsalva has become part of routine workup for those considered for elective sitting position craniotomy. However, there is a significant drop-off between the incidences of diagnosed VAE, PAE, and

subsequent neurologic sequelae. Therefore, in the rare patient with a demonstrated shunt that still requires sitting position craniotomy, it is not routine to proceed to percutaneous shunt closure. Rather, it serves to heighten the surgeon's awareness for absolute, meticulous control of venous bleeding because it is the presence of open entraining vessels that ultimately determines the risk of VAE.

- *Other complications of the sitting position and their impact on the patient*. General anesthesia in the sitting position is associated with a greater degree of hypotension compared with other positions. This is in large part due to venous pooling in the dependent portions of the body causing a fall in preload, coupled with anesthetic depressant effects on systemic vascular resistance and inotropy. This results in a fall in stroke volume and cardiac output, which is compensated in otherwise healthy patients with increases in heart rate and vasoconstriction. Conditions that exaggerate this fall in MAP include hypovolemia and preoperative diuresis, cachexia, advanced age, and therapeutic β-blockade, all of which can blunt compensatory autonomic responses. The concern with aggressive fluid loading intraoperatively is that it could run counter to the therapeutic goals of diuresis and ICP reduction, and the subsequent redistribution when returned to the supine position can cause an exaggerated increase in cardiac filling pressures. Furthermore, the use of vasoconstrictors to maintain adequate MAP in the face of a preload deficit increases the risk of end-organ hypoperfusion and dysfunction, particularly the kidneys. This is particularly relevant if electrolyte derangements coexist because they may worsen with perioperative renal injury.

The additional hydrostatic gradient between the heart and cerebral vasculature in the sitting position places the brain at a greater risk of hypoperfusion, particularly in patients who have

underlying carotid or vertebrobasilar atherosclerosis. This history should be actively sought because these patients may require higher MAPs intraoperatively to maintain adequate CPP, and intraoperative MAP measurements should be made at the level of the circle of Willis. There is also a hydrostatic gradient in lung perfusion when under positive pressure ventilation, with the lung apices being susceptible to hypoperfusion. Functionally termed West Zone 1, after the physician and physiologist John West, this area becomes alveolar dead space. A hallmark of increasing alveolar dead space is a broadening arterial–Et_{CO_2} gap, which places the patient at risk of hypercarbia and increased ICP if Et_{CO_2} is used as a surrogate for Pa_{CO_2} monitoring. Increases in alveolar dead space also place a greater ventilatory burden on the rest of the lung, which may be of particular concern in patients with obstructive airway disease, despite the gains in functional residual capacity and ventilation/perfusion matching in the dependent portions of the lung in the upright position.

Patients with cervical spinal stenosis and occult atlantoaxial instability are at an increased risk of cervical spinal cord ischemia from compression in the anterior flexed neck position and cord hypoperfusion for the reasons discussed earlier. Quadriplegia is a rare but well-documented complication of the sitting position. The patient should be carefully examined for motion that elicits neurologic symptoms, and these findings discussed with the neurosurgeon. Similarly, patients with macroglossia and obstructive sleep apnea should be identified because they are at risk of further airway swelling and potential obstruction postextubation due to direct compression and potential decrease in venous drainage. Finally, the presence of pressure sores and preexisting peripheral neuropathies should be evaluated because these can potentially worsen even with careful padding in the sitting position.

- *Invasive monitoring*. This involves planning for the detection and management of potential VAE as well as routine invasive arterial pressure monitoring. Patients with neck pathology, scarring from prior central access or irradiation, and morbid obesity can increase the difficulties of central venous or right atrial catheter placement and render emergency placement impossible. This may influence the decision to place a central line preoperatively under radiologic guidance. Collateral flow for arterial catheterization should also be assessed, and the patient interviewed for contraindications for TEE if it is a part of the management plan.

B.7. How should the patient position ultimately be determined?

This requires careful patient evaluation and clear communication between the surgeon and anesthesiologist. Surgical exposure should be a primary determinant for patient positioning; however, the vigilant anesthesiologist should be aware of specific patient conditions that may preclude certain positions, anticipate any physiologic insult that may result, and ensure adequate access and planning to treat these occurrences. If there are significant safety concerns, the anesthesiologist is obliged to discuss these with the neurosurgeon and advocate for

alternative positioning if appropriate. One such safety concern is the presence of patent foramen ovale or right-to-left intracardiac shunt. Other conditions may be amenable to a trial of positioning prior to anesthetic induction or surgery. For example, a patient with cervical spinal canal stenosis should be evaluated for neck and shoulder positions that precipitate neurologic symptoms. A patient with compromised pulmonary compliance or reserve can be positioned prone and monitored during other preparations, with alternative positioning sought if the trial fails.

It bears repeating that the risk of VAE is such that we are very reluctant to use the sitting position except where there are overwhelming surgical exposure considerations.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1868–1910.

B.8. Should this patient receive premedication?

Although preoperative anxiety is common among neurosurgical patients, pharmacologic premedication in patients with intracranial mass lesions presents risks that can result in neurologic decompensation, outweighing any benefit in reducing the sympathetic stress response and increasing patient satisfaction. It is prudent, therefore, to avoid sedative premedication outside of the operating room in these patients. Emphasis should instead be placed on nonpharmacologic methods to address anxiety, including a professional, empathetic preoperative visit from the neuroanesthesiologist. Psychoactive medications can unmask subclinical neurologic symptoms and can have lingering effects at the end of surgery, which at best confuses the postoperative neurologic examination, and at worse can contribute to a failure to emerge from anesthesia. Opioids can cause sedation, partial upper-airway obstruction, and hypoventilation, all of which lead to hypercarbia and increases

in intracranial blood volume. In patients with limited intracranial compliance reserve, this small degree of hypoventilation can lead to dangerous increases in ICP. For these reasons, it is imperative that sedating premedication only be administered in a fully monitored setting and under the direct supervision of an anesthesiologist who is able to rapidly intervene and take over ventilation. Once the patient is transferred to the operating room and monitored, we would then administer small doses of short-acting agents to facilitate placement of invasive monitors prior to induction as needed.

Oral dosing of gabapentin and clonidine will attenuate the hemodynamic instability resulting from laryngoscopy and head pinning when given before anesthetic induction and potentially decrease postoperative pain and nausea. The effects of clonidine can likely be mimicked by starting an infusion of dexmedetomidine—also an α_2-adrenergic agonist—as soon as the patient arrives in the operating room.

C. Intraoperative Management

C.1. What are the anesthetic goals for craniotomy?

It goes without saying that the anesthetic goals for craniotomy include the basic principles of physiologic stability that are

common to all anesthetic management. Additionally, craniotomy incurs several specific goals that follow from the effects—both helpful and unhelpful—of anesthetic drugs on the brain. In short, the anesthetic goals specific to craniotomy are to protect the brain from injury resulting from mechanical or physiologic insult during the perioperative period. *Direct* protection (often referred to simply as *neuroprotection*) can be conceptualized as actions that facilitate the ability of neural tissue to withstand ischemic episodes without inflammation or activation of the apoptotic cascade leading to infarction. Less discrete is the concept of *indirect* protection, which aims to minimize the anteceding ischemic episodes. The principal elements are as follows:

- Management of CBF and CPP
- Management of ICP while the skull is intact
- The provision of a "relaxed" brain. This optimizes surgical exposure, which is critically important in many cases because the field of view available to the surgeon in many craniotomy approaches can be extremely narrow. Furthermore, relaxation reduces the parenchymal pressure exerted by the retraction devices on underlying brain tissue.
- Implementation and timing of pharmacologic measures specifically intended to effect direct neuroprotection, traditionally involving anesthetic-induced burst-suppression pattern on the EEG (although experimental data suggest that anesthetics can be protective without burst suppression)
- Strict management of physiologic parameters that may contribute to brain injury, such as serum glucose, osmolarity, and acid–base balance
- Minimize the effect of anesthetic pharmacology, cerebral perfusion, and temperature on neurophysiologic monitoring, such as EEG, BAERs, or SSEPs.
- Facilitate early neurologic assessment.

C.2. What monitors should be used during craniotomy?

In addition to electrocardiography (ECG), noninvasive blood pressure, pulse oximetry, temperature, and capnography monitoring, an arterial line is considered mandatory for all except the most superficial and nonvascular supratentorial tumors, even in those without significant comorbidity. The real-time dynamic assessment of arterial pressure is of paramount importance in patients with intracranial pathology and impaired autoregulation, as CPP and CBF become entirely dependent on MAP. There are multiple occasions of high hemodynamic stress that require rapid measurement and management of blood pressure such as induction, intubation, head pinning, epinephrine infiltration of scalp, and emergence (intraoperative emergencies notwithstanding). It also allows for repeated arterial blood monitoring of CO_2, glucose, acid–base physiology, hematocrit, and electrolytes, all of which critically affect patient

management. A key concept in neuroanesthesia practice is to ensure the measured arterial blood pressure reflects cerebral inflow pressure. In the prone or sitting position, the head may be significantly higher than the level of the heart, so care must be taken to position the arterial pressure transducer at the level of the circle of Willis, which corresponds approximately to the level of the tragus.

The use of central venous and right heart catheters is less common in craniotomies, except in cases where the sitting position is planned, or where preexisting comorbidity or therapies require it. A central venous catheter allows the safe infusion of hypertonic saline and allows for air aspiration in the event of VAE, although its performance is variable. Beyond these reasons, there is little additional advantage in patient management. Because of this and the potential for complications in its placement, the placement of central lines is not routine in our practice.

Depth of anesthesia monitors, if surgical access allows, is commonly used in some institutions to allow for titration of anesthetic agent and for possible induction of burst suppression. It is rarely used in our practice, mostly because of our frequent use of intraoperative neuromonitoring, which provides similar useful data from the cortical tracing on SSEPs. The use of neurophysiology monitoring such as EEG, EMG, BAERs, or SSEPs is determined by the location of the tumor; although these methods are often performed by neurophysiologists, the anesthesiologist must understand the principles behind them and be aware of the effects of anesthetics, other drugs, and physiologic variables on their integrity.

Gropper MA, Cohen NH, Eriksson LI, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier; 2020:1868–1910.

C.3. Would you monitor for venous air embolism (VAE)?

What are the monitoring options?

VAE can potentially occur whenever there is an open venous channel beyond the venous fluid column to the heart. The sitting position confers the highest risk of VAE, although it is also been described in prone and lateral position craniotomies where the head is typically slightly elevated above the heart. An additional consideration is that the posterior fossa contains several major dural venous sinuses and their confluences, which are noncollapsible, drain into the internal jugular vein. For these reasons, any posterior fossa craniotomy, regardless of position, should be considered for VAE monitoring.

- TEE is the most sensitive monitor for VAE and PAE, able to detect volumes of 0.02 mL per kg in both the right and left heart, but is invasive and requires expertise in interpretation. Furthermore, it requires constant vigilance and can divide attention from other essential monitoring.
- *Precordial Doppler ultrasound* is noninvasive, highly sensitive (able to detect air volumes of 0.05 mL per kg), and is a part of our routine monitoring for posterior fossa craniotomies. It provides audible feedback, thereby minimizing distraction from other monitoring. However, the requirement for precise placement of the Doppler probe over the right heart becomes challenging when the variety of surgical positioning is considered and is particularly difficult in the prone position. This limits its sensitivity when applied in real-world scenarios. We find that rapid intravenous injection of 5 to 10 mL of saline is useful to ensure adequate detection of turbulent flow, which causes a characteristic coarse change in the basal “swishing” sound of normal pulsatile blood flow.
- *Pulmonary artery catheters* are a less sensitive detector of VAE (0.25 mL per kg air), and invasiveness generally limits use in patents with no other indication for right heart

monitoring. Characteristically, a sudden increase in pulmonary artery pressures occurs with VAE, first from reflex pulmonary vasoconstriction and later from the air lock formed by the embolus at right ventricular outflow tract.

- *End-tidal nitrogen (N_2) monitoring* is not routinely available on anesthesia gas monitors but is noninvasive and highly specific for air embolism. It is superior to Et_{CO_2} despite the latter's ubiquity, being more sensitive, specific, and rapidly responsive to air in the pulmonary circulation, but can be difficult to interpret when using air–oxygen carrier gas mixtures. Both end-tidal N_2 and CO_2 can be affected by pulmonary hypoperfusion.
- *Esophageal stethoscope* is discussed here for its historical interest in producing a characteristic mill wheel murmur but is too low in sensitivity (1.7 mL per kg air) and of limited use in detecting late, large VAE.

In our experience, the combination of precordial Doppler, Et_{CO_2}, and arterial pressure monitoring is minimally invasive and extremely effective at detecting clinically significant VAE.

The use of a right atrial catheter as a means to aspirate air should be considered in any situation when the risk of VAE is high. Catheter tip position, type, and size have been extensively studied over the years, but consensus on the ideal approach remains disputed. Large-bore (14 gauge), single-lumen, multiorifice catheters have performed best in animal and human studies. Traditionally, the ideal catheter tip position is 2 cm distal to the superior vena canal–right atrial junction. This can be established through TEE, radiographic or intravascular ECG guidance. In the last method, the patient is attached to standard three-lead ECG and the catheter inserted in the usual manner. The lumen is then flushed with sodium bicarbonate ($NaHCO_3$) to reduce electrical impedance along the catheter, and the right-

arm ECG lead is attached to a conductive connector placed on the line. The catheter should then be advanced into the right ventricle, which can be detected by transducing the pressure waveform. It should then be drawn back until the P wave on the catheter lead is biphasic (midatrium) and then back further to the point at which the P wave and QRS complex are of equal amplitude. The catheter is then pulled back another centimeter and secured. The right atrial catheter can confirm the presence of VAE through the aspiration of air, but its principal utility is therapeutic: It enables significant volumes of air to be rapidly extracted from the right atrium, thus breaking the "air lock" that causes the loss of cardiac output. Nonetheless, even under controlled conditions using ideal equipment, the success rate of air aspiration is 30% to 60% at best, and the catheter is liable to migrate as patient position is changed.

C.4. What specific risks are associated with induction of anesthesia?

The key considerations for anesthetic induction in the patient with marginal intracranial reserve include the onset of apnea and the hemodynamic effects of anesthetic agents and intubation. With prolonged apnea and hypercarbia, CBV and CBF increase, worsening ICP. Hypoxemia also has similar effects on ICP, although unless it is in the extremes, hypoxemia causes more

deleterious effects by impacting oxygen delivery to the brain.

Hypotension from induction agents compromises CPP, whereas hypertension with laryngoscopy and coughing from inadequate neuromuscular blockade abruptly increases CBF and CBV further. The end point of all these events is a tendency to increase ICP and reduce CPP, leading to decreased cerebral oxygen delivery, ischemia, and potentially herniation in a patient with minimal intracranial compliance.

C.5. How would you induce anesthesia?

In the absence of potential airway difficulty, the most common choice of anesthetic agents will involve an opioid, induction agent, and neuromuscular blocker. Benzodiazepines are not recommended due to their prolonged elimination and disinhibiting effects, especially in the elderly, and can delay awakening and cloud the postoperative neurologic examination. If preinduction anxiolysis is required, dexmedetomidine can be given as a preinduction infusion in the operating room during monitor placement and invasive access. It has advantages over benzodiazepines including preservation of respiratory effort, minimal disinhibition, and reduced interference with EP monitoring. The infusion can be continued through the case, with the additional benefits of MAC reduction and improved intraoperative hemodynamic stability.

A common induction technique is to coadminister large doses of opioid. This reduces the ED50 of intravenous anesthetic

dosing (thereby limiting postinduction hypotension), blunts the responses to intubation, and diminishes the hypertensive spike seen with head pinning. Fentanyl (slowly titrated to a total dose of 5 to 10 μg per kg), remifentanil bolus and infusion (1 μg per kg bolus, followed by infusion at 0.1μg/kg/min or a target effect site concentration of 3 ng per mL), and alfentanil (30 μg per kg bolus) are all effective regimens. Fentanyl has the advantage of achieving these characteristics without the inconvenience and technical risks of a continuous infusion but at the expense of titratability. All contribute to a relatively hemodynamically stable induction (especially with an appropriately decreased dose of the intravenous anesthetic agent) and steady maintenance levels, thereby extending MAC- and ED50-sparing effects through the procedure. If volatile agents are used, this allows us to run at less than 1 MAC (and typically at 0.5 to 0.6 MAC) with greater confidence in adequate anesthesia while limiting deleterious effects on ICP. Despite these advantages, high-dose opioids can cause significant sympatholysis, particularly in patients with a dominant sympathetic tone (such as the elderly), necessitating small doses of phenylephrine (40 to 120 μg) or ephedrine (5 to 10 mg) to support the cardiac output. All opioids given in high dose, particularly the more potent drugs such as remifentanil and alfentanil, can precipitate chest wall rigidity, which can compromise ventilation and increase ICP. Finally, it should be reiterated that this technique is only safe if there is certainty that immediate control of ventilation can be achieved.

Propofol is the induction agent of choice, given its favorable effects on CBF, $CMRO_2$, and ICP. However, its vasodilating and negative inotropic effects can cause significant hypotension even in the dose-sparing presence of opioids. With the loss of thiopental from our regular armamentarium, etomidate should be considered in patients where the cardiodepressant effects of

propofol are considered dangerous. Ketamine is inappropriate at induction doses in patients with marginal intracranial compliance due to increases in CBF, $CMRO_2$, and ICP, despite promising data of its protective effects in neurotrauma literature. An alternative is to add lidocaine 1.5 mg per kg to a high-dose opioid induction, which can further reduce the ED50 of the induction agent further.

Although succinylcholine is not contraindicated in patients with increased ICP, the risks and benefit should be assessed prior to its use. It is preferred in situations where a rapid sequence induction is required and IOM is proposed. However, because fasciculations can transiently increase ICP, it is recommended to administer a small precurarizing dose of nondepolarizing agent or lidocaine 1.5 mg per kg prior to the administration of succinylcholine. In recent years, with the increased availability of sugammadex, it would also be acceptable to consider using a rapid sequence induction dose of rocuronium with immediate reversal upon securing the airway. Sugammadex 16 mg per kg can be used for the reversal of neuromuscular block 3 minutes after administration of rocuronium allowing for adequate IOM. In most other situations, the use of nondepolarizing neuromuscular blockers is generally preferred.

C.6. What are the effects of anesthetics on cerebral metabolic rate of oxygen ($CMRO_2$), CBF, and ICP? With this in mind, how would you maintain anesthesia?

Volatile Anesthetics

Volatile anesthetics have the characteristic of being direct cerebral vasodilators while reducing $CMRO_2$ in a dose-related fashion. This has been described as an "uncoupling" the flow-metabolism relationship; however, autoregulation remains largely intact at doses of up to 1 MAC. It is more accurate to say that it is a balance between the reductions in $CMRO_2$ with the concomitant decrease in CBF, and the direct vasodilator effect, which causes an increase in CBF. At 1 MAC or greater, autoregulation is lost and the vasodilating effect becomes dominant. In most patients, this increased CBF would be potentially beneficial to the extent that it improves the supply–demand balance (termed *luxury perfusion*), with minor, compensated effects on ICP. In patients with intracranial pathology, however, this increase in CBF causes an increase in CBV and can potentially elevate ICP while the cranial bone is intact, or impede surgical exposure once the bone plate is removed. At doses below 1 MAC in the normal brain, this increase in CBV and ICP can be fully reversed by hypocapnia, as cerebrovascular CO_2 reactivity is preserved. However, as previously discussed, this is impaired or absent in pathologic states.

At equivalent doses, isoflurane causes the greatest decrease in

$CMRO_2$, which mitigates some of its direct cerebral vasodilator effect leading to a proportionately modest increase in CBF and ICP. Desflurane has effects similar to isoflurane but appears to cause greater increases in ICP on normocapnic patients and in those with intracranial mass lesions. Sevoflurane causes minimal or slight changes in CBF and ICP despite dose-related decreases in $CMRO_2$ and appears to have the most favorable characteristics in patients with raised ICP.

Additionally, all volatile anesthetics appear to exert neuroprotective effects. And although isoflurane has best been described in animal and human studies, sevoflurane appears to have a similar effect at clinical doses (**Table 17.6**).

TABLE 17.6 The Effects of Anesthetic Agents on Cerebral Blood Flow, Metabolism, and Intracranial Pressure

	CBF	$CMRO_2$	ICP
Nitrous oxide	↑↑	↑ or =	↑↑
Halothane (1 MAC)	↑↑↑	↓↓	↑↑
Isoflurane (1 MAC)	↑ or =	↓↓↓	↑ or =
Sevoflurane (1 MAC)	↓ or =	↓↓	↑ or =
Desflurane (1 MAC)	↑	↓↓	↑
Propofol	↓↓↓	↓↓	↓↓
Thiopental	↓↓↓	↓↓↓	↓↓
Ketamine	↑↑	=	↑ or =
Etomidate	↓↓	↓↓	↓
Fentanyl	= or ↓	= or ↓	=
Lidocaine	↓↓	↓↓	
Dexmedetomidine	= or ↓	= or ↓	=

CBF, cerebral blood flow; $CMRO_2$, cerebral metabolic rate of oxygen; ICP, intracranial pressure; MAC, minimum alveolar concentration.

Nitrous Oxide

Despite conflicting studies, N_2O is generally agreed to increase CBF, $CMRO_2$, and ICP. The difficulty with interpreting data on the cerebrovascular effects of N_2O is the heterogeneity of

existing literature, with large variations in the anesthetic regimens. When given as a sole agent or with minimal adjuvant anesthesia, N_2O markedly increases global CBF, $CMRO_2$, and ICP. This effect is preserved when N_2O is given together with volatile anesthetics, but attenuated with intravenous anesthetics are administered. As an *N*-methyl-D-aspartic acid (NMDA) antagonist, both neuroprotective and neurotoxic effects have been attributed to N_2O through its modulation of glutamate excitotoxicity. N_2O has also been shown to induce neuronal apoptosis via its effects on homocysteine and the formation of reactive oxygen species. At best, N_2O offers no neuroprotection, and at worst, its effects might be neurotoxic and counterproductive to surgical exposure. When considered together with its other detrimental effects, including the increased risk of vascular thrombosis, postoperative nausea and vomiting, and the potential expansion of air in the cranium and vasculature, the use of N_2O should be limited in craniotomies.

Intravenous Anesthetics

The intravenous anesthetics that act through GABAergic mechanisms (e.g., barbiturates, propofol, etomidate) cause a dose-dependent reduction in $CMRO_2$, CBF, CBV, and ICP. In contrast to volatile anesthetics, CBF–$CMRO_2$ coupling is preserved in the basal state, with no added vasodilatory effect. Thus, the direct effect of a drug such as propofol is to cause a reduction in $CMRO_2$, and the decreases in CBF, CBV, and ICP follow from intact normal physiologic responses. CO_2 reactivity is preserved. $CMRO_2$ can be reduced to as low as 40% of resting values in the presence of an isoelectric EEG. The preservation of CBF–$CMRO_2$ coupling affords many benefits but also carries an underappreciated risk: If hyperventilation is instituted, it will have an additive effect on the decreases in CBF caused by an

intravenous anesthetic. The result is an appreciable risk of inadequate CBF and hypoperfusion ischemia. It must be remembered that the mantra of "craniotomy → hyperventilation" owes its legacy to a time when most neuroanesthetics involved the use of MAC equivalents of vasodilating volatile agents. Etomidate impairs collateral perfusion of ischemic brain in animal experiments through inhibition of nitric oxide synthase and is thus relatively contraindicated in cerebral ischemia.

The NMDA-antagonist ketamine can increase $CMRO_2$, CBF, and ICP, although in small doses concerns about these effects are probably overstated. Indeed, although ketamine may change the oxygen supply–demand relationship in an adverse way, recent studies suggest that ketamine possesses direct neuroprotective effects, especially when combined with GABAergic agents. There is no definitive evaluation of its clinical use; nevertheless, judicious use of ketamine can probably be justified where there are appropriate indications.

Opioids

Broadly speaking, synthetic opioids such as fentanyl, alfentanil, and remifentanil have minimal effects or slightly decrease $CMRO_2$, CBF, and ICP. In human and animal studies, opioids appear to complement the cerebrovascular effects of the background anesthetic, displaying vasoconstrictor effects in the presence of vasodilating agents and minimal effects when used with vasoconstricting anesthetics. In the spontaneously breathing patient, however, it must be remembered that opioids cause hypoventilation and hypercarbia, leading to increases in CBF, CBV, and ICP.

Many neuroanesthesiologists favor a maintenance strategy of total intravenous anesthesia (TIVA) in an oxygen and air mixture, which is difficult to fault provided that hyperventilation

is not excessive. A TIVA approach maximizes the ability to reduce $CMRO_2$ without impairing surgical exposure through increased CBF or causing cerebral steal, but it incurs the disadvantage of complex pharmacokinetics. Other neuroanesthesiologists (including the authors) favor a mixed volatile-intravenous regimen as a primary strategy in most patients. We typically use 0.3 to 0.5 MAC equivalent of a volatile agent, with propofol titrated to the EEG as an end point. Dexmedetomidine and (usually high-dose) opioids are added to blunt hemodynamic responses and confer hemodynamic stability. This strategy causes a reduction in $CMRO_2$ but with minimal impairment of surgical exposure. Unless precluded by monitoring, a nondepolarizing muscle relaxant is added to ensure that the patient does not move while the head is fixed. We revert to TIVA if there is inadequate brain relaxation or if monitoring dictates.

C.7. How would you manage ventilation and maintain arterial carbon dioxide (CO_2)?

A reduction of $Paco_2$ decreases CBF and CBV within minutes. Therefore, hyperventilation is a rapidly effective measure that can be instituted to decrease ICP and undoubtedly can improve surgical exposure. Nevertheless, hyperventilation has substantial limitations. At $Paco_2$ values less than 25 mmHg, cerebral ischemia can result from a critical reduction in CBF combined with impaired oxygen unloading caused by a large left shift of the oxyhemoglobin dissociation curve due to respiratory alkalosis. Prolonged hyperventilation results in a compensatory loss of serum bicarbonate and can result in rebound acidosis if hyperventilation is rapidly terminated. Furthermore, hyperventilation-induced alkalosis decreases in ionized Ca^{2+}, leading to hemodynamic difficulties and prolonged emergence from effects on synaptic function.

It is important to remember that the difference between $Paco_2$ and $Etco_2$ can vary greatly. Therefore, arterial blood gas analysis should be performed as soon as possible after induction to establish the arterial–end-tidal gradient in CO_2 partial pressure. A $Paco_2$ of approximately 35 mmHg is reasonable unless ICP is elevated. If, once the bone plate is removed, the surgeons determine that exposure is suboptimal,

hyperventilation to a $Paco_2$ of 30 mmHg for a limited period is helpful for temporizing while other methods to improve brain relaxation are implemented. Further hyperventilation is reserved for situations in which establishing adequate exposure is extremely difficult. To avoid postoperative acid–base instability, hyperventilation can be gradually reduced throughout the closure, permitting reestablishment of bicarbonate and Ca^{2+} equilibrium.

C.8. How would you approach diuretic therapy?

The purpose of diuretic therapy in intracranial procedures is to dehydrate the brain, thereby leading to a reduction in the volume of the fluid compartment. This facilitates surgical exposure and reduces the requirement for brain retraction. Through the same principle, mannitol is used as therapy for elevated ICP states when the cranium is closed.

Mannitol is an osmotic diuretic that is usually prepared in a 20% solution (20 g per 100 mL). It should initially be given in a dose of 0.5 to 1 g per kg; the total dose can be increased to 1.5 g per kg if initial efforts are ineffective. Higher doses have been reported to lead to cardiac arrest from disruption of cardiac cellular function. Because mannitol initially draws water into the vascular space before it is excreted, rapid dosing can cause a transient increase in ICP, so it should be infused over 20 to 30

minutes. If there is very little intracranial compliance reserve, aggressive dosing should be synchronized with the removal of the bone plate.

If mannitol does not provide adequate surgical conditions, the loop diuretic furosemide can be used. In a naive adult patient, a dose as low as 5 mg might be adequate. Furosemide does not have the problem of an initial increase in vascular volume and so is preferred in patients with marginal cardiac function who can develop congestive heart failure with a large mannitol load. The combination of mannitol and furosemide can cause electrolyte abnormalities and severe systemic dehydration, placing the patient at risk for hemodynamic instability and cardiac arrhythmias. The use of point of care testing for electrolyte derangements is extremely useful in correcting acute changes in serum sodium and potassium. Because mannitol therapy alone is often adequate, we do not administer furosemide routinely, instead reserving its use for situations when surgical exposure is suboptimal. There is evidence in the neurocritical care setting that substituting loop diuretics with an aldosterone antagonist (which is potassium-sparing) may reduce the severity of potassium flux and arrhythmias; however, this is infrequently used in the perioperative arena.

In cases of extreme cerebral edema, hypertonic saline in concentrations of up to 20% can be used—although the most common concentrations used are 2% or 3%. This can be effective in refractory intracranial hypertension and might even be superior to mannitol for routine diuresis, particularly in patients with preexisting hypovolemia. Its use requires caution because of the risk of severe hypernatremia, and central access is required. Patients who are already receiving hypertonic saline should usually have the infusion maintained during the operative period.

C.9. How would you manage serum glucose?

Serum glucose control and its impact on critical care outcomes have been exhaustively studied in the last decade. There is, however, a paucity of literature specific to neurosurgical patients, and fewer yet focus on the influence of intraoperative glucose control on morbidity and mortality. To date, no study has definitively recommended one strategy over another for neurosurgical patients—much of the neuroanesthesiologist's practice is guided by the medical and general surgical critical care experience.

The relationship between glucose control and morbidity can be described as a U-shaped curve, with worsened outcomes seen with both hypo- and hyperglycemia. Hyperglycemia in neuroanesthesia is common, due to the surgical stress response and perioperative administration of steroids. It is associated with increased rates of infection and sepsis, renal insufficiency, and longer duration of intensive care admission. Conversely,

hypoglycemia is particularly detrimental to the brain, which is reliant on glucose as a major metabolic substrate.

The two dominant treatment strategies are intensive insulin therapy (IIT) to maintain serum glucose between 80 and 100 mg per dL, and standard therapy (ST) to maintain serum glucose below 180 mg per dL. Neurologic subgroup analyses of the landmark study by Van Den Berghe et al. suggested that IIT was associated with a reduction in ICP, seizures, critical illness polyneuropathy, and diabetes insipidus. More recent data from the Normoglycemia in Intensive Care Evaluation-Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) study investigators, however, did not demonstrate benefit in IIT over ST and actually suggested IIT might be harmful due to higher rates of severe hypoglycemia. This is supported by microdialysis studies in traumatic brain injury patients showing that IIT can cause precipitous neuroglycopenia and increase neuronal injury. For these reasons, it would be prudent to aim for serum glucose levels between 110 and 180 mg per dL in the intraoperative setting while taking meticulous care to avoid hypoglycemia.

C.10. How would you approach fluid management?

If the BBB is intact, the principal determinant of brain tissue water is the osmotic gradient across the BBB. It is this importance of osmotic gradient that guides the use of hypertonic solutions such as mannitol or hypertonic saline to reduce interstitial water and reduce ICP or to optimize surgical exposure. By the same principle, hypotonic solutions are rarely used because they favor the transport of water into the brain interstitium, thereby promoting the development of edema.

In regions where the BBB is not intact because of pathology and surgical tissue injury, osmotic particles can cross from the capillaries into the interstitial tissue. Therefore, the benefits of hypertonic solutions are lost in these areas. It follows that the benefit obtained from the use of hypertonic solutions is because of an *overall* effect on the brain, not from a *specific* effect in localized regions of brain injury.

These considerations favor the use of isotonic fluids as maintenance fluid in craniotomies. Conventionally, normal saline has been the preferred crystalloid solution; however, concerns over the risk of developing a non–anion gap, hyperchloremic metabolic acidosis has led to the use of other isotonic crystalloids such as Plasma-Lyte (**Table 17.7**). More controversial is the approach to volume management. Historically, craniotomy patients have been kept deliberately hypovolemic in the belief that this will increase the passage of free water from the brain in situations involving a disrupted BBB. Relatively recent evidence suggests that there is in fact

very little reduction in interstitial water and that it comes at the price of significant systemic hypoperfusion and hypotension. Therefore, the favored approach to fluid management is now maintenance of isovolemia with isotonic fluids. Dextrose-containing solutions should never be used except to treat hypoglycemia. Colloids such as 5% albumin can be used when volume expansion is a requirement. Albumin has a plasma half-life of 16 hours, and little is known about how the passage of albumin across a damaged BBB influences interstitial water movement over this time period. Therefore, its routine use is not recommended.

TABLE 17.7 The Osmolarity and Composition of Commonly Used Crystalloid Solutions

	Osmolarity (mOsm/L)	Sodium Concentration (mmol/L)	Chloride Concentration (mmol/L)
Plasma	280–300	140	100
0.9% Saline	308	154	154
Lactated Ringer's	273	130	109
Plasma-Lyte	294	140	98
5% Albumin	290	145	0

C.11. Once the bone plate is removed and the dura retracted, the surgeon reports that the brain is still "tight." What would be your response?

In almost all cases, the most effective initial response is to transiently increase hyperventilation to a $Paco_2$ of approximately 27 to 30 mmHg. If mannitol 1 g per kg has already been administered, small doses of intravenous

furosemide can be given until a diuresis is established. If a volatile agent is being used, this should be discontinued and the maintenance strategy converted to TIVA. If the patient has a CSF drain, this can be opened and CSF removed in no greater than 10- to 20-mL aliquots, with reassessment in between. Hypertension should be addressed and treated, and the patient should be well anesthetized to attenuate CBF responses to surgical stimulation. Positioning should be reassessed to eliminate any obstruction to jugular venous outflow. Deliberate hypotension can reduce swelling but incurs the risk of inadequate CPP and hypoperfusion ischemia and is thus instituted sparingly.

C.12. If deliberate hypotension is indicated, how will you achieve it?

Although sodium nitroprusside and volatile anesthetics are historically the most commonly used drugs to achieve sustained decreases in blood pressure, both are very far from ideal. Nitroprusside is highly effective and titratable over extremely short periods, but because it causes cerebral vasodilation, it can actually increase vascular engorgement. Nitroglycerin is also a potent cerebral venous vasodilator, and so it has the same limitation. Similarly, high levels of volatile anesthetic have direct cerebral vasodilatory effects. Furthermore, the uncoupled cerebral vasodilation caused by nitrates and volatile anesthetics can theoretically produce cerebral steal.

In most cases, the required level of blood pressure reduction can be achieved with the use of high-dose remifentanil (or other opioid) and propofol, possibly with the addition of a β-adrenergic blocker. Remifentanil enables a profound but rapidly reversible opioid level without unfavorable effects on CBF or vasodilation. Similarly, propofol can produce hypotension through systemic vasodilation but does not cause cerebral

vasodilation and is rapidly reversible. The mixed adrenergic receptor blocker labetalol is often effective as an adjunctive agent. However, the calcium channel blocker nicardipine is probably the most versatile drug for blood pressure control: It is titratable over relatively short periods and is an excellent choice if hypotension is required in situations in which opioids and anesthetic agents are not appropriate—such as during emergence or in the ICU—although it might impair autoregulation. Esmolol infusions can be utilized for a rapidly titratable β_1-adrenergic blockade but are not especially effective if the problem is refractory hypertension.

C.13. While the surgeon is resecting tumor from near the brainstem, the patient's heart rate suddenly drops to 20 beats per minute. What is your assessment and management?

Surgery near the brainstem nuclei can result in dramatic autonomic disturbances. Profound vagal reflexes can be alarming, sometimes resulting in asystole. These are often followed by a compensatory parasympatholytic-sympathetic reflex. Under such circumstances, the hemodynamics can shift from extreme bradycardia and hypotension to tachycardia and hypertension in a matter of seconds.

The first step is to alert the surgeon to stop operating, which almost always alleviates the problem. Once the hemodynamic

status has stabilized, an "autonomic blunting" prophylactic regimen can be given. Glycopyrrolate should be titrated until a 15% to 20% increase in heart rate is observed; if sympathetic reflexes are also involved, β-adrenergic blockade can be added. This approach is usually effective in attenuating the reflexes. In surgery in which an elevated risk of autonomic instability is present, the institution of parasympatholytic prophylaxis should be strongly considered from the outset.

The sudden development of bradycardia should always alert the anesthesiologist to the possibility of a sudden increase in ICP, leading to the Cushing reflex. In this case, hypertension would also be seen, and the surgeon should be immediately notified.

C.14. Are there any measures you can take to prevent VAE?

Prevention is the cornerstone to the management of VAE because current treatment methods of established VAE are limited in their efficacy. The best prevention of VAE is the neurosurgeon's meticulous control of venous bleeding and the tolerance of lower head positions. Extra vigilance on the part of the neuroanesthesiologist also plays an important role—observing a lack of bleeding on the cut edge of bone during removal of the craniotomy bone flap is an early sign of negative venous pressure and an increased likelihood of VAE. Active measures to reduce VAE include raising the venous fluid column by ensuring adequate hydration, and minimizing venous capacitance through the use of pneumatic calf compression

devices and avoidance of venodilators such as nitroglycerin. The use of positive end-expiratory pressure (PEEP) is controversial: PEEP increases cerebral venous pressure and can reduce the risk of entrainment, but it also increases surgical bleeding and can potentially impede CPP. It promotes right-to-left intracardiac shunting, which increases the risk of PAE in susceptible patients, and sudden releases of PEEP (such a ventilator adjustment, or a recruitment maneuver performed during craniotomy) can increase air entrainment as well as the propagation of PAE. We recommend a limitation of PEEP to <5 cm H_2O and only as a means to optimize patient oxygenation. The use of N_2O has clear theoretical disadvantages in posterior fossa craniotomy, not only in the risk of expanding subclinical intravascular air but also in postoperative tension pneumocephalus. Although there is no clear clinical data to demonstrate these associations, its additional adverse effects on CBF and metabolism, ICP and neurotoxicity makes it difficult to justify its use, particularly with the easy availability of excellent alternatives in neuroanesthesia.

Giebler R, Kollenberg B, Pohlen G, et al. Effect of positive end-expiratory pressure on the incidence of venous air embolism and on the cardiovascular response to the sitting position during neurosurgery. *Br J Anaesth*. 1998;80:30–35.

C.15. During the procedure, the precordial Doppler becomes loud and turbulent. The end-tidal CO_2 ($EtCO_2$) drops from 31 to 13 mmHg, and the systemic pressure from 121/63 to 64/32 mmHg. What is your

assessment and management plan?

This is a classic presentation of VAE. Immediately inform the surgeon, institute 100% oxygen, and call for skilled assistance. The surgeon should flood the field with saline and urgently prepare the field for lowering the head (e.g., placement of a protective drape over the operative site, adjusting the head fixation device to allow for position change). Where possible, an assistant should reach under the drapes and apply pressure to the jugular veins to prevent further entrainment (but not enough to occlude carotid flow), although this should be only a transient measure. If a right atrial catheter is in place, an attempt should be made to aspirate air with a large syringe (enough to accommodate 15 to 20 mL air). Intravenous fluids should be opened to full flow, and inotropes and vasopressors should be titrated to support the altered hemodynamics. The head should then be lowered to a level below the heart, or as much as possible. The left lateral decubitus position has been advocated but is probably of little benefit.

If the VAE is detected early, the episode will usually resolve. It is almost always appropriate to resume and complete the surgery, although placement of additional monitors before resumption might be warranted. Undetected, massive, or prolonged entrainment of air can lead to cardiac arrest. If cardiac arrest is present or imminent, and the patient is in a prone or semiprone position, the anesthesiologist must prepare the surgeon and others in the room for an emergent move to the supine position to enable resuscitation. For this reason, a stretcher must always be available outside the operating room when patients are in the prone position.

vascular air embolism. *Anesthesiology*. 2007;106:164–177.

C.16. What is your approach to emergence? What if the patient does not regain consciousness?

Providing an early neurologic assessment is one of the most valuable contributions of the anesthesiologist to outcome in neurosurgical patients. Therefore, it is imperative to have patients emerge quickly, even when surgery has been prolonged. At the same time, the emergence from anesthesia incurs substantial changes in pressure, $Paco_2$, CBF, and autonomic activity and therefore must be carefully planned. Transitioning from hyperventilation should be gradual in order to prevent rebound acidosis. Adrenergic blocking agents should be administered to attenuate the sympathetic effects often seen during and following emergence in these patients. Nicardipine or labetalol can be considered if the patient exhibits refractory hypertension or hyperreactivity. Reversal of neuromuscular block should be carefully titrated to avoid autonomic instability, with care taken to ensure that the patient does not move while the head is fixed in pins. Antiemetic therapy should be aggressive because the elevation in ICP caused by retching and vomiting are particularly undesirable in craniotomy patients.

Coughing or "bucking" during emergence causes dramatic spikes in ICP and must be avoided. Several approaches can be used to avoid this, including the use of intravenous lidocaine, an opioid-based anesthetic, or a deep extubation. In the case of a deep extubation, it must be kept in mind that there is always a risk that an intraoperative neurologic event might cause delayed or failed emergence. A strategy of converting the final phase of the anesthetic to a high-dose remifentanil 0.3 to 0.4 μg/kg/min infusion can be highly effective and enables the volatile agent to be eliminated without the patient reacting. After return of ventilation and cognition, remifentanil infusion is stopped and

the patient's trachea is extubated.

A failure to emerge can represent a neurologic event resulting from the surgery (such as an intracranial bleed, vessel occlusion, embolic event, or seizure), metabolic derangements, or a pharmacologic effect. In such cases, the time to diagnosis is a critical determinant of outcome. The anesthesiologist must be able to state with confidence that the delayed emergence is unlikely to be pharmacologic. A rapid assessment can be made in the operating room to exclude nonneurologic causes of failure to emerge (**Table 17.8**); unless there is a clear cause found, a computed tomography (CT) scan should immediately be performed. Should this be necessary, the operating room should be left available in the event that an emergent return is required.

TABLE 17.8 Rapid Assessment of Persistent Coma Immediately Postcraniotomy

Intervention	Assess Cause of Coma
Pupillary exam	• New anisocoria suggesting herniation • Pinpoint pupils suggesting narcotic overdose • Dilated reactive pupils suggesting central anticholinergic syndrome
Arterial blood gas with electrolyte and glucose analysis	• Hypoxia • Hypercarbia • Acidosis • Hypoglycemia/hyperglycemia • Hyponatremia/hypernatremia
Processed electroencephalogram (e.g., BIS monitor, IOM)	• Assess depth of anesthesia • Seizure activity
Nerve stimulator	• Deep neuromuscular blockade
Core temperature	• Hypothermia
Review medication syringes, infusions, vaporizer	• Inadvertent overdose • Medication swap • Consider reversal agents: – Naloxone in 40 μg aliquots, up to 400 μg – Flumazenil 200 μg aliquots, up to 1 μg – Physostigmine 1.25 mg, if centrally acting anticholinergics administered
CT scan	• Hemorrhage

	• Thrombosis (consider basilar artery thrombosis) • Pneumocephalus • Cerebral edema
Other considerations	• Hypothyroidism • Addisonian crisis

BIS, bispectral index; CT, computed tomography; IOM, intraoperative neurophysiologic monitoring.

In some posterior fossa procedures—especially when near the brainstem—postoperative edema can lead to an anticipated worsening of neurologic status before subsequent improvement on the first or second postoperative day, thereby necessitating prolonged intubation. In these cases, the patient can be awakened at the conclusion of the surgery and once a neurologic assessment is obtained, resedated for transport to the ICU. A remifentanil infusion of approximately 0.1 μg/kg/min usually enables an intubated patient to perform a cognitive examination and tolerate the presence of the endotracheal tube.

D. Postoperative Management

D.1. What postoperative complications are of greatest concern? What level of monitoring is required?

Part of the neurologic assessment conducted immediately on emergence should be an evaluation of the lower cranial nerves. Damage to the nerves or to nuclei can result in difficulty swallowing and protecting the airway. The principal concern is the development of edema or hematoma causing compression of the brainstem or midbrain structures. The brainstem sits in an

anatomic location with very low compliance; even small degrees of edema that would be well tolerated following supratentorial procedures can lead to catastrophic neurologic compromise. It is critical to appreciate that edema and hematoma can develop over the course of several hours following the procedure; a patient who had a satisfactory emergence might deteriorate neurologically in the middle of the night. In certain circumstances, the risk of postoperative edema is so high that the patient is left intubated prophylactically, as discussed earlier. Deterioration cannot always be anticipated, and these patients should be initially monitored in an intensive care setting in all cases.

D.2. What is your approach to postoperative pain control?

Optimal pain control after craniotomy has traditionally been hampered by several challenges. First is the misconception that craniotomy and tumor resection causes minimal pain, despite the rich nociceptive afferents to the meninges, dura, falx, and calvarial periosteum. Using traditional analgesic approaches, nearly 70% of postcraniotomy patients experience moderate to severe pain on the first postoperative day, and just under half continue to do so on the second postoperative day.

Another dogma that persists to this day is that most analgesics are dangerous for the postcraniotomy patient and should be dosed sparingly. Concern remains that opioids have the potential

to cause sedation and respiratory depression in the neurologically vulnerable patient. Despite this, patient-controlled analgesia (PCA) opioid regimens have been used safely in supra- and infratentorial postcraniotomy patients, improving both pain control and patient satisfaction.

In addition to opioid PCAs, we suggest a multimodal approach to minimize opioid use and their side effects. Acetaminophen is nonsedating and safe in recommended doses in the absence of liver disease. Neurosurgeons have traditionally avoided nonsteroidal anti-inflammatory drugs (NSAIDs) in the perioperative period due to risk of postoperative hematoma, although what little evidence exists is not robust. Nonetheless, it behooves the neuroanesthesiologist to discuss the use of NSAIDs with the surgeon before prescribing. Scalp blocks or scalp infiltration performed at the end of surgery have little morbidity and improve pain control in the early postoperative period. Although this effect is not sustained beyond the first postoperative day, there is evidence to suggest this technique reduces the development of chronic postcraniotomy pain. An alternative option would involve regional blockade of the lesser and greater occipital nerves by the anesthesiologist. Preferably, these would be done immediately prior to surgery as anatomy may be altered by the surgical procedure. These have proven to be an effective alternative to scalp block for craniotomy and have longer duration of analgesia. Preinduction gabapentin, in addition to its beneficial effects on minimizing the hemodynamic response to laryngoscopy and head pinning, also decreases postoperative pain and opioid requirements, although it may result in greater sedation and slow emergence. Tramadol has been used successfully for postcraniotomy pain; however, due to its increased risk of nausea and vomiting, and the lowering of the seizure threshold, we do not recommend it as part of a first-line analgesic regimen.

D.3. In the ICU, the patient's neurologic status deteriorates and ICP monitoring is instituted. What are the different methods of monitoring ICP, and what are their limitations?

ICP monitoring is commonly used in neurosurgical critical care as a marker of intracranial compliance and to allow a more objective calculation of CPP. Typically, an ICP monitor is placed at a discrete anatomic point of measurement, and data from this monitor is extrapolated to the whole brain. It is

important to remember, however, that significant differences in regional ICP can exist, particularly in patients where there is a pathologic disruption of normal CSF circulation. In the case of this patient, for instance, an ICP monitor positioned in the supratentorial region may not accurately represent the pressure in the posterior fossa.

There are many methods of ICP monitoring available, differing on the basis of invasiveness, site of measurement, and degree of validation. An external ventricular drain (EVD) is considered the gold standard and allows for both ICP measurement and CSF drainage to treat intracranial hypertension (although not simultaneously). The catheter tip is introduced into one of the lateral ventricles via a blind technique or with imaging guidance and connected to a fluid column with a pressure transducer and drainage system. It is the most invasive method of ICP monitoring and is associated with significant rates of intracranial infection and bleeding during placement. Other limitations of the EVD include difficult placement in patients with midline shift, catheter malfunction, and potential CSF overdrainage. An alternate method of measuring ICP is through the use of microtransducers. These devices transduce an external force (e.g., applied by edematous brain tissue) to an alteration in electrical or light signal. Fiberoptic devices transmit light to a flexible reflective tip that is displaced by an external force, and the change in light reflection is extrapolated into a change in ICP. Similarly, electronic strain gauge devices are deformed by external pressure thereby inducing a change in electrical resistance. These devices are miniaturized to the extent that their placement into brain parenchyma would cause little damage and are typically secured to the skull with a bone bolt. Depending on manufacturer, microtransducers may also be introduced into the subarachnoid, epidural, or subdural spaces, with some attrition in accuracy.

The primary advantages of microtransducers are the decreased rate of intracranial infection, the absence of catheter-related malfunction, and the stability of the fixation bolt. However, these devices are prone to zero drift over time (between 1 mmHg per 1 to 5 days) and cannot be re-zeroed without removing the device entirely. Further limitations include local sampling of parenchymal pressure and significantly higher cost compared to catheter systems.

More recently, the use of transcranial Doppler (TCD) has been proposed as an alternate, noninvasive method of ICP and CPP measurement. This method analyzes middle cerebral artery flow characteristics for degree of pulsatility. This pulsatility index (PI) has been used as a surrogate measurement of a variety of neurovascular parameters, including cerebrovascular resistance, vasospasm, and CPP. Although initial reports showed good correlation between TCD-PI and ICP, subsequent studies have revealed wide discrepancies in predicted ICP and measured ICP with a catheter-based system. Further investigations are needed before TCD can be considered an acceptable alternative to invasive methods of ICP measurement.

18 Carotid Artery Disease

Priscilla Nelson and Hugh C. Hemmings Jr.

An 85-year-old woman is scheduled for a left carotid endarterectomy (CEA) for asymptomatic left carotid stenosis. She has 90% occlusion of her left carotid artery and 60% occlusion of the right carotid artery. Her past medical history is remarkable for hypertension, insulin-dependent diabetes mellitus, and coronary artery disease. She had coronary artery bypass surgery 4 years ago. Her blood pressure is 170/80 mmHg, and her pulse is 59 beats per minute and regular.

A. Medical Disease and Differential Diagnosis

1. What are the presenting symptoms of carotid stenosis?
2. What is the prevalence of carotid artery disease?
3. What is the natural course of carotid artery disease as it relates to stroke?
4. What in the patient's history puts them at higher risk for having carotid atherosclerosis?
5. Do we screen patients for asymptomatic carotid stenosis?
6. What is the risk of stroke and cardiovascular events in asymptomatic carotid atherosclerosis?
7. What are the current medical options that the patient has for treating carotid atherosclerosis?
8. What are the indications for CEA and carotid artery stenting

(CAS) in asymptomatic carotid atherosclerotic disease?

9. What are the indications for performing a CEA in symptomatic carotid stenosis?
10. Is there any role for CAS in symptomatic patients?
11. Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.
12. Discuss cerebral blood flow (CBF) in the presence of carotid artery disease.
13. Discuss the different surgical approaches to carotid revascularization.
14. Discuss the endovascular approaches to carotid stenting.
15. What is normal CBF?
16. What is critically low CBF as measured by the electroencephalogram (EEG)?
17. What is cerebral autoregulation?
18. How does $Paco_2$ affect CBF?
19. What are the principal determinants of CBF?
20. What is meant by the term *luxury perfusion*?
21. What is meant by the term *intracerebral steal*?

B. Preoperative Evaluation and Preparation

1. What will you look for in your preoperative evaluation of this patient?
2. Is this patient's blood pressure too high for elective surgery?
3. What laboratory data are required preoperatively?
4. Will you treat this patients' blood glucose?
5. Will you premedicate this patient?

C. Intraoperative Management

1. How will you monitor this patient?
2. How will you know that the patient's cerebral perfusion is adequate during surgery?
3. Discuss the differences and relative advantages and disadvantages of unprocessed EEG and processed EEG

monitoring.

4. How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique?
5. Describe the use of stump pressure and its limitations.
6. Describe the use of transcranial Doppler (TCD) and its limitations.
7. Describe the use of jugular venous oxygen saturation ($SjvO_2$) and its limitations.
8. Describe the use of cerebral oximetry and its limitations.
9. Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during CEA.
10. What type of anesthesia will you choose for this patient if she chose to have an endarterectomy?
11. What type of anesthesia will you choose for this patient if she chose to have a carotid stent?
12. How will you induce and maintain general anesthesia in this patient for CEA?
13. How would you proceed if the patient were to receive regional anesthesia?
14. Discuss the effects of anesthetics on CBF.
15. Discuss the protective effects of anesthetic agents on cerebral function.
16. How will you manage this patient's ventilation under general anesthesia?
17. How will you manage this patient's blood pressure intraoperatively?
18. Discuss reperfusion injury following CEA and CAS.
19. What intravenous fluids will you give this patient intraoperatively?

D. Postoperative Management

1. The patient does not "wake up" from general anesthesia. Why?
2. Postoperatively, the patient's blood pressure is 170/96 mmHg.

Will you treat this?

3. What immediate postoperative complications might you expect after a CEA?
4. What postoperative complications might you expect after a CAS?
5. Discuss postoperative neurocognitive dysfunction following uncomplicated carotid intervention.

A. Medical Disease and Differential Diagnosis

A.1. What are the presenting symptoms of carotid stenosis?

Carotid stenosis is often asymptomatic, only to be discovered on physical exam as a carotid bruit or incidentally on imaging.

- Symptomatic carotid stenosis presents with focal neurologic deficits in the corresponding carotid artery territory. These focal neurologic deficits can be characterized as a transient ischemic attack (TIA) or ischemic stroke. A TIA is a transient focal neurologic deficit attributable to a vascular cause **without** corresponding appropriate lesions on imaging.
- An ischemic stroke is characterized by an acute onset of focal neurologic symptoms that leaves permanent injury either seen clinically, or by appropriate corresponding lesions on imaging. Ischemic symptoms from carotid stenosis originate from the vascular distribution supplied by the internal or external carotid artery. The symptoms can be from artery-to-artery embolization of the plaque or from cerebral hypoperfusion caused by the stenotic lesion.
- Ischemic symptoms can be divided into three main categories: (1) Ocular ischemia or infarction, (2) ipsilateral hemispheric signs, and (3) atypical symptoms. Ocular ischemia or infarction symptoms include partial or complete blindness in one eye. Ipsilateral hemispheric signs include

contralateral homonymous hemianopsia, hemiparesis, or hemisensory loss. Specific ischemic signs associated most commonly with left-side lesions include aphasia, whereas right hemispheric symptoms can include visuospatial neglect. Atypical symptoms include unilateral limb shaking and transient monocular vision loss when exposed to bright light, which can also occur from ischemia downstream to the embolus.

A.2. What is the prevalence of carotid artery disease?

Carotid artery disease is a marker of generalized arteriosclerosis. The prevalence of asymptomatic carotid disease, which is defined as stenosis greater than 50%, ranges from 4% to 8%. In a meta-analysis of 40 studies, the prevalence of moderate stenosis increased with age in both men and women. Men at all ages have the highest prevalence estimates. Approximately 10% to 15% of strokes (approximately 200,000 strokes per year) in the United States are attributable to carotid stenosis.

A.3. What is the natural course of carotid artery disease as it relates to stroke?

Carotid artery disease carries a typical natural course of plaque development, which is cumulative. Continued development leads to possible stenosis or the possibility of plaque rupture. Atherosclerosis in the extracranial carotid arteries is usually most severe within 2 cm of the bifurcation of the common carotid artery. Atherosclerotic lesions are predominantly found in the posterior wall of the internal carotid artery. Over time, the plaque extends proximally into the common carotid artery and the stenotic lesion takes on an hourglass shape. Extracranial carotid atherosclerotic disease can lead to stroke by embolism of cholesterol crystals or debris, artery-to-artery embolism, dissection or disintegration of arterial wall, and decreased cerebral perfusion because of the stenosis causes by plaque buildup. Although the risk of stroke has historically been correlated to the degree of carotid stenosis, new markers for plaque vulnerability as it relates to disease severity are emerging. They include plaque progression, ulcerations seen on plaques, echo-lucency, intraplaque hemorrhage, and high lipid content of the stenotic lesion. The risk factors for the development of carotid artery disease are similar to those causing atherosclerotic occlusive disease in other vascular beds, namely, increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia.

Mathiesen EB, Joakimsen O, Bønaa KH. Prevalence of and risk factors associated with carotid artery stenosis: the Tromso Study. *Cerebrovasc Dis*. 2001;12:44–51.

A.5. Do we screen patients for asymptomatic carotid stenosis?

The prevalence of asymptomatic carotid atherosclerosis in the general population is approximately 3%. The U.S. Preventive Services Task Force (USPSTF), American College of Cardiology and American Heart Association (AHA) and American Stroke Association (ASA) recommends against routine screening.

Brott TG, Halperin JL, Abbara S, et al. 2011 ASA/ACCF/AHA/AANN/AANS/ACR/ASNR/CNS/SAIP/SCAI/SIR/SNIS/SV guideline on the management of patients with extracranial carotid and vertebral artery disease: executive summary. *Circulation*. 2011;124:489–532.

Wolff T, Guirguis-Blake J, Miller T, et al. Screening for carotid artery stenosis: an update of the evidence for the U.S. Preventive Services Task Force. *Ann Intern Med*. 2007;147:860–870.

A.6. What is the risk of stroke and cardiovascular events in asymptomatic carotid atherosclerosis?

Although ischemic stroke is the most feared event with carotid atherosclerosis, the estimated risk is approximately 0.5% to 1% per year ipsilaterally in patients with >50% stenosis. Asymptomatic carotid stenosis is considered a risk equivalent for coronary artery disease and is a marker for increased risk of myocardial infarction (MI) and death.

Goessens BM, Visseren FL, Kappelle LJ, et al. Asymptomatic carotid artery stenosis and the risk of new vascular events in patients with manifest arterial disease: the SMART study. *Stroke*. 2007;38:1470–1475.

Spence JD. Management of asymptomatic carotid stenosis. *Neurol Clin*. 2015;33:443–457.

A.7. What are the current medical options that the patient has for treating carotid atherosclerosis?

Best medical therapy was outlined by the Asymptomatic Carotid Surgery Trial (ACST) and includes the use of a 3-hydroxy-3-methylglutaryl-coenzyme (HMG-CoA) reductase inhibitors, aggressive blood pressure control with antihypertensive drugs, strict glycemic control for patients with diabetes mellitus, smoking cessation, and the use of antiplatelet drugs.

Meschia JF, Bushnell C, Boden-Albala B, et al. Guidelines for the primary prevention of stroke: a statement for healthcare professionals from the American Heart Association/American Stroke Association. *Stroke*. 2014;45:3754–3832.

A.8. What are the indications for CEA and carotid artery stenting (CAS) in asymptomatic carotid atherosclerotic disease?

The recommendation for surgical treatment by many societies are based on three major trails that took place in patients with asymptomatic carotid stenosis: the Veterans Administration (VA) trial, the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial, and the ACST trial.

The indications differ by society. The AHA and the ASA note the following with respect to CEA: If the risk of perioperative stroke, MI, and death are low (<3%), it may be reasonable to consider CEA in asymptomatic patients with >70% stenosis. AHA/ASA with respect to CAS: In asymptomatic patients with >60% stenosis by angiography or >70% by duplex ultrasound, prophylactic CAS might be considered but its effectiveness compared to medical therapy is not well established.

The Society for Vascular Surgery notes the following: Asymptomatic patients with >60% diameter stenosis CEA should be considered if the patient has a 3- to 5-year life expectancy and the perioperative and death rates are less than 3%. They do not recommend CAS for asymptomatic patients because there are insufficient data.

There are three main trials that examined carotid stenting *versus* endarterectomy for asymptomatic stenosis. They include the Asymptomatic Carotid Trial (ACT) 1 trial, the Carotid Revascularization Endarterectomy Versus Stenting (CREST) trial, and the Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial. A meta-analysis of these trials indicated that both endarterectomy and CAS are viable long-term options for patients with carotid atherosclerosis. The evidence suggests that the 30-day risk of stroke or death is higher with CAS compared to CEA, but after

30 days the risk of stroke and death are similar. Patients older than 70 years of age had poorer outcomes with stenting than endarterectomy.

Significant progress has been made since the late 1980s and early 1990s when the major CEA trials were underway. At that time, the best medical treatment was antiplatelet therapy with aspirin. Since then, the utility of statins, antihypertensive drugs, smoking cessation, and lifestyle modification has been shown. This change in medical therapy and its effect on carotid stenosis became apparent from the ACST. Over the 10-year course, statin usage became more prevalent from 17% in 1993 to 1996 to 58% from 2000 to 2003. With this modern multimodal approach to medical therapy, many experts argue that the gap between medical and surgical treatment of carotid disease has narrowed for reducing the risk of stroke.

If a surgical option is chosen, keep in mind that it is a long-term investment and that the benefit may not be apparent until 2 years or more. Also, trials show that there was a trend toward CEA being less effective in women and older individuals and that these procedures should be performed at institutions where the perioperative stroke and death rates are less than 3%. Contralateral stenosis also matters when considering a surgical option. When a subgroup analysis was performed, CEA with contralateral total occlusion provided no long-term benefit.

A.9. What are the indications for performing a CEA in symptomatic carotid stenosis?

Symptomatic carotid stenosis is defined as focal neurologic symptoms, attributable to the appropriate carotid distribution, that have occurred within the past 6 months. Decisions for care in symptomatic disease come from three main trials, which

include the North American Symptomatic Carotid Endarterectomy (NASCET) trial, the European Carotid Surgery Trial (ECST), and the VA trials.

Guidelines issued in 2014 by the AHA/ASA make the following recommendations with respect to CEA:

- CEA is recommended for severe symptomatic stenosis (70% to 99%) as long as the perioperative morbidity and mortality risk is estimated to be less than 6%. The number needed to treat (NNT) to prevent one stroke at 5 years is 6.3.
- CEA is also recommended for moderate symptomatic patients (50% to 69% stenosis) depending on patient characteristics if the perioperative morbidity and mortality risk is estimated to be less than 6%. The NNT to prevent one stroke over 5 years is 22 in moderate symptomatic stenosis.
- CEA or stenting (CAS) is not recommended for less than 50% stenosis. Carotid revascularization was found to be harmful for symptomatic patients with less than 30% stenosis.

In studies leading to these recommendations, surgeries were performed at high-volume centers where the combined morbidity and mortality did not exceed 6%. Although it may be difficult to decipher one surgeon or institution morbidity or mortality rate, a rate over 6% can negate the benefit gained from a CEA. Other factors that may impact the benefit gained from CEA include timing of surgery, age, sex, presenting symptoms, and plaque morphology. There is evidence that performing CEA within 2 weeks of a nondisabling TIA or stroke improves outcomes compared with later surgery, but that performing it within 48 hours of a stroke or TIA leads to an elevated risk of stroke. This decline in benefit with time was more rapid with women than men. It was also noted that women who did not have their CEA within 2 weeks did not gain any benefit from the procedure irrespective of degree of stenosis. Best medical therapy has also improved significantly from when the first CEA

trials in the 1980s were started. As such, the NNT may be higher to prevent one stroke today with current medical therapy.

A.10. Is there any role for CAS in symptomatic patients?

CAS and CEA achieve similar long-term outcomes for symptomatic disease, but the periprocedural stroke or death rate was greater with CAS than CEA. The increased risk of stroke was only found in patients over 70 years of age. Although old age was originally proposed to be high risk for surgery and therefore an indication for stenting, studies have shown that older adults have worse outcomes with CAS. Age above 70 years linearly correlated with the risk of stroke during CAS. The CAS group had a lower rate of MI, cranial nerve palsy, or access site hematoma.

The guidelines issued in 2014 by the AHA/ASA make the following recommendations with respect to CAS.

CAS is indicated as an alternative to CEA for symptomatic patients at average or low risk of complications associated with endovascular intervention for stenosis >70% by noninvasive imaging or >50% with angiography as long as the anticipated perioperative morbidity and mortality is less than 6%.

Consider patients age when choosing between CEA and CAS as patients older than 70 years may have improved outcomes

with CEA. For patients younger than 70 years, CAS is equivalent to CEA with respect to periprocedural complications namely stroke, MI, and death.

CAS is reasonable for patients with symptomatic severe stenosis who have anatomic or medical conditions that greatly increase the risk of surgery.

Carotid revascularization is not recommended for patients with severe disability caused by cerebral infarction that precludes useful function or for patients with chronic total occlusion of the targeted artery. Conditions thought to increase the risk for surgery include radiation-induced stenosis, contralateral vocal cord paralysis, and tracheostomy.

A.11. Discuss the anatomy of the cerebral vasculature, including the carotid artery and the circle of Willis.

The common carotid arteries originate in the thorax. The right common carotid artery originates at the bifurcation of the brachiocephalic trunk, and the left originates from the aortic arch. In the neck, the common carotid arteries travel within the carotid sheath. At the level of the thyroid cartilage, each common carotid artery bifurcates into the internal and external carotid arteries.

Branches of the external carotid artery include the superior thyroid, lingual, facial, ascending pharyngeal, occipital, posterior auricular, maxillary and superficial temporal arteries.

The internal carotid artery passes through the neck without branching to enter the middle cranial fossa. It enters the middle cranial fossa through the carotid canal of the temporal bone, adjacent to the sphenoid bone. It supplies the hypophysis cerebri, the orbit, and the major portion of the supratentorial region of the brain. The cerebral arteries are derived from the internal carotid and vertebral arteries. The anastomosis they form at the base of the brain is known as the *circle of Willis* (**Fig. 18.1**). The two anterior cerebral arteries form the circle anteriorly. They are connected through the anterior communicating artery. The two posterior cerebral arteries form the circle posteriorly, which then ends at the junction of the basilar artery. The posterior cerebral arteries are connected to the internal carotid arteries by the two posterior communicating arteries. The middle cerebral artery primarily supplies the lateral surface of each cerebral hemisphere. The anterior cerebral and posterior cerebral arteries supply the medial and inferior surfaces of the cerebral hemisphere.

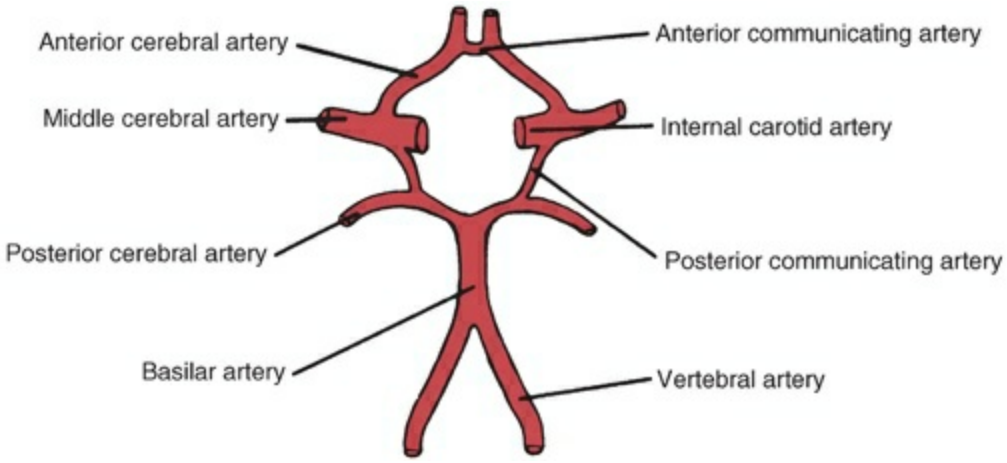

FIGURE 18.1. Arterial circle of Willis.

Moore KL. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006:930–931.

A.12. Discuss cerebral blood flow (CBF) in the presence of

carotid artery disease.

Stable CBF is maintained within a given range of systemic blood pressure through autoregulation and collateral flow. Whereas most studies focus on the degree of carotid stenosis and the risk of stroke, emerging evidence indicates that downstream hemodynamic effects distal to the stenosis also play an important role in stroke risk classification.

Cerebrovascular reserve is the capacity of the brain to increase cerebral blood volume through vasodilation to maintain a constant regional CBF in the face of low cerebral perfusion pressure (CPP). When CPP is reduced, the cerebral vasculature autoregulates by dilation of cerebral arterioles to maintain CBF. With severe carotid stenosis, vasodilatory capacity is maximally exhausted, and a further decrease in CPP, such as with induction of anesthesia can also decrease CBF and increase the risk of stroke.

The hemodynamic intracerebral effects of carotid stenosis also depend on collateral flow. The circle of Willis is the primary collateral circulation of cerebral arteries, followed by the ophthalmic artery, leptomeningeal vessels, and anastomoses among the perforating cortical arteries.

Current understanding of CBF is incomplete as most of our knowledge of cerebral hemodynamics comes from changes that occur in the large vessels. Flow in the large cerebral vessels may not correlate to flow in the capillary network, which limits our current knowledge of microvascular perfusion

A.13. Discuss the different surgical approaches to carotid revascularization.

CEA is performed through either a transverse incision or an incision bordering the sternocleidomastoid muscle (also known as a carotid incision). The subcutaneous tissue and platysma muscle are divided, and the carotid sheath is exposed. Usually, dissection is performed exposing the common carotid artery to a point distal to the bifurcation of the internal carotid artery and external carotid artery. Next, in this order, the internal, common, and external arteries are sequentially clamped, and the patient is given a heparin bolus. Depending on institution and surgeon preference, carotid stump pressures can be obtained by attaching a transducer into the common carotid artery after clamping the proximal common and external carotid artery. A mean pressure of 40 to 50 mmHg suggests adequate collateralization through the circle of Willis from the contralateral carotid artery. Some

use lower stump pressures as an indication for shunt placement manipulation of the carotid bulb can result in hemodynamic instability (e.g., bradycardia) due to the carotid sinus reflex. Typically, reducing direct surgical pressure will allow for return of normal sinus rhythm. Pharmacologic therapy can involve direct injection of lidocaine into the sinus or intravenous administration of atropine, both of which can lead to cessation of the reflex.

To remove the lesion, a longitudinal arteriotomy is performed below the level of the bifurcation and extended both proximally and distally. At this point, some surgeons routinely place shunts, others choose to do so only if there are signs of cerebral ischemia, and others opt to not place shunts altogether and decrease the cerebral metabolic rate by requesting an increase in anesthetic depth to achieve EEG burst suppression. If a shunt is placed, it is done after the vessel is open but before the plaque is removed. The plaque is dissected and freed from the deep layers of the media after which the arteriotomy is repaired. Some surgeons do a primary repair while others patch the artery with a synthetic or biologic patch. The clamps are sequentially released to back bleed the external and internal carotid arteries and forward flush the common carotid artery. After the suture line is completed, flow is restored in the external then internal carotid artery. A Jackson-Pratt drain can be placed to prevent incisional hematoma. A completion study to assess integrity of the repair is usually performed using a duplex ultrasound or contrast angiogram. Another variation of the conventional CEA is eversion endarterectomy. Here, the carotid is transected horizontally at the carotid bulb, and the artery is turned inside out or everted, although this variation is infrequently performed. There is no evidence indicating one technique is superior to the other; the surgical method is usually chosen because of institution and surgical preference.

A.14. Discuss the endovascular approaches to carotid stenting.

Access to the carotid artery is obtained usually through the common femoral artery. Transcervical (though a cutdown or percutaneously) via the common carotid or transradial approaches have also been used. If the transfemoral approach is chosen, an angiogram is performed to identify the aortic arch anatomy to safely maneuver the catheter, wires, and embolic protection device up to the internal carotid artery. If the transcervical route is chosen, the arch is bypassed. This approach is appealing but currently only a handful of centers are adept with this technique.

The patient is heparinized prior to manipulating guidewires and catheters. The goal is to maintain an activated clotting time (ACT) of 250 to 300 seconds. The common steps for stenting are (1) advancement of a guidewire, (2) sheath placement, (3) embolic protection device placement, (4) carotid lesion predilated (if needed), (5) stent positioning, (6) stent deployment, and (7) stent expansion with post-stent angioplasty to ensure good apposition against the arterial wall. As it can be difficult to get the wire and embolic protection device across a

stenotic lesion, predilation may be needed. Predilation is recognized as a risk factor for perioperative stroke and vasospasm. During dilation, stenting, and angioplasty, bradycardia and hypotension due to baroreceptor activation can occur and are usually treated with vagolytic drugs such as atropine. The carotid baroreceptors are located within the adventitia of the origin of the internal carotid artery and innervated by a branch of the glossopharyngeal nerve called the sinus of Hering. The baroreceptors are stretch-sensitive mechanoreceptors that respond to alterations in blood pressure.

The two main considerations in the stent procedure are the type of stent utilized and the type of embolic protection device that is used. The two types of bare-metal carotid stents that are common placed are open and closed architecture stents. Open stents are typically more flexible and are used for complex angulated carotid lesions. Closed stents cover more surface area and are commonly used in straighter less complex carotid lesions. Randomized clinical trials have failed to show any relationship between the type of stent used and complications that stem from CAS.

Embolic protection device technology is evolving but in general fall into three main types: (1) distal filter, (2) distal occlusion devices, and (3) proximal protection devices. The filter design allows for antegrade flow through the internal carotid artery during stent placement and is commonly used. The main limitation of distal filter devices is that they need to cross the lesion, which in and of itself can lead to embolism. Distal occlusion devices have a low profile and require a short landing zone. This is advantageous for tortuous vessels. The lesion is crossed with a wire, the balloon inflated, and angiography used to confirm that there are no leaks. After the stent is deployed, an aspiration catheter is advanced to the occlusion device to remove all debris after which the balloon is deflated. The main

concerns are intolerance to occlusion of the artery and embolism. Careful preoperative assessment of collaterals (i.e., via the circle of Willis) is important. Retrograde flow devices are the newest advancement in embolic protection devices and are designed to promote flow and debris away from the internal carotid artery. Balloons are deployed in the common carotid and external carotid artery causing flow stasis or reversal. With these devices, there is no interaction with the plaque until reversal or stasis of flow is achieved. Some patients may not tolerate occlusion or flow reversal in the internal carotid artery. Evidence of which embolic protection device to use and whether they decrease the rate of periprocedural stroke and death is conflicting, although the studies trend toward a decrease in the risk of perioperative stroke.

A.15. What is normal CBF?

Normal CBF is approximately 50 mL/100 g/min for the entire brain. Blood flow is about 4 times higher in gray matter than in white matter, or 80 and 20 mL/100 g/min, respectively.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:294–332.

Lassen NA, Munck O. The cerebral blood flow in man determined by the use of radioactive krypton. *Acta Physiol Scand*. 1955;33:30–49.

A.16. What is critically low CBF as measured by the electroencephalogram (EEG)?

Assuming normal temperature and hematocrit, 100 mL of blood contains approximately 20 mL of oxygen. Normal global CBF of 50 mL/100 g/min delivers oxygen to the brain at a rate of 10 mL/100 g/min. This is more than the high metabolic requirements of the brain for oxygen (3 to 5 mL/100 g/min), which affords a relative margin of safety. The CBF at which ischemia becomes apparent in the EEG is approximately 20 mL/100 g/min. Changes on EEG may be delayed for up to 150 seconds following onset of ischemia. It is not currently possible to define the specific changes that represent irreversible

ischemia. In the setting of an isoelectric EEG, oxygen delivery to the brain may be adequate to keep neurons alive but may provide insufficient energy for them to function.

Development of cerebral infarction depends on both the degree and duration of ischemia. Jones et al. showed in an animal model of reversible ischemia that with CBF of 18 to 23 mL/100 g/min, animals recovered from impaired neurologic function when blood flow was returned to normal levels regardless of the duration of the ischemic period. Infarction development at lower flows depends on both the degree of regional CBF reduction and the duration of ischemia. Neurons that are nonfunctional but will recover fully with restoration of adequate flow are said to be in an ischemic penumbra. Neuronal death occurs with CBF less than 10 mL/100 g/min.

A.17. What is cerebral autoregulation?

Cerebral autoregulation is the tendency of the brain to match cerebral oxygen delivery with metabolic oxygen requirements despite variations in blood pressure. In normotensive individuals, CBF is relatively constant between mean arterial pressures of 70 and 150 mmHg. It is generally considered that the lower limit of autoregulation is a mean arterial pressure of 50 mmHg based on animal studies. Above and below the plateau phase, CBF is dependent on pressure and varies linearly with CPP. Note that the limits of autoregulation are a conceptual construct and not an “all-or-none” phenomenon. In addition, autoregulation is affected by the underlying level of vasodilation

or vasoconstriction that depends on the $PaCO_2$ or anesthetic conditions among other things.

In hypertensive patients, the upper and lower limits of the autoregulatory curve are shifted to the right, to higher arterial pressures (**Fig. 18.2**). What this means is that a mean arterial pressure of 60 mmHg, which would be well-tolerated in a normotensive individual, may actually be below the lower limit of autoregulation in the hypertensive individual, resulting in cerebral hypoperfusion. Conversely, hypertensive patients tolerate marked increases in mean arterial pressure better than their normotensive counterparts. In treated hypertensive patients, the limits of autoregulation are shifted with time toward normal.

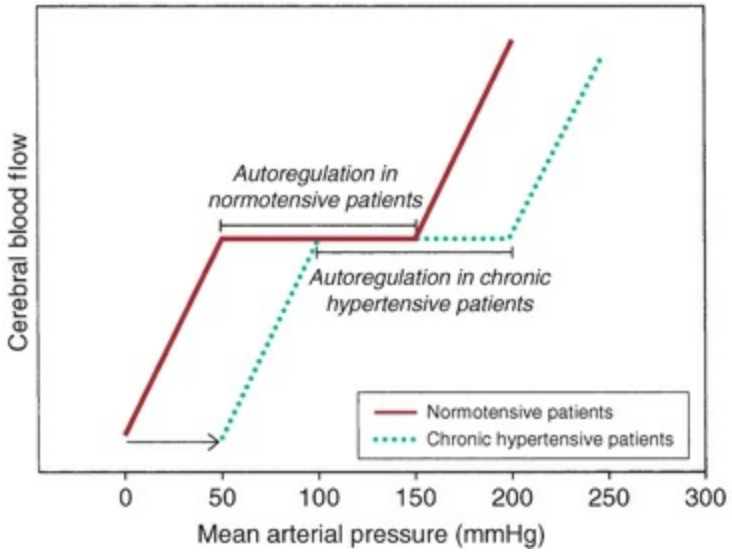

FIGURE 18.2. Cerebral autoregulatory curves in normotensive and chronic hypertensive patients. A shift in the autoregulation curve occurs with chronic hypertension. The curve shifts back to normotensive range once hypertension is well controlled.

Paulson OB, Strandgaard S, Edvinsson L. Cerebral autoregulation. *Cerebrovasc Brain Metab Rev*. 1990;2:161–192.

A.18. How does $PaCO_2$ affect CBF?

Hypercarbia results in cerebral vasodilation, and hypocarbia in

cerebral vasoconstriction. CBF changes about 4% for each mmHg increase or decrease in arterial $Paco_2$ for partial pressures between 20 and 80 mmHg. The appropriate level of $Paco_2$ during carotid revascularization has not been established, and because there are no clear clinical benefits to either hypercapnia or hypocapnia, it is recommended to maintain normocapnia.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Edinburgh, United Kingdom: Elsevier Saunders; 2017:19–58.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:294–332.

A.19. What are the principal determinants of CBF?

The principal determinants of CBF are nerve cell activity, CPP, blood viscosity, $Paco_2$, pH of brain extracellular fluid, Pao_2, and neurogenic influences.

Cottrell JE, Patel P, eds. *Cottrell and Patel's Neuroanesthesia*. 6th ed. Edinburgh, United Kingdom: Elsevier Saunders; 2017:19–58.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:294–332.

A.20. What is meant by the term *luxury perfusion*?

Luxury perfusion is blood flow that is in excess of metabolic need (increased CBF relative to cerebral metabolic rate for oxygen). It is most frequently observed in tissues surrounding tumors or areas of infarction. It has also been described in tissues that have been manipulated during surgery.

Cottrell JE, Patel P, eds. ***Cottrell and Patel's Neuroanesthesia***. 6th ed. Edinburgh, United Kingdom: Elsevier Saunders; 2017:19–58.

A.21. What is meant by the term *intracerebral steal*?

Intracerebral steal is a paradoxical response to carbon dioxide in which hypercapnia decreases blood flow to an ischemic area.

With hypercapnia, normally perfused arterioles vasodilate, and this shunts blood from the ischemic lesion. This occurs because at baseline, hypoperfused regions in the brain are maximally dilated and cannot dilate further to hypercapnia. As a result, it is common practice to maintain normocapnia during carotid surgery.

Paulson OB. Cerebral apoplexy (stroke): pathogenesis, pathophysiology and therapy as illustrated by regional blood flow measurements in the brain. *Stroke*. 1971;2:327–360.

B. Preoperative Evaluation and Preparation

B.1. What will you look for in your preoperative evaluation of this patient?

Once the presence of a carotid lesion amenable to surgical treatment has been documented by Doppler ultrasonography or angiographic studies, the anesthesiologist will be asked to evaluate the patient regarding readiness for surgery. Because a majority of patients who have carotid disease also have coexisting cardiac atherosclerosis, the main focus of the preoperative evaluation will be to optimize cardiac function. Evidence of medical conditions associated with arteriosclerosis, such as coronary artery disease, hypertension, renal disease, obesity, diabetes mellitus, and pulmonary disease secondary to cigarette smoking, should be sought.

The patient's neurologic status also needs to be evaluated preoperatively. Although it would be preferable to medically optimize the patient with uncontrolled hypertension or untreated metabolic disease, or if possible delay surgery in the patient with a recent MI, the presence of symptomatic carotid disease may not allow that option. This is because there is good evidence that

surgical intervention should take place within 2 weeks of symptoms in order to reap the benefits of surgery.

The patient's airway needs to be assessed for ease of ventilation and intubation. A patient who is difficult to ventilate may become hypercarbic during induction, and the increase in $PaCO_2$ may have adverse effects on regional CBF. As part of the airway evaluation, the range of motion of the patient's neck that is tolerated without evidence of cerebral ischemia needs to be determined so that relative extremes of extension and lateral rotation of the neck during ventilation, intubation, and finally patient positioning can be avoided. Extreme extension and rotation of the neck can occlude the vertebral artery and contribute to postoperative neurologic deficits.

Rerkasem K, Rothwell PM. Carotid endarterectomy for symptomatic carotid stenosis. *Cochrane Database Syst Rev*. 2011;(4):CD001081.

B.2. Is this patient's blood pressure too high for elective surgery?

Although hypertension is present in most patients presenting for CEA, its rapid correction is not recommended because this may exacerbate cerebral ischemia. If this patient had evidence of myocardial ischemia at this blood pressure and was stable from a neurologic standpoint, blood pressure could be gradually decreased with antihypertensive medications.

Normal myocardial and cerebral function need to be preserved. These goals are not necessarily at odds with each other. To decrease myocardial oxygen consumption, one would

want to decrease heart rate, blood pressure, and myocardial contractility. In this patient population, decreasing heart rate can decrease myocardial work, whereas CPP is maintained with adequate mean arterial pressure. If a hypertensive patient presents with an unstable neurologic status, it may be necessary to control blood pressure only once the obstruction to CBF has been relieved.

A single blood pressure measurement is of little use in the preoperative assessment of the patient. It is the range of the blood pressures normally tolerated by the patient that will guide perioperative blood pressure management. For example, if the patient's blood pressure is measured at 80/50 mmHg and at 170/100 mmHg, preoperatively, and at these blood pressures, she does not develop any new neurologic deficits or myocardial ischemia, the clinician will be inclined to treat blood pressures only beyond these two extremes.

Because this patient is hypertensive, one can expect that wide swings in blood pressure will occur while she is receiving anesthesia. Variations in blood pressure should be minimized because these have been related to increased cardiac and neurologic morbidity. The anesthesiologist must be prepared for blood pressure variations by having both vasopressors and vasodilators readily available. Total fluid administration should be limited to no more than 10 mL per kg for a typical 2-hour operation in most patients because fluid overload can contribute to postoperative hypertension.

B.3. What laboratory data are required preoperatively?

Laboratory tests should be ordered based on the patient's cardiac, respiratory, and metabolic status. Hemoglobin and hematocrit should be determined preoperatively because values may be abnormal in a patient with advanced age, renal or pulmonary disease. A type and screen while routinely performed at most institutions is rarely needed as transfusion after CEA or stenting is rare. A baseline basic metabolic panel is useful to determine the electrolyte status. Blood urea nitrogen and creatinine help to determine baseline renal status.

An electrocardiogram (ECG) should be examined preoperatively to look for arrhythmias, evidence of ischemia, previous MIs, or left ventricular hypertrophy. Where appropriate, the preoperative ECG should be compared with earlier studies to determine whether interval changes have occurred.

If present, a chest radiograph should be examined to look for cardiomegaly, evidence of pulmonary edema, chronic obstructive pulmonary disease, or pneumonia. If the patient has a history of chronic obstructive pulmonary disease, a preoperative arterial blood gas reading should be obtained once the arterial line is placed to identify the baseline $PaCO_2$. In patients who are chronically hypercarbic, rapid adjustment to normocarbia intraoperatively will result in relative hypocarbia and CBF will be reduced accordingly. Management of intraoperative ventilation should be aimed at maintaining normal arterial carbon dioxide partial pressure.

B.4. Will you treat this patients' blood glucose?

Hyperglycemia lowers the ischemic threshold in clinical and experimental models. Poorly controlled diabetes mellitus is a marker for vascular disease, and preoperative optimization if time allows may improve perioperative outcome.

McGirt MJ, Woodworth GF, Brooke BS, et al. Hyperglycemia independently increases the risk of perioperative stroke, myocardial infarction, and death after carotid endarterectomy. *Neurosurgery*. 2006;58:1066–1073.

B.5. Will you premedicate this patient?

Ideally, the patient should present to the operating room calm and awake. Preoperative anxiety should be alleviated in these patients because it can lead to hypertension, which has been associated with adverse neurologic outcome. Increases in heart rate in the anxious patient lead to increased myocardial oxygen consumption and, potentially, ischemia, ventricular dysfunction, and arrhythmias.

Premedication, however, can lead to ventilatory depression, with resultant hypercarbia and alterations in CBF that can exacerbate cerebral ischemia. Sedation can also interfere with the immediate postoperative neurologic assessment of the patient because it may cause delayed awakening from anesthesia. One of the anesthetic goals for CEA under general anesthesia is to have a patient who promptly emerges from anesthesia and is able to cooperate with a basic neurologic evaluation.

To achieve these goals, a thorough and reassuring preoperative visit alone may provide sufficient anxiolysis. The anesthesiologist should explain the preoperative procedure and what can be expected in the postoperative period, answering any questions that the patient has. If an anxiolytic is chosen, a short-acting agent should be used after documentation of the patient's neurologic exam.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1120–1127.

C. Intraoperative Management

C.1. How will you monitor this patient?

Regardless of whether the patient is having an awake CEA or a carotid stent, routine monitoring of cardiovascular, pulmonary, and metabolic function is important. ECG leads II and V_5, noninvasive blood pressure monitor, pulse oximetry, end-tidal capnometry, and temperature are monitored. An intra-arterial catheter should be used to monitor arterial blood pressure closely. Its presence will permit immediate identification of blood pressure changes and allow for repetitive sampling of arterial blood gases.

Rarely is a central venous catheter or a pulmonary artery catheter required to monitor cardiac function. Large fluid shifts or major blood loss is not anticipated, and most anesthesiologists place one 18-gauge or larger bore peripheral intravenous.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1120–1127.

C.2. How will you know that the patient's cerebral perfusion is adequate during surgery?

In the awake patient undergoing CEA or stent under local anesthesia, repeated neurologic examinations can be done to assess the adequacy of cerebral perfusion. This is the most sensitive and specific way to detect intraoperative cerebral ischemia.

If the patient receives general anesthesia, neuromonitoring is generally employed in order to detect and treat ischemia in a timely fashion. Various neuromonitoring modalities exist, which are classified in the categories of brain activity monitoring,

cerebral perfusion monitoring, and brain oxygen saturation monitoring. These include the EEG, SSEPs, TCD, internal carotid stump pressure, $SjvO_2$, and near-infrared spectroscopy (NIRS). No one monitor is routinely used in all operating rooms, and each modality has its own specific indication as well as strengths and weaknesses. Therefore, the simultaneous application of more than one monitoring device is recommended.

Pennekamp CW, Moll FL, de Borst GJ. The potential benefits and the role of cerebral monitoring in carotid endarterectomy. *Curr Opin Anaesthesiol*. 2011;24(6):693–697.

C.3. Discuss the differences and relative advantages and disadvantages of unprocessed EEG and processed EEG monitoring.

The 16-channel EEG is a sensitive indicator of cerebral ischemia. Intraoperative changes in EEG related to ischemia are classified as mild, moderate, or severe. Severe EEG changes (>50% decrease in waveform amplitude in a generalized or lateralized distribution) suggest a need for blood pressure augmentation by the anesthesiologist or shunt placement by the surgeon. The EEG is neither a measure of CBF nor a way to determine whether irreversible neuronal damage has occurred. Rather, it is an indicator that areas of the brain may be at risk for infarction. Changes that occur in the EEG with hypothermia, hypocarbia, hypoxemia, and deep anesthesia mimic those of ischemia. In patients who have had a cerebrovascular accident, the processed EEG does not predict cerebral ischemia.

Problems associated with intraoperative monitoring of the 16-lead EEG have detracted from its popularity. These include difficulty in obtaining a meaningful recording in the electrically

noisy environment of the operating room, the bulk of the equipment required, and the need for specially trained personnel for interpretation.

The processed EEG has eliminated many of the problems associated with the 16-channel EEG. The equipment is generally compact, and the data display allows for ease of interpretation. One commonly used processed encephalogram is power spectrum analysis. For this analysis, the EEG is studied in short time intervals of 2 to 16 minutes, called *epochs*. Each epoch then is subjected to a fast Fourier transform analysis during which the complex waveform of the unprocessed EEG is broken down into its component sine waves of varying amplitudes and frequencies. The power spectrum is calculated by squaring the amplitude of the individual frequency components. The power spectrum can then be displayed in various forms, two of which are the compressed spectral array and the density-modulated spectral array. Data are displayed in these two forms as relative power versus frequency (**Fig. 18.3**).

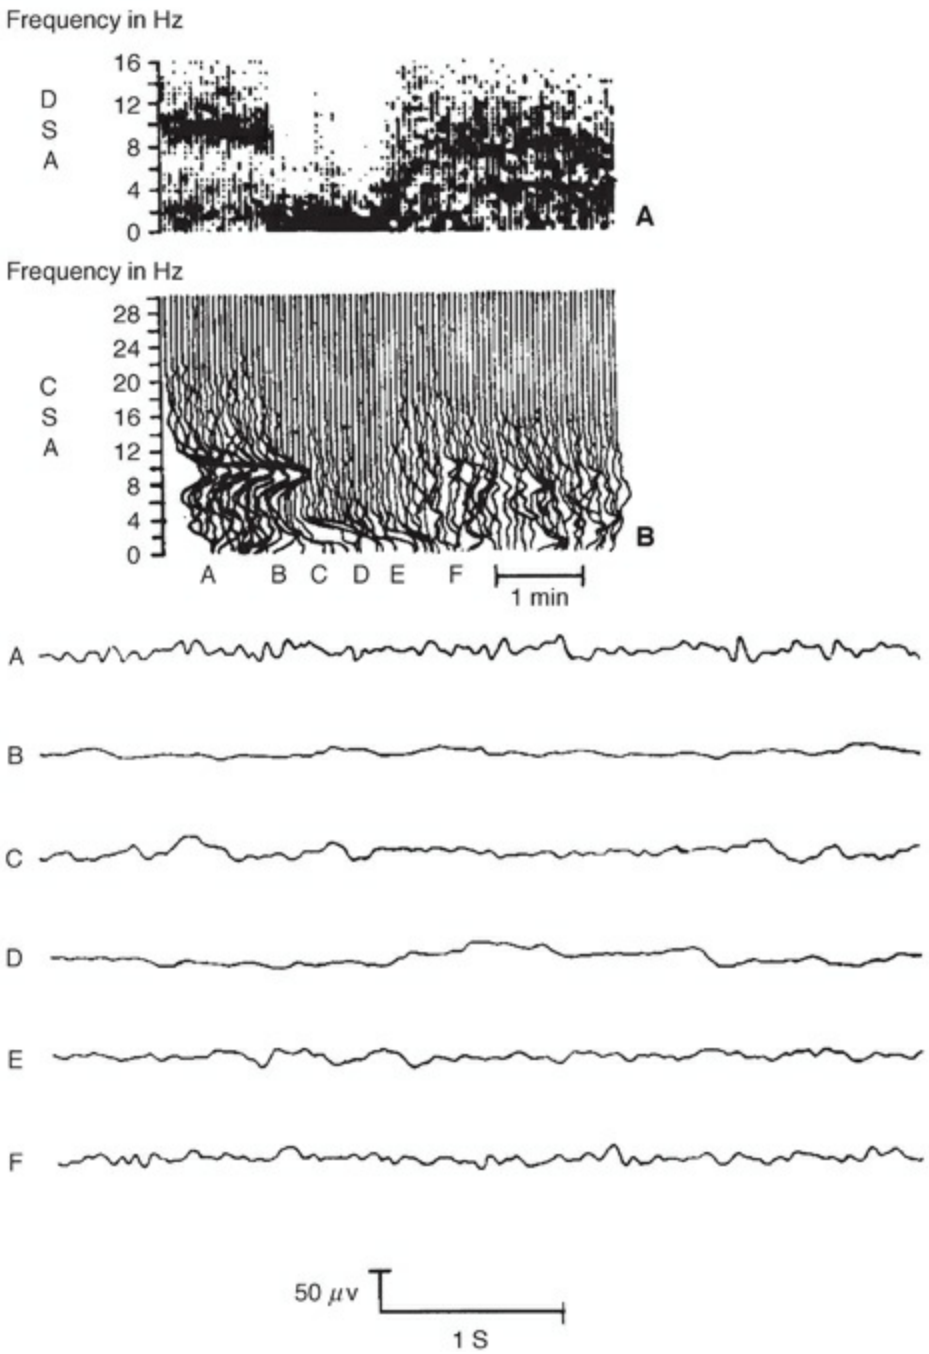

FIGURE 18.3. An example of density spectral array (A) and compressed spectral array (B) during a period of marked hypotension during initiation of bypass. Slowing waveform activity in the unprocessed EEG (B to E) is also evident in the density-modulated spectral array (DSA) and compressed spectral array (CSA). (*Reprinted with permission from Levy WJ, Shapiro HM, Maruchak G, et al. Automated EEG processing for intraoperative monitoring*. Anesthesiology. *1980;53:223*.)

The processed EEG is only as good as the original from which it was obtained. Therefore, meticulous recording

techniques are required even when monitoring a processed EEG. During CEA, generally two or four channels of the EEG are monitored to determine right and left symmetry in neuronal activity during interruption of CBF.

The bispectral index (BIS) monitor is another commonly used processed EEG parameter that uses a proprietary methodology to calculate indices of the EEG power spectrum, burst synchronization, and phase coupling. It is primarily used as a monitor to assess depth of anesthesia. Although the BIS may have some utility as a marker of global cerebral ischemia, it is unreliable as an indicator of hemispheric cerebral ischemia during carotid cross-clamping.

Deogaonkar A, Vivar R, Bullock RE, et al. Bispectral index monitoring may not reliably indicate cerebral ischaemia during awake carotid endarterectomy. *Br J Anaesth*. 2005;94:800–804.

C.4. How will you measure CBF intraoperatively? What are the relative advantages and disadvantages of each technique?

CBF can be indirectly measured by neurophysiologic monitoring. Monitoring techniques can be broken down into techniques that assess the overall integrity of cerebral function, cerebral flow, and cerebral metabolism. EEG, SSEPs, and motor evoked potentials (MEP) assess the integrity of cerebral

function. Cerebral perfusion monitoring can be done indirectly with internal carotid artery stump pressures or directly with TCD, which assesses flow in large intracranial vessels. Brain oxygen saturation monitoring can be done with jugular venous bulb monitoring ($SjvO_2$) or cerebral oximetry by NIRS, and they assess overall cerebral metabolism.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1120–1127.

C.5. Describe the use of stump pressure and its limitations.

Internal carotid artery stump pressure is one way to assess cerebral perfusion; however, this is indirect because it measures perfusion pressure and not flow per se. Typically, the stump pressure is obtained after the initial clamping of the internal carotid artery. The stump pressure presumably reflects pressure transmitted through collateral vessels. Maintaining stump pressures from 25 to 70 mmHg has been described as necessary to avoid neurologic injury. Nevertheless, this range of stump pressures may not reliably represent the adequacy of collateral CBF because it does not correlate consistently with changes in the EEG, regional CBF, or changes in the neurologic status of the awake patient. Furthermore, anesthetic agents can alter carotid stump pressure without changing regional CBF. Inadequate stump pressures have been shown when measured regional CBF was adequate. If shunting during CEA were to be done only on the basis of stump pressures, some patients would unnecessarily receive shunts. Finally, because stump pressure is not continuously monitored, it only gives a snapshot in time of cerebral perfusion and therefore this technique is less commonly used.

Harada RN, Comerota AJ, Good GM, et al. Stump pressure, electroencephalographic changes, and the contralateral carotid artery: another look at selective shunting. *Am J Surg*. 1995;170:148–153.

C.6. Describe the use of transcranial Doppler (TCD) and its limitations.

Another technique that can be used to assess CBF is TCD ultrasonography, which uses pulse wave Doppler ultrasound to measure flow in the ipsilateral middle cerebral artery. It can aid in determining the need for a shunt by detecting a decrease in the middle cerebral artery blood flow velocity with placement of the carotid cross-clamp. It allows for continuous assessment of shunt function. It can be used to assess the adequacy of pharmacologically induced intraoperative hypertensive therapy. TCD also allows detection of air or particulate embolization with endarterectomy or stenting. A higher embolic burden has been associated with stroke. The disadvantage of TCD is that it is technically demanding and not obtainable in approximately 20% of patients. As changes in flow velocities can be due to changes in arterial diameter or low perfusion, it is not very sensitive or specific for assessing cerebral perfusion.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1120–1127.

C.7. Describe the use of jugular venous oxygen saturation ($SjvO_2$) and its limitations.

$SjvO_2$ follows oxygen saturation obtained from a catheter that is inserted into the internal jugular vein of the carotid surgical site. The major disadvantage of $SjvO_2$ monitoring is that it is a global and not regional monitor for ischemia. $SjvO_2$ also has a wide range of normal values, and there is a possibility of extracranial blood sampling. This technique has not shown to improve

outcomes with CAS or CEA.

Barash PG, Cullen BF, Stoelting RK, et al, eds. *Clinical Anesthesia*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2017:1120–1127.

C.8. Describe the use of cerebral oximetry and its limitations.

Cerebral oximetry uses NIRS to detect regional cerebral oxygen saturation. This is done by applying small adhesive monitoring pads to the forehead. The major limitations to NIRS is that there are wide variations in baseline readings in a single individual, and the lack of agreement as to what constitutes ischemic changes to warrant interventions like shunt placement. The ability to detect ischemia is limited to the region in the frontal cortex and limited by the sampling window.

Grubhofer G, Plöchl W, Skolka M, et al. Comparing Doppler ultrasonography and cerebral oximetry as indicators for shunting in carotid endarterectomy. *Anesth Analg*. 2000;91:1339–1344.

C.9. Discuss somatosensory evoked potentials (SSEPs) as a monitor of CBF during CEA.

SSEPs are a specialized form of electrophysiologic monitoring that reflects the presence of intact sensory pathways from a stimulated peripheral nerve to the cortex, where electrical activity is monitored. Evidence exists that distortion of certain waveforms is associated with ischemia. These SSEP changes are not consistently associated with changes in the EEG. Questions have been raised regarding whether SSEPs can overpredict the presence of ischemia and the need for shunting. If SSEPs are a useful indicator of ischemia, they may be used when ischemia cannot be detected on an EEG tracing, such as during barbiturate anesthesia. During barbiturate anesthesia, the isoelectric EEG

can only indicate that neurons are quiet. It cannot indicate whether these same neurons are ischemic. The SSEP tracing remains intact with barbiturate anesthesia and, therefore, would potentially be more useful as a clinical monitor. Patients who have had strokes have some asymmetry in baseline SSEP waveforms. This asymmetry does not appear to affect the SSEP as an effective clinical monitor, which may also be a relative advantage over the EEG in patients with prior stroke.

C.10. What type of anesthesia will you choose for this patient if she chose to have an endarterectomy?

Regional or general anesthesia can be used for patients undergoing CEA. Each type of anesthesia has advantages and disadvantages that must be considered when choosing the optimal anesthetic for each patient. Benefits of general anesthesia include a still patient and a quiet operative field; early control of the airway and ventilation; and the ability to "protect" the brain should ischemia, which cannot be eliminated, develop. A disadvantage of general anesthesia is the inability to perform repeated neurologic evaluations during surgery. Therefore, patients receiving general anesthesia should have their CBF or neurologic function monitored as previously discussed.

The primary advantage of a regional anesthetic is that the patient remains awake allowing for repeated neurologic evaluations. Although anecdotal reports support that regional anesthesia allows for greater stability of blood pressure, decreased requirement for vasoactive medications to support blood pressure, and decreased incidence of perioperative MI,

further outcome studies are warranted. Potential complications associated with regional anesthesia include seizures, alteration of mental status with cerebral ischemia, and loss of patient cooperation associated with cerebral hypoperfusion, inadequate ventilation, and sedation.

Early analyses of mainly nonrandomized trials comparing regional and general anesthesia for CEA initially suggested a reduced risk of morbidity and mortality with regional anesthesia. However, subsequent analyses of larger, randomized trials have generally refuted this finding. The general anesthesia versus local anesthesia for carotid surgery (GALA) trial was a multicenter, randomized controlled trial that included 3,526 patients with symptomatic or asymptomatic carotid stenosis who were randomly assigned to surgery under general anesthesia or regional anesthesia. This study showed no definite differences in the primary study outcome (stroke, MI, or death within 30 days), quality of life, or length of hospital stay. However, there was a nonsignificant trend toward a higher rate of MI in the regional anesthesia group as well as a nonsignificant trend toward a higher rate of stroke among patients with bilateral carotid disease in the general anesthesia group.

A meta-analysis of 14 randomized trials involving 4,596 procedures (the majority of which came from the GALA study) found that there was no statistically significant difference between general and regional anesthesia groups in the proportion of patients who had a stroke or died within 30 days of surgery. In this meta-analysis, there was a nonsignificant trend toward lower operative mortality with regional anesthetic; however, none of the individual studies or the meta-analysis were adequately powered to reliably detect an effect on mortality. Therefore, evidence suggests that patients and surgeons may choose either anesthetic technique, depending on the clinical situation and individual preference.

C.11. What type of anesthesia will you choose for this patient if she chose to have a carotid stent?

Carotid stents are usually performed under local anesthesia. Patients get minimal to no sedation so that a continuous neurologic assessment can be performed. An arterial line is placed in addition to standard monitoring as hemodynamic instability is common during and after stenting is performed. During the angioplasty and stent placement, studies have reported bradycardia, hypotension, and asystole. Bradycardia and hypotension are seen more often when angioplasty is performed prior to stenting. The interventionalist will usually ask for prophylactic atropine or glycopyrrolate before balloon angioplasty and stent deployment. Satya et al. reported an approximately 5% incidence of asystole after stenting and found a higher association with right-sided stents in patients with reduced left ventricular ejection fraction and significant contralateral stenosis.

carotid artery stenting. *J Endovasc Ther*. 2011;18:513–517.

C.12. How will you induce and maintain general anesthesia in this patient for CEA?

Any anesthetic regimen is suitable if it provides hemodynamic stability, does not exacerbate cerebral ischemia, and allows for prompt emergence from anesthesia at the end of surgery. Premedication with midazolam has the potential to compromise early neurologic assessment and is usually avoided. Following preoxygenation, anesthetics should be titrated slowly with special attention to their effect on blood pressure. Control of the airway should be taken as soon as the patient is no longer able to breathe adequately to maintain normocarbia. While breathing oxygen, short-acting opioids are administered until the patient is comfortably sedated. Lidocaine 1 mg per kg is administered intravenously at least 2 minutes before laryngoscopy and intubation to blunt the hemodynamic response to airway manipulation. Following administration of propofol or etomidate, controlled ventilation is instituted with 100% oxygen to avoid hypoxia and hypercarbia. A muscle relaxant is administered to facilitate tracheal intubation. Succinylcholine should be avoided in hemiparetic patients because of the possibility of a hyperkalemic response. Nondepolarizing muscle relaxants with significant hemodynamic effects such as sympathomimetic activity, vagolysis, or histamine release should be avoided. Once the patient is relaxed, expeditious laryngoscopy and intubation are performed. Atomized lidocaine can be used prior to intubation to minimize stimulation by the endotracheal tube during surgery and prevent coughing on emergence.

During the induction and intubation sequence, blood pressure is kept in the patient's normal range using vasopressors or vasodilators as indicated. Short-acting and easily titratable

vasoactive medications should be chosen to facilitate blood pressure control.

Anesthesia can be maintained with volatile anesthetics or intravenous agents. The addition of short-acting opioids to a volatile or intravenous anesthetic will decrease heart rate and when properly dosed, allow for a prompt, smooth emergence from general anesthesia. Maintenance of a light anesthetic appears to have several advantages over deep anesthesia. It allows ischemic patterns on the EEG to be recognized easily. It also facilitates maintenance of blood pressure. In addition, administration of a light anesthetic, compared to a deep anesthetic using phenylephrine to maintain blood pressure, results in a lower incidence of perioperative MI. Arterial blood pressure should be maintained in the high normal range throughout the procedure. When the carotid artery is clamped, induced hypertension (10% to 20% above baseline) is often requested by the surgeon to increase contralateral flow and prevent ischemia. During surgical manipulation of the carotid sinus, sudden bradycardia and hypotension can occur. Alerting the surgeon and asking them to stop manipulating the area usually restores hemodynamics.

C.13. How would you proceed if the patient were to receive regional anesthesia?

Patient cooperation is essential for a regional anesthetic to proceed successfully. For a patient to be adequately anesthetized, a sensory blockade is required in the C2–C4 dermatomes. This can be accomplished with either deep or superficial cervical plexus blocks. In doing the blocks, care must be taken not to excessively palpate the neck because part of the plaque in the carotid artery may dislodge and embolize.

Superficial cervical plexus blocks are performed by infiltrating along with middle third of the posterior border of the sternocleidomastoid muscle with local anesthesia. Deep cervical plexus blocks are performed with three injections along a line drawn from Chassaignac tubercle (C6) to the mastoid process. The C4 nerve root is located at the intersection of that line with one drawn horizontally from the lower border of the mandible. C2 and C3 are located by dividing the distance between the mastoid process and the horizontal line into thirds. Alternatively, a single injection of local anesthetic can be made on the line between the mastoid process and Chassaignac tubercle at the level of C4 with the needle directed medially and slightly caudad.

Patients receiving regional anesthesia must be both cooperative and not overly sedated with intravenous medications. If they are unable to cooperate and become obtunded, the primary advantage of regional anesthesia (which is continuous neurologic evaluation) is lost. Intravenous sedation, therefore, must be given judiciously, if at all, to these patients.

for carotid endarterectomy. *J Cardiothorac Vasc Anesth*. 2013;27(6):1379–1383.

C.14. Discuss the effects of anesthetics on CBF.

It is important to remember that all general anesthetics affect CBF and cerebral metabolic oxygen consumption. This can be used to the anesthesiologist's advantage when the decrease in oxygen consumption is greater than the decrease in CBF.

In general, volatile anesthetics are cerebral vasodilators and intravenous anesthetics are cerebral vasoconstrictors. Ketamine is an exception because it can increase in both CBF and cerebral metabolic rate. Volatile anesthetics produce a dose-dependent increase in CBF. The magnitude of vasodilation depends on the balance between the anesthetic's intrinsic vasodilatory property and vasoconstriction secondary to its reduction in cerebral metabolic rate.

Studies suggest that anesthetic agents only affect the blood flow in normally perfused areas of the brain. If this is the case, volatile anesthetics could cause a steal phenomenon, in which the blood vessels in normal brain dilate and steal blood flow away from ischemic areas of the brain that are both already maximally vasodilated and unresponsive to further vasodilating effects of the anesthetics.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:1825–1867.

C.15. Discuss the protective effects of anesthetic agents on cerebral function.

Although it has not been proven that general anesthetics afford brain protection, agents that cause the greatest decrease in cerebral metabolic oxygen consumption should lessen the risk of cerebral ischemia. Whether a particular anesthetic is optimal for

these patients is an area of discussion. Obviously, avoiding or eliminating ischemia is preferable to protecting against it.

Messick et al. examined the effects of volatile anesthetics on critical regional CBF, that is, the regional CBF at which EEG evidence of cerebral ischemia became apparent. They found that critical regional CBF in patients receiving isoflurane was less than 10 mL/100 g/min, and in patients receiving halothane was 18 to 20 mL/100 g/min. This decrease in critical CBF suggests that isoflurane may offer some protective effect. Because of the potential to cause a decrease in blood pressure and reflex increase in heart rate, it probably should not be used at high concentrations as the sole anesthetic. A significant proportion of patients with carotid artery disease also have coronary artery disease and may not tolerate the hypotension and tachycardia associated with the use of high-dose isoflurane. By using this anesthetic in low concentrations in combination with other anesthetic agents, one can better maintain hemodynamic stability while perhaps providing for an increased tolerance of cerebral hypoperfusion. Other evidence suggests that isoflurane may not offer protection during regional cerebral ischemia.

The newer agents sevoflurane and desflurane have been investigated for their possible role in neuroanesthesia. Compared to isoflurane, desflurane has no significant difference in its effects on decreasing cerebral glucose utilization, increasing blood flow, and maintaining coupling between local CBF and local cerebral glucose utilization. Although sevoflurane showed no significant difference in its effects on decreasing cerebral glucose utilization and coupling between local CBF and local cerebral glucose utilization at one minimum alveolar concentration, it did show less of an increase in CBF. This difference between isoflurane and sevoflurane was independent of their effects on systemic blood flow and cardiac output. Hence, desflurane and sevoflurane may have similar

neuroprotective effects as isoflurane and, with their lower blood gas solubility coefficients, may promote a more rapid recovery from anesthesia, allowing faster evaluation of neurologic status.

Thiopental affords cerebral protection against focal or incomplete global cerebral ischemia. It is a cerebral vasoconstrictor, as are most other intravenous anesthetics. It will also transiently decrease cerebral metabolism from 40% to 50% of baseline. The combined effect is that cerebral metabolic oxygen consumption is decreased more than oxygen delivery. The reduction in oxygen demand is the result of inhibition of functioning neurons, which can be observed as a quiet or isoelectric EEG. When dosing barbiturates for cerebral protection, the EEG should be monitored and repeated doses given to achieve and then maintain a burst suppression pattern. Once the EEG is isoelectric, indicating lack of neuronal function, further doses of thiopental do not provide additional protection. It is generally not recommended that thiopental be used for cerebral protection during CEA. As mentioned previously, avoidance of ischemia is preferable to its treatment. If thiopental is used, the EEG, because of its isoelectricity, becomes useless as a monitor of cerebral ischemia. This is especially problematic if selective shunting is to be done. Furthermore, the doses of thiopental required to suppress the EEG may cause hypotension and a delayed emergence from anesthesia. Barbiturate use to minimize the possibility of cerebral ischemia has been advocated for the patient undergoing carotid bypass procedures in which temporary occlusion of the recipient vessel is required. Whether treatment of patients with a 3 to 5 mg per kg dose of thiopental affects their outcome in terms of neurologic deficit is not known, although it has been shown to be efficacious in animal models.

Like barbiturates, the intravenous anesthetics propofol and etomidate also decrease brain electrical activity and cellular

oxygen requirements while preserving cerebral autoregulation of blood flow. Although the available evidence for the protective effects of etomidate and propofol during CEA is inconclusive, these agents reduce brain infarction and prolong tolerable ischemia time in patients undergoing temporary ischemia for intracranial aneurysm clipping. Additionally, animal studies have suggested a degree of neuroprotection with propofol.

Dexmedetomidine is a selective α_2-adrenergic agonist with sedative, analgesic, and anxiolytic properties. It does not cause respiratory depression. In animal studies, dexmedetomidine reduces ischemic damage after transient and permanent ischemia. Its mechanism of neuroprotection is unclear. One hypothesis suggests that with the onset of cerebral ischemia, one of the initial responses in the central nervous system is the excessive release of norepinephrine and glutamate during energy failure. If the increase in norepinephrine release is a causative component of injury, an α_2-adrenergic agonist may decrease the damage afforded by cerebral ischemia. Dexmedetomidine has been shown to reduce arousal and decrease CBF in volunteers.

C.16. How will you manage this patient's ventilation under general anesthesia?

Because carbon dioxide is a potent cerebral vasodilator, patients undergoing CEA historically were hypoventilated intraoperatively to achieve hypercarbia and cerebral vasodilation. However, it is now accepted that hypercapnia should be avoided in patients with carotid artery disease. Carbon dioxide causes vasodilation in normally reactive, nonischemic, vascular beds. In patients with carotid artery disease, this means that blood flow is diverted away from the already maximally dilated vessels in the territory of the occluded carotid and toward normal areas of the brain. This decrease in regional CBF in ischemic areas of the brain with increased CBF in normal areas of the brain is known as *intracerebral steal*.

Other authors have recommended extreme hypocapnia during CEA, reasoning that this would result in an "inverse steal" or "Robin Hood" phenomenon. Hypocapnia will cause constriction of cerebral vessels in normally perfused areas of the brain, possibly diverting blood flow into the maximally vasodilated, unreactive, hypoperfused regions of the brain. Clinical trials have been unable to demonstrate any benefit from hypocapnia, and animal studies have shown that it may, in fact, exacerbate ischemia. This most likely happens not only because of intense vasoconstriction but also because of a leftward shift of the oxyhemoglobin dissociation curve so that hemoglobin is less able to give its oxygen to tissues.

The general recommendation for patients with

cerebrovascular disease is that normocarbia or mild hypocarbia be maintained. After repair of their carotid stenosis, some patients will have a marked hyperemia with CBF of 100 mL/100 g/min. In these patients, decreasing both blood pressure and arterial carbon dioxide tension to decrease their CBF is indicated. Without a decrease in CBF, these patients are at risk for postoperative intracerebral hemorrhage.

C.17. How will you manage this patient's blood pressure intraoperatively?

Various factors need to be considered in the blood pressure management of patients undergoing CEA. In the patient with carotid artery disease, a loss of autoregulation occurs in ischemic areas of the brain. In areas of chronic hypoperfusion, vessels are maximally vasodilated and unresponsive to vasomotor stimuli. Perfusion in these ischemic areas is pressure dependent.

During cerebral arterial occlusion, systemic blood pressure may need to be increased to augment collateral blood flow. The primary collateral pathways include the Willisian channels. If Willisian channels are not available, either because of the patient's anatomy or a therapeutic intervention, secondary collateral channels are available that bridge adjacent major vascular territories. These pathways are known as the *pial-to-pial collateral* or *leptomeningeal* pathways.

Because of the adjustment of the autoregulatory limits in hypertensive patients and because of a lack of autoregulation in

ischemic areas of the brain, hypotension should be avoided. Blood pressure should be maintained in its high normal range. During arterial occlusion, the only practical way to increase collateral blood flow may be by increasing the collateral perfusion pressure by raising the systemic blood pressure. The extent to which the blood pressure should be raised depends on the nature of the disease. During deliberate hypertension, the systemic blood pressure is raised by 30% to 40% above the baseline or until ischemic symptoms resolve. Both maintenance of and increases in blood pressure can be accomplished with light anesthesia and, when necessary, infusion of the α-agonist phenylephrine. Phenylephrine has no direct effect on the cerebral vasculature; therefore, cerebral perfusion is increased by an elevation in the CPP. Phenylephrine increases blood pressure, CPP, stump pressure, and regional CBF. It also increases myocardial oxygen consumption. Because it increases afterload, care must be taken when it is used in patients with coronary artery disease, and it can exacerbate myocardial ischemia and congestive heart failure. In patients with coronary artery disease, blood pressure should not be increased above baseline unless evidence of cerebral ischemia develops. Extreme increases in blood pressure can and should be managed with easily titratable intravenous vasodilators.

Once the stenosis has been relieved and the carotid cross-clamp removed, the patient's blood pressure should be maintained in its low normal range. This lowering of blood pressure offers several advantages. It decreases myocardial oxygen consumption by decreasing the work of the heart, it decreases the amount of stress on the suture line in the carotid artery, and finally, it minimizes the possibility of reperfusion hemorrhage.

C.18. Discuss reperfusion injury following CEA and CAS.

Reperfusion injury involves cerebral hemorrhage or the development of cerebral edema after obstruction to flow through the carotid artery has been relieved. Although rare, it is an often fatal complication of CEA. Patients present with headache, seizure, focal neurologic signs, brain edema, and intracerebral bleeds. The incidence of intracerebral hemorrhage after CEA ranges from 0.4% to 2.0%, and it usually occurs 1 to 5 days after surgery. Patients with a previous stroke are most likely to suffer reperfusion hemorrhage, but it can occur in otherwise normal brain tissue. Poorly controlled blood pressure after the carotid cross-clamp has been removed contributes to this complication. One proposed mechanism for this injury is that once flow is returned to normal, vascular beds in previously hypoperfused areas of the brain are unable to respond properly with vasoconstriction. They are unable to maintain normal flow with increased perfusion. Because hypoperfusion distal to the carotid stenosis has been long-standing, these vessels have lost their ability to autoregulate. Once the carotid stenosis is eliminated, the perfusion pressure distal to the former site of the stenosis is markedly increased. Because of the lack of autoregulation in this area, CBF increases with increasing perfusion pressure. The patients at highest risk for reperfusion injury have the greatest degree of stenosis and the greatest pressure drop across the

carotid lesion. Again, maintaining blood pressure control with antihypertensive medications once the carotid obstruction is eliminated decreases the incidence of reperfusion injury.

C.19. What intravenous fluids will you give this patient intraoperatively?

Because moderate hyperglycemia has been shown to worsen neurologic outcome after ischemia, care must be taken to avoid increasing glucose by exogenous administration. Balanced intravenous fluids such as PlasmaLyte, lactated Ringer's solution, or another buffered crystalloid solution would be appropriate choices for patients undergoing CEA.

These patients should not be vigorously hydrated intraoperatively. It is best to limit their intraoperative fluids to what is required for maintenance, with additional colloid and blood replacement being given as needed. Intraoperative overhydration may lead to some of the frequently observed postoperative hypertension and in patients with myocardial disease may exacerbate congestive heart failure.

D. Postoperative Management

D.1. The patient does not "wake up" from general anesthesia. Why?

Once other causes of slow emergence from general anesthesia (e.g., hyperglycemia or hypoglycemia, hypothermia, anesthetic overdose, hypercarbia, and hypoxemia) have been ruled out, the possibility of an adverse intraoperative event having occurred needs to be considered. Patency of the carotid artery should be evaluated. This can be done by Doppler studies while the patient is still in the operating room. If no blood flow is seen in the carotid artery, the incision can be reexplored immediately. If Doppler studies are normal, the possibility of a cerebral infarction from prolonged hypoperfusion or from emboli must be considered. The patient should remain intubated while further studies, including a computed tomography (CT) scan and cerebral angiography, are done as expeditiously as possible. The incidence of new perioperative neurologic deficits is 3% or less in centers where the operation is done commonly.

D.2. Postoperatively, the patient's blood pressure is 170/96 mmHg. Will you treat this?

This patient's blood pressure needs to be carefully controlled

because postoperative hypertension is associated with bleeding at the operative site, myocardial ischemia, arrhythmias, intracerebral hemorrhage, and cerebral edema.

Hypertension is observed more commonly than hypotension after CEA. Causes of hypertension include hypoxemia, hypercarbia, pain, and a full bladder. Obviously, if any or all of these causes are present, they need to be dealt with promptly. Another common cause of postoperative hypertension and tachycardia is blunting of the carotid baroreceptor mechanism secondary to carotid sinus dysfunction caused by surgical trauma. If this is the cause of hypertension, therapy with antihypertensive agents should be started.

This patient's blood pressure should be maintained in her low normal range postoperatively. Elevated blood pressure can be treated with hydralazine in 5-mg increments or, if the patient is not bradycardic, labetalol in 5- to 10-mg increments. Alternatively, infusions of nicardipine, sodium nitroprusside, or nitroglycerin can be used. β-Blockade with metoprolol or an infusion of esmolol may be added to this regimen.

Gropper MA, Eriksson LI, Fleisher LA, et al, eds. *Miller's Anesthesia*. 9th ed. Philadelphia, PA: Elsevier Saunders; 2019:1825–1867.

D.3. What immediate postoperative complications might you expect after a CEA?

Immediate postoperative complications include neurologic deficits, hemodynamic instability, and respiratory insufficiency. Evaluation of the NASCET showed that 8.1% of patients had medical complications: 1% with MIs, 7.1% with other cardiovascular disorders such as arrhythmias and congestive heart failure, 0.8% with respiratory complications, 0.4% with transient confusion, and 0.7% with other complications. CEA is

1.5 times more likely to be associated with complications in patients with a history of cardiac disease or hypertension.

Postoperative neurologic complications are usually embolic in nature, occurring during surgery. Other neurologic complications result from reperfusion injury and intracranial hemorrhage.

Circulatory instability is common after CEA, with either hypotension or hypertension observed. Hypotension can have any of several causes, as does hypertension, as noted previously. These include hypovolemia, depression of the circulation by residual anesthetics, prolonged effect of intraoperatively administered antihypertensives, dysrhythmias, and myocardial ischemia. Each of these causes needs to be sought and, if present, treated. Another possible cause of hypotension is an excessive reflex response because of increased sensitivity of the carotid sinus after exposure of the baroreceptor mechanism to a higher pressure with removal of the plaque. If this is the cause, therapy needs to be instituted with fluids and vasopressors.

Postoperative respiratory insufficiency is a rare but potentially life-threatening complication. This can be due to vocal cord paralysis from intraoperative traction on the laryngeal nerves. Should this present with inability to protect the airway, the patient should be reintubated immediately. A prospective trial found that 12.5% of patients had nerve injuries after CEA, but all were transient, lasting from 1 week to 37 months. No patient had life-threatening respiratory insufficiency from the nerve injuries. The most commonly injured nerves were the hypoglossal, recurrent laryngeal, superior laryngeal, and greater auricular nerves.

Airway obstruction can also occur from hematoma formation at the operative site, from either arterial or venous bleeding. The hematoma needs to be evacuated as quickly as possible, and depending on ventilatory status, the patient may need to be

intubated. This is most easily done after evacuation of the hematoma if the clinical condition allows. Supraglottic edema may also be a rare cause of postoperative upper airway obstruction after CEA. CT analysis of airways postoperatively showed reduction in the volume of the airway in all patients, with a greater reduction seen in intubated patients (63% ± 9%) than in nonintubated patients (32% ± 7%).

Tension pneumothorax can result from air dissecting through the wound and the mediastinum to the pleura. This diagnosis should be considered in all patients after CEA who seem to have respiratory distress and no evidence of upper airway obstruction. Absence of breath sounds over half of the chest and hemodynamic instability would support this diagnosis.

Chemoreceptor function is irreversibly suspended in most patients after CEA for up to 10 months. Lack of chemoreceptor function means that there is a loss of circulatory response to hypoxia and an increase in resting Pa_{CO_2} of approximately 6 mmHg. This complication is potentially very serious, and one needs to be most concerned about its development in patients who have had a previous contralateral CEA, where function may be lost bilaterally. In all patients after CEA, supplemental oxygen should be provided and opioids administered cautiously.

D.4. What postoperative complications might you expect after a CAS?

Complications after CAS include hemodynamic instability, stroke, MI, renal failure, and access-related problems. In a pooled analysis of 27 studies, Mylonas et al. found that approximately 39% of patients experienced some degree of hemodynamic instability (bradycardia/hypotension) after CAS, but in a majority of patients it resolved in 8 to 10 hours. Stroke following CAS could be secondary to thromboembolism, hypoperfusion, stent thrombosis, intracranial hemorrhage, or cerebral hyperperfusion. In several pooled meta-analysis studies, the periprocedural risk of stroke following stenting appears to be higher than CEA, but this is debated as stroke rates have improved since the introduction of CAS. The risk of MI in CAS ranges from 1% to 4%. Renal dysfunction following CAS is attributed to contrast-induced nephropathy, atheroembolism from instrumentation of the aorta or hypoperfusion from hemodynamic instability. Access-related problems are related to pseudoaneurysm formation, bleeding, and atheroembolism to the lower extremities.

D.5. Discuss postoperative neurocognitive dysfunction following uncomplicated carotid intervention.

CEA can reduce the incidence of stroke in patients with high-grade carotid artery stenosis. Increasing evidence suggests that as many as 28% of surgical patients have significant neuropsychological dysfunction 1 day after carotid artery surgery. Between 9% and 23% of these patients continue to exhibit cognitive decline 1 month after surgery.

The apolipoprotein E (APOE)-ε4 allele has been associated with worse outcome following stroke. In a prospective trial, 75 patients undergoing CEA were studied. Of 75 patients, 12 (16%) possessed the APOE-ε4 allele. Of the 75 patients, 8 (11%) experienced cognitive dysfunction on postoperative day 30. One month after CEA, APOE-ε4-positive patients were more likely to have suffered a neurocognitive injury (42%) than APOE-ε4-negative patients (5%). The presence of the APOE-ε4 allele increases the risk of neurocognitive dysfunction 62-fold 1 month after surgery. Diabetes mellitus and obesity also predisposed to injury.

Evidence also indicates increased cognitive dysfunction in patients with carotid stenosis treated with stenting performed under cerebral embolic protection. In a prospective case control study, 41% of patients undergoing carotid stenting developed moderate-to-severe cognitive dysfunction compared to a matched control group. The average deficit score was significantly higher in the CAS group at 1 day. These differences were independent of age and history of stroke or TIA. The absence of oral statin medication may increase the probability of cognitive dysfunction.

The influence of regional versus general anesthesia in postoperative subclinical cognitive dysfunction remains unclear, although a study by Heyer et. al showed no difference in the incidence if cognitive dysfunction in patients who underwent CEA under general or regional anesthesia. Most concur that multiple factors, including surgical technique, anesthetic technique, and patient status, influence postoperative outcome.

19 Awake Craniotomy for Mapping and Surgery in the Eloquent Cortex

Thomas A. Moore II and
Kenneth G. Smithson

A 30-year-old right-handed male presented with increased seizure frequency and tumor progression following two prior awake craniotomies. The initial pathology was reported as a World Health Organization (WHO) grade II oligodendroglioma. Following the second awake craniotomy, the tumor had undergone malignant transformation to a WHO grade IV glioblastoma multiforme (isocitrate dehydrogenase [IDH]-mutated). Magnetic resonance imaging (MRI) revealed a 5.6 × 2.9 × 3.6 cm heterogeneously enhancing lesion with associated marked vasogenic edema in the right frontoparietal and temporoparietal white matter, with effacement of the right lateral ventricle (**Fig. 19.1A**). His anticonvulsant medications were increased, and he was given a short course of a corticosteroid with symptom improvement. He underwent functional MRI (fMRI) that revealed asymmetric cortical activation in the right motor cortex when compared to the left side. The primary descending fibers of the corticospinal tract (CST) were intimately associated with the medial enhancing margin of the tumor (**Fig. 19.1B**). He underwent a third uncomplicated awake craniotomy with motor and sensory mapping. He was discharged to home on postoperative day 2. Final pathology

revealed a WHO grade IV glioblastoma multiforme (IDH-mutated).

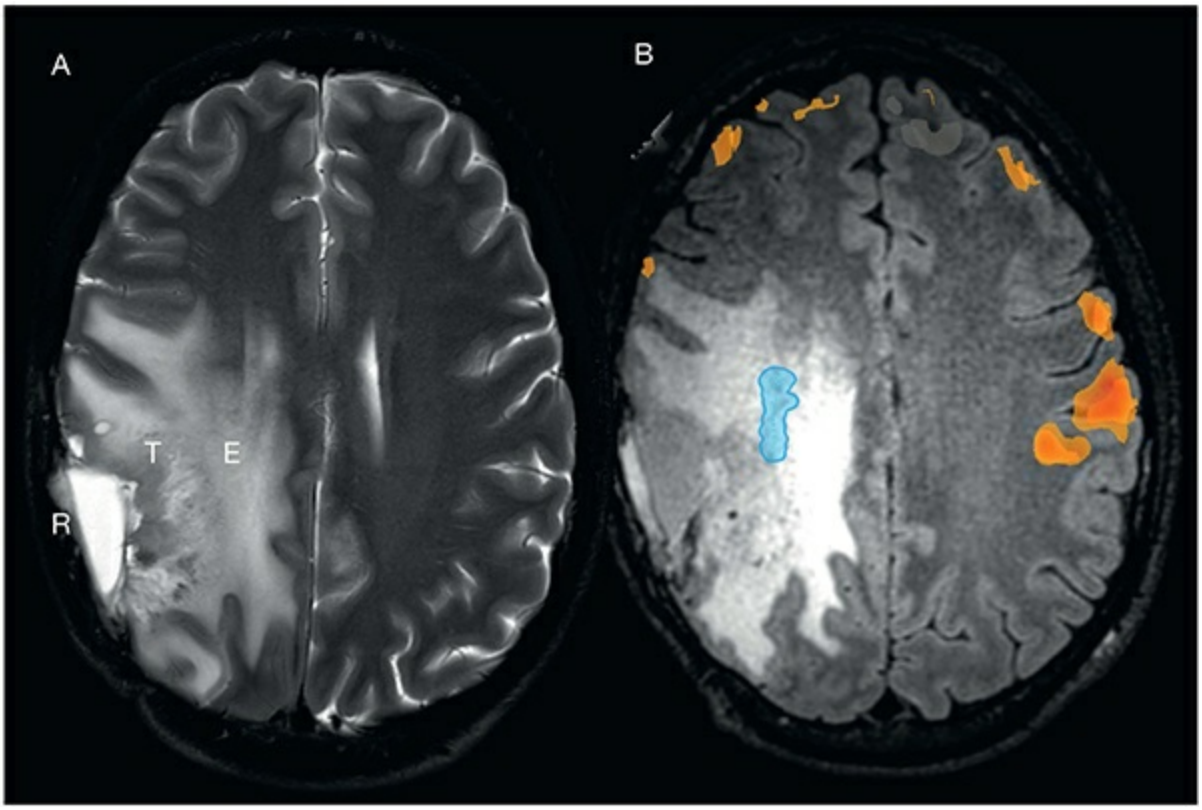

FIGURE 19.1. A. A 30-year-old male with a known glioblastoma presents with increasing seizure frequency and tumor progression on follow-up studies. Note the remarkable level of vasogenic edema (E) surrounding the tumor (T) and extensive effacement of the right lateral ventricle. This patient underwent an uncomplicated redo-awake craniotomy with motor and sensory mapping. Final pathology was a WHO grade IV glioblastoma multiforme. R, prior resection cavity. **B.** A 30-year-old male with recurrent glioblastoma undergoing a repeat awake craniotomy. fMRI demonstrates asymmetric cortical activity from bilateral and right-hand tapping in orange color. The intimate proximity of the CST, in blue, to the medial enhancing margin of the tumor is evident. Juxtaposition of new tumor growth, pervasive edema, and more important, the cortical spinal tract proximity made simple resection via stereotactic methods virtually impossible. Only an awake patient who is actively involved in cortical mapping via task performance could minimize damage to the CST.

A. Medical Disease and Differential Diagnosis

1. What is the eloquent cortex?
2. What is the underlying pathology?
3. What determines intracranial pressure (ICP)?
4. How does a space-occupying mass alter ICP?

5. What is autoregulation, and why is it important?
6. How is cerebral blood flow (CBF) regulated?
7. What drug therapies may be associated with this pathology?

B. Preoperative Evaluation and Preparation

1. Why is the craniotomy performed awake?
2. What neurologic symptoms of the patient are important?
3. What is the status of their other comorbid conditions?
4. Are there anesthetic implications from current treatment drugs?
5. What laboratory data are required?
6. What radiology data should be reviewed?
7. How do you prepare the patient for an awake craniotomy?
8. Should this patient receive premedications?
9. What precautions should be made for airway management?

C. Intraoperative Management

1. How should this patient be monitored?
2. Does this patient require invasive monitoring?
3. Can current drug therapy alter eloquent cortex mapping?
4. Why use hypertonic fluids during a craniotomy?
5. What intravenous fluids (IVFs) are recommended?
6. Would a lumbar drain for cerebrospinal fluid (CSF) removal benefit this patient?
7. Venous air embolism (VAE): Is it a concern in this case?
8. How is the eloquent cortex mapped?
9. How are intraoperative seizures treated?
10. How will you conduct this anesthetic?

D. Postoperative Management

1. What are the major concerns following craniotomy?

A. Medical Disease and Differential Diagnosis

A.1. What is the eloquent cortex?

Eloquent cortex is a term usually used to describe functional areas of the cerebral cortex associated with motor, language, and sensory activity. Traditionally, tumors or epileptic foci within or near these areas have been termed *inoperable* because of the devastation caused to the patient by injury to these critical brain regions.

De Benedictis A, Moritz-Gasser S, Duffau H. Awake mapping optimizes the extent of resection for low-grade gliomas in eloquent areas. *Neurosurgery*. 2010;66(6):1074–1084.

A.2. What is the underlying pathology?

The underlying pathology requiring an awake craniotomy for mapping and resection within the eloquent cortex can be either a space-occupying lesion or epileptic foci. In either case, mapping of the cortical and subcortical structures with an awake and cooperative patient is necessary to minimize neurologic injury and maximize lesion resection. Mapping of the motor cortex is often done under general anesthesia, and more specifically a total intravenous (IV) anesthetic typically with a propofol and remifentanil infusions, after reversal of any residual muscle relaxant because the stimulated area(s) can usually be seen by an observer. Additionally, motor responses are directly measured electrophysiologically as muscle motor evoked potentials (mMEPs). These same techniques can also be done in the awake patient. Nevertheless, there are several potential problems. In the case of a space-occupying lesion, the neuronal pathways can become distorted secondary to the expanding mass and mislead the surgeon who is searching not only for the functional area but also a “quiet” area of cortex through which to do the resection. In addition, these patients are frequently in a lateral decubitus position, with the side to be observed in the down position, obscuring small motor responses. Visualization of the patient

can be further obstructed with sheets, blankets, forced warm-air blankets, and other patient-positioning devices. Hence, we tend to map the motor cortex in an awake craniotomy whenever possible and monitor mMEPs simultaneously. Furthermore, in cases involving complex sensory or motor activities such as language comprehension or speech production, our current electrophysiologic and imaging techniques remain limited as compared to the awake and interactive patient.

Supratentorial brain tumors are about 31% gliomas, 15% meningiomas, 12% metastatic lesions, and 8% pituitary tumors (**Fig. 19.1**). Metastatic lesions are most frequently lung, breast, and gastrointestinal tract tumors. Additional space-occupying lesions include blood and blood vessels, infections, hydrocephalus, cerebral infarctions, radiation necrosis, arachnoid cysts, and cerebral edema. Several of these often coexist depending on the primary pathology of the lesion.

These space-occupying lesions can present in various manners. The most common presentation of brain tumors is a progressive neurologic deficit (68%), usually motor weakness (45%), headache (54%), and seizures (26%). Others may present from progressive focal deficits resulting from infiltration of tumor cells and destruction of normal brain cytoarchitecture or compression or displacement of normal brain structures by the mass itself or peritumoral edema. Additional presentations include nausea or vomiting, vertigo, lethargy, apathy, and changes in mental status as several examples.
